As the limits of ethnocentric practices became better understood, the multicultural thrust began to include development of cultural competence requirements for practitioners. In attempting to summarize various authors, a basic doctrine emerges throughout the literature. The multicultural position maintains that for therapists to be competent and successful:

1. Therapists must be knowledgeable about the history, beliefs, values, and norms of the client’s reference group. They must also be knowledgeable about each group’s status in relation to the dominant society.

2. The therapist must be mindful of the effects of social oppression and be willing to actively combat oppressive social forces.

3. To avoid pitfalls of bigotry and “cultural mismatches” the therapist must also be aware of their own cultural norms, beliefs, and values. They must be mindful of how their implicit cultural beliefs enter into and affect the therapy process.

4. The therapist must be aware of the ways in which their own worldview and the worldview of the client may be similar or different and accommodate the therapy to the client’s worldview as much as possible.

5. The therapist must have the skills to respond appropriately to the client’s verbal, non-verbal, affective, and cognitive cultural norms. This includes knowing and responding to culturally acceptable

FIGURE 3 2050 projected population in thousands (U.S. Census Bureau).

norms for interacting with authority figures, non-family members, and strangers.

6. The therapist must possess knowledge of the cultural norms that govern asking for help and establishing a relationship.

7. The therapist must know the culturally prescribed expressions of different symptoms and must know how to accurately interpret and respond to the meaning of different affective and cognitive concepts.

8. The therapist must know the different cultural criteria for mental illness, as well as the criteria for healthy individual and social functioning.

9. Therapists must be knowledgeable of how cultural variables affect results of psychometric tests and measures. They must know which test instruments are suitable for use with which ethnic groups. They must be able to accurately interpret test results of various ethnic minorities.

10. Therapists must maintain an attitude of respect and valuing of each group, no matter how much that group differs from their own group. When therapists are able to maintain this attitude of "intercultural" valuing, both the therapist and the client can grow as human beings, developing from ethnocentric beings to a higher maturity of intercultural identities.

Based on a foundation of cultural relativism and pluralism, multiculturalists have attempted to establish new directions for psychology therapy practice, assessment, research, and training. To make psychotherapy culture sensitive, psychologists are encouraged to study the cultural norms of different groups, study specific personality traits relevant to each group, and explore developmental issues for each group. Culture-centered psychotherapies are also being developed. Assessment issues include test content, examiner bias, and culturally-competent test administration. A main focus of assessment is the degree of acculturation of the ethnic minority person being assessed. Identity development issues also play a strong part. The identity models that have been developed are generally consistent with one another. These models posit that ethnic minority identity develops along a series of cognitive stages. The stages begin with naive precontact with members of the dominant society and then some conflictual encounter leads to a rejection of the dominant society and an immersion into the ethnic group of reference. This stage eventually gives way to an autonomous/independence stage that eventually matures into a humanitarian/universal self. Research issues include problems with assessment, that is, reliability and validity studies of newly developed tests. Other important questions being studied are questions of operational-

izing cultural competencies and evaluation of culture-sensitive therapies. Training issues concern development of training models and evaluation of effectiveness of training programs. There are two problems that persist in making these efforts difficult. One is the fact that there is more within-group than between-group variance, and another is that the process of acculturation is a fluid and changing, not static phenomenon.

II. MULTICULTURAL APPROACHES TO PSYCHOTHERAPY

A. Ethnographies

Ethnography has flourished in anthropology as a research method. Anthropological data are collected in the field when the anthropologist spends long periods living within the cultural community being studied. By using native informants to describe, translate, and clarify cultural beliefs, rituals, practices, values and norms, the anthropologist strives to understand unique and universal cultural realities. Two kinds of ethnographic data are used. Emic data are gathered directly from informants and are particular to the culture being studied. Etic data are the translation of emic data to universal cultural principles.

Various authors have presented ethnographic-based studies as one approach to culturally-sensitive psychotherapy. By adapting ethnographic descriptions of different ethnic groups, psychologists have utilized what might be called applied ethnography. The groups most represented in the literature are groups with the greatest increases in numbers in the U.S. population. Many applied ethnographic studies encompass African Americans, Asian Americans, Hispanic Americans and Native Americans. Other groups include immigrants from Eastern Europe and the Middle East.

When applied ethnographies are used for formulating treatment approaches three caveats are repeatedly emphasized:

1. Within-group variables are often larger than between-group variables.
2. The therapist must determine the extent to which cultural norms apply to the individual client.
3. Individual clients depict different social adaptations, identity formation stages, and acculturation issues.

1. Applied Ethnographies

a. African Americans. When working with African American clients the therapist must be knowledgeable

about the impact of history. African Americans have had to struggle through slavery, in all of its brutal aspects, and racist attitudes toward Blacks continue in the larger society. Although there has been improvement, there are still crucial links between racism and poverty that affect large numbers of Blacks. Poverty rates are higher for Blacks than for Whites. Among lower-class Blacks, 70% of households are headed by single females. Black teens face an unemployment rate of 50%, and many are subjected to violence, including homicides. Black teen suicide rates are increasing.

African Americans often live in poor neighborhoods where substandard housing, crime, and violence are prevalent. Schools located in impoverished neighborhoods can be poor environments for learning. This combination of social problems leads to high levels of stress and higher incidence of both physical and mental illnesses associated with stress. Many lower-class Blacks, especially teenagers, feel that there is not much hope for a better future.

Since slavery, European physical characteristics have been preferred among many African Americans. Caucasian features such as light skin color, straight hair, thin lips, and light eye-color have been symbolic of higher status and greater attractiveness than African Americans with more African physical features. These preferences can cause social, economic, and interpersonal conflicts among African Americans. Although there were significant changes in these attitudes during the 1960s and the Black power movement, residual physical characteristics issues can cause additional stress and self-esteem problems.

Basic values present in Black culture include sharing responsibilities, respect for parents, pride in heritage, spirituality, and strong family ties. Many single women raise children with the help of extended family, boyfriends, and family friends. There is no empirical evidence that Black children raised in fatherless homes suffer from lower self-esteem than children raised in two-parent homes. Black churches have been a central source of community support since the days of slavery. In many Black families, whether headed by one parent or two, children often take on adult-level responsibilities at an earlier age than White children. African American men and women have traditionally shared domestic duties, with women working outside the home and men participating in child care and household tasks.

(1) *Within-Group Differences.* There are approximately 32,147 million African Americans in the United States. The majorities of Blacks are actually bicultural and have been able to adapt to living in a generally hostile domi-

nant society. One third of Black Americans are middle class or higher. Most of these African Americans live in two-parent families and are pursuing lifestyles similar to European Americans. Yet, certain stressors are associated with the Black middle class. Job stress can come in the form of feeling that one has to compromise one's Black values to fit into work settings that are dominated by White values. Some middle-class Blacks must cope with racist attitudes at work, such as less chance for promotion or lower salaries than their White counterparts. There is some evidence that marital stress and alcohol abuse are often factors related to job stress. Middle-class Blacks do embrace White middle-class values to a larger extent than poor Blacks, but they are often victims of the stressors inherent in a bicultural lifestyle. Many middle-class Blacks live in predominantly White suburban neighborhoods and send their children to mostly White public and private schools. Yet, many of these African Americans seek out activities within the Black community to instill pride in heritage in their children.

(2) *Treatment Approaches.* Due to a history of racism many Blacks, especially Black families, are reluctant to seek outpatient mental health services. Despite such reluctance some studies show that people in Black communities do have knowledge of what is involved and expected in mental health centers and do believe that therapy can be helpful. Reluctance to seek services is usually based on the fear that White therapists will not understand the realities of African American racial oppression. Others have difficulties with transportation or child care arrangements. Many Blacks, especially those who have assumed adult responsibilities at an early age, are taught that they should take care of their own problems and are reluctant to ask for help.

Establishing trust is the most crucial aspect of forming a therapeutic alliance. There is no research support for matching Black clients with Black therapists as a therapeutic necessity. Trust is best established when the therapist behaves in a way that conveys honesty and sincerity and when differences in education and social status are not flaunted. It is important to provide straightforward answers to questions. The therapist should be easy to talk to but should avoid the pitfalls of "color blindness" and "paternalism" or feel that it is necessary to "buy into" a victim's stance. It is sometimes necessary to confront and challenge the client's thinking and beliefs if they are self-defeating or maladaptive.

In most therapy situations the Black client's attitudes and behavior in therapy are more likely to be determined by social class, personal experiences, and education status than by racial concerns. When a Black client

behaves in a manner that is hostile, apprehensive or nonengaging it should not be assumed that the problem behaviors are racially motivated. To discover the basis of the problem it is necessary to distinguish between racial hostilities and fears versus the manner in which the therapy is being conducted.

Most authors agree that the White therapist must be open to initiating a conversation about racial differences within the beginning sessions. A frank, non-defensive discussion about the client's feelings and concerns, if there are any, suggests to the client that candid talk about racial matters is an acceptable part of the therapeutic process. Others suggest that it would be more prudent for the therapist to wait for the client to bring up the subject. In any case, the therapist must be prepared to discuss racial difficulties as openly as possible with Black clients.

It is also important for the therapist to pay attention to the possibility of practical problems. Black clients may need help with survival skills: finding employment, seeking further education, coping with crime and poor housing in their neighborhoods, and so on. The therapist may have to accommodate the therapy process to transportation and child care problems. It is best to be flexible and willing to negotiate scheduling, and fee arrangements that allow the client to attend sessions and pay for sessions in a way that works best with their job and family situations.

The client's family life should be explored and evaluated as part of the therapy process. It should be noted, however, that the Black family should not be evaluated in terms of healthy or desirable White family values. Healthy Black families have adapted to very different circumstances, and the healthy functioning of the Black family should be evaluated in terms of those norms. Family therapy work, including parenting training, can be constructive. It is also advisable to include the client's spiritual community.

Therapy should include exploration of the client's personal experiences with racism and the ways in which they have attempted to cope with it. Including extended family members and community and church resources can also augment therapy. There is evidence that African American clients, overall, respond best to a problem-focused, brief, cognitive-behavioral treatment approach. There is also evidence that African American clients respond favorably to a directive and educative approach to problem solving.

b. American Indians. The cultures of the American Indians were transformed dramatically with the arrival

of Europeans. From 1492 until 1790 a series of disease epidemics greatly reduced their numbers. During the period from 1829 until 1890, a series of wars, White settlers claiming American Indian lands, and relocation of American Indians onto reservations were sources of further population devastation. It has been estimated that by the turn of the 20th century that the American Indian population had been reduced by over 90%.

The policy of the U.S. government has been to think of American Indians as a group to be "managed." Thus, the plight of American Indian cultural life has been governed by a series of treaties and laws, with the federal government. Until 1887 laws were designed to force American Indians onto reservations, prevent the practicing of their cultural traditions, and force a policy of assimilation into European culture. Thousands of American Indian children were routinely taken from their families and placed into boarding schools or adopted by White families. The subsequent loss of American Indian children from tribal communities is estimated at 25% to 55%. Traditional cultural practices, including religious ceremonies, were discouraged or forbidden. The policy of seizing American Indian lands continued into the 1920s, and the practice of placing American Indian children into boarding schools and other institutions continued until the 1970s.

American Indians were not granted U.S. citizenship until 1924, however, at this point racist policies gradually began to change. The 1934 Indian Reorganization Act terminated much of the federal controls over American Indian life, but many American Indians were relocated to urban centers where they were beset with expanding unemployment, welfare, and alcoholism. In 1955 the Indian Health Service was formed and established the Mental Health Services in 1969. In 1978 the Indian Child Welfare Act became the means to halt the seizing of children from American Indian families. The American Indian Religious Freedom Act of 1978 protected religious practices. With these recent legal freedoms has come a resurgence of interest in reclaiming cultural roots, with increasing numbers of American Indian peoples attending powwows and other cultural heritage events and ceremonies.

Depending on the political perspective, different terminology can be used when addressing this group of Americans. The term "Indian" began when European explorers thought they were in the Asian country of India and named the Caribbean tribes "Indians." Correcting this problem the term Native American became preferred. Native American, however, also has the problem of not distinguishing between native peoples

and those Europeans whose ancestors settled in America before the 1700s. Generally, the term American Indian is used, despite its negative political connotations. In Alaska, the term Alaska Native is preferred. Really correct, is to address an American Indian person by his or her tribal or clan name, because personal identity usually acquires from the tribal affiliation, then extends to include the entire group of American Indian nations and finally extends to the larger U.S. citizenship.

In traditional American Indian society bonds within the tribal group and harmony with nature and others in the group are primary values. Giving and sharing with others is a major source of status in the group. One strives to maintain balance between the natural, human, and spiritual worlds. American Indian values predispose American Indians to have difficulty in situations that reward individualism, control over others, competition, verbal aggressiveness, and talking openly about personal problems with strangers. Prolonged eye contact can be interpreted as aggressive, but prolonged silence is tolerated. Shaking hands should be slight contact, not a firm grasp.

American Indians have the highest high school dropout rate of any ethnic group. Basic problems for many American Indian clients are problems with the loss of the family, isolation from the tribal group, poor education, depression, alcoholism, and underemployment.

(1) *Within-Group Differences.* Today there are approximately 2,119 million American Indians living within the United States. Estimates of the number of federally recognized "entities" range from 505 to 517; the number of state-recognized tribes is cited as between 304 to 365. There are approximately 200 to 250 tribal languages still being spoken. Yet, the definition of who is an American Indian is somewhat problematic. The U.S. Census Bureau figures are based on self-report, and the numbers of people reporting American Indian ancestry is increasing at a rapid rate. The Bureau of Indian Affairs and different tribal organizations have different systems based on percentages of blood ancestors; therefore, it is difficult to get a firm fix on the actual group numbers.

Vast differences exist within American Indian groups, including regional differences. It is important to remember that American Indian tribes populated the entire American continent. Tribal customs and languages varied considerably between in the eastern, southern, western plains, and northwestern regions of the country. Cultural worldviews vary from ethnocentrically isolated families who live mainly on reservations, to bicultural families who reside predominantly

in urban areas, to acculturated families who may never have set foot on a reservation and have few connections to other American Indians in their daily lives.

Problems can occur with bicultural lifestyles. Many American Indians seeking work and education leave the reservations to live in urban areas. They may feel isolated from their families and cultures. Additional problems exist between generations as younger American Indians acculturate to European lifestyles and values. Younger generations may feel that they have little in common with older, more traditionally oriented parents and grandparents, thus causing further deterioration in family bonds.

(2) *Treatment Approaches.* It is a well-known fact that American Indians underutilize mental health services. This is true for three reasons. Many American Indians do not know about the existing services, there are few existing services and many distrust the reception and responses they will receive when they seek services. Several studies show that, on the whole, American Indians came to one therapy appointment and did not return for a second. Many American Indians fear that they will encounter a power difference that will amount to more forced assimilationism of European values. Many American Indians prefer to seek the services of traditional American Indian healers because, aside from the fact that they are probably effective, they are seen as the "keepers" of their cultural heritage.

When treating an American Indian client it is important for the therapist to understand the crucial necessity to spend sufficient time getting to know the client. It is important to establish a bond based on the degree of acculturation of the client. The therapist should take the lead to establish the structure and then proceed toward gathering personal history information. Questions about family relationships, education, employment, and where the client usually resides help to gauge the extent of acculturation. On the other hand, it is important to avoid prying too deeply at first, and avoid lengthy personal questions as well as lengthy questionnaires and agency forms. The therapist can encourage trust building by being willing to disclose information about themselves, as long as it is not too personal in nature. In American Indian culture words are considered important and lulls in conversation are not only acceptable, but also preferable to banter. The therapist should not expect the client to engage in emotional demonstrativeness, introspection, or self-examination. The therapist should take a directive but slow approach, allowing the client to pace the interview.

It is best to build a positive social support relationship. This can include family and friends who are available for participating in the therapy process. It is also advisable to inquire about use of traditional healers and to include those resources where appropriate.

The therapist should be willing to arrange flexible appointment times and be available for crisis interventions. American Indian clients might present a concrete problem at first to gauge the degree of social support and interpersonal bonding. When working with American Indians the therapist should be willing to bond with clients and their families. Connecting to clients outside the therapy structure is more important with this group than with any other.

Therapy approaches that appear to get the best results consist of social learning, behavioral, and family systems orientations. Teaching social skills, assertiveness skills, alcohol and drug education, suicide prevention, and parenting skills are effective and desirable treatment methods for American Indian clients. A homogeneous (only American Indians, separated by gender) group therapy can be especially helpful. The group should include pleasant and traditional activities. In a group approach elder American Indians can provide wisdom and guidance.

c. Asian Americans. Asian Americans are the fastest growing minority group and have the largest within-group variance. The Chinese began arriving in the 1840s to work on the railroads and gold mines. The Japanese began coming to the United States in the 1890s to work in the agrarian economies. Both groups soon encountered racist attitudes and were the victims of violent assaults, especially when work was scarce for White workers. The Federal Chinese Exclusion Act of 1882 banned immigration of Chinese. The Act was not repealed until WWII. In 1941, shortly after Pearl Harbor was bombed, Executive Order 9066 made Japanese Americans political prisoners. Japanese citizens were ordered into internment camps with no evidence of espionage or subversive activities. The Immigration Act of 1965 lifted restrictions on Asian immigration, and in 1988 The Civil Liberties Act offered reparations and apologies to Japanese Americans.

South East Asians have been arriving in large numbers since the mid-1970s. Many of the earlier 1970s immigrants were middle-class, educated Vietnamese, many of whom had worked for the U.S. government. Later South East Asian immigrants were poorer, and many were refugees escaping oppression after the fall of Saigon and the rise of the Cambodian Pol Pot

regime. Many of these refugees have been victimized by pirates and subjected to brutal rapes, murders, and robberies. Many refugees have spent months and sometimes years, in refugee camps before arriving in the United States.

Ancient values based on Confucian and Buddhist thought are predominate moral and social codes in the cultures from Asia. Strong emphasis is placed on filial piety (respect, obedience, and loyalty for parents and other authority figures), emotional reserve, harmony with others, hard work, self-sacrifice, and endurance. Fathers are the respected heads of the family and mothers provide domestic nurturance. Fathers are to be obeyed by the children, including adult children, and mothers have a more supportive role. Interpersonal harmony is maintained by speaking indirectly around the point, rather than direct confrontation. Because expression of intense feelings is considered inappropriate, it has been theorized that Asian Americans tend to present with somatic symptoms, rather than emotional concerns.

Proper individual behavior and personal shortcomings are regulated by shame and guilt. Conformity to the group is valued and is also a way of avoiding being shamed or "losing face." Personal problems are kept in the family, because to reveal them to the community places people at risk for feeling shamed. There is strong parental pressure exerted on children to be successful. A poor work or achievement performance can result in intense feelings of shame and guilt.

(1) Within-Group Differences. There are approximately 10,418 million Asian Americans. The subgroups are numerous with large variations in history, culture, and languages. The largest subgroups are Chinese, Filipinos, Japanese, Koreans, Vietnamese, and Cambodians. There are also substantial numbers of Hmong and Laotian citizens. Percentage wise more Asian Americans have college degrees than any other minority group. The median income is the highest of any group, including Whites. Yet, one half of Asian Americans are poor and undereducated. Urban ghettos, such as "Chinatowns" are often filled with poverty.

Some Japanese adults whose parents or grandparents were interned are often coping with the shame that the family experienced. Family members often refuse to talk about their internment experiences because of the shame and because talking about intense feelings is not culturally appropriate. Such suppression of feelings can lead to symptoms of anxiety and depression.

Many immigrants and refugees face problems with language barriers and with learning to fit in socially.

Pressure to acculturate is always in conflict with loyalty to family and cultural values. Recent immigrant children can face difficulties at school. They are sometimes subjected to racist attacks and ostracization. Children typically acculturate faster than adults, thus, Asian American children are often bicultural and speak native languages at home and speak English in school. This leads to intergenerational stress problems, which are difficult to deal with, especially when the children speak English and the parents do not. As children become acculturated they are often in conflict with values of strict obedience to authoritative parents. Problems with anxiety, loneliness, depression, and a sense of “not belonging” are common mental health concerns.

Many recent immigrants and refugees practice traditional healing methods of Chinese medicine, herbalists, and cope with evil spirits with coin rubbing. It has happened that Vietnamese parents were accused of child abuse when their son appeared at school with bruises on his torso. The school officials did not realize that well-meaning parents had rubbed his body with coins to heal his troubled spirit.

(2) *Treatment Approaches.* There is some evidence that Asian Americans underutilize mental health services. The problem appears to be fear of stigma and conflicting cultural values. When working with an Asian American client the degree of acculturation is a crucial consideration. If the families are recent immigrants or refugees, care should be taken to not offend and to behave in ways that are considered respectful and proper. Respect for authority is important in Asian culture, so the therapist should take an active, directive, teaching role. The therapists must show themselves to be credible and trustworthy. Many South East Asian clients expect concrete problem solving and advice giving. The therapist should be aware, however, that though they may offer advice it may not be followed. The therapist should not expect clients to talk about personal problems and personal feelings in an open fashion, especially in the beginning stages of therapy. Asian American clients often experience feelings of shame for having personal difficulties that require professional help and for bringing problems to a non-family member.

Language difficulties must be considered as well. Much literature has focused on the need for interpreters, but the results are mixed. Use of interpreters is generally discouraged unless they have been extensively trained in the proper role of an interpreter in a therapy context. It is not wise to use children or relatives as interpreters. A bilingual therapist is best, if one is available.

Major immigrant therapy issues include feeling socially isolated, struggling with gender and intergenerational adjustments in a new culture, and learning to adapt to new ways. Recent immigrants are often lonely and have lost loved ones or have lost social status by having to flee oppression. Japanese Americans may need encouragement to talk about the family internment history. South East Asian immigrants may need to talk about the traumas of refugee camps and victimizations by pirates.

Family therapy is advisable to deal with intergenerational problems if acculturated adolescents and traditional parents are not getting along. It is wise to show deference to the father, at least in the first session. It is never wise to insist that Asian adolescents, or adults, defy their parents openly. Acculturation takes time, and families can be helped to adjust if they are given hope for the future and a realistic sense of the amount of time it takes to adjust. Where possible, normalize problems to reduce feelings of shame.

d. Hispanic Americans. Hispanic Americans are growing rapidly in numbers. Due to high birth rates and a flow of immigrants, these Americans are the second largest minority group. The term Hispanic applies to all persons of Spanish-speaking descent. Other terms are in current usage including Latinos. Mexican American and Chicanos, are also common terms. Hispanic applies to a diverse group of peoples originally from Mexico, Puerto Rico, Cuba, and a number of Latin American countries, including Guatemala, El Salvador, the Dominican Republic, Honduras, and Nicaragua. The largest subgroups are Mexicans, many of whom have resided in parts of the southwest before the area became part of the United States in 1848, Puerto Ricans, who have been U.S. citizens since 1917, and Cubans many of whom have fled the Castro regime since the 1950s.

The history of Hispanics is filled with colonization and religious conversions. Many Mexican Americans have been victimized by racist policies, especially in the southwest. Many Hispanics are poor, with a median income below the national average. Migrant worker children drop out of high school at a rate of 50%, the second highest dropout rate.

Hispanics place great importance on the extended family and most live in two-parent families. Males are expected to value machismo, which has come to have many negative connotations, but has many positive ones as well, such being chivalrous, courageous, respectful, and protective. Men are heads of the household and are

expected to be responsible providers. Women are taught to value *marianismo*, which means high moral virtue. Indeed, women are expected to set the moral standards for men. Boys are expected to be independent, but girls are often restricted by the close supervision of their families. Children assume adult responsibilities at an early age, for working and helping to raise younger children. The influence of the Catholic church is strong. It has been theorized that part of the church influence is that many Hispanics believe in the inevitability of fate and may display resignation during hard times or when faced with personal problems.

(1) *Within-Group Differences.* There are approximately 34,334 million Hispanic Americans in the United States today. Hispanic Americans live in diverse places. Most Mexican Americans live in the southwest, Puerto Rican Americans reside mainly in urban areas of the east and Cubans tend to reside in the south, especially Florida. Cuban Americans have the highest incomes, and Puerto Rican Americans the lowest. Rates of acculturation vary greatly. Some Hispanics are monolingual for English, some are monolingual for Spanish, and many are bilingual. Recent immigrants may have little knowledge of English. Intergenerational problems, including conflicts about gender roles, are family problems associated with acculturation. These problems appear less often if the family is middle class or not Catholic. Less acculturated Hispanic families also experience adjustment and educational problems with children in schools, especially where English is the dominant language.

After centuries of intermarriage with American Indians, Blacks, Europeans, and Asians, Hispanics show a wide variety of skin colors. Each skin shade has its own term and relative status. Since the Spanish colonizations, lighter-skinned children are preferred in some groups. Such preferences, however, are not a given.

(2) *Treatment Approaches.* Hispanics historically underutilize mental health services. The reasons appear to have to do with language barriers, seeking help inside the extended family and concerns about conflicting values. Many Hispanics first seek folk healers—the *curandera*. Many may use folk healers and professional healers simultaneously. Common mental health concerns include acculturation adjustments, alcoholism, drug use, and intergeneration family conflicts. Poverty is also a concern that should be considered.

The therapist should assess the degree of acculturation as a first step in the therapy process. The therapist should learn how to properly pronounce Spanish

names and address people using their last names, at least in the first sessions. A therapist should also offer non-intimate self-disclosure to establish trust and to forming a working alliance. If the client offers a gift it is rude to not accept it.

Many Hispanic clients expect the therapist to offer suggestions that are practical and problem-solving oriented. Hispanics may think that therapy will be brief or perhaps only one session, so it is good to offer suggestions by the end of the first session. Problems with racism and identity formation should be explored and discussed. It is also advisable to address practical problems with jobs, food, clothing, and housing. The therapist should make flexible arrangements for session times, and be flexible if the client is late, misses appointments, or needs transportation.

Because of the importance of family ties, a family systems approach can be effective with Hispanic clients. Because of the emphasis on family cohesion and hierarchies, Structural family therapy is preferable to other approaches. It is important that the therapist show the family proper respect. Address the father first in the initial sessions.

Language problems must be dealt with. The literature is mixed concerning the use of interpreters. Some Hispanic clients resent the intrusion of a third party, whereas others feel that providing an interpreter is sign of caring about and respect for the cultural differences. A bilingual, bicultural therapist is preferable, if one is available.

Behavioral approaches tend to work best. Behavioral orientations have the cultural fit advantage of being goal oriented, action, rather than feeling oriented and here-now oriented, as well as brief. Social skills training and systematic desensitization are effective treatments for clients suffering from the stress and anxieties associated with making social adjustments. These are also methods associated with empowering clients and helping them to make changes in their adjustments to the new environment. Assertiveness training can be helpful for some clients, but with women clients the therapist should take care to not encourage role difficulties that make the client alienated from their families and cultures.

III. MULTICULTURAL ASSESSMENT

When assessing intelligence, achievement, and personality the psychologist is proceeding incompetently if certain culturally determined moderator variables are not taken into account. The major moderator variables that must be considered are acculturation, identity

development, values, and attitudes toward the larger society. Misdiagnosis and misguided treatment failures are common problems when working cross-culturally. For example, two of the most widely used personality tests—the MMPI–2 and Rorschach—were standardized using a majority of European participants. Subsequently, the tests are used as etic measures, when in fact they are emic measures. That is, they are culturally specific in their underlying constructs and test designs but are being applied throughout the world in mental health settings as if they are measuring universals.

Cross-cultural application of culture-specific tests is prone to errors in predictive validity and reliability. It has also been demonstrated that ethnic minorities as a group show more pathology and have lower performance scores on all known psychometric and intelligence tests. Generally, when persons are unacculturated and have been poorly educated, especially combined with low social economic status (SES), then test scores show more pathology or lower intelligence.

The problem of test bias has yet to be solved. Instrument bias occurs when the test is designed in a way that the task is unfamiliar to the test participants. For example, some cultures do not have familiarity with pictorial tests, such as the Rorschach. It is then difficult to know whether the Rorschach scores are a result of the internal processes of the participants or their lack of knowledge about the test stimuli. Construct bias is a problem when the test does not have equivalent constructs in the other culture. It may be impossible to create a “culture-free” test, but it is also very difficult to construct a “culture-fair” test. For example, the MMPI–2, does not measure constructs like “face” or “harmony,” both of which are immensely important social variables in Asian cultures. Moreover, it is not clear if concepts such as “depression,” “guilt,” “aggression,” and “filial piety” are equivalent across cultures.

Language barriers are also a source of bias. Translations of the MMPI–2 may not provide cross-cultural accuracy, especially if the test is translated directly, (i.e., with one interpreter of the second version). The only method that appears to have language accuracy is back translation, where two interpreters are used. One interpreter translates from the first language into the second language, and then a back interpreter translates back into the first language. When the third translation matches the first, then accuracy of the second language version can be assumed.

Examiner bias is also a concern. If the examiner harbors a preference for Eurocentric, assimilationist thinking, then test administration and interpretation may be biased. Eurocentric norms can be applied to clients, and

the given assumption is that any deviance for European norms is pathological. For instance, the examiner commits the error of functional bias if aggression is given a pathologic score for peoples for whom aggressive behavior is the norm in certain situations. Another example is to assume that the client is being negative, noncooperative or inept if they do not self-disclose in the assessment interview. Such behavior may be determined by the client’s culture, values conflicts, the situation or the examiner’s behavior, or all of these.

Multicultural research with the existing tests has been conducted for many years. Results are mixed. Research has also mainly focused on comparisons of African American tests scores and has not progressed very far with other ethnic minority groups. Research on the MMPI–2, for instance, has shown mixed results. Some authors report group differences comparing *T* scores of African Americans and White participants. Other authors, matching and controlling for social class and education background, found no significant differences between the two groups.

Accuracy in assessment outcomes can only be accomplished by first, assuming that cultural moderator variables are present, unless it is possible to rule them out. Second, the examiner has been carefully trained in recognizing the impact of culture on the testing and interview situation. Third, the tests themselves must be either altered to become culture sensitive or the norms of each group must be known or calculated. Fourth, and probably most important, the degree of acculturation of the client must be determined and the assessment process should be guided by this variable. Finally, test selection, administration, and interpretation should proceed only after all of these considerations have been met.

Few culture-specific intelligence and personality tests have been constructed, but existing tests are being researched for cultural accuracy, and new tests are under construction. Some researchers are working on developing truly etic, (i.e., universal measures, but these are not well developed yet). A number of culture-specific tests do exist to measure acculturation. Of the tests surveyed all were found to have adequate reliability and validity. Despite advantages of using these measures, they are currently used mainly for research purposes and have not become widely used for clinical work.

A number of scales exist to measure the attitudes, values, identity formation and degree of acculturation for different groups. Others measure acculturation and identity formation across groups. The number of existing scales is too numerous to offer a complete review here. Some scales that are gaining in recognition are

measures specific to African Americans, and those have concentrated on developmental issues of identity and racial attitudes, rather than acculturation, because most African Americans are bicultural. The Racial Identity Attitude Scale (RIAS-B), the Black Identification Scale (BIS), and the Developmental Inventory of Black Consciousness (DIB-C) and the Black Personality Questionnaire (BPQ) are examples of measures currently available. Some measures of White identity have also been developed. The White Racial Identity Attitude Scale (WRIAS) and the White Racial Consciousness Development Scale (WRCDS) are currently in use.

Some measures are designed to measure degree of affiliation and the degree of acculturation with a specific group. Some examples include, the American Indian Self-Identification Scale, the Acculturation Rating Scale for Mexican Americans (ARSMA-II), the Measure of Acculturation for Mexican Americans, the Bicultural Involvement Questionnaire (for Cuban Americans), the Suinn-Lew Asian Self-Identity and Acculturation Scale (SL-ASIA), the Ko Mental Health Questionnaire (KMHQ), and the Chinese Personality Inventory (CPAI).

Other scales are designed for multiethnic use. These include, the Multigroup Ethnic Identity Measure (MEIM), the Bicultural Inventory (BI), the Acculturative Balance Scale (ASC), and the Scale of Effects of Ethnicity and Discrimination (SEED).

Some measures are being developed to assess the competencies of the mental health services and counselors. The Agency Cultural Competency Checklist, the Multicultural Environmental Inventory (MEI), and the Institutional Racism Scale (IRS) are available for agencies and degree programs. The Cross-Cultural Counseling Inventory-Revised (CCCI-R), the Multicultural Counseling Knowledge and Awareness Scale (MCKAS), and the Multicultural Awareness-Knowledge-and-Skills Survey (MAKSS) are measures of the cultural competency of the therapists.

It is still an important question, however, as to how to measure acculturation. Acculturation is not static, levels of acculturation change over time. Another problem is that there are such great variations within groups that the validity of any group measure can be questioned. There are also wide differences between different regions of the country, and between urban and rural residents. Persons may also be totally unacculturated (speaking little if any English and spending little, if any time in the larger society, bicultural (speaking both English and their native language or dialect and spending equal amounts of time in both cultures) or totally

acculturated (speak only English and have little, if any contact with their native culture). How do these different levels, with many points in between, become accurately measured? Moreover, it is possible for an individual to have multiple identities, depending on the situation and the reference group. At present, until these problems are resolved, it is considered preferable to use available measures despite these difficulties.

IV. RESEARCH ISSUES

Research in multicultural assessment and practice has been moving along steadily, but much remains to be done. There are still at least five important problems to be addressed.

1. More information is needed on the epidemiology and prevalence of disorders in ethnic minority populations.
2. Further outcome data is needed to answer the questions as to whether or not alternative culture-sensitive therapies are actually more effective with minority clients.
3. Further research on usage patterns is needed to explain the mixed information existing in the literature.
4. More empirical studies are needed to evaluate ethnic-specific assessment instruments.
5. More work is needed on ethnic minority identity development and formation.

Not much is known on incidence and prevalence of various disorders. This is partly true because most studies have been carried out either in hospitals, where only limited diagnostic data is obtained, or in community mental health settings, with few minorities presenting for therapy. As has been pointed out, a lack of help seeking should not be equated with a lack of mental health problems. The research on usage is inconsistent. Many studies show that ethnic minorities tend to underutilize mental health services but other, more recent studies, show that some minority groups are utilizing services at a comparable rate to White clients.

Controlling for the different variables that affect mental disorders is not an easy task. In fact, it is very cumbersome. For instance, much has been written about the linkage between SES and mental illness. It is, therefore, important to have some consistency between studies as to how SES is determined. Should the criteria be the income of the head of the household, or occupation of the head of household or total extended family financial re-

sources? Studies are being conducted using different criteria. How do these inconsistencies between studies affect the research results and conclusions? It is also difficult to get broad research participation in some minority communities, due to a historically based lack of trust between minority peoples and the larger society.

Most of the ethnic-specific instruments have been developed using college students. Analogue methods for test construction and clinical training have been shown to have drawbacks. Again, under these circumstances there can be confounds between power-level discrepancies, SES, gender, the acculturation of the participants and the constructs being measured. Test instruments need further norming within client settings and among the general populations of ethnic minorities. Questions of equivalence must be addressed. Are the tests measuring the same constructs? The cross-cultural equivalence problems with existing instruments are well known, but construction of truly ethnic measures will be a daunting task. Large sample sizes are needed, and these are hard to acquire. It will also be necessary to compare across more than two cultures, as well as controlling for the usual variables of age, education, SES, and so on. A particularly difficult problem concerns different meanings attributed to words in different cultures. More rigorous control for use of language, especially in personality tests, is required.

If alternative methods are more effective, the question then is which particular methods and with which ethnic groups? If alternative methods are not more effective then why not? Treatment satisfaction results are mixed. Most studies reviewed here report that minority clients prefer a directive approach. However, some studies dispute this, showing a preference for non-directive approaches. More research is needed on insight-oriented therapies, especially those that are conducted with culture-sensitive modifications. Given the present state of the research it cannot be assumed that insight therapies are not effective with ethnic minority clients. Nor, for that matter, can it be assumed that only directive/behavioral therapies are preferred. More is needed on effectiveness of ethnic and gender matching. Again, studies are mixed in the results obtained. Some studies show that minority women and men differ in their preferences on this dimension.

Bicultural identity development research work is barely beginning. As the demographics of the U.S. population change, more people are self-reporting biethnic or mixed ethnic identities. Minority and White identity development models need further clarification and research on the connection between identity formation

and the therapy process. Definitions of ethnic identity must be widened to include persons who claim multi-ethnic or multicultural backgrounds.

Possible explanations for research results discrepancies include the following:

1. The variables being tested are not specific enough. In particular, the linkages between SES, gender, and treatment satisfaction have not been consistently controlled.

2. The acculturation levels of clients is another crucial variable that has not been adequately controlled for.

3. Many studies have been based on an entire ethnic subgroup, (i.e., Asian American or African American, or Hispanics, or even non-White vs. White clients, etc.). Studies such as these are not conducted with sufficient regard for the enormous within group differences.

4. Cultures are not separate or static. Whenever different ethnic groups encounter each other a series of mutual cultural exchanges and influences begin that forever alter the participants. This cultural exchange variable, while always present, is difficult to isolate.

V. TRAINING ISSUES

Many psychologists feel reluctant and ambivalent about treating poor and minority clients. The essential questions for training programs are "What happens when a therapist encounters a client who is different?" "Is the therapist able and willing to engage in conversations that are meaningful to the client?" This would include participating in appropriate discussions about group inequalities and the painful experiences of people who have been subjected to oppressive social conditions. Given our nation's history, the very subject of racial and social class relations is loaded with conflictual, painful, and anxiety-provoking content. These subjects have been treated as taboo topics, with little substantive conversation in the media or in school settings. Most psychologists are from White and/or middle-class backgrounds. They have had little, if any, experience living or working among poor or ethnic minority peoples. Their own degree of unfamiliarity can be felt as a barrier to forming meaningful therapy relationships. Furthermore, the topic of multicultural practice is loaded with complex concepts, complex skills and a long list of behaviors that a psychologist is expected to master. The prospect of becoming multiculturally competent can feel overwhelming.

Given the difficulties inherent in the subject matter, combined with the rapidly changing demographics in

the country, it follows that graduate degree programs must step up their training efforts in multicultural practice. Up-to-date information on the curricula of degree program offerings in multicultural training is sketchy. What is apparent is that some programs offer specific courses, practica, and workshops, and so on, while other programs offer little, if anything, specifically designed to train graduates in this area. Some programs focus on specific cultural groups, that is, training in working with African Americans or working with American Indian clients, and so on. Others take a broad-based approach. In some programs multicultural training is a degree requirement, in others training is an elective.

The literature reviewed here is consistent on the viewpoint that effective training models should strive to integrate four major goals:

1. Increasing awareness of the student's own and other people's cultural norms.
2. Increasing specific cultural and clinical knowledge about different cultural groups.
3. Developing skills about how to interact effectively with peoples who are culturally different.
4. Consciousness raising about how cultural differences affect the therapy process and learning to become comfortable with those differences.

Training should also be comprehensive enough to cover cognitive, behavioral, and affective learning.

Course work in a didactic format with lectures, discussions and term papers, and so on, is mainly viewed as a beginning platform to which other components are added. Specific knowledge about cultural groups, their histories, cultural norms, and so on, can be conveyed in this format. There are so many different groups, however, that programs should offer several subcourses that offer in-depth knowledge about different groups and the clinical issues associated with each. It is unlikely that a single comprehensive course can be designed to do justice to this entire topic.

Other goals intended to increase awareness and skills can only be achieved through combining multiple learning techniques. Increasing self-knowledge, including learning about one's own cultural norms and assumptions, is a crucial component. How to train students in this aspect is still being developed. The Pedersen Triad model is an example. In this model students role play working with a culturally different client while an "anticounselor" voices the negative thoughts of the client and the "procounselor" voices the positive thoughts of the client. This training technique is intended to bring to light the differences between the

client and the counselor and to enhance the counselor's awareness of the impact of differences on the therapy process. Another model for increasing awareness is the Hines & Pedersen Cultural Grid, which offers comparisons of same versus different expectations, values, and behaviors. Another method is the use of "synthetic" cultures. Using IBM staff personnel from around the world, Hofstede identified four cultural dimensions: small versus large power distances, weak versus strong uncertainty avoidance, masculinity versus femininity, and collectivism versus individualism. From these dimensions synthetic cultures named Alpha (high power distance), Beta (strong uncertainty avoidance), Gamma (high individualism), and Delta (high masculinity) were developed. The Leong and Kim Intercultural Sensitizer method presents students with a case story in which some culturally based misunderstanding occurs. After reading these short stories students choose from four possible explanations for the misunderstandings. Each possible choice is accompanied by a rationale for why each choice is correct or incorrect.

Using vignettes based on the Cultural Grid, synthetic cultures or Intercultural Sensitizer counselors can examine their assumptions, attitudes, and predispositions and how their cognitions affect the client case. Other methods for developing skills and awareness include role plays and real-life client-counselor sessions using videotapes and case studies. Students watch videotapes of cross-cultural interactions and then analyze the underlying cultural assumptions and their impact on the interactions.

To consolidate the learning process, it is important that training go beyond the classroom. A cultural immersion experience is suggested to complement academic and skills-building components. A number of immersion experiences are possible. In some cases the immersion experience is a placement in a community mental health center that serves ethnic minority clients. In other settings, especially where there are no suitable community placements, the immersion experience can be volunteer service work. Another approach is to use field trips to relevant ethnic communities, social programs, and agencies. Some schools have adopted a "buddies" system technique, in which students are paired with a foreign student and engage in social activities. After contact with peoples in the immersion experience it is advisable to provide debriefing sessions in which trainees can analyze their experiences.

It is important that graduate programs realize that multicultural training can be stressful. Training programs should be carefully planned to provide a format in which certain inevitable affective responses and reactions can be discussed and resolved. Students often

feel anxious when asked to engage in open, honest discussions with or about people who are different. Many are anxious when in contact with people who are different. Students are often anxious about revealing any “hidden” or unintentional racism, sexism or homophobia, and so on. Students may experience feelings of guilt or shame. The training format should help students cope with these emotions. Students should learn to become comfortable with differences and the unavoidable interpersonal and intergroup conflicts that will arise. Trainees need a format that allows for the emergence of intergroup conflicts and that also allows for the resolution of conflicts. Trainees need to be trained in the appropriate, that is, therapeutic methods for establishing rapport with clients who may be identified with being social victims. Training needs to be conducted over a sufficient period of time, utilizing a stage model with increasing degrees of difficulty of course material, personal awareness, and interpersonal skills development as the training progresses.

As of yet, there is little information on the frequency of use of these models in training programs. There are few studies on the evaluation of training models. Little is known about the effectiveness of different models. For instance, there is little information on pre- and posttests to demonstrate effectiveness of graduate student training. More work is needed to examine the effectiveness of existing training models and to develop additional models. Degree-granting programs in psychology will eventually be pressured by the rapidly changing population demographics to provide sufficient training in working with ethnic minority and bicultural clients. For the first time the U.S. Census Bureau included a multiracial category in the 2000 census. 6,826,228 million (or 2.4 percent) respondents checked two or more races. The future arrives sooner than we think.

GLOSSARY

desensitization The gradual overcoming of a symptom or behavior by the presence of a counter behavior or idea in the presence of the provoking stimulus, usually in a graduated degree of intensity.

exposure Behavioral technique that involves confrontation with the symptom provoking stimulus.

multimodal Refers to different modes of therapy that involve social, cognitive, emotional, behavioral, and biological dimensions of the individual's life. Also refers to different ways of doing therapy based on these different issues, such as family therapy, medications, psychotherapy, etc.

mustabatory An Ellis term referring to the set of ideas formed by the individual's sense of social necessity or the requirements of other important people. Frequently, these ideas have a rigid and preemptory quality.

Rational emotive behavior therapy (REBT) was originated in January 1955 as a pioneering cognitive–experiential–behavioral system of psychotherapy. It is heavily

cognitive and philosophical, and specifically uncovers clients' irrational or dysfunctional beliefs and actively and directly disputes them. But it also sees people's self-defeating cognitions, emotions, and behaviors as intrinsically and holistically connected, not disparate. It holds that they disturb themselves with disordered thoughts, feelings, and actions, all of which importantly interact with each other and with the difficulties they encounter in their environment. Therefore, with emotionally and behaviorally disturbed people, REBT employs a number of thinking, feel, and action techniques that are designed to help them change their self-defeating and socially sabotaging conduct to self-helping and socially effective ways.

REBT theorizes that virtually all humans consciously and unconsciously train themselves to be to some degree emotionally disturbed. Therefore, with the help of an effective therapist and/or with self-help materials, they can teach themselves to lead more satisfying lives—if they choose to do so and work hard at modifying their thinking, feeling, and behaving.

Albert Ellis, the originator of REBT, was trained in Rogerian person-centered therapy in graduate school in clinical psychology (1942–1947), found it too passive and abandoned it for psychoanalytic training and practice (1947–1953). But psychoanalysis, too, he found ineffective because it was too much insight-oriented and too little action-oriented. His clients often saw how they originally became disturbed—supposedly because of their family history. But when he stayed

with typical psychoanalytic methods, he failed to specifically show them how to think and act differently and to thus make themselves more functional.

So Ellis went back to philosophy, which had been his hobby since the age of 16, and re-read the ancient philosophers (especially Epicurus, Epictetus, Marcus Aurelius, and Gautama Buddha) and some of the moderns (especially John Dewey, Bertrand Russell, and Paul Tillich) and found that they were largely constructivists rather than excavationists. They held that people do not merely get upset by adverse life conditions, but instead often choose to disturb themselves about these adversities. A number of philosophers also said that people could choose to unupset themselves about minor and major difficulties; if they made themselves anxious and depressed, they could reduce their dysfunctional feelings and behaviors by acquiring a core philosophy that was realistic, logical, and practical.

Following these philosophers, Ellis started to teach his clients that they had a choice of experiencing healthy negative emotions about the misfortunes they encountered—such as feelings of sorrow, disappointment, and frustration; or they could choose to experience unhealthy negative reactions—such as panic, depression, rage, and self-pity. By using rational philosophy with troubled clients, he saw that when they faced adversities with self-helping attitudes they made themselves feel better and functioned more productively. But when they faced similar adversities with irrational (self-defeating) philosophies they made themselves miserable and acted ineffectively. When he convinced them that they almost always had the choice of helping or hindering themselves, even when their desires and goals were seriously blocked, they often were able to make that choice.

I. THE ABCs OF RATIONAL EMOTIVE BEHAVIOR THERAPY

During the 1950s, Ellis put this constructivist theory into the now well-known ABCs of REBT. This theory states that almost all people try to remain alive and achieve basic Goals (G) of being reasonably content by themselves, with other people, productively working, and enjoying recreational pursuits. When their Goals are thwarted and they encounter Adversities (A) they are then able to construct Consequences (C)—mainly feelings and actions—that either help or hinder them satisfy these Goals. They largely (although not completely) do this by choosing to follow rational, useful Beliefs (B) or to follow irrational, dysfunctional Beliefs. Therefore, although the Adversities (A) they experience are impor-

tant contributors to their emotional and behavioral Consequences (C), they do not directly or solely cause these Consequences. When at C, people feel and act dysfunctionally or self-defeatingly, their irrational Beliefs (B) and their experienced Adversities (A) bring on their disturbed reactions. So A does not by itself lead to C. A interacts with B to produce C; or $A \times B = C$. However, people tend to be aware that C follows A, but not that B is also included in the process. They therefore think that adverse As automatically lead to disturbed Cs—that their internal reactions are controlled by external events.

Ellis noted in his first paper on REBT at the Annual Convention of the American Psychological Association in Chicago in August 1956, that when people feel and act disturbedly (C), they have 12 common irrational or dysfunctional Beliefs (B) about the undesirable things that happen to them (A). When they change these to rational or functional Beliefs (in therapy or on their own) they become significantly less disturbed. Both these hypotheses have been supported by many empirically based studies, first by followers of REBT and then by other cognitive behavior therapists who largely follow and have tested the ABC theory of REBT. Hundreds of published studies have given much support to this theory.

After using REBT for a few years in the 1950s, Ellis came up with clinical evidence for Karen Horney's hypothesis about the "tyranny of the shoulds." He realized that the many irrational Beliefs with which people often disturb themselves can practically always be put under three major headings, all of which include absolutistic shoulds, oughts, and musts. With these three core dysfunctional ideas, people take their strong preferences for success, approval, power, freedom, and pleasure, and elevate them to dogmatic, absolutistic demands or commands.

The imperatives that frequently accompany dysfunctional feelings and behaviors seem to be (1) "I absolutely must perform well at important tasks and be approved by significant others—or else I am an inadequate person!" (2) "Other people absolutely must treat me kindly, considerately, and fairly—or else they are bad individuals!" (3) "Conditions under which I live absolutely must provide me with what I really want—or else my life is horrible, I can't stand it, and the world's a rotten place!"

These three common irrationalities lead to innumerable derivative irrational Beliefs and frequently are accompanied by disturbed emotional and behavioral Consequences. In fact, REBT hypothesizes that people would find it difficult to make themselves disturbed without taking one or more of their major preferences and transforming them into absolutistic demands. Individuals with severe personality disorders and psychosis

also disturb themselves by turning their healthy preferences into unhealthy musturbating, but they often have other biochemical and neurological characteristics that help make them disturbed.

REBT also theorizes that the tendency to elevate healthy preferences to insistent demands, and thereby to think, feel, and act unrealistically and illogically, is innate in humans. People naturally and easily take some of their strong goals and desires and often view them as necessities. This self-defeating propensity is then exacerbated by familial and cultural upbringing, and is solidified by constant practice by those who victimize themselves with it. Therefore, especially with seriously disturbed people, psychotherapy and self-help procedures can, but often only with difficulty, change their dysfunctioning.

Many therapy techniques—such as meditation, relaxation, a close and trusting relationship with a therapist, and distraction with various absorbing activities—can be used to interrupt clients' musturbatory tendencies and help them feel better. But in order for them to get and stay better, REBT holds, they usually have to consciously realize that they are destructively escalating their healthy desires into self-sabotaging demands and then proceed to D—to actively and forcefully Dispute the irrational Beliefs that are involved in their disturbances. By vigorously and persistently Disputing these Beliefs—cognitively, emotively, and behaviorally—they can change their self-destructive shoulds and musts into flexible, realistic, and logical preferences. They thereby can make themselves significantly less disturbed.

II. RATIONAL EMOTIVE BEHAVIOR THERAPY TECHNIQUES

To help people specifically achieve and maintain a thoroughgoing antimusturbatory basic outlook, REBT teaches them to use a number of cognitive, emotive, and behavioral methods. It helps them gain many insights into their disturbances, but emphasizes three present-oriented ones:

Insight No. 1: People are innate constructivists and by nature, teaching, and, especially, self-training they contribute to their own psychological dysfunctioning. They create as well as acquire their emotional disabilities—as the ABC theory of REBT notes.

Insight No. 2: People usually, with the “help” and conivance of their family members, first make themselves disturbed when they are young and relatively foolish. But then they actively, although often unconsciously, work hard after their childhood and adolescence is over

to habituate themselves to dysfunctional thinking, feeling, and acting. That is mainly why they stay disturbed today. They continue to construct dysfunctional Beliefs.

Insight No. 3: Because of their natural and acquired propensities to strongly choose major goals and values and to insist, as well as to prefer, that they must achieve them, and because they hold these self-defeating beliefs and feelings for many years, people firmly retain and often resist changing them. Therefore, there usually is no way for them to change but work and practice—yes, work; yes, practice—for a period of time. Heavy work and practice for short periods of time will help; so brief rational emotive behavior therapy can be useful. But for long-range gain, and for clients to get better rather than to feel better, they require considerable effort to make cognitive, emotive, and behavioral changes.

REBT clients are usually shown how to use these three insights in the first few sessions of psychotherapy. Thus if they are quite depressed (at point C) about, say, being rejected (at point A) for a very desirable job, they are shown that this rejection by itself did not lead to their depression (C). Instead they mainly upset themselves with their musturbatory Beliefs (B) about the Adversity (A). The therapist explores the hypothesis that they probably took their desire to get accepted and elevated it into a demand—for example, “I must not be rejected! This rejection makes me an inadequate person who will continually lose out on fine jobs!”

Second, clients are shown—using REBT Insight No. 2—that their remembering past Adversities (A), such as past rejections and failures, does not really make them depressed today (C). Again, it is largely their Beliefs (B) about these Adversities that now make them prone to depression.

Third, clients are shown that if they work hard and persistently at changing their dysfunctional Beliefs (B), their dire needs for success and approval, and return to mere preferences, they can now minimize their depressed feelings—and, better yet, keep warding them off and rarely falling back to them in the future. REBT enables them to make themselves less disturbed and less disturbable.

III. MULTIMODAL ASPECTS OF RATIONAL EMOTIVE BEHAVIOR THERAPY

To help clients change their basic self-defeating philosophies, feelings, and behaviors, REBT practitioners actively and directly teach and encourage them to use a good many cognitive, experiential, and behavioral

techniques, which interact with and reinforce each other. It is one of the pioneering integrative therapies. Cognitive methods are particularly emphasized, and often include (1) Active disputing of clients' irrational beliefs by both the therapists and the client; (2) rational coping self-statements or effective philosophies of living; (3) modeling after people who coped well with Adversities similar to, or even worse than, those of the clients; (4) cost-benefit analyses to reveal how some pleasurable substances and behaviors (e.g., smoking and compulsive gambling) are self-sabotaging and that some onerous tasks (e.g., getting up early to go to work) are unpleasant in the short term but beneficial in the long run; (5) REBT cognitive homework forms to practice the uncovering and disputing of dysfunctional Beliefs; (6) psychoeducational materials, such as books and audio-visual cassettes, to promote self-helping behaviors; (7) positive visualizations to practice self-efficacious feelings and actions; (8) reframing of Adversities so that clients can realize that they are not catastrophic and see that they sometimes have advantages; (9) practice in resisting overgeneralized, black and white, either/or thinking; (10) practical and efficient problem-solving techniques.

REBT uses many emotive-experiential methods and materials to help clients vigorously, forcefully, and affectively Dispute their irrational demands and replace them with healthy preferences. Some of its main emotive-expressive techniques include the following: (1) Forceful and persistent disputing of clients' irrational Beliefs, done *in vivo* or on a tape recorder; (2) experiencing a close, trusting, and collaborative relationship with a therapist and/or therapy group; (3) steady work at achieving unconditional other-acceptance (UOA), the full acceptance of other people with their failings and misbehaviors; (4) using visualizations or live experiences to get in touch with intense unhealthy negative feelings—and to train oneself to feel, instead, healthy negative feelings; (5) role-playing difficult emotional situations and practicing how to handle them; (6) using REBT's shame-attacking exercises by doing "embarrassing" acts in public and working on not denigrating oneself when encountering disapproval; (7) engaging in experiential and encounter exercises that produce feelings of discomfort and learning how to deal with these feelings.

REBT uses many activity-oriented behavioral methods with clients, such as (1) Exposure or *in vivo* desensitization of dysfunctional phobias and compulsions; (2) taking deliberate risks of failing at important projects and refusing to upset oneself about failing; (3)

staying in uncomfortable situations and with disturbed feelings until one has mastered them; (4) reinforcing oneself to encourage self-helping behaviors and penalizing oneself to discourage self-defeating behaviors; (5) stimulus control to discourage harmful addictions and compulsions; (6) relapse prevention to stop oneself from sliding back to harmful feelings and behaviors; (7) skill training to overcome inadequacies in assertion, communication, public speaking, sports, and other desired actions that one is inhibited about.

These are some of the cognitive, emotive, and behavioral techniques that are frequently employed in rational emotive behavior therapy. Many other possible methods are individually tailored and used with individual clients.

The main therapeutic procedure of REBT is to discover how clients think, feel, and act to block their own main desires and goals, and to figure out and experiment with ways of helping them get more of what they desire and less of what they abhor. As they make themselves less disturbed and dysfunctional, they are helped to actualize themselves more—that is, to provide themselves, idiosyncratically, with greater satisfactions. At the same time, clients are helped to stubbornly refuse to define their preferences as dire necessities and thereby tend to reinstitute their disturbances.

IV. REVIEW OF THE LITERATURE

When Ellis originated it in 1955, rational emotive therapy was unique. It was followed by somewhat similar forms of cognitive behavior therapy (CBT) in the 1960s and 1970s, particularly cognitive therapy of Aaron Beck, rational behavior therapy of Maxie Maultsby, Jr., cognitive behavior modification of Donald Meilchenbaum, and Multimodal Therapy of Arnold Lazarus. REBT was soon supported by about 300 published studies that showed its effectiveness with many different types of clients.

Many of these have been surveyed in comprehensive reviews by R. DiGiuseppe, N. J. Miller, and L. D. Trexler, by T. E. McGovern and M. S. Silverman, by D. Hajzler and M. E. Bernard, by L. C. Lyons and P. J. Woods, and by M. S. Silverman, M. McCarthy, and T. E. McGovern.

As a result of its many successful outcome studies, REBT has become one of the most practiced psychotherapies. It is widely used with children, adolescents, couples, families, people with sex problems, and in other forms of counseling and psychotherapy. In ad-

dition, it is often used in business and industry, in education, in sports, in assertion training, in stress management, in parenting, and in many other fields.

Finally, REBT has revolutionized the self-help industry and has been widely adapted in scores of best-selling books, workbooks, and audio-visual cassettes, such as Wayne Dyer's *Your Erroneous Zones*, Albert Ellis' *A Guide to Rational Living*, and David Burns' *Feeling Good*.

The Albert Ellis Institute in New York, and in its many American and foreign branches, trains therapists and counselors in REBT and certifies them in its practice. To date, it and its affiliates have certified well over 5000 therapists.

V. SUMMARY

Rational emotive behavior therapy (REBT) was originated in 1955 as the first of the major cognitive behavior therapies. It has been shown to have effective outcomes in hundreds of published studies and has become one of the most popular psychotherapies. It looks like it, as well as cognitive behavior therapy, will continue to thrive in the 21st century.

GLOSSARY

- choice theory** The underlying principles of reality therapy that emphasize behavior as chosen for the purpose of satisfying inner genetic instructions or needs.
- environment** The therapeutic atmosphere or climate that serves as the basis for specific interventions.
- WDEP** The delivery system of reality therapy, signifying wants, direction and doing, self-evaluation, and planning.

Founded by William Glasser reality therapy has its roots in the work of Alfred Adler, who emphasized that human beings are social in nature and that behavior is goal centered. Glasser extended his early ideas to include genetic instructions or human needs as sources of human behavior. Accordingly, human beings originate their own behavior. It is not thrust on them by their families, their environment, or their early childhood conflicts. Rather, behavior is seen as chosen. In the early stages of its evolution, the formula for reality therapy was described as involving eight steps. Used widely in therapy, counseling, corrections, as well as in education,

reality therapy attempted to avoid coercion and punishment and teach inner responsibility. Its current formulation as a delivery system, developed by Robert E. Wubbolding in his books *Using Reality Therapy* and *Reality Therapy for the 21st Century*, is summarized with the letters WDEP. Its use now extends to self-help, as well as management, supervision, and coaching employees.

Describing the root of human strife as flawed relationships, Glasser has provided a theoretical and conceptual blueprint for addressing human conflict. Wherever human relationships are improved, productivity increases in the workplace, families remain intact, students achieve, and organizations achieve their goals and function more humanely.

I. DESCRIPTION OF TREATMENT: ENVIRONMENT AND PROCEDURES

Figure 1 presents an outline of the delivery system for reality therapy. Establishing a safe atmosphere or environment provides the basis for the more specific interventions known as procedures. As in any therapy the therapist listens to clients' stories presented in their own words and seeks to become part of their inner discourse. In the language of choice theory the therapist becomes part of the clients' quality world (i.e., someone who is capable of providing needed help). The procedures are the specific tools for helping clients clarify and prioritize their wants, evaluate their actions and self-talk, and finally, make plans for effective change. The "Cycle of

CYCLE OF MANAGING, SUPERVISING, COUNSELING AND COACHING

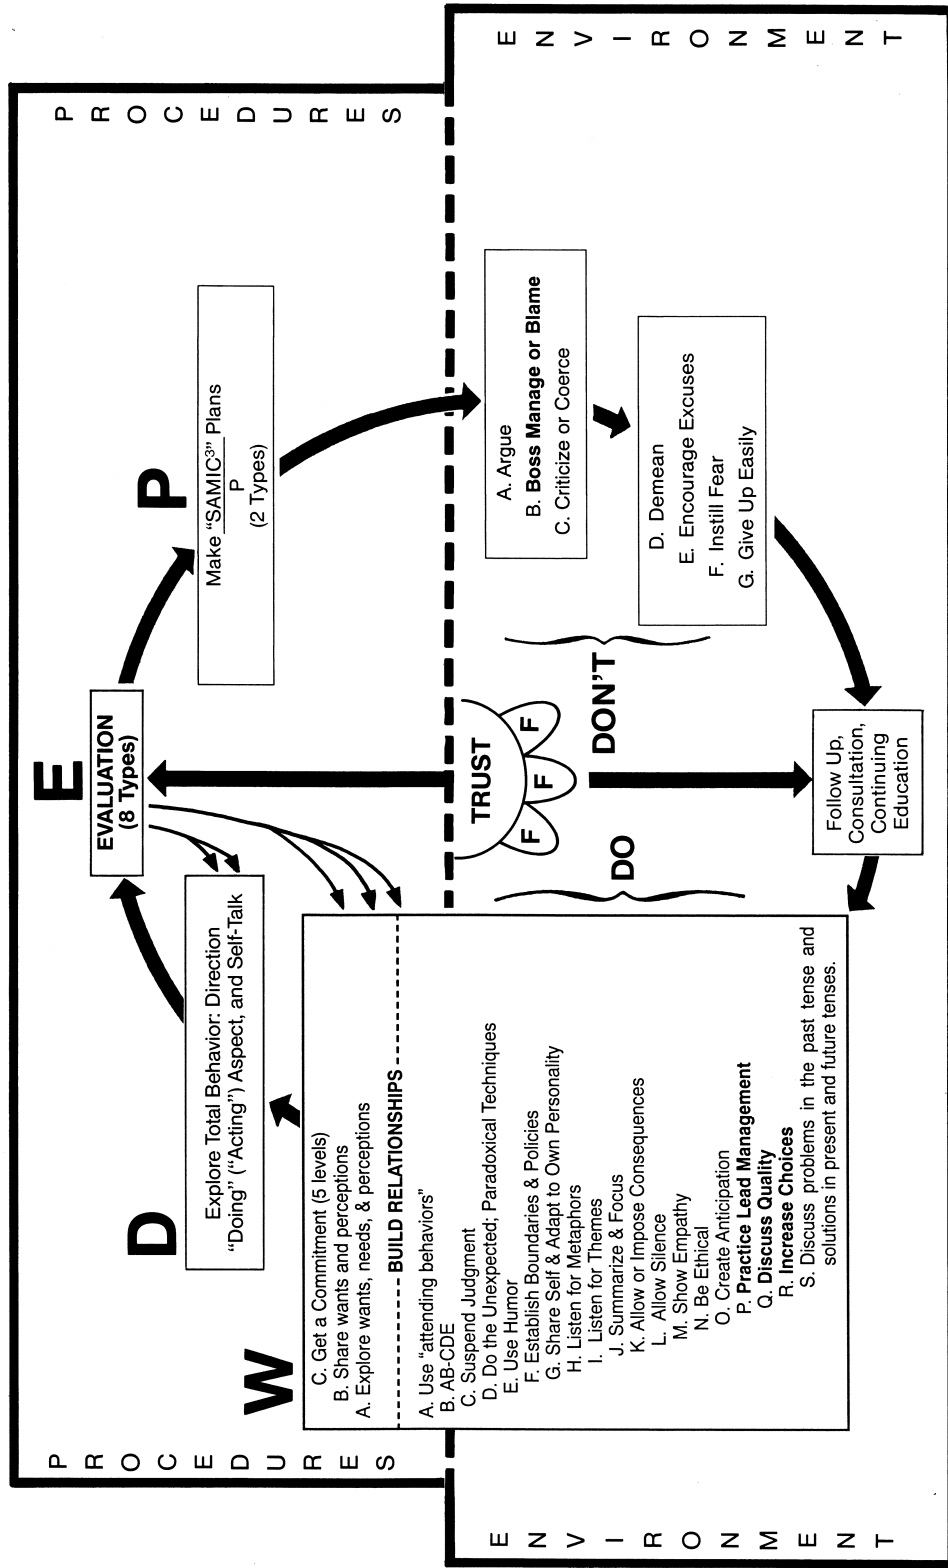

FIGURE 1 Outline of the delivery system for reality therapy. Adapted from the works of William Glasser. Copyright 1986 Robert E. Wubbolding. Reproduced with permission.

Summary Description of the Cycle of Managing, Supervising, Counseling and Coaching

Introduction:

The Cycle consists of two general concepts: Environment conducive to change and Procedures more explicitly designed to facilitate change. This chart is intended to be a brief summary. The ideas are designed to be used with employees, students, clients as well as in other human relationships.

Relationship between Environment & Procedures:

1. As indicated in the chart, the Environment is the foundation upon which the effective use of Procedures is based.
2. Though it is usually necessary to establish a safe, friendly Environment before change can occur, the "Cycle" can be entered at any point. Thus, the use of the cycle does not occur in lock step fashion.
3. Building a relationship implies establishing and maintaining a professional relationship. Methods for accomplishing this comprise some efforts on the part of the helper that are Environmental and others that are Procedural.

Environment:

DO: Build Relationship: a close relationship is built on TRUST through friendliness, firmness, and fairness.

- A. Using Attending Behaviors: Eye contact, posture, effective listening skills.
- B. AB = "Always Be..." Consistent, Courteous & Calm, Determined that there is hope for improvement, Enthusiastic (Think Positively).
- C. Suspend Judgment: View behaviors from a low level of perception, i.e., acceptance is crucial.
- D. Do the Unexpected: Use paradoxical techniques as appropriate; Reframing and Prescribing.
- E. Use Humor: Help them fulfill need for fun within reasonable boundaries.
- F. Establish boundaries: the relationship is professional.
- G. Share Self: Self-disclosure within limits is helpful; adapt to own personal style.
- H. Listen for Metaphors: Use their figures of speech and provide other ones.
 - I. Listen to Themes: Listen for behaviors that have helped, value judgements, etc.
 - J. Summarize & Focus: Tie together what they say and focus on them rather than on "Real World."
 - K. Allow or Impose Consequences: Within reason, they should be responsible for their own behavior.
 - L. Allow Silence: This allows them to think, as well as to take responsibility.
 - M. Show Empathy: Perceive as does the person being helped.
 - N. Be Ethical: Study Codes of Ethics and their applications, e.g., how to handle suicide threats or violent tendencies.
 - O. Create anticipation and communicate hope. People should be taught that something good will happen if they are willing to work.
 - P. Practice lead management, e.g., democracy in determining rules.
 - Q. Discuss quality.
 - R. Increase choices.
 - S. Discuss problems in the past tense, solutions in present and future tenses.

DON'T:

Argue, Boss Manage, or Blame, Criticize or Coerce, Demean, Encourage Excuses, Instill Fear, or Give up easily.

Rather, stress what they can control, accept them as they are, and keep the confidence that they can develop more effective behaviors. Also, continue to use "WDEP" system without giving up.

Follow Up, Consult, and Continue Education:

Determine a way for them to report back, talk to another professional person when necessary, and maintain ongoing program of professional growth.

Procedures:

Build Relationships:

- A. Explore Wants, Needs & Perceptions: Discuss picture album or quality world, i.e., set goals, fulfilled & unfulfilled pictures, needs, viewpoints and "locus of control."
- B. Share Wants & Perceptions: Tell what you want from them and how you view their situations, behaviors, wants, etc. This procedure is secondary to A above.
- C. Get a Commitment: Help them solidify their desire to find more effective behaviors.

Explore Total Behavior:

Help them examine the Direction of their lives, as well as specifics of how they spend their time. Discuss ineffective & effective self talk.

Evaluation - The Cornerstone of Procedures:

Help them evaluate their behavioral direction, specific behaviors as well as wants, perceptions and commitments. Evaluate own behavior through follow-up, consultation and continued education.

Make Plans: Help them change direction of their lives.

Effective plans are Simple, Attainable, Measurable, Immediate, Consistent, Controlled by the planner, and Committed to. The helper is Persistent. Plans can be linear or paradoxical.

Note: The "Cycle" describes specific guidelines and skills. Effective implementation requires the artful integration of the guidelines and skills contained under Environment and Procedures in a spontaneous and natural manner geared to the personality of the helper. This requires training, practice and supervision. Also, the word "client" is used for anyone receiving help: student, employee, family member, etc.

FIGURE 1 (Continued).

Managing, Supervising, Counseling, and Coaching” is applicable to many relationships and is used in many settings where human relationships are paramount: teaching, therapy and counseling, consultation, management, and supervision. Moreover, reality therapy employs several strategies common to all counseling theories.

Also, although the environment is the foundation upon which the procedures are built, there is no absolute line of demarcation between them. Thus “Build Relationships” is both environmental and procedural. Nor is the “Cycle” a simplistic lock-step method to be entered unwaveringly at the same place with every patient. People using reality therapy in their human interactions, enter the “Cycle” at various points. Although a therapist generally establishes a friendly, warm relationship before employing procedures that lead to change, helping clients evaluate their own behavior and making plans often occurs early in the therapy process.

Finally, because reality therapy is used in corrections, in classrooms, and in many relationships besides therapy, specific helpful and hurtful and behaviors as well as attitudes are described under environment such as “don’t criticize” and “don’t encourage excuses.”

A. Environment

The word “environment” implies an effort on the part of the therapist to establish an atmosphere in which the patient can feel safe, secure, and motivated. As shown in Figure 1, hindrances to establishing a trusting, helpful, safe environment include arguing, bossing, blaming, criticizing, demeaning, colluding with excuses, instilling fear, and giving up easily. In consulting with parents, educators, managers, and others, therapists often teach the ineffectiveness of such choices.

Opposite the ineffective environmental behaviors is a wide range of helpful, effective, and facilitative suggestions leading to a trusting atmosphere. These include attending behaviors, use of paradoxical techniques and metaphors, listening for themes related to procedures, skill in demonstrating accurate empathy, and helping clients find choices even amid their feelings of depression, perceptions of oppression, and lack of opportunities to fulfill their own needs.

B. Procedures: The WDEP System

The environment serves as a foundation for the effective use of procedures that lead to change. They are not a series of recipes used mechanically. Rather they are a network or a system defined by the acronym WDEP. Therefore, depending on the presenting and un-

derlying problem, the therapist extracts from the system appropriate components for application.

W: Explore Wants, Needs, and Perceptions

Essential to the process of change, as well as facilitating the relationship, is a clear determination and definition of clients’ wants or desires. They are asked to describe current pictures or to insert firmly in their “quality worlds,” exactly what they want. Using the analogy of wants as pictures, it is evident that clients often have blurred wants. They are unclear about what they want, so when they are asked, “What do you want from your job, from your spouse, from your parents, from your children?” the answer is, “I don’t know” or “I’m not sure.” An adolescent often wants “my parents off my back” or “to be left alone” but is unable to provide a detailed and unambiguous description of this desire. Consequently, the reality therapist helps clients clarify and define wants, which is the process for the beginning of effective action on the part of clients.

Another part of the W is the exploration of clients’ perception or viewpoint. The therapist asks the parent of a child, “How do you see your son or daughter?” In the case of a severely upset child, the parent might answer, “I see a lazy, rebellious, surly, uncooperative, and ungrateful child.” Of course, such questioning is combined with an exploration of wants, for example, “What do you want from him or her?”

To the workaholic parent of a child, the therapist could say, “I see your 18 hour days not as a ‘rendezvous with destiny’ but as a collision course for you and your children.” To the parent of the teenager, the counselor might say, “I see your son or daughter as a person who needs a compliment for even a minor success or change.” In the practice of reality therapy, therapists take an active but nonauthoritarian role, and see themselves as a partners in the process of change.

D: Doing (Total Behavior)

Behavior is composed of four aspects: doing, thinking, feeling, and physiology. A popular misconception is that reality therapy neither deals with nor allows for a discussion of feelings and emotions. This erroneous perception is perhaps derived from the accurate statement that in reality therapy the action aspect of the behavioral system is emphasized (although not to the exclusion of the other components). Still, there are two important aspects to this procedure: exploration of overall behavioral direction and specific actions or choices.

The therapist encourages clients to be specific in the discussion of behaviors, such as exploring a specific segment of time: a day, a morning, an hour, an incident, or an event. Although it is important to examine the

overall direction of total behavior, direction will change only with small measurable changes made one at a time. Thus, therapists help clients become a television camera describing specific rather than typical events.

E: Self-Evaluation

If the entire process of environment and procedures is a cycle, the procedures appear as an arch with its keystone self-evaluation. This component is a prerequisite for change in human behavior. No one chooses a more effective life direction or changes a specific behavior without making at least a minimal self-evaluation that the current course of action is not advantageous. Effective change rests on judgments related to total behavior, wants, perceptions, and other aspects of the client's life.

The term "Evaluation" has a meaning in reality therapy that is different from its meaning in other theories. In reality therapy, the procedure described here is not an assessment evaluation or "clinical diagnosis." Rather, it is a series of value judgments, decisions, and changes in thought made by the client. In the restructuring of thought, clients come to the conclusion that their life direction is not where they want to go, that a certain exact and specific current behavior is not useful or not helpful, that what they want is not attainable or helpful, that a perception is not effective, and that a future plan of action represents a more need-fulfilling behavior.

In the "Cycle" evaluation comprises an axis that closely connects procedures and environment. Reality therapists help clients evaluate their own choice systems (wants, behavior, perceptions) as well as devote considerable effort toward the evaluation of their own specific professional behaviors and generalized competencies.

P: Planning

If evaluation is the keystone of the procedures, planning is the superstructure or the goal. A plan of action is crucial to change. It can sometimes be complicated and sometimes simple. There must always be a plan. People who go through life without some sort of long-term plan, are like ships floundering without rudders. This procedure is the easiest to bring about if the therapist has prepared the way by the effective use of the more subtle procedures and environmental components already described. Nevertheless, if the plan is to be effective, it should be characterized by as many as possible of the following qualities summarized by the acronym SAMIC³.

- S = Simple: The plan is clear and not complicated.
- A = Attainable: Realistically doable rather than grandiose and impossible.
- M = Measurable. An effective plan is precise and exact.

I = Immediate. Implementation immediately after or even during the therapy session is desirable.

C = Controlled by the planner. A plan should not be contingent on the behavior of another person.

C = Committed to. The reality therapist elicits a firm commitment.

C = Consistent. The plan should be repeated.

The WDEP system should be seen as a unit, a system in which one component affects the others, and so, the subsystems W, D, E, and P are not isolated steps that must be followed one after another. Rather, it is more appropriate to extract from the system whatever component is most relevant at the moment. Through listening, practice, and supervision, a user of reality therapy can develop a sense of where to start and how to proceed through the "Cycle."

II. THEORETICAL BASES: CHOICE THEORY

The practice of reality therapy is based on choice theory. Previously lacking a theoretical framework for reality therapy, Glasser employed the relatively obscure principles of control system theory to explain its effectiveness, and extended the theory to provide a basis for clinical practice by presenting a detailed explanation of human needs, total behavior (actions, thinking, feelings), perceptions, and inner wants or "quality world," the phrase used to describe our specific wants and intense desires. Control system theory is based on the principle that living organisms originate their behavior from the inside. They seek to close a gap between what they have and what they perceive they need at a given moment. This discrepancy, called a "perceptual error," sets the behavioral system in motion so as to impact the external world. Human organisms act on their external worlds to satisfy needs and wants. They gain input from and generate output toward the external world. Because of the emphasis on inner control and especially because of the emphasis on behavior as a choice, the theory was renamed choice theory in 1996.

III. EMPIRICAL STUDIES

The question is often asked, "Does reality therapy work? Is it effective?" Robert Wubbolding has provided an extensive summary of research conducted on its efficacy. Investigators have found an increase in the self-esteem of clients and a greater realization of the meaning

of “addict,” a significant reduction in the rate of recidivism with juvenile offenders, and a complete resocialization of a large number of prison residents, all of whom received reality therapy treatment.

Much research has been conducted in schools measuring the effects of counselor and teacher training in reality therapy. Teaching students to self-evaluate their behavior and their work has resulted in a drop in teacher referrals for discipline and other problems.

A sampling of research in a variety of settings illustrates the wide use of this system. Participants in training workshops leading to certification represent psychology, social work, counseling, classroom teachers, administration, corrections, geriatrics, and other disciplines. Although there is ample research to demonstrate the viability of reality therapy as a therapeutic method, more is needed. Wubbolding recommends that close attention be given to the quality of training provided for therapists, teachers, and others who use the system so that the genuine use of reality therapy is measured. Also, more studies measuring outcome (i.e., change in behavior) are needed.

IV. SUMMARY

Reality therapy, formulated as WDEP, is a practical and jargon-free system based on choice theory. Its philo-

sophical principles include the belief that people choose their behavior. It is not imposed from early childhood or by external stimuli. Therapists help clients define their wants, evaluate their behaviors as well as their wants, and make plans for future change.

GLOSSARY

behaviorism School of thought that stresses the importance of studying behavior objectively and dealing only with directly or potentially observable stimuli and responses.

reinforcer sampling rule Before using an event or stimulus as a reinforcer, sampling of the reinforcer is required in the situation in which it is to be used.

token economy Reinforcement system in which individuals earn symbolic reinforcers that can be exchanged for a tangible reward for performing adaptive behaviors, or lose symbolic reinforcers for performing maladaptive behaviors.

Reinforcer sampling is the procedure of noncontingently presenting a portion of a reinforcer prior to a response to (1) determine that a stimulus or event is, in fact, reinforcing, and (2) increase the motivation of the organism to engage in behavior to obtain the reinforcer. This article will present a review of the theoretical and empirical bases of reinforcer sampling, provide ways in which reinforcer sampling has been used in clinical populations, and provide other practical examples of its utility.

I. DESCRIPTION OF TREATMENT

Reinforcer sampling is a procedure to identify or increase the reinforcing value of a stimulus or event. In order to identify whether a potential reinforcer is desirable to the subject, the reinforcer is presented noncontingently (i.e., the subject receives or “samples” the reinforcer without doing anything for it). After the subject has sampled the reinforcer, the probability that the subject will work to gain access to the reinforcer in the future may change. A response or set of responses are then specified upon which the reinforcer is made contingent. It is hoped that since the subject has had a chance to experience the reinforcer, he or she will be more motivated to obtain it, and thus will be more likely to engage in the desired behavior.

Reinforcer sampling could be used in a situation in which a parent wishes to obtain a specific behavior from a child. For example, a mother may want her child to pick up his toys when he is finished playing with them. To alter his behavior using reinforcer sampling, this mother could noncontingently introduce a potential reinforcer, such as a new computer game, several random times in the home. Then, after it appeared that her son liked playing the game and looked forward to playing it, the mother could tell him that he would be able to play the computer game only after he picked up all of his toys, therefore making playing the computer game contingent upon picking up his toys. Importantly, prior experience, or sampling the computer

game, would be necessary for this stimulus to have any relevance to the boy.

II. THEORETICAL BASES

Reinforcer sampling was described by Teodoro Ayllon and Nathan Azrin in their 1968 book on the token economy system of motivational and rehabilitational therapy. A token economy system requires individuals to earn tokens for adaptive behavior that can be exchanged for numerous reinforcers, such as meals, activities, and so on. The theory behind the token system is that individuals will engage in adaptive behaviors in order to gain access to available reinforcers. However, this will only be effective if the implementers of the token economy system accurately identify those stimuli or events (i.e., reinforcers) that may serve the function of increasing the probability of the occurrence of targeted responses (i.e., truly reinforcing stimuli). Ayllon and Azrin reported that many individuals in a token economy system would not engage in what was assumed to be a reinforcing activity. That is, the activity was not truly reinforcing to these individuals. Reinforcer sampling is a way of determining the reinforcing properties of a stimulus or event. Although the sampling of an event does not guarantee that it will be reinforcing, it will increase familiarity with the event. Thus, if the individual does not seek the reinforcer, one is assured that this is not simply due to unfamiliarity with it.

In their book, Ayllon and Azrin presented the Reinforcer Sampling Rule, which states that before using an event or stimulus as a reinforcer, sampling of the reinforcer is required in the situation in which it is to be used. This is important for several reasons. First, if an individual has not previously or recently come into contact with the potentially reinforcing event, then it may not be reinforcing to that individual. Second, a previously identified reinforcer may lessen or lose its reinforcing qualities in a new situation. In other words, while a stimulus may be familiar and somewhat reinforcing, it may not be worth the effort when subjects are required to engage in certain behaviors to obtain it.

The principle of stimulus generalization suggests that the probability of a response increases as a function of the degree of similarity of the stimuli to those previously present at the moment of reinforcement. Thus, to increase the odds that an individual will work for a reinforcer, the situation should closely approximate the original situation that existed when the individual initially obtained the reinforcer. Reinforcer sampling procedure allows the individual to be briefly presented with

the reinforcer before the response, thereby reproducing all of the stimuli associated with the onset of the reinforcer. After the individual has sampled the reinforcer in the new situation, and thus has become familiar with the reinforcer in the new context, the remainder of the reinforcer could then be delivered after the individual has produced the desired response.

The sampling rule is often used in businesses. An example is the woman who hands out free food and drink samples at the grocery store hoping that shoppers will find the sample good (i.e., reinforcing) and buy the product (i.e., engage in the desired behavior).

III. EMPIRICAL STUDIES

In the 1960s, Ayllon and Azrin conducted a series of studies evaluating the use of reinforcer sampling with psychiatric inpatients. Each study evaluated the number of psychiatric inpatients that engaged in different activities, (e.g., a fair, a walk, watching a movie, a social evening, a music session, and religious services), without first being allowed to “sample” the event. The patients had to use one of their earned tokens to attend the event. In the second phase, patients were allowed to “sample” the event by being present at the fair grounds or watching the first few minutes of the religious service, and then were allowed to decide whether they wanted to use their token to attend the event for a longer duration. Ayllon and Azrin found that the patients were more likely to attend the event if they had been allowed to sample the event first. However, with a return to the regular procedure in which the patients were not allowed to sample the event before deciding whether they wanted to attend it, they were less likely to choose to use a token to participate. Ayllon and Azrin reported that this suggests that reinforcer sampling is an effective means of increasing utilization of a reinforcer, and that it can be used with a variety of different reinforcers. They also suggested that reinforcer sampling should be used for as long as the specific behavior is desired, as their results showed that patients decreased their utilization of the reinforcer event when the reinforcer sampling procedure was discontinued.

Reinforcer sampling does not appear to work solely by familiarizing individuals with reinforcers. That is, the experiments demonstrated an increased utilization of the reinforcer once sampling was available, even in patients who had previous experience with the event.

Since Ayllon and Azrin studied reinforcement sampling procedures in psychiatric inpatients, other studies have replicated their findings with other samples of

psychiatric inpatients, as well as in different populations. Often, reinforcer sampling has been studied in the context of token economy systems used with severely mentally ill individuals or individuals with mental retardation. In these populations, reinforcer sampling is used to encourage individuals to work for reinforcers and activities that are available. For example, in token economy systems, individuals earn tokens by engaging in specific desirable behaviors and then are allowed to use the tokens to “purchase” meals, access to objects such as musical instruments, and activities such as social events or outdoor passes. In research conducted in the later 1960s through the 1970s, with an occasional study in the 1990s, researchers examined the effectiveness of reinforcer sampling in increasing mentally ill or developmentally delayed individuals’ utilization of positive reinforcers (e.g., arts and crafts) provided in a long-term care setting. Similar to Ayllon and Azrin, researchers have predominantly found that allowing individuals to sample the reinforcer prior to using the reinforcer as a contingent event or stimulus has increased the chances that individuals will choose to engage in the reinforcing activity.

Researchers have also experimented with alternate forms of reinforcer sampling. For example, some have employed response exposure as a form of sampling. Response exposure involves allowing an individual to observe a desired response being chosen or enacted by another person followed by receipt of reinforcement.

IV. SUMMARY

Reinforcer sampling is a procedure that can enhance the relevance of a reinforcer. Reinforcer sampling in-

volves presenting a potential reinforcer noncontingently to an individual prior to requiring a specific behavior so that the individual’s motivation to obtain the reinforcer is increased. This procedure is useful when individuals are unfamiliar with the reinforcer, or are unfamiliar with the context in which the reinforcer will be used to obtain a desired behavior. Reinforcer sampling also helps to identify those events, objects, or activities that will be reinforcing to a specific individual or group of people. Reinforcer sampling has been used primarily with psychiatric inpatients and developmentally delayed populations. However, behavioral principles suggest that it could be useful with a variety of types of populations.

GLOSSARY

abstinence violation effect (AVE) Occurs when a client lapses and irrationally concludes that the lapse is so severe that they may as well relapse (e.g., since I broke the rule and I had one shot of whiskey, I may as well finish the bottle); a form of perfectionist or “all or none” thinking.

high-risk situation A situation identified by client and therapist as one in which the client has a greater likelihood to experience a lapse or relapse. Part of a behavior chain that probabilistically could lead to a lapse or relapse.

idiographic A self-referenced, as opposed to norm-referenced, context (e.g., comparisons with the client's previous level of function would be idiographic, whereas comparisons with the client's peers would be nomothetic).

lapse An occurrence of an undesired behavior in the context of behavior cessation or reduction program (e.g., smoking a cigarette by the client in a smoking cessation program or visiting a bar by an alcoholic). A lapse is always less serious than a relapse.

problem of immediate gratification (PIG) The orientation to positive, usually smaller, short-term consequences with adverse, usually larger, long-term consequences, rather than to adverse or unwanted short-term consequences for a more beneficial long-term consequence.

relapse A violation of the contract or terms of the behavior cessation or reduction program. Sometimes defined as a return to pretreatment levels of the problem behavior.

seemingly irrelevant/unimportant decisions (SIDS/SUDS) Decisions early in a behavior chain that place the client in a high-risk situation (e.g., the pedophile deciding to get milk from the market near the day care center rather than the market near the commercial district).

I. OVERVIEW

When one thinks of psychotherapy, a picture comes into view of a more or less theoretically inspired set of techniques that are employed as a primary clinical intervention to treat a constellation of psychological symptoms. Unlike most of the psychotherapies that are described in this volume, relapse prevention (RP) did not evolve as a front-line treatment for a particular mental disorder. It was instead a calculated response to the longer-term treatment failures of other therapies. It was not conceived as an alternative to those interventions, but as a supplemental tool that would make a variety of treatments, particularly for addictive behaviors, more effective.

Another unique feature of RP is that it was not originally concerned with all of the phases of treatment; for example, it did not address the precontemplation, contemplation, preparation, and action stages of treatment. The original target of RP was the maintenance phase of treatment, when patients are no longer receiving

a regular dose of the primary treatment and the positive effects brought about by regular treatment contact can begin to wane. RP was conceived as an answer to the problem of maintaining initial gains. Arguably the most difficult challenge for any patient is maintaining treatment gains over time without the structure and accountability of therapy, or the support of a therapist or group. RP provides some tools for maintaining treatment gains over time.

This article provides the history of RP and its evolution in the treatment of addictions and other impulse control problems. We describe some of the various forms of RP and its basic components. Relevant research is presented and we discuss the future potential of RP with the additions of motivational interviewing, stepped-care approaches to health, and harm reduction concepts.

II. THEORETICAL BASES

Relapse Prevention is a broad phrase that is used to describe a varied set of cognitive-behavioral techniques that are employed to maintain desirable addictive and impulsive behavioral changes. Alan Marlatt and Judith Gordon developed the approach over the course of several years and many discussions. Marlatt and his colleagues were working in the treatment of substance abuse and became increasingly concerned with follow-up data. Results indicated that although significant treatment gains could be produced in addictive behaviors such as drug, alcohol, and tobacco use, those gains also diminished significantly over time if no further intervention was implemented. In 1995 D. Richard Laws wrote of findings suggesting that within 1 year of ending treatment over 80% of patients would relapse (resume the undesired behavior) and two-third of these resumptions would occur in the first 3 months. Marlatt and his colleagues concluded that it was not the cessation treatments themselves that needed to be altered. These approaches initially appeared to facilitate abstinence for many patients. Instead, Marlatt reasoned that a supplemental treatment was needed that would focus on the maintenance of the gains that were acquired during the original treatment period.

The primary assumption of RP is that there it is problematic to expect that the effects of a treatment that is designed to moderate or eliminate an undesirable behavior will endure beyond the termination of that treatment. Further, there are reasons to presume a problem will reemerge, such as a return to the old environment that elicited and maintained the problem behavior; forgetting the skills, techniques, and information taught

during therapy; and decreased motivation. Treatments typically involve an intense but limited period of time during which patients are brought into contact with new influences (some mental health workers, some patients like themselves), information, and contextual components that aid in creating changes in their behaviors. There is an accountability factor that is built into these techniques as well as a regular dose of treatment given reliably over a period of time. These accountability and dose elements are commonly removed after the client has reached his or her treatment goals (treatment is terminated) and the client must learn to implement the skills and knowledge he or she learned in a new context with little or no assistance. Generalizing the skills to varied situations poses a significant challenge and many treatment failures are the result.

Marlatt and his colleagues believed that treatment failures could be analyzed in order to discover internal and external variables that increased risk for relapse. They further reasoned that knowing items such as situational factors, mood states, and cognitions would identify individualized targets of change for clients, targets focused not on the acquisition of quitting behavior, but the maintenance of that behavior. Based loosely on Albert Bandura's 1977 social learning theory, the RP model proposes that at the cessation of a habit control treatment, a client feels self-efficacious with regard to the unwanted behavior and that this perception of self-efficacy stems from learned and practiced skills. Over time the client contacts internal and external risk factors such as seemingly irrelevant decisions (SIDS, sometimes seemingly unimportant decisions, or SUDS) and/or high-risk situations (HRS) that threaten the client's self-control, and consequently his or her perception of self-efficacy. According to the model, if the client has adaptive coping skills to adequately address the internal and external challenges to his or her control, the client will not relapse. However, if his or her skills are not sufficient to meet the challenge, a lapse or relapse may occur (this will be described in greater detail below). In response to a resumption of the change behavior at some level, the client has a reaction that either increases attempts to implement adaptive coping skills, or fails to cope effectively and engages in the undesirable behavior because it provides immediate gratification. Embedded in this model is Marlatt's supposition that the targets of intervention are cognitions and behaviors that are collectively referred to as coping skills. Marlatt and his colleagues' treatment therefore employs cognitive-behavioral techniques to improve the retention and accessibility of adaptive coping responses.

In the short period of time since its introduction, RP has evolved in numerous directions. It has been applied

to new problem areas such as risky sexual behaviors, overeating, and sexual offending. It has additionally come into use as a full program of treatment and lifestyle change, instead of simply a supplemental intervention strategy. That is, RP is often a primary treatment program in addition to addressing the maintenance issue. Lastly, RP is emerging as a bona fide theory of compulsive habit patterns and the processes of relapse. It should be noted that RP is most widely used with behaviors deemed volitional in origin (e.g., behaviors of consumption); however, some practitioners have applied RP in problem behaviors where the volitional element is less clear (e.g., schizophrenia, depression).

Tony Ward and Stephen Hudson in 1996 argued that this conceptualization often fails to accurately capture the addictive processes for which it was used. For example, the theoretical link between high-risk situation and lapse, as well the link from lapse to relapse has not been sufficiently demonstrated. As Ward and Hudson suggest, RP has rightfully undergone increasing scrutiny in recent years. Additional researchers and scholars have critiqued and extended the RP theory that commenced with the ideas of Bandura, Marlatt, and Gordon. See the edited work by Laws, Hudson, and Ward (2000) *Remaking Relapse Prevention with Sex Offenders* for the latest developments in RP theory in general, and treatment applications for sexual offenders.

III. TREATMENT COMPONENTS

In 1995 Laws outlined the tenets of RP. He provides 12 principles that serve as the foundation of this approach. Briefly summarized, the components of RP are identification of a maladaptive behavior, a process of change defined by commitment and motivation, behavioral change and maintenance of behavior change, identification of lapses (a single instance of the maladaptive behavior) and relapses (a complete violation of the self-imposed abstinence rules), lifestyle balance between obligatory and self-selected behaviors, recognition of the ideographic aspects of the maladaptive behavior, and recognizing and planning behavioral responses for high-risk situations. In practice, RP addresses the issues of identifying high-risk situations, seemingly irrelevant decisions, and the problem of immediate gratification. Therapists using RP to treat sex offenders also include skills training components, such as social skills and coping skills.

In general, relapse prevention's foci are first, identification of high-risk situations, and second, employing appropriate self-control responses. High-risk situations

are determined by an analysis of past offenses and by reports of situations in which the client feels or felt "tempted." These situations may be a bar or tavern for smokers and drinkers, playgrounds and shopping malls for sexual offenders, and casinos for gamblers. Appropriate responses are those behaviors that lead to avoidance of high-risk situations, or if in a high-risk situation, behaviors that foster nonoffending actions. For example, if an offender realizes he is having a fantasy about offending, he can employ a thought-stopping behavior, such as saying out loud "Stop!" or distracting himself such that the deviant fantasy is interrupted. Laws suggests that responding with an appropriate coping response to high-risk situations will lead to increased self-efficacy and a decreased probability of relapse. He also indicates that if appropriate coping responses are not utilized or not in the behavioral repertoire, there will be a decrease in self-efficacy, an increased likelihood of positive outcome expectancies (perception of positive experiences resulting from engaging in maladaptive behavior), a lapse, and an increased probability of future lapses.

A. High-Risk Situations

This component often involves the ideographic assessment of high-risk situations. The client and clinician work together to identify the situations in which the client has previously engaged in problematic behavior and those situations in which the client is likely to engage in problematic behavior. The client will be asked to generate a list of situations that are lowrisk, and to determine what aspects of those situations differentiate them from high-risk situations. The focus will be to train the client to recognize themes and commonalities in his or her high-risk situations so that the client can generalize the ability to assess level of risk in a novel situation. The therapist works with the client to ensure that the client is realistic in his or her assessment of the level of risk in a variety of hypothetical situations. For example, the therapist often creates a series of hypothetical situations, based on the client's self-report of risk factors, to assess the client's ability to determine the causes and severity of risk.

B. SIDs/SUDs

Seemingly irrelevant decisions (SIDs) (also seemingly unimportant decisions or SUDs) are those behaviors that might not lead directly to a high-risk situation, but are early in the path of decisions that place the client in a high-risk situation. For example, if the client reports that he is more likely to engage in the problematic

behavior after drinking during lunch, a SID would be agreeing to attend a two-martini luncheon with a co-worker. In addressing SIDs, the therapist works with the client to determine which decisions lead to high-risk situations. Coping skills are often taught in conjunction with therapeutic work on SIDs. Once the client can identify high-risk situations and SIDs, the client needs to learn effective coping strategies. For example, the therapist may direct the client to brainstorm strategies to resolve a high-risk situation without employing the problematic behavior. For example, the client may choose to walk away or the client may wish to change the situation so that the risk is lowered (e.g., for a smoker, moving a conversation to a room in which there are more nonsmokers, away from the break room or smoking area). The therapist must work with the client to ensure that client solutions and skills are adequate and appropriate. The therapist may also role-play situations with the client to allow the client a chance to practice skills in a hypothetical high-risk situation.

C. Problem of Immediate Gratification

The problem of immediate gratification (PIG) is the orientation of the client to smaller positive short-term consequences with larger adverse long-term consequences, rather than adverse or unwanted short-term consequences for a more beneficial long-term consequence. With smokers, the immediate relief from withdrawal symptoms provided by a cigarette is the proximal consequences, while emphysema, lung cancer, and death are more distal consequences. To address the PIG, the therapist typically employs psychoeducational approaches to teach the client how to create a decision matrix. This is usually a written exercise, in which the matrix contains the positive and negative outcome expectancies for engaging or not engaging in the problematic behavior, in both the immediate and short-term frame of reference. The therapist then confronts any unrealistic outcome expectancies until the client is able to generate more realistic outcomes. Following this, the therapist directs the client to analyze past situations in which the patient engaged in the problematic behavior, and to compare the immediate gratifications against the long-term consequences.

D. Abstinence Violation Effect

The abstinence violation effect (AVE) highlights the distinction between a lapse and relapse. Put simply, the AVE occurs when a client perceives no intermediary step

between a lapse and a relapse. For example, overeaters may have an AVE when they express to themselves, "one slice of cheesecake is a lapse, so I may as well go all-out, and have the rest of the cheesecake." That is, since they have violated the rule of abstinence, they "may as well" get the most out of the lapse. Treatment in this component involves describing the AVE, and working with the client to learn alternative coping skills for when a lapse occurs, such that a relapse is prevented. The AVE occurs when a client is in a high-risk situation and views the potential lapse as so severe, that he or she may as well relapse. The client and therapist will practice identifying and coping with lapses. The treatment is not lapse prevention; lapses are to be expected, planned for, and taken as opportunities for the client to demonstrate learning. It is relapse prevention. Most often, relapse tends to be construed as a return to pretreatment levels of occurrence of the targeted behavior. Although there is some debate about the best definitions of lapse and relapse from theoretical and conceptual levels, these definitions should suffice.

E. Outcome Expectancies

An example of skills training is seen when addressing outcome expectancies. The client is asked to construct a decision matrix: on one dimension, the choice of offending versus not offending, on the second dimension, the positive and negative outcomes, and on the third dimension, the short- and long-term consequences. Often, the client will not generate accurate outcomes, and is instructed in more likely outcomes for their offending and nonoffending behaviors. Another component in some manifestations of RP is enhancing victim empathy. Clients are asked to do a variety of tasks, such as watching a videotape of victims telling of the effects of their victimization, imagining how the client and a loved one would feel if victimized, and writing a letter from the victim's point of view.

F. Cognitive Distortions

Therapists trained in CBT often find it necessary to address the client's cognitive distortions when dealing with clients who engage in problems of self-control. In 1989, as part of Laws's book on RP for sex offenders, Katurah Jenkins-Hall described the steps for changing cognitive distortions in sexual offenders as identification of the thoughts that lead to maladaptive behavior, analyzing the validity and utility of the thoughts, and an intervention designed to change the cognitive distortions into more adaptive cognitions. Jenkins-Hall

details how cognitive therapy can be adapted to sexual offenders. Step one is providing alternative interpretations in that the “client is taught that his initial interpretation of a given situation may not be the most accurate. He is asked to generate a list of alternative explanations.” Step two, utilitarian counters, asks the client to evaluate whether his thinking assisted or hindered the achievement of the desired outcome (e.g., did having a biased interpretation of the victim’s behavior make it easier for you to justify your actions to yourself?). In step three, objective counters, the therapist helps the client analyze the logic behind certain types of thinking. Step four, disputing and challenging, is based in Ellis’s rational emotive therapy. In this stage the client is asked to identify irrational types of thinking and beliefs, and these irrational statements and beliefs are challenged in therapy.

G. Social Skills

Another common problem in some self-control problems relates to deficits in social skills. Clients may be misperceiving both verbal and nonverbal behaviors by those in high-risk situations. An ideographic assessment can be used to learn which, if any, key social skill deficits are present. The clinician should address relative deficits in perception, interpretation, response generation, enactment, and evaluation. In conducting social skills training with these clients, clients and therapists typically discuss the abstract principles of the particular class of social skills. The therapist then models the specific set of social skills. The client and therapist then role-play a situation that emphasizes the specific social skills relevant for the client. For example, for a client working sexually inappropriate behavior in the workplace, the client and therapist may role-play joke-telling situations, socializing, or other critical situations common at the workplace. The therapist would then provide feedback for the client regarding the skills present and absent during the role-play.

H. Aftercare

As with any therapeutic intervention, therapists are obligated to design a plan for aftercare. With RP, one of the essential elements of the psychoeducational process is instructing the client about the role of misbehavior in the context of one’s life. Although the goal of RP is the prevention of the occurrence of problematic behavior, the lifestyle must be addressed. The repairing of a damaged boat hull is an appropriate analogy. Patching the hole is well and good (reducing problematic behav-

ior), but the pilot of the boat should also learn not to run the ship aground, through rapids, or into icebergs (lifestyle balance).

Often, the development of positive addictions is presented. Positive addictions are healthy behaviors and hobbies, such as reading and bowling, in which the client can engage without experiencing adverse consequences. Lastly, each element of the RP approach, e.g., high-risk situation, the PIG, the AVE, and cognitive distortions are reviewed in the larger context of RP. For example, in work with sexual harassers, the harasser is directed to review the role of cognitive distortions as a component involved in sexual harassment, and then relate to how cognitive distortions are involved in the RP model.

I. Planning for Lapses

To dissuade the client from buying into the AVE, a realistic aftercare plan should include a plan for addressing lapses, because they are likely to occur. To plan for lapses clients should know how they would handle situations in which they feel at risk for engaging in the problematic behavior. What is the client’s support group? How will the therapist work with the client to devise strategies for seeking help, should the need arise after therapy? The therapist and client should also review plan to prevent a lapse from becoming a relapse. One way to do this is to practice these skills beforehand, for example, the client and therapist can role-play situations in which the client will need to ask a friend or loved one for help, call a therapist for an appointment, and tell a new friend about their history of problematic behavior and what the new friend can do to help the client when the client is in need.

There is gradual waning of the active role of therapy and the therapist in the client’s life. However, practitioners employing RP typically inform their clients that the clients will struggle with this problem for life, and they will likely never be “cured.” To enhance the gains made in therapy, and during RP aftercare for other primary interventions, RP sessions are often faded to biweekly, then later to monthly, then bimonthly, and sometimes continue annually for years.

J. Data on RP

In 1995 Gordon Nagayama Hall demonstrated the effectiveness of a community-based outpatient RP program for male sexual offenders, while Karl Hanson has spearheaded an effort to collect and organize data from an international pool of researchers on the effectiveness of RP programs with sex offenders. Most of

these studies were limited by a lack of random assignment to conditions due to ethical and pragmatic difficulties. The effectiveness of RP with other problematic behaviors has been demonstrated as well, specifically with alcohol, tobacco, and overeating. Efforts to gather increasingly informative treatment outcome data are extensive and ongoing. In general, there is some evidence that RP can be an effective intervention to prevent the reoccurrence of many problematic behaviors. However, there exists a disconcerting lack of data on the theoretical foundations of RP, such as covert pathways to relapse and the role of motivation in treatment success. For example, there has not been a clear demonstration of the necessary and sufficient internal and external conditions that will predict instances of lapses and relapses. What the field does have is a bevy of clinical experience across a broad domain of client problems, all suggestive that RP is plausible as well as popular with both clients and therapists.

IV. FUTURE DIRECTIONS

A. Denial and Minimization— Motivational Interviewing

A common problem in working with clients who would likely benefit from RP is the evaluation and treatment of denial and minimization. In their 1993 work with sexual offenders, William O'Donohue and Elizabeth Letourneau developed an intervention that was designed to help the client to admit to the offense and be motivated to seek and participate in therapy. An adaptation of their techniques to the treatment of general self-control problems would include presenting the probable outcomes of receiving versus not receiving treatment (e.g., gainful employment versus lower wage or no employment) and likelihood and consequences of future instances of misbehavior (e.g., if treated, lower likelihood of re-offense, if untreated, higher likelihood of re-offense and more severe consequences).

In addition, therapists have successfully used intervention of motivational interviewing (MI). MI has been shown effective in a variety of other RP treatment evaluations (see the 1991 edited work by Miller and Rollnick, *Motivational Interviewing*.) MI involves presenting the client's data in a matter-of-fact manner in which problems are not discussed, but rather, a simple review of the facts is performed. This is thought to allow the client to make an informed choice about engaging treatment.

B. Stepped Care

Stepped care involves the gradual introduction of interventions of increasing cost and severity. The initial interventions are the least intensive, most costeffective, and have the lowest response cost to the client and have the greatest possibility of success. If this level of intervention fails, then more intense, high-cost interventions are introduced. As the level of intensity increases, fewer clients should require that level of intervention. As the active components of RP are better understood, the treatment dose and content may be tailored to the individualistic problem such that resources are used efficiently. In addition, as RP techniques are better documented and available to clients, the involvement of RP therapists may become limited or obsolete in some cases.

C. Harm Reduction

Laws describes the change in focus between RP and harm reduction (HR) as a difference based on expecting an absolute cessation of the problem behavior (RP) as opposed to a manageable and acceptable reduction (HR). In his work with sex offenders, Laws describes as recognizing that offenders may have the occasional fantasy or desire to act out sexually. By owning up to this reality, Laws indicates that client and therapist goals can be more realistic. Furthermore, lapses, when they occur in the HR model, can be seen as learning experiences rather than failures.

V. SUMMARY

Relapse prevention was not produced as a stand-alone treatment derived from theoretically based and empirically supported foundations. Instead, RP was created as a supplement to existing treatments to address as the treatment failures seen in other therapies for problematic behaviors often conceptualized as problems of self-control. Furthermore, RP was not an "intervention" per se, but rather a structured aftercare regimen to assist in the maintenance of treatment gains.

Over the course of time, RP was taken from the research laboratories at the University of Washington and field tested with problem drinkers, smokers, overeaters, and sex offenders, to name only a few. In its many manifestations, RP addresses high-risk situations, the avoidance of those situations, the management of those situations, and skills for recovery after encountering those situations. The data on RP, while

sparse, suggest that RP is generally effective for a variety of self-control problems. The future of RP includes motivational interviewing, stepped care, and harm reduction, as well as further clarification of the theoretical underpinnings, mechanisms, and outcomes of relapse prevention.

GLOSSARY

intersubjectivity A developmental achievement in which both individuals within a dyad recognize each other's subjectivity.

multiple selves The concept that people experience themselves not as unitary and unchanging but as consisting of multiple selves that may be compatible or incompatible with one another.

mutuality The idea that both patient and analyst participate in the analytic process, that they mutually regulate or influence each other, consciously and unconsciously.

projective identification A process by which the patient's disavowed feelings are projected onto the analyst who has become a container for the dissociated features of the patient's experience.

transference-countertransference matrix Transference and countertransference are interdependent, mutually determined experiences that are shaped by both patient and analyst.

I. DESCRIPTION

Relational psychoanalysis is an intensive form of psychotherapy that places human relations at the cen-

ter of motivation, psychopathology, and treatment. It is an alternative to classical Freudian psychoanalysis (including its modifications in psychoanalytic ego psychology). It considers relations to others, not drives, as the basic building blocks of mental life. From the relational perspective, individual experiences and the internal structures of the mind are viewed as deriving from and are transformations of relationships with significant others.

The term "relational psychoanalysis" is a relatively new coinage. It refers to a theoretical and clinical sensibility that integrates a variety of psychoanalytic theories that have evolved following the promulgation of Freud's seminal ideas. Thus, it is a contemporary eclectic approach that has been in a process of growth and development in the United States for the last 20 years. This new perspective includes recent developments within, and cuts across, U.S. interpersonal psychoanalysis, the British school of object relations, self psychology, and currents within contemporary Freudian theory. It is concerned with the intrapsychic as well as the interpersonal, but the intrapsychic is seen as constituted by the internalization of interpersonal experiences. Although these internalized interpersonal experiences may be biologically mediated, relational psychoanalysis is primarily concerned with the psychological determinants of experience.

There is considerable variation in the practice of relational psychoanalysis, but all relational analysts share a sensibility in which the therapeutic relationship plays a superordinate role in the treatment. Thus,

the analyst's subjectivity and personal involvement, including partially blinding entanglements, are given serious consideration. Gender, class, race, culture, and language are additional factors of great significance to relational analysts.

II. HISTORICAL DEVELOPMENT

The sea change that has been taking place in contemporary U.S. psychoanalysis in the last two decades is in sharp contrast to the popular view that modern-day psychoanalysis is a footnote to Freud. Psychoanalytic practice has evolved considerably since Freud's original creative contributions. Freud's body-based instinct (drive) model emphasizes intrapsychic conflict among id, ego, and superego as the child passes through the psychosexual stages of development. Interpretation, the main form of clinical intervention in Freudian analysis, is for the purpose of making unconscious content, such as sexual and aggressive impulses, conscious. In the Freudian model, relatedness is a derivative of the primary drives of sex and aggression.

The current paradigm shift away from the classical drive model to the relational model had its origins in the work of two psychoanalytic pioneers: the Europeans Sandor Ferenczi and Otto Rank. Both were students of Freud and in 1924 collaborated in exploring the primacy of experience in the here and now of the transference. After their collaboration, Ferenczi theorized about the mutuality of relationships in human development and clinical process. Rank went on to elaborate a theory of the birth of the self and the centrality of early relationships in the therapeutic interaction.

Working in the United States before World War II, Harry Stack Sullivan revised Freudian psychoanalytic ideas in his development of an interpersonal psychiatry. In an informal collaboration with Erich Fromm, Karen Horney, Freida Fromm-Reichman, and Clara Thompson, Sullivan came to disagree with the prevailing view of psychopathology as residing in the individual. He believed that human beings are inseparable from their interpersonal field and that focusing on the individual without considering past and present relationships is misdirected. Sullivan emphasized that human relatedness is a prerequisite of psychological well-being and a safeguard against anxiety. In treatment, he urged concentration on the here and now of the therapist-patient interaction. Subsequently, Thompson assembled the emerging concepts that constituted an interpersonal psychoanalysis and helped institutionalize them through the Washington School of Psychiatry and the William

Alanson White Institute in New York City. Over time, two different clinical approaches emerged in the interpersonal tradition: Sullivan's emphasis on empathy and tact and Fromm's emphasis on frankness and confrontation. In stressing the role of actual and specific interpersonal relationships in personality development and psychopathology, interpersonal psychoanalysis came to be caricatured as social psychology by the mainstream and medical psychoanalytic power circles of the day. In recent years, however, interpersonal psychoanalysis has gained increased acceptance with the elegant writings of Edgar Levenson, who stressed that what was talked about between analyst and patient was also concurrently being enacted between the two.

Contemporary British object relations theories began to have a significant presence in the United States in the 1970s. The theoretical and clinical innovations of the British school stressed the importance of the pre-Oedipal stage and especially the early mother-infant relationship. Emphasis was placed on the conflictual nature of internalized relationships to others. Moreover, nonverbal phenomena, regressed states, and the actual relationship between analyst and patient were also highlighted. Melanie Klein's theorizing about greed, envy, aggression, and projective identification also played an influential role. As represented by Michael Balint, W. R. D. Fairbairn, D. W. Winnicott, and Harry Guntrip, the British school of object relations was a thorn for U.S. Freudian psychoanalysis in that the centrality of the Oedipus complex was downplayed.

A third psychoanalytic paradigm that contributed to relational approach is self psychology. In the late 1970s, Heinz Kohut reformulated Freud's ideas, first in terms of the concept of narcissism and then in terms of theory and practice. He emphasized the chronic traumatizing milieu of the patient's early human environment, not the intense sexual and aggressive pressures that Freud had defined as basic to human motivation. He viewed aggression and rage in treatment not as an expression of a fundamental force but as result of deep vulnerability. The self psychology school of psychoanalysis developed into a powerful presence and influenced the thinking and practice of many.

In their more contemporary cast, these three schools of psychoanalysis seemed to be moving along similar paths, toward a focus on self-other relations, an interest in feelings and experience rather than drives, and toward a less authoritarian stance on the part of the analyst. Furthermore, the clinical focus is often on the patient-analyst relationship and the way in which small, but subtle interactions and enactments dominate the clinical situation.

Other theoretical influences in the development of a relational approach were the works of Hans Loewald and John Bowlby. Hans Loewald, a prominent ego psychologist in the 1970s, redefined id, ego, and superego in terms of interpersonal experience giving drives a relational character. He argued against the Freudian idea that the human mind can be an independent unit of inquiry without taking into account the analyst's participation. John Bowlby's work on attachment theory in the 1960s and the subsequent rich research on attachment has also played an important role in recent relation theorizing. Bowlby and his followers have placed intimate attachments to others at the "hub" around which a person's life revolves throughout the life span.

In 1983, Jay R. Greenberg and Stephen A. Mitchell published their landmark treatise, *Object Relations and Psychoanalytic Theory*, in which they distinguished two distinct approaches to psychoanalytic theory: the drive-structure model and the relational-structure model. Despite its title, their book was not only about object relations theories. It compared various models including interpersonal theory and self psychology. In addition to making detailed comparisons, the authors argued that theoretical positions in psychoanalysis are inevitably embedded in social, political, and moral contexts. They used the term relational to bridge the traditions of interpersonal relations, as developed within interpersonal psychoanalysis, and object relations, as developed within contemporary British theorizing.

During the early 1980s, Merton Gill, a prominent leader in U.S. ego psychology, published a series of articles recognizing the contributions of the interpersonal theorists and their views. He contrasted the drive model with the more humanistic model in which relationships are given primary importance. He identified the depth of clinical process and the exploration of transference-countertransference issues as the defining characteristics of clinical psychoanalysis. Later in the decade, the English translation of *The Clinical Diary of Sandor Ferenczi* was published after having been suppressed for more than half a century. Consisting of Ferenczi's clinical experiments with mutual analysis, it demonstrated an objection to the hierarchical arrangement of the traditional analytic relationship between an analyst who dispenses interpretations and a patient who receives them.

Conceptually, two other broad developments occurred in the last two decades of the 20th century that facilitated the development of relational psychoanalysis. The first development was feminism. It launched a major critique on Freudian notions by deemphasizing the phallogocentricity of its theories and practice. Sexuality was

unlinked from both physical constitution and reproductive function, and homosexuality no longer pathologized. Using a feminist approach, Jessica Benjamin published *The Bonds of Love* in 1988. This work masterfully argued the importance for psychoanalytic theory to include both an intrapsychic and an intersubjective perspective. The second development was constructivism, in its moderate postmodern form. Basically, psychoanalytic theorists have used a constructivist approach to critique essentialism, positivism, and any pretext to objectivity. Constructivism is used to understand transference not as simply a distortion emanating from the patient as in Freudian psychology. Transference, according to Irwin Hoffman, is viewed as involving the analyst's subjectivity in a process of co-creation with the patient. In his 1998 book *Ritual and Spontaneity in the Psychoanalytic Process*, Hoffman brilliantly critiques theorists such as Sullivan, Kohut, and Winnicott charging that they are similar to Freud in that they suggest that analysts can keep their own subjective experience from "contaminating" their patients' transferences.

Organizationally, relational psychoanalysis was greatly bolstered by four developments. The Division of Psychoanalysis of the American Psychological Association operating outside the control of the traditional American Psychoanalytic Association acted as a forum for the relationally minded psychoanalyst and allowed for numerous creative and scholarly panel presentations at its annual conferences. This in turn gave relational psychoanalysis a national network and identity. The second organizational development took place in 1988 at the New York University Postdoctoral Program in Psychoanalysis and Psychotherapy where a "relational track" was established to go along with its Freudian, interpersonal, and independent tracks thus adding a prestigious university training legitimacy to relational psychoanalysis. Third, the establishment of the highly successful *Psychoanalytic Dialogues: A Journal of Relational Perspectives* in 1990 led to further consolidation of the identity of relational analysts. Finally, the formation of the International Association of Relational Psychoanalysis and Psychotherapy is well under way and will be inaugurated with a clinical conference in New York City in January 2002 titled *Relational Analysts at Work: Sense and Sensibility*.

III. THEORETICAL CONCEPTS

As articulated by Jay Greenberg and Stephen Mitchell, there are at least two different and incompatible views of human nature in psychoanalysis. Drive

theory is derived from a philosophical tradition that sees a person as an essentially individual animal and human goals and desires as essentially personal and individual. In contrast, relational theory holds the philosophical position that a person is a social animal and that human satisfactions are realizable only within a social community. Consequently, the relational position is not interested in the single mind as a unit of study. It is interested in the relationship as a unit of study.

Although unconscious processes, the Oedipal complex, dreams, slips of the tongue, and free associations are of importance to relational theorists, they do not hold privileged positions. Wary of privileging any conceptual notion, relational theory nevertheless places the conscious and especially the unconscious relationship between patient and analyst at the heart of the therapeutic effort.

The relational matrix involves conflict, constructivism, and an overarching two-person perspective. Unconscious conflict is central to the drive model. In this model, the analyst strives to help the patient come to understand that sexuality and aggression are not as dangerous as they appear to be in the patient's fantasy-dominated child's mind. In the relational model, the traditional notion of conflict is maintained, but it is understood as containing conflicts over loyalties to parents, an idea attributable to W. R. D. Fairbairn's object relations theory. Thus, conflict is not located "in the person" but rather conflict may best be explained as both intrapersonal and interpersonal.

Constructivism in psychoanalysis holds that the observer plays a role in shaping, constructing, and organizing what is being observed. Psychoanalysis is a particular method for organizing what there is into unique patterns, but the patterns can be understood and organized in any number of ways. Thus, ambiguity and uncertainty are features of all human relatedness. This does not necessarily lead towards nihilism. On the contrary, it can propel theorists toward further elaboration and synthesis. For Irwin Hoffman, the paradigm shift in contemporary psychoanalysis is not necessarily from the drive model to the relational model, but from the positivist model to the constructivist model. Thus, the great divide is between dichotomous and dialectical thinking. What is meant by dialectic is a process in which each of two opposing concepts creates, informs, preserves, and negates the other, each standing in a dynamic relationship with the other. Among the pairs of phenomena Hoffman considers dialectically are doubt and certainty, possibilities and constraints, hierarchy and egalitarian relations; risk taking and responsibility; neurotic and existential anxiety; psychoanalysis as an instrument of healing and as cultural symptom; the an-

alyst's intentions versus the patient's will; action and reflection; and analytic rituals and the analyst's spontaneity. Last, constructivism in psychoanalysis holds that analytic therapists do not have privileged access to their own motives, nor are they able to know exactly what is best for their patients. Hence, the patient's perception of the analyst's subjectivity is critical.

Stephen Mitchell has argued that the distinction between a monadic theory of mind (a one-person psychology) and an interactional relational theory of mind (a two-person psychology) is pivotal to understanding psychoanalytic concepts. In general, those theories greatly influenced by classical analysis have been referred to as one-person psychologies. They emphasize the individual experience of the patient and view the analyst as a blank screen onto which the patient projects wishes and fantasies. The two-person psychologies are influenced by the notion of the analyst as co-participant in the therapy. Emmanuel Ghent has described the history of psychoanalysis as constituted by dialectical shifts between one-person and two-person psychologies. Neil Altman has added to the dialogue by suggesting that we consider not a one-or two-person psychology but a three-person psychology. A good example of a three-person psychology would be thinking through the therapeutic relationship as it operates in a particular clinic or in conjunction with a specific insurance company.

Another important concept in relational psychoanalysis is that of intersubjectivity. Jessica Benjamin's work on intersubjectivity emphasizes mutual recognition as an intrinsic aspect of the development of the self. She argues that we need to maintain a tension in our theory between relating to others as objects and relating to others as separate subjects. The infant research of Daniel Stern on the development of a sense of self yields evidence for intersubjective relatedness, a relatedness that includes the recognition of subjective mental states in the other as well in oneself. By contrast, for Robert Stolorow and his colleagues, the term intersubjective is applied whenever two subjectivities constitute the field, even if one does not recognize the other as a separate subjectivity.

Recently, relational thinkers have been hypothesizing about how the mind is structured in an effort to redefine notions of the self. The self has usually been thought of as a continuous, unitary phenomenon. Philip Bromberg has described a state of multiple selves. This concept holds that people experience themselves not as unitary and unchanging but as consisting of multiple selves that may be compatible or incompatible with one another. For example, an adult self may be taking in a logical

explanation about an interaction, while at the same time a child self simply feels vulnerable and angry. Multiple self-states are created not by unmet developmental needs, but by unintegrated, sometimes traumatic, early interactions with significant others. The therapeutic goal is to bring the different self-states into awareness and into a useful dialogue and not necessarily integration. For Jody Messler Davies multiple selves suggest a central role for the process of dissociation and consequently a very different vision of the unconscious. Unlike drive theory that utilizes the metaphor of an onion or an archaeological site for the unconscious, Davies prefers the metaphor of a kaleidoscope with which each glance through the pinhole of a moment in time provides a unique view and an infinite constellation of interconnectedness.

A fundamental principle in the relational model of psychoanalysis is that of mutuality. Mutuality is a process in which patient and analyst mutually regulate or mutually influence each other both consciously and unconsciously. What is regulated is subtle, but it can often involve feelings, thoughts, and actions. Heinrich Racker pointed out that analysis is not an interaction between a sick person and a healthy one, but rather an interaction between two personalities, each with healthy and pathological dynamics. Thus, the classical authority of the analyst has given way to a more democratic, respectful exploration of a joint reality. Mutuality means that the analyst and the patient are partners in the treatment, albeit unequal ones. This mutuality requires a certain type of emotional honesty from both participants. In the relational model, the analyst cannot function as a blank screen or a detached observer encouraging intense feelings in the patient and responding in a neutral manner. When mutuality in the clinical process is taken into account, dialectical tensions can arise. One such dialectical tension occurs between the patient's sense of the analyst as a person like himself or herself and the patient's sense of the analyst as a person with superior and magical power. Although the analyst engages in relative subordination of personal interests, the resolution of such tensions can be powerful emotional experiences for both participants.

IV. CLINICAL PROCESSES

The clinical attitude conveyed by a relational analyst depends very much on the particular analyst's personality, training, and the specific impact of a particular patient. She does not act as a judge of reality and nor does she presume that there is only one way to see something

accurately. The patient's own sense of reality is greatly respected and encouraged. Compliant surrender to the analyst's presumed superior vision is not encouraged. The patient's observations and perceptions about the analyst are encouraged. Notwithstanding these attitudes, it is likely that there will develop repetitive reenactments of some of the most warping features of the patient's earlier experiences. These reenactments will likely involve the analyst and consequently also involve a range of feelings from attraction to conflict in relation to the analyst.

To a large extent, traditional analysis requires that the analyst interpret the true meaning of the patient's reactions to her. In contrast, when a patient feels discontent with her analyst, the relational approach requires both parties to examine how and why they are in conflict and to negotiate the conflict as best they can. This is a shift involving a move away from interpreting observer to active participant. The in-depth exploration will require that both parties track the way the patient's observations lead to conclusions about the analyst and how they might be reenactments in the here and now of earlier relationship difficulties.

Clinical psychoanalysts have tended to centralize the experiences of early childhood. The relational orientation acknowledges this importance as well, but it does not consider the uncovering of the past to be the major task of treatment. In the classical approach, the patient's problems are the result of repression; cure entails the release of impulses, fantasies, and memories from repression. The analyst interprets both the content of the repressed and also the ways the patient is defending against the content. The analyst helps the patient gain insight thereby releasing from repression unconscious conflicts and thus being cured. A number of relational approaches, particularly the British object relations school and the self psychology school, assume that from the moment of birth, the child's whole being has developed in the context of experiences with others. Normal development is thwarted due to inadequate parenting. What is curative in the analytic relationship is the analyst offering some form of basic parental responsiveness that was missed early on. The interpersonal approach regards the analyst's response to the patient as organized not along parent-child lines but rather along adult-to-adult lines requiring honest responses and engagement. Hence, relational analysts differ with respect to their use of efforts to reanimate stalled developmental processes or their use of frankness and authentic confrontations. For many espousing a more integrated relational approach, however, the belief is that the patient can be both child and adult. Both

the realities and the fantasies of early childhood experiences are important to understand in detail, but the realities and fantasies of adulthood are also important to understand in detail.

In the most general sense, all psychoanalytic treatment paradigms value the analysis of transference. The relational paradigm, however, considers more than just the transference; it values the transference–countertransference matrix. Transference represents the emergence of feelings toward early childhood figures, displaced onto the person of the analysts. Historically, countertransference is the displacement of feelings from the analyst's past into the analytic situation. This was considered a seriously negative developmental in the analysis. The analyst was enjoined to rid herself of it through self-analysis or to return to her own psychoanalyst for help. Relational analysts have a different approach. They believe that countertransference is a normal state of affairs and that it can advance the analytic work. The transference–countertransference matrix is mutually determined and shaped by the conscious and unconscious beliefs, hopes, fears, and wishes of both patient and analyst.

The clinical approach of the relational model holds that the analytic situation is more than an arena for playing out the past; it is also where the patient is firmly engaged in the present. Thus, the patient is not simply displacing feelings from earlier relationships onto the analyst; he or she is likely to have observed a great deal about the analyst and to have constructed a plausible view of her. This view is, in part, based on the patient's own past and his typical way of organization experience. For example, an analyst can be experienced by a patient as critical of certain actions on the patient's part, and indeed that may be an opinion of the analyst. However, an in-depth exploration of a patient's observations about the analyst can show that the criticism is different from the patient's mother and does not require allegiance from the patient for a personal connection to be maintained.

With the qualification that indeed psychoanalysts can suffer from the very same problems they are trying to assist patients with, relational ideas stress that countertransference can be (a) an ordinary, common responses to the sort of interpersonal positions and pressures a patient can set up; (b) an analyst–patient reenactment of a patient's past relationships; (c) a complex result of the patient's projective identification; and (d) something the patient is doing to strike responsive chords in the analyst.

Given that all analysts have a less than complete understanding of their own defenses, and that the patient

may have picked up features of the countertransference that the analyst is not aware of, some analysts like Lewis Aron and Irwin Hoffman have argued for the usefulness of extended explorations of the patient's experience of and hypotheses about the analyst's experience. Such explorations give permission to patients who grew up feeling that their perceptions of their parents were forbidden and dangerous, and discounting their own observations albeit subtle and sometimes unformulated. Aron prefers to speak of the analyst's subjectivity instead of the analyst's countertransference. He believes that the term countertransference implies that the analyst's experience is reactive rather than subjective. The patient's perception of the analyst's subjectivity does not replace the historical analytic focus on the patient's experience, but it is seen as one component of the analysis.

To a large extent, relational analysts view self-disclosure as a form of intervention. It may involve the analyst revealing to the patient information, such as her thoughts or feelings about an interaction, something about the analyst's personal life, or the analyst's values and biases. Although the information may be useful, it is not disclosed as oracular. Other information besides the analyst's countertransference is necessary to confirm an idea about the patient's experience or to provide an interpretation. Nonetheless, many relational analysts believe that judiciously chosen self-disclosures can be helpful.

Finally, the two-person framework is interactive and makes more demands on the analyst to be attentive to the field—from disclosures that may momentarily focus attention on the analyst's mind, through analysis of interaction, to interpretation of the patient's intrapsychic activity. Clinical techniques are not to be objectified into a hard set of rules and regulations. Rather, psychoanalytic techniques are an interlocking set of clinical concepts that the analyst uses as a framework for analyzing the unique interactive matrix. The dialectical tension between the rules of restraint in the analytic relationship and the analyst's personal participation is a major controversy in contemporary psychoanalysis. The relational framework considers the joint critical reflection of such dialectical events crucial to the clinical process.

V. CONCLUSION

Relational psychoanalysis is a selective integration of various theoretical approaches. Its origins can be traced to contributions by various psychoanalysts and schools of psychoanalysis primarily interpersonal psychoanalysis, British object relations, and self psychology. In the

last two decades it has evolved dramatically in the United States and is now the major challenge to the traditional Freudian school of psychoanalysis. Its current state of theoretical development and clinical innovations may make it a revolutionary challenge.

A major premise of relational analysis is that one's history of early relationships and present realities are critical. While classical Freudian theory holds that relatedness is a derivative of instinctual drives, relational theory considers relatedness to be at the center of human development and psychotherapy. In the clinical situation, relational analysts continuously track both the patient's subjectivity and their own. The relational matrix is understood to involve mutuality, conflict, and co-creation. Overall, the aim of relational psychoanalysis is to enrich the patient's experience, to expand the patient's degrees of personal freedom, and to examine the enormous complexities of the mind.

The success of the relational turn in psychoanalysis is consistent with a whole range of movements in other intellectual disciplines such as postmodernism. However, perhaps the major reason for its success is that it has proven to be a more useful approach to the problems in living that are presented in the consulting room of today. This utility in the day-to-day clinical work is based not on empirical research, which relational thinkers believe is only one of many narratives that can be useful, but on rigorous thinking, honest self-reflection and continuous cross-checking with clinical experience.

I. DESCRIPTION OF TREATMENT

“Relaxation training” is a general term that refers to methods that are used to teach and learn specific techniques to help people moderate or control reactivity or arousal that is problematic to them. Often this term is associated solely with muscle relaxation, but given the commonalities among all relaxation-induction methods, we use it as an omnibus term. This label, then, includes various arousal control methods, such as muscle relaxation training, autogenics, biofeedback, meditation, imagery, and paced breathing. Hypnosis, often used to induce relaxation, has many similarities with these other methods, but is not reviewed in this article. The hyperarousal targeted by these techniques often is considered to be physiological (e.g., muscle tension), but can be cognitive (e.g., intrusive thoughts) or behavioral (e.g., fidgeting) as well. The widespread use and effectiveness of relaxation training have led some to call it “behavioral aspirin.” The “training” component of relaxation training implies that it is a skill learned by someone, often a client or patient in a clinical setting, who ultimately can utilize it to induce relaxation on his or her own, in a variety of situations and settings. This procedure for producing relaxation then distinguishes it from other methods that are evoked by other persons (e.g., massage therapy) or substances (e.g., anxiety-reducing medications).

GLOSSARY

- autogenics** Use of autosuggestions to evoke relaxation responses.
- autosuggestion** Process by which clients make self-statements, usually silently, that they then accept and believe.
- biofeedback** Integration of physiological assessment instrumentation (e.g., to record the temperature of the skin surface on one’s finger) with audio or video stimuli (e.g., an outline of a human hand on a video monitor, with different colors indicating varying skin temperatures) to help a client learn to control physiological functions (e.g., skin temperature, muscle tension).
- imagery** Set of mental stimuli, existing cognitively, that can encompass all the senses (i.e., sights, sounds, tastes, smells, and tactile cues) that can be used to evoke a particular emotional or cognitive state (e.g., attention).
- meditation** Act of focused, quiet contemplation used to achieve a relaxed state.
- patter** Slow, rhythmic speech used by a therapist to maintain and enhance relaxation; repetition of statements often is involved.
- relaxation** Reducing or preventing levels of reactivity or arousal, in physiological, behavioral, or cognitive realms, which are so high as to constitute a problem.

A. The Role of Relaxation Training in Behavior Therapy

Relaxation training often is used in behavior therapy as a means to reduce anxiety, tension, and stress. Research has shown it to be effective in a variety of disorders and conditions, primarily those related to anxiety, fear, and stress (e.g., specific phobias), but including those in the realm of behavioral medicine and dentistry, such as acute and chronic pain (e.g., tension headaches), hypertension, and coping with nausea related to chemotherapy. Training patients to relax typically involves providing a rationale, demonstrating exercises, and practicing relaxation in treatment sessions in clinics and hospitals. In addition, patients almost always are asked to practice (“homework”) between therapy sessions. Often, forms or log books are used for patients to record details about their practice. Relaxation training can be relatively brief or long and more comprehensive. The former type has been referred to as “abbreviated” and the latter method as “deep,” and has been associated with muscle relaxation.

Relaxation is a crucial ingredient in many empirically supported contemporary psychosocial treatments for various disorders, including such therapies as the Mastery of Your Anxiety and Panic program, which is a treatment for panic disorder. Relaxation training, in its various forms, is used most often as an adjunctive intervention, comprising one part of a comprehensive treatment program. Relaxation training also can be used to help facilitate communication during a therapy session with a client who may be too tense or anxious to communicate effectively with the therapist. Relaxation training (especially progressive muscle relaxation) often is used in conjunction with systematic desensitization, a procedure designed to lower fear or anxiety toward a specific stimulus (or stimuli) by pairing the feared stimulus or thoughts of the feared stimulus with relaxation.

B. Types of Relaxation Training

1. Progressive Relaxation Training

Progressive relaxation training (PRT) focuses on muscle relaxation; it is a widely used relaxation technique in behavior therapy, and has been the subject of considerable empirical research. Under the direction of the therapist, the client alternately tenses and then relaxes isolated muscle groups, until the entire body is completely relaxed. The rationale is that tensing the muscles before attempting to relax allows the client to become more aware of muscle tension, so as to be able to identify

it when it occurs. The contrast between the tense and relaxed states also may help the client achieve a deeper state of relaxation than would be possible when beginning from a resting state. By focusing on the feelings of tension and relaxation, the client can even learn to induce deep relaxation at a later time by using a recall procedure, allowing him or her to achieve a similar state of relaxation without actually creating muscle tension.

The exercises of progressive relaxation training follow a general sequence of individual muscle groups; each muscle group is relaxed as completely as possible before moving on to the next one. The most common contemporary methods include 16 muscle groups. As training progresses, the muscle tension exercises can be combined into 8 and then 4 groups. The specific order of muscle groups used varies according to the practitioner and his or her adherence to a particular sequence recommended in the literature, as well as to individual needs of the client. One possible sequence involves the following order:

1. Right (or dominant) hand and forearm
1. Right (or dominant) biceps
2. Left (or opposite) hand and forearm
3. Left (or opposite) biceps
4. Shoulders and upper back
5. Neck
6. Lower cheeks and jaws
7. Upper cheeks and nose
8. Forehead
9. Chest (breathing)
10. Abdominal region
11. Right (or dominant) thigh
12. Right (or dominant) calf
13. Right (or dominant) foot
14. Left (or opposite) thigh
15. Left (or opposite) calf
16. Left (or opposite) foot

The entire procedure is carefully controlled by the therapist; each exercise is precisely timed. Muscle tension is maintained for 5 to 7 seconds, during which the clinician may make such statements as “feel the tightness of the muscle; notice what the tension in the muscles feels like.” The therapist will then instruct the client to relax, and make statements to direct the client’s attention to the feelings of relaxation. This relaxation “patter” is used to capture the client’s attention, to soothe and to encourage focusing of attention, and to promote quiescence. The relaxation part of the cycle continues for 30 to 40 seconds, after which the tension-release cycle is

repeated. During early sessions of progressive relaxation training, the tension-release cycle typically is performed twice on each muscle group to ensure complete relaxation. In later sessions, after the client is familiar with the feelings of tension and relaxation, the procedure is often abbreviated, as already noted, to fewer steps by tensing combined muscle groups (i.e., both legs simultaneously instead of each leg individually).

Once clients are comfortable with the briefer procedure, a recall procedure may be taught that can be used in a wider variety of settings. This “cue-controlled relaxation” does not involve any actual tensing of the muscles, but rather the client recalls the feelings of relaxation using a cue word such as “relax.” The cue word is paired with relaxation in treatment sessions and becomes associated with the feeling of deep relaxation through conditioning. Another use of PRT is in differential relaxation training, in which clients are taught to recognize the muscles that are necessary in which activities (e.g., while standing) so that one can ensure that muscles not involved in that activity have minimum tension.

Edmund Jacobsen pioneered PRT in the 1930s. In his research, he found that persons who deeply relaxed their skeletal muscles did not show a normal startle response. Expanding on these findings, he developed a technique in which alternately tensing and releasing individual muscle groups, and learning to attend to and discriminate between the feelings of tension and relaxation, could moderate tension and produce relaxation. In the 1940s and 1950s, progressive relaxation training came to the attention of Joseph Wolpe, who in his research with cats, had discovered that a conditioned fear response could be diminished and even eliminated if an incompatible response (such as relaxation) was induced at the time of fear. Wolpe shortened Jacobson’s methods, to make it feasible to use them in clinical settings. He used PRT in conjunction with systematic desensitization, as a way of producing relaxation during the reconditioning of fears in clinical patients. In 1973, Douglas Bernstein and Thomas Borkovec also streamlined Jacobson’s approach, and produced a step-by-step treatment PRT manual for therapists. Since that time, there has been a great deal of research on PRT, and numerous variants and extensions of it have been forwarded.

2. Behavioral Relaxation Training

In 1988 Roger Poppen published a book on behavioral relaxation training (BRT), a variant of PRT based on modeling and operant conditioning. Like progressive muscle relaxation training, it emphasizes overt motoric behavior, which is important because it facilitates

direct observation of the behavior by both the client and the therapist. Behavioral relaxation training is unique from progressive muscle relaxation training in its emphasis on observable behavior, including posture. Clients are instructed to observe their overt postures, as well as to be aware of feelings of relaxation. BRT also is somewhat different from progressive relaxation in that it is composed of four discrete steps for each of 10 postures or activities, including the hands, breathing, and other components very similar to that of PRT.

1. *Labeling*: A one-word label (e.g., feet) is assigned to each behavior (or posture) to facilitate communication between client and therapist.

2. *Description and modeling*: The therapist explains and demonstrates the relaxed posture, and contrasts it with frequently occurring unrelaxed postures.

3. *Imitation*: The client displays each posture.

4. *Feedback*: The therapist praises accurate posture portrayal, or provides corrective cueing if the client’s posture is incorrect. Gentle manual guidance may be used by the therapist if the client is unsuccessful in achieving correct relaxed postures after several attempts. Positive feedback is then given for the correct postures.

The client maintains each correct posture for 30 to 60 seconds while being aware of the relaxation feelings. There are specific postures or behaviors for the hands, feet, body, shoulders, head, mouth, throat, quiet breathing, and eyes.

As a method of behaviorally assessing relaxation, Poppen devised the Behavioral Relaxation Scale (BRS). There are 10 descriptions of postures and activities in the BRS that are considered to be characteristic of one who is completely relaxed. Relaxation is assessed during an observation session at the conclusion of the session, or before relaxation as a baseline measure. Although the BRS was designed for use with BRT, it can also be used to assess relaxation induced by other methods.

Poppen proposed a taxonomy for analyzing complex behavior that can be easily applied to relaxation. His conceptualization of behavior is that it occurs in four domains: motoric, verbal, visceral, and observational. Poppen claimed that most relaxation techniques emphasize only one or another of these modalities while ignoring the others. BRT is intended to address all four of these areas.

3. Applied Relaxation

Another variant, and an extension of PRT, is applied relaxation, which was described by Lars-Goran Öst in

1987. It is conceptualized as a coping technique that focuses on physiological reactions when a person encounters a phobic object or situation. The intent is for the relaxation skill to be applied rapidly when confronted with such an event, to foster coping. Applied relaxation is intended to counteract, and later to prevent, phobic-level physiological reactions. Training includes the recognition of anxiety signals early in the chain of reactions to phobic events. PRT is then taught, followed by a shortened version in which only the relaxation (or muscle release) component is included. Cue-controlled relaxation is then reviewed, followed by differential relaxation. A somewhat unique component of applied relaxation is its focus on rapid relaxation in the natural environment. Then, application training ensues, first in generally stressful but nonphobic situations, and later in actual exposure to phobic objects or situations.

4. Stretch Relaxation

Much like PRT, stretch relaxation also is based on achieving a quiescent state through decreased muscle tension. The major distinction is that stretch relaxation does not require the individual to tense and release muscle groups. Rather, the reduction in tension is achieved through the systematic stretching of individual muscle groups. This technique was developed by Charles Carlson and colleagues, in part because some patient populations find the tensing and releasing of muscles painful or distressing, or that it is inappropriate for them. For example, some pain patients find that tensing their muscles increases pain and does not readily allow subsequent relaxation. Patients with certain cardiovascular problems, such as patients in whom creating muscle tension could cause arrhythmias or elevated blood pressure, also may be inappropriate candidates for progressive muscle relaxation. Stretch relaxation training is often an effective alternative treatment for these patients.

The process involves a series of 14 muscle-stretching exercises. Prior to the actual stretching exercises, the individual is instructed to assume a quiet resting position and breathe slowly and deeply. After 3 to 4 minutes of physical resting and relaxed breathing, the client or patient begins the stretching exercises, starting with the lower right leg and progressing through the 14 muscle groups. Similar to PRT that involves muscle tensing, stretching is utilized for the separate muscle groups in the extremities, back, buttocks, stomach, chest, forehead, eyes, jaws, neck, and shoulders. Examples of stretching exercises are those for the upper leg, in which

one knee is raised and placed over the other leg to sag, and those for the shoulders and upper arms, in which the fingers of the hands are interlocked and the arms are raised over the head.

Each stretch is held for 15 seconds, and is followed by 60 seconds of relaxation. Clients are instructed to focus their attention on the sensations of stretching and relaxation and to breathe using a slow, regular rhythm.

5. Autogenic Training

Autogenic training (AT) is a passive autosuggestion technique with the goal of self-produced relaxation with a minimal amount of training. AT is used extensively in Europe, Russia, and Japan, but is less popular in North America. Some of the conceptualizations and wording are not common in American culture. In contrast to progressive muscle and stretch relaxation, AT is passive rather than active. It consists of six mental exercises that are based on short autosuggestions, or "formulas." Sensory feelings and states are emphasized, including heaviness and warmth in the extremities, regulation of respiration and cardiac activity, abdominal warmth, and coolness of the forehead. The therapist uses a calm, relaxed voice and makes statements about these feelings and physical states, which the client then repeats internally. The exercises are learned in a specific sequence, and the client achieves each state before initiating the next exercise. The six exercises or "formulas" are:

1. *Heaviness formula:* This exercise is intended to affect the muscles and reduce muscular tension. The therapist might utter a statement such as: "My left leg is very heavy."

2. *Warmth formula:* Blood circulation and dilation of blood vessels is the focus of this formula. The clinician focusing on this area with clients might suggest: "My right arm is very warm."

3. *Heart regulation:* Encouraging awareness of heart activity is the primary consideration, after which regulation of heart activity is the goal, consistent with statements such as "My heart is beating calmly and strongly."

4. *Breathing regulation:* Regular respiration is the key issue for this formula. Voluntary changes in breathing pattern are considered undesirable because that can involve tensing muscles and movement. Passive phrases are used, such as "It breathes me."

5. *Regulation of the visceral organs:* Clients focus their attention on the solar plexus as the central nerve center for the internal organs. A typical statement may be "Warmth radiates over my abdomen."

6. *Regulation of the temperature of the head:* Using statements such as “My forehead is cool,” clients imagine the feeling of a cool cloth on their forehead, with the result of localized movement of blood away from the surface of the skin (i.e., vasoconstriction) on the forehead, creating sensations of coolness.

Autogenic training developed along a similar timeline to progressive relaxation training. In 1932, a German physiologist named Johannes Schultz began developing AT as a passive form of controlling arousal. Early psychophysiological studies led him and his colleagues to assert that the state brought about by AT was unique, and different from conscious awareness, sleep, or hypnosis. Electroencephalograph (EEG) recordings during AT led to the conception of the autogenic state as similar to a “pre-sleep state.” Schultz believed that the shift from consciousness to the autogenic state was a specific process that involved changes in both psychological and physiological functioning, and allowed the person to “step behind” or “dive under” the usual conscious waking state. Schultz and his colleague Wolfgang Luthe believed that the mental and physical relaxation brought about by their procedure could eventually lead to relief from many physiological and psychological problems.

6. Biofeedback

The term biofeedback refers to a variety of procedures that provide ongoing information about physiological activity to persons attempting to learn to modify their physiological levels and responses. In particular, electromyographic (EMG) biofeedback is often employed as a relaxation technique to help people to control their levels of muscle tension. Thermal biofeedback also is common, in which the temperature of the skin surface is monitored, usually on a finger or foot, as increased blood flow to the skin surface is associated with relaxation. The general aim of biofeedback is to teach clients to use the feedback to gain conscious control of biological responses (e.g., skin temperature, heart rate) that have been operating maladaptively and that were previously thought to be uncontrollable. Biofeedback is shown to be effective across a variety of conditions, most notably anxiety disorders, tension headache, insomnia, and hypertension. In many cases biofeedback does more than teach individuals how to regulate their biological functions; it can also help improve their sense of personal control and ability to cope with stressful situations by showing that it is in fact possible to control the physiological events that accompany everyday life.

There are three major stages in biofeedback training. In the first stage, the client becomes aware of the maladaptive response (e.g., muscle tension) and learns that certain thoughts and biological events can influence the given response. The patient can relax some with a conscious effort. In the second stage, the client gains better control over the maladaptive response and can consciously relax with greater ease. The third stage marks the point at which the client can readily transfer the control to daily life, and can relax with little or no conscious effort.

Biofeedback training requires the use of instrumentation of varying degrees of sophistication. The essential requirement is that clients be provided with either visual or auditory information regarding their bodily state, usually in “real time,” as the person’s physiology is responding. The form of the feedback varies, can be shown visually on a video monitor, and/or can be transmitted by auditory tones or clicks, with higher or lower frequencies indicating the physiological response is increasing or decreasing.

Interest in biofeedback as a therapeutic technique burgeoned in the 1960s as a result of the work of various investigators. Among them, Joe Kamiya developed a technique of controlling alpha (EEG) rhythm by use of a tone to indicate that the brain was producing alpha waves. Second, Neal Miller demonstrated that autonomic responses could be conditioned through operant procedures in animals. Also, Thomas Budzynski and his colleagues built an alpha EEG feedback device with the intent of teaching subjects to produce more pleasant, tranquil alpha brain wave activity. Thereafter, attention shifted away from alpha feedback and toward skin surface feedback, generally measured through electrodes placed on the forehead to record facial muscle activity. This progression in research was based on investigations that found that the frontalis muscle of the forehead was a reliable indicator of anxiety, tension, and arousal. Over the years since this early research, EMG biofeedback has been demonstrated to be effective in helping clients to learn to reduce tension in the muscles of the head and scalp, thereby producing long-lasting reductions in tension headaches, among other uses.

7. Meditation

One of the currently most popular methods of relaxation is meditation. Examples are transcendental meditation and mindfulness meditation. In many forms, meditation enjoys widespread use across many lands and cultures. Quite old forms of meditation are involved in yoga practice; Japanese Zen, Chinese Tao, Hindu, and

Buddhist meditation are other forms. Some forms of meditation are associated with religious and spiritual beliefs about lifestyle. Others have no connection with religion or spirituality, but focus specifically on feelings of peacefulness and concentration. Across types of meditation, there are some qualities that are common to most or all of them.

First, meditation requires a comfortable position, usually sitting or lying down. Second, like other relaxation techniques, it usually must take place in a quiet, peaceful setting where interruption is unlikely. Thirdly, individuals regulate their breathing to a slow steady pace. Fourth, mental or cognitive activity during meditation often is focused on a particular word or phrase (e.g., a “mantra”). Some types of meditation, however, require the individual to empty the mind, think of nothing, and meditate on that mental silence.

One meditation technique that deserves special attention is one developed by Herbert Benson in 1975 termed “the relaxation response.” Benson based his technique on laboratory observations of practitioners of transcendental meditation. He found that during meditation, the oxygen consumption and blood lactate levels of his subjects dropped to levels similar to those seen in sleep or hibernation. He concluded that meditation led to a hypometabolic state, which he termed the “relaxation response.” Benson went on to specify a method to meditate in which one can achieve the desired response through four crucial elements:

1. *Quiet environment:* A quiet place is essential for meditation practice, so as to eliminate distracting noises. Also, in this and most other forms of relaxation, the client closes his or her eyes, to reduce distracting visual stimuli.

2. *Target object to dwell on:* The target can be a repeated word, phrase, sound, symbol, or image, or can involve focusing on a particular feeling.

3. *Passive attitude:* The individual should allow thoughts and feelings to drift in and out of awareness without concentrating on them. Ongoing self-evaluation of progress with meditation practice should be avoided. Maintaining a passive attitude was identified by Benson as the most crucial factor in eliciting the relaxation response.

4. *Comfortable position:* As with most forms of relaxation, it is usually necessary for the person to be in a sitting position that can be comfortably maintained for at least 20 minutes.

Although Benson’s technique has not been subjected to the same amount of empirical research as other tech-

niques such as PRT or biofeedback, it has enjoyed widespread popularity in the United States and elsewhere.

8. Guided Imagery

In the use of guided imagery, the therapist and client develop imagery scenes that produce feelings of calmness, tranquility, or pleasure for the client. It is critical that the therapist consult with the client as to the appropriateness of scenes, as a scene thought to be calming (e.g., sitting at a waterfall) may not be relaxing to a particular individual (e.g., one who is phobic of water). The scenes are embellished with as much sensory detail as possible, both to make the imagery seem more real and to completely involve or “absorb” the client in the experience. Common settings for guided imagery include the beach, a tranquil forest, or a mountaintop. Note the sensory detail in these scene instructions:

Close your eyes, sit back, take a few deep breaths, and relax. While your eyes remain closed, sitting in the chair and feeling relaxed, think about yourself on a tropical island. Make this image as real as possible, as if you really are there. As you look up, there are a few wispy clouds scattered across the brilliant blue sky. The turquoise ocean tumbles toward the shore in gentle, foam-capped waves. Gulls fly overhead; you hear their distant squawks. You feel the bright, warm rays of sun over your entire body and the light breeze blowing over your skin. You taste the salt from the air, as the wind blows in from the water. Walking along the beach, you encounter pleasing flowery scents from the nearby groves of tropical trees.

Actual scenes can be much longer. After the scene has been developed, clients are instructed to practice using the scene. In practicing, clients often focus on the scene for approximately 30 seconds, trying to picture, feel, and otherwise sense as much detail as possible. Over time, they should be able to readily and reliably evoke the image, leading to relaxation. It is possible also for clients to use the imagery to inoculate themselves from stressful or fear-provoking situations, or to mediate those reactions once they have begun. Guided imagery is often used as a distraction from pain during medical and dental procedures, or to combat anxiety during a feared situation.

Guided imagery relies somewhat on the clients’ abilities to vividly imagine scenes, so in clinical practice, it may be important for the therapist to assess the clients’ abilities in this area. Imagery ability can be assessed informally by asking clients to recall a particular event they enjoyed. Allowing clients to relax, the therapist then asks for as many details as they can provide, after

which clients rate the vividness of the image, for example, on a 1 to 10 scale. Another way to assess imagery ability is to use a rating scale in which the clients are instructed to imagine a variety of scenes and to rate the vividness of each. For clients whose skills are not well developed, imagery training can be employed to help them effectively utilize guided imagery.

9. Paced Breathing

Deep, regular breathing is a component of most relaxation training strategies. Many clients who experience problem levels of stress often have breathing-related complaints, and most of the symptoms associated with stress are those associated with hyperventilation. Variations in breathing patterns have an effect on cardiovascular functioning. Diaphragmatic breathing is a technique that teaches clients to breathe deeply using the diaphragm, expanding the abdomen rather than the chest. One of the most common ways of teaching diaphragmatic breathing is to have clients place their hand on the abdomen while breathing slowly. The client is instructed to breathe so that the hand on the abdomen raises up, minimizing any movement in the upper chest. Breathing in this manner allows the individual to inhale more air than normal shallow breathing. Deep breathing has been shown to release stress and tension, build energy and endurance, help with pain management, and to enhance mental concentration and physical performance. It can be taught as part of another relaxation technique or alone. Deep breathing usually is easily taught in one therapeutic session, and has the advantage that it can easily and unobtrusively be used by clients during the day whenever a stressful situation emerges.

C. Clinical Assessment and Treatment Issues

As with any treatment, assessment is a key issue in relaxation training. Identifying who can and cannot benefit from a given treatment is a critical consideration, although psychological science has not yet evolved to the point that it is known which treatments match to which clients. Those relaxation methods that focus on muscle tension or stretching may be particularly appropriate for clients who have high levels of tension and tension-related ailments, such as tension headache. Persons with highly reactive cognitive processes (e.g., worry, intrusive thoughts) may be well suited for those techniques that emphasize control over one's thinking. Relaxation skills can be taught in individual or group settings. There are numerous commercially available re-

laxation programs, including various media (e.g., audiotapes), for clients and therapists.

There are some considerations to be addressed in employing relaxation training. The first of these considerations is medical in nature. Before deciding on relaxation training, the clinician should ensure that medical problems have been properly evaluated, and that treatment has been provided or is ongoing. Many times, relaxation methods are a helpful adjunctive treatment for clients who have diseases (e.g., cardiovascular disease), and can be used in conjunction with medications. Another consideration is the possibility of contraindications to the use of relaxation training. Some clients (such as chronic pain patients, and those with temporomandibular joint [jaw] dysfunction) are advised not to tense certain muscle groups, so techniques that involve the tensing or stretching of muscles may not be the treatment of choice, although if only a few muscle groups are involved, the tension component can be skipped for them. Another issue to consider in using relaxation training is the source of the tension. If a person's tension is excessive or out of proportion to a situation, then relaxation training may be particularly appropriate. If, however, there is a life situation (e.g., marital disharmony) that is amenable to change that is leading to the problem tension, then addressing that problem directly (e.g., marital therapy) may be the treatment of choice. Another point to consider is that tension may be a conditioned response to some specific environmental stimuli. In this case, relaxation training alone may not be sufficient. Instead, systematic desensitization or *in vivo* exposure may be more appropriate. Finally, the preference of the client should be a prime consideration in choice of a relaxation strategy. As there presently are no hard and fast guidelines about which methods to use with which persons, client preferences may well be one of the most important factors currently in predicting treatment success.

Not everyone will benefit from relaxation training. Although it is rare, relaxation training sometimes can actually induce anxiety or even panic in some clients. There have been several explanations offered for such a reaction. One is that relaxation causes new and unusual sensations in the body, such as feelings of disorientation, or "floating." These unfamiliar feelings may provoke anxiety in some clients. Other patients may have a fear of losing control. It has been hypothesized that some people with chronic, pervasive anxiety may have learned to control their anxiety by never letting go or permitting themselves to relax. The feeling of loss of control associated with relaxation can cause excess anxiety in such individuals.

II. THEORETICAL BASES

By emphasizing “training,” the conceptual underpinnings of relaxation training obviously include learning. It is assumed that individuals learn a new skill, enhance existing abilities, or learn to utilize existing adaptive responses. Some individuals may need relaxation training because of extreme life circumstances (e.g., undergoing chemotherapy). Others may have a unique psychophysiology, behavioral functioning, or cognitive processing that predisposes them to psychological problems that are amenable to relaxation training. The problem response may either be chronic (e.g., hyperactivity in the muscles due to job-related stress), acute (e.g., intense response to a phobia, such as public speaking phobia), or both. Regardless of the reason for the problematic physiological, cognitive, or behavioral response, training is utilized to develop, enhance, or prompt relaxation-related skills.

There are elements of classical conditioning, operant conditioning, and observational learning in relaxation training. The relaxed state is classically conditioned to various stimuli (e.g., sitting in a dimly lit room, closing one’s eyes while sitting in a relaxed posture). Operant conditioning principles are employed, for example, when therapists use positive reinforcement for praising clients for proper use of relaxation procedures. When therapists model or demonstrate appropriate relaxation postures, for example, observational learning occurs. Moreover, in some forms of relaxation training (e.g., PRT), the individual is specifically taught to discriminate between tense and relaxed states. This training allows clients to discern more accurately tense and relaxed states, particularly in terms of muscle tension, which should allow them to prevent tension before it reaches problematic levels. In other types of relaxation training, the focus is on learning the relaxation response itself, and clients are encouraged to turn their attention away from impediments to relaxation (e.g., intrusive thoughts).

III. EMPIRICAL STUDIES

There is a wide body of literature that supports relaxation training as an effective therapy for a wide range of disorders. One problem with much of the existing data, however, is that most studies combine relaxation training with other forms of therapy; it rarely is used in isolation. Charles Carlson, who originated stretch relaxation, and a colleague, conducted a review in 1993 of 29 experiments with relaxation training. Their statistical analyses suggested that relaxation training is effective for a range

of disorders, particularly including tension headache. Individual training was found to be superior to group sessions, and training audiotapes for home practice were determined to increase treatment effectiveness. Longer treatment duration in each session, and greater numbers of sessions, also were associated with more positive treatment outcome. In addition to this “meta-analysis” of the findings of a number of studies, recent individual experiments also provide strong support for the effectiveness of various forms of relaxation training.

One example is an investigation by F. Dudley McGlynn and colleagues in 1999; they examined the effects of PRT on levels of fear and arousal during *in vivo* exposure to phobic stimuli. There were 10 snake phobic individuals who were given six sessions of progressive relaxation training, while another 10 were not. All participants were then exposed six times to a 4-minute viewing of a caged snake on a conveyor; they were able to control how close the snake came to them. The distance between the subject and the snake was measured, a self-report measure of fear was obtained, and heart rate and sweat gland activity were recorded. Data analyses showed that the individuals trained in progressive relaxation had significantly lower fear ratings, and a smaller degree of heart rate change, throughout the course of snake exposure. These findings support the use of PRT prior to *in vivo* desensitization procedures.

As another example, a study of applied relaxation by Lars-Goran Öst and a colleague in 2000 compared it to cognitive therapy in the treatment of generalized anxiety disorder. There were 36 patients who met criteria for this anxiety disorder who were randomly selected to receive either one or the other of the treatments. At posttreatment assessment, both treatment groups showed clinically significant and lasting improvements in a variety of areas, including worry, cognitive and somatic anxiety, and depression.

IV. SUMMARY

Varying types of psychosocially based relaxation inductions have been used across known history. In the latter part of the 20th century, and into the 21st century, empirically tested forms of relaxation training have become widely available. There are many commonalities among the various forms of relaxation training, but each has its own unique characteristics. Some of the differences among these methods are based on societal perceptions, and the different labels that are used to describe them. Some of the similarities of these methods include the client being in an environment relatively

free of distractions (e.g., a quiet, dimly lit room) so as to reduce distractions, reposing in a relaxed posture (usually sitting), focusing on a specific stimulus (such as the therapist's voice in PRT, or a "mantra" in meditation), and having guidance by a practitioner using a soothing voice and calm manner. Clinicians now have a wide array of relaxation methods to choose from, allowing more individualized treatment for clients with complaints including anxiety, hypertension, insomnia, pain (including tension headaches), and many others. As in any science, research will progress to reveal more information about relaxation and its beneficial effects and limitations, and techniques will continue to improve.

GLOSSARY

effect size A statistic that often is used in therapy research to indicate the magnitude of the difference in outcomes (or “effects”) found in a research study between alternative treatments or between a treatment and an un- or minimally treated control group.

external validity A concept that refers to the inferences that can be accurately drawn from a research study’s findings, specifically the confidence with which findings can be assumed to “generalize” or extend to situations, people, measures, times, and so on other than those particular to the study. A study’s research design and methodology are major determinants of the external validity of its findings.

internal validity A concept that refers to the inferences that can be accurately drawn from a study’s findings, specifically the confidence with which a causal relationship can be assumed to exist between a study’s independent variables (e.g., forms of therapy) and dependent variables (e.g., outcomes or effects in a therapy study). The fit between a study’s hypotheses, research design, and methodology is a major determinant of its internal validity.

managed care corporation A for-profit business that sells health care insurance contracts to employers and to individuals. Managed care corporations differ from traditional indemnity

insurance companies in that the former directly oversee and control access to treatment by those who hold its contracts.

outcome research Studies that are designed primarily to test hypotheses and answer questions about the effects of psychotherapy and other treatments. “Outcome” is used as a synonym for “effects.” For example, outcome studies can be designed to answer comparative treatment questions like, “Is cognitive-behavioral therapy associated with more improvement in depression than interpersonal psychotherapy?”

patient In the therapy research literature one of two words, “patient” or “client,” usually is used to refer to a person who is the direct recipient of psychotherapeutic services. “Patient” typically is used in more medically dominated settings such as departments of psychiatry, “client” in more psychologically dominated settings such as university counseling clinics. Herein, the term patient is used.

psychoneurotic A global psychodiagnostic term that was in common use until about 1980. It connotes a wide range of problems that now (2002) are called anxiety disorders, unipolar depressions, and personality disorders in the American Psychiatric Association’s diagnostic nomenclature (*Diagnostic and Statistical Manual of Mental Disorders*). “Psychoneurotic” typically did not refer to what are considered more severe disorders such as schizophrenia and bipolar disorder.

psychopathology research A field that is focused on (a) distinguishing normal and abnormal human psychological, emotional, and behavioral functioning; (b) identifying causes for abnormalities; and (c) developing methods to assess and taxonomies for varieties of abnormal functioning.

psychotherapy Psychotherapy is used in this article as a synonym for “psychological therapies.” It refers to all forms of treatment in which the primary therapeutic agent is a person

(e.g., in contrast to an instrument or machine) who relies exclusively on verbal/conceptual, psychoeducational, or behavioral methods, rather than on pharmacological or other somatic methods (such as electroconvulsive treatment or rapid transcranial magnetic stimulation), to ameliorate a broad array of behavioral and psychological problems, many of which fall under the contemporary medical terms, “mental illnesses” and “psychiatric disorders.”

statistical significance A mathematically derived index of the probability that a research finding is valid versus due to chance.

I. INTRODUCTION

Psychotherapy research in the United States is a relatively young field, about 60 to 80 years old depending on the perspective taken. It encompasses a diverse array of activities, a uniting goal of which is to create a scientific foundation for the practice of psychotherapy. Alan Kazdin, a contemporary expert on psychotherapy research, described its aims this way: “To understand alternative forms of treatment, the mechanisms and processes through which these treatments operate, and the impact of treatment and moderating influences on maladaptive and adaptive functioning.”

A broad mix of research strategies and methods are used to achieve the preceding aims. They span a continuum from relatively “uncontrolled” methods (e.g., systematic, naturalistic observation) to experimental procedures that are used to control (reduce the potential impact of) some variables so that the operation of others can be observed more clearly and precisely. Psychology and, in particular, clinical psychology often are said to be the parent disciplines of psychotherapy research in the United States. Other disciplines, notably psychiatry, also have made important contributions to it from the outset. The relatively short history of psychotherapy research includes marked shifts of focus (“turning points” herein), as well as scientific advancements (“milestones” herein). The field also has some long-standing, unanswered fundamental questions.

One goal of this article is to convey the dynamic nature of psychotherapy research—its responsiveness to social issues, government needs for information on which to base policy, developments in related fields—as well as to its own discoveries and other advances. A second goal is to provide an overview of some of the field’s defining, substantive features as they have evolved to the present. The features described are primarily key research questions. A few, related research methods also are described. Detail on the conduct of

psychotherapy research is not provided, nor are findings on different questions reviewed in depth. Relevant research methods (e.g., study design, measurement, statistical data analysis strategies) are extensive and are well described in many excellent sources, a few of which are listed in Further Reading. Similarly, sophisticated and comprehensive reviews of findings from the thousands of psychotherapy research studies that have accumulated over the years can be found in the five editions to date of *The Handbook of Psychotherapy and Behavior Change*.

A single article on an entire field of research requires many inclusion and exclusion decisions. This article is focused solely on the development of psychotherapy research in the United States. It also is limited to research on individual psychotherapy (not group or family therapy) for adults (not children or adolescents). The content pertains most directly to therapy research for problems other than addictions (e.g., to alcohol and drugs of abuse such as heroin) because substance abuse treatment research in the United States followed a partially separate developmental path. Within the preceding delimitations, a guiding principle was to highlight scientific milestones and turning points. Turning points herein are findings or events that changed the direction of at least a notable constituency of therapy researchers. Milestones are findings or other research-related developments that improved the possible scientific quality of research or its immediate value for informing clinical practice (the two are not distinct: “findings” from studies with poor scientific quality rarely if ever are properly regarded as having immediate implications for practice). Of course, the identification of milestones and turning points lies in the eyes of the beholder. To reduce the extent to which the topics discussed mainly reflect idiosyncratic biases of the author, several dedicated experts in psychotherapy research graciously reviewed the article (see Acknowledgments).

The preceding precaution could not eliminate another type of limitation. Doing psychotherapy research teaches well the general lesson that some “facts” are highly dependent on the perceiver. The author has been involved in therapy research for over 25 years in a variety of settings. Nevertheless, a participant–observer’s perspective always is limited to just part of “the elephant” that is one’s field. In addition, the perspectives herein on the primary forces that prompted turning points are likely to both overlap with and differ somewhat from descriptions by others who had different vantage points and who were influenced by different contingencies.

II. HISTORICAL OVERVIEW

Psychotherapy research is a branch of research on treatments for psychological, emotional, and behavioral problems, that is, for problems often referred to by the medically oriented term, “mental illnesses.” The development of psychotherapy research has a strong historical link to clinical psychology. The link was solidified in 1949 at the Conference on Graduate Education in Clinical Psychology that was held in Boulder, Colorado. The “Boulder model,” also known as the scientist–practitioner model of graduate-level training in clinical psychology, was established then. The essence of the Boulder model is that the doctoral degree (Ph.D.) in clinical psychology should be based on training both in research methods and in the clinical application of (i.e., direct use with people) psychotherapeutic interventions. To this day, Ph.D. clinical psychologists are expected to be able to conduct and evaluate research relevant to their field, as well as to provide psychotherapeutic services.

The psychotherapy studies done by clinical psychologists and other therapy researchers examine a broad range of questions. Some are designed mainly to answer more basic questions (e.g., “How do psychotherapies work?”), whereas others are designed to answer questions that have immediate implications for the practice of psychotherapy such as, “Which of the available forms of treatment has the best probable outcomes for depression in adults?” Both types of studies are said to have “applied” aims. Treatment-relevant research that primarily has applied aims is referred to as “clinical research.” Psychotherapy research correctly is regarded as a branch of clinical, mental health research.

A. How Psychotherapy Research Relates to Other Mental Health Research

Psychotherapy research is distinguished from other types of clinical mental health research such as psychopharmacology (medication) research, which is strongly linked to the field of psychiatry and to the pharmaceutical industry. However, from the mid-1980s to the present an increasing number of outcome studies include psychotherapeutic interventions, pharmacological interventions, and their combination, thereby blurring the boundaries between psychotherapy and psychopharmacology research. Psychotherapy research also is distinguished from mental health services research. Traditional services research is intended to obtain data on the natural functioning of community-based, clinical

care delivery systems. Typical data include how such systems are organized, their accessibility, fiscal features, and outcomes at a global level (e.g., recidivism). Services research usually utilizes large databases (e.g., several thousand service recipients and clinic “contacts” or visits) and provides information useful at a programmatic level. It is not designed to test and develop specific treatments. Psychotherapy research also can be differentiated from psychopathology research, although the two fields historically and presently overlap.

B. Psychotherapy Research versus Behavior Therapy Research

For many years (from about the 1950s through the 1970s), therapy researchers themselves drew a clear distinction between behavior therapy research and psychotherapy research. The distinction reflected what aptly has been described as an internecine struggle between those who endorsed forms of therapy that were grounded in theories and findings of subdisciplines of psychology known as learning and behavior (“behavioral” therapies), and those who favored therapies derived from Freudian psychodynamic theory or from humanistic principles (e.g., Rogerian client-centered therapy). The distinction was instantiated in the founding by psychologists of two scientific organizations at approximately the same time: the Association for the Advancement of Behavior Therapy (1966) and the Society for Psychotherapy Research (circa 1968). Both flourish to this day.

By the late 1970s, tangible signs of a rapprochement between the two camps emerged. One such sign was the “psychotherapy integration movement” that was spearheaded by psychologists such as Paul Wachtel and Marvin Goldfried. The period of rapprochement was spurred in part by outcome findings that indicated that behavior therapy-based and psychotherapy-based treatments both were associated with measurable benefits, often of comparable magnitude. Neither camp could claim unqualified victory. Indeed, contrary to the hopes and expectations of many, some studies in which a behavioral therapy was compared directly to a non-behavioral therapy (e.g., psychodynamic psychotherapy) failed to detect statistically significant outcome differences. A prototypic study like this was published in a 1975 book by Sloane, Staples, Cristol, and colleagues, *Psychotherapy vs. Behavior Therapy*.

At least partially due to mutually humbling outcome research findings, animosity between the camps substantially diminished, and some cross-fertilization even occurred. The two arms of therapy research also retained

some distinctiveness, as reflected in one of the field's most influential recent milestones, a listing of empirically supported forms of therapy ("ESTs") for specific types of problems. The list was first published in 1995, based on the work of the American Psychological Association's Task Force on Promotion and Dissemination of Psychological Procedures. The Task Force was chaired by Dianne Chambless from 1993 to 1997. (Initially, the term "empirically validated therapies" was used for the list. It was changed to ESTs in part because the word "validated" could mistakenly connote that the process of validation for a therapy had been completed and no additional research on it was needed.) The list includes some therapies that are essentially behavioral (e.g., exposure and response prevention for obsessive-compulsive disorder), as well as some that are not such as interpersonal psychotherapy for depression (a type of psychotherapy that was developed by psychiatrist Gerald Klerman and colleagues, published in 1984).

The long-standing distinction in the literature between behavior therapy and psychotherapy, and between the corpus of research focused on each, marks a historically important epoch in the development of research on psychologically based interventions. Herein the term "psychotherapy research" includes research on all forms of psychologically based treatments.

C. "Coalescence" Phase of the Field of Psychotherapy Research

So, when did all this start? Several reviews of therapy research indicate that the earliest outcome studies of psychotherapies were published in the late 1920s, slightly over 80 years ago. A 1916 study was mentioned in a review by Allen Bergin, an unusually knowledgeable reviewer. The number of outcome studies published per year was very low at first—about two every 5 years between 1920–1930. The rate increased to about 10 every 5 years after that and during World War II. Starting in the early 1950s, the publication rate of psychotherapy outcome studies began to increase exponentially.

By 1958, the field of psychotherapy research definitely had emerged in the United States. In that year, the Division of Clinical Psychology of the American Psychological Association held the first national conference on psychotherapy research. The National Institute of Mental Health (NIMH) provided financial support for the conference. Broadly stated, its purpose was to evaluate the status of therapy research and to thereby provide information that also could stimulate further research. An important additional aim was to

strengthen research collaboration and interdisciplinary relations between psychologists and psychiatrists. Psychiatrists were among the invited participants and also were asked to join the conference planning committee.

Several forces are likely to have contributed to the accelerating growth of psychotherapy research that was evident by the 1950s. The end of World War II played a role. For example, resources of many types became more available, and the kinds of acute problems that psychiatrists observed in soldiers led to greatly expanded interest in psychotherapy after the war. A closely related development was the U.S. Veterans Administration's promotion of the use of psychologists both to administer psychotherapy and to conduct research. Another factor was the methodologically groundbreaking and exemplary psychotherapy research program that was developed by Carl Rogers, his colleagues, and students at the University of Chicago beginning in 1949. The availability of funding from the NIMH, after it was established in 1949, was certainly growth promoting. The previously noted adoption in 1949 of the scientist-practitioner model for education in clinical psychology also contributed. Moreover, doubtless, what was reacted to by many as a gauntlet thrown down by Hans Eysenck in 1952 energized and focused psychotherapy outcome research initiatives.

In perhaps the most widely cited therapy research publication of the era, Eysenck presented data that he interpreted as evidence that existing outcome studies did not show that psychotherapy was associated with better improvement rates than occurred, over time, in untreated individuals who had comparable problems. The latter was termed "spontaneous remission." Eysenck used two previously published naturalistic data sets to estimate improvement rates that would occur in psychoneurotic problems over 2 years without the benefit of "systematic psychotherapy." One set of figures was from discharge records of neurotic patients from New York state hospitals; the other was from an insurance company's disability claims for psychoneuroses for a 5-year period. According to Eysenck's calculations, improvement rates found in psychotherapy outcome studies and improvement rates for the same types of problems in those who did not receive psychotherapy both were about 66%.

The validity of Eysenck's methods and conclusions were challenged by many therapy researchers over the years. The kinds of questions asked included "Was his assumption accurate that those in the naturalistic studies had not received any psychotherapy?"; "Were the improvement criteria used in the naturalistic studies

comparable to those used in therapy outcome studies?"; "Was spontaneous remission an established finding," as Eysenck's argument suggested it was? It was not until 1977 that data were presented (by Mary Smith and Gene Glass) that finally put to rest Eysenck's conclusion that no evidence existed that psychotherapy was effective. More about this in Section III.

Before leaving the topic, a key fact is worth noting. The heated debate stimulated by Eysenck's 1952 paper (and by a later, similar paper of his published in 1960) was to some extent both fueled by and a manifestation of, the aforementioned behavior therapy versus psychotherapy struggle. Eysenck, himself, became a leader in the behavior therapy movement.

Despite the field's burgeoning growth since the 1950s, as recently as 20 years ago (1980) psychotherapy research was quaintly described as a "cottage industry" by some observers. The term seems to have originated mainly from comparison of psychotherapy research to psychopharmacology research, a field whose primary and huge funding source is the pharmaceutical industry. Among other things, cottage industry status connoted that outcome studies of psychotherapy typically had relatively small sample sizes—20 or fewer individuals included in each treatment condition. In addition, many studies were un- or underfunded and conducted by individual investigators who did not closely coordinate their efforts with those of others working on the same or related questions. Thus, findings did not typically build on each other, thereby creating a cumulative and obviously progressing body of knowledge. Although the quality of studies could be excellent, their findings typically were not highly influential in terms of affecting either the practice of psychotherapy or public policy on mental health treatment. (Cottage industry or not, the field was an active one. According to Michael Lambert who reviewed the psychotherapy research literature in 1980, 4,000 studies of various types had been published by then.)

D. "Coming of Age" Phase: Therapy Research Enters the Mainstream of Clinical Mental Health Research

The milestones and turning points described in the next subsections, with one exception (the NIMH treatment development grant mechanism), were in some way controversial within the field of therapy research. Indeed, controversy probably is a marker for publicly observable events that have the potential to precipitate widespread change. The points of contention are not

discussed here but readily can be found in the psychotherapy research literature.

1. Large-Sample, Multisite Studies, Randomized Clinical Trial Design

A clear turning point for the field of therapy research began to take shape in about the late 1970s. Larger-scale outcome studies of psychotherapies—250 or more individuals treated—began to be undertaken with the assistance of substantial funding from the NIMH. The shift was at least partially due to a leadership role taken by NIMH staff like Morris Parloff and Irene Elkin, both of whom were experienced psychotherapy researchers. Psychiatrist Gerald Klerman also facilitated the changes from his position at the helm of the Alcohol, Drug Abuse and Mental Health Administration, the federal government agency that oversaw the NIMH at the time.

One study, in particular, marked the defining shift for psychotherapy research from its so-called cottage industry status to a recognized, influential branch of clinical research. The study is known as the NIMH Treatment of Depression Collaborative Research Program (TDCRP). Irene Elkin of the NIMH played a key role in the study's oversight and conduct throughout its course. Work began on conceptualizing and designing the TDCRP in 1977. Its initial outcome findings were published in 1989, a mere 13 years ago. The TDCRP was the first time that a collaborative, multisite outcome study of psychotherapies (i.e., the same research design and procedures were implemented simultaneously at three, geographically distant research settings) was conducted using the randomized, controlled clinical trial research strategy. Until then, collaborative clinical trials were commonly used for pharmaceutical company-funded research on psychoactive medications but not for psychotherapy research.

2. Selection of Patient Samples by Psychiatric Diagnoses

The TDCRP also illustrates the impact of a development external to the field of psychotherapy research that became a momentous turning point for it shortly after 1980. In 1980, the American Psychiatric Association published the third edition of its diagnostic nomenclature of psychiatric disorders, the Diagnostic and Statistical Manual of Mental Disorders (*DSM-III*). The *DSM-III* was a major revision of the Association's existing nomenclature. The overhaul was undertaken in part to remediate features of prior versions of the *DSM* that made it an inadequate diagnostic system to

support clinical research—both psychopathology studies and outcome studies of psychopharmacological and other treatments. For example, the descriptions of diagnoses were not specific or detailed enough to enable diagnoses to be assigned reliably to the same patient by different, even expert, psychiatrists. Poor interrater reliability of diagnoses was a fatal handicap from a research perspective, and it created many problems from a practice perspective too.

The *DSM-III* had a major impact on psychotherapy research despite the fact that many mental health professionals from all disciplines and many psychotherapy researchers did not endorse it. Some even condemned it. They did not believe that the *DSM-III* was either a valid system for classifying psychopathology or a treatment-relevant nosology for selecting and planning most types of psychotherapeutic interventions. Despite rejection of the nomenclature by many therapy researchers, the *DSM-III* and its subsequent editions changed the direction of psychotherapy research. After the mid-1980s, psychotherapy outcome studies started to be focused on disorders as they were defined in the *DSM*, such as panic disorder and major depression. The TDCRP was a harbinger of this trend.

Developments at the NIMH in 1985 contributed to the impact on psychotherapy research of the *DSM-III* and its later editions. In 1985, the NIMH Division of Clinical Research was reorganized such that many of its subdivisions or “branches” were identified by disorders that appeared in the *DSM-III*. For example, the existing Psychosocial Treatments Research Branch was abolished and replaced by the Affective and Anxiety Disorders Research Branch. (“Psychosocial” was a term that was adopted at the NIMH by branch chief Morris Parloff in part to span the aforementioned rift in the field between behavior therapy and psychotherapy.) Prior to the NIMH reorganization, psychotherapy researchers often sought guidance from staff of the Psychosocial Treatments Research Branch on their grant applications. After the reorganization, many therapy researchers did not know which, if any, branch was the appropriate one to contact about their treatment study ideas and potential proposals. Moreover, it became evident rather quickly to researchers that the NIMH grant review committees were, in essence, requiring grant applications for psychotherapy outcome studies to be focused on a specific disorder. Study patients were to be selected primarily by diagnostic criteria, and disorders as defined in the *DSM* seemed most likely to be viewed as acceptable by review committees.

For the last 20 years and into the present, the largest and most influential psychotherapy outcome studies

have been designed to test psychotherapies for specific *DSM* disorders—despite the continuing reservations of many therapy researchers, practicing mental health professionals, and psychopathology researchers about the validity of much of the nomenclature. One major result is that a cumulative body of treatment research findings has been achieved. At the same time, substantial and scientifically well-founded skepticism about aspects of the nomenclature continues among mental health researchers and practitioners from all disciplines, including psychiatry.

3. “Time-Limited” Courses of Therapy

The TDCRP illustrates yet another characteristic feature of therapy outcome research during its coming-of-age phase through the present. The length of therapies studied typically has been relatively short—12 to 24 sessions over 3 to 4 months. Particularly to psychotherapy research pioneers who espoused the psychodynamic orientation, examining therapies of less than 1 or more years duration was of uncertain relevance, at best, to the phenomenon of psychotherapy. Several forces converged by the late 1970s that resulted in the focus of psychotherapy outcome research, particularly federally funded studies, on time-limited treatments. Society’s and insurance companies’ concerns about the costs of long-term psychotherapy played a role, as did scientific considerations that made the conduct of interpretable studies of long-term psychotherapy problematic. Indeed, few outcome studies of long-term psychotherapy exist at this time. A study done of psychodynamically oriented therapy at the Menninger Foundation in Topeka, Kansas, from about 1954 to 1974 is a famous exception.

Findings from studies of time-limited treatments, particularly for depression, are renewing interest in conducting studies of longer-term therapy—up to 1 year. Disappointing percentages of individuals who reach a “recovery” criterion and evidence that a notable proportion of patients relapse after time-limited treatments support the interest. Indeed, 18-month follow-up findings from the TDCRP contributed to the currently nascent tendency to conduct outcome studies of longer-term courses of psychotherapy. A well-established trend is outcome studies of “maintenance” therapeutic interventions (e.g., monthly “booster” therapy sessions following time-limited, acute phase treatments) to determine if posttreatment relapse rates can be reduced. A contrasting direction, consistent with economic considerations and cost-cutting interests of managed care organizations, is the examination of very short treatments—three sessions for some types of anxiety problems. In addition, the

potential of technological advances, such as handheld computers (“Palm Pilots”), to enhance psychotherapy is being explored, e.g., between-session use of Palm Pilots by patients with panic disorder to prompt behavior change and to reduce the amount of contact with a therapist that is required to get desired outcomes.

4. Treatment Development Grants

Efforts of NIMH staff, such as psychologist Barry Wolfe, led to another pivotal milestone in the history of psychotherapy research. In 1993, the NIMH made available a type of funding opportunity called a “treatment development grant.” NIMH’s action followed a similar initiative by the National Institute on Drug Abuse that was cultivated by Lisa Onken, then of its Clinical and Experimental Therapeutics Branch. The appearance of the treatment development grant was embraced by psychotherapy researchers as a crucial attempt to help offset a very long-standing handicap from which the field suffered, particularly in comparison to psychopharmacology research. Pharmaceutical companies are and have been a major source of non-federal funding for psychopharmacology outcome research, as well as for the development and initial testing of new medications for psychiatric problems. The field of psychotherapy research never had a counterpart to this mammoth corporate funding source for treatment development. The development of new forms of therapy, or modified versions of existing ones, was completely dependent on the unfunded initiative of individuals before treatment development grants became available. The preceding major impediment to the development of psychotherapies was long recognized by therapy researchers.

E. Unfolding Directions

Three more turning points for psychotherapy research surfaced in the 1990s, the ultimate impact of which on the field and on the practice of psychotherapy in the United States is yet to be known. Two of the three were spawned directly by the NIMH. It, in turn, was responding to a host of forces, prominently including economic concerns (continually increasing costs of all forms of health care) and public health policy issues (e.g., what direct recommendations for typical clinical care settings could be made from existing treatment research?). One turning point was a call for cost data to be included in mental health treatment studies. A second began as the “efficacy versus effectiveness debate” and culminated in the intentionally revolutionary endorsement by the NIMH of “the public health model” as a new paradigm for mental health treatment research. The

third, not completely distinct from the other two in terms of causal forces, was the introduction to therapy research of a “patient-focused” research paradigm.

1. Cost-Effectiveness, Cost-Benefit, and Related Methodology

By the mid-1970s if not before, insurance companies and various U.S. social institutions voiced concerns about the cost of mental health treatment. By the early 1990s, rising health care costs were a major focus of the U.S. Congress. In addition, managed care treatment delivery systems, an intended antidote for rising costs, were actively seeking cost-effectiveness data on mental health treatments. Concurrently, the NIMH began making concerted efforts to get investigators to obtain cost data in treatment outcome studies. (The concept of costs is very broad and includes resources of many types that are used in the delivery of treatments such as office space, supplies, and transportation.) Various types of cost information were needed by federal and local health care policymakers and by managed care entrepreneurs—the comparative costs of alternative treatments, such as medication and psychotherapy for the same problem; the relative benefit obtained for resources consumed by different treatments (cost benefit); and savings in medical expenses, work days lost, and so on, that might be associated with mental health treatments (cost offset).

Highly sophisticated and complex methods for assessing costs associated with treatments existed though they rarely were used in psychotherapy outcome research at the time. The NIMH recommended that health care economists be added to outcome study grant applications to ensure that adequate cost data would be obtained. Now, in 2002, experts in cost analysis are on NIMH treatment grant review committees. The impact is not yet widely evident of cost data from outcome studies on practice patterns and on directions in psychotherapy research.

2. From Efficacy versus Effectiveness to the Public Health Research Paradigm

From a public health perspective, a core issue of what often is called “the efficacy versus effectiveness debate” is the generalizability to community-based, clinical practice settings of treatments examined in, and outcome findings from, randomized controlled studies. Sometimes the issue is characterized as the “transportability” of treatments from research into typical practice settings. From a scientific perspective, the debate’s core issues are: (a) alternative experimental designs and methods that can be used for clinical treatment studies,

and (b) the kinds of inferences (conclusions) for practice in non-research, community settings that most confidently can be drawn from them.

The seeds of the efficacy versus effectiveness debate were sown years before its rise to the forefront as a bonafide scientific debate in the mid-1990s. Its emergence then was a side effect of several forces, including: (a) dramatic shifts in health care delivery that occurred in the United States beginning about the mid-1980s, (b) the U.S. Congress's (failed) attempt in 1993 to reform national health care, and (c) escalating dissatisfaction of practitioners with the output of therapy research (e.g., manuals for therapists that describe how to implement specific types of psychotherapy).

In the mid-1980s, health care delivery patterns increasingly moved away from indemnity insurance coverage toward managed care. The managed care model gained momentum from the mid-1980s on as a way to contain and cut health care costs. Both managed care and the health care reform movement spotlighted the need for valid information about existing treatments to guide decisions of government policymakers and managed care entrepreneurs. Both groups were motivated to make decisions rapidly that would affect the treatments that millions of citizens could receive using insurance benefits. Gaps became widely evident between the types of information wanted by these and other stakeholders in mental health treatment (e.g., its "consumers" and clinical providers) and what was available from existing therapy and other mental health-related research. Recognition of the limitations fostered lively debates about how treatment research, particularly federally funded research that is mandated to meet broad public health needs, should be designed.

From a scientific standpoint, two concepts that are key to the efficacy versus effectiveness debate are internal and external validity. The concepts first were proffered in the early 1960s by Donald Campbell and Julian Stanley as part of a conceptual framework that linked different experimental designs and methods to the types of questions that could most validly (logically correctly) be answered with them. Internal validity relates to designs and methods that increase a study's logical strength for drawing causal conclusions about the relationship between its independent (e.g., form of psychotherapy) and dependent (e.g., outcome indices) variables. When a therapy outcome study has a design and methods that maximize internal validity (e.g., random assignment of patients to the treatment conditions that are being compared; inclusion of a "control" condition of some type to provide an estimate of the improvement that could occur, without treatment, over

the same period of time that a study treatment is provided), confidence is maximized that its findings can be interpreted as evidence that the therapy or therapies examined caused the outcomes obtained. Studies that have high internal validity are referred to as "efficacy" studies in the parlance of the debate. The aforementioned TDCRP is a prototypic efficacy study.

External validity relates to study designs and methods that enhance the generalizability of study findings. Generalizability means the confidence with which a study's results can be assumed to extend to situations, people, measures, times, and so on, other than those particular to the study. For example, say a finding is that cognitive therapy plus progressive muscle relaxation for generalized anxiety disorder is associated with more reduction in anxiety than nondirective therapy plus relaxation. The external validity features of the study's design and methods determine the types of "real-world" clinical settings, therapists, patients, and treatments to which we can confidently generalize the expectation (i.e., infer) that the same cognitive therapy plus relaxation will be associated with more reduction in anxiety in generalized anxiety disorder than an alternative therapy will be. Studies with designs and methods that achieve high external validity are referred to as "effectiveness" studies in the efficacy versus effectiveness debate.

In a series of actions that became clearly evident to psychotherapy researchers by about 1998, the NIMH indicated it wanted to receive grant applications for studies that were designed to have external validity strengths in the sense of having direct implications for practice in typical care settings. In actuality, a much more dramatic and far-reaching change was in progress, a change that has the potential to affect therapy research at least as profoundly as the 1985 NIMH reorganization did.

Another major reorganization of the NIMH funding by programs occurred in 1997 under the leadership of a new director. Once again, as in 1985, psychotherapy researchers interested in federal funding needed to determine what new branch of the NIMH they should contact with their ideas, and so on. In addition, a Clinical Treatment and Services Research Workgroup was established and charged by the new NIMH Director Steven Hyman to advise on "strategies for increasing the relevance, speeding the development, and facilitating the utilization of research-based treatment and service interventions for mental illnesses into both routine clinical practice and policies guiding our local and national mental health service systems." In 1999, the Workgroup's report, *Bridging Science and Service*, became available. Moreover, in 1999, Dr. Hyman co-authored a

publication with key NIMH treatment research administrators that said that NIMH was now dedicated to advancing “a public health model approach to clinical research.” The model is intended to eventually fill the information gaps that various stakeholders need and want. It also is expected to meet the treatment dissemination and other goals, described earlier, that the Workgroup was charged to consider.

Obviously, yet another major turning point for therapy research is underway, spurred by the NIMH's recent transformation and new aims. As yet, the field's new directions, questions, and findings largely remain its unforeseen future.

3. Patient-Focused (versus Treatment-Focused) Research

In 1996, Kenneth Howard and colleagues presented a research strategy that was new to the field of therapy research. It was called “patient profiling.” The strategy was an outgrowth of Howard's direct knowledge of contemporary trends in the provision of psychotherapy in managed care delivery systems and lifelong career doing therapy research in naturalistic settings. Patient profiling also was an outgrowth of the application of developments in data analysis techniques. Other therapy researchers concurrently pursued similar directions, using what now are sometimes classified as “patient-focused” research strategies. In general, patient-focused research answers questions like, “Is this patient's therapy working?” It is contrasted with conventional or “treatment-focused” therapy research that addresses questions like, “Does this type of therapy work?”

A main difference between patient-focused and treatment-focused studies (like the TDCRP) is that the aim of the newer strategy is to provide information that can be used to evaluate the progress of a specific patient's treatment by comparing his or her ongoing treatment response in real time to an expected response of clinically comparable individuals. The expected (or predicted) response is estimated from archival data on many treated patients, that is data of the type collected by managed care corporations.

The potential value and impact of patient-focused research on the main questions in therapy research is yet to be known. A hope is that it will, at minimum, provide one type of bridge across an ironic and chronic gap between therapy research and clinical practice. For example, the utility of patient-focused research currently is being examined for giving community-based therapists up-to-date information on how a patient is progressing compared to a predicted course so that therapists can consider modifying the treatment that they are providing.

F. Comment

The foregoing has been a thumbnail sketch of trends in and forces that have shaped psychotherapy research in its first 60 or so years. One aim was to illustrate that psychotherapy research is characterized so far by noteworthy shifts in focus and style. Many of the shifts described reflect the responsiveness of the field to external forces rather than to its own findings or findings in closely related fields such as psychology and other behavioral sciences. Therapy research has responded to research priorities established by the NIMH to meet public health and policy needs; developments in psychiatry; and insurance providers' demands for data on the efficacy, safety, and costs of psychotherapies to form and defend their mental health care reimbursement policies. Indeed, the applied (practice-relevant) potential of psychotherapy research can make it a quickly changing, exciting field both to work in and to observe. Unfortunately, many of the sources of excitement and the sense of urgency associated with studying practice-relevant questions also can challenge the maintenance of scientific integrity.

III. KEY QUESTIONS

Fundamental features of a scientific field are its focal aims, focal questions, theories, and primary research methods. In research, aims are instantiated in the form of specific questions and hypotheses. Several key questions that have been examined by psychotherapy researchers are reviewed in this section. The emergence of milestones and turning points along the way is noted.

A. What Can Be Learned about Personality Psychology from Psychotherapy?

During the late 1940s and 1950s when psychotherapy research was beginning to coalesce as a scientific field, an aim endorsed by many investigators was to use psychotherapy as a method to advance personality theory, a major subdiscipline of psychology. At least into the early 1960s, some psychologists were exploring the question of whether psychotherapy provided a “valid method for the science of psychology.” In other words, psychotherapy as a vehicle for advancing basic academic, rather than applied, research questions was of considerable interest.

Psychotherapy had several features that suggested its promise as a sort of laboratory for systematically

investigating human personality and behavior. Psychotherapy provided a relatively standard, simple-to-construct situation in which a person and his or her psychological processes could be observed closely. Moreover, to achieve therapeutic goals, the psychotherapy situation specifically was designed to enable people to reveal themselves in the most complete and honest way possible. This feature also afforded a unique opportunity to achieve scientific goals. It was hoped, for example, that both observations of people and information they revealed about themselves and their life histories might answer basic questions about personality, its developmental antecedents, and also provide data from which a valid taxonomy of personality traits (cross-situationally consistent patterns of perceiving and behaving) might be derived and tested. In turn, from the preceding types of knowledge, principles of personality change could be developed.

The foregoing early trend in psychotherapy research reflected, in part, Freud's legacy. Freud viewed psychoanalysis as both a treatment and a method to examine hypotheses about personality and its development. A similar perspective was prominently displayed at the first conference on psychotherapy research in 1958 that was mentioned in Section I. The authors of a summary of the conference, Morris Parloff and Eli Rubinstein, noted that many of the researchers present were relatively uninterested in outcome studies compared to research that was intended to advance understanding of personality.

B. What Is “the Problem” to Be Treated?

The early interest of psychotherapy researchers in personality psychology points to the intrinsic link between psychotherapy research and models of psychopathology. The development and identification of efficacious, efficient psychotherapeutic interventions are fundamentally contingent on conceptualizations of the problem(s) to be treated. Widely endorsed models of psychopathology have been elusive, although models have not been in short supply. None have generated widespread acceptance despite their lynchpin role for the development, refinement, and evaluation of psychotherapies. The lack of consensus has been an enduring handicap for psychotherapy research, as well as for other types of clinical mental health research.

Why has the development of consensually agreed-on models of psychopathology been unattainable to date? One reason is that many problems that seem to be legitimately regarded as mental health concerns are neither objectively observable nor measurable deviations from

clearly definable and delimited “normal” functioning and states of mind. Even though behaviors of the type that often are the focus of mental health treatment can be observed, their deviation from “normalcy” frequently is a judgment call. (The preceding two statements do not apply to psychotic and manic symptoms of conditions like schizophrenia and bipolar disorder that are associated with obvious impairments in adaptive functioning. The two conditions exemplify a few that are consensually viewed as more “severe” by mental health professionals across disciplines.) In brief, the nature of the problems that can be the focus of psychotherapy (and of psychopharmacology by current practice patterns) often is much different than the physical anomalies and abnormal processes that typically are the focus of medical treatment.

Medicine characteristically has the relative luxury of being directed to physically observable and, thus, readily agreed-on deviations from equally observable, normal functioning of the human organism. Obvious examples are broken limbs, flesh wounds, and cancers. Many serious medical problems are not observable by the unaided eye, but technological aids such as microscopes, x-rays, and imaging equipment allow their presence to be observed and consensually assessed. Mental health complaints often are not similarly available to visual inspection or verification and, thus, to consensual agreement on the nature of (or even presence of) the problem to be treated. Moreover, attitudinal, emotional, and behavioral functioning that is regarded as in the normal range seems to be much more heterogeneous than physical functioning in the normal range. Thus, using indices of normality as a benchmark from which to create models of psychopathology is unlikely to be as helpful as it has been in medicine. The medical model is only partially applicable, at best, to dimensions of “mental” functioning.

Unfortunately, attempts so far to develop models of psychopathology that could provide strong foundations for psychotherapy research and for other mental health treatment research often have elicited, or have been notably influenced by, guild interests of the various mental health professions. Such factors compound the difficulty of an extremely difficult, yet crucial conceptual challenge for psychotherapy research and for mental health treatment, in general.

C. Does Psychotherapy Work?

Alternatively stated, the question is, “Is psychotherapy effective?” Its answer requires results from studies that are designed to determine if a type of psychotherapy

is associated with greater or different change than no treatment, using a standard criterion to judge whether or not a difference exists.

1. A Compelling, Affirmative Answer

It was not until 1977 that data were presented that provided a widely influential and convincingly positive answer to the simplistic yet fundamental question, “Does psychotherapy work?” The answer came from the application of meta-analysis, a statistical technique, to data from nearly 400 (in 1977) and then 475 (in 1980) therapy outcome studies, many of which included a no- or minimal treatment control condition. The two meta-analyses (the first authored by Mary Smith and Gene Glass; the second by Smith, Glass, and Thomas Miller) were a major milestone for the field of psychotherapy research. The larger one showed that when findings were pooled from outcome studies in which treated individuals were compared in the same study with either (a) untreated or minimally treated individuals, or (b) groups who received placebo treatments or “undifferentiated counseling,” the average person who received a form of psychotherapy was better off on the outcomes examined than 80% of those who needed therapy but were not treated. The advantage for psychotherapy was larger when the meta-analysis included only studies in which therapy groups were compared to no- or minimal treatment groups. Subsequent meta-analyses to date, often focused on the effects of psychotherapy for specific problems (like depression), have supported the conclusion that it is an effective treatment modality.

As noted previously, numerous and often painstaking prior attempts were made to effectively challenge Hans Eysenck’s 1952 conclusion that no evidence existed from outcome studies that psychotherapy was associated with a higher rate of improvement than could be expected to occur, over time, without therapy. For some years, a major impediment to disproving Eysenck’s conclusion was a lack of psychotherapy outcome studies that included a no- or minimal treatment condition whose outcomes were compared with those of the therapy of interest. The presence of such a condition provides an experimental way to estimate or “control for” change that might occur without treatment—with just the passage of time and normal life events. Randomized controlled psychotherapy outcome studies became increasingly prevalent over the years following 1952. Thus, a lack of controlled studies was not the only impediment to the appearance, before 1977, of a compelling counterargument to Eysenck’s proposition.

Before Smith and Glass applied meta-analysis to controlled outcome studies of psychotherapy, others had

summarized the results of such studies using a “box score” or tallying method. That is, the results of available studies were coded on whether or not the therapy of interest was associated with statistically significantly more improvement than was the no- or minimal therapy control condition. Conclusions based on the box score method were not as convincing as those of a meta-analysis. This was partially because the possibility of finding differences between therapy conditions in outcome studies is heavily influenced by a study’s sample size. Larger studies have a greater probability of obtaining statistically significant differences between therapy and control conditions.

2. How Should the Question Be Formulated?

Even while many therapy researchers were trying to disprove Eysenck’s conclusion that psychotherapy did not work, they already had concluded that the global question, “Does psychotherapy work?,” was not a productive one to guide research. For example, in a 1966 paper that, itself, qualifies as a milestone for the field, Donald Kiesler argued for the need to study “which therapist behaviors are more effective with which type of patients.” In a similar vein, in 1967 Gordon Paul framed the question for outcome research as: “*what* treatment, by *whom* is most effective for *this* individual with *that* specific problem, and under *which* set of circumstances” (original emphasis)? Others, such as Nevitt Sanford noted as early as 1953 that the global question, “Does psychotherapy work?,” was inadequate from a scientific standpoint to guide the field and suggested alternatives—“which people, in what circumstances, responding to what psychotherapeutic stimuli” However, it was Paul’s phrasing of the question that essentially became a mantra for psychotherapy research.

One of the most recent and major milestones in the history of psychotherapy research illustrates the field’s answers so far to a partial version of the applied question that Paul formulated for it 30 years earlier. The milestone was the aforementioned 1995 (updated in 1998) American Psychological Association list of empirically supported psychotherapies for various types of problems, such as depression and panic attacks.

D. What Is “the Treatment”?

For years, many researchers’ energy and attention was directed toward answering the question, “Does psychotherapy work?,” before methods were developed that enabled them to know of what, exactly, “the therapy” consisted that was done in outcome studies. Particularly for research on non-behavioral therapies, the field

essentially was in the position of saying “it works (or it doesn’t), but we don’t really know for sure what ‘it’ is.” More interesting, many therapy researchers were not fully aware that they were in the foregoing position. Investigators often assumed that study therapists were conducting the type of therapy that they said they were (e.g., “psychodynamic”), and that all therapists who said that they used a particular form of therapy implemented it more similarly than not. Donald Kiesler brought “myths” like the foregoing ones to the field’s attention in 1966 in his previously mentioned, classic critique of conceptual and methodological weaknesses of therapy research at the time. The increasing use of audiotaping technology in therapy research no doubt contributed to the uncovering of mythical “therapist uniformity assumptions” like those which Kiesler identified.

It was not until the mid-1980s that detailed descriptions of non-behavioral psychotherapies were put into written, manual form for therapists to learn from and follow in outcome studies. (Manuals began to be used in behavior therapy research about 20 years earlier, the mid-1960s.) The development of therapy manuals for all types of therapy was a crucial milestone for psychotherapy research. In effect, manuals were operational definitions of the main independent variable(s) of psychotherapy outcome studies. They also enhanced the scientific quality of research on psychotherapies in other ways.

Manuals made it more possible for all the therapies examined in a study to be implemented as they were intended to be. Manuals contributed to consistent, correct implementation in two primary ways. First, they facilitated systematic training of therapists in the conduct of a study’s therapies. Second, they provided criteria that could be used to monitor each therapist’s implementation of a therapy for accuracy (i.e., Is the therapist “adhering” to the manual?) throughout the entire course of each study therapy that he or she did. In addition, and very important from a scientific perspective, therapy manuals greatly facilitated attempts to replicate outcome findings in different settings, with therapists from different disciplines and experience levels, for example. Finally, from both the practice and public health perspectives, manuals aid widespread and efficient dissemination of therapies that are found to be efficacious in outcome studies.

In 1984, Lester Luborsky and Robert DeRubeis observed that “a small revolution in psychotherapy research style” had occurred with the use of manuals. What is particularly interesting is not that the revolution of manualization occurred, but that this fundamental methodological advance did not occur earlier. How

could a clinically-relevant, scientific field conduct valid tests of its treatments without first clearly articulating and defining them? As already noted, manuals were used in behavior therapy research almost 20 years before they were widely used in research on other forms of therapy. The lag largely reflected different fundamental assumptions of those who endorsed psychodynamic and some humanistic therapies, compared to therapies based on principles of learning and behavior. For example, a common view among psychodynamically oriented researchers and practitioners was (and is) that the treatment could not be “manualized” because it essentially requires artful and ongoing responsiveness of the therapist to shifts in the patient. When the aforementioned emphasis on time-limited forms of therapy occurred, it began to seem more possible to advocates of non-behavioral therapies to extract the theoretically essential change-promoting principles and techniques from their therapies, and codify them into manuals for the conduct of time-limited versions of the therapies.

As alluded to earlier in this article, ironically, one of the most important scientific advances for psychotherapy research—*therapy manuals*—became one of its most ferociously criticized accomplishments by practitioners in the 1990s. The reaction is only one example of a well-chronicled, perpetual gulf between research and practice. Historically, a central problem was that practitioners ignored therapy research and described its findings as irrelevant to or otherwise unhelpful for their work. More recently, practitioners do not feel as free to ignore findings. External pressures exist (e.g., from managed care payers) to make their care conform with findings by being able to provide manualized treatments found to be efficacious in treatment studies. The gulf is, of course, especially fascinating given that therapy research was fostered largely by the scientist–practitioner (Boulder) model of training in clinical psychology.

E. What Does It Mean to Say a “Psychotherapy Works”?

Two of many basic, yet conceptually and methodologically difficult questions that therapy researchers encountered early on were: “What effects (outcomes) should be measured to evaluate the usefulness of a psychotherapy?” and “How can the effects of interest be measured reliably (with precision) and validly (correctly)?” As investigators formulated answers to the first question, and both used and contributed to developments in psychometric methods to answer the second one, their findings revealed considerable additional

complexity. Some of the complexity will become evident in topics that are discussed next. Many, if not most, of the relevant issues continue to be debated: “How frequently should effects of interest be measured in a therapy outcome study?”; “What is the impact on the validity of outcome data of repeated measurement?”

1. The “Perspective” Problem

By the early 1970s, findings unequivocally indicated that the answer to the outcome question often depended on whom was asked. The patient’s assessment typically differed from the therapist’s perspective on the same effect (e.g., degree of improvement in self-esteem). For example, it was not unusual to find very low coefficients of correlation—0.10—between patients’ and therapists’ ratings of patients’ status on the same outcome variable. (A correlation of 0.80 or larger typically is regarded as high. Squaring a correlation coefficient indicates how much overlap, or “shared variance” scores on two measures have— $0.80 \times 0.80 = 64\%$.) Moreover, both perspectives could differ from the judgment of a clinically experienced, independent assessor. (Independent assessors’ ratings came to be included in outcome studies for several reasons such as to obtain a judgment from someone who was not invested in either the benefit experienced by individual patients or the study results). In the rare instances when family members or others who knew a patient well were asked to evaluate outcomes, this “significant other” perspective did not necessarily agree with any of the other three.

In 1977, Hans Strupp and Suzanne Hadley presented a conceptual “tripartite model” of mental health and therapy outcomes. The model helped to resolve the problem of ambiguous outcome findings posed by low agreement between perspectives. It identified three parties who have a vested interest in a person’s mental health (“stakeholders” in current parlance): the individual, mental health professionals, and society. The model included the idea that no one perspective was inherently more valid than another, although each perspective differentially valued aspects of an individual’s functioning and experience. For example, the individual can be expected to be most interested in subjective experiences of well-being and contentment. Society is likely to be most interested in the adaptive qualities of a person’s behavior. Another research-relevant idea of the tripartite model was that multiple perspectives should be obtained on the primary outcomes measured in an outcome study. The standard continues to this day.

The perspective problem was only one of many discoveries along the way that indicated the complexity of the focal phenomenon of interest in psychotherapy re-

search. It also illustrates the challenges that the phenomenon poses for obtaining simple answers from even the most sophisticated applications of scientific methods to the study of psychotherapy.

2. Statistical Significance versus Clinical Significance of Effects

In a series of papers from the mid-1980s to 1991, Neil Jacobson and colleagues provided a solution to a basic limitation of what were then state-of-art psychotherapy research methods. Their contribution was a major conceptual and methodological milestone for psychotherapy outcome research. At the time, statistical significance typically was the sole criterion used to determine if study results indicated that a therapy worked or worked better than an alternative treatment. For example, if the difference between a therapy group’s and a minimal treatment control group’s post-treatment scores on an outcome measure was statistically significant favoring the therapy group, the therapy was concluded to be efficacious (assuming, of course, that the study design and methods had adequate internal validity to test the question).

An important problem was that the criterion of statistical significance could be met even if treated individuals remained notably impaired on the outcomes of interest. For example, a therapy group’s average posttreatment scores could indicate that, although statistically significant improvement had occurred in symptoms of depression, most people’s outcome scores were still not in the normal (non-depressed) range on the outcome measure. Thus, statistical significance did not give a full picture of the potential usefulness or effectiveness of a therapy. Jacobson and colleagues’ milestone contribution was a set of logical and statistical procedures that provide information on how close to normal or to individuals with non-impaired scores on outcome measures those who receive a therapy are.

3. A Note on Data Analytic Techniques

The development of clinical significance methodology for evaluating outcomes illustrates the central role that data analytic techniques and statistics play in the kinds of conclusions that are possible from therapy research. As noted previously, the topic is excluded from this article. However, many developments in data analysis have been stimulated by or appropriated for psychotherapy research and are properly regarded as milestones for the field because they have had a profound impact on the kinds of questions that can be asked and answered. For example, effect sizes—as described by Jacob Cohen in 1970 and as used in the

aforementioned technique of meta-analysis—came to be preferred over statistical significance indices for comparing the outcomes of treatment and control conditions. An effect size is a statistic that can indicate the magnitude of differences between two alternative treatments or a treatment and a control condition. Random effects regression and hierarchical linear modeling are other examples of techniques that were not available to therapy research during its coalescence phase that subsequently extended how outcome and other questions can be examined and answered.

4. Stability and Longevity of Effects

Obtaining data from outcome studies on the question, “How long do the desired benefits of a psychotherapy last?,” was recognized as important early in the development of psychotherapy research. For example, Victor Raimy’s 1952 chapter in the *Annual Review of Psychology* noted both the importance and absence of posttreatment follow-up data on the outcomes of psychotherapies. By about the mid-1960s, the collection of follow-up data was regarded as a crucial component of therapy outcome studies.

The need to know how long a therapy’s effects last to fully evaluate its utility is another fundamental question that has proven to be an intransigent one. Over time, as more and more alternative treatments for the same problem have become available (e.g., various forms of psychotherapy and various medications for depression), data on the stability of effects of treatments have become particularly important because they bear directly on the relative desirability of the alternatives. Yet, it seems accurate to say that as of 2001 it is impossible to derive conclusive, no caveats, answers to stability of effects questions using currently available research methods.

A major problem is the phenomenon of attrition (loss) of study subjects during follow-up periods. Post-treatment follow-up periods typically range from 3 months to 2 years. Some portion of treated individuals inevitably become unable to be located or unwilling to continue to provide data. The longer the follow-up period, the larger the attrition problem typically becomes. The lack of complete follow-up data from all individuals treated in a study raises the possibility that the data obtained are biased in some way, that is, do not reflect the follow-up outcomes of the entire original sample (also called the “intent-to-treat” sample). For example, perhaps those who experienced more positive outcomes are more likely to agree to provide follow-up data. One obvious solution is to offer study participants large financial incentives to provide follow-up data. However, such a procedure raises the ethical concern of

coercion of participants and typically is frowned upon by human subjects research review committees.

All the limitations associated with collecting unequivocally interpretable stability of effects data notwithstanding, interesting evidence exists for a variety of problems. For example, a recently completed multisite comparative outcome study of cognitive-behavioral therapy, medication, and their combination for panic disorder by David Barlow and colleagues suggested that the treatments that included medication (medication alone or combined medication and therapy) were associated with less stable benefits after treatments were discontinued than were treatments that did not include medication (i.e., therapy alone or therapy plus pill placebo).

F. How Does Psychotherapy Work: Mechanisms of Action

The question of how psychotherapy works often is stated in the contemporary therapy research literature as a “mechanisms of action” question: “What are the primary mechanisms and processes by which psychotherapeutic treatments potentiate desired changes (outcomes)?” Using no jargon, William Stiles and David Shapiro stated the essential question this way in 1994: “How do the conversations between therapists and clients (psychotherapy process) reduce psychological suffering and promote productive, satisfying ways of living (psychotherapy outcome)?” Many therapy researchers have devoted substantial parts of their careers to this and related questions.

Mechanisms of action questions have been examined since at least the 1940s when Carl Rogers and associates began doing methodologically groundbreaking research on them. Such questions have been studied from widely divergent vantage points—a range that has been characterized as “elephant to amoeba.” For example, at a macro level, studies are done to identify therapeutic processes that might operate in all forms of psychotherapy (i.e., “nonspecific” or “common” factors) and that, thus, characterize psychotherapy as a treatment modality. At a more intermediate level, mechanisms of action are tested that are posited by the theory of a specific type of psychotherapy (“specific” factors) such as Beckian cognitive therapy for depression. At a micro level, “therapeutic change events” are examined—patterned sequential shifts in a patient’s focus of attention and affect states in a therapy session—that might constitute universal psychological change processes that can be prompted by specifiable therapist interventions.

The importance of mechanisms of action research cannot be overemphasized. Without knowing the

causally dominant processes by which a form of psychotherapy can prompt desired changes, therapists cannot structure their interventions to achieve a therapy's potential effects as quickly and as completely as is possible. Therapists can identify very specific goals for a patient's progress and improvement. Yet, without knowing a therapy's active mechanisms, they cannot rationally guide their interventions in the most effective and efficient ways to help a patient attain identified goals. Without mechanisms of action knowledge, therapists' moment-to-moment choices between alternative interventions must be based mainly on their knowledge of the theory that underlies a form of therapy, more general theories of how therapeutic change can be facilitated, or on their reflexive sense of what to do (or not do) next. Even the most well developed theories are not detailed enough to guide all the momentary decisions that therapists must make. Moreover, theories remain just that until posited mechanisms of action are tested and supported by empirical findings.

1. Process and Process-Outcome Research

The importance of conducting research on mechanisms of action questions has been matched so far by the difficulty of answering them. Pursuing such questions required therapy researchers to develop new methods, a task on which great strides have been made. The relevant methods collectively are referred to as process research methods. The development and refinement of process methods was a key advance for the field of therapy research during the last 50 years. Several colleagues and students of Carl Rogers at the University of Wisconsin in the 1960s such as Donald Kiesler, Marjorie Klein, and Philippa Mathieu-Coughlan made major early contributions to the needed methodological infrastructure.

The traditional type of process methods are observational. The researcher(s) or trained raters are the observers. Observational process methods involve systematic examination of actual therapy session material (i.e., the "process" of therapy), such as videotapes and/or transcripts of therapy sessions. Process methods extend to the collection of other types of data on therapy sessions such as patient and therapist self-report questionnaires completed immediately after sessions. The term "systematic examination" is a deceptively simple one that masks much complexity when used to describe process research methods. For example, it refers to detailed procedures for selecting (sampling) therapy session material to examine in order to answer a particular research question. It also refers to the development of psychometrically sound instruments that are needed to observe and quan-

tify therapy process variables of theoretical or pragmatic interest (e.g., the therapeutic alliance). Process outcome research is a subset of process research that specifically involves combining therapy process data and outcome data from the same patients with the aim of identifying the aspects of therapies that can be either helpful or harmful.

Donald Kiesler authored a classic, still relevant text on observational process research, *The Process of Psychotherapy: Empirical Foundations and Systems of Analysis*. The book was the first attempt to compile and systematically review process methods, methodological issues, and "systems" (instruments and related instructions for their use) that had been developed. Seventeen major therapy process research systems of the time are reviewed in detail. Only process methods used to study non-behavioral types of psychotherapy are included, an omission consistent with the aforementioned bifurcation of the field at the time into "behavior therapy" and "psychotherapy" research. In 1986, Leslie Greenberg and William Pinsof edited a similar volume that included many of the then, major process research systems. A succinct contemporary summary of process research methods and issues can be found in Clara Hill and Michael Lambert's chapter in the most recent edition (5th edition) of the *Handbook of Psychotherapy and Behavior Change*.

2. Process-Outcome Research: Problems with the Paradigm

David Orlinsky and colleagues described process-outcome research in their 1994 review of existing studies this way: "Process-outcome studies aim to identify the parts of what therapy is that, singly or in combination, bring about what therapy does." An enormous amount of effort has been devoted to investigations of this type. Even after using specific definitions to delimit process-outcome studies, Orlinsky recently estimated that about 850 were published between 1950–2001. However, the yield from them, in terms of identifying mechanisms of action, was judged to be disappointing by many therapy researchers as of the late 1980s. Newer studies have not modified the overall disappointment of researchers' and practitioners' wish to know precisely (a) what the active agents of change are, and (b) how they can be reliably initiated and supported by a psychotherapist's actions. Yet, useful knowledge has been obtained from process outcome research.

Cardinal advances to date include the identification of overly simplistic conceptualizations that drove much process outcome research, that is, hypotheses about

how therapeutic interventions might causally potentiate desired outcomes. For example, advances include: (a) elucidation of limiting assumptions that underlie the correlational design, a traditional one in process outcome research; (b) enhanced recognition that a network of contributing variables must be taken into account in this type of research; and (c) proposals for alternative, more complex strategies that incorporate (a) and (b).

a. Limiting Assumptions: The Drug Metaphor. Several limiting assumptions were highlighted for the field in a 1989 paper by Stiles and Shapiro with the attention-getting title: "Abuse of the Drug Metaphor in Psychotherapy Process-Outcome Research." The authors' general thesis was that "slow progress" in identifying the mechanisms of action of therapies was due to the ubiquity of a research paradigm in which therapeutic techniques were tacitly assumed to act like medications. So, for example, study designs reflected the assumption that therapeutic "ingredients" were dispensed by a therapist to a passive patient. Many studies also reflected the assumption that the relationship between a therapy's potentially helpful interventions and desired outcomes was linear and ascending—more is better.

The linear dose–response assumption guided many, if not most, of the mechanisms of action studies through the 1980s. That is, theoretically posited or other possible agents of change, measured with process methods in therapy session material, were correlated with outcome scores obtained at the end of a therapy. Such correlational designs are based on the assumption that a linear function accurately describes the relationship between two variables. For example, severity of depression scores (outcome variable) might be correlated with the frequency of therapist interventions in sessions that were intended to help the patient identify and change ways of thinking and behaving that (theoretically) were creating and maintaining symptoms of depression.

Most therapy researchers were at least dimly aware of the limitations of correlational designs for examining mechanisms of action hypotheses and of the other conceptual simplicities that Stiles and Shapiro elucidated. Yet, the research strategy continued to be used (overused) for a variety of reasons. As Stiles and Shapiro noted, the correlational design is not inherently flawed for use in process outcome research. Rather, it is highly unlikely to reveal all of the ways in which therapeutic interventions might robustly potentiate desired changes.

The drug metaphor analysis of process outcome research fostered widespread awareness of the need to formulate and test alternative hypotheses about relationships between outcomes and theoretically posited and

other possible mechanisms of action of psychotherapies. It helped to solidify, disseminate, and encourage the implementation of "new ways to conceptualize and measure how the therapist influences the patient's therapeutic progress," in George Silberschatz's words.

b. Network of Contributing Variables: Moderators and Mediators. Pioneers in psychotherapy research were very much on target when they endorsed Gordon Paul's aforementioned formulation of the overarching question for psychotherapy research, that is, "what treatment, by whom, is most effective for this individual ... and under which set of circumstances (original emphasis)?" Increasingly, therapy researchers have tried to identify "moderator" and "mediator" variables that might modify and determine the potential therapeutic outcomes of a psychotherapy. A paper by Reuben Baron and David Kenny that helped clarify therapy researchers' thinking on the issues appeared in 1986. In brief, moderators and mediators are "third variables" that can affect the relationship between independent variables (like a type of psychotherapy) and dependent variables (e.g., reduction in symptoms of depression). So, for example, a therapist technique that is specific to a form of therapy, as interpretation is to psychodynamic psychotherapy, is a therapy process variable that is hypothesized to be a primary mediator of the potential benefits of psychodynamic psychotherapy. Specifically, as defined by Baron and Kenny, a mediator is "the generative mechanism through which the focal independent variable is able to influence the dependent variable of interest." A moderator is "a qualitative (e.g., sex, race, class) or quantitative (e.g., level of reward) variable that affects the direction and/or strength of the relations between an independent or predictor variable and a dependent or criterion variable."

The impact of possible moderating and mediating variables on hypothetically important mechanisms of actions of therapies (which also are posited mediators of outcome) is increasingly being attended to in process outcome research.

G. How Does Psychotherapy Work?: Specific versus Non-Specific (Common) Mechanisms of Action

The specific versus non-specific question is an enduringly central one for psychotherapy process outcome research. The basic question is: "What is the contribution to therapy outcomes of the specific therapeutic techniques that characterize different forms of therapy, compared with other possibly therapeutic, but

common (non-specific) features that characterize psychotherapy as a treatment modality?" The potential causal contribution of common factors to therapy outcomes was convincingly argued 40 years ago by Jerome Frank.

In a classic book, *Persuasion and Healing: A Comparative Study of Psychotherapy*, Frank tried to account for the fact that existing psychotherapy outcome studies typically failed to show that markedly different types of psychotherapy had different outcomes. He specifically noted three types of null or "no-difference" findings. One was that "about two thirds of neurotic patients and 40 percent of schizophrenic patients are improved immediately after treatment, regardless of the type of psychotherapy they have received." Second, comparable improvement rates were found even when patients had "not received any treatment that was deliberately therapeutic." Third, follow-up studies, although very few at the time, did not demonstrate differences in long-term outcomes of diverse treatments.

The lack of evidence for any clearly superior form of therapy was, itself, perplexing. It was completely inconsistent with the expectations of many therapy researchers and nonresearcher, practicing mental health professionals alike. Different forms of therapy, such as Rogerian client-centered therapy and Freudian-derived psychodynamic therapy, were based on very different theories of the psychological processes that needed to be potentiated to achieve desired benefits. In addition, each theoretical orientation endorsed very different specific therapist techniques—techniques that were believed to potentiate the theoretically posited and theoretically required, psychological processes. In other words, a fundamental assumption was that the specific techniques of a type of therapy made a causal contribution to the outcomes that were sought. In addition, proponents of each orientation assumed that its underlying theory was more valid than the theories of alternative forms of therapy. Failure to find any one therapy that was superior to others was a stunning challenge to the preceding widely held assumptions.

Given that the results of therapy outcome research did not support the specific factors hypothesis (at least, not when using research methods and statistical analyses that were accepted at the time), Frank posited an alternate hypothesis. He suggested that similar improvement rates were due to psychologically influential elements that were common to all types of psychotherapy. Moreover, he posited that the common factors were those that operate in all human healing relationships and rituals, including religious healing. For example, he identified the arousal, or rearousal, of

hope (e.g., the expectation of help) as one common factor. Frank did not, however, completely dismiss the role of specific factors. He hypothesized that improvement rates in outcome studies reflected changes due to common factors in many patients plus change due to specific factors in some patients who did, indeed, respond to the particular form of therapy that they received. So, Frank's common factors hypothesis included the idea that specific techniques of different forms of therapy could be helpful to certain individuals although they were not needed by all those who could benefit from psychotherapy.

By 1971, Frank had further developed his common factors hypothesis and identified six "therapeutic factors" that are present in all forms of psychotherapy. For example, one was giving the patient a rationale or "therapeutic myth" that included both an explanation for the cause of the distress and a way to remedy it. Frank posited that his or her therapeutic action of such rationales, whatever their specific content or validity, includes strengthening a patient's confidence in the therapist. This, in turn, can reduce a patient's distress by reducing anxiety, as well as make the patient more open to the therapist's "influence" (e.g., suggestions for needed changes in attitudes and behaviors, and possible ways to achieve such changes).

Currently, 40 years after Frank's common factors treatise, research designed to identify the contributions to therapy outcomes of specific therapeutic techniques compared to common factors still is of central importance to the development of maximally effective and efficient psychotherapies. In general, it continues to be true that much less evidence than expected exists for the contribution to outcomes of specific techniques endorsed by different forms of therapy. Many researchers have attempted to explain why the null findings persist, given that process research has repeatedly demonstrated that purportedly different forms of therapy (e.g., cognitive therapy for depression and interpersonal therapy for depression) are associated with observably different and theoretically consistent, specific therapist interventions. For example, Alan Kazdin summarized and evaluated the situation this way for the 1994 *Handbook of Psychotherapy and Behavior Change*:

Comparative studies often show that two different forms of psychotherapy are similar in the outcomes they produce. ... This finding raises important questions about whether common mechanisms underlie treatment. Yet methods of evaluation are critical to the conclusion. It is possible that the manner in which treatment is studied may lead to a no-differences finding. The vast majority of therapy studies, by virtue of

their design, may not be able to detect differences among alternative treatments even if differences exist.

It is of interest that a similar situation exists for medications commonly used to treat depression. Classes of medications that have demonstrably different effects at the level of brain neurochemistry, such as selective serotonin reuptake inhibitors and tricyclics, have not yet been found to be associated with notably different outcomes. (Side effect differences are documented, however.) The similar failure to find outcome differences in medication treatments that differ at another level of observation lends some credence to contentions that current, standard methods for evaluating therapy outcomes might not allow different effects of psychotherapies to be observed. It also could be that the current difficulty demonstrating outcome differences between therapies that are demonstrably different at the level of implementation (therapeutic techniques) is a repetition of the fact that it could not be convincingly demonstrated that psychotherapy was better than no psychotherapy until the effect size statistic was applied to the task.

H. Do Some Forms of Psychotherapy Work Better Than Others?

Questions about the comparative efficacy of different forms of therapy have been a central focus of therapy research. As already noted, to the continual amazement of advocates of various specific forms of therapy, an enduring finding when different forms of therapy are compared is that their effects are not demonstrably different.

Over the years, the creative language skills of many experts in psychotherapy research have been stimulated by the frequent failure to demonstrate differential efficacy of different forms of therapy. For example, in a widely-cited 1975 paper, Lester Luborsky and colleagues adopted the Dodo Bird's salubrious verdict from *Alice in Wonderland* that "all have won and all must have prizes" to describe the weight of the evidence. Almost 10 years later, in 1984, Morris Parloff similarly summarized the findings as "all psychotherapy works, and all psychotherapy works equally well." However, the title of Parloff's paper highlighted a less sanguine implication of the no difference results: "Psychotherapy Research and Its Incredible Credibility Crisis." Shortly thereafter in 1986, William Stiles and colleagues analyzed possible reasons for the "equivalence paradox," that is, the fact that comparative outcome studies repeatedly found no differences in outcomes, yet the therapeutic techniques used in the different treatment conditions

had been demonstrated (via process research methods) to be different.

As of now, 2002, very detailed and comprehensive reviews of the comparative outcome study literature on different types of problems (e.g., anxiety disorders like obsessive-compulsive disorder and generalized anxiety disorder) and different patient groups (e.g., children, adolescents, and adults) suggest that it is not completely true that all therapies work and work equally well for every type of problem. For example, evidence exists that different specific forms of behavior therapy (such as exposure plus response prevention vs. progressive muscle relaxation) are differentially effective for obsessive-compulsive disorder. However, the general situation remains that less evidence for differential effects of specific forms of therapy exists than predicted by prevailing theories of psychotherapy and their posited mechanisms of action.

I. How Well Do Psychotherapies Work Compared to and Combined with Medications?

Increasingly, since about the early 1980s, psychotherapy researchers have collaborated with experts in psychopharmacology research to design and conduct comparative outcome studies of medications and psychotherapies. Comparative studies that include a combined medication plus psychotherapy condition also have become more frequent. A keen interest currently exists in comparative medication, psychotherapy, and combined medication and therapy outcome studies. The interest reflects the fact that medications have become more and more widely used in mental health treatment. Increased use can be traced to many forces including, of course, the aforementioned national emphasis on cost containment and cutting in mental health care.

In the early 1960s, Hans Strupp noted that chemical means were likely to be a challenge for psychotherapy. Indeed so. Within the past 3 years (since 1999), psychoactive medications (e.g., for depression) started to be advertised in television commercials in the United States. Viewers now are even encouraged to inform their doctors when new forms of existing drugs are available (e.g., an extended time release, once weekly, Prozac pill). As yet, no forms of psychotherapy are advertised in this way.

Conducting comparative psychotherapy and medication outcome studies heightened therapy researchers' awareness of some of the assumptions on which their standard research methods were based. For example, in therapy outcome studies the posttreatment outcome assessment traditionally is done after therapy sessions have been discontinued. The procedure is consistent

with both internal and external validity aims because of a general assumption about how psychotherapeutic interventions work. Historically, diverse forms of therapies all were expected to continue only for a time, to foster desired changes during that time, and then end when the patient had learned or otherwise “internalized” the ameliorative psychological processes that the therapy was intended to potentiate. When therapy researchers started to collaborate with psychopharmacology researchers, they observed alternative procedures for measuring outcome. For example, in medication studies, the convention was to obtain outcome assessments while patients still were taking the study medication. Differences in research methods made therapy researchers more aware of alternative methods and indicated the need for careful selection of methods that would yield “fair” and clinically-relevant findings from comparative studies of psychotherapies and medications.

Focal questions examined in comparative medication and therapy studies include rate of reduction in symptom severity, percentage of treated patients who reach a recovery criterion, stability and longevity of recovery, length of continuing treatment needed to retain response, and cost-effectiveness. Additional questions are associated with testing combined medication plus therapy treatments such as, “In what sequence should each intervention be administered to obtain the best outcomes?” An example of such a sequence is: Provide medication alone first for 2 months, then add in psychotherapy for 3 months, then discontinue medication while therapy continues for 3 months.

Fascinating, yet now completely unknown mechanisms-of-action questions about how medications and psychotherapies can interact are likely to be key to our ability to ultimately devise the most effective and efficient combined treatments. For example, do a particular medication and a psychotherapy interact in an additive way to affect certain problems so that the benefits of combined treatment are equal to the sum of the separate effects of each component? Alternatively, is the interaction “permissive” meaning that the presence of one component is needed to enable the other component to have its potential benefits? Alternatively, is the nature of the interaction inhibitory so that the presence of one component reduces the potential effects of the other component?

It is difficult to provide concise, general summaries of the findings from comparative studies of psychotherapies and medications, and their combination. Results exist for a variety of problems that differ markedly in symptoms and functional impairment (e.g., various anxiety disorders, types of mood disorders, schizophrenia). The find-

ings are not the same across disorders. It is of interest, though, that for at least some disorders (major depressive episode, panic disorder) the common expectation that combined treatment would be more effective than single modality treatment (either medication or psychotherapy alone) generally has not been supported yet. For example, as mentioned previously, some evidence exists that combined treatment of panic disorder is associated with poorer stability of response after treatment is discontinued than cognitive-behavior therapy alone is. For major depression, the evidence now indicates that combined treatment is not generally more effective than monomodality treatment of either type except, perhaps, for individuals with more severe or chronic (e.g., ≥ 2 years) symptoms of unipolar depression.

J. Can Psychotherapy Be Harmful?

The importance of conducting research to determine the frequency and nature of negative effects of psychotherapeutic interventions has been recognized by various therapy researchers over the years, such as Allen Bergin in the early 1960s, and Daniel Mays and Cyril Franks in the early 1980s. In the mid-1970s, Strupp and colleagues received a contract, initiated and funded by the NIMH to examine the topic. Their conclusions were published in a 1977 book, *Psychotherapy for Better or Worse: The Problem of Negative Effects*. In 1983, Edna Foa and Paul Emmelkamp edited a book focused on unsatisfactory outcomes, not negative effects per se, *Failures in Behavior Therapy*. The book illustrates the effort to improve the effectiveness of existing therapies by studying cases in which their effects are disappointing. The value of studying poor outcomes was noted in 1954 by Carl Rogers in a book that reported on the first 5 years of the therapy research program at the University of Chicago Counseling Center, *Psychotherapy and Personality Change*: “The field of psychotherapy cannot come of age until it understands its failures as well as it understands its successes.”

Research on deterioration, negative effects, and failures associated with psychotherapeutic interventions has not been prolific, but many questions have been examined. For example, the possible contribution of therapist personality features to poor outcomes has been studied as has the interaction of treatment approach (e.g., supportive vs. more “confrontational”) with patient characteristics.

A review of research on the important topic of negative effects is included in Michael Lambert and Allen Bergin’s chapter in the 1994 *Handbook of Psychotherapy and Behavior Change*. The review does not include

relevant findings and methods that now are emerging from patient-focused research strategies. Such information can be found in Lambert and Ogles' chapter, "The Efficacy and Effectiveness of Psychotherapy" in the fifth edition of the *Handbook of Psychotherapy and Behavior Change*.

IV. CONCLUDING COMMENTS

Much ground has been covered in this article. Even so, some milestones in psychotherapy research have not been discussed, such as research on the therapeutic alliance (a subject that is covered in a separate article in this volume). Important topics have been skipped (e.g., research on training in psychotherapy) or referred to only in passing (e.g., the gulf between therapy research findings and clinicians' satisfaction with their utility for practice). Moreover, the Key Questions section doubtless has left the impression that some crucial and basic discoveries are yet to be made. For example, much more remains to be learned than is known about the major causal agents of change in existing therapies, and the relevant moderating variables.

Bountiful evidence has been provided that conducting informative, reasonably conclusive research on psychotherapy is difficult. Sol Garfield, one of the field's major contributors and astute critics, is among those who observed that a core problem is that clinical research is very unlike controlled laboratory experiments. The central variables in therapy research (e.g., patients, therapists, extratherapy events, outcomes) have proven to be particularly intransigent both to evaluation and to the kind of experimental controls needed to obtain unambiguous findings. Given the challenges, many of which were revealed as researchers tried to answer the field's fundamental questions, Michael Lambert and Allen Bergin's appraisal of progress as of 1992, seems apt: "Psychotherapy research has been exemplary in facing nearly insurmountable methodological problems and finding ways of making the subjective more objective."

Given the difficulties of the endeavor, one might ask, "Why do psychotherapy research?" The field's first 60 to 80 years has revealed that the work can be painstaking and can yield results that, although very informative and important, are surprising and disappointing—sometimes especially to those who worked to find them. But what are the implications for clinical practice and for the patients who are served by it if therapy research is not pursued? Lee Sechrest, in an

electronic mail message to the Society for the Study of Clinical Psychology in 2000, observed: "reliance on authority (teachers, supervisors, trainers) or on one's experience does not allow you to know whether you are right or wrong." In the same message, Sechrest credited C. P. Snow for saying: "Science cannot guarantee that you will be right forever, but it can guarantee that you won't be wrong forever." For those who are dedicated to the responsible and ethical provision of mental health treatments, Paul Meehl's observation in 1955 (*Ann. Rev. Psych.* 6) exemplifies a compelling justification for psychotherapy research:

The history of the healing arts furnishes ample grounds for skepticism as to our nonsystematic "clinical" observations. Most of my older relatives had all their teeth extracted because it was 'known' in the 1920s that the clearing up of occult focal infections improved arthritis and other disorders ... Like all therapists, I personally experience an utter inability not to believe I effect results in individual cases; but as a psychologist I know it is foolish to take this conviction at face value.

Acknowledgments

Morris Parloff, Donald Kiesler, and Marvin Goldfried all key contributors to and observers of the development of psychotherapy research in its first 60 to 80 years, generously provided comments and perspectives on the content of this article. Lisa Onken and Barry Lebowitz, two experts on the field who view therapy research from leadership positions at the U.S. National Institutes of Health, also graciously provided comments. Winnie Eng, a student of therapy research, made helpful suggestions. Responsibility for errors, omissions, and interpretations of events remains the author's. GLOSSARY

character A person's enduring patterns of thinking, feeling, and acting, as well as habitual ways of resolving inner conflict.

compromise formation The mind's attempt to resolve conflict between various aspects of a person's inner world and external reality by reorganizing the various aspects of the inner world so that competing interests are all given expression. For example, a fantasy may represent a compromise formation in that it expresses a wish, as well as defenses against the wish and ways a person imagines being punished for the wish.

defense A general term used to describe the mind's, usually unconscious, attempts to protect itself from felt dangers, such as loss of love or of the loved one, loss of physical integrity, or a harsh conscience and all the attendant uncomfortable feelings.

drive (instinctual drive) A strong endogenous motivational force, especially of a sexual or aggressive nature, that motivates behavior toward a particular end.

interpretation The analyst puts into words his or her understanding of what the patient has been expressing, perhaps even without knowing it, to add new knowledge about a patient's mental life.

object relations The particular, individual patterns of relating to others that are characteristic of a person.

repression The exclusion of painful ideas, impulses, and feelings from conscious awareness.

transference The largely unconscious process of shifting feelings, thoughts, and wishes originally experienced with significant figures in childhood onto current figures in one's life.

unconscious Mental content that one is not aware of at any given time, though one may get glimpses of it through dreams, slips of the tongue, and disconnected thoughts.

Resistance is a term used to describe the various ways patients in psychotherapy oppose the process of change. This article briefly traces the development of this concept in Freud's thinking and then presents contemporary psychoanalytic views of resistance. In addition, psychoanalytic views will be contrasted with a behavioral perspective. Finally, clinical examples illustrate how a psychoanalytically oriented psychotherapist might understand and treat resistance in a treatment situation.

I. DEFINITION

Perhaps the clearest and most direct definition of resistance was Freud's deceptively simple statement in 1900, in his landmark work, *The Interpretation of*

Dreams: “Whatever disturbs the progress of the work is a resistance.” His discovery of the phenomenon, his attempts to understand it, and his work with it led him to some of his most important technical and theoretical discoveries in psychoanalysis. The concept of resistance still stands today as a cornerstone of psychoanalytic theory and practice; however, precise definition of the term remains elusive. In fact, any comprehensive definition of resistance includes almost all the key analytic concepts: drive, defense, compromise formation, character, and transference.

II. FREUD ON RESISTANCE

Early in his psychotherapeutic career Freud worked with Joseph Breuer treating women with hysterical symptoms. In their jointly published book, *Studies on Hysteria*, Freud describes his work with Fraulein “Elisabeth von R.,” his first reported full-length analysis of hysteria and his first case report of resistance. By this time Freud had seen the limitations of using hypnosis and the power of suggestion to help his patients give up their hysterical symptoms, and he had already turned to encouraging his patients to talk freely as a method of cure. As Freud worked with Elisabeth, she would fall silent and refuse to speak. When Freud asked her what was on her mind she replied, “Nothing.” Freud surmised that her not talking was a way of resisting treatment. Undiscouraged, Freud was able to make virtue out of a defect. He realized that resistance was not an obstacle to be overcome, but a way in and of itself to reach the repressed and overcome neurosis.

Freud learned through clinical experience how tenacious and persistent resistance could be even in patients truly interested in symptom relief and in the process of therapy. Anything could be used as a resistance to treatment: falling silent, forgetting, intellectual discussions about theory and treatment, coming late, seeing the therapist as the enemy. Equally suitable for resistance was coming on time, finding everything the therapist says helpful and brilliant, talking without hesitation.

At first blush, resisting treatment seems irrational. Why would someone who is suffering and coming for help in relieving that suffering resist efforts to get better? The attempt to answer this question led Freud to the discovery of key aspects of his theory and therapy. Freud posited that people fall ill due to the repression of painful memories or wishes, that is by pushing painful experiences out of conscious awareness. They get better by remembering those painful experiences.

However, to readmit those warded-off mental contents into consciousness is inherently marked by conflict. It entails undoing or giving up the mental structures that have been created to achieve some form of adaptation, however costly and unsuccessful. The patient, understandably, resists recognition of painful experiences, and, in essence, mounts the same efforts that brought about the repression of the pain in the first place.

When Freud attempted to overcome this resistance through suggestion and authority, he was met with increased resistance. This led him to recognize the importance of interpreting the resistance rather than directly interpreting the warded-off aspects of the patient’s experience. Resistance to treatment begins to seem more understandable in light of the patient’s fear (perhaps even unconscious) that the “cure” may be worse than the “disease.” Competing wishes are doing battle within the patient: the wish to leave well enough alone and the desire to ally with the therapist to be able to “remember” in the hopes of eventual relief of suffering. Ultimately the patient must ally with the therapist well enough to develop a partnership in exploration, and first and foremost exploration of his resistances.

In one of Freud’s technical papers “Dynamics of Transference,” he elaborates: “Resistance accompanies the treatment at every step; every single association, every act of the patient’s must reckon with this resistance, represents a compromise between the forces aiming at cure and those opposing it.” In fact, Freud defined psychoanalysis in terms of resistance. In a later work he wrote,

It may thus be said that the theory of psychoanalysis is an attempt to account for two striking facts of observation which emerge whenever an attempt is made to trace the symptoms of a neurotic back to their sources in his past life: the facts of transference and resistance. Any line of investigation which recognizes these two facts and takes them up as the starting point of its work has a right to call itself psychoanalysis, even though it arrives at results other than my own.

Freud’s first attempt to inventory resistances was in his previously cited book, *Studies on Hysteria*. Here he recognized that some resistances are manifest and some are hidden which led him to recognize the unconscious aspects of resistance and ultimately to see that his current model of the mind (topographic theory of conscious and preconscious) was not sufficient to account for the clinical phenomena he observed. Consequently he developed the structural theory of id, ego, and super-ego. Reflecting the further development of his ideas

Freud was still expanding his inventory of resistances 25 years later in “Inhibitions, Symptoms and Anxiety” in which he outlined three types of resistances: ego resistances—repression, transference resistance, and secondary gain from illness; superego resistances—unconscious guilt and need for punishment; id resistances—such as the repetition compulsion.

As Freud developed his theories of psychoanalytic technique he continued to emphasize the central role of interpreting resistance, along with the transference (i.e., relating to the therapist as if he or she were an important figure from the patient’s past). In fact, he viewed transference itself as, in part, a resistance in that the patient was enacting a prior relationship rather than remembering and verbalizing it. Freud came to see that transference and resistance both impede and facilitate cure. The desire to remember is opposed by the desire to forget. According to Freud, analytic technique must first and foremost address itself to overcoming resistance.

III. CONTEMPORARY PSYCHOANALYTIC VIEWS

Psychoanalytic thinking, including the theory of resistance, has developed along several paths since Freud laid down his original ideas. Psychoanalytic thinkers since Freud have been trying to sort out his somewhat diverse legacy concerning resistance. At times Freud seemed to consider resistance as something to be overcome and at other times as psychical acts that could be understood. That same duality persists today in those who endorse techniques designed to overcome or bypass resistance and make the unconscious conscious, and those who would seek to recognize and clarify resistance at work and to try to analyze the perceived threat to the patient’s functioning posed by trying to overcome the resistance. Adherents to the work of Melanie Klein in Great Britain (Kleinians) have been responsible for the development of the former view, while ego psychologists in North America (contemporary Freudians) have been developing the latter view. In addition, another school of thought has developed inspired originally by the works of Hans Kohut (self psychology, interpersonal or relational psychology) that has taken psychoanalytic theory and technique in quite a different direction. Although the ego psychological perspective has been the dominant view in North America, the influence of the Kleinians and the self psychologists is increasingly felt and is working its way into the mainstream of analytic thinking.

A. Ego Psychology

The central role of resistance in theory and technique has been best preserved in analysts schooled in an ego psychological approach (contemporary Freudians). Resistance, along with its successful interpretation by the analyst, is held as the essential unit of clinical psychoanalysis. A patient resists not just remembering but also resists understanding the nature of the felt dangers that caused the original repression. The patient is seen as struggling with internal conflicts not with the therapist. Resistance is a ubiquitous, recurring, ever-present aspect of the psychotherapeutic work. Successful therapy does not bring about removal of resistances but an understanding of them so that a new set of resistances can emerge and be explored. Successful psychoanalysis is the successful negotiation of one resistance after another. Problems occur when the patient becomes stuck in one particular resistance and cannot move on to other ones.

Contemporary Freudian efforts to develop Freud’s ideas on resistance have focused on the defensive aspects of resistance. In this vein contemporary analytic thinkers view resistance as whatever gets in the way of a patient being able to recognize what comes to mind, as well as how and why it comes to mind. Paul Gray and his followers have led the field in contemporary efforts to develop Freud’s ideas on resistance. Gray is particularly interested in the defensive aspects of resistance. He argues that traditionally analysts work to get past the resistance to get at what the patient is experiencing but not why the experience is so painful that the patient resists knowing it. Gray and his adherents argue for an approach that takes into account the importance of understanding why something is resisted as well as what it is that is being resisted. In Gray’s view, it is not just that an experience is painful that it is avoided but that it threatens the patient with feeling overwhelmed and losing the capacity to function adequately.

B. The Kleinian School

In this school the emphasis has been on penetrating interpretations aimed at reaching the deepest levels of a person’s unconscious experience. Trying to locate and articulate unconscious fantasies takes precedence over interpreting resistance. Resistances are seen in terms of object relationships rather than as impersonal mechanisms of the mind. That is to say they occur in the context of the relationship between the analyst and patient or between figures in the person’s internal world.

C. Self Psychology, Interpersonal or Relational Psychology

In this framework resistances are not viewed as ways the patient is avoiding communicating or knowing something about the self, but as yet another way the patient has of communicating something important about the self to the analyst. What another analyst might see as resistance, a relational analyst would view as a communication from the patient to the analyst about something the patient wants the analyst to know and to hold in the analyst's mind because the patient cannot yet tolerate knowing it consciously. It is then the analyst's job to "contain" the communication and eventually to put this "unspeakable, unknowable" mental content into words.

In sum, a contemporary analyst might hear Freud's patient, Elisabeth's response of "Nothing" when asked what was on her mind as an attempt to keep painful experience out of mind and hence avoid feeling overwhelmed (ego psychology); as an unconscious repetition of an internal object relationship (Kleinian); or as an attempt to communicate something about herself to the analyst (self psychology/interpersonal psychology).

IV. BEHAVIORAL THERAPY PERSPECTIVES

Behavior therapy, of course, is a multifaceted approach about which generalizations should be made cautiously. So it would be misleading to state that there is a particular perspective or approach to the idea of resistance emanating from behavior therapists. Nevertheless, certain similarities and differences can be noted. For one, although behavior therapists and psychodynamic psychotherapists both believe that human behavior is more or less lawful and ultimately understandable, the laws that are in question are fundamentally different between the two approaches. Behavior therapy is based on the idea of the preeminence of the environment in controlling and shaping actions whereas the psychodynamic psychotherapist is concerned with the internal environment of the individual actor and the role of unconscious mental processes in governing behavior. Naturally then, when faced with the inevitable difficulty of the patient in complying with the prescribed treatment, adherents to the two approaches will see different (from one another) forces at work. Behavior therapists will look to the environment as the source of the problems while the psychoanalytically oriented therapist will see the key environment driving the patient as being located within the patient.

The definitions of resistance of the two perspectives are also different. For behavior therapists resistance is antitherapeutic behavior. For the psychodynamic psychotherapist resistance is the force working against making conscious unconscious processes in the context of the patient's effort to make changes in action, thinking, and feeling. In both perspectives, the patient acts in a way to keep the therapy from having a full effect. Behavior therapists tend to see resistance as something that has to be changed or eliminated. Psychoanalytic therapists see resistance as an essential element of the change process. For the behavior therapist, resistance is usually conceptualized as the therapist's failure to perceive accurately and fully the lawful rules by which the environment is influencing the behavior of the patient. The behaviorists think of resistance as just another part of the patients' world that has to be taken care of in the delivery of the therapy. For the behaviorist, it is not a central or core concept.

V. CLINICAL EXAMPLES

Though psychotherapists today may not be familiar with the history of Freud's thinking about resistance they are intimately familiar with the same clinical phenomena that led Freud to his theoretical and technical innovations. Day by day, hour by hour, psychotherapists confront powerful resistance on the part of even the most motivated patients.

Ms. A., usually very responsible in her time management, found herself over the course of a number of weeks arriving later and later for her psychotherapy appointment. At times she was as much as 15 or 20 min late and would berate herself for wasting valuable time. "How will I ever get better if I can't even get here on time to talk about my problems?" she asked. Her therapist suggested that perhaps she had mixed feelings about her therapy, wanting to be here to get better, but perhaps she was also aware of something that felt uncomfortable about being here. Several weeks later Ms. A. arrived only a few minutes late and saw the previous patient leaving her therapist's office. She felt a wave of jealous, competitive feelings come over her that she immediately wanted to disavow. Instead she decided, reluctantly, to talk to her therapist about her feelings of jealousy and dislike for the woman who saw him in the hour before her. As they talked about this the therapist suggested that these jealous feelings that clearly disturbed her might be playing a part in her recent pattern of coming late to her sessions. Immediately she saw that she had unwittingly avoided these feelings by coming

so late she would never run into any “rivals” leaving her therapist’s office. This understanding of her resistance led her to talk more about the role of jealous and competitive feelings in her life and also led her to resume coming to her therapy hour on time.

Mr. B. came to treatment feeling desperately unhappy about almost every aspect of his life. He had few friends, was not able to sustain romantic relationships, and felt stymied in trying to choose among various career paths open to him. Mr. B.’s therapist noticed that no matter what kind of comment she made to Mr. B., Mr. B. rejected it. For example, Mr. B. was talking about being in a social situation the previous evening and described becoming extremely anxious as he began to talk to a particular woman he found attractive. His therapist, thinking she was empathically reflecting what he had already said, responded that Mr. B. seems to become anxious around women he finds attractive. Mr. B. immediately responded, “Well, not exactly. I mean maybe but not always.” After repeated efforts to try to talk with Mr. B. about his feelings and dilemmas the therapist realized that the work would go nowhere until the resistance was explored. The therapist pointed out to Mr. B. that every time she attempted to say something, even if it was something the patient has just described, the patient would reject it. The therapist interpreted that the patient seemed to be having trouble taking in anything from the therapist. Over time with the therapist’s help the patient was able to observe this response over and over again in their conversations, and he began to be curious about it. He came to understand more about his attempts to shut out the therapist in this way and about the ways this related to his experiences with his intrusive mother as well as with others in his present life.

In these examples we can see that resistance is not just an obstacle to be overcome but the expression of essential aspects of the patient’s characteristic ways of relating to themselves and others, the exploration of which can lead to significant therapeutic gains, as well as open doors to further areas of conflict and to transference manifestations.

VI. SUMMARY

All psychotherapists are faced with the many ways patients seek and resist help in the same endeavor. How that resistance is defined, understood, and worked with varies widely between schools of therapy, as well as within a particular school of thought. There is no single voice in psychoanalysis or in behavioral therapy, yet meaningful distinctions between the two schools of thought exist.

Practitioners of behavior therapy and psychoanalysis treat the clinical phenomenon of patients’ opposition to the effects of the treatment in very different ways. Adherents of both perspectives recognize the clinical phenomenon and its salience for the effectiveness of the treatment. In the case of the psychoanalytic perspective, resistance is seen as an essential, indeed necessary element of the treatment process. It is inevitable, and there are technical, specific strategies and clinical rules and theoretical formulations designed to address this phenomenon. Of course, this conceptualization depends on the existence of an unconscious mental process that can both enhance as well as oppose conscious motivations and intentions at the same time.

Behavior therapy practitioners, on the other hand, tend to conceptualize the patient’s inability to follow the treatment program as a lack or defect on the part of the therapist in not accurately understanding and formulating the contingencies in the patient’s life. Behavior therapy provides no such motivational construct of patient-originated resistance to the treatment. Rather, behavior therapists locate the problem as existing in a faulty understanding of and/or application of treatment on the part of the therapist. Indeed, behavior therapists make room for the prospect that it would be impossible for all therapists at all times to understand all patients. The responsibility, however, for the treatment progress or lack thereof rests clearly on the shoulders of the therapist.

The different ways of conceptualizing the phenomenon of patient-originated opposition goes to the core of the differences between behavior therapy and psychoanalysis. Psychoanalysis postulates underlying and unwitting motivational complexes that can be in conflict with one another, and behavior therapy locates these conflicts entirely in the contingency environment of the patient.

GLOSSARY

AB design A case study design in which the behavior of interest is first measured in the absence of treatment (during Condition A). Treatment is then applied (during Condition B). Changes of the behavior in Condition B cannot be attributed to the change from Condition A to Condition B.

ABAB withdrawal design A single subject research design in which A = baseline (no treatment) conditions; B = treatment conditions in which, after the occurrence of baseline (no treatment) treatment is presented for a number of sessions and then is withdrawn, and then is re-presented. The intent is to establish the effect of treatment.

aggression Behavior directed toward another individual that either produces or intends to produce physical or emotional damage.

alternating treatment design A research design in which several treatments are presented in succession in random order within sessions.

aromatic ammonia The use of ammonia as a punisher by holding it under an individual's nose contingent upon the emission of undesirable behavior (often pica).

BAB design Where B = treatment and A = no treatment; same as ABAB withdrawal design except that the study starts with the treatment condition immediately.

demand condition A diagnostic condition in which an individual is asked to perform a response the result of which is aggression by the individual against the asker with the intent that the aggression will make it less likely that the demanded response will be performed.

differential reinforcement of incompatible behavior (DRI) Reinforcement of a response (R_1) that is functionally incompatible with another response (R_2) with the intent of reducing in frequency that other response (R_2). The intent is that R_1 will occur frequently enough because it is being reinforced so there is limited opportunity for R_2 to occur.

differential reinforcement of other behavior (DRO) Reinforcement of the absence of a response (R_1) for a period of time with the intent of reducing it in frequency. At the end of the period of time whatever response (R_0) is occurring, as long as it is not the response that is supposed to be absent (R_1), is reinforced. As with DRI, the intent is that R_0 occurs frequently enough because it is being reinforced so there is limited opportunity for R_1 to occur.

facial screening A punishment technique in which the individual's face is briefly covered with a towel whenever an undesirable behavior occurs.

fading procedures Any of a number of procedures in which the known controlling stimuli of a discriminated response are gradually diminished in their apparentness such that their stimulus control passes to other stimuli that are more apparent in the current environment.

forced arm exercise Raising and lowering the arms of an individual in rapid succession as a punishment technique.

generalization of punishment The occurrence of the effects of punishment (i.e., the reduced frequency of the punished response) in an environment in which the response was not formally punished.

hand biting A self-injurious response in which the hand is inserted in the mouth and bitten, often with resulting tearing of the skin.

head banging/hitting Any response of an individual that brings the head into forceful contact with an object or body part.

lemon juice (therapy) Typically a squirt of lemon juice in the mouth contingent upon the emission of an undesirable behavior; often used with individuals who ingest nonedible substances in an attempt to punish such ingestion.

mental retardation Any endogenous or exogenous condition the result of which is an individual who has significant challenges in functioning independently in everyday life.

mouthing Putting an open mouth on objects or more typically on other body parts (e.g., skin) usually to the point where the other body part is damaged.

multiple baseline across settings The sequential treatment of a response in each of several settings; while being treated in one setting measurements of the frequency of the treated behavior occur in the other settings. If no change in frequency occurs in the other settings until and only if the behavior is treated in that setting, causal inferences about the treatment are typically thought to be strengthened.

pica The ingestion of inedible substances.

positive reinforcement Response-contingent presentation of a stimulus that has the effect of increasing the frequency (strength) of the response that it follows; both parts of this definition are necessary to the inference of positive reinforcement.

prepunishment baseline The frequency of occurrence of a response before punishment of the response.

programmed generalization The processes that produce the occurrence of a behavior therapeutic outcome in an environment in which it was not treated.

punisher A punishing stimulus, the presentation of which causes a decrease in the frequency of the response on which it is contingent.

punishment Either the presentation of a stimulus or the withdrawal of a stimulus, which has the effect of reducing the frequency of the response on which such presentation or withdrawal is contingent.

punishment procedure Either the response-contingent presentation or withdrawal of a stimulus, which has the effect of reducing the frequency of the response on which such presentation or withdrawal is contingent.

response Anything an organism (person) does or says that can be reliably observed and reported.

response-contingent faradic shock Electrical current delivered to an individual contingent upon the emission of a response, typically a self-injurious or aggressive response.

response-contingent water mist Water misting a person contingent upon that person's emission of a response, typically a self-injurious or self-stimulatory response.

restitutional overcorrection The overcorrection procedure in which the individual undergoing the procedure returns the environment to its former (presumably unspoiled) state, such as righting furniture that may have been thrown over during a tantrum. May also include a component in which the individual is required to improve on the unspoiled environment, such as polishing the furniture.

self-choke Any response of an individual that has the effect of cutting off the supply of oxygen to the brain.

self-injury Tissue damage caused by an individual's own behavior, such as head banging or head slapping.

self-injurious (behavior) responses Any response an organism emits that is either immediately tissue damaging or is tissue damaging in the long term.

self-stimulatory behavior (responses) Behavior that occurs in the absence of apparent, empirical reinforcement; typically assumed to be inherently reinforcing.

side effects Unprogrammed outcomes of behavioral procedures that may be positive or negative.

skin tearing Picking/pulling at loose pieces of skin.

stereotypic behaviors Peculiar responses that are emitted repetitively across long periods of time (e.g., mouthing), may be synonymous with self-stimulatory responses.

time-out (from positive reinforcement) Either the removal of a person from a reinforcing environment for a few minutes or the removal of the reinforcing environment from the person for the same few minutes contingent upon the emission of some undesirable response; a punishment technique.

water mist The spray from a water bottle.

water misting The act of spraying water mist at a person; typically a reaction to the occurrence of a self-injurious behavior by that person.

Response-contingent water misting has been used as a mild punisher to suppress self-injurious behavior (SIB) and/or self-stimulatory behavior in people with mental retardation. It is the subject of a little over a dozen clinical and research papers in the literature. Response-contingent water misting came to prominence as a function of the search by behavior analysts for mild punishers to use when reinforcement-based behavior reduction techniques had failed and stronger punishment techniques were inappropriate, as discussed by Bailey and colleagues in 1983. This article describes the use of the technique, its effectiveness, and drawbacks to its use. It also provides a chronological, annotated bibliography of the known literature.

I. EQUIPMENT

In its most prevalent use, water, at room temperature, is placed in a plastic spray bottle. Spray bottles used for

the purpose of water misting are those commercially obtained for household use. They are manufactured in a variety of sizes that hold up to 1 liter of water. Spray is emitted from the nozzle of the spray bottle when a hand pump/trigger that is part of the nozzle and the cap to the bottle is squeezed. Each squeeze of the pump dispenses about 0.5 cc. The nozzle is usually adjustable to produce gradations from a thin stream of water (like that from a squirt gun) to a fine mist. The mist usually describes a diffuse arc of water greater than 90 degrees and travels no more than about 46 cm. Thus, those operating the water mist must hold the spray bottle within 30 cm of the subject of the water misting.

II. OPERATIONAL DEFINITION

Room temperature water mist is sprayed in the recipient's face from a distance of 30 cm contingent upon the emission of a defined response. As is the case with all punishment procedures, unless the procedure is being used for research purposes, water misting does not occur absent concurrent positive reinforcement for behavior incompatible with the water-misted response.

III. FUNCTIONAL OUTCOME

The desired outcome is complete cessation of the water-misted response. Such an outcome is rare. Rather, the technique most often produces good, but partial, suppression of the response. Thirty to 90% suppression of the contingent response roughly encompasses the range of suppression in the literature. Suppression of the contingent response appears to be enhanced by the concurrent positive reinforcement of behavior incompatible with the contingent response. Response-contingent water mist does not appear to produce permanent suppression of the contingent response, as there is often recovery when the procedure is withdrawn, as discussed by Bailey et al., in 1983, Dorsey et al. in 1980, and Osborne et al. in 1992. Recovery is often incomplete; that is, the rate of the punished response does not return to the prepunished baseline. One implication of the recovery finding is that the procedure must be used chronically to maintain suppression of the responses on which it is contingent. However, fading procedures, in which the spray bottle is kept near to hand but where its presence cannot be discriminated by the subject, are effective in producing generalization of suppression beyond the occasions and environments of therapy, according to research by Jenson et al. in 1985 and Rojahn

et al. in 1987. In these procedures, the bottle has been made smaller so that it can be easily concealed.

IV. SUBJECTS

Subjects in the clinical and research literature have been primarily individuals with severe to profound mental retardation, often with additional challenges such as impaired vision and hearing and limited mobility. Most subjects described in the literature had been exposed to many other procedures to reduce the self-injurious or self-stimulatory responses that are frequently the focus of their behavioral programs, in the absence of good effect. These procedures are often the differential reinforcement of other behavior (DRO) or the differential reinforcement of incompatible behavior (DRI) in which the attempt is made to strengthen behavior that—when it occurs—precludes the occurrence of the self-injurious or self-stimulatory behavior. The literature is silent on how effectively these other procedures were applied. As these other procedures usually are mentioned as the reason to proceed with water misting, their ineffectiveness is assumed.

V. SIDE EFFECTS

No negative side effects have been reported. However, as with any punishment procedure there is always a chance of aggression against the therapist, according to Rojahn et al. in 1987. It may be notable that many of the subjects of this procedure appeared to be less than capable of aggression against a therapist because they were nonambulatory and confined to wheelchairs as discussed by Dorsey et al. in 1980, or they had visual impairments according to Dorsey et al. in 1980, Fehr & Beckwith in 1989 and Osborne et al. in 1992. Positive side effects appear to include enhanced effectiveness of concurrent positive reinforcement, as described by Fehr and Beckwith in 1989, and increased social interaction, as discussed by Singh et al. in 1986, which are common to other punishment procedures as well, according to Risley in 1968.

VI. OBSERVATIONS AND OPINIONS

Water misting was initially used for several reasons, as discussed by Dorsey et al. in 1980. First, it was easier to administer than other punishment procedures such as faradic shock or restitutional overcorrection. Second, the equipment (a spray bottle) was inexpensive

and highly portable. Thus, it could be used in many different environments. Third, unlike other punishment procedures (e.g., response-contingent faradic shock), water misting appeared not to present any health risks to those on whom it was used. Fourth, because of its relative simplicity, it was easy to train staff in its use. Fifth, staff had fewer objections to using water mist than they did other punishment procedures. Sixth, given all of the foregoing, water misting—as punishment—could be considered relatively innocuous.

Notwithstanding these reasons, no evidence suggests that the technique has been used in the past decade. Since this time period is concurrent with the absence of virtually all other applied punishment research, it is concluded that the national crusade against the utilization of formally described punishment procedures is responsible. (I say formally here, because most therapists involved with institutionalized people understand that informal punishment procedures continue to be used by the staff of such institutions.)

Water misting is not a completely effective punishment procedure. If it were, it would produce complete cessation of responding, no negative side effects, no avoidance of the therapist, and generalization outside treatment sessions. Therefore, it is possible that the reason that it is no longer used is that it was not effective enough. However, absent complete suppression, there are no negative side effects of the procedure, there is no evidence of avoidance of the therapist, and there is some evidence of generalization outside treatment sessions. Therefore, response-contingent water misting is an effective—if not completely effective—punishment procedure. Utilization of the procedure has suffered the fate common to the formal application of all other punishment procedures.

In the beginning, water misting was used as an alternative to more effective punishment procedures, such as response-contingent faradic shock, according to Dorsey et al. in 1980. It was used also because it was thought that society would tolerate its use better than had been shown to be the case for faradic shock. Clearly, this was an incorrect supposition. No behavior analyst ever feels good about administering any form of punishment during therapy sessions, particularly to a subject who is not capable of escape. Water misting was no exception. Colleagues worried about changes in subjects' dignity and self-worth. Yet, such concerns were overridden by the felt need to help reduce what was, and is, perceived to be serious self-injury and its long-term effects. Response-contingent water misting seemed a good compromise.

A possibly serious restriction on the effectiveness of response-contingent water misting is the absence of application of this procedure to normal populations. The procedure would seem, on its face, to constitute a possible backup to ineffective verbal reprimands by parents of their young children. It could constitute a viable alternative to the more uncontrolled use of corporal punishment. Absent any such information, however, it should be understood that generalization of the effectiveness of contingent water misting beyond the rather restricted populations on which it has been successfully used is unwise.

VII. CHRONOLOGICAL ANNOTATED LITERATURE REVIEW

1. Peterson, R. F., & Peterson, L. W. (1977). Hydropsychotherapy: Water as a punishing stimulus in the treatment of a problem parent-child relationship. In B. C. Etzel, J. M. LeBlanc, & D. M. Baer (Eds.), *New developments in behavioral research, theory, method, and application*. Hillsdale, NJ: Lawrence Erlbaum.

Study Design. Single subject, ABAB withdrawal design imbedded in contact/no-contact context; punishment only in contact context; during no contact, parent ignored child's head banging; followed by time-out phase.

Subject. 3.5-year-old male; with mental retardation.

Response. Head banging/hitting.

Treatment. 4-oz water splash delivered by parent from a water glass from a distance of 18 to 30 cm concurrently with a shouted, "No!"

Results. Good suppression by water splash over baseline in contact and no-contact periods; suppression not as good during no-contact context; but no-contact period provided evidence of generalization of punishment. Recovery during withdrawal phase, but phase stopped before recovery could further increase. Time-out was about as effective as water splash. Suppression maintained during follow-up, however, time-out was continued during this period.

Critique. Not really water misting. Study included because it appears to be a precursor to the water-misting procedure. Note difficulty of governing amount of water to be splashed and how much less water appears to be as effective when using water misting.

2. Murphrey, R. J., Ruprecht, M. J., Baggio, P., & Nunes, D. L. (1979). The use of mild punishment in combination with reinforcement of alternative behaviors to reduce the self-injurious behavior of a profoundly retarded individual. *AAESPH Review*, 4, 187–195.

Study Design. Single subject, BAB design.

Subject. Profoundly retarded male.

Response. Self-choke.

Treatment. Water squirt in the area of the mouth for self-choke; positive reinforcement of other behaviors; treatment application in six different settings; utilization of seven different therapists.

Results. Good suppression of self-choking (near 90%); quick recovery during treatment cessation (A); considerable recovery by follow-up after 20 months.

Critique. Treatment begun in the absence of a recorded baseline. Good attempt at programmed generalization.

3. Dorsey, M. F., Iwata, B. A., Ong, P., & McSween, T. E. (1980). Treatment of self-injurious behavior using a water mist: Initial response suppression and generalization. *Journal of Applied Behavior Analysis, 13*, 343–353.

Experiment 1:

Study Design. ABAB within-subject, reversal designs.

Subjects. Seven nonambulatory persons with profound mental retardation, with additional auditory and visual impairments, 5 to 37 years old.

Responses. Mouthing; hand biting; skin tearing; head banging.

Treatments. Water mist contingent upon SIB.

Results. Substantial reductions in SIB frequencies during treatment conditions—but not to zero—followed by recovery (instantly in four of the seven cases) to prior levels during treatment absence (baselines).

Critique. No concurrent positive procedures. No generalization outside sessions.

Experiment 2:

Study Design. Single subject; case study with successive treatments, across two environments; i.e., AB1B2B3 where A = baseline; B1 = response contingent “No”; B2 = “No” + water mist + DRO 1 minute; B3 = “No” + DRO.

Subjects. 21-year-old female, nonambulatory, with profound mental retardation; 26-year-old female, nonambulatory, from Experiment 1.

Response. Hand biting.

Results. Little or no suppression during B1; good suppression in one environment each for each subject during B2, but not in the second environment; addition of DRO helped with suppression for one subject but not the other in the second environment; upon withdrawal of water mist (B3) there was continued suppression in both subjects in the previously successful environment and good suppression in the remaining environments for both subjects.

Critique. No measurements beyond treatment sessions. Authors anecdotally note no generalization in

terms of long-term maintenance of suppression across the entire day.

4. Gross, A. M., Berler, E. S., & Drabman, R. S. (1982). Reduction of aggressive behavior in a retarded boy using a water squirt. *Journal of Behavior Therapy & Experimental Psychiatry, 13*, 95–98.

Study Design. Single subject; ABAB design with follow-up.

Subject. 4-year-old male with mental retardation.

Response. Biting; gouging (i.e., aggression).

Treatment. Baseline continued a hand slap and “No!” contingent on aggression that was already in place; treatment consisted of water misting—with mister set to the concentrated stream setting.

Results. Good suppression by water squirt over the hand slap procedure; some recovery during withdrawal of water squirt, but not back to original baseline; subsequent good suppression during second treatment application; zero frequencies at 6-month follow-up.

Critique. All day use of technique may have helped its success. Note that the study is only one of two (see work by Peterson and Peterson in 1977) that use water not in mist form.

5. Bailey, S. L., Pokrzywinski, J., & Bryant, L. E. (1983). Using water mist to reduce self-injurious and stereotypic behavior. *Applied Research in Mental Retardation, 4*, 229–241.

Study Design. Single subject; ABAB design with no treatment probes.

Subject. Ambulatory 7-year-old male with severe mental retardation with autism.

Response. Mouthing; hand biting.

Treatment. Water misting contingent upon finger/hand mouthing; all other contingency-based programs continued; including time-out for aggression during water misting.

Results. Excellent, but not complete, suppression during treatment periods; suppression also during no-treatment probes but not nearly as much as during treatment periods; recovery—but not complete recovery—during withdrawal phase; good suppression thereafter in no-treatment probe conditions.

Critique. Lengthy study, but no follow-up.

6. Friman, P. C., Cook, J. W., & Finney, J. W. (1984). Effects of punishment procedures on the self-stimulatory behavior of an autistic child. *Analysis and Intervention in Developmental Disabilities, 4*, 39–46.

Study Design. Single subject; ABACADAB where A = baseline; B = water mist; C = lemon juice; D = vinegar with follow-up.

Subject. 11-yr-old male with severe mental retardation and autism.

Response. Hand touching (hand clapping; hand jabbing; finger jabbing).

Treatment. Water mist to the face or lemon juice squirted in the mouth; or vinegar squirted in the mouth.

Results. Partial suppression during water mist followed by complete recovery during withdrawal; less suppression with lemon juice; about same suppression as water mist with vinegar; more suppression in second water mist phase; follow-up was continued use of water mist by staff and teacher with very good suppression.

Critique. Sessions were only 5 minutes. Baseline conditions and background in all treatment sessions consisted of structured play that involved therapists telling subject what to do explicitly—a demand condition that may have contributed to baseline frequencies.

7. Reilich, L. L., Spooner, F., & Rose, T. L. (1984). The effects of contingent water mist on the stereotypic responding of a severely handicapped adolescent. *Journal of Behavior Therapy & Experimental Psychiatry, 15*, 165–170.

Study Design. Single subject; multiple baseline across settings and teachers with follow-up.

Subject. 15-year-old female, deaf and blind.

Response. Stereotypic behavior (e.g., picking up coats, paper, etc., and covering her head with these items).

Treatment. Head coverings removed and water mist applied to subject's face immediately, while during baseline she was allowed to keep covered for 2 minutes before covering was removed.

Results. Good, but not complete, suppression on application of water misting in each environment only when water mist applied; good suppression in the presence of each teacher. Zero frequency at 17 months follow-up.

Critique. Not a very exciting response. There did not seem to be anything life threatening about it, nor did it have the qualities of stereotypic behavior (that is, on its face, did not seem highly self-stimulatory). Rather, response appeared to be attention getting. However, DRO had been tried and had failed.

8. Jenson, W. R., Rovner, L., Cameron, S., Peterson, B. P., & Keisler, J. (1985). Reduction of self-injurious behavior in an autistic girl using a multifaceted treatment program. *Journal of Behavior Therapy and Experimental Psychiatry, 16*, 77–80.

Study Design. Single subject; case study with generalization and follow-up.

Subject. 6-year-old-female, autistic, with moderate to severe mental retardation.

Response. Hand biting.

Treatment. Contingent water mist plus loud “No!” Size of spray bottle reduced across phases (fading). Parents also used program at home.

Results. Virtually complete suppression. Long-term follow-up showed almost complete suppression also.

Critique. Case study design. However, fading size of bottle and having parents do procedure at home, may have contributed substantially to long-term effectiveness.

9. Singh, N. N., Watson, J. E., & Winton, A. S., (1986). Treating self-injury: Water mist spray versus facial screening or forced arm exercise. *Journal of Applied Behavior Analysis, 19*, 403–410.

Experiment 1:

Study Design. Single subject; alternating treatments design with follow-up.

Subject. 17-year-old female, with profound mental retardation.

Response. Face slap.

Treatment. Alternation of contingent water mist with facial screening counterbalanced across the two daily sessions.

Results. Substantial reductions in frequencies of face slapping by both water misting and facial screening with slightly more reduction by the facial screening.

Critique. No generalization or measurement to other times of day.

Experiment 2:

Study Design. Same as Experiment 1.

Subject. 17-year-old female with profound retardation.

Response. Finger licking.

Treatment. Same as Experiment 1.

Results. Only about 25% reduction by water mist; much greater reduction by facial screening; socially positive interactions increased.

Critique. No generalization or measurement to other times of day.

Experiment 3:

Study Design. Same as Experiment 1.

Subject. 17-year-old female, with profound retardation.

Response. Ear rubbing.

Treatment. Water misting alternated with forced arm exercise.

Results. Water mist reduced ear rubbing by 80%; but forced arm exercise reduced it by 90%; socially positive interactions increased.

Critique. No generalization or measurements to other times of day. Forced arm exercise may have been more effective because subject was precluded from ear rubbing during the exercise.

10. Rojahn, J., McGonigle, J. J., Curcio, C., & Dixon, M. J. (1987). Suppression of pica by water mist and aromatic ammonia: A comparative analysis. *Behavior Modification, 11*, 65–74.

Study Design. Simultaneous (alternating) treatment design with fading.

Subject. 16-year-old female, autistic, with severe mental retardation, with mild cerebral palsy.

Response. Pica (tacks, staples, crayons, strings, woven material, paper, cigarette butts).

Treatment. Three daily sessions (7.5 minutes). Water mist, aromatic ammonia, and no treatment alternated across these sessions; location of bottle faded; generalized to other therapists.

Results. Virtually complete suppression of pica by water mist. Early ammonia administration produced increase in pica followed by decrease. Possible increase in collateral mild aggressive behavior. No increase in collateral SIBs.

Critique. No long-term follow-up. Absence of concurrent positive reinforcement program.

11. Fehr, A., & Beckwith, B. E. (1989). Water misting; Treating self-injurious behavior in a multiply handicapped, visually impaired child. *Journal of Visual Impairment and Blindness, 83*, 245–248.

Study Design. Single subject; case study; combined multiple baseline across settings and ABA design.

Subject. 10-year-old male; visually impaired; auditory agnosia; profound mental retardation.

Response. Head hit.

Treatments. Fine water mist spray to face contingent upon head hit, preceded with “No!” Food contingent on peg placement and toy play.

Results. Substantial reductions of head hitting in breakfast and lunch environments but not in class or residence hall until positive reinforcement for appropriate behavior was added in the latter two.

Critique. No follow-up. No measurement of response outside of treatment sessions and environments.

12. Paisey, T. J. H., & Whitney, R. B. (1989). A long-term case study of analysis, response suppression, and treatment maintenance involving life-threatening pica. *Behavior Residential Treatment, 4*, 191–211.

Study Design. Single subject.

Subject. 16-year-old male with profound mental retardation.

Response. Wandering; pica.

Treatment. Phase 1: Assessment. Pica observed in 4 settings—observers present; subject alone; baits on the floor but neck screen on (blocked vision of floor); neck screen on but baits on furniture, unlimited edibles,

contingent mesh hood (did not permit ingestion); contingent water mist accompanied by loud “No!”, contingent lemon juice. *Phase 2. Lemon juice punishment for pica and boundary training using water mist; Phase 3: Residential treatment package.* Lemon juice punishment for pica; water mist contingent upon crossing a taped line (wandering); DRI; DRO.

Results. Assessment. Pica greatest during alone context; pica lowest during lemon juice, mesh hood, and ad lib edibles, high during water mist contingency. Still mean frequencies of pica were reduced by half during water misting. *Program Development.* Excellent suppression of pica by lemon juice; good suppression of boundary crossing by water mist and warning. *Residential treatment package.* Lemon juice suppressed pica about 50%; with addition of water mist for boundary crossing there was additional suppression; upon withdrawal of lemon juice and water mist after 30 months there were some increases in pica but suppression was still about 50%.

Critique. Water mist shown not to be too effective with pica, but more effective with boundary crossing (wandering); Excellent study length, although disappointing to see that after so much time there was still an increase in pica after withdrawal of water misting and further increase in pica after withdrawal of lemon juice.

13. Peine, H. A., Liu, L., Blakelock, H., Jenson, W. R., & Osborne, J. G. (1991). The use of contingent water misting in the treatment of self-choking. *Journal of Behavior Therapy and Experimental Psychiatry, 22*, 225–231.

Study Design. Single subject, case study; AB design with treatment generalization and follow-up.

Subject. 25-year-old deaf, blind, male with profound mental retardation.

Response. Self-choke.

Treatments. Fine water mist spray to face contingent upon self-choke, paired with “No!” 20-second absence of self-choke produced face wipe, juice sip, and hug or pat on back.

Results. Approximately 2 responses/min in baseline to .03 to .12 responses/min during treatments—17- to 70-fold reduction. Zero responses during 8-month follow-up.

Critique. AB case study design; no disaggregation of water misting and the positive reinforcement procedure. Except for follow-up—an important exception—no measurement of response outside of treatment sessions and environment.

14. Osborne, J. G., Baggs, A. W., Darvish, R., Blakelock, H., Peine, H., & Jenson, W. R. (1992). Cyclical self-injurious behavior, contingent water mist treatment, and the possibility of rapid-cycling bipolar disorder.

der. *Journal of Behavior Therapy and Experimental Psychiatry*, 23, 325–334.

Study Design. Single subject, case study; multiple probe design in which pre- and posttreatment baselines were taken before and after each treatment session.

Subject. 45-year-old female; visually impaired, with profound mental retardation.

Response. Head slap.

Treatments. Water mist spray to face contingent upon head slap, paired with “No hitting!” DRO 1 to 6 minutes for social and tangible reinforcers. Session end contingent upon a successful DRO interval.

Results. Subject cycled between high- and low-frequency periods of SIB lasting 4 to 14 weeks. Mean reduction from pre-session baseline during treatment was 71% for high-frequency periods; mean reduction from pre-session baseline during treatment baseline was 85%. No difference between pre-session baseline and treatment during low-frequency periods; reduction to zero in post-treatment baselines after treatment during low-frequency periods.

Critique. Use of pre- and posttreatment baselines shows recovery of SIB frequencies from posttreatment to next pretreatment baselines. DRO procedure not uncoupled from water mist procedure. No effect of water mist procedure on length of this subject’s high- and low-frequency SIB periods.

GLOSSARY

point-based response cost procedure Point removal in a point economy contingent on a targeted undesirable behavior.

response cost A punishment procedure in which a person loses a reinforcer or a portion of reinforcers following an undesirable behavior. A naturally occurring example of response cost is a traffic fine following an arrest for speeding.

I. DEFINITION

Response cost is the removal of a person's or group's reinforcer(s) as a consequence of an undesirable behavior. Although the entire reinforcer can be removed, more commonly, only a portion is removed. Response cost derives from the notion that the probability of the occurrence of a behavior is related to its physical or monetary cost. That is, the greater the cost of performing a behavior, the less likely it is that the behavior will be performed. Some authors specify that

the lost reinforcers must be conditioned, but they may also be primary, as in the loss of a portion of a person's edible reinforcers.

II. CONCEPTUAL SYSTEM

A response-cost procedure that results in a decrease in the future rate of a certain behavior is classified as Type II punishment. It differs from Type I punishment in that a reinforcer is removed rather than an unpleasant event (e.g., a loud verbal reprimand) being applied. Response cost differs from extinction, which involves termination of the delivery of ongoing reinforcers. It differs from time-out, which specifies a period of time in a less reinforcing environment following an inappropriate behavior. Response cost does not involve a temporal component, although a person can lose allotted minutes from a desired activity. Response cost is similar to time-out in that both procedures have an aversive component.

Hierarchies of restrictiveness of decelerative procedures usually place response cost as more restrictive than extinction and equal in restrictiveness to time-out procedures. The present author recommends that this classification be revised because response cost is quicker acting and associated with fewer undesirable side effects than extinction. Also it does not require physical intervention (e.g., removing people from ongoing activities), as do many time-out applications.

III. FORMS

The most common form of response cost is evident when a government fines its citizens for traffic violations, paying taxes late, or failure to obey health and safety regulations. A precondition for its application is that an individual have something to lose. Therefore, in order for a response-cost procedure to be applicable, a person must either have reinforcers to lose or must be provided with them.

Often, response-cost procedures are carried out in the context of token-reinforcement programs. Tokens in the form of points, stars, chips, check marks, smiley faces, and so on are removed contingent on display of inappropriate behaviors. The tokens are conditioned reinforcers that can be exchanged periodically for backup reinforcers. The amount of tokens an individual is penalized is crucial since it must be large enough to impact behavior, but not so large that a person quickly loses all of her or his reinforcers.

In one common form of response cost, people lose reinforcers from an existing pool. The pool of reinforcers can already exist in the person's possession or can be provided to the person by the program implementer. For example, a client could be fined \$25 each time she missed an appointment at a weight-control clinic. Or a teacher could give a student 15 tokens each day and remove one each time he violated a classroom rule.

In a second form of response cost, a person could start the day with no reinforcers, but earn reinforcers for appropriate behavior and lose them for inappropriate behavior. The popular television quiz show, "Jeopardy," is conducted according to this format. People residing in group homes often experience programs of this type. Thus, the individuals may receive points for carrying out household chores and for prosocial behaviors and lose points for violations such as fighting and failing to do assigned work.

Variations of each of these approaches can also be applied. First, response cost can be carried out on a group-contingent basis. Thus, students can be given 10 extra minutes of free play, but lose 1 minute each time a classmate breaks a classroom rule as follows:

10, 8, 8, 7, 6, 5, 4, 3, 2, 1, 0

In this case there were a total of three violations; thus, each member of the class had 7 extra minutes of free time.

In a second variation, free reinforcers can be retained on an all-or-none basis. This modification, frequently mislabeled as differential reinforcement of low rate of

response (DRL), could involve allowing a child to stay up an extra 15 minutes if she takes her brother's toys less than three times during the day. If she violates the rule three or more times, she loses the privilege of staying up 15 minutes late.

Finally, as was the case in the two previous examples, program implementers can program penalties from a bonus pool. That is, people can be offered a bonus for refraining from inappropriate behavior. Rule violations then result in the loss of the bonus, rather than what was already due the individual (e.g., the regular recess time). This variation can reduce ethical objections to the use of response cost.

IV. APPLICATIONS

The variety of settings, populations, and behaviors to which response cost has been successfully applied is immense. Settings include traditional homes, schools, clinics, group residences, work sites, correctional facilities, playgrounds, and athletic fields. Populations include children and adults, with and without handicaps. A partial list of behaviors comprises classroom disruptions, aggressiveness, sleep difficulties, excessive drinking, overeating, inattentiveness, speech disfluencies, psychotic speech, food scavenging, toileting accidents, failure to use seatbelts, occupational injuries, failure to keep appointments, failure to hand in assignments punctually, and hair and eyelash plucking. In a naturalistic environment, it has been shown to radically reduce directory assistance calls and could probably be employed to combat resource shortages involving fuel usage and water consumption.

V. ADVANTAGES

Response cost is one of the most effective interventions available. It commonly produces immediate, large, and enduring changes in behavior. It can be applied immediately, easily, and precisely following an undesirable behavior. The application typically does not interfere with the ongoing activity. Unlike time-out, response cost does not remove a violator from the setting in which the problem behavior occurred. Thus, a student who committed an infraction would not lose academic time. Unlike time-out and overcorrection, response cost does not involve physical interaction that could lead to injury. Compared to extinction, response cost works more quickly and produces greater decreases in behavior.

Unlike other punishment procedures, response cost is seldomly associated with adverse side effects. At times it results in desirable side effects. Thus, a reduction in disruptive behavior through response cost has sometimes resulted in appropriate social interactions. Also response cost rarely incurs public objections. It tends to fall within society's norms on how people should treat each other and is compatible with the principle that those who break a rule should pay proportionally.

VI. DISADVANTAGES

Although uncommon, adverse side effects of response cost have been noted. These include emotional responses and aggression following reinforcer removal and avoidance of the environment in which response cost occurs. Also response cost calls attention to the inappropriate behavior, possibly reinforcing its occurrence. All of these problems can be reduced or eliminated by combining response cost with positive reinforcement for appropriate behavior. Thus, a person will not avoid an environment that is mostly reinforcing, but employs occasional response cost. Also attention to appropriate behavior will lessen the likelihood that response cost will reinforce inappropriate behavior.

A significant problem that can occur is that a person could lose all of her or his reinforcers, thereby nullifying the response-cost procedure. In such cases a back-up system such as time-out might be necessary. Another problem is that, due to its effectiveness and ease of implementation, response cost can be overused. It might, for example, be effectively applied to minor infractions that do not justify a punishment procedure. Finally, given the numerical nature of many response-cost procedures, some mastery of quantification is often necessary. This may limit its usefulness with very young or severely cognitively limited individuals.

VII. CONSIDERATIONS IN USING RESPONSE COST

Given that response cost is a punishment procedure, it should only be used when more constructive approaches, such as positive reinforcement, are unreasonable or ineffective. Also the usual operations concerning any behavioral intervention should be employed. This includes defining the behavior(s) of concern, measuring its occurrence during baseline and intervention, specifying

the rules of the operation, and revising the procedure when necessary.

In point-based response-cost procedures, point removal should be immediate, obvious, and follow all infractions. The point removal should be done in such a manner as to provide feedback to the offending individual, but should not involve comments that could reinforce inappropriate behavior (through attention) or trigger additional problems.

Significant issues with point-based response cost are setting the upper limit and determining how many points to remove on each occurrence. As indicated earlier, the procedure can be negated when all points are lost. Baseline measures can help set the upper limits for response cost. Thus, the upper limit for a person who displays 40 misbehaviors might be 20, whereas the upper limit for someone who displays 5 misbehaviors might be 3. Research has indicated that the removal of two points per infraction is more effective than removing one. Yet, removing two points might cause the upper limit to be exceeded more quickly than removing one point. In general, the effectiveness of response cost is so great that the upper limit is seldom reached.

Without exception response-cost procedures should be combined with positive reinforcement for appropriate behavior. This can take the form of bonuses or can simply consist of praise for appropriate behavior. The combination of response cost and positive reinforcement is more effective than either procedure used alone. The combination of procedures also allows for the possibility of gradually removing the response-cost procedure and maintaining improved performance with positive reinforcement procedures alone.

VIII. SUMMARY

Response cost is a punishment procedure in which a person loses a reinforcer or a portion of reinforcers following an undesirable behavior. It is powerful, easily implemented, and socially acceptable. It has been successfully used across a wide variety of behaviors, populations, and settings. For reasons of effectiveness and humaneness, it is best combined with positive reinforcement for appropriate behavior.

GLOSSARY

chamber REST A type of REST that involves secluded bed rest in a small light-free and sound-attenuated room.

dry flotation REST A type of REST that involves a sound and light attenuated enclosed chamber designed so that the research participant is separated from the fluid, a solution of $MgSO_4$, by a velour-covered thin plastic polymer membrane.

restricted environmental therapy/treatment (REST) An experimental psychotherapeutic practice that, through the use of a solitary environment and a drastically reduced level of external sensory stimulation (i.e., light, sound, touch, and gravity) can produce beneficial effects on medical, psychological, and behavioral health outcomes, particularly when used in conjunction with other therapies.

wet flotation REST A type of REST that involves the use of a specially designed sound and light attenuated enclosed tank filled with a skin temperature aqueous solution of Epsom salts and water.

I. DESCRIPTION

Two decades ago, Peter Suedfeld coined the term restricted environmental therapy or technique (REST) as a less pejorative description of sensory deprivation. REST

was born out of experimental methods designed to study the affects of environmental stimulus reduction on human beings. The earliest and most relevant preliminary research was published in the 1950s by Donald Hebb of McGill University who, with his students and collaborators, described the effects of “severe stimulus monotony” on his research participants to test his theory of centrally directed behavior. Hebb’s experimental setup consisted of a completely light-free and sound-attenuated chamber in which the participant was isolated on a bed for a period of 2 to 3 days. Further sensory reduction was attempted by using variations of the basic setup such as having the participant wear translucent goggles and cardboard sleeves that fit over the hands and arms to limit visual and tactile stimuli and/or enclosing research participants in “iron lungs.”

Shortly after publications involving chamber REST methods, John C. Lilly, a neuropsychologist at the National Institute of Mental Health, published findings from his sensory reduction research that focused on the effects of many natural or non-experimental experiences of isolation. These included details of autobiographical accounts from individuals who were isolated geographically or situationally. As a result of these findings, Lilly and his associate, Dr. Jay Shurley, pursued the origins of conscious activity within the brain and whether the brain required external stimuli to keep its conscious states active. To fully address this question, Lilly designed the flotation tank, which restricted environmental stimulation as much as was practical and feasible.

The experimental setup of flotation REST required that the research participant be submerged up to the neck in an enclosed tank of water. A diving helmet acted to block out outside visual stimulation and a breathing apparatus was used so that the participant could respire if the nose and mouth should drop below the level of the water. Although the helmet decreased visual stimuli, the breathing apparatus was anything but noise free. Over the years, Lilly continued his experiments with flotation, simplifying and improving the general design of the tank. Lilly found that one could float in a more relaxing supine position, rather than suspended feet downward in fresh water, if more buoyant salt water was used. This method allowed for the subsequent elimination of the breathing apparatus. Other refinements, such as water heaters, air pumps, and water filters for the reuse of the Epsom salts, were added and by the early 1970s, Lilly had developed the flotation tank in much the design that is used today.

Early studies addressing chamber and flotation REST tested participant endurance, often up to several days, and included setups that were ultimately stressful (being enclosed in iron lungs, cardboard sleeves and/or goggles, or having to rely on a noisy breathing apparatus for respiration as well as being almost completely submerged). It was no wonder that many of the findings from the initial reports were dramatic and negative. Such findings included aversive emotional reactions, disruptions of conscious states, negative hallucinations, interference with thinking and concentration, and sexual and aggressive fantasies. Later research suggested that these negative findings could be understood on the basis of a negative experimental set (aberration and endurance), of an excessive duration of isolation, and of demand characteristics. The most frequent and replicable results of REST are an openness to new information, increased suggestibility, increased awareness of internal cues, decreased arousal, and attentional shifts. These results not only contradict earlier studies, they actually hint at some potential benefits of REST. Research evidence indicates that REST consistently has beneficial effects on medical, psychological, and behavioral health outcomes, particularly when used in conjunction with other therapies.

Current use of REST involves three differing optimal methods and one method that can be used in clinical settings without substantial accommodations. The first, chamber REST, involves secluded bed rest for a variable amount of time, generally 24 hours or less, in a small, completely dark, and sound-attenuated room. Most of the data to date has been generated through

the use of this technique. The second method, wet flotation REST, involves the use of a light-free, sound-attenuated flotation tank, resembling a large covered bathtub filled with a skin temperature solution of saturated Epsom salts and water. The research participant floats supinely in the tank for a time period that is generally 90 min or less. The third method is termed dry flotation REST. This method includes a rectangular chamber that is designed so that the research participant is separated from the fluid, a solution of $MgSO_4$, by a thin, plastic polymer membrane. Again, the float time is generally 90 min or less. In clinical settings it is possible to restrict the environment by using darkened goggles, earplugs, sound maskers, and a room with reasonable sound attenuation.

II. BIOLOGICAL AND PSYCHOPHYSIOLOGICAL EFFECTS

The research examining the biological and psychophysiological effects of chamber and flotation REST has been based on more than 1,000 incidents in which 90% of the individuals interviewed reported marked feelings of relaxation and a greater focus on internal processes because external stimuli is limited. A summary of specific findings regarding the relaxation response and cognitive processes are discussed in this section. Such findings include both subjective and objective measurements of various effects.

The relaxation response can be understood by studying several different biochemical and psychophysiological parameters. First, subjective measures of REST have been collected to study relaxation effects using various instruments including the Spielberger State Anxiety Scale, Zuckerman Multiple Affect Adjective Checklist, subjective units of disturbance scale (SUDS), and the profile of mood states (POMs). These instruments conclude that REST participants perceive significantly lower levels of subjective measures of stress and feelings of calmness, alertness, and deep relaxation.

Endogenous opiate activity has been studied, as it is frequently associated with increased pleasure responses and is related to a reduction of stress and pain, and increased relaxation. Results of these studies suggest that REST increased central nervous system availability of opioids across sessions. In addition, a state of relaxation can be defined as exhibiting low levels of the biochemical substrates involved in the stress response. The stress response is a fairly complicated reaction that involves hormone changes from the adrenal glands in

particular. Basically, the hormones triggered by stress in this response include norepinephrine, epinephrine (commonly known as adrenaline), adrenocorticotropin (ACTH), cortisol, renin, and aldosterone. Each of these hormones play a role at various organ systems that results in the increase of heart rate, blood pressure, respiration, and muscle tension. Therefore, stress response parameters studied in REST research include blood pressure, muscle tension, and heart rate, as well as the adrenal axis hormones mentioned earlier.

Research studies that have examined heart rate, muscle tension, blood pressure, and various plasma and urinary adrenal hormones conclude that REST consistently produces significant decreases both within and across sessions of these measurements. Other hormones have been measured in conjunction with those mediating the stress response to provide an experimental control. These hormones have included testosterone and lutenizing hormone (LH) and have been found to remain consistent in a 1990 study by Charles R. Turner and Thomas H. Fine. Significant reductions in blood pressure was a finding that was established through case studies of hypertensive individuals, and later in controlled research studies that began in the early 1980s. Researchers that studied REST's effects on hypertensives included Fine and Turner, Jean L. Kristeller, Gary E. Schwartz, and Henry Black, and Suedfeld, Cuni Roy, and Bruce P. Landon, to name a few. This research concludes that a significant decrease in both systolic and diastolic blood pressure can occur in hypertensives. Furthermore cortisol and blood pressure have been shown to maintain these effects 9 months after cessation of repeated REST sessions in a follow-up study by Kristeller, Schwartz, and Black in 1982. Thus, the effects of REST are more than an immediate response that is reversible.

Cognitive effects of REST include a shift in cognitive processing strategies away from analytic, sequential, and verbal thinking toward non-analytic, holistic, and imaginal thought processes. A review of common reports by Helen Crawford in 1993 describes a decrease in external stimuli with redirection to internal stimuli or more narrowly focused external stimuli with possible shifts in attentional processing (changes in focused and sustained attention). The increases in internally generated stimuli, such as fantasies and thoughts, tend to be more vivid and involving. Since 1969, researchers have studied the effects of REST and increased suggestibility. Arreed F. Barabasz and Marianne Barabasz found that floatation REST enhances hypnotizability in participants who scored low on the Stanford Hypnotic

Susceptibility Scale: Form C in 1989. Findings by A. Barabasz have also revealed that chamber and dry flotation REST dramatically influence hypnotizability whereas wet flotation REST elicits spontaneous hypnosis in participants that are highly hypnotizable.

A 1990 A. Barabasz study involving measurements of electrocortical (EEG) activity showed significantly increased theta (4–8 Hz) after flotation REST. Fine, Donna Mills, and Turner compared frontal monopolar EEG and frontal EMG readings of wet flotation versus dry flotation REST in 1993. The results showed that wet flotation REST had higher amplitude alpha frequency components. They concluded that wet flotation REST is qualitatively different in terms of central nervous system activity and may resemble the “twilight learning state.” This state is induced through hypnosis and Stage 1 sleep. Differences between dry and wet flotation REST include humidity, temperature, and amount of tactile stimulation available to the participant. It is unknown which of these factors may contribute to differences in EEG readings.

III. APPLICATION EFFICACY

In 1982, Suedfeld and Kristeller suggested that, based on the implications of research and theory, REST should be “particularly appropriate” in two types of clinical situations: habit change and states of lower arousal and relaxation. Habit change, is based on the known cognitive effects of REST. The lack of distraction, increased hunger for stimuli, and increased openness to new information associated with the stimulus reduction experience, leads to a uniquely focused state of awareness. Lower arousal or relaxation effects of REST facilitate treatments addressing problems associated with chronic or acute stimulus overload such as dysfunction of information processing and stress-related disorders. Research findings have shown that chamber REST applications are particularly effective for the modification of habit disorders, whereas flotation REST sessions have been applied and have been found to be effective in the treatment of stress-related disorders, chronic pain, anxiety disorders, and sports performance enhancement. Notwithstanding the promising outcomes of REST as a treatment, as well as an augmentation strategy, the status of REST is predominantly an experimental procedure with many open questions regarding its utility and appropriateness in the clinical setting. Subsequently, REST research has been applied to a variety of problems, disorders, and opportunities for performance enhancement.

Smoking cessation studies combining REST with other traditional treatments have shown considerable promise as an augmentation strategy with multiple research sites demonstrating success rates of over 50% with follow-up periods ranging from 12 months to 5 years. In a few clinical studies, 1 to 2 years in duration, REST has been combined with weekly support groups. In those instances 75 to 80% with support group and tailored message have maintained abstinence for the length of the study.

Controlled studies have also demonstrated efficacy in decreasing the alcohol consumption of heavy drinkers. In 1987, Henry B. Adams, David G. Cooper, and John C. Scott studied the effects of REST on heavy social drinkers treated with 2.5 hours of REST with an antialcohol educational message during the treatment. The results of the study showed 55% reduction in alcohol consumption in the first 2 weeks after the treatment whereas control participants showed no significant reduction. A replication of this study showed similar results and alcohol reduction was maintained at 3- and 6-month follow-ups. A 1990 study by M. Barabasz, A. Barabasz, and Rebecca Dyer found that, for heavy drinkers, after exposure to one 12-hour or 24-hour chamber REST session, the average daily consumption of alcohol continued to drop over 6 months of follow-up. The 24-hour group's average consumption before REST was 42.7 ounces per day, immediately post-REST, it was 23.3 ounces per day, 16.0 ounces per day at 3 months, and 12.7 ounces at 6 months. Chamber REST was studied by David Baylah in 1997 as a relapse prevention technique with substance abusers enrolled in outpatient substance abuse treatment programs. At the end of 4 years of follow-up, 43% remained continuously sober and drug free, whereas none of the control group did after an 8-month follow-up.

Eating disorders have also been responsive to REST in a number of controlled studies. In a study that examined REST as a treatment for bulimia, the elimination of purging behaviors was a significant finding with a 50% success rate. In three studies using REST as a treatment for obesity, a slow continuous weight loss over a 6-month follow-up period after treatment was noted. In 1990, Dyer, A. Barabasz, and M. Barabasz utilized a true experimental design using a 24-hour REST treatment with a message (participants were asked to focus on the importance of diet and exercise and the role their particular problem foods had in their weight problems) and a REST treatment with problem foods (problem foods were brought into the chamber with the participants). Participant's total caloric consumption, problem food consumption, and body fat percentage were significantly lowered, and interviews revealed that REST appears to

facilitate the resolution of conflicting attitudes and behaviors about food. Those individuals who had 25 to 30 or less pounds to lose benefited most from the study, whereas participants who had more weight to lose reported initial losses of 5 to 10 pounds and then reported that they were unable to maintain diet and exercise regimens. Non-REST participants did not show significant weight loss in the study.

Recreational, competitive, and intercollegiate sports including basketball, archery, tennis, gymnastics, rowing, darts, skiing, and rifle marksmanship have been the focus of flotation REST treatments to enhance performance. A performance enhancement study has also been done on commercial pilots, and REST treatments showed significant improvement on instrument flights tasks as opposed to control in a Lori G. Melchiori and A. Barabasz study. REST greatly enhances mental imagery, relaxation, and visualization of skills and has been shown to produce remarkable results in anecdotal and controlled performance studies. Studies in 1991 by Jeffery D. Wagaman, A. Barabasz, and M. Barabasz have been done on improving basketball performance. In these studies, improvements on shooting foul shots in a non-game session has been shown with REST, as well as improvements on objective performance skills and coaches' blind ratings as compared to a control group. Six sessions of flotation REST plus performance enhancement imagery of approximately 50 min over a 5-week period produced improved skill in passing, dribbling, shooting, and defense game and non-game measures when compared with an imagery-only control group.

An intercollegiate tennis study by Patrick McAleney in 1991 controlled for relaxation and guided imagery confounds noted in previous research on the enhancement of human performance using REST. Twenty participants took part in 50-min flotation REST treatments with visual imagery group or an imagery-only group. Participants were pre- and posttested on athletic performance and precompetitive anxiety measure. The analyses of performance scores revealed a significant performance enhancement effect for first service winners for the flotation REST plus visual imagery group in contrast to the group that received visual imagery only. No other performance analyses (key shot, points won or lost) were significant. The results of the analyses of anxiety scores were not significant. Another study by A. Barabasz, M. Barabasz, and James Bauman in 1993 looked at the enhancement of rifle marksmanship scores to determine the effects of dry flotation REST versus hypnotic relaxation, which is a confounding variable because flotation REST elicits spontaneous hypnosis in participants that are highly hypnotizable. Twelve participants who took

part in a rifle marksmanship training course, and who were exposed to dry-flotation REST, showed significantly higher rifle marksmanship scores than 12 participants who were exposed to relaxation only. This suggests that REST's positive effects on marksmanship go beyond the induction of relaxation by hypnosis.

As mentioned previously, REST increases relaxation effects and pleasurable effects via endogenous opiate activity. Flotation REST has been studied as a treatment for chronic low back pain and chronic pain in rheumatoid arthritis, fibromyalgia, and premenstrual syndrome. Wet flotation REST was consistently associated with improved range of motion and grip strength and decreased pain both within and across sessions in all participants involved a Turner, Anna DeLeon, Cathy Gibson, and Fine 1993 rheumatoid arthritis study. Responses with dry flotation REST were less consistent and less vigorous. The moisture and heat associated with wet flotation REST are likely factors in the differences between the two types of REST treatments because rheumatoid arthritis is relieved by moist heat. A different study found that the pain associated with rheumatoid arthritis significantly decreased in participants treated by REST and autogenic training (a form of self-hypnosis). Studies on low back pain, fibromyalgia, and premenstrual syndrome also yielded significant relief of pain from REST treatments.

Stress and anxiety-related disorders are the focus of many flotation REST studies because of the role that REST plays in decreasing adrenal axis hormones associated with the stress response. Many foundational studies have been done that have illuminated REST's effects on lowering specific stress-related hormones. Other studies on anxiety-related disorders such as social anxiety, obsessive-compulsive disorder (OCD), trichotillomania (chronic hair pulling), psychophysiological insomnia, and induced stress have added to the growing body of research demonstrating that REST is effective at reducing physiological arousal related to stress and anxiety.

REST has also been used as an augmentation strategy for exposure treatments. In one case study involving a treatment refractory OCD patient, REST was used, along with an imaginal exposure treatment (using a loop tape), to treat severe contamination obsessions and compulsions. It was determined that the primary reason for the patient's unresponsiveness to traditional exposure treatments was his inability to focus on the stimulus. Subsequently, he would not meet the basic requirements of a sufficient time of exposure, as well as a lack of focused arousal. After an initial period of "REST

only," the patient was exposed to the loop tape containing the fear-evoking material. This unconventional use of REST resulted in a substantial reduction of OCD symptoms.

IV. SUMMARY

REST has come a long way since its conception in the 1950s. Although it was initially used to test hypotheses about human endurance in monotonous, sensory-deprived environments and to test theories regarding brain processes, several side effects emerged from that early research that included an openness to new information, increased hypnotizability, increased focus on internal processes, and lower arousal. These cognitive and relaxation effects of REST were studied as they were seen as potential treatments for a wide variety of psychophysiological problems, addictive behaviors, and performance enhancement. In the past decade, REST has emerged as an effective therapeutic treatment with a low occurrence of negative side effects. The relaxation and pleasurable effects of REST have been used as a mechanism to decrease anxiety and pain in treatments of stress-and pain-related disorders. The cognitive effects of REST have been effective in modifying addictive behaviors and treating phobias and compulsive behaviors. Although there are many theoretical questions that remain to be answered as well as many possible applications that have yet to be studied, continued research builds its credibility and increases its visibility and practicality as a sound therapeutic treatment.

GLOSSARY

enuresis Involuntary discharge of urine after an age at which urine control should have been established.

micturition The passage of urine; urination.

Retention control training (RCT) is an intervention developed for the treatment of nocturnal enuresis. This article discusses the basic components of RCT, incorporating a brief description of the clinical phenomena for which it is used. Next, the theoretical and empirical basis for the development and use of this intervention is described. Finally, a review of the effectiveness of this intervention with nocturnal enuresis is provided.

I. COMPONENTS OF THE INTERVENTION

Enuresis is a condition that involves the involuntary passage of urine by a child after the age at which urinary control would be expected. According to the American

Psychiatric Association's *Diagnostic and Statistical Manual, Fourth Edition, Text Revision (DSM-IV, TR)*, an individual must be at least 5 years of age, chronologically or developmentally, in order to be diagnosed as enuretic and experiencing repeated voiding of urine into bed or clothes, either intentionally or involuntary, at least two times per week for 3 consecutive months. If the enuretic behavior has not been present for the specified period of time, then clinically significant distress or impairment in social, academic, or other important areas of functioning must be present. Enuresis cannot be the result of a medical condition or the physiological effect of a substance, such as a diuretic. Furthermore, enuresis can be classified as either nocturnal (during sleeping hours), diurnal (during waking hours), or both. In addition to the subtypes of enuresis, it can also follow two different courses. Primary enuresis is characterized when the individual has never had a period of time with urinary continence, whereas enuresis is characterized as secondary when it begins after the individual has once established urinary continence.

Enuresis has a relatively high prevalence rate among young children and decreases as age increases. The literature reports there to be a 14 to 20% prevalence rate for 5-year-olds, 5% for 10-year-olds, 1 to 2% for 15-year-olds, and approximately 1% for 18-year-olds. In addition to differences across ages, the prevalence rate of enuresis also differs across gender. Males are twice as likely to be enuretic than females: 7% and 3%, respectively, at age 5; 3% and 2%, respectively, at age 10; and 1% and less than 1%, respectively, at age 18. Enuretic

individuals may also experience a period of spontaneous remission without treatment. The likelihood of spontaneous remission is reported to be approximately 14% between the ages of 5 and 9, 16% between the ages of 10 and 14, and 16% between the ages of 15 and 19. Finally, a strong indicator of enuresis has been found to be family history. According to the *DSM-IV, TR*, 75% of children with enuresis have a first-degree biological relative who also experienced the disorder.

RCT is an intervention technique used for the treatment of nocturnal enuresis. As an intervention, RCT is relatively simplistic and typically involves the implementation of procedures during waking hours as a means of indirectly altering urine retention during sleeping hours. In general, RCT involves instructing the enuretic child to delay micturition from the time that he or she first senses the urge to urinate. In this manner, the child is learning to increase the amount of urine that can be held in the bladder prior to urination, thus establishing appropriate inhibitory responses. In addition to delaying urination, children are typically instructed to increase fluid consumption above normal levels. By doing so, they experience more frequent urges to urinate, providing more frequent opportunities for mastering retention control.

There are several variations in the basic procedures of RCT described in the current literature. First, procedures may differ regarding the method used to delay urination. One model instructs the child to delay micturition by programming successively longer periods of time. For example, the child is encouraged by parents to increase the delay between feeling the urge to urinate and doing so by 10 minutes across successive weeks. During the first week of intervention, the child is requested to delay urination for 10 minutes. The delay is then increased to 20 minutes and 30 minutes during the second and third weeks of treatment, respectively. In contrast, another variation of RCT entails the requested delay to be systematically increased over time by first instructing the child to go to the bathroom and urinate. The child is then provided with 500 ml of fluid and coached to delay urination as long as possible. Parents note the time at which the child requests to use the toilet, ask the child to delay urination for as long as possible, and then note when the child uses the restroom. From this information, postponement time can be calculated. This latency period serves as the baseline used during subsequent training trials so that the parents and therapists can monitor that the child is delaying urination 1 to 2 minutes longer with each consecutive attempt. Finally, RCT can involve a proce-

dure that involves instructing the child simply to delay urination for as long as possible.

Second, the use of rewards for successful retention of fluids may also differ. Parents may be instructed not to provide any tangible reinforcement contingent upon successful delay of urination, to administer praise only, or to utilize procedures that involve the delivery of tangible rewards contingent upon increased fluid consumption and/or successful delay. Further, methods of reinforcement may also include instructing the child to change his or her own bed linens after voiding during sleep prior to returning to bed.

A third variation in RCT involves the child delaying urinations during the night. With this method the parents are instructed to give a large drink (i.e., 1 pint) to the child before bed and wake him or her every hour. At each awakening, the child is asked if he or she could delay urination for another hour. If so, the child returns to bed. If not, he or she is encouraged to delay urination for a few more minutes, is praised for doing so, and then is allowed to void. The child is then given another large drink and returned to bed; the amount of fluid loading may vary. Current research has only evaluated using this specific routine during the first night of treatment.

As mentioned earlier, methods of RCT may vary. To date, research has not systematically compared the various methods of administering RCT to determine which is most effective. Therefore, deciding which variation of the intervention to use depends on the structure of the child's environment (i.e., the willingness of the parents and the child) and the comfort level of the therapist with the different methods of the procedure.

II. BLADDER CAPACITY AND ITS ROLE IN NOCTURNAL ENURESIS

Various theories have been put forth to explain enuresis. Currently, enuresis is considered to be a functional disorder that is multiply determined, often with more than one causal mechanism operating with any given child. Physical causes accounting for the disorder include, but are not limited to, urinary tract dysfunctions and infections, nervous system dysfunctions, and bladder capacity deficits. Further, psychological and behavioral causes that have been shown to account for enuresis include toilet training practices and emotional disturbances.

Some research suggests that a proportion of children who experience nocturnal enuresis display small functional bladder capacities (i.e., the volume of urine at

which contractions designed to evacuate the bladder occur). Thus, although the structure of the bladder is normal, its capacity to hold typical amounts of urine is underdeveloped. This smaller-than-expected functional bladder capacity may result in excessive urination diurnally in response to small amounts of urine in the bladder, resulting in fewer opportunities to learn micturition inhibitory responses. In fact, researchers have determined that a significant portion of enuretic children urinate more frequently than nonenuretic peers. At night, this may translate into an enuretic episode given the likelihood of decreased sensitivity to urination urges while asleep. RCT is based on the assumption that increasing functional bladder capacity will result in a decrease in enuretic episodes. In order to increase the bladder capacity, enuretic children are prompted to engage in certain behaviors during the day to train their bladders to hold increasing amounts of urine before voiding.

III. EFFECTIVENESS OF RETENTION CONTROL TRAINING

A significant amount of research has been conducted over the years in regards to the effectiveness of RCT and other behavioral treatments for nocturnal enuresis. Not surprisingly, RCT has been empirically demonstrated to increase functional bladder capacity. For example, in 1960 S. R. Muellner demonstrated that enuretic children produced greater urinary output following the use of RCT. Further, in 1975, Daniel Doleys and Karen Wells demonstrated that RCT resulted in normalized functional bladder capacity for a 42-month-old child. Regarding its effectiveness in treating nocturnal enuresis, RCT alone has been found to be effective in decreasing enuretic episodes in 50 to 75% of individuals. Further, it has been shown to be 30 to 50% effective in producing complete cessation of bedwetting episodes.

RCT reduces enuresis by normalizing bladder capacity and is thus more beneficial to those with a low functional bladder capacity. A child's bladder reaches full development around the age of 4 to 5. In a 1996 study, Tammie Ronen and Yair Abraham found that the rate of increase in bladder capacity is directly related to the age of the individual utilizing RCT. Specifically, they reported that the closer one is to the typical age of bladder maturity, the faster one can increase bladder capacity. Further, the rate of increase is slower for children much younger and much older than age 4 to 5.

This is consistent with the results found in a 1990 study by Sandra Bonser, Jim Jupp, and Daphne Hewson. They implemented RCT with a 13-year-old female. Prior to implementing the treatment, the adolescent female was required to track her daily number of urinations and number of wet and dry nights for 5 weeks. This information continued to be monitored during the treatment and then for 1 week during each of the 2 months following termination of the intervention. In this study, RCT involved the adolescent holding her urine for successively longer periods of time. During the first week of treatment, she was instructed to hold her urine for 15 minutes after she first felt the urge to urinate. After 15 minutes, she was allowed to void. During the second week she was instructed to hold her urine for 20 minutes and then follow the same procedure as the previous week. In weeks 3 through 8, the adolescent was required to load her bladder with extra fluid as a means of increasing bladder capacity while continuing to hold her urine for 20 minutes. To accomplish this, she drank three large glasses of fluid in addition to her normal daily fluid intake throughout the day at breakfast, lunch, and after school. Finally, a reward system was in place based on the number of dry consecutive nights experienced. It took 8 weeks for her to decrease from seven wet nights per week to two wet nights per week and at 6-month follow-up she was experiencing only one wet night per week.

In 1970 H. D. Kimmel and Ellen Kimmel were among the first to systematically investigate the use of RCT in modern times. Three female children ages 4 and 10 participated. Baseline data revealed almost nightly bedwetting for all participants. RCT involved encouraging fluid intake (via reward contingent upon consumption) at any hour of the day and rewarding successively longer periods of retention of urine in the bladder, up to 30 minutes. Results showed that complete cessation of nocturnal enuretic episodes occurred for two of the participants within approximately 7 days of the initiation of RCT, and within 14 days for the third. Further, follow-up data indicated that none of the subjects had more than one enuretic episode during the year following treatment.

In 1972 A. Paschalis, H. D. Kimmel, and Ellen Kimmel conducted a more extensive investigation of RCT with 35 children who exhibited nocturnal enuresis. Treatment was essentially the same as that described by Kimmel and Kimmel in 1970 and was conducted for 20 days. Results showed that 40% of the participants met the criteria for success (i.e., seven consecutive nights without an accident) during the treatment period, and

an additional participant achieved success through a continuation of the treatment beyond 20 days. Of those who were successful, no relapse was noted over a 90-day period.

As mentioned previously, reinforcement methods are at times used as a component of, or in addition to, RCT. In 1987, M. Carmen Luciano used an A-B-C single-subject design to test the effects of RCT plus reinforcement on nocturnal enuresis in two male participants, ages 11 and 12. After first obtaining baseline data, Luciano introduced RCT for 5 weeks in order to evaluate the effects of increasing bladder capacity on enuretic behaviors. RCT entailed the children drinking as much fluid as possible throughout the day and then holding their urine as long as possible for progressively longer periods of time until they reached 45 minutes. In addition, the children were told to practice stream interruption exercises (i.e., physically stopping and starting the voiding of their urine) three to five times each time they voided. The boys received points throughout the day for following directions as part of a reward system. The occurrence of bedwetting was recorded daily. Results showed that the use of RCT both increased bladder capacity and reduced the number of wet nights. However, because complete cessation of the enuretic episodes was not achieved, Luciano introduced differential contingency dry wet bed (DCDWB). DCDWB entailed an inspection of the child's bed each morning with a parent. If the bed was dry, a token reward system was implemented and the parent praised the child. If the bed was wet, the child was instructed to replace the dirty linens with clean ones and to wash his soiled nightclothes. From the point at which DCDWB was initiated, the nocturnal enuresis stopped within 5 to 6 weeks for both boys. At weeks 17 and 18, fading procedures were implemented by gradually decreasing the daily monitoring, exercises, and reward system. These findings are consistent with other studies demonstrating that providing tangible rewards plus fading as a treatment for nocturnal enuresis has a higher success rate (85%) and lower relapse rate (37%) than both dry bed training and the urine alarm.

In 1982, J. Bollard and T. Nettlebeck implemented a component analysis of dry bed training, a comprehensive treatment for enuresis consisting of the urine alarm, RCT, waking schedule, and positive practice/cleanliness training. This study included 177 enuretic individuals between the ages of 5 and 17. Each individual was randomly assigned to one of the eight groups. Group 1 was considered the standard condition, which entailed the use of the urine alarm during sleep. Group 2 involved

the use of a waking the schedule in addition to the urine alarm. The waking schedule consisted of waking the individual every hour to void during the first night and one time 3 hours after falling asleep during the second night. Then after each dry night, waking would occur one-half hour earlier than the previous night, until the waking time was equal to 1 hour after sleep onset. Group 3 entailed the use of the urine alarm in addition to RCT. Here, RCT included the third variation of RCT at night that was discussed earlier (i.e., fluid loading before bed, hourly waking, prompting urine retention). The fourth group included the use of positive practice, cleanliness training, and the urine alarm. Positive practice entailed the child lying in bed with the lights off and counting to 50. When the child reached the set number, he or she was to go to the toilet and try to void. This process was repeated 50 times before falling asleep. Immediately following an enuretic accident, the child was reprimanded and sent to the toilet. The child then implemented cleanliness training, which involved changing one's nightclothes, removing and replacing the soiled bed linens, and drying and repositioning the detector pad of the urine alarm. Prior to returning to bed the child again had to carry out the positive practice exercises 20 times. There were also four additional groups that were composed of combinations of the first four groups. Group 5 included waking and RCT. Group 6 entailed waking, positive practice, and cleanliness training. Group 7 included RCT, positive practice, and cleanliness training. Finally, Group 8 was composed of the full dry bed training package. Bollard and Nettlebeck found that groups 6 and 8 had significantly fewer wet nights than each of the other groups. Further, they found no significant differences between the other groups. However, they did report that each of the four groups that included the waking schedule responded faster to the treatment than those without the waking schedule. In the RCT group specifically, 11 of the 12 participants met the criterion for becoming dry with an average of 24 wet nights during the 20-week treatment period.

As noted, studies have evaluated the combined effectiveness of RCT and other intervention methods as a means to stop enuresis. In 1986, Gary Geffken, Suzanne Bennett Johnson, and Dixon Walker compared the effects of the urine alarm alone against the urine alarm plus RCT with 50 5- to 13-year-old enuretic children. Baseline measures of wetting frequency were collected over a 2-week period of time; in addition, classification of either a small or large maximum functional bladder capacity was determined prior to randomly assigning participants to each of the

groups. All participants were instructed to use the urine alarm. Half were also instructed to implement RCT based on Paschalis, Kimmel, and Kimmel's 1972 model of RCT. In this study, children in the RCT plus urine alarm group were instructed to hold their urine for progressively longer periods of time until they reached 45 minutes beyond the initial urge. Over the course of treatment, 10 participants dropped out. Of the 40 remaining participants, 92.5% ($n = 37$) achieved 14 consecutive dry nights, although 41% ($n = 16$) of the children relapsed. The fewest bedwetting accidents occurred in children with a large functional bladder capacity who were in the urine alarm only group and with the children who had a small functional bladder capacity and were in the urine alarm plus RCT group, suggesting a relationship between functional bladder capacity and method of treatment. This decrease in bedwetting may have also been a result of the increase in nighttime arising to use the toilet. This suggests that RCT was able to increase the sensitization to a full bladder but not actually increase functional bladder capacity as has been suggested throughout the literature.

Research on the effectiveness of RCT and other behavioral methods, such as dry bed training and the urine alarm, continue to provide information regarding the effective treatment of nocturnal enuresis. Further, treatment of nocturnal enuresis tends to produce a high dropout rate due to the demands placed on the parents to implement and follow through with the treatment. As discussed, different variations and combinations of RCT and other methods will result in different outcomes. It is important to choose a method that best suits the therapist and the family being treated.

IV. SUMMARY

RCT is an intervention model used to decrease the presence of nocturnal enuresis. Enuresis is the voluntary or involuntary voiding of urine in clothes or in bed after the age of 5. RCT encourages the holding of urine

for extended periods of time after the first urge to urinate is detected. This functions as means of increasing the functional bladder capacity of an individual. Variations of RCT may also include fluid loading and reward systems as methods of reinforcement for increased fluid consumption, delayed urination, or both. On average, RCT is effective with 50 to 75% of individuals in reducing nocturnal enuresis, and with 30 to 50% of individuals in completely eliminating bedwetting. Based on the varying methods of implementation and the results of previous studies, specific intervention programs for treating enuresis should be tailored to the specific family and individual being treated.

GLOSSARY

confederate An individual who pretends to be a participant in a research study, but is actually part of the research study.

modeling A procedure in which a particular behavior or behaviors is/are demonstrated for an individual to allow that individual to emulate the behaviors.

operant conditioning A theory of behavioral modification that states that behaviors are controlled by contingencies that occur following the behavior.

role reversal The client acts “as if” they are another individual involved in a problematic situation.

Role-play is a procedure in which scenarios are designed to elicit particular behaviors from an individual. The individual is asked to respond “as if” the situation were actually occurring. The individual may respond to another person or to a situation presented by video- or audiotape. This article presents a review of the uses of role-play in therapy, guidelines for use, advantages and disadvantages of this techniques, and information regarding empirical studies of the technique.

I. DESCRIPTION

Role-playing, also known as behavioral rehearsal, has a number of uses in behavior therapy, in terms of both behavioral assessment and treatment. Whether used as part of an assessment or intervention, role-playing requires the client to act “as if” they are in a real-life situation involving a problematic behavior. Role-play may enable clinicians to directly observe deficits (e.g., unassertiveness) or excesses (e.g., aggression) in an individual’s behavioral repertoire. Role-play may also be used in treatment for a number of behavior-based problems including phobias, anxiety, social skills training, and interpersonal difficulties.

Role-play sessions can be audio- or videotaped in order for the behaviors to be rated by either the therapist, the client, or an objective judge. Frequently, behavior checklists are used to rate target behaviors the client is attempting to learn. Behaviors can be rated in terms of their effectiveness, frequency of occurrence, duration, or presence or absence. Clients can also provide ratings of self-perceived competence or level of arousal while performing the behaviors. Based on the ratings, a therapist provides feedback to the client. Feedback includes specific information regarding the individual’s performance and suggestions for improvement and additional practice.

A. Assessment

Often, it is not possible for a therapist to observe directly a problem behavior in the natural setting in

which it occurs. In these cases, it may be possible to recreate the situation in the therapists' office. Role-play frequently involves the therapist and client reenacting a problematic interpersonal situation. Outside models may also be used to better simulate the actual situation. For example, if the client is a male college student reporting difficulties asking women for dates, the therapist may want to recruit a young female assistant to assist in the role-play.

Role-play may also be beneficial if the client has a difficult time verbally expressing the nature of the problem. Enacting a similar situation with the client may provide the therapist with specific knowledge of the client's behavioral excesses and deficits that he or she is not able to verbalize. For instance, if the college student described above is not able to explain the nature of his difficulties interacting with women, conducting a role-play may clarify the specific nature of the problem.

B. Intervention

Role-play is often conducted within the therapy session to assist clients in learning and practicing new skills, decrease and extinguish undesirable behaviors, and increase and reinforce desirable behaviors. Through role-play exercises, the therapist is able to observe the client's behaviors directly and provide feedback regarding strengths and limitations, and to reinforce the target behavior. For example, a therapist engaging in social skills training may describe the procedure to the client, provide a rationale for its use, establish several scenarios that approximate the problematic situations, model the appropriate behavior with a confederate, then ask the client to respond to a confederate (live, audio, or video) "as if" the situation is occurring. Feedback is then provided to the client on her or his performance. Role-play is also frequently used to assist parents in teaching new skills or modifying behavior of a child. Role-play may be first conducted in session with parents. The parents are then instructed to engage in role-play practices at home with their child. For example, role-play may be appropriate for teaching an aggressive child socially appropriate means of interacting with other children.

Role-play is also useful for helping a client attend to internal processes of which they are unaware. For instance, while enacting a scene in which the client is practicing assertive behavior, the therapist may call attention to thoughts, feelings, and stimuli to which the client typically does not attend. Once the client has identified the internal processes, role-play can be used

to learn new ways of responding to the situation. For example, clients with social anxiety may not be aware of automatic, distorted cognitions (e.g., "Everyone in the audience thinks I'm stupid") that may be increasing their levels of anxiety.

Role-play is frequently used to introduce the concept of generalization of therapeutic techniques to other contexts. For example, if a client has been working on increasing his assertive behavior with his wife around money issues, the therapist may ask him to role-play confrontation with a friend or a problem at work. Further, a therapist may ask the client to take on various roles to gain other's perspectives on a problematic situation. This type of role-play is termed role reversal and is useful in challenging and modifying automatic thoughts concerning how a client is perceived by others.

Other forms of behavioral rehearsal that may be used as an adjunct to role-play are instruction, physical guidance, modeling, and imagery rehearsal. The decision to incorporate other techniques will depend on the desired skill or the behavior to be changed, the nature of the situation, and the current level of client functioning. For example, if the goal is acquisition of a new skill or if the client's behavioral repertoire is lacking, modeling appropriate behaviors may be required prior to initiating role-playing. Effective intervention with complex new skills may require breaking the skill down into smaller components and role-playing each component, gradually piecing together the total skill. An individual with a severe snake phobia may need to practice imaginal exposure or watch others interact with snakes before he or she is able to role-play exposure to a toy snake.

C. Guidelines for Use

The effectiveness of role-play techniques may be increased with the following strategies:

1. Make the scenarios as realistic and as close to the actual problematic situation as possible.
2. Start role-play with simple situations and graduate to more complex situations and behaviors.
3. Use a variety of different scenarios to help generalize skills to different contexts.
4. Specific role-plays should target the most salient problem behaviors for each client.
5. Monitor a client's progress over time. It may be helpful to provide a graphic depiction of the client's progress. For example, if the frequency of occurrence of target behaviors is the rating focus, the

therapist can plot changes in this frequency within and across sessions.

5. If role-plays are to be conducted across time as part of an ongoing assessment, care should be taken to standardize instructions and scenarios to ensure that it is the client's behavior that is being assessed, not changes in the scene, environment, or other individual(s) in the scene.

D. Advantages and Disadvantages

As with any procedure, there are numerous advantages and disadvantages to the use of role-play in assessment and as a therapeutic intervention.

1. Advantages

Role-play allows for the direct observation of clients' verbal and nonverbal behaviors. It can be used to corroborate self-reports of problem behaviors. Role-play assessments of target behaviors are easily conducted in the research laboratory or the therapist's office and are inexpensive. It provides a rich record of client responses that are difficult to assess using paper and pencil measures or interviews. Role-play scenarios are typically brief, so many can be conducted within one session.

Role-play can have many advantages in therapy. Clients frequently experience difficulties completing homework assignments at home. Role-playing within session may help decrease fears about the assignment and increase compliance. Role-play allows clients to achieve small successes, which in turn increase motivation for change. Further, role-play can be used as a steppingstone for performing more complex skills or conducting *in vivo* practice of target behaviors.

2. Disadvantages

There are also several disadvantages to consider. Scenarios need to be standardized in order to provide an accurate assessment of behavior change. Inconsistencies in the behavior of a confederate or the format of stimuli used may impact the behavior of the client and may inaccurately suggest improvement and make comparisons difficult. Perhaps the most salient limitation is the questionable criterion validity of role-play. The participants' or clients' behavior in session or in a research setting may not be an accurate representation of their behavior in a natural situation. Also, the therapist is not able to sample all possible scenarios, thus there is a potentially erroneous assumption of cross-situational consistency. Finally, the accuracy of the simulations themselves may not be completely acceptable in all scenarios.

II. THEORETICAL BASIS

In this discussion, role-play is presented as a behavioral technique and its utilization is based on the behavioral principle of focusing assessment and treatment on observable behaviors. It is not meant to provide an understanding of the etiology of a behavior; rather, problematic behaviors are identified and modified through practice in simulated situations regardless of etiology.

The theory of operant conditioning holds that the probability of the occurrence of specific behaviors is determined by the contingent consequences of those behaviors. The frequency of a behavior can be increased through positive (i.e., adding a desired stimulus) or negative (i.e., removing an aversive stimulus) reinforcement and decreased through positive or negative punishment. In cases in which the target behavior does not occur or is not yet a part of the client's behavioral repertoire, modeling (i.e., observational learning) may be used to introduce the behavior. Depending on the complexity of the target behavior, shaping (i.e., reinforcing approximations of the target behavior) may be incorporated in the role-play.

Once the skill is learned and the behavior performed, the therapist uses positive reinforcement to increase the occurrence of the behavior and to encourage the client to engage in the behavior outside of the therapy session. It is hoped that the modified behavior will positively impact the contingencies, further reinforcing the client's desire to engage in the behavior.

III. EMPIRICAL STUDIES

Research evaluating the validity of the use of role-play in either an assessment or as part of a therapeutic intervention is somewhat limited and dated. One of the primary difficulties involved in conducting such research is the lack of standardization of role-play stimuli used across studies. For the most part, research demonstrates that ratings of subjects' behavior responding to simulated situations correlates highly with evaluations of those who knew respondents well. Role-play (alone or as part of a treatment protocol) has been found to be effective for emotional and behavioral disorders including depression, social skills training, anxiety, phobias, aggression, and interpersonal problem solving. Role-play also has some support for prevention efforts. In 2000, Arthur Perlini and Christine Ward investigated the effectiveness of HIV prevention interventions and found that role-play was associated with increased

knowledge about AIDS and HIV in comparison to video, lecture, or no intervention.

technique for a variety of difficulties including anxiety and interpersonal interactions.

IV. SUMMARY

Role-play techniques have been widely used in behavioral assessment, as part of therapeutic interventions, and as a means of evaluating therapeutic interventions. Empirical support for role-play is fair; however, there are a number of factors that limit one's ability to evaluate techniques across studies. There are numerous advantages (e.g., brief and inexpensive) and disadvantages (e.g., questionable criterion validity) to consider when deciding whether or not to use role-play. However, it appears to be an appropriate

GLOSSARY

psychosis A mental state characterized by loss of reality testing as in delusions and hallucinations, often accompanied with severe interferences with the capacity to meet the ordinary demands of life, maintaining social and personal boundaries, manage profound levels of anxiety, focus attention, and experience pleasure.

schizophrenia A disorder of cognition and behavior that lasts for at least 6 months and includes two or more of the following: delusions, hallucinations, disorganized speech (positive symptoms), grossly disorganized or catatonic behavior (disorganized symptoms), emotional flattening, poverty of thought, and speech and severe impairments in motivation (negative symptoms).

I. INTRODUCTION

Contemporary treatment of patients with schizophrenia is an amalgam of its biopsychosocial determinants, heterogeneous presentation, and phasic course. It includes psychopharmacological, psychoeducational, and rehabilitative interventions, and a continuum of care

with a variety of ambulatory-based alternatives. Comprehensive treatment tailors these interventions to the phase of illness and is reinforced with a variety of flexible and supportive psychotherapies that emphasize medication compliance, problem-solving tasks, community reintegration and tenure, and in its most stable phase, conflict resolution and personal growth. This article describes the evolution and implementation of these psychotherapies as well as their interface with the various above-mentioned interventions.

II. HISTORY

Although Sigmund Freud was skeptical about the use of psychoanalytical therapy for patients with schizophrenia, many practitioners from early in the 20th century applied his methods for these patients. Because of their withdrawal from the external world and essential narcissism (e.g., autism), Freud felt that patients with psychotic disorders were unable to form a meaningful, stable, and workable transference, the basis of psychoanalytic treatment. This inability made it difficult to work through unconscious conflicts and their accompanying defenses as they appeared in relation to the therapist. Other psychoanalytic pioneers and followers of Freud, such as Paul Federn, Karl Abraham, and Carl Jung, felt otherwise and began a long tradition of utilizing insight-based techniques that developed side by side with psychodynamically oriented psychotherapy generally. To the earliest list was added the

work of Victor Tausk, A. A. Brill, Wilhelm Reich, Gregory Zilboorg, Sandor Ferenczi, and Ernst Simmel. Simmel and Georg Groddeck introduced the psychodynamic approach into the mental hospital. It is noteworthy that all these early practitioners recommended modifications of the traditional analytic technique to be more directive, less focused on the transference, and employing more techniques than interpretation alone.

Use of these modified approaches reached its peak in the United States in the post-World War II decades of the 1940s and 1950s. Represented in the work of Harry Stack Sullivan, Frieda Fromm-Reichman, and Harold Searles, practitioners of the interpersonal school of psychiatry worked with patients as if schizophrenia were fundamentally a disorder of interpersonal relatedness. Along with British object relations theorists and practitioners such as Melanie Klein, Wilfred Bion, and Herbert Rosenfeld, these therapists believed that the illness was caused and could ultimately be cured, or at least significantly ameliorated, by interpersonal, psychotherapeutic, and interpretive techniques. Although much of the focus of treatment remained with an elucidation of the meaning of various symptoms and their relationship to the patient's past and current stressors, modifications in classical technique continued with patients being seen face to face, often less than daily, and with much more interaction between patient and therapist.

In the decades of the 1960s and 1970s clinicians like Lewis Hill, Milton Wexler, and Victor Rosen continued the psychodynamically oriented approach to patients with the idea that psychosis was just like neurosis only more so. Others, like Ruth and Ted Lidz, Steven Fleck, and Lyman Wynne, supported somewhat by the previous work of Searles, believed that schizophrenic pathology made it difficult to attain adequate separation from important figures in the patient's life. As opposed to the primacy of intrapsychic conflict, this more developmental or family point of view focused on the etiological role of dysfunctional events and faulty communication patterns within families. At the same time, this approach led to a more reality-based, adaptive thrust with straightforward language and problem-solving techniques. Unfortunately for those espousing this approach, the dysfunctional impact on families of living with a family member with schizophrenia was not adequately considered.

After reaching a peak in the two decades between 1950 and 1970, the clinical use of, reimbursement for, and educational input toward the psychodynamically informed psychotherapy for patients with schizophrenic, schizoaffective and psychotic depression steadily declined in the United States. The causes for

this decline are well known and reflect a myriad of documented social, scientific, and economic realities. The development of the earliest antipsychotic medications dramatically reduced some of the most dramatic symptoms of psychosis. Research efforts were unable to confirm the effectiveness of psychotherapy, whereas others demonstrated a lack of its effectiveness. Questions about patient selection invalidated many of the remarkable and compelling anecdotal case reports of successful treatment. In addition, there was a dramatic proliferation of nonpsychological forms of treatment, and trends in the overall practice of psychotherapy itself shifted in ideology from psychodynamic to interpersonal to cognitive-behavioral modalities of therapy.

III. CONTEMPORARY APPROACHES

This nearly 30-year decline in the practice of dynamically informed psychotherapy for patients with psychotic disorders appears to be slowing down and even leveling off. There are several factors that account for this shift, not the least of which, paradoxically, is the revolution in and explosive growth of neuroscience over the last two decades. This growth directly affected psychotherapeutic work in two ways. First, there has been a clear-cut, experimentally verified recognition of the dynamic interplay between heredity and environment, between hard wiring and experience and between protein synthesis at the receptor site and input from the perceptual apparatus. Thus, a modern conception of severe mental disturbance suggests that the structure of a psychosis derives from the patient's genetic predisposition, prenatal environment, constitution and brain; whereas its content (the expression and experience of illness) issues from the patient's developmental environment, meaning system and mind. Because the interaction of psychosocial stressors and brain vulnerability leads to dysfunctional adaptation, optimal treatment addresses both sides of the interaction.

The second and more practical effect of the remarkable advances in *neuroscience* is the ability to design pharmacological agents to enhance effectiveness with the positive and disorganizing aspects of the illness and diminish some of those agents' most irritating side effects. Far from being perfect, the new so-called atypical antipsychotics also show promise for mitigating negative symptoms without the troubling extrapyramidal side effects of earlier neuroleptics. Much like the application of a brace to the paralyzed limb of a stroke victim, the antipsychotics appear to protect the

receptor site on an affected neuron against continued overstimulation. Neither intervention cures the fundamental pathological condition, but in both cases their removal activates the symptoms: in the first case, hemiplegia; and in the second, decompensation and the exacerbation of psychotic symptoms.

The ability to manage positive, negative, and disorganized symptoms, the most debilitating aspects of schizophrenic illness, have made the patient more available for psychotherapy and brought the following crucial treatment issues into bolder relief: personality and character, treatment compliance and therapeutic alliance, and long-standing cognitive, social, and vocational deficits. With respect to personality and character, it was within the past decade that many believed that a diagnosis within Axis I of schizophrenia or schizoaffective illness precluded the personality or character diagnoses of Axis II. This was because regression to psychotic levels was presumed to have a fundamental and disorganizing effect on identity, personality, and coherence of the self-concept. Most people who work closely with these patients, however, believe the personality remains essentially intact and, depending on its configuration, can have both facilitating and inhibiting influences on the treatment, the treatment alliance, and the course of illness. The emergence of personhood in the previously withdrawn and disorganized patient makes the patient available to discuss the substantial problems of living that result from debilitating illness and form the centerpiece of an effective psychotherapeutic process. Other issues that may come to the foreground as a result of effective medication include depression, negative symptoms, and a profound demoralization and despair about the afflicted individual's deviance from the mainstream of friendship and social life.

The reduction of disorganizing symptoms also makes it possible to look more closely at the treatment alliance and some of its resistances, and secondarily, of course, the whole question of treatment compliance. Treatment alliance is critical for the success of any of the therapies proposed in this section and takes us immediately into the realm of object relations and interpersonal theories. Unlike Freud's conceptualization of the narcissistic neurosis, it is now more commonly believed the problem with the transference in these patients is not that there is not enough for a treatment alliance; rather, the issue appears over and over to be a very intense and highly unstable alliance and difficult to manage transference reaction. As mentioned there is by this time an enormous anecdotal literature on this subject, most of which precedes the modern pharmacological era. Clinicians

continue to report on this kind of work with patients. In these highly evocative accounts, the vicissitudes of attachment and separation and transference and countertransference suggest much that can be reexplored and investigated with today's patient in an entirely new context and without the same level of anxiety about losing or doing damage to a patient. Psychodynamically oriented psychotherapy, however, with its emphasis on the regressive transference neurosis, may well be overstimulating for many of these patients especially in the early and more volatile phases of the illness. Thus, keeping in mind issues of separation and attachment while helping the patient reintegrate and cope—without focusing on them—becomes the task of the therapy.

Very often the psychotherapist of the patient with schizophrenia must perform auxiliary ego functions such as reality testing, assistance with impulse control, anticipation of consequences (judgment), and sharpening self-object differentiation. Therefore, the most widely practiced form of psychotherapy for patients with schizophrenia is supportive. The techniques include the establishment and maintenance of the therapeutic alliance, a steady focus on medication compliance and side effects, and paying attention to and helping reduce stress. These techniques are supported with clarification, education, and reassurance and are the heir to the psychodynamic tradition in which the relationship between therapist and patient is crucial and adaptive defenses are encouraged and reinforced. Finding the appropriate synthesis of the modifications from traditional psychotherapeutic technique, developing and maintaining a stable and durable therapeutic alliance, while keeping in touch with the dynamic unconscious, comprise the art of the therapeutic work with these patients. Furthermore, supportive psychotherapy is the basis of the majority of contemporary psychotherapies for the illness in virtually all its forms and phases. Figure 1 outlines the historical trends in the psychodynamically oriented psychotherapy of patients with schizophrenia.

Compliance with effective medication regimens is one of the most important issues in the ongoing treatment of patients with schizophrenia. The idea of learning in more detail about a patient's reluctance to continue a medication that is fostering the reintegration of his or her personality may be quite helpful. Is noncompliance the same or does it go beyond the same kind of denial of illness that one sees in any chronic illness, diabetes for example, in which issues of pride and autonomy play such a strong role in problems with compliance? Or is this denial significantly connected to the patient's low awareness of symptoms?

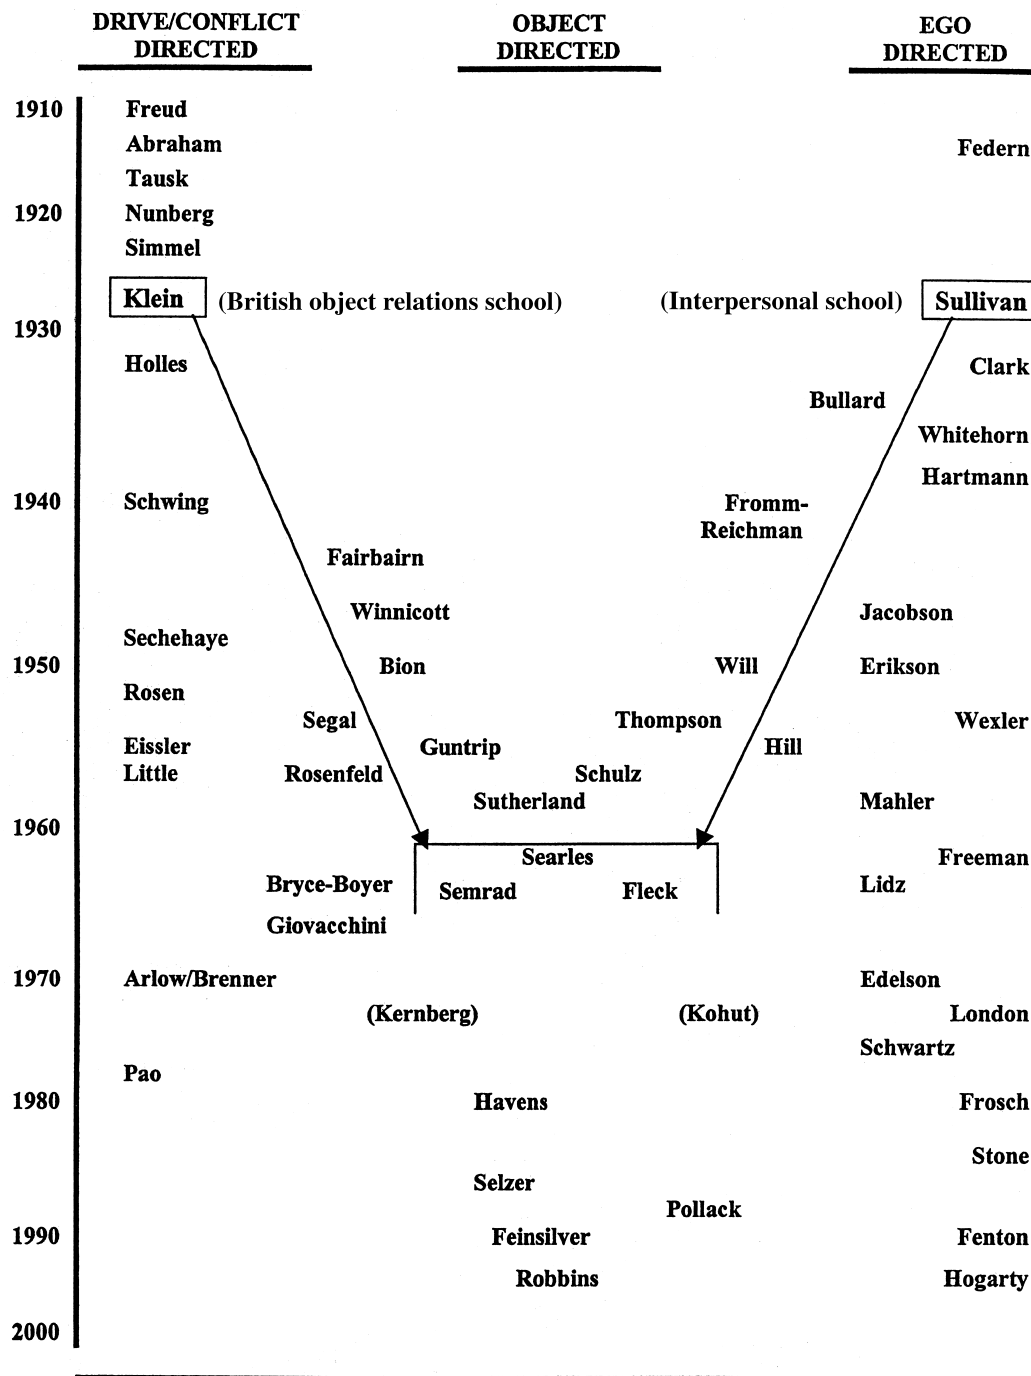

FIGURE 1 Major theoretical/clinical trends in psychotherapy of schizophrenia. Reproduced with permission from Spiegel (ed.). (1999). *Efficacy and Cost-Effectiveness of Psychotherapy*. Washington, DC: American Psychiatric Press.

Or is the reluctance to continue medication more like the patient with a bipolar disorder who stops their lithium or valproic acid because they miss the intense high associated with a manic state? Or is it a flight

from inner deadness, a manipulative effort to obtain more from the treatment team, or a retreat from the despair associated with the many demands of external reality in the absence of requisite adaptive skills? Or

finally, is it yet another manifestation of basic faults in internalized object relations alluded to when speaking of issues of attachment and separation earlier?

When a patient is not threatened so immediately and unpredictably by disorganizing symptoms, the psychotherapist is in a much better position to understand the dysfunctional interaction of these relevant and dynamic issues. It is noteworthy, however, that these issues may be sidestepped in many contemporary educative and rehabilitative approaches that take the position that non-compliance has more to do with a poor understanding of the illness, its symptoms, and the role of medications.

One of the most painful but important issues to emerge as a result of more effective psychotropic medication is the clear-cut cognitive, social, and vocational deficits that inhibit the functional adaptation of many of the patients with serious and persistent mental illness. In an increasingly technological age it may be preferable, in fact, to be considered mentally ill than it is to be labeled a "drop-out." There are many patients who have emerged from several years of psychosis and withdrawal only to discover they are way behind their peers in the capacity to solve the problems of everyday life, to feel socially attuned, to enter the workforce, or otherwise construct a meaningful life. These represent another kind of deficit, a deficit that results from being more or less "out of it" and which adds a new dimension to the illness itself. Various forms of psychotherapy are especially helpful with the problems in living that are functional and emotional sequelae of severe mental illness.

IV. LINKING PSYCHOTHERAPY WITH PHASE OF ILLNESS

Growing from the work of John Strauss and his colleagues at Yale utilizing longitudinal patterns and an interactive-developmental model, Wayne Fenton and his colleagues at the Chestnut Lodge Hospital formulated a set of phases through which symptoms develop, progress and retreat. The phases include

1. A prodromal period signaled by a constellation of symptoms including sleep difficulty, perceptual abnormalities, and social isolation.
2. An acute or active phase with the characteristic signs of decompensation.
3. A subacute or convalescent phase characterized by a reduction in florid symptoms, some reorganization of function, especially reality testing, and postpsychotic depression.

4. Moratoriums or adaptive plateaus during which, somewhat like the latency period of psychosexual development, there is a consolidation of gains, a gradual restitution of personal identity and a strengthening of confidence and adaptive skills.

5. Change points, called "mountain climbing" by Strauss during which there may be upward shifts in functioning (moving from halfway house to community; beginning a job, etc) either self-motivated or initiated by others but that carry potential for improvement or relapse.

6. Stable plateaus which can be more or less enduring and range from remission to fixed deficits or persistent symptoms.

Instead of a monolithic therapeutic approach to patients with psychotic disorders, the contemporary clinician flexibly modifies his or her interventions and contact according to the phase of illness. In this approach, that sensitive clinicians have long understood, therapeutic contact may range from quite time limited, reality based, problem solving, and ego supportive along one end of the continuum to more exploratory, nondirective, interpretive, and insight oriented along the other end. More specifically, during the acute phase, at onset of the psychosis, exacerbation or relapse of illness, the focus is on acute symptom stabilization, and the therapist is encouraged to be supportive and directive. Because patients in the acute phase are often out of touch with reality and highly sensitive to social stimulation, group therapy is contraindicated at this time.

In the subacute and convalescent phase, the supportive and directive approach is continued with the additional task of assessing stressors and vulnerabilities, mobilizing social supports and constructing the treatment team. The subacute and convalescent phase corresponds in timing and intervention to the basic phase of so-called personal therapy outlined by Hogarty and his colleagues at Pittsburgh. If group modalities are used during this phase, they should also be supportive and interactive as opposed to uncovering and insight oriented. Group therapy can be helpful in this phase if the patient does not have prominent paranoid or negative symptoms, and it can be helpful with discharge planning and return to the community.

In the first moratorium or adaptive plateau, the therapist can begin focusing on the treatment alliance and helping the patient with problem solving. In this phase interventions are tempered with considerable reassurance, supporting defenses and strengths. This approach is consistent with the idea that this is a phase

in which the patient is consolidating gains and restoring self-esteem. It is at this point that Hogarty's personal therapy would also introduce a step-by-step plan for the resumption of expected roles as well as the provision of social and avoidance techniques from social skills training. Group therapy during this phase is dependent on the patient's baseline level of functioning: for patients who can converse normally and function well between episodes, an interactive, non-insight-oriented approach is recommended; for those with chronic conditions and relatively good premorbid functioning, behaviorally oriented approaches should be used (see later).

When the patient moves to the next phase, begins to contemplate or becomes involved in changing status or venue, the therapy, now based on a reasonably solid treatment alliance, might begin to identify individual-specific prodromal and relapse factors because this is a very vulnerable time. This is also a phase when denial of illness may become prominent, so the therapist must pay attention to the patient's level of acceptance of illness. This phase roughly corresponds to Hogarty's intermediate phase. At this point his team provides internal coping strategies that include the identification of individual, cognitive and somatic indicators of distress, and the appropriate application of basic relaxation and cognitive reframing techniques.

After stable plateaus have been achieved and community reintegration and tenure sustained, the regular and by this point more traditional admixture of supportive and expressive psychotherapy can be employed. Here, interpretations continue to be quite modest, signs of regression are monitored very closely, and it is the patient who sets the pace of discovery. The later phases of recovery from the illness are usually those in which rehabilitative modalities are employed, inevitably highlighting the patient's premorbid difficulties, stressful familial patterns, and vulnerability to the social and technological demands of modern culture. This phase corresponds to Hogarty's advanced phase of personal therapy and includes encouragement for social and vocational initiatives in the community, progressive awareness of one's affect, together with its expression and perceived effect on the behavior of others. This latter phase also includes principles of criticism management and conflict resolution. Although it is a relatively recent addition to technique, personal therapy has modest research support.

Higher functioning patients may utilize an interactive group psychotherapy on an outpatient basis to learn more about their illness, to understand and uti-

lize their medications more effectively, apply reality testing as positive symptoms threaten to emerge, and learn communication and problem-solving skills. Ambulatory patients with more severe disorders are best served with approaches derived from cognitive and problem-solving techniques, as well as skill training derived from more recent psychiatric rehabilitation methods. Many recommend co-therapists in groups for patients with schizophrenia, somewhat more personal disclosure as compared to that in groups for patients with character disorders, and a steady focus on the techniques of clarification, support, and the here and now of interpersonal interactions. There is virtually universal agreement that interpretive activity aimed at uncovering unconscious conflict is contraindicated in group work with this population.

In the resurgence of psychotherapy for patients with serious disorders, the psychodynamics are far more part of the understanding than they are of the technique. The psychotherapy is much more a part of the treatment than the principal element in or the guide of the treatment. The psychotherapy is more flexible, adjusting to the phase of illness and primarily supportive, focal and educative rather than explorative, general and insight oriented. It is more about coping, adapting, problem solving, and coming to terms with deficits rather than collaborating in a regressive enterprise to uncover and resolve conflict. Emerging from the ego psychological point of view, this version of supportive psychotherapy is more reality based and adaptive and closer to a developmental and educative rather than an interpersonal and interpretive focus. It might even be called rehabilitative psychotherapy. This point of view is closest to that held by Lidz and others, and it contrasts with a more interpersonal and interpretive point of view outlined by Harry Stack Sullivan and held by Otto Will, Elvin Semrad, and Michael Robbins (see Table 1).

V. COGNITIVE STRATEGIES

The last two decades have seen a rapid increase in an interest in schizophrenia from a neurocognitive perspective, beginning with a focus on attentional dysfunction and moving to the more recent focus on working memory and its various components. This interest has naturally led to innovative treatment approaches. Cognitive-behavioral therapies (CBT) for patients with schizophrenia and other psychoses represents a radical departure from traditional, and even from the flexible

TABLE 1
Listening to the Patient with a Psychotic Disorder: Interpersonal and Developmental Psychodynamic Views

<i>Issue</i>	<i>Interpersonal</i>	<i>Developmental</i>
Advocacy	Sullivan, Will, Semrad, Selzer, Robbins	Lidz, Fleck, Wynne, MacFarland, Leff
Etiology	Interpersonal Primary versus secondary incapacity to cathect an object	Interfamilial Actual Dysfunctional events Faulty communication patterns
Symptom	Failure to connect with objects	Failure to separate from objects
Best theory	Closer to object relations	Closer to self-psychology
Treatment goal	Address deficits interfering with therapeutic alliance (self-other differentiation, faulty reality testing, observing ego).	Address pathogenic family transactions interfering with continuing development (marital schism, marital skew, double binds)
Individual psychotherapy	Conflict resolution Transference-countertransference Relate associations, restitutional phenomena to alliance	Problem solving Real, tangible life problems Discourage free association and exploration of restitutional phenomena
Milieu organized to:	Support psychotherapy; more confrontation	Support adaptive skills; less confrontation
Similarities	Both approaches look for and reinforce health functioning, tolerate regression, and minimize the use of somatic modalities.

and personal psychotherapies of the last decade. CBT shifts the focus of intervention from the internal, dynamic, and supportive expressive to the external, symptom centered, and highly structured. Rather than a model of the mind based on psychoanalytic thought and various theories about the etiology of severe psychopathology, CBT addresses distortions in the cognitive sets or schemata that individuals develop to organize and understand their experience. These distortions may effect social-cognitive, perceptual, and inferential processes and lead to such diverse phenomena as hallucinations or delusional beliefs. Thus, rather than confronting or interpreting a delusion, the form and content of that false percept or belief, CBT's approach establishes a therapeutic alliance that increases the awareness and inconsistency of the belief. The goal is the replacement of the dysfunctional and maladaptive belief with one that is more evidence and reality based.

CBT for patients with schizophrenia and psychotic symptoms are based on the cognitive therapy developed in the 1960s and 1970s by Albert Ellis and Aaron Beck for patients with depression and anxiety. The emphasis placed on a nonthreatening and supportive therapeutic alliance, the effort to find aspects of the patient that are normal to help solve problems and a focus on adaptation and current problems harkens back to the

developmental perspective on individual psychotherapy and have much in common with other contemporary psychotherapeutic treatments. The collaborative and accepting mode of the treatment focuses on the symptoms and problems that the patient wishes to address. A rational and common-sense approach is taken to the patient's attitudes, underlying assumptions, symptoms, and problems of daily living.

The major CBT approaches to these disorders include belief modification, focusing/retribution, normalizing, cognitive therapy following acute psychosis, cognitive therapy for early psychosis, coping strategy enhancement and combinations of these. In belief modification, the patient is urged to view a delusion as only one possible alternative explanation of events. Without telling the patient that the belief is wrong, evidence for the belief may be challenged while inconsistencies are pointed out. Nonconfrontational verbal challenge and empirical testing help modify the degree of conviction patients may hold toward their beliefs.

Focusing/retribution is the intervention most suited for patients with auditory hallucinations. Over a series of sessions the patient is asked to focus on specific aspects of the hallucinatory experience, from the characteristics of the voices, their content, and the patient's

beliefs and thoughts about the voices. Following sessions, patients are given “homework” assignments to record these matters that are then used to discuss the timing and context of the hallucinations. The ultimate goal of this technique is to change the attribution of the voice from external to the patient to the patients themselves. Similarly, in the normalizing technique, the therapist attempts to help the patient describe the situation and stressors immediately preceding the onset of symptoms, as well as elucidate the cognitive distortions at the time of the onset. Normalizing also utilizes relaxation and anxiety management techniques, as well as the diary and notebook assignments as in the homework sessions described earlier. Much like the interpersonal school of psychoanalysis, every effort is made to emphasize the continuity of psychotic and normal experience and to reduce stigma and distress.

CBT interventions in acute psychosis and early psychosis combines many of the elements listed earlier but also include small group work in which patients are exposed to the irrationalities and inconsistencies of other group members, thus reducing some of the pressure on the individual patient. Efforts are also made to help patients integrate the experience, much like in the normalization technique, and families are encouraged to cooperate in helping reduce stress. These techniques also include illness education and focus on issues of motivation and stigma. Many of these techniques mirror the early phase of illness work in flexible and personal psychotherapies described earlier.

Coping strategy enhancement involves the reinforcement of those techniques already employed by patients to compensate for their illness. This method helps patients identify those environmental stressors that trigger dysfunctional cognitive, behavioral, and physiological reactions leading to psychotic symptoms. The process includes the careful and systematic identification and following of symptoms and their contexts, enhancement and development of ongoing strategies in response to the symptoms, and practicing new strategies in the sessions, and with homework assignments between sessions. Patients are taught to prioritize symptoms, whether or not to increase or decrease their activity, sensory input or social involvement in response to each symptom.

Because cognitive therapies have clear protocols, it is easier to design studies of effectiveness than with more dynamically oriented treatments. Since 1990 there have been well over a dozen variably controlled studies of the types of CBT mentioned earlier. The results are best for those patients with clear-cut symptoms and who acknowledge those symptoms as ones to be addressed.

Within that group the most effective results are with those patients with delusional symptoms. Investigators in the field are calling for better controlled studies with better and more random patient selection with respect to severity and concurrent treatments.

VI. RELATED MODALITIES

The final developments that have modified the practice of psychotherapy for patients with psychotic disorders is the increased sophistication in other modalities of treatment beyond psychotherapy and psychopharmacology. These techniques include psychoeducation, psychiatric rehabilitation, case management and assertive community treatment. These techniques serve to reduce stressors, facilitate adaptation, improve thinking, and mobilize resources in ways that reinforce self-esteem and enlarge the conflict-free zone, freeing the psychotherapist to more collaboratively share a focus with the patient in a more expansive and interrelated manner. These modalities address areas that were rarely meant to be dealt with in traditional psychotherapies.

Psychoeducational approaches do not dwell on the past and do not employ confrontative nor particularly interpretive techniques; rather, they make an effort to increase the family's knowledge of the illness and facilitate a rapprochement between parent and afflicted child, thus decreasing the pressure on both. Gone are the efforts to separate patients and their families. By reducing the stressors associated with dysfunctional interactions, experimental evidence has indicated a reduction in relapse rates. Then, like the early advertisements about medication, the patient becomes more amenable to and more continually available for the previously described, phase-appropriate psychotherapeutic interventions.

It is clear that medication, dynamic, personal, psychoeducational, and cognitive-behavioral therapies do not solve all the problems confronting the patient with a psychotic disorder. This is the case because most problems in living, especially for someone recovering from psychosis, have many interrelated components. With respect to the matter of social adjustment, for example, it is worth noting just how much might be involved from the different neuropsychological spheres encompassing sending, receiving, and processing. Starting at the foundation, social adjustment requires molecular skills such as eye contact and what to say in an introductory conversation—sending information. Acquiring these skills requires a sufficient level of motivation. Another critical element at the foundation for social

adjustment is the ability to perceive social cues, such as knowing when one might be welcome versus when one might be interrupting—receiving information. Acquiring social perception requires the capacity for self-object differentiation as well as the ability to recognize affects in the other. The final element in the foundation is problem solving. As mentioned, problem solving depends on intact cognitive processes, especially as has been more recently demonstrated, memory and visual-spatial mechanisms—processing information. Thus, effective treatment for social adjustment—a crucial factor in community reintegration and tenure—could involve cognitive remediation, social skills training, and psychotherapy—three separate treatment modalities, before coalescing into the molar skills necessary for social competence. And even then, these instrumental skills must be integrated with attachment needs. Insofar as some patients have the instrumental skills premorbidly, then a dynamically oriented psychotherapy that is helpful around issues of affiliation and attachment may be all that is needed. It is unusual, however, that this kind of intervention is sufficient for the modal patient with a psychotic disorder. Personal therapy as practiced by Hogarty and his colleagues appears to combine the elements most important for social adjustment. Their recently published study of 151 patients demonstrated a steady improvement in social adjustment for those patients living within a family. Their treatment had no effect on symptoms or anxiety and actually increased relapse rate in those patients living outside a family. Thus, like the recommendations of Fenton, they recommend that the later phases of their treatment await symptom and residential stability. Figure 2 outlines the many factors involved in social adjustment.

There is an important note to be made about the new modalities in the context of psychotherapy. Incompatible as they may seem on the surface, there are aspects of the contemporary treatment of schizophrenia and other psychotic disorders that are heir to the psychodynamic tradition in the continuing treatment of the seriously and persistently mentally ill. In determining a patient's specific rehabilitation goals, ideal environment and readiness for these interventions, the patient's interest and motivation, meaning system, symbolic, and value-laden world are critical. These emerge from the biopsychosocial model of illness and a thorough understanding of the patient and provide the energy for and shape of the treatment plan.

Expecting too much from or being too quickly discouraged with the lack of progress of a recovering patient can replicate exacerbating features such as high levels of tension or demoralization. Therefore, issues of

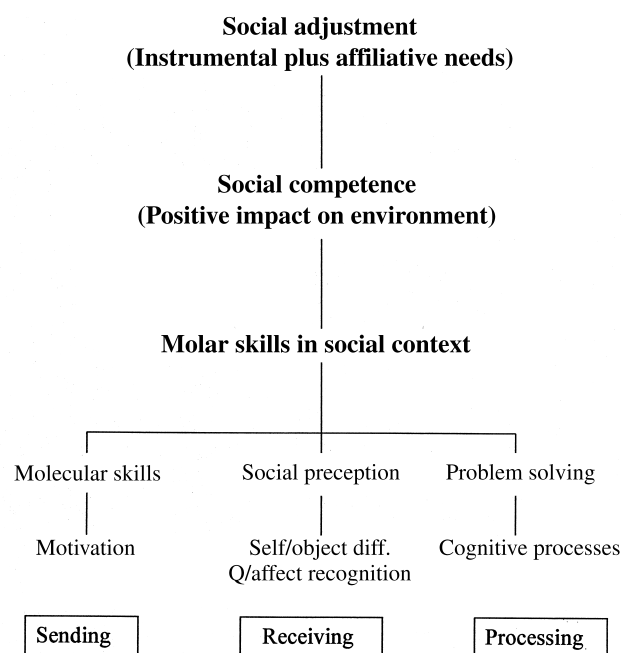

FIGURE 2 Elements of social adjustment.

psychological safety and trust are paramount, leading to difficulty coming to a shared reality and experiencing helpful intentions from a caregiver. A familiarity with the principles of psychodynamic psychiatry, with its emphasis on unconscious mental life, its principle of multiple determinants of actions, thoughts, and feelings, areas of sensitivity and vulnerability, and the presence of the past in the present—especially as represented in self- and object relations and transference phenomena, can only enhance the sensitivity and effectiveness of the treatment professional. Finally, the effectiveness of other treatments makes it possible for more appropriate technical neutrality than has often been the case in the psychotherapy for patients with a psychotic disorder. This is not meant in the sense, of course, of being a neutral object; rather, it means freeing the psychotherapist to shape the psychotherapy to fit the patient, whether it be from the point of view of therapeutic activity as previously mentioned, or whether it concerns itself with the patient's drives, ego operations, object relational, interpersonal, or self-system paradigms.

GLOSSARY

- anticipatory anxiety** Anticipating one's future anxiety when thinking about an anxiety-producing situation.
- counterconditioning** The replacement of one conditioned response to a stimulus by another.
- hierarchy** An arrangement of anxiety-producing scenes, from low anxiety arousal to high anxiety arousal.
- in vivo desensitization** Desensitization based on exposure to real-life anxiety-producing situations, generally by the practice of coping strategies.
- proprioceptive responses** Internal physiological responses, such as muscle tension, that occur in response to anxiety-producing situations.
- reciprocal inhibition** The inhibition of a learned anxiety response by pairing a new adaptive response with the original anxiety-producing situation.
- self-control desensitization** Desensitization based on a coping skills mediational format involving sensitivity to proprioceptive cues and cognitive relabeling.
- systematic desensitization** Reducing the connection between an anxiety-producing stimulus and anxiety by pairing an anxiety-incompatible response with the original stimulus.

I. DESCRIPTION OF TREATMENT

Self-control desensitization is a variant of systematic desensitization that gives more control of the procedure to clients than does the latter, which is therapist run. It is also based on a somewhat different theoretical model. In self-control desensitization, clients are given a rationale that is essentially coping skills oriented in nature. They are told that they have learned, on the basis of past experience, to react to certain situations by becoming anxious, tense, or nervous. They are then told they will learn new coping strategies to replace these negative reactions with more adaptable ones. They are taught the relaxation skills and other coping methods, such as breathing control and attention to internal sensations, and are then instructed to use them in a hierarchy of anxiety-producing situations to relax away tensions and provide covert rehearsal for situations they may face. The anxiety-producing scenes in the hierarchy are constructed jointly by the therapist and the client, and the client is asked to imagine them for 10 to 15 sec if there is no anxiety response. If there is such a response, the client is asked to terminate the scene and concentrate only on relaxation, relaxing away any tension. It is important that the use of these coping strategies be practiced repeatedly for the new coping skills to become well learned. This is especially important for scenes that arouse considerable anxiety.

The construction of the hierarchy originally followed the guidelines described by Wolpe in which it

was considered necessary to construct separate hierarchies for each specific anxiety-producing situation. However, in accordance with a more mediational paradigm, clients were taught to cope with their internal proprioceptive responses rather than coping directly with the situations that caused the anxiety. Thus, early on the use of exact hierarchies was not considered to be as important in self-control desensitization. In fact, the therapist was urged to include items that reflected a series of different anxiety-producing situations.

In systematic desensitization, it was considered important that scenes in the hierarchy be terminated if anxiety was aroused. In self-control desensitization clients are encouraged to remain in the scene if anxiety increases and to cope with this anxiety by relaxation or other coping strategies. Clients are encouraged to practice these new skills in real-life (*in vivo*) situations. The *in vivo* practice of these coping strategies in actual anxiety-producing situations should lead to enhancement of these skills.

II. THEORETICAL BASES

Systematic desensitization, as originally developed by Joseph Wolpe, was theoretically based on reducing anxiety by causing a response antagonistic to this anxiety to occur in the presence of the anxiety-producing stimulus. Thus, if the presence of a snake (the anxiety-producing stimulus), which normally produces anxiety, was paired with relaxation (a response antagonistic to anxiety), then a reduction in anxiety should occur. Wolpe thought that in this fashion the bond between the fear-producing stimulus (the snake) and the anxiety response would be weakened or reciprocally inhibited. Wolpe thought that it was important that a hierarchy of fear-producing stimuli (ranging from looking at the snake to approaching the snake to touching the snake) be constructed so the individual was not overwhelmed by anxiety early in the process. The procedure was based on the counterconditioning model in which the original bond between stimulus and anxiety response was automatically reduced or eliminated by the introduction of an antagonistic response.

Self-control desensitization was originally developed by Marvin Goldfried in 1971 and was based on a somewhat different theoretical rationale. Rather than considering relaxation as “reciprocally inhibiting” the anxiety response, Goldfried proposed a mediational model that was a forerunner of cognitive-behavior therapy. This mediational model consists of two aspects: the active construction of the muscular relaxation response and a

cognitive relabeling of the entire sequence between the fear-producing stimulus and the fear response. Theoretically, the client learns a method of actively coping with the anxiety rather than an automatic weakening of a psychological bond taking place. The client also learns to identify proprioceptive cues that are associated with muscular tension and to relax them away, essentially coping with these proprioceptive anxiety responses rather than the actual situations that elicit the anxiety. With considerable repetition, the client also learns to react to anticipatory anxiety with anticipatory relaxation, and eventually this process can become automatic in nature. However, both self-control desensitization and systematic desensitization are based on an important assumption of the counterconditioning model that the relaxation response must be stronger than the anxiety response for counterconditioning to occur.

Both systematic desensitization and self-control desensitization originally postulated that the construction and use of a hierarchy of anxiety-producing stimuli was important because a too-rapid introduction of an anxiety-producing stimulus might overwhelm the new relaxation response. If that occurred, it was thought that anxiety would reduce the relaxation rather than the reverse. However, research by Goldfried and Goldfried indicated that the use of a hierarchy of target-relevant behavior was not necessary for effective self-control desensitization. More recent research conducted on systematic desensitization itself has shown that a hierarchy may not be as necessary as originally thought. Implosive therapy (or “flooding”), in fact, is based on the opposite rationale—that it is more effective to begin at the top of the hierarchy rather than the bottom so that rapid extinction might take place. Thus, the construction of a hierarchy has been deemed less important as the theoretical explanatory model shifted from a counterconditioning to a coping skills model. Likewise, in line with the mediational model, it was not considered as important to terminate the anxiety-producing scene if anxiety increased; rather the client should implement the model by coping with the anxiety itself and relaxing it away. Only if the client is unable to tolerate the anxiety should the scene be terminated. The coping skills model assumes that skills are enhanced by practice and success under somewhat adverse conditions.

III. EMPIRICAL STUDIES

The majority of the empirical research on self-control desensitization was conducted in the 1970s and early 1980s, with some doctoral dissertations

conducted in the late 1980s. Summary literature and case studies combining self-control desensitization with similar techniques, such as applied relaxation and Suinn's Anxiety Management Training, have appeared well into the 1990s. Especially noteworthy are the series of studies conducted by Jerry Deffenbacher and his colleagues on comparisons of self-control desensitization with Anxiety Management Training and self-control relaxation. Other studies have compared it to systematic desensitization, rational restructuring, and neurolinguistic programming. Its use has been investigated primarily with anxiety disorders but also with related problems such as phobias, vaginismus, and the management of psychotic patients and individuals with mental retardation.

The research has shown that, although self-control desensitization is effective when compared to control groups receiving no treatment, it is no more effective than a variety of alternative treatments. Furthermore, the use of a graduated targeted hierarchy does not appear to be necessary. What appears to be the mechanism of its effectiveness is the gradual installation of coping skills by practice, perhaps with the attendant nonspecific effects of hope, confidence, and optimism.

IV. SUMMARY

Self-control desensitization is a modification of systematic desensitization, as originally developed by Joseph Wolpe. It relies on an active, mediational, coping skills model of change rather than a passive counter-conditioning model. It utilizes coping skills such as relaxation as alternative responses to an anxiety response in the presence of anxiety-producing stimuli. A hierarchy of anxiety-producing situations is often used although research and clinical observation have shown

that it is not as necessary as was once thought. Rather than terminate the scene as soon as anxiety is felt, clients are encouraged to remain in the situation and relax away the anxiety. *In vivo* practice in actual anxiety-producing situations is encouraged. It is similar in many ways to other self-control anxiety reduction techniques such as applied relaxation and Anxiety Management Training. Research has shown that self-control desensitization is effective for a variety of anxiety disorders but is not more effective than other cognitive or behavioral techniques.

GLOSSARY

self-management therapy A highly structured manualized, cognitive-behavioral therapy program for depression. Based on Frederick Kanfer's model of self-control, the treatment involves self-monitoring, self-evaluation, and self-control.

self-reward A strategy to increase probability of accomplishing difficult subgoal behaviors by setting up contingent rewards for their completion using a list of pleasurable activities for that purpose.

Self-control therapies involve teaching people skills and techniques for controlling their own behavior when striving to achieve long-term goals. It is usually assumed that people employ self-control implicitly in their efforts to change behavior, such as when starting a diet or exercise program. The self-control therapies attempt to teach these strategies in an explicit way. Many theories and therapies can be considered self-control theories. This article focuses on self-management therapy for depression developed by Lynn Rehm and his colleagues.

I. DESCRIPTION OF TREATMENT

Self-management therapy is a highly structured, manualized, cognitive-behavioral group therapy program for the treatment of depression. The program is currently presented in 14 weekly, one-and-a-half-hour sessions. Each session includes a didactic portion, a discussion period, in-session paper-and-pencil exercises, and weekly homework assignments that are reviewed at the beginning of the next session. It is an illustration of self-control therapies in that it is "transparent" to the participants. They are told that the depressive target of the intervention is identified, they are instructed in applying the intervention on their own, and they are told the theoretical rationale for the intervention. Participants are consciously applying psychological principles to change their own behavior.

Self-management therapy can be thought of in three ways. First, it is targeting specific components of depression and teaching the participants self-change techniques for modifying each target behavior. Second, it can be thought of as teaching principles of self-change in the context of depression. Third, it can be seen as teaching behaviors that are the opposite of depression, that is, positive self-esteem and self-control behaviors. People with positive self-esteem are people who accurately view their world, have a realistic sense of their abilities, set reasonable standards and goals, and are able to control their behavior with feedback to themselves.

The first session of the self-management therapy program serves to introduce the participants to one

another and to the program. The nature of depression is described and related to the symptoms presented by the participants. A brief overall description and rationale for the program is presented by the therapist. Homework for this first session involves keeping track of daily mood by rating average mood for each day on a scale of 0 to 10, where 0 is the worst most depressed day ever and 10 is the happiest day ever. The purpose of the assignment is to focus on daily variations in mood and to get participants used to the mood scale.

In the second session homework is reviewed with emphasis on participants' observations on their mood variability during the week and any correlates of their mood that they might have observed (e.g., felt better on days when they got out of the house). The didactic presentation in this session conveys a central idea in the program. The program is premised on the idea that mood is influenced by behavior and cognition, that is, activities that people engage in daily and the "self-statements" they make to themselves about what they do. Although the relationship may go both ways, the program is premised on the idea that depressed participants can change their daily mood and, thus, their depression by changing activities and self-statements. In various ways the rest of the program involves strategies for increasing positive activities and positive self-statements. The homework assignment is to continue monitoring mood and, in addition, to list positive activities and self-statements. This self-monitoring assignment is continued throughout the program with a variation in focus with each new topic.

In session three, the relationship between mood and events is demonstrated to participants by graphing their week's homework. For each day of the week the mood rating is graphed with a connected line. Then the total number of activities and self-statements for each day is graphed on the same form. Parallel lines illustrate the relationship between mood and activity. The homework assignment is to continue the self-monitoring logs daily.

The topic covered in the next session is the idea that any event has both positive and negative immediate and delayed consequences. When they are depressed, people tend to focus on immediate consequences. Activities can be positive either because they are immediately pleasurable or because they produce some delayed, or long-term positive outcome. Eating ice cream is immediately pleasurable whereas mowing the lawn may be a positive activity because the end product of a nice-looking lawn is pleasing. The homework assignment is to list each day at least one positive activity that is positive because it has a delayed positive effect. Each time such an activity is listed, a positive self-statement is to be listed noting the positive long-term effect.

Having covered the effects of activities, the next few sessions focus on their causes. Depressed persons are seen as making external, unstable, and specific attributions for positive events. "That was nice, but it wasn't my doing. It was just luck and may never happen again." Exercises in the session teach the participants to realistically take credit for positive activities. The exercise includes having participants take positive events from their self-monitoring logs and examine their causes. The homework assignment is to include in each day's self-monitoring log, one positive self-statement recognizing credit for taking responsibility for a positive activity.

In a parallel session, the idea is presented that depressed people tend to blame themselves for negative events. For a negative event, depressed persons tend to make internal, stable, and global attributions. In effect they are saying "It was my fault. I always fail in this way and I fail in everything else of this type." Again an exercise takes participants through a series of examples teaching them not to take excessive blame for negative effects, but instead, to see that some of the reasons for negative events are external, unstable, and specific. The homework assignment is to write a self-statement daily that diminishes blame from oneself for negative events.

Goal setting is the focus of the next sessions. Depressed persons tend to be disconnected from long-term goals, and they often set goals poorly. Drawing from the behavioral literature on goal setting, good goals should be positively stated, concretely defined, in the person's control, and attainable. Participants are asked to choose any goal of intermediate range that they can work on in the next few weeks. With a goal-setting form they are guided through an exercise to define their goal and to establish a list of component subgoals necessary to reach the main goal. The homework assignment is to include the accomplishment of subgoals on the daily self-monitoring log list of positive activities. The intent of the homework is for participants to acknowledge to themselves progress toward the distal goal.

Following the goal-setting topic, the idea of self-reward as a means of motivating oneself to pursue the goal is introduced. Essentially one can increase the probability of accomplishing difficult subgoal behaviors by setting up contingent rewards for their completion. Participants construct a list of pleasurable activities that they could use to reward themselves when they accomplish difficult subgoal behaviors. For example, when completing shopping for the materials necessary for a goal of completing some home repairs, the participant might self-reward with a stop at a favorite donut shop.

The homework here is to list the subgoal activities accomplished on the self-monitoring log and also to record contingent reward activities.

The final topics of the program deal with the way in which depressed people talk to themselves. Depressed persons typically talk to themselves in ways that are punishing and diminishing of motivation. For example, "Why should I try to do this? I'll never succeed. I always make a fool out of myself by failing at things like this." The idea presented is that talking to oneself in realistically more positive ways can increase rather than decrease motivation. Self-talk can be a self-administered reward or punishment. In one exercise, participants are asked to make a list of comfortable statements that acknowledge a positive accomplishment. As one person might say to a friend "You did a great job with that task," the person might list for him- or herself "I did a great job with that task." The corresponding homework assignment is consciously to practice contingent self-rewarding statements daily and to record them in the self-monitoring log as positive self-statements.

A final session allows for continued practice of the lessons taught in the program and review of the ideas involved. The therapist is given some latitude in deciding when to go on to a new topic during the weeks of the program. The extra sessions may be spent earlier to go over a topic that the therapist feels needs further effort.

II. THEORETICAL BASES

The self-management therapy program is based on an integrative model of depression that takes elements identified by other models and subsumes them in a larger coherent framework. In doing so, the model adds a focus on depression as a problem in disconnection from long-term goals. Frederick Kanfer's model of self-control provided the basis for Rehm's self-control model of depression. According to Kanfer, when an individual initiates an attempt to achieve a new long-term goal (e.g., quitting smoking, losing weight, getting "in shape"), that person regulates his or her own behavior via a three-phase feedback loop, including self-monitoring, self-evaluation, and self-reinforcement. Self-monitoring involves observing one's own behavior, including antecedents and consequences. Self-evaluation involves comparing one's behavior to an internal criterion or standard. On the basis of this comparison one feels good or bad about progressing toward the goal. Rehm added another consideration in thinking about self-evaluation. To self-evaluate and feel good or bad about a behavior, an internal attribution is nec-

essary. The person does not experience self-control if the control is actually external (e.g., spent the day in a nonsmoking environment).

The third phase of Kanfer's model is self-reinforcement. Kanfer argues that people influence their own behavior in the same way they may influence another person, by rewards and punishments. Metaphorically, if people are successful in their self-control attempts they "pat themselves on the back," and if they do poorly they "kick themselves." The reactions function as rewards and punishments to maintain the self-controlled behavior in the face of external stimuli and reinforcers operating against the behavior change (e.g., smoking urges, the effort of exercising). Self-reinforcement can be overt (rewarding oneself with a movie) or covert (feeling good about an accomplishment).

Rehm's model of depression uses Kanfer's self-control model as a framework. Rehm views depression as a failure of self-control to supplement external controls. When people are depressed they are hypothesized to show six deficits in self-control behavior. First, depressed people tend to self-monitor negative events to the relative exclusion of positive events. They are vigilant for things to go wrong. A similar idea is described by Aaron Beck as selective abstraction and a negative view of the world. Second, depressed people tend to self-monitor the immediate as opposed to the delayed consequences of behavior. Although they may ruminate about long-term goals they tend to be self-indulgent and respond to immediate consequences (watch TV rather than complete the housework).

Third, in terms of self-evaluation, depressed persons tend to set stringent self-evaluative standards for themselves. They view their own behavior as never good enough and tend to make all-or-none judgments that their behavior was either perfect or a complete failure. Perfectionism has been cited by various authors as a component of depression. Fourth, depressed people make negative attributions for their behaviors. Martin Seligman has elaborated this point in an extended attributional analysis of the behavior of depressed people.

The fifth and sixth deficits in the depression model are lack of contingent positive self-reinforcement and excessive self-punishment. Peter Lewinsohn's behavioral model of depression posits a loss or lack of response contingent positive reinforcement as the source of depression. This model assumes that self-administered rewards and punishments supplement external sources. A person with good self-control skills can successfully manage to get through a time of lack of external reinforcement with self-reinforcement and other self-control skills.

As can be seen, the elements of the model are dependent on earlier elements. The person who focuses on negative events and immediate consequences does not take credit for positive events, sees efforts as not meeting standards, fails to self-reinforce, and excessively self-punishes will be disconnected from long-term goals and suffer depression when the environment does not reinforce behavior benignly. The model forms the basis for the therapy program. Each deficit is focused on in sequence with a didactic presentation of the idea, an exercise to help participants understand the idea, and a homework assignment to try out more effective self-control behavior.

III. EMPIRICAL STUDIES

Self-control therapy was first examined in a series of six studies conducted by Rehm and his colleagues. The first two studies conducted were traditional outcome studies, in which self-management therapy was compared to a control group. In 1977, C. Fuchs and Rehm randomly assigned depressed female community volunteers to 6 weeks of self-control therapy, nonspecific group therapy, or a wait-list control condition. Self-control therapy was found to be the most effective treatment for alleviating symptoms of depression. In a second study in 1979 Rehm, Fuchs, D. Roth, S. Kornblith, and J. Romano assigned depressed women from the community to 6 weeks of self-control therapy or a behavioral assertion skills training program. Self-control therapy was found to be more effective than the assertion skills training program with regard to improving self-control and reducing symptoms of depression, whereas the assertion skills training program more effectively improved assertiveness. One year follow-up data on participants in these two studies, reported by Romano and Rehm in 1979, indicated that treatment gains were maintained over time. However, differences between the self-management and other active treatment conditions were no longer significant. Individuals in the self-management condition did report fewer additional depressive episodes and less severe recurrences of depression.

Next, to examine the various components of self-management therapy, two dismantling studies were conducted. The first study, conducted in 1981 by Rehm, Kornblith, M. O'Hara, D. Lamparski, Romano, and J. Volkin, examined five conditions, including: (1) self-monitoring plus self-reinforcement; (2) self-monitoring plus self-evaluation; (3) self-monitoring alone; (4) the complete therapy package; and (5) a wait-list control condition. All four treatment groups outperformed the

wait-list control condition with regard to self-reported and clinician measures of depression, with no consistent differences found between the active treatment groups. In a similar study, Kornblith, Rehm, O'Hara, and Lamparski compared four groups, including: (1) self-monitoring and self-evaluation alone; (2) self-management training without homework assignments; (3) the complete self-management therapy program; and (4) interpersonally oriented group psychotherapy, serving as the control condition. All four groups were successful in alleviating symptoms of depression, with no significant differences found among the groups.

Next, specific behavioral and cognitive targets of self-management therapy were examined. The self-control manual was revised, and programs were developed that focused primarily on cognitive targets (i.e., focusing on self-statements), behavioral targets (i.e., focusing on increasing activities), or both (i.e., the "combined" version). In 1985, Rehm, Lamparski, Romano, and O'Hara compared the three versions of treatment with a wait-list control group. All three treatment groups improved more than control subjects with regard to symptoms of depression, with no differences found between the treatment groups. In 1987, Rehm, N. Kaslow, and A. Rabin again compared the three versions of self-management against each other, using a larger number of participants. Again no differences were found between the three groups, with each group showing significant improvement in self-reported and clinician measures of depression over time. They also improved equally in behavior and cognition.

Self-management therapy has been evaluated by a number of other researchers in various contexts. B. M. Fleming and D. W. Thornton, in 1980, assigned depressed volunteers to self-management therapy, cognitive therapy, or a nondirective therapy control condition. At posttest and follow-up all three groups showed significant improvement, with the self-management group showing the greatest improvement on a number of measures. In 1980, D. P. Tressler and R. D. Tucker conducted a disassembly study in which depressed female volunteers were treated with either the self-monitoring and self-evaluation components alone, or the self-monitoring and self-reinforcement components alone. The self-monitoring and self-reinforcement combination was found to be superior at posttest and at a 12-week follow-up. In 1982, D. Roth, R. Bielski, M. Jones, W. Parker, and G. Osborn compared self-management therapy alone, to the combination of self-management therapy and a tricyclic antidepressant; although there was a faster response in the combined condition, no significant differences were found between the two

groups at posttest and a 3-month follow-up in self-reported symptoms of depression. S. Rude in a 1986 paper assigned depressed women to both cognitive self-control treatment (a modified version of Rehm's therapy) plus assertion skills training (administered in random order), or to a wait-list control group. Participants who received the combination of self-control and assertiveness training experienced significantly larger reductions in depressive symptoms than the control group. However at the midtreatment point, when each participant had only received one form of therapy, no significant differences were found between the three groups. R. Thomas, R. Petry, and J. Goldman in a 1987 paper assigned depressed female volunteer participants to 6 weeks of self-control therapy or cognitive therapy. Both forms of therapy were effective in alleviating depression, with results remaining at a 6-week follow-up. In 1995, J. H. C. van den Hout, A. Arntz, and F. H. J. Kunkels compared 12 weeks of self-control therapy plus standard treatment, to standard treatment alone, for depressed patients in a psychiatric day-treatment center. The addition of self-control therapy was significantly more effective than standard treatment alone with regard to improving self-control, self-esteem, and depression. Although gains were maintained at a 13-week follow-up, significant differences were no longer found between the two groups.

Self-management therapy has also been applied to diverse populations. In 1982, P. Rogers, R. Kerns, Rehm, E. D. Hendler, and L. Harkness found self-management therapy to be more effective than nonspecific individual psychotherapy in reducing depression in renal dialysis patients. S. Bailey in a 1996 study examined the effect of self-management therapy compared to a wait-list control condition as a treatment for abused women. Treated participants experienced significantly greater improvement than control subjects in symptoms of depression, self-control, and dysfunctional attitudes.

Self-management therapy has also been modified for use with depressed children and adolescents. In 1986, W. Reynolds and K. I. Coats assigned moderately depressed high school students to self-management therapy, relaxation training, or a wait-list control condition. Both therapy groups, compared to the control group, experienced significant reductions in depression and anxiety, as well as improvements in academic self-image. K. Stark, Reynolds, and Kaslow (1987) assigned children, ages 9 to 12, to either behavioral problem solving, self-control therapy (a child version), or a wait-list control condition. At posttest and 8-week follow-up, both treatment groups showed significant improvements in self-reported and clinician-rated de-

pression, whereas the wait-list control group showed little change. In 1996, Rehm and R. Sharp reported the results from a study in which self-management therapy was provided to fourth- and fifth-grade students; although little improvement was seen in depression across participants, those children who were classified as "depressed" at pretest significantly improved with regard to symptoms of depression, social skills, and attributional style.

Self-management therapy has also been applied to older adults (age 60 or older). P. Rokke, J. Tomhave, and Z. Jovic in a 1999 paper assigned depressed older adults to one of two forms of self-management therapy (one with a cognitive focus and one with a behavioral focus), or to a wait-list control condition. Both self-management groups, compared with the control group, experienced significant reductions in depressive symptoms (with gains maintained at a 3-month and 1-year follow-up), as well as improvements in depression-related cognitions, learned resourcefulness, self-control, and self-reinforcement. No differences were found between the two versions of self-management therapy. In a similar study published in 2000 Rokke, Tomhave, and Jovic randomly assigned depressed older adults to 10 weeks of self-management therapy, an educational support group, or to a wait-list control condition. No differences were found between the two treatment groups, each of which was more effective than the control group in alleviating depression and improving self-reinforcement, learned resourcefulness, and self-control knowledge. In addition, reductions in depression levels were maintained at the 1-year follow-up.

IV. SUMMARY

In sum, Rehm's self-management therapy program is a structured, manualized, cognitive-behavioral group therapy program, designed for the treatment of depression. The therapy is designed to address deficits in the three phases of the self-control feedback loop, including self-monitoring, self-evaluation, and self-reinforcement. A number of empirical evaluations have validated the efficacy of self-management therapy as an effective treatment for depression.

GLOSSARY

helper-therapy principle Introduced by Riessman in 1965 to convey the notion that in the act of helping others, the member is empowered, both to help others and simultaneously to help him- or herself.

professional-centrism The tendency of professionals to view self-help groups with higher levels of professional involvement as being more helpful than non-professional self-help groups. This leads them to be more likely to refer to and support groups with higher levels of professional involvement.

self-help clearinghouses Organizations dedicated to cataloging and referring interested parties to the self-help groups in a particular district or region.

self-help groups Voluntary associations of persons who share common concerns or problems and who try to support and help each other at little or no cost.

self-help organizations Refers to a more complex and broader level of organization (regional, national, or international associations) that foster the development and management of local self-help groups.

I. OVERVIEW AND HISTORY

Despite rather humble beginnings, self-help groups have become a pervasive phenomenon in the United

States. Although their history can be traced as far back as the guilds in the Middle Ages and likely before, the origination of modern self-help organizations is most typically associated with the start of Alcoholics Anonymous (AA) in June of 1935. AA is the largest and oldest self-help organization in the United States. It started as the brainchild of two recovering alcoholics, Robert Holbrook Smith and stockbroker William Wilson. AA is the prototype for modern self-help groups in the United States and Canada and, in fact, has become one of the most commonly utilized groups among those seeking treatment for alcohol problems. There are now estimated to be more than 55,000 AA groups in the United States, and Canada.

Other well known self-help groups include Recovery, Inc., the National Alliance for the Mentally Ill (NAMI), Narcotics Anonymous, and Schizophrenics Anonymous as well as lesser known groups for epileptics, families of suicide victims, a variety of neurological diseases, eating disorders, a multitude of serious emotional crises (retirement, widowhood, loss of a child, various illnesses, handicaps, unemployment, divorce), almost all chronic diseases, minorities, marginalized peoples, and parenting to name but a few of the groups available. This list is by no means exhaustive because estimates suggest that there are over 400 distinct types of self-help groups in the United States alone.

Self-help clearinghouses have sprung up due in part to the wide variety and the sheer number of self-help groups in any one geographical area. These clearinghouses are dedicated to cataloging and referring interested parties to

the self-help groups in a particular district or region. For example, Gerald Goodman reports that in 1993 the California Self-Help Center clearinghouse alone, with 4,600 groups in its database, referred about 120 people a day to self-help groups.

Self-help groups have grown at an astounding rate. At present, it is estimated that the number of people being treated in self-help groups exceeds those in professionally-led individual and group therapy combined. It is surmised that roughly 25 million Americans have attended one of 500,000 self-help groups at some point in their lives. Telephone surveys of random individuals indicate that almost 7% of people admit to being actively engaged in a self-help group at any one time.

Despite the ubiquitous nature of self-help groups, there is less clarity on what is meant by the term. Mental health professionals have struggled for years to define these groups. Part of the difficulty lies in the fact that the concept itself is somewhat fluid. For instance, each one of the estimated 500,000 self-help groups add their own unique contributions to the definition. Despite this challenge most researchers have settled on four basic definitional tenants:

1. Members have common concerns or problems that they are dealing with.
2. Members of the group have control over the structure and format of the group.
3. Help that is received is given primarily through other members in the group.
4. There is little or no cost for the members of the group.

Although this definition has utility as an anchor point, it is important to keep in mind that individual self-help groups will vary on each one of these dimensions. For example AA groups and other "Anonymous" groups are built on a structured 12-step approach in which local chapters are facilitated by a larger national organization. Thus, although local members have some control over the structure and format of the group, much of what happens in group is a result of the structure set by the national program.

Other self-help groups are entirely controlled by local members without any affiliation with local or national organizations. In fact, given the earlier definition, a group of three or four single mothers who get together a couple of times a month for lunch to talk about their struggles could be classified as a self-help group. Of course, these self-help groups will never be classified by clearinghouses, receive publicity, and are

closed to other outsiders; nonetheless they fall under the rubric of self-help groups.

Given the aforementioned definitional variability, is there a typical self-help group? The answer depends on whether one includes AA and the approximately 150 other 12-step groups as the model group. A persuasive argument for such is offered by Kathryn Davison and colleagues who found that out of 12,596 self-help groups identified in four major cities for 20 different diseases or disorders, 10,966 (87%) were AA groups. Given the pervasive nature of AA groups, a brief overview is warranted.

AA meetings are divided into four types.

1. Open Meetings: Any interested person may attend.
2. Closed meetings: Only people who are alcoholic or who have a desire to stop drinking may attend.
3. Discussion meetings: Typically the chairperson suggests a topic for the group.
4. Speaker meetings: The speaker presents his or her life before entering the group and gains made since then.

AA and other "Anonymous" groups follow a 12-step program. The first 3 of the 12 steps deal with the admission of defeat or powerlessness over addiction. Steps 4 through 9 consider healing the ruin of the past, and the last 3 steps deal with maintaining peace and serenity. There is an unmistakable emphasis on religious or spiritual influences in 12-step groups, which has led to their marginalization in some contexts. Nevertheless, 12-step programs have flourished and are considered by many professionals today to be an integral part of treatment for addictions.

The majority of all self-help groups (about two-thirds) formally introduce existing group members to new members and have new members introduce themselves. Some (about one third) ask new members to share personal experiences related to the group's stated purpose. With few exceptions new members are welcomed and accommodated. In recent comprehensive surveys, as many as 40% of self-help groups were oriented toward the treatment of physical illness. Attendance at these group meetings varied considerably, with some being very large (50 people in attendance) and others involving only 2 to 5 individuals (average attendance is in the range of 13 to 21 people). Most self-help groups recruit new members by word of mouth, but a significant number also use newspaper or magazine advertisements or solicit professionals for referrals.

Some authors have tried to differentiate self-help and mutual support groups (also referred to simply as

support groups). The usual distinction is the level of professional involvement in leading, sponsoring, or otherwise controlling the nature of the group. Support groups are more frequently aligned with mental health professionals and are often led by a trained therapist. On the other hand, self-help groups are usually viewed as being relatively autonomous from professional involvement, and peer leadership is endorsed.

Critics of professional involvement voice their concern about the loss of the self-help group's ideology and effectiveness when a professional assumes the leadership role. This is based on an important therapeutic principle that self-help group members experience autonomy, control of the group, and a sense that they are the experts on their difficulty. Opponents to professional involvement postulate that when an authority steps in, the unique benefits of self-help groups are lost, and the members of the group may begin to engage in docile "patient behavior." This concern has led some writers in the field to characterize groups by the presence or absence of professional involvement with the former being classified as a treatment group (psychotherapy or psychoeducation).

The distinction between groups with and without professional involvement may have more ideological and historical value because modern self-help groups often incorporate professionals. More specifically, recent research indicates that most "self-help" groups have some professional involvement. In 1993, Morton Lieberman reported that over 60% of observed groups were professionally facilitated while simultaneously being characterized as self-help. Eight years earlier (1985), Jennifer Lotery randomly sampled 850 self-help groups in California and found that 14% "frequently" had professionals in the role of solo leader with another 35% using professionals as co-leaders. Thus nearly one half the groups experienced a professional as part- or full-time co-leader. More recently, Scott Wituk's work in 2000 found that in a sample of 253 randomly selected self-help groups only 27% were peer led with no professional involvement. Other recent random samples have also shown similar results, that is, a growing trend to include professionals in self-help groups.

Lotery's survey suggests that most self-help groups welcome professionals, especially as a referral source, speaker, teacher, student, or co-leader. Respondents also stated an interest in having professionals serve as solo leaders or coordinators/organizers. In general, most self-help organizations echo this sentiment. For instance, a recent study reports that groups with a combination of both peer and professional leadership had

greater longevity and continued group membership than either professional or peer-led groups. Thus, peer-leadership versus professional leadership seems to fall on a continuum rather than the dichotomous variable that early researchers conceptualized.

Despite potential for collaboration and consultation, it is important to note that self-help groups and professionals often view the consulting role rather differently. Self-help group members can view professionals as wanting to control the group using their clinical experience and training. Thus, it is important for professionals to approach self-help groups with an attitude of mutual respect and partnership rather than as a source for expert solutions that may conflict with self-help group ideology. Several recent studies of mental health professionals' perceptions of self-help groups suggest that the majority view groups with higher levels of professional involvement as being more helpful, effective, good, strong, healthy, understandable, active, interesting, predictable, and safer than groups with less professional association. This phenomenon has been labeled by Mark Salzer as "professional centrism" and has been well documented. Professionals are more likely to refer to and support those groups with higher levels of professional involvement. Paradoxically, scant research exists to either support or refute professionals' faith in self-help groups with more professional involvement.

II. HOW SELF-HELP GROUPS WORK

Members of self-help groups are empowered by not only being responsible for helping themselves, but also by being accountable for helping others. This is known in the self-help literature as the "helper-therapy principle." In helping his or her peers the member is enabled, both to assist others and at the same time to help him- or herself. The opportunity to help others with a similar problem is often a catalyst for personal change. Some research supports the help-therapy principle. Specifically the number of helping statements made by a member has been directly and significantly correlated with increasingly positive outcomes by Linda Roberts and her colleagues. Being in a position to help others with similar problems may be a unique experience for members of self-help groups, an opportunity not present in individual psychotherapy. In most self-help groups, even members who are experiencing serious challenges are given an opportunity to help others in the group.

A second source of therapeutic potential for self-help groups is the opportunity to observe strong role models

of individuals who have overcome similar problems. According to Festinger's social comparison theory, people have a drive to evaluate their opinions and abilities by comparing themselves to others that they deem as similar. Self-help groups provide a unique opportunity to compare oneself with homologous others who have overcome analogous problems. Strong role models can exemplify success, reinforce group norms, provide empathy, and promote identification and motivation. In self-help groups, many successful members continue to attend to share their success and offer support to new or struggling members. This continued long-term involvement is possible because the groups are usually free from financial obligations. Moreover, research suggests that the longer a person participates in a self-help group the more likely they are to benefit from it.

III. EFFECTIVENESS

The scientific study of self-help groups has been slow and difficult at best. The traditional research paradigm for studying the effectiveness of psychotherapy groups involves randomly assigning participants to experimental and control conditions and then observing differences between the two groups. Application of this protocol to self-help groups is problematic because they are not under the researcher's control and participants cannot be randomly assigned to a no-treatment or wait-list control condition. More specifically, refusing or delaying fellowship to interested members is in direct opposition to the open philosophy of the self-help movement.

Critics have also argued that there is an inherent selection bias in studies that assess the outcome of self-help groups. Indeed, research has shown that individuals who do not expect to benefit from self-help groups drop out. This phenomenon led Leon Levy to argue those who remain in self-help groups will undoubtedly find the group to be effective thereby skewing the effectiveness results in the "positive" direction.

A final obstacle in the scientific study of self-help group effectiveness lies in the purported effects. In traditional group psychotherapy therapists focus on the removal of symptoms by treating the underlying causes for pathology (maladaptive relationships, distorted cognition, etc.). On the other hand, self-help groups focus on mutual support. In short, the expected outcomes for the self-help and traditional psychotherapy groups are different. More specifically, one measure of effectiveness for self-help groups may be the amount of support these groups give to each other and not the re-

duction of psychopathology. Members often highlight the salubrious effect of the group on their feelings of isolation and social seclusion rather than reduction in pathology reporting high levels of satisfaction. Although robust empirical data on the effectiveness of self-help groups is scarce, the current literature does support their effectiveness. Participation in self-help groups has been linked to improved subjective well-being, attenuated use of professional services, strengthened coping skills, shorter hospital stays, less denial of problems, less identification with the patient role, and reduced psychiatric symptomatology. Self-help groups also help individuals form a new identity, give them a sense of belonging and association, and assist in personal transformations through support, advocacy, and empowerment. Self-help groups are recommended by a majority of treatment programs for substance disorders. In fact, studies that evaluated AA as one element in a treatment program suggest that alcoholics who attend AA in addition to other treatment modalities do better than those who attend only AA or use professional treatment alone. In general 12-step groups have produced beneficial outcomes.

It is important to note that not all research has supported the effectiveness of self-help groups. In 1999, Sally Barlow and colleagues focused on self-help groups in the medical field. Seventeen studies that compared controls with active self-help treatment groups when examined as an aggregate found no evidence that members of medical self-help groups improve more than a non-treated control group. However, this does not mean that members of the self-help groups were not satisfied with their groups or that they did not receive benefits other than those objectively measured by the researchers.

IV. THE FUTURE

Self-help groups are not an endangered species. Gerald Goodman and Marion Jacobs predicted that self-help groups will become the nation's "treatment of choice" in the next 10 to 20 years. Given self-help groups' exponential growth in recent years, it is hard to imagine a mental health field without them. In fact, with the increasing scarcity and lack of availability of mental health services to the general public, self-help groups are virtually assured a position of prominence in the future. It is also likely that professional involvement in self-help groups will not only continue but intensify over time. Self-help groups are being recognized as a

legitimate resource for clients and, as such, increasing numbers of professionals will vie to become involved with these groups.

Online groups are beginning to gain acceptance as a viable treatment alternative to the formal self-help group venue. They are likely to become increasingly common as more and more people gain access to this mode of communication. Advantages of online self-help groups include their availability (24-hours-a-day), breadth (worldwide), specificity (support for those with relatively rare conditions), and lower level of interpersonal risk (anonymity and indirect participation). Online self-help groups appear to be expanding despite the fact that almost no research exists to delineate whether participation is helpful or satisfying—a topic in need of future research.

V. SUMMARY

Self-help groups have grown exponentially since the inception of AA and are now a primary treatment method for many individuals. Although defining self-help groups has been problematic given the variety of groups available, they are typically composed of members with common concerns who have control over the structure and format of the group and who give mutual aid and support to each other for little or no cost. Of the over 400 documented types of self-help groups, most have some professional involvement, especially as a referral source, speaker, teacher, or consultant. Core therapeutic principles include giving members oppor-

tunities to help others, motivating them to emulate successful others in the group, and offering friendship and support. The study of how effective self-help groups are has been fraught with a number of problems that center around self-selection. Despite these problems, most research indicates that they are effective. In addition, most members of these groups report being highly satisfied with their group experience and rate the group as beneficial. It is likely that in the coming years self-help groups will become even more common.

GLOSSARY

- chronic insomnia** Insomnia persisting more than 1 month.
- insomnia** A condition involving difficulties falling asleep, staying asleep, early morning awakening, or nonrestorative sleep.
- meta-analysis** A quantitative method using a common metric (z score) to summarize the data from different studies.
- primary insomnia** Insomnia that is not associated with another medical, psychiatric, or sleep disorder.
- self-help treatment** Intervention based on printed information or audio/video material designed to improve a medical or psychological condition.
- sleep efficiency** A measure of sleep continuity obtained by dividing the total amount of time slept by the time spent in bed, multiplied by 100.
- sleep hygiene** Education about the impact of lifestyle and environmental factors on sleep.
- sleep-onset latency** Time required to fall asleep at bedtime.
- sleep restriction therapy** Behavioral procedure consisting of limiting time in bed to the actual time spent sleeping.
- stimulus control therapy** Behavioral procedures aimed at establishing a consistent sleep-wake rhythm and reassociating the bed and bedroom with sleep rather than with insomnia.

I. INTRODUCTION AND DEFINITION

Insomnia is a prevalent condition affecting about 10% of the adult population on a chronic basis. It involves either difficulties falling asleep, staying asleep, early morning awakenings, or nonrestorative sleep. Insomnia can occur as a unique disorder, as in primary insomnia, or may be secondary to another medical (e.g., cancer) or psychological condition (e.g., depression or anxiety). Chronic sleep disturbances are often associated with negative daytime consequences such as fatigue and mood disturbance, thus significantly affecting one's quality of life. Despite its high prevalence and potential impact on social or occupational functioning, only a small portion of individuals with chronic primary insomnia actually receives any treatment. For those who do seek relief for their insomnia, the first interventions are usually self-initiated and generally involve medications bought over-the-counter, natural products, or the use of alcohol. When insomnia is brought to the attention of physicians, pharmacotherapy is the most widely used and often the only recommended treatment option, despite the controversy existing over the long-term use of hypnotic medications. In the past 20 years, there has been an increasing interest in psychological and behavioral factors contributing to insomnia. This has led to the development of diverse psychological therapies for insomnia, many of which have been shown to produce significant and

durable effects. However, these interventions remain underutilized because they are not well known to health care practitioners and are less easily accessible, both physically and financially, than pharmacotherapy. A self-help treatment for insomnia is a valuable alternative to overcome some of these barriers by making treatment more accessible, at a low cost, to a larger number of individuals with insomnia. Self-help treatment refers to any intervention, either for a psychological or physical condition, that is implemented with the assistance of printed material (e.g., books, pamphlets), audio- or videotapes, or any other medium (e.g., Internet). It can be implemented with or without guidance from a health care professional. The objective of this article is to provide an overview of self-help treatments that have received empirical validation in the management of primary insomnia.

II. DESCRIPTION OF TREATMENTS

Self-help treatments for insomnia incorporate much of the same information and material provided in a face-to-face therapy. Interventions that have received adequate empirical support and that are usually included in self-help treatment programs include stimulus control, sleep restriction, cognitive therapy, sleep-hygiene education, and relaxation procedures. The main goals of these interventions are to induce sleep rapidly at bedtime, to sustain it with minimal interruptions throughout the night, to enhance sleep quality and duration, and to improve daytime functioning. To achieve these outcomes, treatments focus on psychological and behavioral factors presumed to perpetuate sleep difficulties. They seek to curtail maladaptive sleep habits, to regulate the sleep schedule, to correct faulty beliefs and attitudes about sleep, to reduce autonomic arousal, and to educate patients about good sleep hygiene. Another common goal of these therapies is to teach self-management skills for coping with residual sleep disturbances once treatment is completed. Some interventions, such as stimulus control instructions, or sleep restriction, are more amenable to a self-help format because they are primarily educational or instructional in nature. Others, like relaxation or cognitive therapy, are likely to require more direct guidance, possibly with the help of a therapist, if they are to be fully effective. Provided next is a brief description of several of the psychological interventions that can be applied in a self-help format.

A. Stimulus Control

Stimulus control therapy consists of a set of behavioral rules designed to bring the patient to reassociate the bed and bedroom with sleep rather than with arousal or the frustration caused by the inability to sleep. This is achieved by curtailing sleep-incompatible activities. A second objective is to establish a consistent sleep-wake rhythm by setting a regular arising time and by avoiding naps. Standard stimulus control instructions are:

- Go to bed only when sleepy.
- Use the bed and bedroom for sleep and sexual activity only; do not read, watch TV, or worry in bed.
- When unable to sleep within 15 to 20 min, leave the bed and go into another room; return to bed only when sleepy again (this step is repeated as often as necessary throughout the night).
- Arise at the same time every morning regardless of the amount of sleep obtained the night before
- Do not take naps during the day.

B. Sleep Restriction

Individuals with insomnia sometimes spend excessive amounts of time in bed in a misguided effort to obtain more sleep. In turn, this practice may cause more fragmented sleep and perpetuate insomnia. The standard sleep restriction procedure consists of curtailing time in bed to the actual sleep time. Once the usual sleep time and time spent in bed have been estimated with the help of a sleep diary kept for at least one week, an initial time window is defined in which the patient can sleep or attempt to sleep (i.e., total time allowed in bed). This window is set to correspond to the average total sleep time and is readjusted periodically (usually weekly), either decreased or increased, based on estimations of sleep efficiency that can be easily calculated from the sleep diary (ratio of total sleep time over time spent in bed x 100). As sleep efficiency improves, the sleep window is progressively extended until an optimal sleep duration is achieved. Although the task of setting and adjusting the sleep window is usually left to the therapist in face-to-face treatments, this procedure, if well explained in written material, can be easily implemented by the individual. Sleep restriction guidelines are fairly operational and easy to follow for adjusting the sleep window: for example, if a person has been able to maintain a sleep efficiency of at least 85% for 1 week, the time allowed in bed is increased by a small amount, usually 15 to 20 min. Conversely, if

sleep efficiency is lower than 80%, the time allowed in bed is decreased by the same amount. Sleep restriction induces a mild state of sleep deprivation, which promotes a more rapid sleep onset, more efficient and consolidated sleep, as well as less inter-night variability. This procedure should however be used with caution with individuals who engage in hazardous activities (e.g., construction workers, truck drivers). In all circumstances, the time allowed in bed should never be less than 5 hrs to prevent excessive daytime sleepiness.

C. Relaxation Therapies

Patients with insomnia are often tense and anxious, both at night and during the day. Relaxation-based interventions are the most commonly used nondrug therapy for insomnia. A variety of techniques target different types of arousal. For example, progressive muscle relaxation, autogenic training, and biofeedback are used to reduce somatic arousal such as muscle tension. Cognitive or emotional arousal in the form of worries, intrusive thoughts, or a racing mind are addressed using attention-focusing methods such as imagery training (i.e., focusing on pleasant or neutral mental images) or meditation. Relaxation therapies may be less easily self-implemented than stimulus control or sleep restriction because they require the learning of specific relaxation techniques through appropriate training. Professional guidance or an audiotape is often necessary, particularly in the initial phase of treatment (e.g., the first 3 weeks), to optimize an adequate use of the techniques. Regardless of the training method selected, therapeutic gains usually require at least 2 to 3 weeks of relaxation training.

D. Cognitive Therapy

Poor sleepers tend to entertain faulty beliefs and attitudes about sleep, which feed into the vicious circle of insomnia, emotional distress, and more sleep disturbance. As such, insomnia often becomes a self-fulfilling prophecy. For instance, the belief that 8 hrs of sleep is an absolute necessity, or the perception that one is unable to function after a poor night's sleep is often enough to produce anxiety and exacerbate sleep disturbances. The objective of cognitive therapy is to alter these types of sleep-related cognitions by challenging them and replacing them with more adaptive substitutes. Several clinical procedures, modeled after those used in treating anxiety and depression, can be used for changing patients' misconceptions about sleep. Such

techniques include attention shifting, reappraisal, reattribution training, and decatastrophizing. Cognitive therapy is also used to teach patients strategies to cope more adaptively with residual difficulties that recur occasionally even after treatment.

E. Sleep Hygiene

Sleep hygiene education fosters healthy habits through simple recommendations about diet, substance use, exercise, and environmental factors that promote or interfere with sleep. Standard sleep hygiene measures include the following:

- Avoid stimulants several hours before bedtime. Caffeine and nicotine, both central nervous system stimulants, can impede sleep onset and reduce sleep efficiency and quality.
- Do not drink alcohol too close to bedtime. Alcohol consumption prior to bedtime can lead to more fragmented sleep and early morning awakenings.
- Avoid heavy meals too close to bedtime, as they can interfere with sleep. A light snack may be sleep inducing.
- Regular exercise in the late afternoon or early evening can deepen sleep. Conversely, exercising too close to bedtime could have a stimulating effect and delay sleep onset.
- Keep the bedroom environment quiet, dark, and comfortable.

III. TREATMENT FORMATS AND PROCESS

Several formats have been used to implement self-help therapies for insomnia, including printed material (books or pamphlets), audiotapes, and videotapes. Some Internet sites are also under construction, a format that should make treatment more interactive. Most treatments available tend to combine different formats, for example by offering a self-help book in conjunction with an audio- or videotape.

The basic structure of a self-help intervention for insomnia is similar to a therapist-led treatment. The first step is to provide basic information about sleep and insomnia. A brief self-assessment method is introduced to ensure proper diagnosis. The daily use of a sleep diary throughout treatment is an essential feature of any self-help intervention for insomnia. Indications and contraindications of self-help treatment are also underlined. Patients should be informed to seek professional help

when they are not sure whether they suffer from insomnia or from another condition (e.g., sleep apnea, depression). Once these preliminary steps have been completed, a conceptual model of insomnia is described, and the rationale behind the treatment is explained. This is particularly important because some treatment procedures, such as sleep restriction or stimulus control for instance, can appear paradoxical to individuals seeking relief for their insomnia, especially when they are sleep deprived. Consequently, it is important to inform the patient that mild sleep deprivation might occur in the initial phases of treatment, and to explain how this procedure will help them if they adhere to the treatment protocol. This understanding may influence the patient's willingness to invest time and efforts in carrying out the therapeutic recommendations.

Although therapist-led treatments often comprise 6 to 10 therapy sessions spread over a period of 10 to 12 weeks, there is no standard time frame when it comes to implementing a self-help treatment. Nonetheless, 4 to 6 weeks of strict adherence to treatment is usually necessary for sleep improvements to become noticeable. As treatment is often multifaceted, it is preferable to introduce each therapeutic component in a sequential fashion. Once basic information about sleep and insomnia and the rationale for treatment has been provided, sleep restriction and stimulus control procedures may be introduced. When these components are well integrated (about the 3rd week), treatment can move on to cognitive restructuring of dysfunctional beliefs and attitudes about sleep. Sleep hygiene education can be incorporated at any point in the treatment. If a relaxation-based component is added to the treatment, it should be introduced early on to allow sufficient time for training.

IV. EMPIRICAL STUDIES: EVIDENCE FOR EFFICACY

The efficacy of psychological treatments (mostly behavioral in nature) for chronic and primary insomnia has been well documented in the last 20 years. Two meta-analyses have shown that psychological treatments are effective in treating sleep-onset insomnia (problems falling asleep) as well as sleep-maintenance insomnia (problems staying asleep). Overall, it is estimated that about 70% to 80% of individuals with insomnia achieve some clinical benefits with behavioral interventions. Typically, treatment is likely to reduce the main target symptoms of sleep-onset latency and

wake after sleep onset below or near the 30-min criterion initially used to define insomnia severity. Sleep duration is increased by a modest 30 to 45 min, but patient's satisfaction with sleep quality is significantly enhanced. Moreover, treatment gains are well sustained or even enhanced up to 24 months after completion of treatment.

There have been only five studies conducted on the topic of self-help treatment for insomnia. Table 1 presents a summary of these studies. The first investigation of self-help treatment for insomnia was conducted in 1979. It was designed to compare the efficacy of two self-administered treatment manuals for sleep-onset insomnia with a waiting-list control condition. One manual included relaxation and standard stimulus control instructions, whereas the other involved a different form of relaxation plus a countercontrol procedure in which participants were instructed to stay in bed when unable to sleep. Sleep-onset latency, number of awakenings, and worries about sleep were assessed with sleep diaries completed daily by the participants. Twenty-nine participants aged between 17 and 80 years old were enrolled in the study. The results showed a significant reduction of sleep-onset latency in both treatment conditions, although the standard stimulus control condition was superior (59% versus 32%). Participants receiving the manual with the standard relaxation and stimulus control procedures also reported higher ratings of sleep quality. Greater improvements were observed in younger individuals as compared to the elder participants. The authors suggest that the higher prevalence of medical conditions in the elderly might interfere with sleep and thereby moderate treatment efficacy.

The next study was performed 10 years later by David Morawetz in Australia. Three questions motivated his study: (a) Is self-help treatment more effective than no treatment? (b) Is self-help treatment as effective as a therapist-led treatment? and (c) What factors moderate the treatment response to self-help interventions? One-hundred-and-forty participants aged from 23 to 63 years took part in the study, including 63 who were taking sleep medication. Daily sleep diaries were again used to evaluate the comparative efficacy of three conditions: a self-help treatment, a therapist-led treatment, and a waiting-list control. The treatment material included basic information on sleep physiology and sleep disorders, a description of the standard stimulus control instructions, and relaxation training instructions. Whether they were in the self-administered or in the therapist-led treatment group, participants

TABLE 1
Summary of Empirical Studies on Self-Help Treatment for Insomnia

<i>Authors</i>	<i>Sample</i>	<i>Design</i>	<i>Self-help format</i>	<i>Treatment content</i>
Alperson & Biglan (1979)	N = 29 17–80 years old	Relaxation + stimulus control Relaxation + counter control Waiting-list	Printed manual	Relaxation + Stimulus control relaxation + in-bed activities
Morawetz (1989)	N = 141 23–60 years old	Self-help treatment Therapist-led treatment Waiting-list control	Audiotape/manual	Sleep information + relaxation + stimulus control
Oosterhuis & Klip (1993)	N = 325 15–86 years old	Single group, quasi-experimental design	Television and radio segments, booklet and audiotape	Sleep information + relaxation + stimulus control + sleep hygiene
Riedel et al. (1995)	N = 100 > 60 years old	Video treatment with or without therapist guidance; good sleepers controls	Videotape/pamphlet	Sleep information + sleep restriction
Mimeault & Morin (1999)	N = 54 18–54 years old	Self-help treatment Self-help treatment + phone consultation Waiting-list control	Treatment manual	Stimulus control, sleep restriction, sleep hygiene education, cognitive interventions

received the same therapeutic components. The results showed significant reductions of sleep-onset latency for the two treatment groups, both at posttreatment and at a 3-month follow-up assessment. No significant improvement was observed in the waiting-list condition. The authors noted only limited improvements among participants who received treatment but were concurrently using a sleep medication. These improvements were nonetheless greater for the group receiving therapist-led treatment than for the group receiving the self-administered intervention. These results suggest that self-help treatment is effective but also highlight the importance of therapist assistance in cases where complicating issues, such as medication use, are present.

In 1993, a Dutch public television channel scheduled a series of television and radio programs that were broadcast in the Netherlands to offer educational material about insomnia and its treatment. There were eight television (15 min each) and nine radio segments. In addition, participants received by mail a relaxation tape and a booklet summarizing the critical information covered during the television and radio programs. The written material incorporated basic information about sleep and sleep hygiene education, relaxation training, and stimulus control techniques. Psychologists Aart Oosterhuis and Ed Klip evaluated the impact of this program. Participants were recruited via a survey and completed a daily sleep diary and different sleep and

mood questionnaires. This program reached an estimated 23,000 individuals. Of 400 participants who volunteered for the evaluation of this program, a total of 105 returned their assessment material. The results showed a significant decrease in sleep-onset latency and in the number of awakenings as well as a significant increase in total sleep time. In addition, 40% of the participants discontinued their medication during treatment. Although the results must be interpreted carefully because of the absence of control, this type of innovative program has the advantage of reaching a large number of individuals who may suffer from insomnia without ever consulting for it.

In a 1995 study, Brant Riedel, Kenneth Lichstein, and William Dwyer evaluated if therapist guidance, added to a self-help video program, influenced the efficacy of a self-help treatment for insomnia in older adults. Participants kept daily sleep diaries and completed a questionnaire evaluating knowledge about sleep. The video lasted about 15 min and contained information about sleep in the elderly, the benefits of restricting time in bed, and the possible hazards associated with the use of sleep medications. Subjects in the video-only condition and the video-plus-therapist guidance condition viewed the video twice with 2 weeks between viewing sessions. Participants in the therapist-guided condition received two additional group training sessions with a therapist. During these sessions, the therapist emphasized the

importance of restricting time in bed. Participants were evaluated before and after each session, and 2 months after the end of the intervention. The results indicate that both self-help interventions were effective to improve several sleep variables, but also that the addition of therapist guidance enhanced treatment outcome.

Véronique Mimeault and Charles Morin conducted the most recent study of self-help treatment in 1999. This investigation examined the efficacy of cognitive-behavioral therapy with and without professional guidance. Fifty-four adults were enrolled in this study after being carefully screened with structured diagnostic interviews. Participants were excluded if there was evidence of another sleep disorder, severe depressive or anxiety symptoms, as well as if they were using an antidepressant medication or if they were concurrently involved in psychotherapy. Participants were randomly assigned to a condition involving a self-help treatment manual only (bibliotherapy), a self-help treatment manual plus weekly telephone consultation (15–20 min), or a waiting-list control group. Treatment outcome was evaluated with daily sleep diaries and different questionnaires. Treatment was implemented over a 6-week period. Participants in both treatment groups were mailed one booklet per week, with each booklet introducing a new treatment component, its rationale, and methods to foster its implementation. Treatment components included basic information about sleep and sleep hygiene, stimulus control, sleep restriction, cognitive therapy, methods for discontinuing sleep medications, and relapse prevention. The results showed that sleep efficiency and total sleep time improved significantly at the end of treatment for both self-help conditions, and that therapeutic gains were well maintained at the 3-month follow-up evaluation. The addition of a weekly telephone consultation enhanced outcome at posttreatment but not at follow-up.

Taken together, the results of these five studies support the efficacy of insomnia treatment implemented in a self-help format. This approach may therefore be considered as a useful and cost-effective alternative to therapist-led treatments. It is important to note, however, that several factors may moderate the efficacy of self-help treatment, including the individuals' age, the use of sleep medications, the presence of medical or psychological factors (e.g., generalized anxiety disorder, depression) and, naturally, the individuals' willingness to comply with behavioral procedures. Older adults are more likely to suffer from sleep disturbances complicated by medical factors and may require a more thorough evaluation before undertaking a self-help treatment

for insomnia. Likewise, individuals who are chronic users of hypnotic medications are more likely to present comorbid anxiety or depressive disorders and may require therapist guidance, both for the initial evaluation and for treatment.

V. ADVANTAGES AND LIMITATIONS OF SELF-HELP APPROACHES

The main advantage of a self-help treatment format for insomnia is that it allows for a greater dissemination of treatment knowledge. The best example of this is with the Dutch television program, which was estimated to reach several thousands of individuals, many of which, might never have sought out treatment for their sleep difficulties. In this regard, it is possible that widespread dissemination of self-help interventions can actually prevent the development of more severe and chronic insomnia. Another advantage of self-help approaches is their low cost, rendering treatment more accessible to individuals who may never have consulted a professional for insomnia because of financial limitations.

Self-help interventions also have several drawbacks. First of all, there is always a danger of self-misdiagnosis. Insomnia can be easily confused with other sleep (e.g., apnea, periodic limb movement) or psychological disorders (e.g., generalized anxiety disorder, depression). In the presence of such disorders, insomnia should not be the initial target of treatment. Second, there is also a risk of inappropriate application of treatment techniques, particularly if the rationale is unknown or misunderstood. The third limitation concerns treatment failure, which can occur either because of misdiagnosis or inappropriate technique application, or because the problem is so severe that the individual is unable to sustain treatment long enough to make any improvement. Regardless of the cause of failure, it may lead to a worsening of the problem and may discourage patients to seek help from a health care professional. Another danger of self-help treatment is that there is no provision for monitoring patient's compliance and for ensuring adequate follow-up.

VI. SUMMARY

Insomnia is often undertreated and behavioral interventions remain underutilized, partly because they are more time-consuming and are not always known or accessible. Self-help behavioral therapies are a cost-

effective alternative to drug therapy for the management of primary insomnia. This type of intervention offers several advantages such as lower costs and greater availability. Treatment information that can be conveyed in a self-help format includes basic facts about sleep and insomnia, standard stimulus control and sleep restriction instructions, relaxation methods, sleep hygiene education, and cognitive restructuring techniques. It cannot be overemphasized that compliance is a critical element for insomnia treatment to be effective, and this is particularly true for self-help approaches. Although guidance from a therapist is not always essential for a self-help method to be effective in improving sleep, it can be particularly useful to enhance motivation and willingness to adhere to the treatment protocol. Professional guidance is more likely to be needed when there is a complicating medical (e.g., chronic pain) or psychiatric condition (e.g., generalized anxiety disorder, depression) or when an individual is using a medication for sleep, because such factors can influence the course and effectiveness of the treatment. It may also be indicated to consult a professional prior to initiating a self-help treatment for insomnia to ensure a proper evaluation and diagnosis. Additional research is needed to determine what is the most adequate administration format (e.g., printed material, audio- or videotapes, Internet), who are the best candidates for this treatment modality, and what are the predictors of the response to self-help treatment for insomnia. More important, it remains to be evaluated whether widespread dissemination of information about healthy sleep habits (through simple self-help programs) could be useful in preventing the development of severe and persist-

ent insomnia in the general population, thus significantly reducing health care costs.

GLOSSARY

empathy A cognitive tool, how a clinician comes to know the internal states of another. Called “vicarious introspection” in the case of the analyst at work, with the aim of understanding another’s experience. Kohut describes empathic ambience as the positive attunement of analyst to analysand and empathic failures as the misattunement of analyst to analysand.

introspection A person’s ability to use self-reflection to know his or her own internal states, including emotions, thoughts, fantasies, and values.

narcissism Used primarily in two ways—first, a way of conceiving of human development, characterized by the growth and stability of the self independent of its transactions with externally experienced others; second, a line of development (vs. a fixed stage or pathological state) characterized by the strivings to form and maintain a vital self. Kohut distinguished between healthy narcissism, a strong and vital self with ambition and ideals striving toward the realization of individual talents and skills, and pathological narcissism wherein self strivings are unsuccessful in maintaining a cohesive and stable self-representation.

self-object The manner by which another is experienced as if that person were an extension of the self and performs functions necessary for the smooth continuity of the func-

tioning of oneself. A self-object relationship aids the experience of the self as cohesive, harmonious, firm in limits of time and space, connected to the past and present. Self-object relationships according to Kohut support mirroring, idealization, twinship, and alterego functions in the development and maintenance of a cohesive self.

transference When the patient responds to the analyst as if the analyst were some significant figure of the patient’s past. Transference provides the self psychologist the means to accurately diagnose the patient’s developmental level.

I. SELF PSYCHOLOGY DEFINED

Self psychology refers to the method, observations, and theory that grew from the novel clinical descriptions put forward by a pioneering psychoanalyst from Chicago, Heinz Kohut, primarily in the late 1960s and 1970s. However, the seeds for the development of self psychology were put in place by Kohut in a seminal 1959 paper titled “Introspection, Empathy, and Psychoanalysis.” In this early paper, Kohut set the groundwork for what was to come by defining the faculties of introspection and empathy as crucial tools and determinants of the clinician in the analytic encounter. Much as an internist uses a stethoscope, an analyst uses introspection and empathy. Introspection was defined as a person’s ability to use self-reflection to know his or her own internal states, including emotions, thoughts, fantasies, and values. By contrast, empathy was defined as “vicarious introspection,” by which Kohut meant a person’s

ability to be cognizant of and accurately apprehend another's mental states, that necessarily involved accessing one's own internal cognitive skills, memories, and emotional states. In defining the arena of psychoanalysis as within the jurisdiction of that which is comprehended by empathy and introspection, Kohut moved psychoanalysis away from a preoccupation with forces, vectors, and structures, and toward subjective states and more explicitly phenomenological processes. It was the "self" rather than a more abstract metapsychological concern that dominated Kohut's thinking, and which was made accessible by introspection and empathy.

How self psychology and classical analysis fit together is a fascinating study of politics in psychoanalysis. In some ways, over the years, self psychology has taken its own path and departed from the mainstream of classical analysis in the United States. However, in other ways, certain key aspects of self psychology have more recently been integrated into the mainstream of classical analysis and has fueled and enriched the entire corpus of contemporary psychoanalytic theory. Thus, although there are many clinicians who think of themselves as "self psychologists," some of the principles of self psychology can now as well be found in the mainstream and are the source of many different and helpful ways of formulating clinical interaction.

II. HEINZ KOHUT

Heinz Kohut was an analyst who emigrated to Chicago from Vienna as a young man. As so many immigrant pioneers in the psychoanalytic movement did, he brought with him the enormous charm and intellectual prowess characteristic of old world scholarship. In a relatively short amount of time, and at a young age, he established himself as one of the leaders of the psychoanalytic world. Trained in analysis at the Chicago Institute, he rapidly rose up in the ranks and was soon to become the leading luminary in the Chicago milieu, the acknowledged leader and pacesetter within that institute. At first a conservative analyst, quite loyal to the tradition of Hartman and ego psychology, he was to break ranks and found the self psychology movement that he came to see was markedly at odds with classical psychoanalysis.

It was largely the description of narcissistic patients that led Kohut to develop his original and, at the time, controversial views. While practicing as a classical analyst, Kohut found that what he called a patients' "self-cohesion" was disrupted when the patient perceived

the analyst to have committed an empathic failure. Kohut came to believe that many failures in analysis were not due to a narcissistic patients' predisposing pathology, but rather to the clinicians' failure to tune in to the analysand's underlying states. Believing that many failures in analysis were due to this factor, Kohut sought to expand the range of patients treatable by psychoanalysis. Although always a controversial topic, prior to Kohut many considered the narcissistic patient untreatable for a variety of reasons attributable to the patient, but rarely the clinician. Most telling, however, was the sense that such patients could not be reached by clinical interpretations, because they would contemptuously reject insight while at the same time displaying characteristics of extreme fragility and hypersensitivity. It was Kohut's inspiration to design a treatment that did not emphasize interpretation and insight, and in so doing, soon was to develop a whole new way of looking at people and the treatment situation. In moving away from interpretation as the primary mutative factor in psychoanalysis, Kohut spoke of "transmuting internalization" as a key concept, when the patient is enabled to take in those experiences that are empathically offered, and then convert them into psychic structure, thereby remediating early developmental failures that had been laying dormant for many years. The concept of transmuting internalization explains how patients change through the provision of empathic ministrations rather than through the acquisition of insight and understanding.

In 1968, Kohut published his first views on narcissistic disorders, which was to lead to his eventual postulate that narcissism was a line of development, rather than a stage, type of energy, or a personality disorder. At first, Kohut sought to meld his views with those of mainstream psychoanalysis. However, as his ideas developed, he perceived the need to carve out an independent niche for self psychology, which took the theoretical form of claiming that a self/narcissistic line of development follows an independent course from what he termed the "object-libidinal" line of development more typically described by classical analysis. Still, in 1971, when his first major book was published, titled *The Analysis of the Self*, it was framed in the patois of classical analysis. In this book, Kohut laid out the fundamentals of his views concerning the treatment of narcissistic patients, including transference and countertransference considerations. Most important, the analyst had to maintain an empathic immersion in the psychological field of the patient and tolerate the emptiness of their own emotional reaction to such individuals. What Kohut termed "empathy" was

crucial, for departures from such empathic immersion lead to profound disruptions in the patient's personality, what Kohut called "fragmentation" of the self. The self became the focus of the analyst treating the narcissistic patient, which was phenomenologically closer to clinical experience than the reigning tripartite model of the classical analysts. The patient grew in the crucible of the analyst's empathic immersion, rather than through the analytic imparting of insight by way of interpretation. The actual experience of the clinical interaction became more important than the knowledge that could be deduced from the interaction.

The fragmented self was seen to result from early failures in what Kohut termed "self-object experiences," which were seen as failures in caregivers' empathic relationship to their children and which tended to get covered over by what Kohut termed the "compensatory structures" of development, that is, defense-like structures that covered over and protected the individuals' self-esteem from these early deficits. Although covered over by subsequent life span experiences, such early failures lurked in the personality of the child and could only be altered through an isomorphic reevocation of the early self-object experience, which Kohut termed a "self-object transference." In particular, he identified two kinds of self-object transference, an idealizing and a grandiose one. Loosely speaking, the idealizing transference can be equated with paternal object relations and the grandiose transference with maternal object relations. The idealized self-object transference referred to the normative need of a child to see the other in perfectionistic terms. The grandiose self-object transference referred to the normative need of a child to experience themselves as omnipotent as mirrored by a caregiver. Eagle has critically written about a developmental psychology based solely on these two types of reconstructed transference configurations. Over the years, Kohut's vision of the child embedded in a world of self-objects has held up to research scrutiny far better than his description of these two types of transferences, which were reconstructed from the analytic situation of adults rather than actually observed in the behaviors of children and their caregivers.

Note again the emphasis on the concept of "self" in Kohut's thinking. The self is quite different than the ego of Freud. Kohut thought of the self and defined it as the center of initiative and action. The self develops through experiences of being independent, mirrored properly, and empathically understood until "self-cohesion" has formed. Self-cohesion is the term Kohut chose to describe the self of an emotionally strong, vig-

orous, expansive, and resilient person. The developing self is understood as potentially traumatized through subtle ways, such as a caregiver's rigidity, lack of empathy, or inability to affectively attune to a growing child. The child is seen as formed into a world of self-objects and is natively happy and prone to fit into such relationship patterns. The mind of the child is more akin to a tabula rosa than that described in classical analysis—children are born good and made bad, rather than inevitably suffering from the frustrations and limitations of intrapsychic conflicts as implied by an epigenetic psychobiological blueprint. This self psychology take on early development is in stark contrast to the classical view of trauma, which is understood more explicitly as an external assault on a psychic apparatus incapable of withstanding overstimulation, understimulation, and affective regulation.

The reception to his 1971 book was mixed. As Kohut inquired deeper and his clinical experience deepened, he felt the need to expand the scope of his investigations. As a consequence, Kohut began to describe what he called "the psychology of the self in the wider sense" that referred to a vision of self psychology as an approach to most patients, not just narcissistic ones (and which he contrasted with the "psychology of the self in the narrow sense"). Encouraged by many of his early followers in Chicago and elsewhere, such as Paul and Anna Ornstein, John Gedo (who was soon to break from this group), Arnold Goldberg, Michael Basch, Marian Tolpin, Joseph Lichtenberg, and Ernest Wolf, self psychology became a movement in its own right. In 1976, Kohut published a book titled *The Restoration of the Self* that became a virtual manifesto of this new movement. No longer seeking a rapprochement with classical analysis, a new vocabulary and new way of looking at virtually all clinical phenomena was born. It was also only a short amount of time before self psychology was to expand far beyond the frontiers of four to five times a week clinical psychoanalysis and become a treatment modality and method of investigation that addressed and incorporated psychotherapy, brief treatments, informed a tremendous amount of research, as well as a remarkable fecundity of applied psychoanalysis (art, history, politics, and literature). Reaching far beyond the borders of Chicago, self psychology became an international movement with chapters worldwide. It also was picked up by many nonmedical practitioners, who sensed a sympathetic and compatible view of people and treatment that they found lacking elsewhere.

As mentioned, in a subtle shift, self psychology overtly became a method of investigation into narcissism as a

line of development rather than as a type of personality disorder. The narcissistic line of development was defined as the relationship of the self to the self, and the object-libidinal line as the relationship of the self to the other. Individuals were seen as growing up among and requiring self-object relationships of all sorts. The self was not seen as boundary by the skin. Self-objects were defined as environmental objects that fulfilled functions required by the self, and in fact were experienced as if they were a part of the self. Although outside the self, they were experienced as if they were inside. Thus, soothing and/or self-regulating self-objects were sought if an individual did not have internalized capacity for self-soothing or self-regulating; then, these functions were treated as if they were internal although they belonged to someone external. This framed a kind of attachment to others, and so individuals were seen as embedded in a social and interactive matrix far more than classical analysis had emphasized. The classical emphasis on infantile sexuality and aggression was markedly deemphasized, in favor of self cohesion and empathic immersion. Self-objects were also defined as incorporating not necessarily people but also ideas, ideals, and other factors such as goals and values.

In his 1976 book, Kohut also addressed many aspects of the treatment situation that were the pillars of the classical approach; for example, he reexamined the Oedipus Complex and claimed that its turbulence was a “breakdown product” resulting from developmental failures in empathic self-object relations rather than a universal period of conflict stemming from entry into the world of triadic object relations. In a series of sharp exchanges, Kohut and Otto Kernberg, a New York-based analyst with a more classical persuasion, engaged in a scintillating and intriguing series of exchanges concerning the treatment of patients with severe disturbances, particularly those termed borderline. At the time, it was unfortunate that many clinicians perceived a rubicon of sorts between classical analysis and self psychology and were drawn into taking sides. This probably delayed or prevented an integrative assessment of the significance of self psychology, as many felt they either had to reject or accept it in its entirety.

Kohut, after the 1976 book, was yet to publish a great many influential papers. One such paper that has captured the attention of a great many scholars of psychoanalytic history was titled “The Two Analyses of Mr. Z” which he said was his analysis and reanalysis of a particular patient; the first employing the techniques of classical analysis, and a second employing the techniques of self psychology. Needless to say, he reported that the second analysis was far more helpful and

reached areas that the first analysis could not. Kohut reported that it was this analysis that truly opened his eyes to the depths and powers of self psychology. Although this cannot be confirmed, several independent sources hypothesize that Mr. Z. was Kohut himself. The two analyses referred to were actually the two analyses Kohut himself underwent.

III. TRANSFORMATION

Heinz Kohut died in 1981. His last book *How Does Analysis Cure* was published posthumously in 1984. With his death, self psychology underwent a profound transformation, as it became unclear whether it consisted of one theory or many. Clinicians such as Robert Stolorow and colleagues, Arnold Goldberg, Michael Basch, Howard Bacal, and others too numerous to name carried on the tradition. Many went their own way without the unifying force of Kohut’s vision. As the group of adherents to self psychology grew, several individuals worked hard to clarify the specific principles of therapy native to self psychology. Although there was disagreement, the unifying thread seems to be that the main goal of treatment is to strengthen the sense of self and to facilitate growth. Treatment works to facilitate the latent potential for self-vitalizing experiences, largely through the positive and affirming experiences that take place in the transaction between the therapist and the patient. It did not necessarily require four or five visits per week nor a couch. As the principles of therapy expanded, so to did the theory of self psychology informing treatment. For example, Stolorow went on to elaborate on a worldview he termed “intersubjective.” Goldberg sought something of a rapprochement with classical analysis, emphasizing that interpretation is and always has been the primary instrument of self psychology. Goldberg wrote persuasively of how empathy and introspection alone cannot define the field of psychoanalysis. Basch went on to describe psychoanalysis as “applied developmental psychology” and using a self psychology framework, brought in the method and findings of general psychology (perception, developmental psychology, brain-behavior correlations, etc.) to elaborate upon such issues as empathy, Freud’s corpus of writings, and principles of psychotherapy.

Many of these authors took issue to some extent with some of the basic and fundamental tenets of Kohut’s work. For example, Stolorow criticized Kohut’s model of the bipolar self for having the potential for reification of self-experience, for mechanistic thinking, and for limiting the number of potential self-object transferences that

can be found in the clinical situation. Basch also criticized the notion of the bipolar self and replaced it with his own version of a functional self-system, with a brain psychology integrating the affective and cognitive information processing activities governing the individual's adaptation to the environment. Bacal argues that self psychology is in reality an object-relations theory, and that the self-object transference is itself a particular type of object relationship; Kohut was explicit that he was not defining an object-relational psychology, which he pejoratively referred to as a "social psychology" that was outside of the arena of psychoanalysis.

As previously touched on, self psychology was informed by and spawned a significant amount of empirical research, particularly in developmental psychology. In many ways, the pioneering research of Daniel Stern in the early 1980s that pointed toward an interactive baby swept up in developmental currents was closer to Kohut's reconstruction of childhood than the child of classical analysis. Relationships rather than intrapsychic conflicts assumed a research priority. Other developmentalists, such as Louis Sander, Edward Tronick, and Beatrice Beebe, found the inspiration and a model in Kohut's description of childhood that fostered a great deal of creativity in their empirical research. Joseph Lichtenberg, himself not an infant researcher, was particularly active in conceptually seeking to integrate experimental and observational infant research with self psychology. Eventually, he was to go on to describe five motivational systems as the engine of action in self psychology, roughly equated with the drives in classical analysis. In several important publications, he described principles of treatments for the self psychological perspective that utilized his notion of these five motivational systems. Certainly one major advantage of these five motivational systems was their grounding in the developmental literature of the time, which in some people's view provided for a scientific grounding that could not be found in Freud's psychology of personality.

Self psychology was to develop its own diagnostic system (a kind of nomenclature) quite different from any other. A good example is depression. Many self psychologists spoke of "empty depression," a sort of experience of depletion or lack of vitality that characterize a sense of futility in connecting with others. Others were concerned with severely disturbed patients. They addressed how patients can develop the all-important capacity to sustain a stable self-object transference and defined this as the border between narcissistic and borderline states. Each has characteristic treatment implications in the self psychology diagnostic nomenclature. In borderline states, the transference was not

stable, and "secondary compensatory structures" interfered too readily, so as to make such an individual not amenable to analysis (although, to be sure, psychotherapy could be embarked on with such individuals). Narcissistic states could thus best be diagnosed from an assessment of the transference, rather than from stable intrapsychic personality factors standing apart from the treatment situation. A very important step became the articulation of translation rules from the diagnostic nomenclature of self psychology to others in the psychodynamic arena thinking and practicing with a different theoretical frame of reference. In many ways, this is a work still in progress.

The study of dreams became a focus of self psychology as it expanded its network of influence. Some self psychologists expanded upon Kohut's notion of a "self-state dream." Whereas classical analysis looked for infantile wish fulfillments lurking within the patient's associations to the manifest content of a dream, self psychology looked for "self-states" in dreams that provided an indication of the patient's sense of connection, mood, and integration. Ernest Wolf, a colleague of Kohut's in Chicago, was one of the first to investigate the self psychology construal of dreams and the departure therein from the prevailing classical analytic theory dating back to Freud's revolutionary portrayal of the role and functions of dreams.

IV. SUMMARY

As is true for many branches of contemporary psychoanalysis, self psychology at present is in a state of flux. In the classical world, it is certainly clear that after an initial period of rejection, many of Kohut's ideas have found their way into the mainstream. For example, Kohut's observations concerning the fragility of the narcissistic person and the need not to interpret transference early on until the patient is able to make constructive use of it now seems to be the dominant view in classical theory. Many classical analysts, such as Evelyn Schwaber, have described how they proceed by always assuming that the patient's perceptions are primary, and that empathically the analyst must always understand the world as seen through the eyes of the patient. Such sensitivity to the subjective states of the patient is an example of the type of technical advancements attributable to Kohut's writings and influence. It is unclear, looking toward the future, whether self psychology will continue as a monolithic tradition, become a loose confederation of post-Kohutian psychologies, or proceed apace toward an integration with the very same points of view it rejected

40 years earlier to make its own way in the evolving psychoanalytic tradition.

GLOSSARY

extinction The weakening of a behavior by withdrawing reinforcement.

learning theory Pertaining to learning through classical conditioning, operant conditioning, or modeling.

reinforcement The presentation of a positive stimulus or the removal of a negative stimulus to increase a desired behavior.

Self-punishment is a behavior in which a person is responsible for removing a positive stimulus or presenting an aversive stimulus to himself to decrease an undesired behavior. This article explains the concept of self-punishment, its behavioral underpinnings, and the limits to its effectiveness.

I. DESCRIPTION

To most people, punishment tends to be equated with a harsh consequence that is expected to teach a lesson, whether it is a part of childrearing, education,

or civil law. A child may be grounded for missing curfew, a student kept in for recess because she failed to complete her homework assignment, or a criminal sentenced to jail for committing a felony. This definition, although adequate for everyday usage, is insufficient to describe the psychological connotations.

Behavioral psychologists, and others familiar with learning theory, appreciate punishment to be the presentation of a negative stimulus or the removal of a positive stimulus so that a particular undesired behavior will be decreased. The lay definition may include the aversive situation that comes with either the presentation of a negative stimulus or the removal of a positive one, but it is often irrelevant as to whether or not the behavior being punished will likely be deterred.

For persons to engage in self-punishment means that they are responsible for implementing the appropriate consequences without external support. For example, if a student tends to daydream while studying, a self-punishment tactic she could use to keep herself from going off-task would be to cancel her usual evening phone call with her best friend whenever she catches herself daydreaming (removal of a positive stimulus). The girl's decision not to call her friend must be self-generated for it to be self-punishment. Should her father revoke her phone privileges whenever she daydreams, it would be an external form of punishment. Similarly, every time a man deviates from his diet by eating fast food he could punish himself by having to drink an extra serving of wheat grass juice (presentation

of an aversive stimulus) instead of having a fruit smoothie (removal of a positive stimulus). If his wife decides that he cannot eat dessert after dinner, it would be external punishment.

II. THEORETICAL BASIS: A BEHAVIORAL PERSPECTIVE

In behavioral psychology, three possible events other than punishment can follow a behavior: negative reinforcement, positive reinforcement, or extinction. Punishment should not be confused with negative reinforcement, which is the removal of an aversive stimulus to increase a desired behavior. Although homework is not designed to be an aversive stimulus, most students would insist otherwise because they have other tasks on which they would much rather spend their time. Therefore, a teacher could negatively reinforce students to participate in class discussions by canceling the homework assignment whenever the entire class actively participates. Another example of negative reinforcement would be the use of an umbrella during a rainstorm: the action of opening the umbrella removes the negative stimulus of becoming wet. Therefore, this reinforces the use of an umbrella when it rains.

Positive reinforcement also serves to increase a desired behavior, but it is achieved by presenting a positive stimulus after a desired response. The term reward is often equated with a positive reinforcement, although it is important to keep in mind that a reward in lay vernacular does not necessarily imply a positive reinforcement. For example, a person may receive a monetary reward for finding a lost pet. The money is meant as a gesture of gratitude, not as a means to induce a person to continue to find more lost pets. In the true psychological sense of the concept, a child who is rewarded with praise and congratulations from his parents for earning good grades at school is likely to continue to earn good grades so that he may continue to receive the positive parental reinforcement.

Extinction is often confused with punishment because it also involves the removal of a particular stimulus to weaken or decrease a behavior. However, extinction is the decrease of a behavior that had been previously learned. A rat could be trained not to press a lever if he no longer receives food pellets with every depression. The rat must have been originally trained to receive the pellets as positive reinforcers for this action to be interpreted as becoming extinguished. Had the action not been trained, it would more likely be interpreted as punishment when the pellets were not supplied.

Extinction is much more complicated in real-life situations than it is in the laboratory. The withdrawal of reinforcers tends to result in the immediate eruption of the undesired behavior. In addition, even if the original behavior has abated, other unexpected patterns of behavior may surface that prove equally problematic. For example, persons who are attempting to quit smoking may use nicotine gum to decrease the number of cigarettes smoked. Eventually, the use of the nicotine gum must also be eliminated, but it is quite possible that they will have uncontrollable nicotine cravings and smoke cigarettes because they no longer have the consolation of the gum.

Extinction is also difficult to implement in nonlaboratory settings because the stimuli that reinforce the undesired behavior are not always known, nor are they easily controlled. It is common for students to misbehave in class because of peer reaction. If a young boy sneaks a frog into the classroom, supportive students will applaud and others will most likely scream, but both reactions serve to reinforce the student for his deed by bringing attention to him. It would be possible although most likely difficult for a teacher to instruct students not to be supportive of such a disruptive act, but it would be even more difficult to tell others not to be afraid. Unless both forms of reinforcement are removed, the behavior cannot be extinguished.

The main problem with any form of punishment is that it does not teach a desired behavior. By definition, it only decreases an unwanted behavior; it does not increase the behavior that is wanted. If you are trying to teach your child to eat all his vegetables at dinner, scolding him when he hides his brussels sprouts in his napkin will not necessarily make him eat his brussels sprouts on a future occasion. Instead, he will find other means to avoid eating his vegetables. Similarly, punishing yourself whenever you eat junk food will not necessarily cause you to eat more healthily.

Punishment can be quite helpful when you are trying to decrease a particular behavior instantly. If you punish your child immediately after he has run into the street, it is likely that you have deterred that dangerous behavior from occurring again. It does not mean, however, that your child will angelically walk alongside you from that point forward. It simply means he will not run into the street again.

With all forms of reinforcement, and punishment, it is important for the ensuing action to be immediate, strong, and consistent. It is difficult to learn a new behavior or terminate an old behavior if the consequences are not easily discerned. It was quite common several decades ago for fathers to be the disciplinarian

of the household. When children misbehaved early in the day, they would often have to wait several hours until their father came home before they were punished for their bad behavior making it difficult for them to associate their punishment with their earlier misbehavior. Instead, they would probably associate their punishment with their father coming home, and learn to fear the return of their father, instead of learning not to misbehave.

Delayed or inconsistent self-punishment would yield similar results. Suppose you are trying to teach yourself not to skip classes. You could tell yourself that every time you fail to attend a class, you would punish yourself by having to spend an extra hour in the library studying. This form of punishment is not likely to be successful because the punishment would not be immediate. For example, because it is such a beautiful day you decide to go to the beach instead of attending class. As you reach that decision, you tell yourself that you will go to the library that night for 3 hrs instead of two because of your truancy. Not only would your punishment be far removed from the misbehavior, but you have also unintentionally positively self-reinforced yourself for missing class by enjoying yourself at the beach. The positive stimulus immediately followed the decision to be truant; therefore, you are more likely to have trained yourself to skip class more often, the exact opposite of your original intentions.

III. EMPIRICAL STUDIES

There is limited evidence that self-punishment, used alone, is an effective method to change one's behavior. In fact, some research even suggests that more harm than good tends to come from self-punishment. In her doctoral dissertation, Sister Mary of St. Victoria Andreoli, R.G.S. found a strong positive correlation between self-punishment and later propensities to be aggressive toward others.

Many therapists have tried to use self-punishment to stop clients from smoking or from overeating. Clients are often instructed to pay a fine (removal of positive stimulus) whenever they engage in the unwanted behavior. Although this form of self-punishment avoids the ethical concerns associated with the presentation of a negative stimulus, M. J. Mahoney, N.G.M. Moura, and T. C. Wade found in 1973 that forcing someone to give up something of value was not an entirely effective means to deter a behavior.

In a study by M. J. Mahoney in 1971, a client was instructed to snap a large rubber band that was worn

around his wrist to decrease the target behavior. This form of self-punishment did prove effective but not because of the presentation of mild pain (aversive stimulus). The punishment interrupted the misbehavior, which then alerted the client to regulate his actions.

W. H. Morse and R. T. Kelleher found that punishment should supplement programs that utilize reinforcement. The punishment can decrease the acute problematic behavior while the reinforcement supports the desired behavior. For example, if parents are trying to convince their teenage son to wear his seatbelt when he drives his car, they should revoke his driving privileges (removal of positive stimulus) whenever he is caught without his seatbelt. They should also extend his curfew (positive reinforcement) whenever he does remember to buckle up without inducement. This theory can be extended to apply to self-punishment. Using self-reinforcement in lieu of or in conjunction with self-punishment punishment would prove more effective. In his study, "Coping with temptations to smoke," Saul Shiffman found that people who used strategies other than self-punishing thoughts resisted the urge to smoke more than their self-punishing counterparts.

IV. SUMMARY

Punishment in any form is not a completely ineffective method to change one's behavior. However, given that it can only decrease a particular action, also engaging in a form of reinforcement would prove more logical and efficient. Although not many studies have been done directly on the concept of self-punishment, it is not unreasonable to extend findings from studies on punishment and apply them to self-punishment. People interested in self-modification will have better results using forms of self-reinforcement than they would if they engage solely in self-punishment.

 - IV. Summary
- Further Reading

self-statement The self-verbalizations or self-talk in which people engage, either overtly (aloud) or silently (covertly).

GLOSSARY

cognitive contents The content of people's self-talk; what they think and the sentences they use. They are close to or just below the level of conscious awareness.

cognitive processes The cognitive distortions people use in interpreting sensory data, for example, overgeneralizing, personalization, and dichotomous thinking.

cognitive structures The network of tacit rules and assumptions people use in interpreting the world that are laid down at an early age. They consist of tacit cognitive contents organized around a theme. They are also called core cognitive schemas and consist of unrecognized assumptions about the self and the world, for example, "I'm unlovable."

covert behaviors (or coverants) Behavior (such as internal verbalization) that is observable only to the behaving and observing individual.

internal dialogue A series of automatic self-statements about a situation or behavior.

operant conditioning Consequential learning based on reinforcement, which increases subsequent behavior, or punishment, which decreases it.

self-instructional training (SIT) A training package that trains people how to assess what they are saying to themselves and then to modify what they say to themselves to overcome behavioral difficulties.

I. DESCRIPTION OF TREATMENT

Self-statement modification is rarely attempted alone; rather it is generally presented as one component of a treatment package that includes other therapeutic ingredients such as modeling, role-playing, behavioral rehearsal, verbal reinforcement, problem-solving, or social skills training. There are two parts of self-statement modification, the assessment of maladaptive self-statements and the learning and production of new, more adaptive self-statements.

There are several methods for assessing self-statements, which were described (in another context) by Dowd in 1995. Interview-based methods include "think-aloud methods" (in which clients are instructed for a period of time to verbalize whatever comes to mind), "thought-listing" (in which clients list for a period of time whatever thoughts they might have had about a specific situation), "prompted recall" (in which clients view a video or audiotape of them in a problematic situation and indicate what their thoughts were at certain times), and "imagery assessment" (in which clients are asked about images they had during problematic situations). Questionnaire methods include such instruments as the Assertive Self-Statement Test (ASST), the Social Interaction Self-Statement Test (SISST), the Automatic Thoughts

Questionnaire (ATQ), the Dysfunctional Styles Questionnaire (ASQ), and the Irrational Beliefs Test (IBT). Some of these assess attitudes at least as much as self-statements but there is no clear demarcation between the two.

Once the maladaptive self-statements have been identified, clients are then taught to emit adaptive or coping self-statements in place of the maladaptive ones. Following the developmental theory of Luria and Vygotsky, Meichenbaum and Goodman in 1971 developed the prototype of the modification of self-statements:

First, E (*experimenter, therapist*) performed a task talking aloud while S (*subject, client*) observed (E acted as a model); then S performed the same task while E instructed S aloud; then S was asked to perform the task again while instructing himself aloud; then S performed the task while whispering to himself (lip movements); and finally S performed the task covertly (without lip movements). (p. 117, italics added)

Thus, the therapist gradually takes clients from overt verbalization of the new self-statements to covert verbalization, recapitulating the development of private speech or self-statements in children.

Examples of maladaptive self-statements might be, "I'll never be able to do this task!", "I just don't have what it takes!", "I'm not as smart as other people." Examples of coping or adaptive self-statements might be, "I can develop a plan to handle this," "I can do it if I slow down and take it one step at a time," "Just relax and let the fear subside," or "It worked! I did it — not perfectly but pretty good!"

As with other therapeutic procedures, repetition is very important in self-statement modification. People do not easily or quickly change long-entrenched and automatic ways of responding, including self-statements. Often they are not even aware of their self-talk until after it has occurred and sometimes not even then, even with therapist prompting. Practice outside of therapy as well as during the sessions is important for sustained progress.

II. THEORETICAL BASES

Self-statements are a universal aspect of human cognitive function and their modification is an important part of cognitive behavior therapy procedures. Indeed they are found in all of the important Cognitive-behavior therapy (CBT) interventions, although often by different names. Self-statements are the statements that people say to themselves in a variety of situations and they can be either positive or negative. Sometimes they are within the area of conscious recollection although often they

are not; that is, we sometimes recognize that we are making these statements while much of the time we do not.

Self-statements are similar in many ways to the automatic thoughts of Aaron T. Beck's cognitive therapy, to the irrational thoughts of Albert Ellis's rational-emotive-behavior therapy, to Marvin Goldfried's cognitive (or rational) restructuring, and to Daniel Araoz's negative self-hypnosis. What they all have in common is an assessment and modification of the covert self-talk that lies at and just below the level of conscious awareness. They are what Meichenbaum and Gilmore refer to as "cognitive contents," or the actual content of our cognitive processes. Perhaps because self-statement modification is functionally similar to or part of other CBT procedures, some writers have not clearly distinguished it from other CBT procedures, such as self-instructional training, cognitive restructuring, rational disputing, and imagery work. It has therefore appeared on occasion that the differences among them are insignificant. Nevertheless, there are distinctions. The automatic thoughts in Beck's cognitive therapy are more idiosyncratic in nature than the more standard irrational thoughts of Ellis. Cognitive restructuring is a more generic term for a set of techniques. Hypnosis and imagery work represent a class of more nonverbal techniques.

Perhaps the best theoretical development of self-statement modification can be found in the self-instructional training (SIT) of Donald Meichenbaum. Meichenbaum based his work on both behavioral and developmental theories, out of which he derived his own cognitive theory of change. His early work in cognitive behavior modification was based primarily on self-statement modification with impulsive children in order to reduce their level of impulsivity. Behaviorally, he considered self-statements to be examples of covert behaviors, subject to the same laws of learning and modification as other behaviors. Generally, the theoretical basis for these laws was operant conditioning. In this, he followed Lloyd Homme's notion of coverants (or covert operants/behaviors) as obeying the same laws as overt behaviors. Covert behavior was reinforced or punished according to the same principles as overt behavior. Developmentally, he referred to the work of the Soviet psychologists Alexander Luria and Lev Vygotsky, who viewed the internalization of self-statements as fundamental to the human development of self-control and regulation of behavior. Luria and Vygotsky argued that self-statements in young children are first overt in nature and mimic the overt talk of significant adults. Later, the child's self-statements become covertly subvocalized and then entirely automatic and nonconscious in nature. It is these automatic thoughts or self-statements

that result in adult behavioral regulation. Children who do not internalize these self-statements have difficulty with self-regulation (most obviously in impulsivity) but internalization of maladaptive self-statements can result in later psychological problems.

Meichenbaum's cognitive theory of change has three phases. The first phase is self-observation, in which clients first become aware of their own behavior. They begin to monitor, with increasing accuracy, their own thoughts, feelings, physiological reactions, and interpersonal behavior. They gradually become aware that their self-statements (internal dialogue) are negative, repetitive, and unproductive and come to reconceptualize or redefine their problems, in part according to the theoretical orientation of the therapist. Thus, the client of a psychoanalyst may come to see his problems as stemming from his early relations with his father while the client of a behavior therapist may come to see her problems as arising from inadequate reinforcement for exploratory behavior as a child. In the process, both gain understanding (and therefore control and hope) of their feelings, behaviors, and thoughts. They begin the process of thinking differently about their problems.

The second phase is incompatible thoughts and observations. Here, as a result of the observations in Phase One, clients begin a translation process from the maladaptive internal dialogue to a more adaptive internal dialogue. They begin to reconceptualize their problems differently. The new internal dialogue affects their attention, their appraisals, their physiological responses, and even instigates new behavior. The increased attention in Phase One helps change the internal dialogue in Phase Two, which in turn guides new behavior.

The third phase is the development of new cognitions about change. In this phase, clients begin a new internal dialogue about the changes they have been undergoing and the new behaviors they have been producing. These changes provide evidence for a change in self-statements that make up the internal dialogue. If their interactions with other people change, they will then reflect on this in their changed internal dialogue. The modified internal dialogue is similar to what in other systems might be referred to as "insight." In other words, behavior change precedes insight, rather than following it, a point made in 1962 by Nicholas Hobbs.

The implication of this theory of change is that therapeutic interventions might profitably focus first on instigating behavior change and then fostering cognitive change as clients reflect on their behavioral change and its implications. But cognitive therapists in general have often focused first on changing cognitive contents (self-statements) or cognitive processes (cognitive dis-

tortions). Indeed, Jeffery Young, in his schema-focused therapy, focuses on cognitive structures, or the network of rules and assumptions that determine how we interpret the world.

III. EMPIRICAL STUDIES

There has been considerable research conducted on self-statement modification, even within relatively recent years. Two meta-analyses of the effects of self-statement modification were published by Dush, Hirt, and Schroeder, in 1983 and 1989, one on adults and the other on children. In the adult meta-analysis, the results for self-statement modification were impressive. Self-statement modification produced a greater effect size than alternative therapies when compared both to no-treatment controls and to placebo controls. However, the effect sizes were smaller when compared to placebo controls than to no-treatment controls. The efficacy of self-statement modification was found to be greater when combined with other cognitive-behavioral procedures. Similar results were obtained in the children's meta-analysis. Self-statement modification produced greater effect sizes than either no-treatment controls or placebo controls, although there was no significant difference between the two types of comparisons, indicating that placebo treatment with children may not be more effective than no treatment. Comparing the two meta-analyses, the effect of self-statement modification appeared to be less for children than for adults, especially when compared to no treatment.

A related meta-analysis examining the treatment of impulsivity in children by Baer and Nietzel found comparable results. The interventions were associated with improvements ranging from one-third to three-fourths of a standard deviation when compared to untreated controls. Self-statement modification in these studies was combined with other cognitive-behavioral interventions.

Other studies have found self-statement modification to be effective in preparing patients for various stressful medical procedures such as coping with office routines and illness management, particularly for children. It has also been found to be effective as part of a treatment program for anger management and in treating such problems as heterosexual effectiveness, assertive training, and dating-skills training. Because it has sometimes been evaluated in combination with other CBT techniques, it is not always clear what unique contribution it makes. However, it has been shown to be at least as, if not more, efficacious than alternative treatments.

IV. SUMMARY

Self-statements, positive and negative, appear to be a ubiquitous aspect of human cognitive and developmental functioning and are heavily implicated in self control. Self-statement modification is found in many of the cognitive-behavioral theories, including those of Aaron Beck, Albert Ellis, Marvin Goldfried, and Donald Meichenbaum, and is designed to replace negative self-statements with positive ones. However, it often goes by different names in different theories. Perhaps the fullest and most complete expression of the technique is found in Meichenbaum's self-instructional training. Self-statement modification consists of assessing the self-talk that clients use about a problematic situation and then training them to emit different, more adaptive, self-statements instead. Research has shown that it is a very effective and versatile technique, although it is often used in combination with other techniques.

GLOSSARY

consequence Any object or event that immediately follows the emission of a response.

discriminative stimulus A stimulus in the presence of which a response is reliably reinforced.

establishing operation A current environmental event, operation, or condition of the organism that alters the relative strength of the discriminative stimulus to control responding.

functional analysis An assessment technique whereby the experimenter directly manipulates potential controlling variables to directly assess their effects on the targeted behavior of interest.

punishment A contingent relationship between a behavior and a behavioral consequence, in which that consequence causes the behavior to decrease in frequency.

reinforcement A contingent relationship between a behavior and a behavioral consequence, in which that consequence causes the behavior to increase in frequency.

I. DESCRIPTION OF TREATMENT

A setting event is a distinct stimulus event or a specific level of a dynamic state of an organism that pre-

cedes and interacts with a particular stimulus and response function. Setting events may momentarily alter the relative control of a discriminative stimulus, resulting in a potentially different response than usually occasioned by that same discriminative stimulus. If a treatment was designed whereby a participant has been trained to emit a vocal response in the presence of a teacher's vocal prompt and subsequently reinforced with praise, the setting event of another person, say the participant's friend, may result in an altered probability of that same vocal response being emitted. In this case the setting event of the friend may result in a higher or lower probability of response emission by the participant. The relative change in response probability is a function of the participant's past history of reinforcement or punishment for similar responses in the context of that setting event. Assuming that the participant has been reliably reinforced for emitting a vocal response following a vocal prompt of the teacher, if now exposed to a similar situation where the friend is present he fails to emit the correct response. The occasioning ability of the teacher's prompt and the reinforcing function of the teacher's praise has been momentarily weakened in the presence of the participant's friend. Figure 1 provides a visual illustration of this example.

In order to establish new behaviors most effectively, one should be aware of the potential influence of setting events on a given treatment approach. Several variables will enhance the likelihood that the resulting treatment will be successful. First, attempts should be made to incorporate into treatment those setting

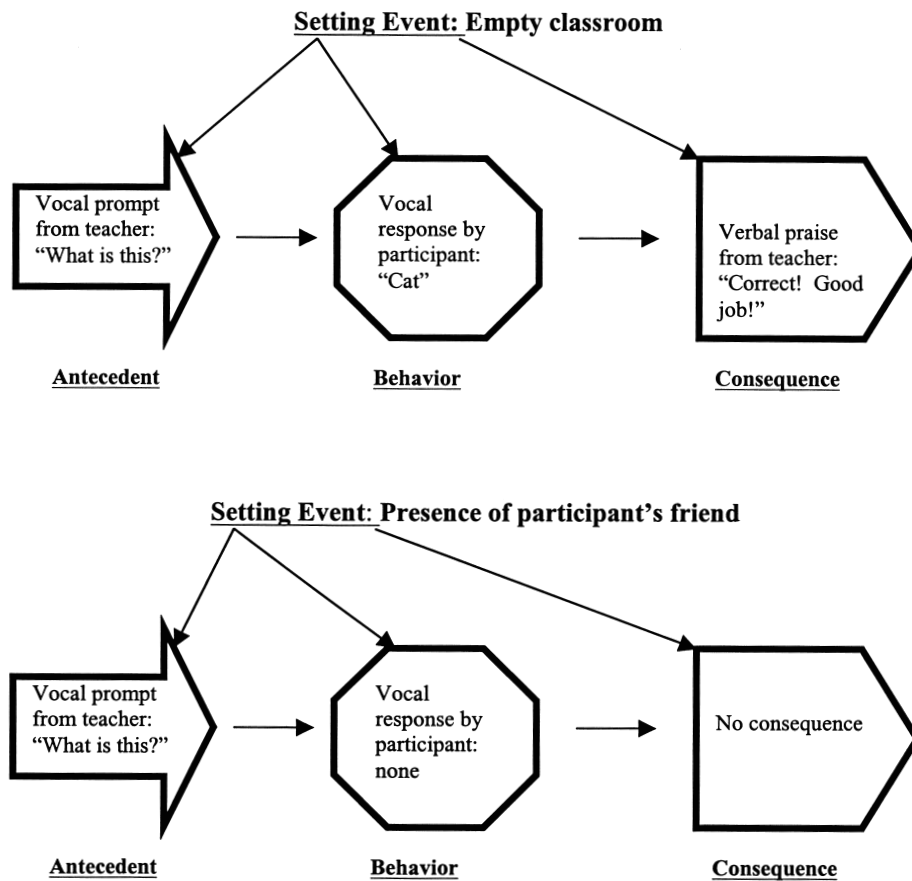

FIGURE 1 Conceptual illustration of the potential influence of a given setting event.

events that have been associated with increased emission of the desired response and eliminate those setting events that have been associated with decreased response emission. Proper identification of the relevant characteristics of the participant's environment that may be functioning as such setting events might be accomplished via an interview with relevant persons, direct observation, or a functional analysis. Second, it should not be assumed that a particular setting event will be directly observable or in temporal proximity to the stimulus-response function question. Setting events such as food deprivation, a fight with a spouse, and stomach pains may either be unobservable or currently absent from the immediate setting. In such cases, proper identification is still possible, yet may require additional exploration. Third, when the elimination of setting events that reduce the probability of treatment success are not possible, one should attempt to minimize their effect. This might be done by withholding the discriminative stimulus, which

will now not occasion the appropriate response, providing additional discriminative stimuli for the appropriate response, or altering the magnitude, density, or salience of the reinforcement to be delivered contingent for the appropriate response. In the earlier example this might consist of the teacher not prompting the participant for a vocal response until his friend leaves the training environment, the teacher providing additional prompts such as "Show your friend how much you know" before presenting the original discriminative stimulus prompt, or the teacher providing a piece of candy coupled with praise as the consequence for a correct vocal response.

II. THEORETICAL BASIS

The concept of setting event was theoretically discussed as early as 1959 by J. R. Kantor, under the name "setting factors." He conceptualized the setting factor as

a general circumstance surrounding the interaction between the stimulus and the response. According to Kantor, the setting may have an effect on the stimulus object, the reacting individual, or the interaction between the two. The role of the setting factor was to facilitate or hinder the occurrence of the particular stimulus–response function. Although the original name has changed in contemporary discourse from “factors” to “event,” the theoretical role it plays on subsequent behavior has not.

The notion of setting event is often added to theoretical conceptualizations of the traditional three-term contingency of (1) discriminative stimulus, (2) response, and (3) consequence, to aid in accounting for the periodic variability in otherwise assumed predictable responding. Setting events differ from other conceptualizations of an additional influence on the three-term contingency in terms of their scope. Setting events can be present in the current environmental context such as the case with food deprivation prior to meal time, yet they can also be somewhat removed in time such as the case with engagement in strenuous exercise the day before coming to therapy, or getting a traffic ticket on the way to work. The former example of food deprivation might be theoretically equivalent to the notion of an establishing operation, although the latter examples would not. Yet all three might exert some change in control over responding. In general the conceptualization of a setting event is broad and not limited by space–time proximity to a current emission of a participant’s behavior.

Additionally setting events may take the form of complete stimulus–response interactions that also affect other stimulus–response interactions that follow it. In other words, the setting event may be both an environmental event and the participant’s response to that event. For example, assume a college student whose studying behavior in her room is typically followed the next day by exceptional test performance, is now interrupted from studying in her room throughout the night by her brother’s playing of the drums downstairs. The no studying–being in her room interaction serves as a setting event for bad test performance the next day. Here it is the case that the previous night’s stimulus–response interaction has a latter effect on observed behavior the next day.

Setting events influencing control over behavior can be identified in ways theoretically similar to those of discriminative stimuli and/or reinforcing consequences. One form of potential identification is through an interview or a rating scale. Caregivers or those known to the participant might be surveyed for potential awareness of the presence of a given setting event. These might in-

clude questions regarding the participant’s daily sleep or eating patterns, medication changes, experience of recent traumatic life events, and the presence or absence of particular persons in a given setting. The interview or rating scale is a cost- and time-effective method for potential setting event identification. This method is also prone to potential problems. First, the skill of the interviewer must be such that appropriate questions are answered. Second, accuracy of responses is subject to the interviewee’s ability to remember specific events. Third, the responses will provide correlated and anecdotal information at best. Current control by a specific setting event may or may not be identical to what has been post hoc reported.

Another form of identification is through observation. The clinician or the participant directly observes the behavior of interest and records current features of the present context that may be in part functioning as a setting event. In the case of the clinician, he or she might have a checklist or scorecard whereby a checkmark or tally is made when the observed behavior is emitted (or not emitted) by the participant in the presence of certain conditions. Self-monitoring might also be conducted whereby the participant attempts to observe and record data on their own behavior and its relation to potential setting events. Self-monitoring is useful when direct observation by another party is limited or not possible. One should keep in mind that accuracy is questionable with self-monitoring. Without contingencies in place to ensure reliability of data collection, there may be incentives for the participant to inaccurately report the presence of a specific setting event. An example here might be a participant who just experienced a toileting accident and fails to record it on her daily tracking sheet of self-initiated activities outside of the house because she is embarrassed.

Like interviews and rating scales, the direct observation of setting events has potential problems. First, observers might not properly identify all relevant setting events. This is especially true when setting events are not in close temporal or spatial proximity to the behavior of interest or when they are covert events such as headaches, feelings of depression, or food deprivation. Second, direct observation is very time consuming to effectively train observers. Third, direct observation will only provide correlational data on the potential effects of a particular setting event. Causal inferences are not possible.

A last form of identification is through experimental manipulation. This technique is often termed functional analysis. A functional analysis assessment would

require the clinician manipulate directly the presence or absence of a particular setting event and then assess subsequent performance. From experimental manipulation, causal inferences can be made about the relative contribution of an assumed setting event on a targeted behavior. For example, if it is assumed that the administration of a given drug to a participant is responsible for that participant's aggressive behavior at the workplace when prompted to complete tasks, the clinician might withhold drug administration on certain days to determine if drug-free days differ from drug-induced days' levels of aggressive behavior.

As with the previously mentioned methods, there also are potential problems in the functional assessment strategy for identification of setting events. Problems include the extensive time and cost for training of clinicians to identify and subsequently manipulate variables, as well as the increased ethical concerns regarding intensifying or postponing treatment for a problematic behavior. In summary, the clinician should use the assessment method for identifying potential setting events that is best suited for the individual circumstances, and be aware of and attempt to control for potential problems with its implementation.

Through the adoption of a theoretical perspective whereby setting events might influence stimulus–response relationships, and upon the utilization of appropriate identification techniques for such setting events, clinicians might eventually accomplish more effective treatments for the participants they serve.

III. EMPIRICAL STUDIES

The following empirical studies demonstrate that through proper identification and manipulation of a particular setting event(s), one can alter the strength of a stimulus–response relationship. Proper techniques should enhance treatment success.

For example, in 1993 Craig Kennedy and Tina Itkonen examined the effects of setting events on the problem behavior of students with severe disabilities. In a series of two studies they examined the relative frequency of problematic behavior occurrences in the presence and in the absence of hypothesized setting events. One of their studies involved a girl who exhibited both aggressive acts during daily transitions and frequent running away or inappropriate grabbing of objects in the presence of dogs, jewelry, or men. The authors assessed possible setting events for these classes of behaviors via a review of the girl's records, a structured

interview, and direct observation of her behavior. Once it was deduced that the potential setting event influencing the occurrence of her inappropriate behaviors was “awakening late in the morning,” a reversal design coupled with a setting event elimination strategy was introduced. The setting event intervention consisted of providing additional incentives for the girl to awake within a set period of time, along with requiring her to shut off her own alarm clock. Resulting frequencies of her problem behavior reduced dramatically upon the removal of the setting event. Similar results were obtained in the authors' second study that involved a girl whose problem behaviors were eliminated upon the removal of the setting event of being transported to school via the city streets. Here the intervention was simply to transport the girl to school via the highway.

A study conducted in 1997 by Mark O'Reilly demonstrated the correlation between the setting event of otitis media (a recurrent or persistent inflammation or infection of the middle ear) and episodic self-injury in a 26-month-old girl with developmental disabilities. In this study, the participant frequently engaged in back banging and ear poking. Upon completion of assessment interviews with the mother and doctor, it was deduced that her problem behavior occurred around 3 to 10 days a month and was thought to correlate with the presence of ear infections. To further investigate these correlations, a comparison across the naturally occurring conditions of ear infected and ear uninfected was conducted. This comparison yielded high rates of problem behavior during most conditions when the girl had an ear infection, and no rates of the problem behavior when her ears were infection-free. These results led the author to further explore the possibility that the setting event of otitis media might have been enhancing the sensory escape function from noise of the self-abusive behavior. Further functional assessment conditions showed this to be the case.

It is often the case that one particular setting event alters the probability of a given response, as in the above studies. Yet, it may also be possible that a combination of two or more setting events will have a collective effect on behavior. For example, in 1992, Lynette Chandler, Susan Fowler, and Roger Lubeck examined the effects of multiple setting events on the social behavior of preschool children with special needs. In their two studies, they attempted to identify the most optimal combination of setting events to produce the greatest number of social interactions of seven preschoolers. After implementing a series of systematic combinations, they concluded that the ideal combination of setting events to

facilitate peer interactions was (1) the removal of the teacher from the activity location, (2) the inclusion of only a limited number of play materials, and (3) a pairing of the child with a socially skilled playmate.

IV. SUMMARY

Setting events are contextual stimuli that momentarily alter the strength of the relationship between a stimulus and a response. Appropriate identification of setting events can assist the clinician in explanation of potential variability in responding. They can also be useful for the development of more appropriate and effective training opportunities. Reinforcement is not a static process uninfluenced by anything other than a simple discriminative stimulus. Rather, the strength of the discriminative stimulus – response – reinforcement relationship is dynamic. That dynamic relationship is often a direct result of the impact of a given setting event on the current context.

etiology All of the causes of a disease or abnormal condition.

organic Of, relating to, or arising in a bodily organ; affecting the structure of the organism.

psychogenic Originating in the mind or in mental or emotional conflict.

I. THE EVOLUTION OF SEX THERAPY: THEORETICAL UNDERPINNINGS

A. Early Views of Sexual Dysfunction

Although difficulties with sexual functioning have undoubtedly existed throughout time, early theories of the development and treatment of sexual dysfunctions first began to appear in the late 19th and early 20th centuries. In 1902, Richard von Krafft-Ebing published *Psychopathia Sexualis*, a book that addressed the existence of dysfunctions and deviations alike. Krafft-

Ebing theorized that many sexual disorders resulted from the improper use of sexual energy, creating a state of moral degeneracy. For men, this loss was conceptualized as a waste of semen on nonreproductive activities such as childhood masturbation and excessively frequent sexual activity in adulthood. Mental health professionals at that time advocated preventive treatment through the use of restraining devices that inhibited children's masturbation, such as metal mittens, and through the maintenance of a bland diet in adulthood to avoid overstimulation of the senses.

Sigmund Freud presented a different view of sexual dysfunction in 1905 with the introduction of the Oedipal and Electra complexes. Sexual disorders were thought to be the result of failing to resolve these complexes and becoming fixated at an immature stage of psychosexual development. Treatment did not involve direct attention to sexual functioning, but instead revolved around indirect psychoanalytic approaches, such as insight attainment and transference techniques.

B. Behavioral Sex Therapy

Despite the failure of Freudian therapy in the successful treatment of sexual dysfunction, it was nearly 50 years before Freud's views were challenged by early behaviorists. These early behavioral psychologists posited that anxiety functioned to inhibit normal sexual arousal, resulting in dysfunction. Treatment consisted of techniques to reduce anxiety such as progressive relaxation and systematic desensitization.

In 1966 and 1970, William Masters and Virginia Johnson published their monumental works on the etiology and treatment of sexual dysfunctions. Masters and Johnson expanded on the theories of early behaviorists by stressing an informal social learning theory approach that emphasized the roles that negative messages about sexuality, lack of knowledge about sexuality, and traumatic first sexual experiences play in sexual functioning. In addition, they introduced the concept of sexual problems as self-maintaining cycles of dysfunctional sexual behaviors mediated by anxiety. They theorized that following a negative sexual experience, an individual might develop an anxious, self-evaluative spectator role that interferes with the normal sexual response cycle and results in the maintenance of sexual dysfunction. In addition to the anxiety reduction techniques utilized by early behaviorists, Masters and Johnson included the instruction of specific sexual stimulation techniques in their treatment protocol.

Later additions to the Masters and Johnson model for sex therapy have included elements of both cognitive and systemic theory. An emphasis was placed on a patient's thinking about sex, with various cognitive distortions becoming a major focus of treatment. Moreover, couple systemic considerations such as power struggles and difficulties with intimacy and trust have increasingly been included in both etiological considerations and treatment focus in a variety of sexual dysfunctions. In 1997, Joseph LoPiccolo termed this melding of theoretical approaches "post-modern sex therapy" and acknowledged that the procedures used by behavioral, cognitive-behavioral, and systemic therapists in treating sexual dysfunctions greatly overlap. As a result, the most comprehensive discussion of current treatment approaches to sexual dysfunctions must include an explanation of the theoretical underpinnings of postmodern sex therapy.

C. Post-modern Sex Therapy

Post-modern sex therapy is a therapeutic approach that uses behavioral, cognitive, and systemic methods to treat a variety of sexual disorders that affect both males and females. This approach is based on a theoretical foundation in which the etiology of sexual dysfunctions is considered to be multifaceted, with both psychological and physiological factors contributing to the onset of a particular disorder. As a result, both diagnosis and treatment of sexual dysfunctions must be considered in the context of a combination of behaviors, thoughts, and emotions.

Problems in sexual functioning are thought to have several potential causes that must be considered when designing the treatment approach. According to LoPiccolo, these include psychological factors, such as family of origin learning history, systemic relationship issues, cognitive distortions, and daily life stressors, as well as physiological or medical issues.

1. Family of Origin Learning History

Although Freudian theories of sexual dysfunction have largely been abandoned by modern mental health professionals, the idea that childhood can play a significant role in later sexual development has not. Most sex therapists today believe that childhood and adolescent experiences can play an important role in the development of both healthy and dysfunctional sexual relationships in adulthood. Issues in family of origin learning history often involve negative messages about sexual expression and a lack of sex education. In addition, many women and men who experience sexual dysfunctions have parents who have modeled unaffectionate and unhealthy sexual relationships.

The most common form of sex education for children who later develop sexual dysfunctions is the absence of sex education. Numerous adults who experience sexual difficulties report that they were not told about the positive aspects of sexuality by their families, and they often say that they did not receive any messages at all about sex. As noted by Susan Walen and Richard Perlmutter in 1988, the absence of communication about an issue does not indicate the absence of an underlying message, and often the topics that are never mentioned are the very topics that are seen as the most distasteful and inappropriate for discussion. By refusing to discuss sexuality, many parents set their children up for believing a multitude of myths about sex that they garner from peers, the media, and other unreliable outside sources of information. These can include misinformation about how one gets pregnant, the ways in which sexually transmitted diseases are transmitted, and the ways in which each partner must give and receive sexual pleasure.

Warren and Perlmutter outlined the "secrets of sex in families" that can contribute to the later development of difficulties in sexual functioning. One such secret is that sex is actually a pleasurable way to share feelings of love and affection with a partner, to express oneself as a healthy or happy person, or is a pleasurable form of recreation. Other deleterious family secrets include the secret that masturbation is a normal and healthy way to explore oneself and experience pleasure, the secret that

children can have appropriate sexual feelings, the secret that adolescence is a normal time to experience sexual impulses and urges, and the secret that parents are sexual. In many of these families, the parents hide their affection and sexuality from their children behind closed doors, and children quickly learn that sex is an activity that needs to be hidden from others. Finally, the most serious sexual secrets that families keep are those associated with incest, rape, and paraphilias. Incest, in particular, is a family secret that very commonly leads to adulthood sexual dysfunction.

This lack of sex education not only leads to negative feelings about sexuality, but it also leads to sexual behavioral deficits in adulthood. Because they are discouraged from communicating with others about sexual issues and from sexual self-exploration, many children grow into adults who are ignorant of their partner's and their own anatomy, as well as the sexual response cycle. Common deficits in education that illustrate the problems associated with several sexual dysfunctions include uncertainty about the location of the clitoris, the belief that women must experience an orgasm through vaginal penetration only, the inability to recognize an orgasm when it does occur, the belief that men must ejaculate every time they have intercourse, the belief that men should be able to quickly regain erections after ejaculation, and the belief that orgasm through intercourse is the only acceptable end to sexual activity. These erroneous beliefs often lead to sexual behaviors that are detrimental to a functional sexual relationship, such as by neglecting to properly stimulate the clitoris to orgasm. In addition, cultural myths about sexuality and aging contribute to these cognitive and behavioral causes of sexual dysfunction. For instance, it is frequently thought that men should be able to attain and sustain an erection with little or no direct stimulation even as they get older.

While a lack of sex education is a common denominator in adults who have developed a sexual dysfunction, many children receive direct, harmful messages about the undesirability of sex. Negative messages about sexuality are communicated to children and adolescents in myriad ways. Strict prohibitions against childhood and adolescent masturbation, and parental negativism toward dating and premarital sexual activities are somewhat common methods of providing youth with messages about the shameful of sexual arousal and orgasm. In addition, traumatic first sexual experiences in childhood and adolescence have been found to be a common causative factor in the development of adult sexual dysfunctions. Finally, direct nega-

tive messages about sex and its consequences are often reported by individuals who suffer from a sexual disorder. Children might be told that sex is wrong, immoral, it hurts, or that it is dirty. Many females are informed that women do not enjoy sex, and if they do, then they are "sluts" or "whores."

Direct negative messages about sex have been linked to female orgasmic disorder by many clinicians and researchers. A "typical" history for these women has been described as involving strong parental prohibitions against nudity, masturbation, and sex play; no preparation for the onset of menstruation; a lack of sex education; and severe restrictions on adolescent dating. However, this same history is also common in women who do not later develop a sexual dysfunction. In 1986, Julia Heiman and colleagues reported that women who are both sexually functional and sexually dysfunctional experience similar culturally bound negative messages about female sexuality. It is still not clear what mediating variables may play a role in causing sexual dysfunction in some women, but not in others.

2. Systemic Relationship Factors

In the history of sex therapy, it has often been thought that sexual dysfunctions were extremely distressing to both the diagnosed individual and his or her partner. Marital dissatisfaction and sexual dysfunction were often considered to be separate problems, and assessment and treatment in one arena was compartmentalized such that marital therapy did not deal with sexual issues, and vice versa. More recently, however, it has been noted that sexual dysfunctions can play an important role in the couple's relationship. Indeed, sexual dysfunctions can sometimes be seen to develop in order to fulfill a role or convey a message within the relationship. As a result, post-modern sex therapy recognizes the important psychological needs that a sexual dysfunction can be meeting for an individual. In these situations, the dysfunction can be seen to introduce or maintain a level of homeostasis in the relationship structure. Understanding the psychological and relationship needs that sexual dysfunctions can help to fulfill is an important component of post-modern sex therapy. In 1997, LoPiccolo noted that inattention to the individual or couple dynamic needs that are being met by the sexual dysfunction commonly results in client sabotage and resistance toward therapeutic progress.

In 1988, LoPiccolo and Jerry Friedman formulated a list of several commonly occurring systemic issues that may be both causes and effects of sexual disorders. These issues include a lack of attraction to the partner,

poor sexual skills of the partner, general dyadic unhappiness, fear of closeness or intimacy, a lack of basic trust, differences between the couple in the degree of personal space desired in the relationship, passive-aggressive solutions to a power imbalance, poor conflict resolution skills, and the inability to blend feelings of love and sexual desire. For example, some cases of low sexual desire disorder may reflect other relationship power disruptions. The diagnosed partner may use his or her lack of sexual desire to gain power in a relationship in which he or she feels very little control by becoming the sexual “gatekeeper.” Alternately, the opposite could occur, where the nondiagnosed partner has a vested interest in the maintenance of the dysfunction because he or she gains some power in the relationship due to feelings of guilt in the diagnosed partner. In both instances, careful attention must be paid to the benefits that occur as a result of the dysfunction and treatment must address the underlying problems in the relationship.

3. Cognitive Distortions and Intrapsychic Factors

Cognitive contributions to the development and maintenance of sexual dysfunctions were first recognized by the early behaviorists who claimed that the major etiological factor associated with sexual dysfunction was anxiety. Masters and Johnson called this performance anxiety, a term referring to the excessive worrying about sexual performance that can in itself interfere with sexual arousal, resulting in sexual failure. Male erectile disorder is a sexual dysfunction that is often associated with performance anxiety, as men with this disorder tend to fear repeat occurrences of erectile failure, worry about it excessively, and spend much of their time during sexual encounters monitoring their arousal and strength of erection. As a result, they do fail to attain or sustain an erection, leading to even greater anxiety and the maintenance of a cycle of sexual dysfunction.

Many cognitive distortions play a role in the development and maintenance of sexual dysfunctions. Individuals who have problems with sexual functioning often engage in dichotomous thinking, in which they take an all-or-nothing attitude toward sexual functioning. A man who experiences premature ejaculation, for instance, may feel that if he cannot control his time to ejaculation, then he is a total sexual failure. This type of belief may even occur despite his bringing his partner to orgasm through other methods of sexual stimulation. Catastrophizing is also common, and can be seen when individuals make negative predictions about their fu-

ture sexual functioning and their ability to overcome dysfunction. Imperatives, in which the client makes “should” and “must” statements about their sexual functioning, are characteristic of many people with dysfunctions. For example, a woman who has never experienced an orgasm during intercourse with her partner may tell herself “I should be able to have an orgasm just from having his penis in my vagina. I shouldn’t have to stimulate my clitoris.” Finally, people who experience problems in sexual functioning often engage in mind reading when it comes to the reactions of their partners, which can lead to even more anxiety. A woman who has vaginismus might make attributions about what her partner thinks about her as a person or a sexual being, such as, “He’s thinking I’m frigid and undesirable.”

According to LoPiccolo and Friedman, other intrapsychic and cognitive factors that are important contributors to a variety of sexual dysfunctions include a fear of loss of control over sexual urges, fears of having children, underlying depression, religious orthodoxy, gender identity conflicts, homosexual orientation or conflict, masked sexual deviation, aging concerns, sexual phobias or aversions, anhedonic or obsessive-compulsive personality, unresolved feelings about the death of a spouse, and attempting sex in a context or situation that is not comfortable for the client.

4. Daily Life Stressors and Operant Issues

A fourth psychological factor in the development and maintenance of sexual dysfunctions are the daily life stresses that an individual experiences and the operant value that the dysfunction may have for either partner. An operant value can be defined as a reinforcing consequence for a sexual dysfunction that comes from the external world, such as through the admiration of friends for sticking by a dysfunctional partner, or devoting extra time to work because of the impaired sexual and marital relationship and experiencing financial rewards as a result. Friends and family may admire a woman who devotes extra time to her children and their activities because she has distanced herself from her low-desire husband. As a result, she may have reservations about making real therapeutic gains on the low sexual desire.

5. Physiological or Medical Factors

Sexual dysfunctions are best understood as existing in a multidimensional realm, with both psychological and physiological factors playing differing roles in the development and maintenance of problems. Although some individuals may experience a disorder caused solely by physiological or psychological factors, most

have a complex intermingling of etiologies that are unique to each individual. Many illnesses that affect the functioning of the neurological system, such as diabetes and multiple sclerosis, result in sexual disorders because they interfere with the very system that controls arousal and orgasm. Other illnesses and diseases that result in chronic pain or fatigue can also interfere with sexual arousal and enjoyment of a variety of sexual activities. Finally, many medications have side effects that interfere with functioning by inhibiting sexual responsiveness. These include a variety of psychotropics, particularly antidepressants and anti-anxiety medications, and drugs prescribed for various medical conditions, such as high blood pressure. Marijuana, alcohol, barbiturates, and other street drugs can also have a deleterious effect on sexual functioning.

These five categories not only serve a causative function in many instances of sexual dysfunction, but they can also work in a variety of combinations to maintain problems that are extremely disrupting to the lives of individuals with disorders. For instance, a man may experience his first erectile failure as a result of a medical problem, such as a reaction to an antidepressant. However, even when taken off of the antidepressant, he may continue to experience problems with attaining or sustaining an erection because he continues to make irrational and anxiety-provoking cognitive distortions. Similarly, a woman may originally experience anorgasmia due to the extremely negative messages she received about sex as a child and adolescent, but the problem may be maintained by her tremendously stressful life as a working mother who has little time to relax and resists adding a sexual role to the others for which she has already assumed responsibility. The combination of causative and maintaining factors that contribute to any individual case of sexual dysfunction must be thoroughly examined and treated within the context of fostering a healthy, mutually pleasurable sexual relationship for the dysfunctional couple.

II. BEHAVIORAL, COGNITIVE, AND SYSTEMIC TREATMENT FOR SEXUAL DYSFUNCTIONS

A. Treatment Overview

Post-modern sex therapy addresses the causal and maintaining factors of sexual dysfunction through a variety of behavioral, cognitive, and systemic treatment methods. In 1997, LoPiccolo outlined nine general principles of sex therapy through which couple change

takes place. First, the sexual dysfunction is conceptualized as a disorder of the couple, with both partners bearing a mutual responsibility for treatment. It is important to take the blame out of sexual disorders and facilitate a team approach to treatment. Both partners should be engaged in the treatment process and willing to take on responsibility for the sexual dysfunction and its treatment. In cases where the nondysfunctional partner refuses to actively participate in therapy, the rates of treatment success can be seriously reduced.

Second, in many cases couples have limited knowledge of the basic anatomy and physiology of human sexual response. Consequently, it becomes necessary for the therapist to provide an informational and educational component to treatment. Clients often need to be educated about the process of sexual arousal in both males and females, as well as about human anatomy. For instance, many couples do not know where the clitoris is located, that vaginal lubrication is not automatic, or that men have a refractory period between the time they ejaculate and the time they can attain another erection. A sex therapist will assist their clients in learning about their bodies and the process of sexual arousal and orgasm.

The third principle of sex therapy is to foster an attitude change in clients who have negative attitudes toward the expression of their sexuality. As noted earlier, negative attitudes can come from a variety of sources, including the family of origin. The therapist must work to combat these negative attitudes and replace them with more positive, accepting attitudes toward sexuality.

A fourth mechanism of change in sex therapy is the elimination of performance anxiety. Many individuals who experience problems in sexual functioning possess negative self-fulfilling expectancies about their sexual abilities and how their sexual encounters will progress. There are many strategies used in sex therapy to help clients begin to enjoy the process of sex as opposed to focusing on sexual goals. Participants in therapy are taught that worrying about the outcome of sex guarantees that they will not attain their "goal," because it directly interferes with arousal. Instead, the emphasis is on enjoying the process of sex. This intervention is paradoxical: Often, as soon as clients are no longer worrying about maintaining an erection or attaining an orgasm, they are free to enjoy sex and experience normal sexual functioning.

A fifth goal of sex therapy is to increase communication skills in the couple. Dysfunctional couples often have many communication deficits that directly affect their ability to have satisfying sexual relationships. For instance, couples with sexual dysfunctions often have trouble communicating their likes and dislikes to one

another for a number of reasons. Some couples are embarrassed about such communication, or they may not feel that it is part of their proscribed sexual role. Others may lack the knowledge of how to convey their preferences in an effective manner, resulting in their partners feeling criticized or humiliated by the communication that does take place. Another common difficulty concerns the initiation and refusal of sexual activity, with many couples developing indirect and ineffective ways of telling their partner when they do and do not want to engage in sexual activity. Sex therapy addresses these common problems by teaching couples effective communication strategies for conveying sexual preferences and responses in a clear, open, and supportive manner, and for initiating and refusing sexual activity in a clear, nonhurtful, and nonthreatening manner.

Changing destructive sex roles and lifestyles is the sixth mechanism of change in post-modern sex therapy. Many people have developed life habits that indirectly interfere with sexual functioning in a number of ways. Problems with extended family, children, and careers can all interfere with the sexual lives of adults. In addition, the sex roles that people acquire can interfere with sexual expression in a relationship. For instance, a common problem experienced by two-income households is the idea that the female partner is still responsible for the majority of housework and child care in addition to her career. This expectation leads many women to feel highly stressed and overworked, which in turn interferes with feelings of sexiness and sexual desire. A destructive sex role for men might include the expectation that they always initiate sexual relations, leading to pressure to be the pursuer and to feelings of uncertainty about their own sexual desirability. Sex therapy addresses these destructive lifestyles and sex roles by helping the client to initiate the life changes that will facilitate healthy sexual relationships.

Seventh, sex therapists must often help couples to change disruptive marital systems and enhance the marital relationship. Commonly, sexual dysfunctions are present in unhappy marital relationships. As such, it is unrealistic to believe that a couple can leave behind their disagreements about parenting, finances, or other issues while working solely on sexual issues. Often, therapists must address these issues in conjunction with sexual dysfunction in order to foster a more satisfactory sexual relationship. Current sex therapy frequently involves direct restructuring of the marital relationship.

Physical and medical interventions are sometimes needed to restore healthy sexual functioning. Many medical diseases can interfere with sexual functioning,

including diabetes, heart disease, and neurological conditions such as spinal cord injury, multiple sclerosis, and pituitary/hypothalamic tumors. In addition, many prescribed medications can interfere with the arousal process. Antihypertensive medications and psychotropic medications such as antianxiety, antidepressant, and antipsychotic agents have been shown to interfere with arousal and orgasm for both men and women. Similarly, recreational drugs such as alcohol, marijuana, heroin, and cocaine can negatively impact sex drive, sexual arousal, and orgasm. Finally, hormone levels in the body can also have major effects on sexual functioning. Disruptions in the levels of testosterone, estrogen, and prolactin can suppress sex drive and negatively impact sexual functioning for men and women. As a result, team approaches to sex therapy are often warranted, with the therapist and a medical practitioner working together to improve sexual functioning.

Perhaps the most distinctive element of sex therapy is the behavioral component: changing sexual behavior and teaching effective sexual techniques. Stanley Althof outlined several goals of behavioral techniques in sex therapy in 1989. These goals include overcoming performance anxiety, altering the previously destructive sexual system, confronting resistances in each partner, alleviating the couples' anxiety about physical intimacy, dispelling myths and educating clients regarding sexual function and anatomy, counteracting negative concerns with body image, and heightening sensuality. For each sexual dysfunction, the therapist prescribes a series of specific sexual behaviors for the clients to perform in their own homes. Clients are confronted with the behavioral challenge of both changing their actual sexual behaviors and understanding the problems they have in implementing this change. In 1995, Walter Vandereycken outlined several common behavioral interventions that are used in sex therapy. Vandereycken divided these procedures into two categories: "nondemand" procedures aimed at decreasing sexual anxiety, and "excitement-awareness" procedures to increase sexual arousal. The nondemand interventions include deemphasizing sexual intercourse by placing a temporary ban on coitus, desensitization techniques, relaxation training, sensate focus, and graded noncoital contact and stimulation. Common excitement-awareness procedures include the development of sexual fantasies and imagery, role-play of an exaggerated orgasm, body awareness and self-exploration, directed masturbation, and guided stimulation by the partner. Although some of these behaviors may be similar for different disorders, the treatment for each sexual dysfunction

includes unique behavioral prescriptions that will be described in detail later in this article.

It is important to note that these mechanisms of change are not a step-wise therapy, with each component being undertaken after the previous ones have been mastered. Instead, post-modern sex therapy is a conglomeration of these overriding principles, with the therapist using these techniques in conjunction with one another. Thus, throughout treatment, therapy is seen as a process for which both partners are mutually responsible, the therapist attempts to foster the development of more effective communication skills, and attention is paid to dyadic relationship satisfaction. All the while, specific behavioral modifications in sexual functioning are made.

B. General Strategies in Assessment and Treatment

Sex therapy usually begins with an evaluation and assessment of the particular sexual dysfunction and its impact on the marital relationship. This assessment has historically included taking an extensive sexual history of both partners, interviewed separately. Masters and Johnson advocated the use of a semistructured interview that typically lasted for several hours. However, as pointed out by LoPiccolo in 1995, the utility of this type of interview has not been empirically demonstrated and its application may not be the most efficient use of therapeutic time. Particularly in this time of insurance-placed restraints on the number of therapy sessions a given person is covered for, it is important for the therapist to be mindful of the benefits that a shortened sexual history assessment can provide for the therapeutic process.

Paper-and-pencil questionnaires are also commonly used to assess sexual history and current sexual functioning. The Sexual Arousal Inventory, developed by Peter Hoon, Emily Hoon, and John Wincze in 1976, and the Sexual Interaction Inventory, developed by LoPiccolo and Jeffrey Steger in 1974, are two questionnaires that can be particularly useful in the assessment and treatment outcome phases of sex therapy. These questionnaires can provide valuable information to the therapist by identifying arousal deficits and problem behaviors that can be the focus of treatment. They are also useful tools for identifying significant discrepancies in thoughts, feelings, and behaviors reported by the partners.

A physiological assessment by medical professionals is also indicated in the assessment of several sexual dysfunctions, including male erectile disorder and dys-

pareunia. Although vaginismus is not caused by organic factors, a medical assessment is still warranted to rule out the possibility that dyspareunia has not been incorrectly diagnosed as vaginismus. Premature ejaculation and female orgasmic disorder are not associated through empirical research with organic factors. Physiological assessments should include a pelvic examination by a specialist, such as a gynecologist or urologist, an assessment of current medications and their potential side effects, and tests for thyroid function, endocrine status, and glucose tolerance. In addition, vascular and neurological examinations are especially important in cases of male erectile disorder.

Following these initial assessment procedures, the therapist presents a comprehensive formulation of the etiology and maintenance of the dysfunction to the couple. Their sex histories, family-of-origin dynamics, cognitive styles, current relationship structure, external reinforcers, and any organic factors are used in this formulation, and the couple is informed about how these factors have interacted to create and maintain their sexual problems. This presentation is useful in initiating change procedures and sometimes has positive effects on the sexual problem itself.

After the completion of the assessment portion of therapy, some simple behavioral interventions are made that are common to all of the dysfunctions. First, the couple is asked to refrain from attempting sexual intercourse until it is prescribed by the therapist. Many sex therapists believe that this prohibition of coitus serves to alleviate performance anxiety, allowing the couple to rebuild their sexual relationship from the beginning. Next, the couple is typically asked to complete a series of sensate focus exercises. Sensate focus is a behavioral intervention that focuses the clients' attention on the sensuality of the body, without the pressure attendant upon sexual behaviors such as intercourse. These exercises include sensual touching of the clients' own bodies or their partners', and consist of caressing, hugging, kissing, and body massage. Participants in sex therapy are instructed to tune in to their sensual response to the touching. Sensate focus exercises serve to reduce anxiety in a number of ways, including providing a no-demand experience to the couple, eliminating the "spectator role," and increasing dyadic communication by giving feedback to the partner about what feels good. Breast and genital contact, intercourse, and orgasm are not allowed as part of these exercises. Vandereycken points out that the ban on intercourse and the inclusion of sensate focus exercises in the therapeutic process are of somewhat questionable value because

they have never been systematically studied. However, their use is indirectly supported through their inclusion in several treatment protocols for different sexual disorders that have been empirically validated.

The next step in post-modern sex therapy is dependent on the exact nature of the couple's sexual dysfunction. Following is a description of each of the major sexual dysfunctions listed in the *DSM-IV*, along with the more specific treatment procedures used for each disorder.

C. Gender-Specific Sexual Dysfunctions

Several sexual disorders are unique to males, whereas some are experienced exclusively by females. These gender-specific disorders occur during both the arousal and orgasm stages of the human sexual response cycle. The male sexual dysfunctions include erectile dysfunction, premature ejaculation, and male orgasmic disorder. Disorders that commonly affect women are female arousal disorder, female orgasmic disorder, and vaginismus.

1. Male Sexual Dysfunctions

a. Male Erectile Disorder Male erectile disorder is characterized by an inability to attain or maintain an erection, resulting in an incapacity to complete sexual activities such as intercourse. The etiology of male erectile disorder can be extremely complex, with a primarily psychogenic cause, a primarily organic cause, or most often, an interaction of the two. Neurological diseases such as multiple sclerosis and diabetes, a failure of blood flow to the penis, medication side effects, and surgical damage are all potentially physiological causes of erectile dysfunction. As stated before, a physical evaluation is extremely important in the assessment of this particular disorder. However, as LoPiccolo noted in 1995, the presence of some degree of organic impairment does not always negate the need for behavioral treatment. Men who suffer from mild organic impairment are often more vulnerable to psychological factors of erectile failure. As a result, treating the psychological difficulties can frequently enable a man to experience a fully functional erection even with the mild physiological impairment. Psychological treatment of erectile dysfunction in men with organic causes serves to help the client function at his optimum physiological capacity.

Psychogenic causes of male erectile disorder can include performance anxiety and the spectator role, as well as a lack of adequate physical stimulation of the

penis. Commonly, men who experience difficulty attaining or maintaining an erection enter each sexual encounter with negative expectancies about their ability to "perform" and consequently, they constantly self-monitor their own level of arousal. These men become anxious observers rather than aroused participants. This sort of mindset prevents arousal, and as a result, the dysfunction is cyclically maintained. Problems with erection can also result from poor sexual techniques, such as inadequate stimulation of the penis. Especially as men age, direct stimulation of the penis for some period of time is necessary for the attainment of an erection. However, many couples expect erections to be automatic and effortless, and therefore do not give the penis adequate stimulation. Consequently, the predominant themes in the psychological treatment of erectile dysfunction are the reduction of performance anxiety and the increase of sexual stimulation.

After engaging in general sensate focus techniques, the couple is instructed to add genital contact to their sessions. They are taught the "tease technique" in which the couple is instructed to cease genital contact if the male should attain an erection. The couple can resume penile contact only after the erection is lost. This exercise teaches clients that erections occur naturally in response to stimulation, as long as the couple does not focus on performance. The male is paradoxically instructed throughout sensate focus that, "The purpose of this exercise is for you to learn to enjoy sensual pleasures, without focusing on sexual goals. Therefore, you should try to not get an erection." This demand to not get an erection frees the male to enjoy sensual situations without the accompanying anxieties that have worked against attaining an erection in the past.

After the couple experiences this process several times, they move on to intercourse. Intercourse is also attempted in several steps. First, the male partner lies on his back while the female partner kneels astride him and uses her fingers to push his flaccid penis into her vagina. This procedure, known as the "stuffing technique," frees him from having to have a rigid penis to accomplish entry. Sometimes called "quiet vagina," the woman remains still while his penis is inside of her. Gradually, the couple can add movement by the female gently moving her hips. Finally, the male is instructed to thrust and the couple resumes full sexual activity, with no further restrictions. Throughout this process, the couple is instructed to achieve the woman's orgasm through manual or oral sex, resulting in the reduction of pressure on the male to perform as well as partner

compliance with treatment. In addition, Althof suggests that guided explicit fantasies can be used when the male is preoccupied with performance issues or when he is having difficulty becoming aroused.

This set of procedures seems to be effective in cases where there is no major organic impairment of erection. For men with more severe physiological problems underlying or complicating their erectile dysfunction, however, physical interventions may be warranted. One of several medical procedures may be useful for men who experience erectile failure as the result of a more severe organic impairment.

Penile injections of drugs that cause rigidity, such as prostaglandin E, phentolamine, and vasoactive intestinal polypeptide, can be an effective treatment for men with irreversible erectile dysfunction. These drugs are self-administered by the patient just before intercourse, and they work by dilating the penile arteries. Research indicates that most men who use penile injections experience erections as a result. In their discussion of organic treatment methods for male erectile disorder in 1989, Leonore Tiefer and Arnold Melman warn that this "quick fix" can often be tempting to men who have a more psychogenic basis for the disorder. However, they warn against using this method of treatment for these men, citing potential risks of scarring of the penis, and research results that indicate these types of men are often very dissatisfied with the treatment.

Another nonsurgical and noninvasive treatment method is the use of a vacuum constriction device. A hollow cylinder is placed over the penis, and a hand pump is used to pump the air out of the cylinder, leaving the penis in a partial vacuum. As a result, blood rushes into the penis. The cylinder is removed and a rubber constricting band is placed at the base of the penis to maintain the erection. This treatment method is most often used for men who have erectile dysfunction rooted in diabetes or neurological problems, and it does not have any known negative effects on the body. It can, however, be awkward and can interfere with the spontaneity of sex.

Artificial erections can also be manufactured in men with severe physical problems through the use of a penile prosthesis. This device consists of a semirigid pair of rods made of rubber and wire, and it is surgically implanted in the corpora. This device does not allow for growth of the penis in width or length during sexual activity. Instead, it can be bent up to an erect position when the man wants to have sex, and bent back down for normal wear. An alternative to this type of prosthesis is a hydraulic inflatable system that allows for

tumescence. Inflatable hollow cylinders are surgically inserted into the penis, a reservoir of saline fluid is placed under the abdominal wall, and tubing connecting the cylinders to a pump is inserted in the scrotum. When he wishes to have sex, the man or his partner can squeeze the pump, forcing fluid from the reservoir to the penile cylinders, which expand and produce an erection. Tiefer and Melman caution that because of their invasiveness and annihilation of any capacity to produce an erection should they need to be removed at a later date, penile implants should be considered the last resort in the treatment of erectile disorder.

Finally, the recent proliferation of advertisements for Viagra speak to its popularity as a pharmacological treatment for erectile disorder. Viagra is an effective treatment, showing positive results in 70 to 80% of cases treated. The drug works by reducing venous outflow once blood has been pumped into the cavernous bodies, not by increasing arterial inflow. As such, men who use Viagra still need adequate sexual and emotional stimulation to achieve an erection. Some of the 20 to 30% of cases in which Viagra fails are not actually pharmacologic failures, but failures to provide adequate physical or emotional stimulation. Consequently, the use of Viagra is contraindicated in instances where couple systemic issues are the only etiological factor involved with erectile difficulties. In addition, Viagra is also contraindicated in instances where low desire is the cause of erectile failure, as the drug has not been shown to increase levels of desire.

b. Premature Ejaculation Premature ejaculation is defined as the persistent onset of orgasm and ejaculation with minimal stimulation, before or shortly after intromission occurs. An important determinant of premature ejaculation is that it causes marked distress in the male and/or his partner. Time criterion have had little use in the assessment of premature ejaculation, as differences in foreplay activity, age, and the use of distraction techniques can artificially increase or decrease the duration of intercourse. A more clinically useful conceptualization of premature ejaculation includes the couple's subjective opinions about the appropriateness of duration, and the pleasure and satisfaction that each partner gains from their sexual encounters. If both partners agree that their sexual encounters are negatively influenced by efforts to delay ejaculation, then premature ejaculation is considered a problem.

In 1970, Masters and Johnson reported that premature ejaculation can be treated with direct behavioral retraining procedures that are successful in nearly 100%

of cases. The standard treatment for premature ejaculation involves the “stop-start” or “pause” procedure, introduced by Semans in 1956. With this procedure, the penis is manually stimulated until the man is highly aroused and he feels that ejaculation is imminent. At this point, the couple stops stimulation until the arousal subsides, and they resume stimulation again when the male no longer feels that ejaculation is imminent. The “squeeze” technique can also be added to help the male delay ejaculation during manual stimulation. In this procedure, the female partner firmly squeezes the penis between her thumb and forefinger, at the place where the head of the penis joins the shaft. For some couples, this procedure can be an effective way to reduce arousal even further than that experienced with the stop-start technique. The stop-start and squeeze procedures are repeated many times so that the male can experience an immense amount of stimulation and arousal without the occurrence of ejaculation. Ultimately, the man should experience significantly more total time of stimulation than he has ever experienced before. These behavioral procedures lead to a higher threshold for ejaculation, with the male gradually gaining the capacity for participating in quite lengthy periods of penile stimulation without ejaculation.

After a few weeks of this training when the necessity of pausing diminishes, the focus of behavioral exercises shifts to include intercourse. The couple continues to practice a modified stop-start technique in which the penis is placed in the vagina without any thrusting movements. The most effective intercourse position during this period of treatment is the woman on top position. The “quiet vagina” exercise is utilized, and the male partner is encouraged to make no movement but to feel free to engage in erotic touching of his partner. If this stimulation produces high levels of arousal and a feeling of ejaculatory inevitability, the penis is withdrawn and the couple waits for arousal to drop off. When good tolerance for inactive containment of the penis is achieved, the training procedure is repeated during active thrusting exercises with a variety of sexual positions. After 2 to 3 months of practice, males who undergo treatment for premature ejaculation are generally able to enjoy significantly prolonged intercourse without the need to use pause and squeeze techniques.

In a 1989 publication of a treatment protocol for premature ejaculation, Barry McCarthy stressed the importance of the process of successive approximation in ejaculatory control exercises. The male is taught to become aware of his level of arousal and the point of ejaculatory control when he is still able to stop short of

ejaculation. It is inevitable that the client will have at least one experience during treatment where he pushes the limits too far, and signals for his partner too late to stop the ejaculatory process. McCarthy emphasized that it is important for the therapist to confront the couple with this possibility early in therapy, and to encourage the couple to use it as a pleasurable learning experience about identifying ejaculatory inevitability rather than experience it as a failure in treatment. He also highlighted the importance of ensuring that the female partner's desires and preferences be given equal attention, with both manual and oral stimulation encouraged as a method to bring sexual satisfaction to the woman during the treatment period. The benefits of this are twofold. First, the female partner is more likely to remain invested in the treatment if the couple's sexual encounters are not always completely focused on the male partner's arousal. Second, the male can learn that women can be sexually satisfied in a number of ways that have little or nothing to do with the penis and intercourse, which in turn leads to the alleviation of performance anxieties. Finally, McCarthy suggested that cognitive restructuring procedures used in conjunction with behavioral interventions can have an important effect on the long-term success of therapy. Couples need to learn that sex is a collaborative process in which neither partner bears the responsibility for performing, in which both partners are integral to changing problematic sexual behaviors and maintaining those changes, and in which intimacy and sexuality are integrated to form a stronger sexual relationship for the couple.

c. Male Orgasmic Disorder Male orgasmic disorder is present when a man experiences a recurrent delay in, or absence of, orgasm following a normal phase of sexual excitement. Formerly known as inhibited ejaculation, male orgasmic disorder is a fairly rare sexual dysfunction, and the cause of the problem often remains unclear. Many psychological factors have been theorized as causes for male orgasmic disorder, such as an autosexual orientation and fear of intimacy with the partner, but there is little supporting empirical research. However, etiology has been established with several physiological factors, including multiple sclerosis, medication side effects, and damage to the hypothalamus.

Treatment of male orgasmic disorder is based on many of the standard strategies used with other sexual dysfunctions. Eliminating performance anxiety and ensuring adequate stimulation through paradoxical sensate focus exercises are the basis for treatment. The couple is instructed that during sex the penis is to be

caressed manually and/or orally until the man is aroused, but that stimulation is to stop whenever he feels he might be close to orgasm. This procedure takes the focus of sex off of orgasm, and paradoxically, allows the man to fully enjoy the pleasurable sensations of stimulation. Additionally, in 1977 LoPiccolo reported that the use of electric vibrators, behavioral maneuvers called "orgasm triggers" (discussed in the section on female orgasmic disorder), and having the client role-play an exaggerated orgasm all seem to have some success with the treatment of male orgasmic disorder.

Physiological interventions are indicated when the primary cause is organic in nature. Drugs that increase the arousal of the sympathetic nervous system have been found to be helpful in some cases, as has increased stimulation of the scrotal, perineal, and anal areas. In particular, direct stimulation of the anus through the use of a vibrator has been found to be an extremely effective orgasm trigger in men who suffer neurological damage.

2. Female Sexual Dysfunctions

a. Female Sexual Arousal Disorder and Female Orgasmic Disorder A persistent inability to attain or maintain sexual excitement through the completion of sexual activity describes female sexual arousal disorder; female orgasmic disorder occurs when sexual excitement is normal, but orgasm does not occur. Both disorders can be successfully treated with many of the same behavioral techniques, including education, self-exploration, body awareness, and directed masturbation. These procedures are particularly effective for women who have never had an orgasm through any form of stimulation.

Directed masturbation, a treatment protocol for female arousal and orgasm disorders, has broad empirical support in individual, couple, and group modalities. This program of therapy is described in *Becoming Orgasmic*, a self-help book and accompanying film written by Heiman and LoPiccolo, and published in 1988. The directed masturbation protocol involves nine steps. In the first step, the inorgasmic woman is instructed to use various diagrams and reading materials to learn about her body, her genitals, and the female sexual response. She is also encouraged to work on her attitudes and cognitions surrounding the acceptability of female sexuality, and to examine her own sexual history to identify negative influences that have carried into her current functioning. Step 2 involves the woman exploring her body and genitals through both sight and touch. Next, in Step 3 the

woman furthers her body exploration by locating erogenous zones, with a focus on the clitoris, breasts, and other genital regions.

The woman is directly instructed in techniques of masturbation in Step 4. She is encouraged to target the erotically sensitive areas that she has identified in previous sessions and increase the intensity and duration of stimulation. Step 5 is erotic masturbation, in which an attempt is made to make masturbation more erotic and sexual. The woman is encouraged to develop sexual fantasies, read erotic stories, or view sexually arousing pictures to increase her feelings of arousal.

The sixth step has three elements. If the woman has not yet reached orgasm, she will begin to use an electric vibrator to increase the intensity of stimulation. Women who experience their first orgasm through the use of a vibrator usually go on to have orgasms through other methods of stimulation, but the vibrator can be invaluable to the attainment of the first orgasm. Second, she will be instructed to act out or role-play an exaggerated orgasm. This procedure helps the woman overcome any fears about looking silly or losing control when she has a real orgasm. In the final element of the sixth step, "orgasm triggers," such as holding the breath, contracting the pelvic muscles, tensing the leg muscles, and thrusting the pelvis are used by the woman.

The final three steps of the directed masturbation protocol integrate the partner into treatment. In Step 7, the woman shows her partner how she likes to be touched and how she can have an orgasm. During this step, the partner also shares his or her own masturbation preferences with the woman so that she can feel less inhibited, and to ensure that the learning process is reciprocal. In the next step, her partner brings her to orgasm with manual, oral, or vibrator stimulation, using the woman's instruction and guidance to increase arousal and sexual satisfaction. Finally, in Step 9, the heterosexual couple resumes penile-vaginal intercourse in positions that permit one of them to continue clitoral stimulation.

During this final stage, it is essential to educate the couple that continued stimulation of the clitoris during intercourse is both normal and often necessary for many women to experience orgasm through this sexual behavior. Many women and their partners are wed to the myth that women should be able to experience orgasm through penile stimulation only. Educating them about the myth of vaginal versus clitoral orgasms is often necessary. In addition, it should be noted that the couple's goals can be vastly different—some couples are

not as concerned with an ultimate goal of orgasm through coitus, and these individuals should be encouraged to see their treatment as successful if they learn to experience an orgasm through any method of stimulation that they find acceptable.

Not all women who seek treatment for arousal and orgasm disorders have difficulty becoming aroused or reaching orgasm in all situations. Such types of situational orgasmic dysfunction include only being able to reach orgasm in solitary masturbation, without a partner present, or through a circumscribed sexual activity, such as oral stimulation. It is important to note that sex therapists do not consider lack of orgasm during intercourse to be an indication for treatment, provided that the woman can have orgasm in some way with her partner, and that she enjoys intercourse. However, some women are distressed by their limited orgasmic experiences, and there are treatment techniques that can be utilized in these situations.

Treatment for situational lack of orgasm includes a gradual stimulus generalization approach developed by Antionette Zeiss, Raymond Rosen, and Robert Zeiss in 1977. This procedure helps the woman to expand the ways in which she reaches orgasm through a sequential series of changes in stimulation. For example, a woman who can masturbate to orgasm wants to experience orgasm during intercourse. The therapist will help her to identify a number of small, intermediate steps between the way she has orgasm now and the wished-for orgasm during intercourse with her partner. As a first step, the woman might be instructed to masturbate as usual, with the addition of having her finger passively inserted into her vagina from the beginning of stimulation. This procedure will enable her to learn to experience orgasm with something contained in the vagina. Other intermediate steps in this example might include thrusting the inserted finger, having the partner present while she masturbates, having the partner manually stimulate the clitoris with first her and then his finger inserted, passive containment of the penis in the vagina while the woman masturbates, and passive containment of the penis while the man manually stimulates the woman. Once the woman has been able to reach orgasm through each of these phases, the couple can attempt active intercourse with concurrent direct manual stimulation of the clitoris. By breaking down the differences between masturbation and intercourse into a series of very small and discrete changes, there is a much greater success in broadening the woman's range of orgasmic responsivity.

b. Vaginismus Vaginismus is characterized by the involuntary contraction of the muscles surrounding the outer third of the vagina. These contractions have a spasmodic quality, and they prevent the insertion of a penis or other objects into the vagina. Women who experience vaginismus are often capable of becoming sexually aroused and experiencing orgasms—it is the possibility of penetration that triggers the muscle contractions. However, they may also present with a variety of other disorders, including an aversion to sex, female arousal disorder, or female orgasmic disorder.

Relaxation training, Kegel exercises, and use of progressive dilators inserted in the vagina are the procedures used to treat vaginismus. The woman is taught deep muscle relaxation and diaphragmatic breathing techniques in order to decrease her overall feelings of anxiety and to help her gain volitional control of her vaginal muscles. Voluntary control of the vaginal muscles is acquired through Kegel exercises, in which the woman practices contracting and relaxing the pubococcygeal muscle. Next, the woman is helped to overcome her fear of penetration by using a set of gradually larger dilators that she inserts into her vagina at home and at her own pace. Once the woman has been able to comfortably insert the largest dilator, she can begin to guide her partner as her or she slowly and gently inserts the dilators. It should be stressed to women in treatment for vaginismus that they go slowly and become comfortable with each step and each size dilator before moving on to the next. If a woman or her partner pushes treatment forward at too quick of a pace, the result is often increased anxiety about penetration and a rapid return to experiencing the spastic contractions. In addition, both partners should be educated about the need for effective stimulation of the woman's erogenous zones, so that the woman can learn to associate penetration with vaginal lubrication, pleasure, and arousal. The use of fantasies and erotic materials can also aid in this process.

After the woman and her partner have been able to successfully insert the graduated dilators, heterosexual couples can begin to attempt penile penetration. First, the partner lies passively on his back while the woman kneels above him and gradually inserts his erect penis into her vagina. Again, the couple is encouraged to go slowly, at the woman's pace. When the woman is able to contain her partner's penis in her vagina comfortably, she can begin to move. Once she is comfortable, the partner can begin to thrust and the couple can explore a variety of intercourse positions that are enjoyable to both of them.

D. Nongender-Specific Sexual Dysfunctions

1. Dyspareunia

The *DSM-IV* defines dyspareunia as persistent genital pain associated with sexual intercourse in either a male or a female. Although dyspareunia can occur in males or females, clinically, pain is much more frequently seen in female clients.

Most cases of dyspareunia involve an organic etiology, such as vaginitis, endometriosis, Peyronie's disease, unrepaired damage following childbirth in woman, and prostate conditions in men. However, this dysfunction must also have some element of psychogenic etiology in order to be diagnosed as a true case of dyspareunia. A complete medical examination is necessary to differentially diagnose dyspareunia from other, similar disorders such as vaginismus or simple medical conditions. In males, painful intercourse is almost always related to an underlying medical condition.

Because psychogenic dyspareunia is often attributed to a lack of arousal, the general sex therapy procedures and the specific techniques for enhancing female arousal and orgasm are commonly used. In addition, because dyspareunia is commonly linked with vaginismus and may in fact be an earlier stage of that disorder in some women, the treatment protocol for vaginismus is often used. Artificial genital lubricants and relaxation training can also be effective additions to therapy.

2. Hypoactive Sexual Desire Disorder and Sexual Aversion Disorder

Hypoactive sexual desire disorder, often called low sexual desire disorder, is characterized by the persistent absence of desire for sexual activity. A person with this disorder feels little or no interest in sex, but they do not have negative emotions associated with the sex itself. Sexual aversion, on the other hand, is defined as an aversion to and actual avoidance of sexual contact by a partner and is based on strong negative emotional reactions to sex that include fear, revulsion, and disgust. Differential diagnosis between these two disorders is imperative for good treatment results.

Low desire used to be thought to be more prevalent in women; however, more recent data suggest that it affects males and females at a relatively equal rate. According to a treatment guide authored by Cathryn Pridal and LoPiccolo in 2000, low desire is characterized by a very low level, or absence of, spontaneously occurring sexual interest. A distinction is made between receptive and proceptive sexual behaviors, with

a lack of proceptive behavior most indicative of true low sexual desire. Just as differential diagnosis is important, so is an assessment of comorbid sexual disorders. Often, individuals with low desire also experience another dysfunction, such as lack of erection or orgasm. In these cases, it is difficult to determine if low desire is the cause or effect of other disorders. Careful assessment must be made to determine which disorder should be treated first. For instance, a woman suffering from posttraumatic stress disorder (PTSD) after a traumatic sexual history as a child should not be treated for low desire or sexual aversion until her abuse has been adequately dealt with.

In 1988, LoPiccolo and Friedman described a four-element sequential model for hypoactive desire and aversion that has been widely adopted. The first component of the treatment program, called affectual awareness, focuses on helping the client to become more familiar with his or her negative attitudes, beliefs, and cognitions about sex. Feelings of anxiety, fear, resentment, and vulnerability are uncovered as the client is encouraged to closely examine his or her attitudes about sex. Many clients begin therapy insisting that they do not have negative feelings about sex, but instead, are merely indifferent to it. Pridal and LoPiccolo recommended that therapists dispute this claim by using an "umbrella metaphor." In the umbrella metaphor, the therapist explains that all humans have an innate sexual drive. Their indifference to sex is an umbrella that blocks their awareness of the negative emotions that are working to block this innate sexual drive. During this stage, both partners are encouraged to make lists about the benefits of gaining a sexual drive, but also about the possible risks to each individual if sex drive increases, and the potential risks to the relationship. These lists help the low-drive partner gain some motivation for therapy, as well as point out any potential issues that would result in resistance to therapy. In addition, clients are encouraged to visualize sexual scenes and talk about sex in a more graphic way so that they can more accurately recognize negative emotions that they were not previously aware that they had. Finally, role-plays in which the low-drive partner pretends to have a sex drive and initiates sexual activity with his or her partner can be useful in helping the low-drive client track his or her emotional state during this process. In this way, individuals with low sexual drive can become more aware of their own negative attitudes and cognitions about sexuality.

The second phase of sex therapy for low sexual desire involves insight-oriented therapy. During the insight

phase, clients are helped to understand the underlying causes for the negative emotions that they have identified. Family-of-origin experiences, religious teachings, depression, fear of having children, life stress, unresolved sexual trauma or abuse, masked sexual deviations, gender identity issues, and relationship problems are explored as possible initiating and maintaining causes of the low desire or aversion. In a sense, this and the previous step are preparatory. The more active treatment follows.

Stage 3 involves cognitive and systemic therapy. This phase of therapy serves to alter irrational beliefs that inhibit sexual desire and to identify and modify relationship problems that are suppressing sexual drive. First, clients are taught that irrational beliefs may be the main cause of their emotional reactions, and they are helped to identify self-statements that interfere with sexual desire. Therapist and client generate a list of coping statements that combat the client's irrational thoughts about sexuality and help him or her to cope with, rather than avoid, negative emotional reactions to sexual situations. Typical coping statements might be "If I allow myself to enjoy sex, it doesn't mean I am dirty or bad" and "When I was younger I learned to feel guilty about sex, but I'm grown up now, and I don't have to feel that way anymore." Second, relationship problems are addressed in the dyad. In couples in which one partner is low drive, a power imbalance in the relationship is often found. This disruption in power can be expressed with either the low- or normal-drive partner having a disproportionate amount of power in the relationship. Systemic therapy addresses this issue and works to make the couple feel more equal in both their sexual and nonsexual interactions.

The final element of treatment for low desire and aversion consists of behavioral interventions. These include sensate focus, skills training and other general sex therapy procedures, as well as some interventions that are more specific to these disorders. Frequently, couples in which one partner has low drive experience a drastic decline in nonsexual affectionate behavior. The normal-drive partner might misinterpret simple affectionate behavior such as a hug as an invitation to initiate sexual activity. Consequently, the low-drive partner learns to squelch all affectionate behaviors to guard against this type of misunderstanding. An important component to treatment, then, is to reintroduce these simple affectionate behaviors to the couple. The couple identifies a number of affectionate behaviors that they agree will not be used to initiate sexual activity. Next, treatment focus is turned to the ways in

which sexual activity can be initiated. Once again, role-plays are used so that both partners can illustrate how they do and do not like to be approached for sex. Additionally, they can communicate with one another about acceptable, nonhurtful ways to refuse sexual activity. These types of assertion training and communication skills training exercises help couples learn how to negotiate their sexual relationship without being coercive or rejecting of their partner.

Pridal and LoPiccolo labeled this next set of behavioral procedures "drive induction." They posited that sometimes people do not become aware of their sexual drive until they expose themselves to external cues and stimuli that trigger it, and individuals with low drive have developed an extraordinary ability to avoid these sexually relevant cues. In therapy, then, low-drive clients are asked to begin attending to sexual cues. A number of interventions are used in drive induction. For instance, low-drive clients are asked to keep a "desire diary," in which they record all sexual stimuli, thoughts, and emotions. They are also instructed to watch films that have sexual content, read erotic books and magazines, read collections of sexual fantasies, note attractive people they see, and so forth. Finally, couples are also often asked to develop erotic fantasies, both alone and together. The low-drive partner is instructed to take several "fantasy breaks" during the day in which he or she spends some time fantasizing about the sexual scenes that have been developed.

III. APPLICATIONS AND EXCLUSIONS

Since Masters and Johnson published their groundbreaking work on sexual dysfunctions, most therapists have switched from treating these disorders individually to treating the couple. However, couples originally were accepted for therapy if they had very circumscribed problems in only the sexual area. Those clients with individual psychopathology and severe marital distress were systematically screened out, as were individuals with medically complicated histories. Today, there is a greater focus on treating all of these problems, as sex therapists have become more cognizant of the fact that the incidence of "pure" sexual dysfunction without concurrent marital problems is extremely rare. Sex therapists and marital therapists find it less important to try to distinguish between sexual and relationship problems, because it is often not possible to segregate these areas of distress in people's lives. Instead, couples can be

helped to find ways of showing caring and love, to work on sex roles and role expectations within the relationship, to understand the effects that children have on the relationship, to deal with jealousy and outside interests, and to express their differing needs for intimacy, independence, companionship, and affection.

Similarly, there has also been a greater tendency in recent years to accept clients with major forms of psychopathology. Many nonsexual disorders have been associated with problems in sexual expression in the literature. For instance, low desire, erectile dysfunction, and problems reaching orgasm have all been associated with depression. Axis II disorders, such as antisocial personality and passive-aggressive personality disorders have also been found to severely complicate the treatment of sexual dysfunction. However, the presence of one of these disorders does not prevent successful sex therapy, provided that the therapist addresses the concurrent psychopathology.

Group therapy for both individuals and couples has also been found to be an effective modality for the treatment of sexual dysfunctions. Therapists often facilitate treatment groups for disorders such as female orgasmic disorder, premature ejaculation, and erectile dysfunction. Heiman and Grafton-Becker cited research in their work on female orgasmic disorder that indicates that group treatment, including assertiveness training, education, and directed masturbation procedures, can be nearly as effective as couples therapy. The group modality is particularly valuable for single individuals in that it provides an environment of mutual support and encouragement. The treatment of individuals without partners can be more difficult than couple-based treatment; however, assertiveness and social skills training, in addition to the procedures described above, can be helpful to single people with sexual disorders. Some procedures can be altered to handle the unique problems that arise when treating singles. For instance, in 1978, Bernie Zilbergeld described a treatment modification for premature ejaculation in which single men are taught skills in delaying ejaculation through masturbation and fantasy exercises. Similar modifications can be made for the treatment of other sexual disorders.

Several special populations present unique challenges to the traditional methods of treating sexual dysfunction. Sex therapy with gay men, lesbians, and bisexuals must be inclusive of sexual identity issues, the many variations of homosexuality itself, the fear of AIDS, and the internalization of heterosexism. In addition, some modification to techniques will most likely be warranted.

Treatment of clients who have experienced a sexual trauma such as rape or child sexual abuse can also be challenging. Judith Becker, in a chapter on this topic published in 1988, pointed out that some women who seek treatment for sexual dysfunction have had a history of sexual trauma. These women often present with symptoms of PTSD. Special attention must be paid to these symptoms, and the initial treatment goal should be to alleviate the impact of PTSD on sexual functioning. Finally, sex therapy with the chronically ill requires some adaptation. Cooperative work with a primary health provider, treating the client in an institutionalized setting, and adjustments in the behavioral interventions may be warranted. However, traditional treatment methods such as emphasizing education to help people understand their sexual functions and capabilities, deemphasizing genital sex as a necessary component to all sexual pleasure, and emphasizing the exploration of other forms of sexual expression beside sexual intercourse can contribute to the kind of program that is helpful for those who have to make adjustments in their sexual behavior because of a chronic medical condition.

IV. EMPIRICAL RESEARCH

This article has focused on the clinical techniques currently used to treat a variety of sexual dysfunctions. Unfortunately, much of this knowledge is based on clinical experience, rather than on empirical research. In 1980, LoPiccolo pointed out that much of the empirical literature in sex therapy is actually a series of demonstration projects that do not involve random assignment to experimental conditions, manipulation of independent variables, or assessment with objective, quantified dependent variables. Other methodological problems include the use of mixed-diagnosis samples, indirect outcome measures, and small sample sizes. Additionally, there have been very few studies attempting to identify which components of the total sex therapy package are active ingredients and which are "inert fillers."

William O'Donohue, Diane Swingen, and Cynthia Dopke published a comprehensive review of the empirical literature for female sexual dysfunctions in 1997. In 1999, they, along with Lisa Regev, published a similar article concerning male sexual dysfunctions. They cite methodological problems, a lack of long-term follow-up data, a lack of treatment manuals, and the disregard for several disorders in outcome research as major problems that have contributed to the lack of concrete

information about the efficacy of sex therapy programs. Only approximately 20% of the published studies on male and female sexual dysfunctions met the inclusion criteria for the O'Donohue reviews: random assignment to treatment conditions, and at least one comparison or control group. For in-depth examinations of these studies, please refer to the O'Donohue and colleague reviews. For the purposes of this article, it is sufficient to note that strong arguments exist for further attention to research design and data analysis in the empirical study of sex therapy outcomes.

Despite the weaknesses in sex therapy outcome research, there is great reason to believe that the outlined treatments produce positive results in the majority of cases. As such, they have been validated in a very meaningful way. In 1995, the Task Force on the Promotion and Dissemination of Psychological Procedures included the directed masturbation program for female orgasmic disorder and behavioral treatment for male erectile disorder on their list of well-established treatments. However, further treatment outcome research is needed in order to firmly establish the efficacy of post-modern sex therapy procedures.

GLOSSARY

clarification The procedure aiming at the restructuring and differentiation of information brought by the patient to make certain points more easily understood.

compromise formation Connotes the product of the unconscious process in which the instinctual gratification (i.e., the discharge of sexual and aggressive instinctual impulses) and the demands of the opposing defensive forces are mutually satisfied through a compromise that partially expresses both tendencies allowing the repressed impulse to find expression in a substitute and disguised form (e.g., symptomatic phenomena).

confrontation The procedure that makes the phenomenon in question evident and explicit, aiming at the overcoming of the evasive and defensive tactics.

defense mechanisms The automatic, complex, and largely unconscious operations (e.g., repression, displacement, reaction formation, projection, etc.) used by the ego as a means of protection against internal (e.g., unacceptable wishes) or external (e.g., events, such as a loss, that elicit anxiety or painful affects) danger situations, aiming at the adaptive restoration of equilibrium.

dynamic Refers to the point of view according to which mental phenomena represent the outcome of a continuous conflict between opposing forces in general (i.e., the id, the

ego, and the superego), and between the unconscious phenomena seeking discharge and a rigorous censorship (i.e., repression) aiming at their exclusion from conscious awareness in particular.

ego The agency of the psychical apparatus that mediates between the id, the superego, and the external reality, aiming at adaptation.

flight into health The phenomenon in which the resistant patient may exhibit a premature and temporary improvement of personal difficulties as a result of the unconscious wish to evade a further psychodynamic exploration of these conflicts.

focalization Refers to the active and collaborative attempt of the patient and the therapist to stay within the confines of the agreed-on focus and to work toward the attainment of specific therapeutic goals. Focalization is instrumental in the shortening of the treatment.

id The agency of the psychical apparatus that contains the instinctual drives.

interpretation The procedure of making the unconscious conscious.

object relations Refers to the distinctive organization of an individual's inner representational world, which stems from his or her interpersonal and developmental history and determines the mode of the individual's intrapsychic and interpersonal functioning. Furthermore, the term object relations, denotes the interplay between the external reality (i.e., interpersonal interactions with actual persons) and the patterns of inner mental representations (i.e., internalized object relations emerging from the interaction of the self with the external object). An inner mental representation is a mental image of the self or an object (self-representation or object representation), which constitute

a complex enduring, cognitive structure within the ego, comprised of dynamic and effective elements. In psychoanalytic theory the term object refers to an actual person, or a thing, or an inner mental representation.

Oedipus complex Refers to the developmentally fundamental constellation of largely unconscious drives, defenses, thoughts, affects, and object relations relating to the child's wish to possess exclusively the parent of the opposite sex, which elicits feelings of rivalry, jealousy, and hostility toward the parent of the same sex and fears of severe retaliation (e.g., castration, loss of parental love) by the perceived rival parent.

Oedipal issues The derivatives of compromise formations (e.g., maladaptive coping strategies) and patterns of object relations (e.g., triangular interpersonal relationships) stemming from an unresolved Oedipus complex.

past-present link The process in which the therapist synthesizes the material brought by the patient in such a way as to help the patient understand the unconscious link between the past feelings for important people and the transference feelings for the therapist (therapist-parent or past-transference link), enabling the patient to utilize the insight to appraise personal behavior from a novel causative perspective, and to achieve a disconfirmation of the non-realistic inappropriate mode of viewing significant people in present life that entangles the patient in circular dysfunctional self-defeating patterns of relating and interacting.

psychodynamic The terms psychodynamic and dynamic are used interchangeably (See dynamic).

regression Denotes a return to an earlier, more developmentally primitive mode of mental functioning.

resistance Any kind of action, thought, or affect, which represents a manifestation of the patient's conscious or unconscious defensive functions and opposing forces, against treatment and the therapeutic progress in general, and the process of making the unconscious conscious in particular.

superego The agency of the psychical apparatus consisting of parental injunctions and inhibitions, as well as ideals and values.

therapeutic alliance The necessary condition for the progression of the psychodynamic work, consisting of an alliance between the patient's higher developmental ego processes and the therapist's facilitating analyzing ego, which alternately signifies the patient's capacity for empathic attunement and active involvement in a joint effort toward the overcoming of the patient's emotional conflicts, and further activates the patient's ability to work cooperatively and purposefully toward the accomplishment of the therapeutic goals.

transference A general, spontaneous, and universal phenomenon consisting of the process of unconscious displacement of feelings, impulses, defenses, thoughts, attitudes, expectations, and patterns of interaction derived from past interpersonal relations onto a person in the present. Transference is characterized by multiformity and ambivalence (i.e., co-existence of opposite feelings), and depending on

its prevailing characteristics can be distinguished in positive (e.g., affectionate) and negative (e.g., hostile). The treatment situation fosters the development and expansion of transference, which is utilized explicitly, and helps in making feasible the resolution of conflict.

transference cure The phenomenon in which the patient may demonstrate an ephemeral symptomatic improvement in an unconscious effort to please the therapist as a result of a developing positive transference.

working through The repetitive process of assimilation and utilization of insight, aiming at the progressive elaboration and overcoming of the resistances that prevent the establishment of enduring adaptive structural, emotional, and behavioral changes.

Short-term anxiety-provoking psychotherapy (STAPP) is a radical, specialized, and research-based type of short-term dynamic psychotherapy (STDP) developed by professor of Psychiatry Peter Sifneos at the Harvard Medical School for the treatment of appropriately selected patients. This article presents the basic technical and theoretical principles of STAPP, as well as, a brief discussion on the research findings concerning treatment's effectiveness.

I. DESCRIPTION OF TREATMENT

STAPP is a kind of brief therapy based on psychoanalytic principles. The psychoanalytic principles include the analysis of transference, resistances, defense mechanisms, and unconscious processes, with the threefold aim of (a) investigating patient's psychodynamics, (b) facilitating the maturational process through the acquisition of insight (i.e., by making the unconscious conscious), and (c) working through the unconscious factors that hamper the accomplishment of the therapeutic goals.

Dr. Sifneos named his technique short-term anxiety-provoking psychotherapy (STAPP) to give emphasis to the basic technical component of his technique that consists of the constructive utilization of anxiety toward the obtainment of a higher level of psychical organization (i.e., increased capacity for anxiety, frustration and ambiguity tolerance, predominance of more adaptive ego defenses, better elaboration and reconciliation of inner conflict, improved affect regulation) and the attainment of more adaptive modes of coping. The STAPP therapist through the appropriate use of anxiety-provoking interventions (clarifications, confrontations, interpretations) is able to increase the emotional intensity during the session and to maintain patient's anxiety at an optimum

level in which it can be utilized as a motivational force toward (a) the understanding of the nature of the nuclear emotional conflict (i.e., the specific emotional conflict—such as the Oedipal conflict—underlying the patient's psychological difficulties) and the recognition of the maladaptive defensive reactions used to deal with it, (b) the achievement of emotional reeducation, and (c) the acquisition of new learning and problem-solving techniques, in a brief period of time. The treatment can be successfully completed in 6 to 14, or at most 20 sessions.

The technique of STAPP consists of specific and intertwined components, which form four successive phases: (a) the patient–therapist encounter, (b) the early therapeutic phase, (c) the central therapeutic phase, and (d) the later therapeutic phase and the termination process.

A. The Patient–Therapist Encounter

The patient–therapist encounter includes two fundamental parameters: (a) the development of a facilitating therapeutic context, and (b) the psychiatric evaluation.

1. *The development of a facilitating therapeutic context:* In STAPP particular emphasis is placed on the development of a strong collaborative relationship between the patient and the therapist. The therapist is very active throughout the treatment. Through the judicious alternating of empathic, anxiety-provoking, supportive, and didactic interventions the therapist is able to establish rapport, to maximize the therapeutic alliance, and to utilize the positive transference to create a safe environment in which self-understanding, new learning, emotional reeducation, and change can take place. This involves the education of the patient about: (a) the importance of the establishment of a full, active, and joint cooperation for the specification, understanding and resolution of the patient's difficulties, (b) the requirements and the focal, goal-oriented, problem-solving, anxiety-provoking nature of the treatment and the ensuing resistances, and (c) the patient's psychodynamics concerning the therapeutic focus. The STAPP patient is considered capable of cooperating efficiently with the therapist focusing on the goal of resolving the emotional conflicts underlying the difficulties successfully over a short period of time, while the attainment of the mutually agreed therapeutic goals is viewed as a joint problem-solving venture.

2. *The psychiatric evaluation represents a global assessment of the patient's personality organization and psychopathology, which consists of five integral components:*

a. *The assessment of patient's presenting complaints:* The evaluator's primary task is to help the patient organize the presentation of chief complaints (i.e., by making the proper questions, and by emphasizing the importance of clarity, specificity, and immediacy for the successful outcome of their joint effort) and to assemble information concerning their onset, development, intensity, duration, sequence, timing, precipitating factors, as well as, other pertinent issues, to form a clear picture of the patient's problems. The presenting complaints of STAPP patients include interpersonal difficulties, specific, mild psychological symptoms, such as anxiety, depression, grief reaction, chronic procrastination, obsessive preoccupation, monosymptomatic phobia, as well as, physical symptoms of psychological origin (e.g., headaches).

b. *The systematic developmental history taking:* The evaluator through the judicious use of open-ended and forced-choice questions is able to obtain a clear and cohesive picture of the patient's emotional development on a longitudinal basis. The history taking follows a successive order from early childhood to the patient's current life. The evaluator investigates certain areas, such as the earliest memories, childhood relations with parents and other family members or key persons, the early family atmosphere and structure, the school history, interpersonal patterns and experiences during puberty, adolescent and early adulthood, the history of sexual development, and the medical history. The systematic history taking is crucial for (a) the identification of areas of conflict, maladaptive reactions, and repetitive difficulties, and (b) the understanding of the emotional problems in psychodynamic terms, which in turn, enables the evaluator to present to the patient a psychodynamic reformulation of his or her presenting complaints.

c. *The using of the appropriate selection criteria:* The evaluator uses five clear-cut criteria for the assessment of patient's ego strength, through which it can be established that the particular patient can be successfully treated in a short period of time. The STAPP candidate must have (a) the ability to circumscribe the presenting complaints (i.e., the patient, with the appropriate support and preparation by the therapist, must be able to make a compromise and to choose one out of a variety of problems for eventual resolution), (b) a history of at least one meaningful relationship (i.e., altruistic, give-and-take) during childhood, (c) the ability to interact flexibly with the evaluator (i.e., to be willing to consider the other person's view and be able to express positive or negative feelings openly and appropriately during the interview), (d)

psychological sophistication (i.e., above-average intelligence and psychological mindedness), (e) a motivation for change, and not for only symptom relief. Motivation for change indicates the patient's willingness to work hard during the treatment assuming an active responsibility concerning the therapeutic task. According to Dr. Sifneos, the patient's motivation for change is probably the most important of all the selection criteria because it has a prognostic value concerning the therapeutic outcome. The evaluation of the patient's motivation for change is assessed on the basis of seven subcriteria: (a) a willingness to participate actively in the evaluation process, (b) honesty in self-reporting, (c) an ability to recognize that symptoms or difficulties are psychological in origin, (d) introspection and curiosity (i.e., self-inquisitiveness), (e) demonstration of openness to new ideas and ability to change, explore, and experiment, (f) realistic expectations of the results of psychotherapy, and (g) willingness to make a reasonable and tangible sacrifice (i.e., the patient is able to make a compromise concerning the appointment time or the fees of therapy) to achieve a successful outcome.

d. *The formulation of a specific focus for the psychotherapy*: The evaluator on the basis of the information offered by the patient constructs a dynamic formulation of the nuclear conflict underlying the emotional difficulties around which the treatment will revolve. The best therapeutic results can be achieved when the foci of the treatment relate to unresolved Oedipal conflicts, grief reactions, and certain difficulties relating to loss and separation issues. Concerning the unresolved Oedipal conflicts, which represent a common focus in STAPP, Dr. Sifneos proposed that there are three categories to be considered: in Category A the patient's attachment to the parent of the opposite sex is based only in the patient's fantasies of being the favorite child, while in reality there is no evidence of an actual encouragement by the parent; in Category B a more complex condition is presented that involves a reinforcement of the Oedipal attachment by the opposite-sex parent; and in Category C, which is the most difficult to resolve, Oedipal issues involve a complicated condition in which there is a combination of a strong reinforcement of the Oedipal attachment and an actual replacement of the parent of the same sex (i.e., as a result of divorce or death).

e. *The "therapeutic contract"*: The evaluator presents the therapeutic focus to the patient and expects an agreement about the resolution of the emotional conflicts underlying it. In addition the outcome criteria are formulated (these involve the

specific therapeutic goals on which the success of the treatment will be evaluated). The mutual agreement concerning the therapeutic focus strengthens the patient's motivation to assume an active responsibility in expanding self-understanding and utilizing the insights to achieve the desirable emotional change. STAPP involves weekly, face-to-face, 45-min-long interviews, which take place at a mutually convenient specified time. The therapist informs the patient that the therapy will be brief but no specified number of sessions is set.

B. The Early Therapeutic Phase

In the early therapeutic phase, the patient's positive feelings for the therapist predominate. The most important technical principle involves the early utilization, and the vigorous and explicit analysis of patient's positive transference feelings. This procedure enables the therapist to establish the development of past-present links and to strengthen the therapeutic alliance.

C. The Central Therapeutic Phase

The central therapeutic phase represents the height of STAPP. The therapist uses repeated anxiety-provoking questions, confrontations, and clarifications in an effort to stay within the confines of the agreed on therapeutic focus, and to establish past-present links that constitute the fundamental technical aspect in STDP. A basic innovative unusual technical aspect of STAPP has to do with interpretations in the form of hypotheses prior to the analysis and clarification of resistances and defense mechanisms. The therapist utilizes the anxiety, which is elicited by the focal interpretive activity, to make explicit the emotional conflicts underlying the focus, as well as, to help to increase the patient's motivation for the acquisition of new more effective problem-solving strategies and for the resolution of old problems. Thus the patient is able to explicitly understand in which way his or her present mode of interpersonal relations is affected by the unconscious repetition of past interpersonal patterns. The patient's expanding awareness over hidden conflicts, fantasies, feelings, needs, and defensive operations, helps the patient to be able to exercise responsibility and control over them. Consequently the therapist by challenging the patient's neurotic entanglements and by providing empathic understanding and encouragement is able to support the patient's capacity to tolerate conflict and to explore new solutions to emotional conflicts. Through this procedure the therapist helps the patient to develop self-understanding and achieve emotional growth.

Even though it has been established through the careful evaluation process that a STAPP patient is sufficiently motivated to decisively achieve the therapeutic goals in a brief period of time, the emotional intensity of the anxiety-provoking focal interaction and the unpleasant realizations, may at times elicit strong resistance and evasive tactics. The therapist through careful note taking records certain verbatim statements of the patient, and at times of resistances is able to repeat the patient's exact words to present the facts which consolidate the patient's interpretations. Another technical tool, which is used for the resolution of the resistance-related impasse, is "recapitulation." This involves the presentation of a synopsis through which the therapist explicates how he or she arrived at the particular conclusion, based on the information that has been provided by the patient. Furthermore, the therapist by reviewing the recorded notes is able to make short-term predictions about the course and future development of treatment.

Patient's resistances and evasive tactics may include discussion of issues that are not relevant to the focus, or regression-like reactions (e.g., the patient may present him- or herself in a state of an apparently overwhelming anxiety) that actually represent a "pseudo-regression." It should be remembered that a STAPP patient has sufficient ego strength and anxiety tolerance. Under those circumstances the therapist's task is to explain to the patient the importance of focalization for the success of their specific agreed-on therapeutic goals and to reestablish the focus. The therapist through the active and systematic avoidance of early characterological issues (such as passivity, dependency, acting out, and manipulative tendencies), which may be used defensively, is able to prevent the emergence and the establishment of actual regressive modes of relatedness, and to accomplish the resolution of patient's nuclear conflicts within a short period of time.

As the therapeutic work is progressing the patient gradually internalizes the therapeutic processes. The demonstrated ability of the patient to utilize the assimilated knowledge to develop new attitudes and behavior patterns, as well as, to generate novel effective ways of dealing with past and present problems, is evidence of progress.

D. The Later Therapeutic Phase and the Termination Process

In the later therapeutic phase the therapist's task is to look out for tangible evidence of change, as well as, to make sure (e.g., through the exploration of specific examples brought by the patient) that the patient's im-

provement does not represent a fortuitous change, or a flight into health, or a transference cure that involve a superficial and transient symptomatic improvement without a clear-cut understanding of the psychodynamics concerning the emotional conflicts underlying the presenting difficulties. The acquisition of sufficient insight about the focal conflicts results in the establishment of tangible evidence of change and signals that the time has come for the termination process. Consequently the termination of the treatment takes place promptly when both patient and therapist agree that the basic therapeutic goals have been accomplished.

II. THEORETICAL BASES

STAPP is based on psychoanalytic theoretical premises consisting of six viewpoints: the topographical, the dynamic, the structural, the genetic, the economic, and the adaptive. A person's behavior or symptoms are interpreted as disguised representations of underlying unconscious processes (topographical viewpoint). The patient's difficulties or symptoms are viewed as an outcome of a conflict and a dynamic interaction in general, and a maladaptive compromise formation in particular (dynamic viewpoint), between: (a) the warded-off pleasure-seeking instinctual drives stemming from the id, (b) the restrictions by the reality-oriented ego that institutes defense mechanisms to maintain psychic equilibrium, (c) the prohibitions imposed by the super-ego (structural viewpoint). In addition, the patient's current conflict and maladaptive pattern of behavior are seen as parts of a continuum from infancy to adulthood (genetic or developmental viewpoint), consisting of two fundamental interrelated factors: (a) the nature of progressions, regressions, and fixations (economic viewpoint) in relation to the psychosexual development (oral, anal, Oedipal, latency, and genital stage), and (b) the quality of interpersonal relations and environmental influences and circumstances to which the individual adjust and to which he or she acts on (adaptive viewpoint).

Dr. Sifneos developed STAPP, while he was the director of the Psychiatry Clinic (from 1954 to 1968) at the Massachusetts General Hospital (a teaching hospital of Harvard Medical School). The prototype for STAPP was a 28-year-old male patient complaining of an acute onset of nervousness and phobias for all forms of transportation, who came to the clinic, requesting therapy to overcome his fears and be able to get married during the next 3 months. Dr. Sifneos decided to proceed with a therapeutic regimen that was successfully completed

in eight sessions. A subsequent follow-up established that a lasting characterological dynamic change had taken place and patient's focal problems had been resolved. The successful results of this treatment encouraged Dr. Sifneos to look at the patient's character structure systematically and to develop criteria for selection of appropriate candidates to receive a similar psychotherapy. It was in this way that the evaluation process was developed, as well as, the anxiety-provoking technique. In sum the evaluation, techniques, and outcome, which were studied and improved over the years have made STAPP a systematic comprehensive and useful psychotherapeutic treatment.

III. EMPIRICAL STUDIES

STAPP represents the oldest type of brief therapy based on systematic research in the United States, and its effectiveness has been validated by several follow-up studies in United States and Europe. Between 1960 and 1987 Dr. Sifneos conducted extensive controlled research studies. These involved follow-up investigation of "experimental" patients who were immediately treated, and wait-list "control" patients who received treatment after a period of time. Impressive follow-up findings were presented, and studies in Europe showed similar and significant long-term follow-up results, as reported in 1985 by Dr. Ragnhild Husby in Norway.

An important educational and research tool in STAPP is the use of videotapes, which Dr. Sifneos called the "microscope of the psychiatrist." The videotape of the evaluation, the treatment, and the follow-up of patients who are willing to participate in research and to give an informed consent, makes the accomplishment of a detailed and systematic analysis of the therapeutic process and outcome, as well as, the accurate comparison of the pre- and the posttreatment condition feasible. The assessment of the efficacy of STAPP in follow-up studies is based on the evaluation of eight specific outcome criteria concerning patient's improvement in psychological or physical symptoms, interpersonal relations, self-understanding, the acquisition of new learning, the development of new effective problem-solving strategies, self-esteem, work or academic performance, and the development of useful new attitudes. According to follow-up outcome studies the STAPP patients after termination are able to efficiently utilize the new learning and problem-solving skills that they have assimilated during their treatment, through a process which Dr. Sifneos called "internal-

ized dialogue," to solve new problems. This process, which facilitates continuous growth and maturation relates to the patient's ability to reconstruct the therapeutic dialogue with the therapist, to reproduce a therapeutic problem-solving effect for the resolution of new difficulties.

IV. SUMMARY

Short-term anxiety-provoking psychotherapy (STAPP) is an innovative, specialized, and systematically studied type of short-term dynamic psychotherapy (STDP), developed by Professor of Psychiatry Peter Sifneos at the Harvard Medical School. It is based on psychodynamic theoretical premises and constitutes the treatment of choice for the resolution of mild neurotic symptoms in appropriately selected patients. The basic technical principles include the establishment of a therapeutic focus, the use of anxiety-provoking interventions, the early utilization of positive transference feelings for the consolidation of a therapeutic alliance and the establishment of past-present links, the avoidance of characterological issues for the prevention of the development of regressive modes of relatedness, and the achievement of an early termination. STAPP is characterized by the establishment of clear-cut specific criteria for the selection of patients (i.e., circumscribed focus, history of a meaningful relationship, flexible interaction with the evaluator, psychological sophistication, and high motivation for change), and the evaluation of the therapeutic outcome (i.e., improvement in symptoms, in interpersonal relations, in self-understanding, in new learning and problem-solving strategies, in self-esteem, in work or academic performance, and in the development of new effective attitudes). The effectiveness of STAPP has been documented by extensive research studies in the United States and Europe.

In particular, a set of principles underlying the implementation of the single case design within clinical practice is described.

GLOSSARY

external validity Concerns the extent to which experimenters can generalize their findings from one particular set of observations (e.g., individual clients, settings, therapists) to another.

idiographic The study of the individual. Common themes are identified by looking for similarities that emerge across individual profiles.

internal validity Concerns the extent to which observations of change can be interpreted as direct evidence that an intervention had a specific effect on the clinical outcome.

nomeothetic The study of groups of individuals. A common theme is extracted from the collective behavior of the group. This is usually based on the average of the group's responses.

Single-case methods can be defined with respect to psychotherapy, as a collection of techniques for evaluating the efficacy of a specific intervention(s) within a single clinical case or a series of cases. This article overviews the range of approaches and applications of these methods to psychotherapy research and practice.

I. APPROACHES AND METHODS

The fundamental questions within psychotherapy research about which treatments are the most effective or what works for whom are frequently mirrored in the mind of the clinician. Am I using the right approach with this client, are they really showing signs of improvement, should I be adopting a different approach? These questions and doubts are answered through the experience and judgments that clinicians make when reflecting on their practice either alone or when in supervision with other therapists. Nevertheless the search for evidence that therapy has been effective has always been part of the process of psychotherapy.

How can we reliably and objectively demonstrate clinical change within the individual? On a day-to-day basis, effectiveness of our interventions are demonstrated via our own perceptions of what seems to work; the satisfaction of the client that may be expressed verbally in terms of compliments or complaints; behaviorally by gifts, nonattendance, and the unplanned discontinuation of therapy; by comments from carers and relatives; or by peer evaluations during the process of "supervision" or clinical audit. However, do these sources of information really constitute evidence of effectiveness? Even if clinical

change is observed, how confident are we that it was our own specific intervention, as opposed to a myriad of other influences ranging from the client's family through to other possible interventions of the multidisciplinary team, that brought about the real change? Single-case experimental designs have been developed in an attempt to provide proof of effectiveness within the individual. Accordingly, it can be argued that these techniques should provide therapists with an objective means of demonstrating the efficacy of their interventions. As such, they represent one approach to evidence-based practice that the psychotherapists might exploit to demonstrate their own effectiveness to a sometimes skeptical world.

Originally, evidence was presented in the form of what has become known as a "case study," which usually included an extensive account of the client including background history and problems, what happened within therapy frequently based on a session-by-session account, and also the therapist's attempts to understand and account for the process of therapy as described. Indeed, the case study became the major vehicle for documenting the nature of psychotherapy and communicating advances in the understanding of therapy to other practitioners. This approach is typified particularly within writings on psychoanalysis and the classical case studies published by Sigmund Freud.

Although case studies continue to be written, particularly during the course of training psychotherapists, today they are no longer considered as providing sufficient evidence that a particular therapy has been effective. Essentially they have been superseded by what are considered as more scientifically rigorous methods. Generally contemporary clinical research is based around the study of large samples of individuals who have been exposed to various different therapeutic approaches or regimes. So-called robust research methods have been developed relying on double blind procedures and randomized control trials to answer and further tease apart the questions of psychotherapy efficacy. Nevertheless there are circumstances when it is still appropriate to ask questions of effectiveness within a single client by a single therapist. This might arise in the course of developing an innovative therapeutic technique, treating a rare condition, or even as a means for therapists to satisfy themselves and others that their therapy has been effective. The purpose of this article is to describe methods that have been developed for systematically evaluating clinical evidence within the single client.

Single-case methods represent a wide range of approaches that have been used extensively across many different areas of study. The intensive study of the indi-

vidual, as opposed to the usual nomothetic approach of studying groups of individuals, can be readily identified across a range of different disciplines. The clinical case study is widely used within medicine and other clinical disciplines, but individually focused research strategies are also commonplace within educational research, experimental psychology, and sociology. Moreover, although it is common within psychology as a discipline to criticize single-case idiographic approaches on the grounds that they fail to generalize to groups of individuals, many basic laws of behavior within psychology have arisen by the careful and intensive study of just a few selected and usually well-trained individuals. With respect to psychotherapy, single-case methods can be defined as a collection of techniques for evaluating efficacy of a specific intervention(s) within a single clinical case or a series of cases.

The range of applications of single-case approaches is also reflected in a diversity of methods. Even the use of the term "case study" extends from anecdotal reports of therapy published in books through to the publication of brief clinical reports in journals, and formal presentations of case studies. The latter are frequently used as assessments of assumed clinical competence within many forms of psychotherapy training. However, in 1981, Alan Kazdin in a now-classical journal article criticized the traditional clinical case study for being biased and unscientific. The subsequent demise of the clinical case study has given way to a range of more scientifically focused techniques, which are commonly described as "single-case experimental designs." These approaches commonly involve the comparison of data derived from a baseline period prior to when no intervention has been offered, with data obtained from an intervention period. The use of a follow-up assessment some months or years following the treatment is also frequently undertaken. These approaches are often termed AB designs, the letters referring, rather confusingly, to baseline (A) and intervention (B), respectively. Because they usually involve the collection of large amounts of data collected daily over time, they are also referred to as "time series" designs. The comparison between baseline and treatment is also frequently repeated either giving rise to "ABAB" designs or the use of several different measures concurrently that are termed "multiple baseline or phase designs." Occasionally, these designs will be repeated across a small series of individuals and this approach is called "a small N design."

In addition to the quantitative experimental approaches described earlier, the case study has also been developed to yield a range of qualitative methods that

are commonly used within sociology. Indeed, observational case studies of particular services or institutions have resulted in dramatic insights and changes in attitudes. A classic example is Erving Goffman's ethnographic study of institutional life conducted in the 1950s and 1960s. Although qualitative approaches are not the main focus of this entry, their potential for understanding therapeutic processes are becoming increasingly recognized by psychotherapy researchers.

II. CLINICAL RESEARCH AND PRACTITIONER APPLICATIONS

Single-case experimental designs have a wide range of applications, which ought to prove useful to both researchers and practitioners. From a clinical research perspective, not every piece of clinical work will be treated as a potential piece of psychotherapy outcome research. Similarly, most practitioners will not be participating in psychotherapy outcome research. As a means of bridging this gap whereby practitioners become more involved in psychotherapy research, it could be argued that evaluating efficacy within a single clinical case is the bottom line as regards "evidence-based medicine." Indeed, it maybe that single-case methods are about to experience a renaissance as the requirements of demonstrating both the evidence base and clinical effectiveness for specific psychotherapy practices becomes more prevalent due to the influence of the "managed care" movement. David and Robin Morgan have recently made such an argument within an article in the *American Psychologist*.

A. Clinical Research Applications

There are several situations when therapists have a particular reason for evaluating their own work and communicating its outcome within the public domain. The most common reason for employing single-case designs is when the therapist is engaged in an innovative approach to therapy and wishes to disseminate through scientific publication the results of this new treatment approach. Single cases have provided the starting points for many commonly used therapeutic techniques that are widely employed today. For example, the cognitive treatment of panic disorder owes its origins to a series of single cases on the use of rebreathing and reattribution techniques published by David Clark and his colleagues some 20 years ago. Similarly, the cognitive therapy of psychotic symptoms was first published in 1994 by Paul

Chadwick and Max Birchwood as a single-case series. Although these publications by themselves do not meet the full rigors of evidence-based medicine they have provided useful starting points for more systematic approaches to therapy. Indeed, in the case of both these examples, evidence from single-case studies has now been superseded by the findings from randomly controlled trials. Within psychotherapy outcome research, therefore, the single case plays a pivotal position as providing a starting point for the development of new therapies. It is also seen as a means by which regular practitioners may involve themselves in research because the demands of single-case methods tend to be less resource hungry than psychotherapy group evaluations.

Another reason for employing single cases includes the study of rare clinical conditions whereby the limited availability of clients precludes a group evaluation approach, especially in the first instance. Examples of this particular strategy include the evaluation of behavioral treatments of tic disorders and the in-depth investigation of neuropsychological patients with specific and unique head injuries. Single cases can also provide important illustrative material particularly about the practical implementation of new treatment approaches. Such accounts are frequently to be found in the appendices of published studies, which have relied on more traditional group evaluative approaches to outcome research. One particularly, important area for the use of such case material is when therapy is ineffective. Single-case approaches have much to offer the study of treatment-resistant cases. However, the degree to which unsuccessful cases are published and discussed tends to be limited by the implicit bias of scientific journals only to publish positive results. This form of bias may seriously distort the perceived efficacy of treatments, which have been evaluated using single-case approaches. It is usual, therefore, that only positive accounts of new treatment strategies are published at the expense of negative findings. A typical example of this involves the use of "ear plugs" to control auditory hallucinations in psychosis whereby singular and enthusiastically published positive results have tended to give way to later publications of case series that have been more skeptical and negative.

B. Practitioner Applications

The adoption of a single-case approach to clinical work may also have some benefits for clinical practice that are completely independent of research. For example, these approaches can be employed to demonstrate

individual effectiveness of a particular approach to skeptical colleagues or managers. Within the context of cognitive behavioral work, using single-case approaches for data collection facilitates a collaborative relationship between therapist and client that can enhance both the client's motivation and "self efficacy." The approach enables client and therapist to sit down together to identify agreed treatment goals, decide on how individual outcomes should be assessed, and how the impact of therapy can be monitored. It is acknowledged, however, that such an open and goal-directed approach to treatment would not be consistent or appropriate for all forms of psychotherapy.

The demonstration of clinical change using objective measures can be particularly important when working indirectly with care staff. Many researchers have demonstrated that staff's subjective perception of clinical change is frequently biased and may not match more objective change measures, especially for chronic or irregular problems. It has been suggested that this might be due to "recency or memory effects," whereby care staff's perceptions are determined by recent events that then makes it difficult for them to track accurately change over an extended period of time. The use a single-case approach allows a more objective assessment to take place. This can be particularly useful in motivating and informing staff that their efforts do yield positive effects particularly with individuals with challenging and chronic or even deteriorating problems who have previously been resistant to change.

Social work educators have argued that the use of evidence-based techniques such as single-case methods might also enhance the overall effectiveness of practitioners. They have suggested that training in single-case methods enhances clinical skills associated with assessment, formulation, and the implementation of therapy. If this were the case, the routine use of single-case approaches would not only provide the evidence of therapy efficacy but would also lead to enhanced effectiveness. To test these ideas effectiveness of various intervention programs have been compared when therapists have been differentially trained in and encouraged to use single-case approaches. Preliminary evidence from this research would suggest that training in these techniques does enhance therapy and that clients also may have a preference and greater satisfaction for working with a practitioner trained in single-case methods.

Finally, it is commonly believed that single-case methods can only be used by therapists working in either a behavioral or cognitive-behavioral framework. Although, it is undoubtedly the case that many exam-

ples of single-case work are published within behaviorally oriented journals, this doesn't have to be the case. Single cases have been studied using a wide variety of different therapeutic frameworks. What is required, however, are that certain goals of therapy can be established, that they are measurable in some way, and that there is a framework (e.g., formulation) that links the therapeutic model to intervention, together with some hypotheses relating to clinical change. The basic principles underlying single-case work will be further elaborated in the next section.

III. BASIC PRINCIPLES OF SINGLE-CASE DESIGN

Single-case experimental designs rely on several widely recognised and important principles, which have been widely discussed in classic texts such as David Barlow's and Michael Hersen's book published in 1984. These usually include: (a) repeated measurement, (b) stable baselines, (c) single and well-specified treatments, (d) reversibility, and (e) generalizability. To understand implementation of single-case designs, it is essential to appreciate the relevance of these principles. Moreover, it is these characteristics that distinguish the experimental single case from the ordinary case study. If a clinical study is unable to address these principles, it is likely that it will be classified as a case study.

Before expanding on the relevance of the earlier principles it is important to understand what a single-case design is attempting to accomplish. As emphasized by Alan Kazdin and others, the traditional case study is flawed because it relies on post hoc explanations that can be subject to different sources of bias and alternative interpretations. The purpose of single-case design is to identify these potential sources of bias, and control for their influence, and in so doing, to eliminate them as potential alternative explanations for the observed pattern of results that constitutes the case study.

What are the potential sources of confounding that might obscure the interpretation that a particular intervention has had a specific effect within a client on a particular outcome? For example, if during the course of therapy a client's relationship breaks down or a colleague alters the level of prescribed medication, to what extent is any clinical change a function of the therapy provided, the relationship difficulty experienced by the client, the change in medication or a combination of all three? Although some might argue that to attempt to disentangle these factors may be totally artificial, the

single-case design attempts to place on the case study certain limits or boundaries that might distinguish or minimize the impact of these confounding variables.

A. Threats to the Validity of a Case Study

One of the foundations of experimental design in psychology is the identification of confounding variables that need to be controlled to rule out alternative accounts of a study designed to test particular hypotheses. These sources of confounding are frequently referred to as threats to internal and external validity. Internal validity concerns the extent to which the findings can be interpreted in support of the proposition that an intervention had a specific effect on the clinical outcome. A series of possible scenarios exist that if present would severely compromise the study and limit the validity of the conclusions drawn. These circumstances include the following:

- *History*: Here extraneous concurrent events (e.g., relationship break-up, change in medication) may happen alongside the clinical intervention studied. These events may either be known or unknown to the experimenter.
- *Maturation*: This refers to a change process, which may be endogenous to the client and independent of the applied experimental intervention or treatment. For example, neuropsychologists and physiotherapists frequently attempt early interventions aimed at facilitating recovery from brain injuries such as a stroke or a closed head injury. However, if left “untreated,” most individuals with head injuries show a degree of spontaneous recovery in functioning following the injury. Any measurement of clinical change must, therefore, be interpreted against a moving baseline of endogenous change associated with recovery.
- *Testing (reactivity)*: The exposure of a client to the assessment process itself is not a neutral act, particularly when structured forms of assessment such as questionnaires or self-monitoring diaries are employed. The very task of inviting the client to self-assess requires a possible shift in self-awareness and focusing on possible new information. The nature of questionnaires might seek to clarify a client’s understanding or attribution of events and by doing so, challenge their existing attributions and explanations. Thus, the very act of participation and assessment within a case study may bring about therapeutic change. Indeed, such changes are fre-

quently observed during the baseline phase prior to the introduction of any formal intervention.

- *Instrumentation (reliability)*: Nearly every assessment tool, which a clinician will employ, will have associated with it some error of measurement, and it is, therefore, important that these incidental changes in measures across time are not misinterpreted as specific treatment effects.

Other sources of internal confounding include regression to the mean, multiple intervention problems, and instability.

Threats to external validity have also been identified as important sources of confounding that require experimental control. These concern the extent to which experimenters can generalize their findings from one particular set of observations to another. With respect to case studies, generalization refers to the degree to which a finding observed within a single individual can be extended to other individuals and in other settings. Essentially, two sources of bias that might limit generalizability may be identified:

- *Selected individuals/samples*: The degree to which individuals or samples are specifically identified will limit the generalizability of the findings. The more heterogeneous the sample from which individual cases are drawn, the more likely that the results will generalize across individuals. In the case of psychotherapy, the importance of generalizing across variables such as social class, education, gender, and ethnicity will be important for establishing the widespread applicability or otherwise of psychotherapeutic approaches throughout across service provision.
- *Biased interventions/settings*: The setting or the specific manner in which an intervention is delivered might affect the specific outcome within a particular individual. For case studies, the issue here is one of clinical replication. Are results obtained within specialized research clinics by presumably highly trained therapists, generalizable to practitioners attempting to replicate similar interventions within routine clinical practice?

These threats to validity need to be carefully considered by researchers wishing to employ single-case designs. Only by being aware of these threats, can the researcher consider and exclude common alternative explanations regarding the relationship between intervention and outcome. The use of a traditional case study exposes the researcher to a variety of interpretative biases that, at best,

have to be accounted for when interpreting the results and, at worst, may be confounded with specific treatment effects leading to misleading conclusions. To compensate for these biases, “experimental” case study designs have been evolved that attempt to control for or minimize these threats to internal validity. For example, a common control for historical concurrent extraneous events is to repeat or replicate the treatment effect. If a specific treatment-outcome relationship can be observed, and this result is repeated a number of times on different occasions, it is unlikely that some other event unrelated to the intervention will have occurred successively to account for this particular repeating pattern of results. The more consistent the replication of the finding, the less likely it is that some other concurrent event has occurred alongside the specific intervention. Traditionally, group evaluation designs address historical threats to validity by examining replication of findings over a sample of different individuals. For single-case research, the replication is over different occasions within the same individual. Another example of designing against threats to validity concerns maturational effects. As discussed earlier, such endogenous changes may take the form of recovery functions. They may be distinguished experimentally from intervention effects, by observing within an individual the form of the recovery function under baseline conditions in the absence of an intervention, and comparing it following the introduction of the intervention. A specific treatment effect would predict a change in the gradient of any preexisting recovery function.

B. Design Principles

The following principles have been evolved for single-case designs to control for threats to validity and include repeated measurement, stable baselines, single well-specified treatments, reversibility, and generalizability. To understand the rationales underlying these principles, it needs to be acknowledged that their origins extend back to experimental studies of animal learning conducted largely in the middle of the previous century. Essentially, psychologists interested in animal learning conducted single-subject/animal experiments to investigate the effects of changes in various environmental contingencies on patterns of animal behavior. Hence, the knowledge base of animal learning derives very much from single-case experimental studies, together with replications, and has relied predominantly on the visual analysis of the graphical displays of results. This is in marked contrast to group nometothetic approaches, used elsewhere within psychology, and the reliance on statistical testing.

It is these basic principles that have been extended to single-case experimental designs. An obvious reason for this extension was the application of learning theory in the form of applied behavioral analysis to a whole range of human problems, but particularly within the fields of learning disabilities and special education within the United States. This resulted in learning theory paradigms and methodologies being transferred into the clinical domain. It has to be emphasized, however, that the single-case approaches that these methods have inspired, are frequently used to evaluate interventions that are no longer associated with learning theory. In these circumstances, it is possible that rationales developed on the basis of learning theory may no longer apply. An example, which we will return to, is the use of either withdrawal or reversal techniques to demonstrate the specificity of an intervention. From a learning theory perspective, strong evidence of an environmental effect can be demonstrated if the contingencies can be manipulated to obtain withdrawal effects or reversals in the pattern of responding observed. Hence, a particular environmental event (e.g., social praise) could be shown to reinforce particular desirable behaviors (e.g., social interaction) in a young person with learning disabilities, if the behaviors increase when the praise is contingently offered but remains constant or decrease when the praise is withheld. Observation of a direct and repeated effect between the behaviors and the environmental effects provides evidence that the contingencies are reinforcing the behavior. However, this is based on certain learning theory assumptions concerning both the short-term and reversible nature of environmental contingencies. As we discuss later, these assumptions do not apply to the vast majority of interventions that are employed within psychotherapy. The evidence, therefore, that can be gathered from reversal or withdrawal designs is limited only to situations whereby the intervention will have short-term and reversible effects, and if these assumptions cannot be made, then the utility of reversal designs as a principle underlying single case methodology is markedly curtailed.

Bearing in mind the origins and possible limitations of the design principles underlying single case designs, each principle will now be briefly reviewed.

1. Repeated Measurement

Perhaps the most important distinguishing feature between a case study and a single-case experimental study is the number of observations or data points that have been obtained. A basic aim of an experimental study is to demonstrate within each individual intra-subject change

using repeated measures. It is hypothesized that when comparing within an individual measures obtained prior to treatment with those during and following treatment, some therapeutic effect will be observed. The greater number of repeated measures obtained, and the greater the consistency of change across these measures, the more confidence that an effect has taken place. This is analogous to a group design comparing say therapeutic and placebo groups whereby the repeated measures are obtained across the different individuals constituting the groups, as opposed to the single case whereby the repeated measures are derived from a single individual but at many different points in time.

To achieve repeated observations, the measures used have to be easily replicable. This means that they can easily be repeatedly administered, reliable, and relatively free of error or bias. This may discount many traditional forms of psychotherapy outcome evaluation that use extensive psychometric questionnaires or interviews designed only to be used on a single or infrequent sessional basis. Instead, daily measures derived from structured self-report diaries or staff observational schedules are frequently employed. Hence, the case study that includes only a single psychometric measure of pre- and postintervention change should not be considered as a single-case design. However, inclusion of additional repeated daily diary measures would allow such an evaluation to be made. The question arises, therefore, as to what the minimum number of repeated measures has to be obtained? The strict minimum according to Barlow and Hersen is probably at least three baseline and three intervention observations per single measure.

2. Stable Baselines

The basic premise for using repeated measures is that clinical change will be self-evident following the introduction of some therapeutic intervention. The degree to which change is discernible depends both on the magnitude of the therapeutic impact and also on the nature of the preintervention baseline. The greatest confidence about therapeutic impact can only be made when a stable baseline has been obtained. If the baseline is unstable (i.e., it displays an existing trend or slope, cyclical variability or excessive variability or noise), the confidence of detecting therapeutic change is much reduced. It is frequently suggested that baselines should be collected until they demonstrate stability. However, this may not be practical within the psychotherapeutic situation and a frequent question posed is what is the minimum length of baseline acceptable? A review of the size of baselines used in 881 studies published in the *Journal of Applied Behavior Analysis* ranged between 3 and 10

observations. In practice, it is likely that baselines will be obtained perhaps within the second and third sessions as part of an overall assessment process. If derived from daily ratings, it is feasible to collect baseline data ranging from 7 to 20 or so observations across a period of a few weeks that ought to be more than sufficient, although this will depend ultimately on the type of analysis to be employed.

3. Treatments Are Well Specified and Documented

In order to assess the effects of an intervention, it is important that essentially only a single treatment is applied at any one time and that its nature can be specified. Many therapists have difficulties with this limitation because it forces them to assess and formulate the case and prescribe a particular therapeutic approach in advance. However, this does not mean that case reformulation and changes in therapy cannot occur; they need to be, if possible anticipated, and incorporated into the design. Another issue of contention is exactly how is "a single intervention" defined? Again this is the responsibility of the therapist and depends largely on why the case is being evaluated in the first place. Therapists frequently argue that they plan to use a combination of different treatment strategies or techniques. If the aim of the evaluation is to assess the overall impact of this package of strategies, then the package, if it can be defined, becomes synonymous with a "single treatment." Another problem frequently encountered is the presence of other therapeutic work such as medication or other inputs from a multidisciplinary team. Two possible approaches to this common problem are available: to negotiate keeping external therapeutic inputs constant (i.e., no planned changes in medication) or directly involving the other therapists in the design and attempting to evaluate the comparative effectiveness of these other approaches with respect to the psychotherapeutic intervention.

4. Designing against Threats to Validity: Replications, Reversibility, and Withdrawals

A myriad of single-case designs have evolved in an attempt by clinical researchers to rule out the various threats to internal validity that have been previously described. Usually these designs involve complex comparisons of different phases of intervention and baseline manipulated across behaviors, settings, and participants. The logic of many of these designs also originates from applied behavior analysis and the application of fundamental learning theory assumptions. As such it is debatable how relevant this complex myriad

FIGURE 1 Withdrawal and reversal designs. The ideal single case design relies on intrasubject replication and is exemplified by the ABAB withdrawal design. The replication of a treatment effect (i.e., increasing slope) on both occasions that the treatment (“B”) is introduced, and the return to baseline on the second baseline occasion (“A”), are seen as strong evidence that the original treatment effect is real and not spurious.

of designs is for psychotherapeutic applications? Accordingly we have avoided describing these different designs in any great detail. Several of the cited references in Further Reading specify different designs, their rationales, and uses. Instead, we concentrate on the most influential design feature, which surrounds the questions of replication.

It is argued that greater confidence in the impact of treatment on intrasubject change can be demonstrated if the effects can be replicated within repeated measures, across different phases of a design, and that the effect of the intervention on the measures can be directly manipulated through either reversals or withdrawals. Replication is largely a means to protect against either historical or maturational threats to internal validity. Hence, if the results from the simplest AB design (baseline vs. treatment) can be replicated, then it is less likely that some extraneous event can account for the original but replicated change from baseline to treatment. This is in essence the logic of ABAB design (see Figure 1), which is frequently advocated as a standard for experimental single cases. However, within the context of many psychological therapies such designs have important limitations. Essentially, their rationale depends on reversible treatment effects analogous to contingency manipulations employed within applied behavioral analysis. Fortunately, at least for the client, many interventions are considered as long lasting and hopefully resistant to reversal, relying on dynamic intrapersonal changes (e.g., cognitive therapy will promote schema changes). It is, therefore, neither theoretically likely nor ethically desirable that a positive treatment effect can be reversed. Hence, ABAB or ABA designs have their limitations because replication due to withdrawal of treatment and return to baseline may not actually be predicted due to the irreversible nature of the intervention employed.

Non-reversible treatments that are usually identified include psychoeducational approaches, skills-based therapies, schema-directed therapies, altered therapeutic environments, staff attitudes and training, and surgical or long-term pharmacological interventions. Nevertheless, introduction of a brief second baseline can be useful to assess and demonstrate the permanence or otherwise of therapeutic change. This can be practically incorporated into “therapeutic holidays,” whereby clients are encouraged to assess progress by putting aside what has recently been learned or suspending temporarily homework exercises or self-coping techniques. Ethically this is defensible on the principle of demonstrating efficacy to the client of an intensive therapeutic regime. It is also likely, that a second baseline will also be introduced at the termination of treatment in the form of a follow-up to specifically assess the permanence and stability of change. If there has been deterioration in therapeutic improvement, this might argue for the introduction of “booster sessions”: such a protocol would result in baseline and treatment phases not that indistinct from a classic ABAB design. A frequent rejoinder to those that criticize the ethics of single-case designs is that it might be considered a greater ethical problem to conduct psychotherapy in the absence of evaluation per se rather than to attempt evaluation through some manipulation of the therapy itself.

5. Evaluation and Interpretation

It is essential for a single-case design that the therapist has engaged in some critical and systematic evaluation of the data. There have been two competing approaches within single-case research: visual inspection and statistical analysis. Traditionally, single-case data have been analyzed visually using graphical presentation, sometimes presented alongside some simple descriptive statistics such as mean or medians. This tradition derives

very much from applied behavior analysis and emphasizes the utility of complex designs that require phase changes and demonstrate intrasubject replication via reversals and withdrawals of treatment components relative to baseline. However, as the scope for replication based around the assumption of reversible treatments becomes less applicable, some authors have argued for a more systematic approach to evaluation using statistical methods. There has also been a concern that visual inspection might be biased toward “Type one statistical errors” where significant change is expected and inferred but not actually substantiated, and at the same time, biased away from “Type two statistical errors” whereby the inherent variability within single-case data prevents the easy detection of reliable change. Unfortunately, due to a unique statistical feature of single-subject data termed serial dependency, the assumptions underlying most of the commonly used statistical tests are violated and hence, this severely limits their application. Accordingly, application of statistical models of single-case data is a specialized area of evaluation and one that requires serious consideration by the single-case researcher.

Finally, even if change could be reliably inferred between treatment phases and baseline conditions, the meaning of these changes requires interpretation. Due to the design limitations of a single case and threats to both internal and external validity, it is essential that observed differences are not simply considered as treatment effects. The limitations of single-case designs are such that it is essential that the clinical researcher is able to identify and where possible rule out alternative interpretations or threats to validity. It is very unlikely that the rigor of the design will have already excluded these possibilities as maybe the case when employing double-blind, randomized control designs within group comparison studies of psychotherapy outcome.

6. Generalizability

A common misconception about single-case designs is that they involve only a single subject. To derive general explanations or laws of behavior change, effects should be generalizable. The converse of this is that these laws ought to account for known sources of variability, and this is often obscured in group designs. Although a single $N=1$ design has limited generalizability, a series of $N=1$ designs should identify sources of variability and lead to greater generalizability. Different types of generalizability include across individual clients or clients with similar attributes, across different therapists, and across different settings or situations. The issue of generalizability

is resolved, therefore, through replication across different clients, therapists, and settings. Hence, $N=1$ studies lead on to $N=1$ series, small N designs with homogenous subjects and well-controlled conditions. Indeed recent exponents of single-case methods have also described meta-analysis procedures analogous to those used in group outcome studies with which to evaluate and summarize the results from a series of individual studies. Finally, it is also important to ensure that single-case research is not only generalizable but also clinically replicable within ordinary clinical settings.

IV. SUMMARY

We have attempted to review the general principles underlying single-case design and to suggest that they might play a role in helping to establish both the efficacy and effectiveness of psychotherapeutic interventions. Such a methodology might assist psychotherapists to address the combined agenda established by the influential “evidence-based medicine” and “managed care” movements and in doing so, encourage practicing clinicians to evaluate their clinical work and engage in clinical research. However, it should be recognized that much of the work published using single-case methods has derived from more experimentally based psychotherapies and that many of the fundamental principles underlying this approach might be antithetical to some psychotherapies, especially those that are more dynamically oriented. Notwithstanding these potential obstacles to the implementation of single-case approaches, I should like to invite the interested therapist to explore how these approaches might be integrated with their own therapeutic work. To achieve this, it will be important to identify clear clinical formulations, which link to therapeutic strategies. These strategies need to identify various therapeutic goals that can then be assessed as clinical outcomes and reliably and repeatedly measured. In addition, the clinician will also need to be disciplined so as to follow a predetermined therapeutic strategy but also to be sufficiently flexible so as to engage the client and be ready to reformulate and redirect the therapy, as the therapeutic process unfolds.

I. OVERVIEW

Single-session therapy is a general term that is used to describe any form of psychotherapy that seeks to address the presenting problems of clients within a single visit. It is hypothetically possible for any form of psychotherapy to be conducted in a single session and, indeed, Freud's case studies include cures that were achieved after one meeting. In practice, however, it is unusual to find either cognitive-behavioral or psychoanalytic brief therapists conducting single-session therapy. This is because the models of change underlying these approaches emphasize the value of repeated experience in building new patterns of thought, feeling, and behavior. The learning models associated with cognitive-behavioral modalities, for example, emphasize the acquisition of skills through deliberate rehearsal. Such practice generally requires more than one visit. (A notable exception would be massed practice in behavioral therapies, where desensitization might be undertaken in a single, extended session, as in the implosive therapy of Levis.) The relationship models underlying brief psychoanalytic therapies stress the importance of creating powerful emotional experiences for clients, which also are rarely undertaken in a highly abbreviated span.

Most single-session therapies draw on contextual models of change that emphasize the constructed nature of client presenting problems. Problems are seen as client construals, not necessarily as illnesses or problems that possess an independent existence. These construals

GLOSSARY

brief therapy Psychotherapy, typically of short duration, in which efficiency in achieving change is an explicit aim. Sometimes referred to as time-effective or short-term therapy.

Ericksonian therapy Psychotherapy, typically brief, derived from the work of Milton Erickson. It seeks to maximize therapist influence through the strategic use of language, the accessing of altered states of mind via hypnosis, and the use of directed tasks.

single-session therapy A form of brief therapy in which there is a planned attempt to address the presenting concerns of clients within a single visit. Often makes use of techniques derived from Ericksonian, strategic, and solution-focused therapies.

solution-focused therapy Form of brief therapy that seeks to identify and/or construct exceptions to client problem patterns and reinforce these as solutions. Inspired by Ericksonian and strategic therapies.

strategic therapy Form of brief therapy that seeks to interrupt and alter self-reinforcing patterns in which attempted solutions to problems actually contribute to their maintenance. Inspired by Ericksonian therapy.

are maintained by elements in the client's intrapersonal and interpersonal contexts and become reified over time. From this perspective, a long-standing problem is not necessarily any deeper than a recent one and might be amenable to short-term treatment. By shifting the contexts in which the client is operating and providing insights and experiences that dislodge problematic construals, therapists can catalyze significant change in a single meeting.

The majority of single-session therapies emphasize the role of the therapist in initiating change, rather than effecting a cure. Although problems can be dislodged and new construals introduced in a single visit, it is generally not possible for clients in single-session therapy to generalize these changes to a variety of life situations. As a result, single-session therapies are not seen as ideal treatment modalities for all people. Commonly cited contraindications for single-session therapy include the following.

- *Chronic, severe presenting problems:* The client with long-standing problems that significantly impair functioning often needs coordinated efforts at rehabilitation, rather than a brief episode of therapy. Although techniques derived from the brief and single-session literatures may be helpful for such individuals, they typically do not meet the full spectrum of client needs.
- *High need for support:* Clients who have poor support systems may want to rely on the therapist as a support and, indeed, may need that support to assist them in leaving an abusive relationship or changing an addictive pattern. A single-session treatment, by definition, cannot offer ongoing support to such individuals and could even prove detrimental to clients with issues related to attachment and separation.
- *Troubled interpersonal history:* Single-session therapies are effective to the degree that they utilize techniques that maximize the influence of the therapist. Clients who have experienced a history of abusive, neglectful, or highly troubled relationships often need an extended period of time before they can learn to trust a therapist. This severely limits the usefulness of single-session work.
- *Low readiness for change:* Clients who are ambivalent about making changes generally need to explore problem patterns and their consequences before developing the motivation to initiate and sustain efforts at change. This generally extends the duration of therapy beyond brief parameters, and certainly beyond the length of a single session.

Although these contraindications are significant, single-session therapies may be more useful for clients than is commonly acknowledged. Studies of utilization of therapy in outpatient settings suggest that approximately one third of all clients only attend a single session, often reporting that the brief intervention was sufficient for their needs. Appropriately utilizing highly abbreviated treatments for clients can preserve resources for others who most need them in capitated settings and clinics with staff limitations. Generally, clients who are the best candidates for single-session therapy display:

- *Adjustment problems, situational problems, and non-severe disorders of recent origin:* Individuals who are not overwhelmed by their presenting problems are most likely to be able to take the results of a single visit and apply them to their lives.
- *High levels of motivation:* Because there will not be future sessions to carry the change process forward, clients who are to benefit from single-session work need to be able to sustain their own efforts at generalization.
- *Awareness of a focal problem:* Limiting therapy to a single session places therapist and client in an action mode from the start. If clients lack a focus for therapy, it is likely that more than one session will be needed to define and implement a therapeutic contract.

Although there are several different approaches to single session therapy, all share features that differentiate them from lengthier brief therapies. These include the following:

- *Beginning therapy before the first session:* A number of writers on single-session work emphasize that change begins at the time the first appointment is made. Often, the therapist will talk with the client at the time of first contact and suggest a task that can be accomplished prior to the first session. By encouraging pretherapeutic efforts at change, therapists can use their single session to focus on positive efforts already under way.
- *Addressing time at the outset of therapy:* Many approaches to brief therapy aim to be efficient but do not expressly address time during the first session. Single-session therapists generally preface treatment with an explanation that one visit is often enough for clients, even as they leave the door open for further meetings as needed.
- *Active attempts to utilize ideas and language introduced by the client:* Single-session therapists do not

have the luxury of stimulating and working through the resistances of clients. Rather, they attempt to build on frameworks already utilized by the client to elicit cooperation.

- *Rapid introduction of impactful interventions:* With a limited time available for catalyzing change, single-session therapists must move quickly from a problem-based mode to one in which new patterns are introduced. Often this is accomplished in ways that will maximize their impact, by employing vivid language, hypnotic suggestions, directed tasks, and novel reframings.

Just as brief therapy appears to represent an intensification of the common factors that account for the effectiveness of all therapies, single-session therapies are, in essence, a distillation of methods utilized in brief treatments. The quick establishment of rapport, rapid definition of a treatment focus, and active introduction of novelty in pursuit of change make single-session therapy a brief version of brief therapy.

II. THEORETICAL UNDERPINNINGS

Much of the writing on single-session therapy owes its inspiration to three strands of practice in the brief therapy literature:

1. *Ericksonian therapy:* A number of authors, including Jay Haley, Richard Bandler, John Grinder, and Stephen Lankton, have attempted to identify the elements of practice that distinguish the work of Milton Erickson. These elements include the creative use of language to influence clients, the introduction of hypnotic trance to shift clients' perception, and reliance on directed tasks to interrupt existing problem patterns. Many of these methods are attempts to bypass the normal, verbal, conscious awareness of individuals and introduce change experientially and emotionally. By affecting clients directly, Erickson found that the duration of therapy could be greatly reduced.

2. *Strategic therapy:* Therapists operating from a systems perspective, including Paul Watzlawick, John Weakland, and Richard Fisch, extended Erickson's pioneering work, creating short-term approaches to therapy that could be used for families and individuals. A central tenet of this strategic approach is that presenting problems are artifacts of self-reinforcing cycles, in which attempted solutions maintain the initial problems. For instance, a spouse hurt and angry over a perceived lack

of attention may attack the partner, producing even further distance. By placing clients in contexts that could not support the self-maintaining cycles, strategic therapists provide powerful experiences that break the old patterns and allow for the introduction of new ones.

3. *Solution-focused therapy:* A new tradition was inspired by the work of Steve deShazer who conceptualized therapy as a search for solutions rather than an exploration and analysis of problems. This solution-focused approach, elaborated by such therapists as William O'Hanlon and Jane and Walter Peller, can be readily adapted to the single-session framework. By focusing on client goals and quickly initiating a search for imagined or experienced exceptions to client patterns, solution-focused therapists are able to quickly move treatment to an action phase, greatly abbreviating the change process.

Common to all three approaches is a postmodern epistemology, which emphasizes that reality is actively constructed, both in the cognitive processes of the individual and in social interaction. When something negative happens on multiple occasions, it becomes an object of attention and may be construed as a problem. Once so identified, the behaviors in question typically elicit further distress and efforts at coping. Many of these dampen distress in the short run, but exacerbate the initial concerns. By introducing novel approaches to the situation, through metaphor, story, or directed task, the therapist aids in the construction of a new reality. This opens the door to more flexible responding and the possibility of developing constructive behavioral patterns.

This postmodern conceptualization of problem formation and change provides much of the rationale of single-session therapies. Many alternate conceptions of therapy emphasize the existence of a problem that must be evaluated and subjected to various therapeutic interventions. The postmodern perspective stresses that the problem, in an important sense, does not exist other than in the eyes of the client; it is part of the client's mental map—not an enduring feature of the landscape. Even relatively small shifts in the map can produce new patterns of thinking, feeling, and acting that can assume a life of their own. This can be observed in the "pivot chords" described by Robert Rosenbaum, Michael Hoyt, and Moshe Talmon, who use ambiguity in client verbalizations to open the door to new ways of construing problematic situations.

An additional theoretical assumption that permeates single-session modalities is the notion that clients essentially possess all they need to overcome their problems.

Rather than view individuals as existing in a deficit state where they need treatment from professionals, single-session therapists emphasize their existing adaptive potentials. This is most clearly seen in solution-focused approaches, in which the emphasis of therapy is on exceptions to presenting problems and patterns. These exceptions may be imagined (“What would life be like if you did not have the problem?”) or may be inferred from the client’s own experience. By framing such exceptions as constructive actions that the client can initiate, the single-session approaches bypass much of the early phase of problem definition and analysis and quickly move to an action stage.

III. RESEARCH FINDINGS

Controlled outcome studies comparing single-session therapy to other forms of intervention have yet to be reported in the literature. Nonetheless, several strands of research represent initial attempts to build an empirical basis for these approaches. Moshe Talmon reports several studies that have found 30% of all clients attending therapy for a single session. Follow-up investigations with those clients found that approximately 80% were satisfied with the limited intervention and reported some or much improvement.

Studies at the Brief Family Therapy Center in Milwaukee have generally supported the effectiveness of solution-focused therapy and have found that pretreatment interventions result in noticed positive change in 60% or more of all clients. This is particularly true of Formula First Session Tasks, which ask clients to observe what is happening when things are going positively. Clients performing such tasks have been found to be more cooperative in therapy than clients not performing the tasks and have reported greater improvement by the second session. Other studies have found that the amount of change-related talk engaged in by therapists and clients is predictive of success.

Although these studies are encouraging, it will remain for controlled outcome studies comparing single-session interventions to other modalities to establish

the long-term success of very brief work and the degree to which outcomes are attributable to specific interventions rather than general factors.

IV. SUMMARY

Single-session therapies are a collection of approaches that attempt to maximize change within a single visit. Most of these approaches owe their genesis to the pioneering work of Milton Erickson and the subsequent development of strategic and solution-focused therapies. Built largely on a postmodern epistemology, they emphasize the constructed nature of client concerns and the role of the therapist in identifying contexts and experiences that allow for alternate constructions. Such approaches are best suited for clients who are motivated to change focal patterns, especially those who are experiencing situational or adjustment concerns and are capable of establishing a rapid therapeutic alliance.

GLOSSARY

coping questions Techniques that are designed to empower clients to manage their life more effectively by addressing their coping style.

miracle question Technical intervention in which the client is asked to think in an unlimited range of possibility and to identify changes that they want to see happen.

scaling questions Technical approach that encourages the client to prioritize and put into an ordinal relationship various issues, including efforts to problem solve, as well as problems.

SFBT (Solution Focused Brief Therapy) is an approach to delivering psychotherapy based on a variety of theoretical positions, such as Milton Ericson's ideas and Wittgenstein philosophy of language. SFBT focuses on solutions rather than problems.

Solution-focused brief therapy (SFBT) was developed through the work of Steve de Shazer, Insoo Kim Berg, and their colleagues at the Brief Family Therapy Center in Milwaukee, Wisconsin. It is a model that has

been developed inductively based on 30 years of sessions with clients. It has been used successfully in a variety of settings including rehabilitation centers, psychiatric hospitals, residential treatment centers, child protection agencies, schools, and private practices. This treatment model is based on the hypnotherapeutic work of Milton H. Erickson, as discussed by Haley in 1967, and influenced by the 1974 work of John H. Weakland, Paul Watzlawick, and Richard Fisch of the Mental Research Institute.

I. BASIC POSTURE

As the name suggests, SFBT is defined by its emphasis on solutions rather than problems. Different from problem-based therapies in which a great deal of time is spent assessing problems, understanding in as much detail as possible what a client is doing wrong, or developing hypotheses about what is wrong with the client and family system, and the therapist prescribing solutions, SFBT focuses on finding solutions and gives minimal attention to defining or understanding presenting problems.

A description of the SFBT treatment model includes the following: therapist attitudes, socializing, goal negotiation, miracle question, exception questions, scaling questions, coping questions, and the consultation break and intervention message. In addition, three types of client-therapist relationships are described: visitor type, complainant-type, and customer-type.

Therapists' beliefs and attitudes influence how and what they listen to when talking with clients. SFBT emphasizes attitudes of client competence, and the importance of how language is used in conversation with clients. All therapists, regardless of their approach, come with certain attitudes and philosophies that affect how they do treatment. For example, all therapists are selective in their choice of what they ask about and what they ignore, depending on the underlying assumptions they hold about what is useful and helpful for their clients to talk about. Far from serving the "objective" purpose of "merely" gathering data, the questions therapists actually raise with clients influence and change clients' thinking about themselves. Solutions for clients are not scientific puzzles to be solved by practitioners, but rather changes in perception, patterns of interacting and living, and meanings that are constructed within the clients' frame of reference. The SFBT therapist assumes that clients are competent at conceptualizing an alternative more satisfying future and at figuring out which of their strengths and resources they can draw on to produce the changes they desire. The client is the expert of his or her problems and has legitimate goals and ways to facilitate change. For example, a client with an alcohol problem may want to improve his relationship with his wife and children and may not initially want to stop drinking. Accepting this initial goal as a reasonable first step makes it possible to further examine his desired state of life.

The therapist assumes a collaborative stance, with the client and therapist working together to bring about goals the client decides on. Berg and De Jong in 1996 described exploring and affirming clients' perceptions as clients describe them as a major share of what is done in SFBT. Even when clients are considering extreme actions—suicide or violence—they do so within a context of several associated perceptions. For example, to a client who thinks of hitting a child, an SFBT therapist might say, "What's happening in your life that tells you that hitting your child might be helpful in this situation? What else? Does it work? Suppose you were to do that, what would be different between you and your child? What would be different between you and your other children, the courts, your family?" As clients are respectfully asked about their perceptions, they usually are able to talk about less extreme possibilities. Berg and De Jong in 1996 described the therapist assuming a "not knowing" or curious stance in talking with clients. The therapist is always in the stance of learning the clients' perceptions and explanations, never knowing a priori the significance of the client's experiences and actions.

Finally, the therapist's job is to learn the language of the client. Rather than believing that language describes reality, it is believed that language also conveys information about what the therapist is interested in learning from the client. Being problem focused, clients often use language as if to describe their relationships and experiences, assuming, for example, that "being close" means the same for everyone. Often, although their language is very meaningful to them, it may be vague to a therapist. Clients use language to describe their relationships and experiences. Examples of techniques that begin to clear up the ambiguity are for the therapist to repeat key words used by a client, clarify what a client means by certain words, and use the actual words a client uses in the conversation. The therapist listens carefully for and explores each client's choice of words. This not only demonstrates respect for the client, it also begins a process in which, as therapists speak the client's language, clients begin to speak the solution-focused language of therapists.

II. SFBT PROCEDURES AND TECHNIQUES

All therapy, regardless of model, begins with a phase of socializing and orienting clients to what is to come. de Shazer and Berg describe initial questions directed at areas in which clients are successful or from which they draw satisfaction or esteem. Early on in the conversation, the SFBT listens for and highlights client strengths and successes. For example, beginning a conversation with clients by asking them what they are good at, what they enjoy, their job, hobbies, talents, past achievements, or ambitions for the future begins a dialogue between the therapist and client about identifying issues they both can agree are going well for the client. Client strengths, resources, and abilities are highlighted rather than their deficits and disabilities. This approach tends to look for what is right and how to use it. Asking clients early on what they are good at sets a different conversational path than "what problem brought you here today?" This communicates to the client that the therapist recognizes that even though the client has problems, he or she also has areas that are successful. Often these strengths, although unrelated to the presenting problem, bring early clues about how the client will solve their problems.

Co-constructing goals with clients is a very important feature of SFBT. Clients generally are much more aware of, for example, the problems and what they do

not want in their lives than they are about what they want to be different. Many clients begin the discussion of goals as the absence of problems; however, SFBT conceptualizes goals as the presence of what the client wants. Berg and Miller describe goals as criteria that the client and therapist determine together that would tell them they have succeeded and can end therapy. They include the following: Goals must be important to the client and be viewed as personally beneficial; they must be small enough so they can be achieved; they must be concrete, specific, and behavioral and stated in positive, proactive language about what the client will do instead of what he or she will not do. Goals must also be perceived as involving hard work for the client. For example, instead of drinking, a client may make an arrangement for a designated driver before going out on the weekend, or get to work on time. This is in contrast to a vague goal of improving one's self-esteem or being happy.

III. THE MIRACLE QUESTION

Berg and De Jong describe how the miracle question gives clients permission to think about an unlimited range of possibilities, and identify changes they want to see happen. Because the question has a future focus, it begins to move the focus away from their current and past problems and toward a more satisfying life. The miracle question stated in the following way frequently draws a rich response from clients.

Suppose (pause) after we talk today, you go home (pause) and sometime in the evening you go to bed (pause) and in the middle of the night (pause) while you are sleeping, a miracle happens and the problem that brought you here today is solved (pause), but because this happens while you are sleeping, you don't know that the miracle happened until you wake up in the morning. So when you wake up tomorrow morning, what will make you wonder, "something is different, maybe there was a miracle last night?"

Getting details of the miracle is important and the therapist's follow-up questions are crucial. Asking "what else will be different, what else?" is a helpful question to explore. The more opportunities a client has to rehearse a successful outcome verbally, the more chance the miracle has of beginning in small ways to become real for him or her. The miracle question can be an empowering experience for clients as they begin to imagine a painful life transformed to a more successful

and fulfilling life. The gift of hope and a vision can be a truly healing experience for clients.

Exception finding questions are another tool used in SFBT. An exception to a problem occurs when the client engages in nonproblem behavior (e.g., does not drink, does not feel depressed, and does not fight with his wife). The therapist's job is to listen for and magnify a client's successes through repeated emphasis on those few, but important, exceptions. When repeated often and examined in detail, successes become more real to the client. The client can then begin to see their success and recognize that they actually have taken steps to improve their life. Thus the client can take responsibility and credit for the solution. An example would be exploring in detail those times when a client does not drink: What was she doing?—Who was she with?—Where was she?—What did other people notice during that time? Other questions to ask include inquiring about times when things have gone better between sessions, and helping clients describe times when some pieces of the miracle have already happened before therapy began. Getting as much detail about what was happening during these times (who, what, when, where, how) and including other important persons behaving differently during these times, provide further contextual information in these important moments.

Scaling questions are another useful technique used in SFBT. As deShazer states, "there is magic in numbers." An example of a scaling question is "on a scale from 0 to 10, with 0 representing the worst things could be for you and 10 the day after the miracle, where on the scale would you say you are now?" Frequently, clients will give a rating of "3." The therapist then helps them describe the differences between "0" and "3" and how other people might see those differences, and what it might take to "get all the way up to 3." Suppose a client answers "1." The therapist may respond "How are you able to keep going?" "What gives you the strength to continue?" When a client is asked to put problems, successes, hope, and level of self-esteem on a numerical scale, it gives the therapist useful information about a client's relationships, confidence in change, and self-esteem, and helps to determine an end point for therapy. An example is, "At what number on the scale will you be when things are going well enough that you no longer feel you need therapy?" It can also help the client describe contextual details of his or her experience. An example is, "Where would your mom/dad/best friend/spouse/boss/probation officer say you are on the scale?" Finally, scaling questions can also help clients create small goals for change. Asking a client what will be different when they go from

a 3 to a 4 (not a 10), forces clients to think about taking small, more realistic steps toward change.

Coping questions can also be very useful in SFBT. Questions about how clients are managing their life can be very empowering to clients. Examples, include, "How are you able to keep going when your life feels like it's falling apart?" "How do you manage day to day?" Questioning clients about how they are coping with big problems shifts the conversation from hopelessness to hope and a sense of control. However small it may seem, the small things the client does to "barely cope" are the very things that the client must do more of "one day at a time" in order to create a basis on which to build more successes. "How come you life is not worse?" is used to "blame" the client for their success. Such "positive blame" assigns the responsibility for positive, helpful behaviors to the client.

Frequently, an SFBT session includes a team behind a one-way mirror and the therapist meets with them 10 to 15 minutes before the end of the session to develop a closing message to the client. Working alone (which is the most common practice) and taking a 5 to 10 minute break after 45 minutes of a session allows the therapist to review the session, take time to think about whether there are well-formed goals, and to decide on a feedback message for the client.

SFBT feedback messages include compliments, which are used with all cases and throughout the treatment process. All cultures use compliments as a means of cementing social relationships at all levels. Clients have personal qualities and past experiences that, if drawn on, can be of great help in solving their difficulties and creating more satisfying lives. Compliments can be direct or indirect. During the interview, for example, direct compliments can be developed from times when clients are resilient in the face of hardships, sober for even 1 week, able to hold down a job, care about their children, work hard, or are willing to come get help. Compliments are best when they are based on reality and incorporate the client's language. Indirect compliments are questions that imply that the client has done something positive. For example, "How have you managed to stay sober for one week?" "How have you managed to stay calm when things are so hectic?" This allows clients to speak aloud themselves about the details of their success. When clients are able to speak themselves, they appear more empowered in their ability to find solutions.

Suggestion for homework is frequently prescribed at the end of an SFBT interview. Deciding on what type of intervention to prescribe depends on what stage of relationship the client has with the therapist. SFBT

describes three types of client-therapist relationships: visitor-type, complainant-type, and customer-type. Visitor-type relationships are those in which the client has not yet created a workable goal. Often these clients are mandated through probation officers, employers, or parents. Interventions with these clients focuses on giving frequent positive feedback on what the client is already doing that is helpful and working. Providing these clients with many compliments is often a very different message than what they have frequently heard, and may help make these clients more interested in treatment. Complainant-type relationships involve clients that have created some workable goals, but view their solutions lying outside of their control. In addition to using compliments, suggestions are made to shift the client's perception from someone who is a helpless victim to someone who can create solutions. Interventions encouraging clients to "observe and think" about what they will notice will be different when the miracle happens is an example. Because these clients are observers, but not yet "doers," this meets the client where he or she is. Customer-type relationships are those in which the client is willing to actively "do" something differently, to actually take steps to find solutions in his or her life. Clients are frequently asked to do more of what is working, pay attention to any part of the miracle that is happening, or imagine a miracle day.

IV. THEORETICAL FOUNDATION

The theoretical underpinnings of SFBT come from several sources including social constructionism, Wittgenstein's philosophy of language, and Milton Erickson's ideas on therapy. Social constructionism maintains that people develop their sense of what is real through conversation with and observation of others. Social constructionism holds that reality, as each individual perceives it, is by definition subjective and created through the process of social interaction and the use of language. SFBT asserts that problems occur in interactions between individuals and do not rest within any one individual. People define and create their sense of what is real through interaction and conversation with others, a form of negotiation carried out within the context of language. SFBT helps clients do something different by changing their interactive behaviors or the interpretations of behaviors. This approach makes no assumptions about the "true" nature of problems. SFBT has a strong orientation toward the present and future and further believes that everyone's future is

negotiated and created. How clients are currently living their lives and their future goals are emphasized, thus orienting the client away from the past problem toward the future solution.

This model differs from the traditional “medical model” in a number of ways. Rather than assessing problems, signs, and symptoms, SFBT assesses for solutions, exceptions to problems, and strengths within an individual and his or her social context. It further focuses on past successes, coping strategies, and resources and collaboratively co-constructs a solution with the client.

Language is a resource that is vital to all therapists’ practices and relationships with their clients. The importance of language in SFBT is crucial. Gail Miller and Steve de Shazer in 1998 wrote about how meanings of words are inseparable from the ways in which people use them within concrete social contexts. Problem-focused language emphasizes what is wrong with people’s lives, and frequently portrays the sources of our problems as powerful forces that are largely beyond our control or understanding. In contrast, solution-focused language focuses on finding ways of managing one’s problems. Solution-focused therapists ask, “Since we talk ourselves into problems and solutions anyway, why not emphasize solutions.” This is not to deny the deprivations and injustices in clients’ lives, but to help get through and beyond them. This model uses post-modern assumptions that problems and solutions are talked into being, and meaning is changeable based on our use of language.

V. FOLLOW-UP STUDIES

Having been inductively developed in clinical settings by de Shazer in 1985, Berg in 1994, Berg and Reuss in 1997, and Berg and Kelly, in 2000, rigorous research that shows its effectiveness is only beginning to emerge. There is a great deal of informal studies scattered throughout in a variety of settings. However, a rigorous study design using random selection of population, controlled, and experimental groups, and pre-post measures is just beginning to emerge. We recognize that such data are necessary. What has emerged so far seems to show promise in its effectiveness and cost in terms of human suffering and dollars.

In 2000, Gingerich and Eisengart performed a review of SFBT outcome research. This article critically reviewed a total of 15 studies. Additionally, it reviewed early follow-up studies documenting SFBT outcomes.

Early follow-up studies used follow-up surveys by asking clients at 6 to 18 months whether they had met

their goal. In the first study, de Shazer in 1985 reported an 82% success rate on follow-up of 28 clients. The next year, de Shazer et al. reported a 72% success rate with a 25% sample of 1600 cases. Subsequent studies by De Jong and Hopwood in 1996 and Kiser in 1988 have reported similar results. Other follow-up studies of SFBT have similar, but somewhat smaller success rates and have used subjective outcome measures, such as those by Lee in 1997, Macdonald in 1997, Morrison, Olivos, Dominguez, and colleagues in 1993, and Schorr in 1997. Although these follow-up studies provide feedback on SFBT outcomes, their lack of experimental control does not permit causal inferences to be made about the effectiveness of SFBT.

Gingerich and Eisengart reviewed 15 controlled studies that implemented SFBT, employed some form of experimental control, assessed client behavior or functioning, and assessed end-of-treatment outcomes. These studies were further divided into well-controlled, moderately controlled, and poorly controlled studies based on the number of standards met for assessing empirical support for psychological treatments developed by the American Psychological Association.

The well-controlled studies included studies on depression in college students, parenting skills, rehabilitation of orthopedic patients, recidivism in a prison population, and antisocial adolescent offenders (the studies were those of Cockburn, Thomak, and Cockburn in 1997; Lindfors and Magnusson in 1997; Seagram in 1997; Zimmerman, Jacobsen, MacIntyre, and Watson in 1996; and Sundstrom in 1993). Four found SFBT to be significantly better than no treatment or standard institutional services. Because these studies did not compare SFBT with another psychotherapeutic intervention, they were not able to conclude that the observed outcomes were due specifically to the SFBT intervention as opposed to general attention effects. One study by Sundstrom in 1993 compared SFBT with a known treatment (IPT) and found SFBT produced equivalent outcomes (no significant differences were found). None of the five studies met all of the stringent criteria for efficacy studies and thus one cannot conclude that SFBT has been shown to be efficacious. They do, however, provide initial support for the efficacy of SFBT. The remaining 10 studies contain methodological limitations that preclude drawing firm conclusion, but their findings are consistent with the general conclusion of SFBT effectiveness.

Gingerich and colleagues identify several future areas of need in subjecting SFBT to empirical test. First is the specification and proceduralization of SFBT itself with the consistent use of detailed treatment manuals

and treatment adherence measures. In addition, future efficacy studies will need to compare SFBT with other empirically validated interventions where therapist allegiance is equally balanced between treatments. Other considerations include specification of study sample, selection of the comparison group, adequate sample size, and using conventional diagnostic groupings.

Although the current studies fall short of what is needed to establish the efficacy of SFBT, they provide early support that SFBT is useful to clients, according to Gingerich et al. The wide variety of settings and populations studied suggests a broad range of applications, but this conclusion awaits more careful study.

GLOSSARY

- behavioral therapy** Psychotherapy directed at changing observable and measurable behavior through a variety of techniques including monitoring, incremental change, shaping, and operant conditioning.
- body dysmorphic disorder** A preoccupation with an imagined defect in appearance.
- cognitive therapy** Psychotherapy directed at identifying and changing dysfunctional thoughts, perceptions, attitudes, and beliefs.
- conversion disorder** A symptom that mimics a neurologic problem (i.e., blindness, paralysis) that is not due to any neurologic problem, other medical condition, or substance but rather is thought to be due to psychological distress from a social stressor or psychological conflict.
- factitious disorder** Physical or psychological symptoms that are intentionally produced to assume the sick role.
- hypnosis** A mental state characterized by relaxation, concentration, and suggestibility in which perception and memory may be altered.
- hypochondriasis** A long-standing worry or fear of having serious illness in which one misinterprets physiologic sensations and minor symptoms.
- iatrogenic** Caused by a physician or his or her treatment.
- narcotherapy** An interviewing and psychotherapeutic technique involving sedative drugs, usually sodium amytal to induce relaxation.
- pain disorder** Pain complaints not completely attributed to a general medical condition. Purely psychological and combined medical and psychological types are described in DSM-IV-TR.
- personality disorder** A pervasive maladaptive pattern of relating to the environment and others that impairs function. Usually personality disorders arise in adolescence or the early adult years.
- primary gain** The decrease in anxiety or other unpleasant feeling attributed to the unconscious suppression of internal drives or conflicts.
- psychoanalytic psychotherapy** Psychotherapy derived from the theories of Freud that emphasizes the use of free associations, dream interpretation, and analysis of transference to bring to awareness repressed emotions and unconscious conflicts. Psychoanalytic psychotherapy focuses these techniques on the current conflicts and problems in the person's life rather than the very early life experiences and conflicts central to classical psychoanalysis.
- psychodynamic psychotherapy** Psychotherapy that incorporates a role for unconscious conflicts and motivations in human behavior but also recognizes the influence of life experience, current situational stressors, and biological predisposition in determining behavior. Techniques and issues emphasized are more varied than in either classical psychoanalysis or psychoanalytic psychotherapy.
- secondary gain** The support obtained from other people or systems due to a symptom or illness or the avoidance of an unpleasant, aversive situation due to a symptom or illness.

selective serotonin reuptake inhibitor (SSRI) Antidepressants that prevent the neuron from recycling serotonin released into the synaptic cleft, thereby increasing the amount of serotonin present at the synapse.

serotonin A neurotransmitter implicated in many mental disorders, especially major depression and obsessive-compulsive disorder.

social learning theory The theory that individual behavior is determined in large part by behaviors one has observed in others.

somatization The general process of presenting physical symptoms and concerns that are not explained by a general medical illness presumably as a manifestation of psychological distress or conflict or social stress.

somatization disorder A long-standing disorder involving multiple physical complaints and many organ systems usually developed at an early age and stable over time.

somatoform disorders The *Diagnostic Statistical Manual of Mental Disorders* category describing disorders that involve physical symptoms not attributable solely to general medical conditions or substances.

supportive therapy Psychotherapy directed at reinforcing a patient's defenses as a way of improving the ability to cope with psychological distress.

I. DESCRIPTION OF TREATMENT

Treatment of individuals with somatoform disorders represents a unique challenge for the psychotherapist in that the core deficit in these individuals is the inability to recognize the role of psychological and social conflicts and stressors in the development of their physical symptoms. These individuals are unlikely to present to psychotherapists for treatment initially and are often resistant to referral for psychiatric or psychological consultation. For many patients with somatoform disorder, the most important therapeutic relationship remains the primary care physician. The mental health consultant may assist this physician in maintaining a therapeutic stance with these often taxing and frustrating patients. For instance, the psychiatrist in this consultant role may assist the physician and patient by confirming the diagnoses and advising the referring physician about the general principles of management of somatoform disorders:

1. Maintain regular, consistent contact with a single physician.
2. Minimize invasive diagnostic procedures and aggressive treatments without objective evidence of physical disease.

3. Gradually, and in a nonconfrontative manner, work toward helping the patient recognize the connection between stressors in their lives and their physical symptoms.

The process of somatization is not limited to individuals with somatoform disorders. Other disorders, especially depression and anxiety disorders, frequently present with prominent somatic symptoms. In addition, individuals with somatoform disorders often suffer from other mental disorders such as depression, anxiety, and personality disorders. Treatment of these co-existing disorders may improve the individual's function even when the somatoform disorder persists.

The somatoform disorders, as described in *DSM-IV-TR* are a heterogeneous group of disorders that currently are lumped together due to the common characteristic of a physical complaint or complaints that are not completely explained by a general medical condition or a substance. Included in this category are somatization disorder, undifferentiated somatoform disorder (an abridged form of somatoform disorder), conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder, and somatoform disorder not otherwise specified (a residual category for presentations that do not fulfill criteria for the other somatoform disorders). Somatoform disorders vary greatly in the number and type of symptoms presented and systems affected, the duration of symptoms, the age of onset, the gender distribution, and the prognosis. In contrast to factitious disorder, the physical symptoms are not believed to be intentionally produced. Treatment approaches, for somatoform disorders, although unified by the general management principles already described also vary. Despite the fact that many of these disorders, especially somatization disorder (also known as hysteria, or Briquet's syndrome), conversion disorder (also named conversion reaction or hysterical conversion), and hypochondriasis have received much attention in the history of psychotherapeutic theories and treatments, there remains a dearth of well-controlled psychotherapeutic trials specific to each disorder. A general summary of treatment approaches for the principle types of somatoform disorder follows. Details of these treatments are discussed under the Empirical Studies section.

A. Somatization Disorder

Somatization disorder is characterized by the onset at an early age, usually late teens to early 20s but by

definition by age 30 of multiple physical complaints. Females are afflicted over males by a ratio of 10 or 20:1. The disorder by definition has been present greater than 6 months. This disorder has in the past been known as Briquet's syndrome or hysteria. The complexity of the criteria has diminished over the years but still requires the presence of multiple symptoms involving several organ systems. The typical patient has had many surgeries at an early age, preceded by multiple workups for a variety of physical complaints. These individuals seldom seek psychiatric or psychological treatment because from their point of view, their problems are physical not mental in nature. In addition, to multiple surgeries and procedures, these patients may also suffer from iatrogenic side effects from a multitude of medications. Direction to the family physician to schedule regular, not as needed appointments, which include focused physical exams, to minimize testing and treatments and to gradually shift the focus of attention from physical complaints to stressors in the patient's life may help decrease health care utilization and avoid complications of procedures and treatments. Group therapy aimed at coping with the stress of a chronic medical condition has also been recommended. In a group setting, these individuals are said to be capable of recognizing and confronting this pattern of somatizing to an extent not possible in individual therapy. In addition, they may benefit from the support of others with similar conditions.

B. Conversion Disorder

Conversion disorder is characterized usually by only one symptom at a time, and this symptom, by definition, mimics neurologic disease. Historically, the type of symptoms has extended beyond those that mimic neurologic disease but neurologic-like symptoms (seizures, paralysis, numbness, deafness, or blindness) have always also been the most prominent. Commonly, the patient has both underlying diseases as well as conversion symptoms. Conversion disorder also is more common in women than in men and is found in both chronic (greater than 6 months) and acute (less than 6 months) forms. Due to the relatively high rate at which individuals either are later diagnosed with neurologic disease or have concurrent neurologic disease, the recommendation to minimize workups to exclude organic causes, generally made for somatoform disorders, is not applicable to conversion disorder. However once this workup is completed, the same principles of supportive, benign management prevails. Most authors advo-

cate a nonconfrontative yet authoritative explanation that recovery is expected over a relatively brief period of time. An explanation that medical tests do not show signs of any serious progressive disease should be provided without confrontation or argument and without suggesting that the problems are "all in your head." These straightforward prescriptions for recovery allow most individuals to return to normal function. In cases in which suggestions and reassurance alone do not result in recovery, physical rehabilitation and other behavioral techniques such as relaxation and rest may be added. If the stressors presumed to be responsible for the conversion symptom in the first place cannot be ascertained from a standard history, then interviewing techniques such as narcotherapy or hypnosis may be used. The primary purpose of identifying the stressors is to be able to modify them through therapy. Narcotherapy and hypnosis may also be used to enhance the suggestion and expectation of recovery from the conversion symptom. Longer-term psychodynamic therapy is advocated by some for those individuals with chronic or recurrent conversion symptoms. Given that the stressor may well include marital or family issues therapy aimed at these areas may also be necessary.

C. Hypochondriasis

The essential feature of hypochondriasis is fear or worry that a symptom (often a minor physiologic sensation) represents a serious illness. This disorder is equally common in men and women. By definition, this preoccupation with disease must be present for longer than 6 months. The same general principles of conservative management with the primary care physician as principle clinician apply. Treatment of concurrent anxiety and depression is important. Cognitive therapies aimed at diminishing the focus and attention of these patients on physical sensations and reinterpreting these sensations as non-disease events has been used individually and in a group therapy format. Framing these therapies as techniques for dealing with physical distress, rather than a more direct psychological approach, may have positive results.

D. Body Dysmorphic Disorder

The essential feature of this disorder is a belief that a physical attribute is deformed or defective. These patients also do not seek mental health treatment but rather see dermatologists, plastic surgeons, and orthodontists. Psychotherapy using cognitive-behavioral

techniques has seen the greatest use in recent years. Pharmacotherapy, particularly antidepressants which inhibit reuptake of serotonin into neurons, has also been shown to be effective.

E. Pain Disorder

Pain, even when the underlying cause is established, has long been known to be influenced by the psychological and social context in which it is experienced. Likewise, psychological techniques, as well as somatic treatments have long been known to modify the experience of pain. The overlap between pain disorder described as a somatoform disorder (those for which psychological factors are thought to play a major role in pain either alone or combined with a general medical condition) and pain due solely to a general medical condition is great. Pain disorder will not be dealt with extensively in this article, but the management principles of carefully coordinating care with one physician, minimizing potentially dangerous evaluations and treatments (especially addictive drugs and radical surgeries), focusing on improving function despite pain rather than curing all pain, and gradually helping the patient recognize the role of stressors in symptom exacerbation share much in common with management of the other somatoform disorders. Although pain management must be carefully coordinated by a primary physician, the multiple techniques employed often require a multidisciplinary team. Behavior therapy is the psychotherapy employed at least initially in most pain programs.

II. THEORETICAL BASES

As mentioned earlier, the disorders currently considered somatoform are quite varied. Historically, they have been united by an assumption that they represented the physical expression of an unrecognized underlying psychic conflict or a reaction to a social stressor. For somatoform disorders, the production of physical complaints is not believed to be under voluntary control as would be the case for a factitious disorder. More recent theories about the development of somatoform disorders have shifted to the role that social learning, amplification of bodily sensations, and even genetics may play. For somatization disorder, there appears to be a link between childhood trauma, especially physical abuse, illness as a child, growing up with an ill family member, and an increased likelihood of developing this disorder. Family studies of somatiza-

tion disorder in females link it with sociopathy and alcoholism in male relatives. The great importance of establishing a therapeutic alliance, usually with a family doctor, which does not depend on ongoing physical complaints or illness behavior to be maintained ties together many of these etiologic theories. It is postulated that for many of these individuals, being ill themselves was the only way to either receive nurture and care or to avoid or counter mistreatment or abuse. Unfortunately, the frustration that these patients can engender in physicians and the invasive tests and procedures that they demand may easily lead to further abandonment or punishment-like experiences. Some neuropsychological studies indicate individuals with somatization disorder may have deficits in attention and memory as well as frontal lobe dysfunction and greater nondominant hemisphere dysfunction.

Conversion disorder contains in its definition an implication of the etiologic role of stress or conflict in the development of symptoms. These symptoms have been conjectured to have symbolic meaning, that is, being unable to hear due to a torrent of past verbal abuse or being unable to move one's arms after killing another in war or in an accident. However, studies have been unable to uphold this conjecture. Similarly, the belief that patients with conversion present with a "la belle indifférence," showing little reaction or emotion to great impairment has not shown to be more characteristic of conversion symptoms versus impairment, due to an organic cause. The presence of secondary gain, whereby, the patient either derives some positive attention or care for the impairment or avoids some aversive responsibility or consequence, also was once believed to discriminate conversion symptoms from other medical conditions, but this does not appear to be true. Psychosocial factors that increase the likelihood of conversion symptoms include sexual abuse, exposure to medically ill relatives, lower social economic status, less education and a rural background, and having a neurological illness oneself. Theoretical outlook has shifted from one emphasizing unconscious conflicts, that is, aggression, sexuality, dependency, which are symbolically expressed to decrease anxiety and are complicated by a resistant indifference and secondary gain, to one that retains the idea that conflicts and stressors play a critical role in development of conversion symptoms but view these as more transparent to both the therapist and the patient. Treatment has shifted emphasis from longer uncovering insight-oriented psychodynamic psychotherapy to brief supportive therapy, which emphasizes suggestion, reassurance, and the prediction of recovery. This is sometimes coupled

with behavioral and physical therapy approaches to address any issues of secondary gain, deconditioning, and other physical sequela and allow a face-saving mechanism for the patient to use in recovery. Psychodynamic therapy is still recommended by some for more chronic or relapsing cases of conversion symptoms.

Theories regarding the development of hypochondriasis include not only how it arises, but also whether it is a discreet disorder or simply a manifestation of other psychiatric illnesses such as anxiety or depression. With respect to anxiety disorders, analogies have been drawn between hypochondriasis and panic disorder, (both are sometimes involved in misinterpretation of normal physiologic sensations), hypochondriasis, and obsessive-compulsive disorder, (both incorporate the need to constantly check and be reassured that something bad hasn't happened with only temporary abatement of anxiety once reassured), and hypochondriasis and generalized anxiety disorder, (both are characterized by overreacting to and dwelling on common worries, often accompanied by physiologic symptoms of muscle tension, aches and pains, and hypervigilance). Somatic presentations of depression also show considerable overlap with hypochondriasis. Comorbidity is common, and treatment for concurrent conditions, for example with SSRI antidepressants may improve patients' overall function and in some cases ameliorate the hypochondriacal symptoms themselves. Psychodynamic theories have included a variety of beliefs including Freud's theories of object libido and later disturbed object relations, in which anger toward others is displaced as hostility toward the body. Other dynamic theories have described guilt, dependency needs, the need to suffer, as well as anger and hostility toward others as important in hypochondriasis. More recent psychological theories have focused on mechanisms of social learning and cognitive and perceptual distortions such as amplification, either alone or in combination. Hypochondriacal patients seem to misattribute normal physiologic sensations as evidence of underlying disease and believe to be free of serious illness one should be relatively free of any symptoms or distress. They are not, as they believe, more sensitive or accurate in detecting bodily sensations or symptoms, but rather they make errors of misattribution and overreporting. Because these patients then inaccurately identify themselves as ill, they then view themselves as entitled to assuming the sick role.

A direct or indirect experience with the sick role is thought by some to be an etiologic factor in development of hypochondriasis, however, data does not exist to confirm this theory. Cognitive-behavioral therapies

have been developed to address the misperceptions and misattribution which hypochondriacal patients make. These therapies may be more successful and better accepted in the setting of a general medical clinic. As with somatization disorder, the initial focus of therapy may be on coping with physical distress rather than a more overtly psychological approach. The general management principles used for somatization disorder (for instance regular appointments with a single physician and minimizing testing procedures and treatments) are essential for hypochondriasis.

Body dysmorphic disorder has shared with hypochondriasis the debate whether it is a discreet disorder or arises from a spectrum of mood or anxiety disorders, especially obsessive-compulsive disorder. Recent successful treatment approaches with SSRI antidepressants and cognitive-behavioral therapies reinforce the belief that body dysmorphic disorder may be etiologically related to depression and/or obsessive-compulsive disorder. As with the other somatoform disorder, psychodynamic theories regarding the dysmorphic symptoms representing a displacement of a conflict on a body part had been made. Some have also commented on the role that societal preoccupation with appearance may play in the development of body dysmorphic disorder.

As noted earlier, the experience of pain has long been recognized to have a number of psychological, physical, and social determinates. Description of the specific theories of pain is beyond the scope of this article.

III. EMPIRICAL STUDIES

Because the somatoform disorders are quite different one from another, empirical studies typically focus on one specific syndrome, and the results from studies of one disorder should not be generalized across the entire category. With respect to general management principles of somatoform disorders, the most study has been done on somatization disorder. G. Richard Smith and coworkers in 1986 described the positive effects on decreasing health care utilization, without worsening health outcomes or changing patients' satisfaction with care, using psychiatric consultation followed by a letter to the referring primary care physician. The letter describes somatization disorder and recommends management with regularly scheduled appointments, physical exam at each visit, avoiding tests and procedures unless clearly indicated, and discourages physicians from telling patients "It's all in your head." This group published in 1995 a similar study on somatizing

patients who did not meet full criteria for somatization disorder, showing similar positive results following a psychiatric consultation letter. The active ingredient here may be education of and support to the primary care physician. The importance of the therapeutic alliance between the primary care physician and the somatizing patient may need to be attended to in a way not formally done in most primary care settings. The primary care physician is coached to offer an analog of the "holding environment" more common psychotherapy settings. That is, to find a safe, predictable forum for the patient to present their distress albeit in the form of physical symptoms without fear of being rejected or abandoned by or overwhelming the physician, and without the sometimes unrecognized danger of being subjected to unnecessary tests and treatments.

When patients will accept overt psychological treatment, either individually or in a group setting, cognitive-behavioral therapies have been shown to improve the function of patients with somatization disorder as well as the other somatizing patients. As noted earlier, these patients may accept referral for these treatments when they are framed as "stress management." Disorders that have been shown to respond to cognitive-behavioral therapies include somatization disorder, hypochondriasis, body dysmorphic disorder, pain disorders, as well as a number of other illnesses in which somatic complaints figure prominently, including chronic fatigue, irritable bowel, chronic headaches, and non-cardiac chest pain.

Some studies of somatoform disorders, especially hypochondriasis, have attempted to answer whether or not these patients experience physiologic sensation differently or whether the error of somatization occurs secondarily in the area of interpretation, attribution, and reporting. Attempts are beginning to be made to discover whether these differences are learned or genetically determined. Explanatory therapy, an approach that emphasizes educating patients with accurate information about somatic sensations, including instruction regarding the amplification due to selective attention, providing reassurance and clarification and using repetition of this information was advocated by R. Kellner in the 1980s and was reintroduced in 2000 by G. A. Fava and colleagues for the treatment of hypochondriasis. They believe it is a simpler approach than cognitive-behavioral therapy and found it effective in a study of 20 patients.

Conversion disorders, sporadic and usually time-limited impairments, by nature have led to a relative lack of randomized control trials of therapeutic approaches. Anecdotal reports and clinical experience have led most to advocate suggestion and the expecta-

tion of recovery along with behavioral and physical therapy approach.

Supportive therapy to help patients identify and modify the psychological stressor postulated to be responsible for the conversion symptom may also be helpful. Sodium amytal interviews and hypnosis are also employed. However, well-controlled trials regarding these techniques for conversion disorder cannot be found. Further complicating studies is the broad range of conversion symptoms and the varying degree of functional impairment, for instance, hemi-paresis versus pseudo-seizures. Taking into account the methodological weaknesses, there appears to be the most empiric support for suggestive and behavioral approaches. Amytal and hypnosis, although enjoying a long tradition of use for assessment and treatment of conversion disorder, suffer from the lack of control trials regarding efficacy. Some advocate there is enough suggestion of positive result utility that further studies are warranted. K. A. Phillips summarizing psychotherapeutic approaches for body dysmorphic disorder relates that cognitive-behavioral therapy including cognitive restructuring, exposure, and response prevention have been shown effective in body dysmorphic disorder. However, these studies have small numbers of participants, and as with other somatoform disorders more studies are needed.

In contrast to the few studies on body dysmorphic disorder, pain management has a relatively large literature. Pain disorders respond to cognitive-behavioral techniques, which include both cognitive restructuring and operant conditioning. Further review of the empiric studies of pain disorders is beyond the scope of this article.

IV. SUMMARY

The treatment of somatoform disorder involves both commonalities and differences. Those disorders that involve a chronic view of oneself as physically ill, somatization disorder and hypochondriasis, frequently present only to the primary care physician and the management principles of regularly scheduled rather than symptom dependent visits have already been summarized. Also critical is the avoidance of unnecessary diagnostic and therapeutic procedures and interventions. Those somatoform disorders in which a specific distortion of thinking can be identified, hypochondriasis and body dysmorphic disorder, are amenable to cognitive techniques aimed at this belief as well as behavioral therapy to change inappropriate behavioral responses such as reassurance seeking. Conversion disorder usually responds to suggestion, reassurance, and expectancy. Behavioral

and physical therapy may enhance these general techniques. Pain disorder is best treated psychotherapeutically with cognitive-behavioral techniques. Although the somatoform disorders, especially somatization disorder, hypochondriasis, and conversion disorder provided some of the formative clinical material for psychiatry, especially psychodynamic psychotherapy, in practice psychodynamic therapy rarely finds itself at the forefront of treatment of somatoform disorders. In some cases of conversion disorder, particularly those for which the psychosocial stressor or conflict is not immediately apparent or which have a relapsing course, psychodynamic therapy continues to be utilized. In addition, skills in marital and family therapy are sometimes necessary particularly when somatoform disorders have resulted in patterns of secondary gain that involve couples or family systems.

GLOSSARY

anorexia athletica Unofficial diagnostic term used to describe a syndrome found among athletes that closely resembles anorexia nervosa (AN), with the exception that an athlete's muscle mass maintains him or her above 85% of the minimum body weight.

creatine Performance-enhancing drug that increases energy transfer for muscle contraction.

deselection Forced suspension of play or retirement due to lack of physical competitiveness.

human growth hormone Performance-enhancing drug that stimulates skeletal and soft tissue growth.

neuropsychological assessment Systematic evaluation of learning and memory abilities commonly performed after an athlete sustains a head injury.

sports psychology Subspecialty of psychology that develops and applies psychological strategies to enhance and optimize athletic performance.

Yerkes-Dodson inverted U hypothesis Theory stating that optimal performance occurs at moderate levels of anxiety, while low and high levels of anxiety disrupt performance.

Sports psychotherapy is a subspecialty of psychotherapy that addresses the unique challenges and needs presented by athletes when they seek mental health services. Although sports psychotherapy has its roots in the sports psychology movement that has sought to enhance athletic performance, it extends beyond this practical goal. This article will present seven broad categories that illustrate the unique considerations of sports psychotherapy, including common psychological problems among athletes (drug use, eating disorders, and adverse reactions to injury) as well as the special developmental, social, and family factors that affect the athlete's mental health.

I. PERFORMANCE ENHANCEMENT AND THE ROLE OF THE SPORTS PSYCHOLOGIST

Performance enhancement refers to psychological interventions designed to increase an athlete's effectiveness and chances for success in competition. In a rapidly growing subspecialty, these interventions are designed and implemented by sports psychologists who provide consultation to college and professional athletic teams. In February 2001, a special issue of the American Psychological Association's journal *Professional Psychology: Research and Practice* discussed the roles and challenges of sports psychologists. For

example, Frank Gardner noted that, particularly in professional sports, modern-day athletes are regarded as extremely valuable (even a kind of financial investment) and hence worthy of psychological support and protection that might optimize their performance. In the same special issue, Mark Andersen, Judy Van-Raalte, and Britton Brewer observed that sports psychologists often resemble coaches more than they do clinicians and have a correspondingly looser set of boundaries between themselves and their clients. For example, sports psychologists may accompany an athlete to a practice, a training meal, or a game.

Despite the fact that sports psychologists may not be regarded as mainstream clinicians, many of the techniques and interventions they employ are borrowed from psychotherapy treatments. In addition, the immediate goal of a performance enhancement intervention is often to reduce some negative feeling or cognitive state, although the more practical concern is competitive success. For example, performance enhancement interventions are often aimed at changing levels of competitive state anxiety, or the level of tension that an athlete feels at game time. Therapists may be guided by the "Yerkes-Dodson inverted U hypothesis," which states that optimal performance follows moderate levels of anxiety (while low and high levels of anxiety disrupt performance). To achieve this moderate level of anxiety, psychotherapists may use progressive muscle relaxation (PMR), deep diaphragmatic breathing (DDB), guided imagery, or hypnosis. PMR involves periodic tensing and relaxing of all muscle groups, typically beginning with the feet and working up toward the head. DDB involves breathing from the lower diaphragm rather than from the upper chest. Guided imagery involves the use of suggestions to create relaxing images (e.g., lying on the beach), while hypnosis also involves guidance and suggestion but in the context of a qualitatively different state of consciousness. Some therapists prefer PMR, DDB, and guided imagery because they are ultimately self-applied and the athlete can leave treatment with a tool to be used in better controlling his or her anxiety before and during competition.

In 1990, Richard Suinn presented a behavior therapy package called anxiety management training (AMT) designed to enhance athletic performance. In 6 to 8 sessions, athletes are taught self-control methods to manage their anxiety levels, including specific relaxation techniques and strategies to revise cognitive self-statements. AMT emphasizes between-session homework assignments that allow athletes to try the skills they have learned in real competitive contexts.

Sports performance may be indirectly enhanced via the psychotherapeutic exploration of an athlete's social support network. Social support has an established research base as a buffer against injury, stress, and the pressures of competition. Interpersonally oriented psychotherapy is one therapeutic modality that might be used by a sports psychologist to target relationship conflicts that can lead to social isolation. Through experiential role-plays and between-session practice exercise athletes can identify and change the problematic ways in which they interact with others. For example, role-plays may help an athlete get along better with teammates on and off the court, thereby improving the team's chances for success.

II. FAMILY THERAPY AND THE ATHLETE

Family therapy refers to the treatment of both individual and interpersonal problems within the context of a family system. In 1995 and 2000 expositions, Jon Hellstedt has described the "athletic family" as a family system that includes parents and their children who are involved in competitive sports. Although the athletic family is not necessarily destined to be problematic or dysfunctional in a clinical sense, it can be imbalanced if there is an overly intense and narrow focus on one member's sports activity. Family members, parents in particular, often project their own unfulfilled athletic (or financial and social) dreams onto their children, thereby becoming overinvolved and unduly pressuring.

Hellstedt has identified four common targets of psychotherapy with the athletic family: the level of cohesion, the nature of emotional boundaries, triangulation patterns, and developmental impasses in the family life cycle. Family cohesion, while it can provide a source of support and stability, may serve to hide tension and conflict. For example, the tightness of a family system may lead to undermining of a child's autonomy and decision-making; psychotherapy might explore this pattern, along with any unexpressed anger and resentment that accompany it. Boundaries refer to the space that separates the emotional and cognitive systems of different family members. These boundaries have been described as ranging from "enmeshed" (too little space between members) or "disengaged" (too much space between members). Psychotherapeutic intervention is typically directed at the two extremes, particularly the enmeshed boundaries often found among athletic families. Triangulation refers to avoidance of conflict between two people (e.g., parents) by focusing on a third

person (e.g., athletic child). For example, parents may become overinvolved in their child's athletic activity as a way of avoiding their own marital discord. Hellstedt notes that a typical presentation in this regard includes a father who becomes overinvolved with his athletic son to the exclusion of his wife. Developmental impasses in the family life cycle refer to tasks and obstacles that arise as a family negotiates transitions. For example, most children leave home for the first time around age 17 or 18. However, young gymnasts often leave their families for extended periods of time for training, resulting in separation stress occurring sooner than is typical in the family life cycle.

Hellstedt summarizes the broad psychotherapy change goals in working with athletic families: identifying sources of stress, promoting healthy independence from the family, improving communication and problem-solving, negotiating developmental transitions, and developing the supportive capacity of the family while minimizing its role as a source of stress to the athlete.

Besides its relevance to specific athletic families, family therapy has been used as a model for understanding and intervening with sports systems and teams. Athletic teams, like family systems, often pursue goals of conflict resolution and facilitation of healthy cohesion. For example, in 1993 Toni Zimmerman and Howard Protinsky offered the following recommendations when using family therapy techniques in consultation to sports teams: meeting with both players and coaching staff, requiring attendance at consultation sessions, and utilizing family therapy models to monitor problematic patterns. Just as in families, athletic teams can experience damaging coalitions (e.g., coach singling out an athlete as his favorite) and significant communication problems.

III. LIFE SPAN DEVELOPMENT OF THE ATHLETE

Life span development refers to an age-appropriate context in which to better understand psychological issues and problems among athletes. For example, youth participation in sports can result in unique, and potentially negative, consequences. In a 1993 review, Robert Brustad explored how a child's psychological readiness for competition may impact on his or her emotional reactions to athletic activity. Psychotherapy with children who engage in sports competition too young (or perhaps too intensely) may involve discussion of the frustration, low self-esteem, and inappropriate achievement goals that have resulted from this involvement. When parents

place undue pressure on children to perform the whole family can become involved in the problem, thereby necessitating a family therapy intervention to establish more realistic and healthy patterns of encouragement.

Undergraduates involved in intercollegiate sports are another group that have unique psychotherapeutic needs. Treatment must acknowledge their dual roles as both students and athletes. Stress management interventions are common among this group of athletes as they struggle to establish and balance multiple priorities. Particularly in Division I schools that serve as a training ground for professional sports, athletes may be exceedingly goal-oriented. This characteristic can be both an asset (e.g., compliance with psychotherapy homework assignments) and an obstacle (e.g., rigidity in the face of revising unrealistic or unhealthy goals) to treatment. Due to the college environment and related subcultural norms, student athletes often present with substance abuse problems, eating disorders, and adverse emotional reactions to sports injury (see later).

A third set of developmentally influenced issues arises in treatment with elite amateur and professional athletes who are retiring. In a 1993 review, Bruce Ogilvie and Jim Taylor discussed three factors that can precipitate career termination: (1) chronological age, (2) deselection (no longer physically competitive), and (3) injury. Although all three of these precipitants necessitate a process of acceptance in psychotherapy, they each bring additional unique considerations. For example, deselection often leads to marked erosion of self-esteem. Young, highly successful professional athletes who suffer career-ending injuries may need to clarify and revise their self-identity in long-term psychotherapy. Ogilvie and Taylor recommend proactive, preventive interventions for athletes who know they are facing retirement. These interventions might help athletes clarify values and goals beyond athletics, or perhaps encourage expression of feelings of frustration, doubt, and loss.

IV. DRUG USE AMONG ATHLETES

Drugs used by athletes include alcohol, recreational illicit drugs, and performance-enhancing drugs. Although there are no reliable data on the prevalence of substance abuse among athletes, alcohol, marijuana, and cocaine remain the most common recreational drugs of choice. Anabolic-androgenic steroids (AAS) are the most commonly used class of performance-enhancing drugs. AAS maximize gains in muscular strength and size, thereby conferring some competitive advantage to the athlete.

More recently athletes have begun to use human growth hormone and creatine to optimize performance.

An understanding of the reasons for drug use among athletes forms a starting point for many psychotherapeutic approaches to the problem. The question of why athletes abuse drugs has perplexed some members of the sports community who find it puzzling that individuals so committed to physical fitness would knowingly undermine this very commitment. In the case of performance-enhancing drugs, the motivations for use are relatively clear (e.g., the use of anabolic steroids for muscular power, the use of stimulants for cognitive focus and endurance), although these drugs can have unintended and negative psychological side effects. The reasons for athletes' use of other addictive recreational drugs are less clear. In 1991, Jim Taylor hypothesized that athletes at the professional and collegiate levels use recreational drugs because they have not developed effective interpersonal skills to cope with the pressures exerted by the media and fans. The peer pressure that originates in sports team subcultures can be especially potent, leading some athletes to use drugs to ensure acceptance. Finally, especially talented athletes may be less adversely affected by drug use, somehow still able to perform better than average when using, and thus more likely to deny that a problem exists.

Each of these potential reasons for drug use may lead to different psychotherapeutic interventions. For example, social skills training and anxiety management can be emphasized with athletes who are using recreational drugs as a coping strategy. Although the teaching of alternative coping strategies may help athletes who are using recreational drugs, long-term group-based rehabilitation may be necessary if serious addiction has resulted (see later). Psychoeducation may help athletes understand the short- and long-term risks of using performance-enhancing drugs (e.g., cardiovascular complications, liver damage, acne, mood swings, aggressive and antisocial behavior) and this alone may be sufficient in treating the problem, particularly where no addictive process has taken hold.

Confidentiality is a significant concern when athletes seek, or are required to receive, treatment for drug abuse. The potential stigmatizing effects of being labeled a drug abuser can be long lasting. Additionally, athletes may be very concerned about how initiation of treatment will limit their play, fearing that a sudden suspension will destroy the confidentiality of their treatment since teammates may not otherwise know a problem exists.

Long-term psychotherapy treatment programs for drug-abusing athletes, like those for members of the

general population, usually include rehabilitation groups. For example, Alcoholics Anonymous and related 12-step programs may be especially effective if groups are composed of athletes with similar backgrounds. Often, athletes begin this kind of treatment at a residential inpatient (or at least day-treatment) facility where they can be fully immersed in the notion of sobriety and an alternative lifestyle. In the early 1980s, Gregory Collins was involved in one of the first organized programs for treating and preventing drug use among professional athletes. In a 2000 book chapter, Collins describes a self-help model used with the Cleveland Browns football team that included regular meetings of drug-involved players in a group called the "Inner Circle." This group placed a special emphasis on relapse prevention. Because the "Inner Circle" is composed of athletes at different stages of sobriety, members can discuss common pressures and triggers to use substances, provide and share effective support and coping mechanisms, and monitor each other's treatment progress.

Besides treatment of drug abuse, both college and professional sports teams have emphasized prevention. Although mandatory drug testing is one way of detecting a problem for early intervention, athletic staff would rather take action before a problem begins. For example, many teams have adopted programs to disseminate accurate information about drugs and to teach effective coping skills. Some prevention programs include required video and workshop orientations for new players where they are educated not just about drugs and their effects, but also about the availability of support and treatment services.

V. EATING DISORDERS AMONG ATHLETES

Sports that overvalue aesthetic appearance of the body (e.g., dance, gymnastics), low body fat (e.g., swimming, running), or maintenance of body weight (e.g., wrestling, horse-racing) may place athletes at a higher risk for developing eating disorders and related body image distortions. In 1994, Jorunn Sundgot-Borgen used the term "anorexia athletica" (diagnosed Eating Disorder, Not Otherwise Specified in *DSM-IV*) to describe a syndrome that closely resembles anorexia nervosa (AN), with the exception that these athletes do not meet AN diagnostic criteria because their muscle mass maintains them above 85% of the minimum body weight. As a clinical subpopulation, athletes are likely to respond to a distorted body image not just by restricting food intake

but also by overexercising, which can in turn lead to further illness and injury (see later).

In a 1998 review, David Garner, Lionel Rosen, and Declan Barry emphasize the importance of confidentiality in working with athletes suffering from eating disorders, noting that they may be especially sensitive to how coaches and teammates will regard their problems. They specifically discourage the treating clinician from talking to other teammates about the athletes' eating problems. To avoid related marginalization, these authors recommend that athletic activity be suspended only if the athlete poses a physical health risk to himself.

Psychoeducation can be especially useful in psychotherapy with athletes suffering from eating disorders, specifically in motivating healthy dietary behavior change. For example, detailed discussion of the negative effects of restricted calorie intake on physiology and performance (e.g., reduced strength, impaired coordination, slower recovery from competition) can mobilize athletes at least to consider alternative strategies to enhance performance.

Recommended psychotherapeutic treatments for athletes with eating disorders include cognitive-behavior therapy (CBT) or interpersonal therapy for bulimia and CBT for binge-eating disorder. CBT attempts to bring eating habits under control through a system of monitoring and dietary change. Interpersonal therapy focuses on how the athlete's disrupted relationships with others (perhaps teammates) result in the impetus to engage in binge and purge cycles.

VI. REHABILITATION FROM ATHLETIC INJURY

Athletic injuries may result from relatively acute, discrete trauma, or from overtraining/overuse. Although it is rather obvious that athletic injury necessitates physical rehabilitation, only recently have psychotherapists become involved in the recovery process. Psychotherapy may facilitate both physical and emotional recovery. As an adjunct to physical rehabilitation, clinicians may help athletes set realistic goals for recovery, which is particularly important for "overuse injuries" and for those athletes who are characteristically overachieving or overexerting. Psychotherapists may also work to increase motivation about and adherence to rehabilitation regimens. For those athletes who have negative thoughts and attitudes about the prospects for recovery, cognitive-behavioral therapists may help an athlete identify cogni-

tive distortions (e.g., an athlete who catastrophizes by assuming "this is the end of my career") and work to challenge and revise these thoughts. Psychotherapists may also indirectly affect commitment to rehabilitation and recovery rate by facilitating positive, healing imagery (e.g., "picture the tissue repairing itself"). In a 1991 study, Lydra Ieleva and Terry Orlick found that athletes using goal-setting, stress control, positive self-talk, and healing imagery recovered faster than those who did not receive these psychological interventions.

Emotional responses to athletic injury, particularly career-ending injury, often resemble reactions to loss. For example, athletes have been observed to move through Kubler-Ross's five grief stages: (1) denial and isolation, (2) anger, (3) bargaining, (4) depression, and (5) acceptance. A first step in psychotherapy is to normalize this grief process. Before acceptance can be forged, athletes may spend extended periods consumed by anger, depression, and even posttraumatic stress. These emotional problems may necessitate targeted psychotherapeutic interventions. For example, injured athletes may experience a precipitous drop in activities they enjoy or "pleasurable events," a common behavioral trigger for major depression. Therapy may identify alternative pleasurable activities and then use behavioral reinforcement contingencies to improve mood functioning. Alternatively, depression following injury may be understood within a cognitive context—sustaining an injury may provoke feelings of vulnerability and the belief that life is a series of uncontrollable events. Cognitive therapy would attempt to change these unnecessarily extreme and distorted beliefs.

Common defense mechanisms employed by athletes to avoid the unpleasant emotion associated with injury include reaction formation (displaying emotions that are the opposite of what is really felt) and intellectualization (discussing the injury in terms of thoughts and ideas without mention of emotion). Permissiveness to feel anger and sadness, and perhaps even induction of these emotions, is a primary objective of psychotherapy with athletes who are unable or unwilling to acknowledge their feelings.

The process of accepting a career-ending injury may require longer term psychotherapy to address erosion of self-esteem, particularly if an individual's valuation of himself or herself was primarily based on athletic success. This work may involve detailed discussion of what needs were fulfilled by athletic experiences and which alternative activities may now be substituted. Encouragement of seeking role models who have suffered career-ending injuries may help some athletes in

psychotherapy, or even a support group of similar others if available.

Sports injury can be strategically exaggerated or even feigned by an athlete looking for secondary gain. For example, an athlete may wish to avoid some negative event (e.g., having parents watch him play) or acquire some positive benefit (e.g., insurance claim) by being injured. This kind of psychological motivation for injury may be addressed in psychotherapy by skills training that would emphasize (1) identifying more active and direct ways of making or denying requests from others, and (2) satisfying needs in a more forthright fashion.

VII. NEUROPSYCHOLOGICAL ASSESSMENT AND CONCUSSION

Neuropsychological assessment and concussion refers to the evaluation of cognitive functioning (e.g., learning and memory abilities) following a sports-related head injury. A developing body of research has suggested that multiple head injuries can have long-term negative psychological and physical health effects, with some players particularly susceptible to repeated head injury. In 1996, the National Hockey League (NHL) began an experimental pilot program to formally assess players who experienced head injuries. This program was intended to prevent a hasty return to play and thereby minimize the risk and consequences of multiple head injuries. The NHL extended this assessment program league-wide in 1997 while the National Football League also began to institute similar protocols.

In 1999, Michael Collins, Mark Lovell, and Douglas McKeag observed that there is some confusion as to when athletes should be examined because there is no universally accepted definition of concussion (e.g., some

believe that loss of consciousness is central whereas others do not). Although evaluation of postconcussion effects may be conducted in a medical rather than psychotherapeutic context, sports clinicians are expected to be familiar with the testing and typical findings. For example, athletes with a history of concussion may experience slowness in processing speed (i.e., pace of response to verbal and visual stimuli) and decrements in executive functioning (i.e., ability to plan and execute decisions). When psychotherapists work with athletes who have suffered these kinds of effects from multiple head injuries, the content and pace of psychotherapy is usually adapted, as it is among other clients who present special cognitive considerations (e.g., young children, older adults).

GLOSSARY

communication skills training A behavioral procedure designed to decrease stress in a couple by teaching attentive listening skills, effective ways to express positive and negative feelings, and how to request behavioral change in a nonhostile manner.

exposure Repeated confrontation with, or approach to, the object that is avoided.

interpersonal therapy Psychodynamically based treatment that aims to alter negative interpersonal situations that maintain depression. The focus is on one of the following domains: (1) loss, (2) role disputes, (3) role transitions, and (4) interpersonal deficits.

problem-solving training Teaching a set of sequential steps for solving problems that minimizes negative emotional undercurrents while maximizing the identification, evaluation, and implementation of the optimal solutions.

systems theory The basis premise of this theory is that the problem shown by the "identified patient" is a sign that something is wrong with the entire family. Problems of the patient are seen as only a symptom of more basic family problems. System-theoretically derived treatment deals with the relationship between the individual family members and the family system, rather than focusing on overt pathological symptoms.

I. DESCRIPTION OF TREATMENT

For present purposes spouse-aided therapy is defined as any psychological intervention in which the partner of the patient with a psychiatric disorder (e.g., anxiety disorder, depression, substance use disorders) is actively involved in the treatment, and the focus of the intervention is primarily on the psychiatric disorder. This means that marital therapy directed exclusively to the marital difficulties of the couple without due attention to the specific psychiatric disorder involved is not discussed here.

There are several advantages for spouse-aided therapy: (1) The spouse is informed about the psychiatric disorder and the kind of treatment delivered, (2) the spouse can give additional information about symptomatology of the patient and treatment progress, (3) the spouse can be emotionally supported, since living with a patient is often a heavy burden; and (4) the spouse can learn to deal more adequately with disorder-related situations, and, if necessary, general communication between partners can be improved.

A. Anxiety Disorders

In anxiety disorders, two different formats of spouse-aided therapy can be distinguished. In partner-assisted exposure the partner accompanies the patient to each treatment session. The couple receives a treatment rationale, in which the focus is on exposing the patient to phobic situations. The partner can assist in making a

hierarchy, consisting of gradually more difficult exposure tasks. At each session the patient is given a number of exposure homework assignments. The role of the partner is to stimulate the patient to do these exercises, to help in confronting the phobic situations, to accompany the patient if necessary, and to reinforce the patient in mastering these exposure exercises successfully. The actual presence of the partner is gradually faded out during the exposure exercises. At the beginning of each new session, the patient's performance on the exposure tasks and the assistance of the partner are discussed with the couple and new homework assignments are given. More difficult tasks are given only if tasks lower in the hierarchy have been performed successfully. The pace at which the patient works through the hierarchy is determined by the couple. Thus, treatment focuses on the phobia. Relationship problems, if any, are not discussed.

Other spouse-aided approaches in anxiety disorders have focussed on interpersonal difficulties thought to maintain agoraphobic symptoms. These approaches include communication training and partner-assisted problem solving directed either at phobia-related conflicts or at general life stresses and problems.

B. Depression

Partner-assisted cognitive-behavior therapy for depression is based on Peter Lewinsohn and Aaron Beck's individual therapy of depression. It is assumed that depressed individuals do not engage in pleasant activities and hence do not get adequate reinforcement, resulting in mood disturbance. During spouse-aided therapy, partners join all sessions. Treatment focuses on the depression and on ways both partners can deal more adequately with depression-related situations rather than on relationship aspects per se. Therefore, spouses are involved in devising reinforcing activities, in stimulating patients to engage in rewarding activities, and participating in role-playing. Further, spouses are asked to attend to the dysfunctional thoughts of the patient and to discuss these with both patient and therapist. In addition, partners are actively involved in designing behavioral experiments to test (irrational) beliefs and are encouraged to take part in challenging the assumptions held by the patient.

In conjoint interpersonal therapy the partner is involved in addressing patient-related unresolved difficulties in one of the following domains: loss (e.g., of a child or parent), role disputes, role transitions, and interpersonal deficits. Moreover, five sessions of conjoint communication training are included.

In cases with co-occurring depression and marital discord, conjoint behavioral marital therapy may be ap-

plied. Here, the emphasis is not only on the mood disorder, but also on the communication between the partners. Generally, in the earlier phase of therapy problems associated with depression that could hinder a successful application of marital therapy are dealt with. Examples of such problems are complicated grief or a low activity level in the depressed patient. Later on the focus of the therapy is shifted to the training of communication skills in both spouses.

C. Substance Abuse

In general behavioral couple treatment for alcohol use disorders focuses on behavioral self-control and coping skills to facilitate and maintain abstinence, improving spouse coping with drinking-related situations, improving relationship functioning in general, and improving functioning within other social systems in which the couple is currently involved. The degree of emphasis on each of these four domains and the techniques used to target these domains varies across different treatment protocols. Two well-known protocols are the ones used in the Harvard Counseling for Alcoholics' Marriages (CALM) project by Timothy O'Farrell and the Alcohol Behavioral Couple Treatment (ABCT) protocol used by Barbara McCrady. The main differences between these two protocols are that O'Farrell's treatment is designed to be used in conjunction with or subsequent to a treatment focusing on cessation of drinking, whereas the treatment developed by McCrady is designed as a stand-alone treatment. Also, part of the CALM treatment is delivered in a group format whereas McCrady's treatment is delivered during individual couple sessions.

Some techniques often used are the sobriety or Antabuse contract to reduce conflict and distrust between the couple, identifying high-risk situations and teaching both partners alternative skills to cope with these situations, and improving communication between the partners by using role-play to reduce conflict, enhance marital satisfaction, and reduce the chance of relapse.

Behavioral couple treatment for substance use disorders other than alcohol are derived from these (and other) alcohol treatment protocols, focus on the same four domains, and use similar behavioral techniques. Another behavioral intervention in which the spouse is usually involved, but also other family members and other individuals from the patient's network, is Azrin's community reinforcement approach. Consistent with operant conditioning principles, this treatment is designed to remove drinking reinforcing behaviors by teaching family and friends to ignore drinking and reward nondrinking.

Originally designed for treating alcoholics, this treatment has been adapted by Stephen Higgins and colleagues for treating cocaine and other drug abusing patients.

II. THEORETICAL BASES

A. Anxiety Disorders

Systems-oriented clinicians hold that phobias and other anxiety symptoms have interpersonal meaning in relationships. For example, Jay Haley defined the marital relationships of agoraphobic patients as compulsory marriages, in which partners do not stay together out of love but are forced to stay together because of the symptoms. Further, the partners of patients with an anxiety disorder have been described by system-oriented clinicians as negativistic, hostile, compulsive, and anxious. It was assumed that improvement of the anxious patient would lead to an exacerbation of symptoms in the partner and/or to marital distress.

No convincing evidence has been provided that partners of patients with anxiety disorders are psychologically abnormal themselves. However, recent empirical studies comparing agoraphobic and obsessive-compulsive couples with healthy control couples suggest there might be some differences regarding marital satisfaction, adjustment, and interpersonal problem-solving skills. These differences, however, are usually rather small. Nevertheless, this view has given impetus to involving the partner of agoraphobic and obsessive-compulsive patients in the treatment.

B. Depression

Depressed persons are characterized by an aversive interpersonal style to which others respond with negativity and rejection. The interaction of depressed individuals with their partner has been characterized by a lower proportion of positive verbal behavior and a greater proportion of negative verbal and nonverbal behavior. A substantial number of depressed patients presenting for treatment also experience marital distress, whereas in approximately half of the couples who have marital problems at least one of the spouses is depressed. These data suggest that depression and marital distress are closely linked. Furthermore, marital distress is an important precursor of depressive symptoms. In addition, persons who, after being treated for depression, return to distressed marriages are more likely to experience relapse. When patients are asked about the sequence of depression and marital distress,

most patients hold that marital distress preceded the depressive episode. Results of these studies suggest that it might be important to enroll the partner in the treatment of depressed patients.

C. Substance Abuse

From a behavioral or social learning perspective alcoholism is a biopsychosocial process, the course of which is determined by multiple factors. According to this model, alcoholism, as well as other addictive behaviors, are habitual, maladaptive methods for attempting to cope with the stresses of daily living. This maladaptive coping is triggered by internal and external cues and reinforced by positive rewards and/or negative punishment. Formerly spouse-aided interventions with substance use disorders were regarded most appropriate for only a subset of clients with severe marital or family problems. These clients were presumed to be in an "alcoholic relationship" with a specific pathological marital structure, in need of different treatment interventions. Research now points in the direction of also involving a significant other, across a broader spectrum of clients.

Within a behavioral framework drinking or drug taking is assumed to have a negative effect on communication between partners and marital satisfaction, and has also been linked to other marital issues such as domestic violence and sexual dysfunction. Research has differentiated families of alcoholics from healthier control families in that the former typically manifest poor communication, organization, problem-solving, conflict management, and affect regulation processes. However, comparing alcoholic couples with nonalcoholic but distressed couples revealed that the latter group was characterized by similar dysfunctional processes as the former. Alcoholic couples do differ from nonalcoholic couples in that they report more domestic violence. Even in nonalcoholic couples more drinking is associated with increased violence.

There is some evidence that specific behaviors of the spouse can function either as a cue or reinforcer in drinking or drug-taking behavior. Furthermore, marital stability has been found to be positively related to success of treatment. In studies of alcohol abusers recovering without treatment intervention, social support, especially from a spouse, was significantly related to successful changes in drinking behavior. Finally, there is some evidence that restoring marital satisfaction and reducing conflicts reduces the chance for relapse. Taken together, the results of these studies suggest a need to investigate the effectiveness of spouse-aided interventions in substance abuse.

III. EMPIRICAL STUDIES

A. Anxiety Disorders

In contrast to expectations derived from general systems theory, there is no evidence that exposure therapy with patients with agoraphobia or obsessive-compulsive disorder has adverse effects on the relationship or the partners' symptoms. The controlled studies in this area suggest that the relationship remains stable or improves slightly, and no exacerbation of symptoms in the partner of the patient has been reported. Thus, the empirical evidence does not support the systems conceptualization of anxiety disorders as being a symptom of more serious marital problems.

Studies investigating the effects of spouse-aided therapy in individuals with agoraphobia and obsessive-compulsive disorder have indicated partner-assisted exposure to be as effective as treatment by the patient alone. The results of the studies that have been conducted thus far indicate that it is not essential to include the spouse in the exposure treatment of patients with agoraphobia or obsessive-compulsive disorder.

The results of studies that evaluated the efficacy of interpersonal skills training interventions are rather mixed, so no general conclusions are allowed. Treatment focusing on general life stress rather than on relationship difficulties was found to be less effective than exposure by the patient alone. In contrast, studies that focussed on relationship issues in addition to exposure led to slightly better results, especially on follow-up. Notably, this was also the case in couples that were not maritally distressed. Given the finding that criticism of the spouse may be related to relapse at follow-up, this may require specific attention to communication training in couples with a critical partner.

B. Depression

In this paragraph only studies are reviewed in which at least one individual of a couple was clinically depressed. Marital distress hinders treatment of the depressive disorder and, given the link between relapse and being in a distressed relationship, increases the chance of relapse in the future. To date, three controlled studies have shown that conjoint behavioral marital therapy in depressed-maritally distressed couples may be a good alternative for individual cognitive-behavior therapy. Taking the results of these studies together, in depressed-maritally distressed couples behavioral marital therapy seems to have an exclusive effect on the marital relationship, which is not found in

individual cognitive-behavior therapy, while it is as effective as cognitive therapy in reducing depressed mood. Not surprisingly, behavioral marital therapy was hardly effective in depressed patients who did not experience marital problems.

Thus far, only one controlled study has investigated the effects of partner-assisted cognitive-behavior therapy and only one the effects of conjoint interpersonal therapy in depressed individuals. The results of partner-assisted cognitive-behavior therapy were comparable with those of individual cognitive-behavior therapy. Both treatments led to statistically significant improvement on depressed mood, behavioral activity, and dysfunctional cognitions. However, none of the treatment formats affected relationship variables, which comes as no surprise because all couples were non-maritally distressed prior to treatment. Thus, partner-assisted cognitive-behavior therapy was as effective as individual cognitive-behavior therapy in depressed individuals. In addition, conjoint interpersonal psychotherapy was equally effective as individual interpersonal psychotherapy on measures of depressive symptomatology. There was some evidence that the conjoint version was slightly more effective than the individual therapy on relationship variables. Finally, there is some evidence that treatment focusing on the interaction of depressed couples is slightly more effective than antidepressants.

C. Substance Abuse

The results of spouse-aided treatment programs in substance use disorders are encouraging. Research suggests that spouse involvement in the treatment of alcohol and drug use disorders produces significant reductions in alcohol and/or drug use, and improves marital functioning. There are also indications that behavioral couple therapy reduces violence in violent alcoholic couples. It should be noted, however, that most research to date was conducted in academic centers and has focused on white, male, higher educated alcoholic subjects. Typically, subjects in these studies had few other axis I or axis II disorders and were in relatively steady relationships with non-substance-abusing partners. It remains to be shown whether these spouse-aided treatment protocols will be as effective when delivered to other populations in a community setting.

IV. SUMMARY

Spouse-aided therapy consists of psychological interventions in which the partner of the patient with a psy-

chiatric disorder is actively involved in the treatment, which focuses primarily on the psychiatric disorder.

Spouse-aided exposure has shown to be effective in treating anxiety disorders (e.g., agoraphobia and obsessive-compulsive disorders). However, there is little evidence of it being more effective in reducing anxiety symptoms, compared to individual exposure treatment programs. There is some evidence that spouse-aided therapy focusing not only on the phobic disorder but also on communication is more effective than treatment of the patient alone. Specific attention to communication training may be required in anxious patients with an overcritical partner.

Evidence suggests that spouse-aided therapy that focuses not only on the mood disorder, but also on improving communication skills and problem-solving skills of both partners, should be the treatment of choice in maritally distressed patients with dysthymia or major depression. Finally, the results of spouse-aided treatment programs in substance use disorders are encouraging.

Although a number of studies have evaluated the effectiveness and efficacy of spouse-aided therapy in anxiety disorders, depression, and substance use disorders, no conclusions may be drawn from these findings regarding its efficacy in other disorders. There is some clinical evidence that spouse-aided therapy might also be used in chronic pain management and in schizophrenia, but controlled studies are needed before firm conclusions about the effectiveness of spouse-aided therapy in these disorders are warranted.

GLOSSARY

masticatory muscle pain Chronic muscle pain disorder affecting the muscles used for chewing and moving the jaw.

musculoskeletal pain Pain involving structures of the musculoskeletal system that includes muscles, bones, joints, ligaments, and tendons.

PBS A three-step strategy for reducing muscle tension that focuses on positioning (P), breathing (B), and stretching (S).

self-monitoring Process of making regular assessments of personal behavior or activity for the purpose of understanding the frequency with which those behaviors or activities under study occur.

stretch-based progressive relaxation A progressive relaxation training approach that uses gentle muscle stretches to teach sensory awareness of muscle groups and to promote volitional relaxation.

Stretch-based relaxation training was developed as an alternative to more traditional progressive muscle relaxation procedures focusing on muscle tension exercises to teach relaxation skills. In contrast to the tense-

release strategy of traditional progressive muscle relaxation, the stretch-based approach uses gentle stretches of major muscle groups to teach sensory awareness and volitional control of muscle activity. Results from randomized clinical trials have demonstrated the clinical efficacy of the stretch-based approach for addressing a range of problems that include face pain, neck pain, and general anxiety. This article presents the theoretical rationale, outcome data, and clinical applications of stretch-based relaxation training.

I. INTRODUCTION

Psychotherapists are faced with a broad array of options for conducting relaxation training. Generally, the goal of relaxation training is to reduce activation, both physical and mental, and promote self-efficacy for regulation of internal states. These skills of self-regulation can be used to enhance the management of personal and interpersonal challenges. Although there are a variety of relaxation training approaches, the use of progressive relaxation is often a method of choice.

Progressive relaxation was introduced just after the turn of the 20th century by Edmund Jacobson. As a physician, he became interested in the processes by which his patients controlled their own levels of physical and psychological activity. He believed that control over muscle tension and cognitions could be obtained through guided practice where an individual learned to

manage her or his level of muscle tension and focus of attention. His primary strategy for teaching this control was conscious activation and relaxation of various muscle groups in a systematic manner. Originally, he conceptualized relaxation training as requiring 40 to 60 sessions of deliberate practice in tensing and relaxing various muscles. Often an entire hour-long session was devoted to only one muscle group. This rather laborious technique of relaxation training spurred an interest among other practitioners for developing shorter progressive relaxation training programs.

One of the most popular variants of Jacobson's original relaxation procedure was the abbreviated progressive relaxation (APR) approach developed by Bernstein and Borkovec. The original series of Jacobson's exercises was reduced to 16 major muscle groups in the initial APR training session. Like the Jacobsonian approach, the basic strategy for APR is to tense the muscle group for 15 to 20 seconds and then quickly release the muscle tension and let the muscle relax for an extended period. The sequence of muscles that are relaxed generally begins with the hands then progressively moves upward to the head and down to the feet. There is a substantial literature attesting to the effectiveness of APR for a wide variety of clinical problems, as is documented in Carlson and Hoyle in 1993 and Carlson and Bernstein in 1995. This literature includes information on anxiety disorders, depression, and medical conditions such as headache, insomnia, and hypertension.

There are conditions, however, where the use of muscle tensing strategies is not indicated. In cases where muscle tension increases pain, or there is a history of cardiac disease such as arrhythmias, muscle tensing strategies should be avoided. Furthermore, the muscle contractions used in progressive relaxation training may increase muscle nerve sympathetic activity and not promote general relaxation. Finally, the rationale for use of muscle tension-based strategies that increase tension in order to reduce tension can often be difficult for clients to accept in the initial phase of treatment when pain, tension, or anxiety is intense. Because of these issues, an alternative to the use of muscle tensing exercises for progressive relaxation training is needed.

From a physiological perspective, if a muscle is contracted, a slow, gentle stretch of the muscle that does not overstretch or tear the muscle fibers will foster the relaxation of the muscle when the stretch is released. One common example of this principle is the familiar case of the "Charley horse" in which the muscle spasm of the lower back leg is most easily reduced by stretching that muscle gently (by moving the toes several inches to-

ward the head and holding them in that position) for an extended period of time. Physical therapists and athletic trainers use muscle stretching on a regular basis to quiet contracted, overly active muscles. Muscle stretching results in reduced excitability of the motoneuron pool that can lead to reduced muscle activity, increased blood flow, and less pain. The value of muscle stretching is well-recognized in the empirical literature related to muscle function.

Jacobson's original intent in using muscle tensing exercises was primarily to teach the discrimination of muscle groups so that one's sensitivity to motor activation was enhanced. His ultimate goal for a client was to learn how to relax without the use of muscle tension exercises. The tense-release sequences were not a necessary part of the process of relaxing a muscle, but rather a learning tool to foster the acquisition of relaxation skills by teaching awareness of subtle sensations of muscle tension. Substituting a gentle stretch of a muscle for a contraction of that muscle is an alternative means by which sensory awareness can be improved while at the same time taking advantage of the natural relaxation effects associated with the release of a gentle muscle stretch.

Given this background, muscle stretches were developed for each of the 16 major muscle groups associated with the APR procedures of progressive relaxation. Although muscle stretches of these muscle groups cannot be performed by an individual without using some muscle tension (e.g., stretching the muscles of the lower back leg by gently drawing the toes of the feet toward the head), the focus of the procedures was on the muscle stretches themselves and the sensory experiences following the stretches. The sequence of the muscle stretches began with the lower legs and proceeded upward to the head region. Each of the muscles was stretched for 15 to 20 seconds and followed by relaxation for 60 seconds. An example of the instructions for a muscle stretch of the forehead (frontalis region) from Carlson and Collins follows:

In order to stretch the muscles of the forehead, place the fingertips of both hands slightly above the eyebrows and gently push the fingers upward toward the hairline, stretching the muscles by applying light pressure. When you reach the hairline, hold the stretch by maintaining the upward pressure of your fingers on the skin.

The stretch-based progressive relaxation approach is presented in either a five-session format for individuals or a six-session group format. The protocol includes therapist scripts, home practice guidelines, audiotape

for home practice, and videotape for therapist training. Diaphragmatic breathing entrainment is included in the presentation of the relaxation procedures to aid in relaxation, as well as to assist in the timing of the stretch-relaxation sequences. The goal of this program is to teach volitional skills of relaxation in as efficient manner as possible using a focus on muscle stretching procedures.

II. REVIEW OF CLINICAL TRIALS

Following completion of a successful clinical case study involving the use of the stretch-based relaxation approach to address a generalized anxiety, 24 individuals self-referred for moderate muscle tension and anxiety were assigned randomly to a stretch-based relaxation group, tension-based relaxation group, or a wait-list control group. After the treatments were delivered, participants in the stretch-based group reported significantly less muscle tension at four muscle sites (right trapezius, right brachioradialis, left tricep, and left tricep) and had significantly less electromyogram (EMG) activity in the right masseter region than did participants in the tension-based relaxation group. These preliminary data from this randomized clinical trial indicated that the stretch-based progressive muscle relaxation procedures were effective in reducing both subjective and objective indices of muscle tension in persons reporting moderate tension and anxiety.

Carlson and colleagues then applied the stretch-based approach to persons with masticatory muscle pain disorder. Masticatory muscle pain disorder is a disorder where there is no evidence of temporomandibular joint pathology, but the muscles of mastication (primarily masseter, temporalis, and pterygoids) are painful enough to cause impaired chewing function. A group of 34 persons with masticatory muscle pain were assigned randomly to either a stretch-based relaxation protocol or to a condition in which the participants were asked to rest in relaxed positions. Results revealed that persons with elevated muscle activity assigned to the stretch-based group had greater reductions in EMG activity at both left and right masseter sites than persons assigned to the rest control condition. There were, however, no differences in self-reports of muscle tension between the two groups. For persons with masticatory muscle pain disorders, the use of the stretch-based relaxation approach was an effective means for reducing ongoing muscle activity even though reductions in self-reports of muscle tension did not differ from persons given instructions to relax by assuming positions of rest.

Kay and Carlson in 1992 directly compared the stretch-based relaxation approach to the tense-release and rest control relaxation procedures in a group of 60 persons reporting chronic neck muscle tension. The effectiveness of the procedures was evaluated by having the participants use one of the relaxation strategies after being exposed to a standard laboratory stressor. Participants were randomly assigned to one of the experimental groups and it was found that those assigned to the stretch-based condition reported greater overall reductions in muscle tension and lower left trapezius muscle activity than those assigned to either of the other two groups. Additionally, the stretch-based group had an overall increase in peripheral skin temperature, whereas the other two groups did not. This latter finding suggests that sympathetic nervous system activity was reduced for the participants using the stretch-based relaxation procedures. Overall, these data indicated that the stretch-based relaxation approach provided an effective relaxation strategy for persons with chronic neck tension.

Sherman and colleagues in 1997 evaluated the influence of stretch-based relaxation procedures on the immune function of persons experiencing persistent facial pain. Twenty-one participants were assigned randomly to either a stretch-based relaxation condition or a rest-control condition. Participants in the stretch-based relaxation condition had greater salivary immunoglobulin A (IgA) secretion rates than those in the rest-control condition. These results indicated that stretch-based relaxation training may have benefits beyond reduction of muscle tension for persons with chronic pain conditions.

Finally, Wynn in 1995 and 1998 conducted a series of controlled trials of stretch-based relaxation training with persons at risk for developing hypertension. This first study involved 32 young adult males with a family history of hypertension. Participants randomly assigned to six sessions of stretch-based relaxation training displayed lower heart rate and blood pressure (systolic and diastolic) responses to a laboratory stressor than did a comparable group of persons randomly assigned to a control condition. Additionally, participants trained in stretch-based relaxation reported less anger and anxiety than the controls. These findings were followed-up in a second study of 48 Black American males at risk for developing hypertension. It was found that those randomly assigned to the stretch-based relaxation protocol demonstrated lower diastolic blood pressure reactivity to a laboratory stressor, as well as lower emotional reactivity than did persons randomly assigned to a group that underwent a health

education program as a comparative control. Taken together, these two studies demonstrated the efficacy of the stretch-based relaxation protocol for reducing reactivity to laboratory stressors in persons at risk for the development of hypertension.

Overall, the data from a series of clinical trials support the use of stretch-based relaxation among persons with muscle tension and facial and neck pain, and those prone to excessive reactivity to environmental stressors. One of the shortcomings of the presently available data is that they are based on studies conducted within the clinical laboratory of the primary author of the stretch-based relaxation protocol. Other well-controlled clinical trials outside the author's laboratory are needed to provide independent confirmation of the effectiveness of the stretch-based relaxation approach. Based on the available data, however, there are strong preliminary data indicating the efficacy of the stretch-based progressive relaxation protocol.

III. TECHNIQUE

A. Initial Evaluation

Before beginning stretch-based relaxation training, the clinician should complete a thorough initial evaluation with the client to ensure that relaxation training is appropriate for that individual. The primary concern in this initial consultation is to determine the nature of the presenting complaints and to understand how the use of progressive relaxation training may be of benefit. There are also conditions for which stretch-based relaxation training may be contraindicated. These conditions would include a history of loss of contact with reality or an ongoing thought disorder whereby there would be significant difficulty with interpreting or understanding instructions. Medical conditions such as diabetes or seizure disorders may be contraindicated in some cases, or need to be closely monitored by medical personnel during the training program. Women who are pregnant should have the approval of their health providers before beginning a relaxation program. Any medical condition that requires ongoing medications (e.g., hypertension) also requires an approval of the health care provider responsible for prescribing the medication, because relaxation training may potentially alter how the body responds to current medication intake. Progressive relaxation training has the potential to alter the level of an individual's overall physiological activity, in addition to altering cognitive and emotional processes. Therefore, clients should be

carefully screened for their participation in a progressive relaxation training program.

B. Presentation of Program

There are four elements to the initial presentation of the stretch-based relaxation program. The first element is to provide the client a historical overview of progressive relaxation training and the stretch-based approach. This overview would include a discussion of the natural use of muscle stretching and the value of systematic application of muscle stretching in the stretch-based relaxation protocol. The second element to discuss with the client is the concept of learning the skill of muscle relaxation. The emphasis of the program is to develop specific and effective skills of quieting the body whenever the individual chooses to do so. The third element of the initial presentation involves the importance of regular practice of the skills introduced in the training sessions. Without systematic practice, the skills are difficult to perfect and to employ in ongoing daily routines. Finally, the central focus of the program is on learning relaxation skills that are under volitional control. The program is not about a therapist "relaxing" the individual, but rather it is about the individual learning how to relax themselves with the skills that she or he has learned through regular practice.

C. Introduction to Basic Techniques

The basic series of 14 muscle stretches is introduced by first describing the importance of not invoking or increasing pain with any of the stretch-based relaxation activities. The client must be assured that the program is not centered on "enduring pain" in hopes of future gains. Then the client is told that each muscle stretch is done for 15 to 20 seconds and followed by a 60-second period of relaxation. The stretching of muscles is always done slowly and only to the point at which a slight muscle stretch is felt. Overstretching or "bouncing" of muscles is not appropriate.

After introducing the general approach to stretch-based relaxation, the client is shown each of the muscle stretches that includes both lower legs, both upper legs, the lower right/left back, stomach, chest, forehead, eyes, jaw, right/left neck, lower arms, and upper arms. The stretches are usually performed from a comfortable, reclined position in which the client's head is supported, eyes are closed (not necessary if closing the eyes creates discomfort), hands in curled and relaxed position, and legs are quiet with toes pointing away from one another at a 45 to 90 degree angle. Breathing

slowly and regularly is also part of the relaxation program and will be important in later sessions of practice as a timing mechanism for each of the stretch-relaxation exercises.

Once the introduction of the exercises has been completed, the client is reminded of the importance of maintaining a relaxed and comfortable position throughout the period of training. Any tight clothing (e.g., belt) may want to be loosened for the training session, and if eyeglasses, contact lenses, heavy jewelry or watches are bothersome, they should be removed for the duration of the training session as well. When the client is ready to begin the relaxation training, the therapist can begin with the following instructions from Carlson and Collins in 1997:

Before beginning the first exercise, take time to breathe in and out slowly and regularly (wait 2–3 minutes).

We are ready to begin the exercises now. For each exercise I will first describe the exercise. Then, when I say the words, “ready, begin” I want you to begin the stretch.

The first exercise involves stretching the muscles in the lower right leg. When I say “ready, begin” you are going to stretch the muscles in the lower right leg by pulling the toes of the right foot toward your head until you meet resistance in the muscles along the back of the right leg. Ready, begin the stretch by pulling the toes toward your head until you feel resistance. Hold the toes at that position while you feel the muscles stretching in the back of the right leg. Hold the stretch (wait 15 seconds) and now release the stretch and let the toes return to a resting position. Notice the difference in the muscle sensations in the back of the lower right leg as the muscles are now relaxing. Just let the muscles relax and become quiet (wait 30 seconds). You can help the muscles continue to relax by focusing your attention on the muscles in that lower leg and encouraging them to become less tense (wait 30 seconds).

Each of the remaining exercises follows a similar format and is done in a prescribed sequence. The sequence of the muscle stretches is designed so that if a muscle is activated to perform a stretch, it will then be stretched, in turn, to foster further relaxation of that muscle. The exercises are sequenced to move from the feet to the head region.

Following completion of the relaxation instructions, the client is encouraged to reactivate herself or himself with the following:

At this time, I will begin counting backwards from 5 to 1. With each number you should gain more aware-

ness. When I reach “1” you will be fully alert and ready to begin your next activity but you will still be feeling relaxed and comfortable. 5—begin to move your feet and legs. 4—move your arms and hands. 3—move your head and neck. 2—open your eyes. 1—you should now be alert with your eyes open; feeling relaxed and refreshed. Should you be lying down, you may want to roll to your side or stomach and then begin to lift yourself. That concludes your initial training session.

The relaxation exercise series should be practiced at least once a day for 5 out of the next 7 days. Generally, the training sessions are spaced at one week intervals. Audiotape instructions are available to assist in this home practice as it has been shown by Carlson and Holye in 1993 that audiotapes can improve the effectiveness of relaxation training. It is also helpful for the therapist to review with the client the importance of practice and addressing common beliefs such as “these exercises are so easy, I don’t need to practice,” “I can’t relax, so why would these exercises work,” or “When I relax, I am afraid that...”. Finally, the client should be given some sort of self-monitoring forms to take home to record periodic levels of muscle tension on a daily basis and to record when relaxation practice sessions occurred. One effective self-monitoring strategy involves the use of 10 cm visual analogue scales (anchored at one end with “least tension” and at the other with “most possible tension”) that the client can fill out periodically. These can be quickly and efficiently scored with a computer program. Another recently developed strategy is to use a hand-held computer that has been programmed to prompt for and to accept self-monitoring data.

The stretch-based relaxation protocol has four additional elements of training after the first session. The first additional element involves completing the entire series of stretches with a shortened set of instructions. The second element involves the use of music during the session and the use of breathing to self-pace the stretches. The third element includes muscle scanning, a procedure for taking “mental measurements” of muscle tension throughout the body, skills for reducing any areas of identified tension, and a shortened version of the muscle stretching protocol. The skills for reducing areas of identified muscle tension involve a stepped-process involving changes in posture, control of breathing, and isolated muscle stretches of those muscle areas identified as tense. The posture, breathing, and stretching (PBS) provides a systematic and progressive strategy for managing tension in the natural environment. The shortened version of the muscle stretching protocol begins from the stomach region so that the stretches of the legs and lower back are

eliminated from the relaxation procedures. The fourth and final element of the relaxation program involves coping with thought intrusions, deepening levels of relaxation, and addressing life stressors that may be contributing to muscle tension. Each of these four elements is introduced in each of the subsequent sessions following the initial training session.

IV. REPRESENTATIVE CLINICAL APPLICATION

The use of stretch-based relaxation training in the clinical environment is generally part of a comprehensive and multicomponent approach to problem management. Within many clinical settings, stretch-based relaxation training can provide a foundation on which to build a comprehensive set of self-regulation skills. It is rare that progressive relaxation training is the sole focus of treatment.

This can be illustrated by the sample case of Ms. X. Ms. X was a 48-year-old female who presented with the chief complaint of excessive muscle tension, pain, and anxiety following an automobile accident. During the initial consultation, the client reported that she now had intense and persistent fears associated with being in and driving an automobile. The fears were so acute that she was very anxious and sweated profusely while in the car. Moreover, she was only able to drive very slowly and in certain geographic areas of her community. There were areas of her community that she fastidiously avoided for fear of being in another accident. Ms. X's clinical presentation was consistent with the diagnostic criteria for Specific Phobia of (*DSM-IV*).

After the initial evaluation, Ms. X was presented with a formulation that described the events leading up to the development of her phobia, accounted for the subsequent elaboration of her phobia, and explained its continuation. Additionally, she was presented with a treatment plan that included a program of systematic desensitization. The first step in the treatment plan was to establish skills in control of muscle tension. Since she reported muscle pain in the region of her neck and shoulders, she was first asked to receive medical clearance for relaxation training. Following the receipt of medical clearance, the stretch-based program for progressive relaxation training was introduced.

Following the five sessions of the individual stretch-based relaxation training, Ms. X reported a decrease in overall tension and pain, but her fears of driving remained high. Therefore, the second phase of treatment that included constructing a desensitization hierarchy

and performing systematic desensitization was initiated. The stretch-based relaxation skills, especially the PBS strategy for decreasing noticeable levels of tension, was used during the desensitization program. The treatment ultimately included an *in vivo* session in which the client demonstrated her driving skills while maintaining control over her level of anxiety and muscle tension.

V. SUMMARY

There are many successful approaches to progressive relaxation training as indicated by the substantial experimental clinical literature that is available (for example, see Carlson and Hoyle in 1993 and Carlson and Bernstein in 1995 for reviews). The stretch-based progressive relaxation protocol provides the clinician with an alternative to the traditional tense-release progressive relaxation programs. It is an approach based on fundamental physiological principles and experimental clinical data. Application of stretch-based relaxation can help a client develop a set of self-regulation skills to maintain volitional control of muscle tension. Particularly for persons with musculoskeletal pain disorders, the stretch-based relaxation protocol offers a viable alternative to the tense-release strategies for achieving effective relaxation skills.

GLOSSARY

- AG and DAG** Attachment group and disaffiliative attachment group. Specific normal and pathological behaviors described by the SASB model.
- case formulation** A specific method of connecting the presenting problems to patterns learned in relation to early caregivers.
- complementarity** Natural interpersonal matches described by the SASB model.
- copy process** Links between current problem patterns and early attachments. The three main copy processes are (1) be like him or her; (2) act as if he or she is still there and in control; (3) treat yourself as did he or she.
- core algorithm** Focus each story on input, response, and impact on the self. Include the ABCs (affect, behavior, and cognition) and try to enhance the growth collaborator while minimizing the regressive loyalist.
- five steps in IRT** (1) Collaboration; (2) learn what your patterns are, where they are from, what they are for; (3) block maladaptive patterns; (4) enable the will to change; (5) learn new patterns.
- growth collaborator** (GC, or Green) is the part of the person that wants to be happier and more functional.
- introjection** SASB model descriptions of what happens when you treat yourself as you have been treated.

IPIR Important person and his or her internalized representation.

regressive loyalist (RL or Red) is that part of the person that is loyal to the old problem rules, norms, beliefs.

SASB Structural analysis of social behavior classifies interpersonal and intrapsychic interactions in terms of attentional focus and two dimensions: love/hate and enmeshment/differentiation. For example, maternal protectiveness consists of focus on other that is friendly and moderately powerful. Complex behaviors can be described by using more than one code. For example, demanding dependency is: TRUST plus BLAME.

similarity SASB model codes when you choose to be like him or her.

I. DESCRIPTION OF TREATMENT

Structural analysis of social behavior (SASB) is to the therapist as a telescope is to an astronomer. You can see some activity in the sky with the naked eye, but there is much more to see and understand if you have an instrument that effectively amplifies available information. In the interpersonal domain, the SASB lens can go beyond the familiar and help the clinician see the quintessence of interpersonal and intrapsychic patterns more clearly. The SASB model also can provide specific predictions about interactions. Of special interest in psychotherapy are the predictions about developmental antecedents and expectable consequences of identified patterns.

The SASB model and technology have been applied by researchers and clinicians to many aspects of psychotherapy, including interpersonal and intrapsychic assessment, therapy process, therapy outcome, and therapy relationship. The model is not limited to any one ideology. It has been successfully used by investigators exploring a variety of approaches such as client-centered, psychodynamic, psychoanalytic, interpersonal, and cognitive-behavioral therapies. Its usefulness extends beyond dyadic individual psychotherapy. There also are published SASB-based reports on individual, marital, family, and group therapy. The SASB system has been used to investigate related problems such as psychopathology, psychophysiology of interpersonal interactions, behavioral genetics, personality, therapist training, and more. For any approach that involves interpersonal or intrapsychic interaction, the SASB system offers precision in description of interactions, predictions, measurement methods (questionnaires for self-ratings, coding system for objective observer assessment), and software (to create well-validated cross-sectional and sequential parameters for use in clinical feedback or research hypothesis testing).

Although SASB technology is useful in a variety of contexts, this article focuses on Benjamin's recommendations for how to use the SASB model to define a specific individual's psychopathology and choose interventions in psychotherapy that consistently target the core of that individual's pathology. These recommendations have emerged from three decades of using the SASB model in research and practice. They are collected under the heading Interpersonal Reconstructive Therapy (IRT). IRT offers a tightly operationalized SASB-based method for assessing a patient's presenting problems, relating them to presumed underlying motivation, developing a treatment plan that explicitly and consistently addresses the organizing underlying motivators of the problem patterns, and then implementing and assessing the success of that treatment plan. Because SASB itself is generic, it is no surprise that IRT directs the clinician to draw from all schools of psychotherapy, using any available method of intervention. The guidelines require that the intervention conform to the case formulation, to the treatment plan, and to the IRT core algorithm. IRT is particularly appropriate for "nonresponders," people who have failed to improve in response to treatment as usual (medications and/or psychotherapy). Typically, these nonresponders carry the label personality disorder. IRT can facilitate profound change in some but certainly not all members of this population. It cannot, for example, help individu-

als who are unable or unwilling to control alcohol or substance use.

The IRT approach will be illustrated by a case example. Mary had an inpatient consultation with L. S. Benjamin following her second overdose attempt. During hospitalization and after discharge, Mary participated in psychotherapy with a graduate student learning IRT. Data presented here were gathered immediately after discharge and 4 months later, at the end of the school semester. Her history and presenting features, like those of many nonresponders, were severe and complex. She began this therapy with most scale scores on a symptom checklist at or beyond the 98th percentile for outpatients. Mary continued therapy with the same therapist through the next school year. She did quite well in that she made no further suicide attempts, needed no additional hospitalizations, discontinued medications, performed well in her new job, and improved in key social relationships. When the student therapist left on internship, Mary terminated earlier than necessary and said she did not need to use our offer of a referral to a new therapist. She failed to return any research forms at that time, but clearly had dropped a palpable distance from her original high level of symptomatology. But neither was she "cured."

Although IRT usually seeks to address the total picture, restricted aspects of Mary's presentation and the related history will be addressed here, because of space limitations. The selected focus is Mary's suicidality, very low self-esteem, and her apparent inability to look after her own interests.¹ These interpersonal and intrapsychic problems will be described in terms of the SASB model, shown in Figure 1.

The poles of the axes of the model, starting at the right-hand side and moving clockwise, are Love, Enmeshment, Hostility, and Differentiation. Points between poles consist of components of the nearest poles. Bold type indicates transitive focus on other; underlined type indicates intransitive focus on self. Italics depict introjected focus from other. For example, **IGNORE** describes behaviors relevant to focus on another person that is hostile and autonomy giving. WALL-OFF involves an intransitive focus on self reacting to another person with hostility and autonomy

¹ IRT theory prescribes that specific affects accompany specific interpersonal positions. Therefore, working with interpersonal patterns can help relieve symptoms. For a simple example, a person who fears rejection may be anxious. Transforming the fear as well as learning to handle actual rejection can reduce anxiety.

FIGURE 1 The simplified SASB cluster model. The poles of the axes, starting at the right-hand side and moving clockwise are Love, Enmeshment, Hostility, and Differentiation. Points between poles consist of components of the nearest poles (see text for further explanation). From Benjamin, L. S. (1996). *Interpersonal Diagnosis and Treatment of Personality Disorder*, 2nd ed. New York: Guilford Press.

taking. *SELF-NEGLECT* represents uncaring transitive focus on the self that is hostile and autonomy giving. Opposites are located at 180 degrees. For example, **PROTECT** is the opposite of **IGNORE**. Complements are shown by adjacent **BOLD** and UNDERLINED pairs. For examples, WALL-OFF matches **IGNORE** and TRUST complements **PROTECT**.

Mary rated herself and important other persons on the SASB Intrex questionnaires. Selected results appear in Figure 2. The top part of Figure 2 shows the SASB-based description of Mary's self-concept (squares) compared to her view of the way in which she remembered her mother focusing on her when she was a child (diamonds).

A glance at the figure shows that Mary rated her mother high on items describing **BLAME**, **ATTACK**, and **IGNORE**. This picture is highly consistent with the content of the clinical narrative. Mary's mother was alcoholic and spent much of her time in bars. Mary, the oldest child, was responsible for running the household. If mother came home in the middle of the night and found a speck of dirt on a dish in the cupboard, Mary would be yanked out of bed and beaten and forced to wash every dish in the cupboard. The mother called Mary all kinds of names and assured her that no man would ever love her.

The data for Introject show how Mary internalized these messages. The two curves at the top of Figure 2 are similar. Mary's mother **BLAMED** her and she **BLAMED** herSELF. Her mother **ATTACKED** her and she **ATTACKED** herSELF. Mother **IGNORED** her, and Mary **NEGLECTED** herSELF. The current suicidal episode included all these elements. The suicidal attack was a conscious internalization of her husband's rejection and criticism ("Nobody wants to be married to me. I deserve to die") and after discharge from the hospital, she neglected herself markedly. For example, she moved out with essentially no overt protest and then she failed to engage a lawyer. Although she needed money and was a competent worker, she did not groom herself before her initial job interviews.

The lower part of Figure 2 compares Mary's self-concept at the beginning of the outpatient treatment (squares), and 4 months later (diamonds). The two curves are starting to separate, with the later assessment suggesting a shift in the direction of more friendly self-control. Her IRT therapy had initially focused precisely on these issues: the need to engage in more self-control and self-care. Her student therapist was competent and warm (**PROTECTive**) and it is assumed that Mary internalized the structure and caring. The therapist's warm control offered the opposite of

Mother's focus and Introject at Time 1

Introject at Times 1 & 2

FIGURE 2 Mary's view of her mother is reflected in her introject (top). Her self-protectiveness and self-control began to improve early in IRT therapy (bottom).

Mary's mother's barhopping, coded, IGNORE. As she continued IRT, Mary internalized aspects of this corrective experience, and came closer to (but did not reach) the goal of letting go of the hope of rewriting childhood (discussed below). As time went by, the therapist offered less overt structure. Mary began to work on other skills, which included self-discovery, self-definition, and other "higher level" goals.

In general, the case formulation method in IRT requires that each presenting problem be linked to a key figure (usually a caregiver in childhood) by one of three

copy processes. These are (1) be like him or her; (2) act as if he or she is there and in control; (3) treat yourself as did he or she. These processes of internalization are respectively called identification, recapitulation, and introjection. Usually copy processes are described directly by the SASB predictive principles. Copy process #1 applies the principle of similarity. Mary did not exhibit this process. Process #2 often reflects complementarity. Mary had recapitulated the violence in her relationship with her mother in her first marriage to a violent man. She retained the role of victim. Her second husband was

not physically abusive, but he did specialize in neglect and rejection. She repeated the fate of being unwanted. Process #3 is introjection. As Figure 2 suggests, Mary introjected her mother's violence and degradation as well as the neglect. Copy processes can sometimes be seen in negative image, measured in terms of points 180 degrees apart on the SASB model. For example, Mary showed negative identification with her neglectful mother in that she had been very, perhaps too, protective of her own child.

This idea that patterns of disorder are replications of patterns learned long ago in relation to loved ones is startlingly simple. It is common for patients in IRT to say "I can't believe it, but it really is true: I am just like him!" Copying is universal, and, according to IRT, the difference between normality and pathology is simply in what is copied. Normal parents function from a baseline described by the SASB points **AFFIRM**, **ACTIVE LOVE**, and **PROTECT**, shown on the right-hand side of Figure 1. Normal children complement these behaviors with **DISCLOSE**, **REACTIVE-LOVE**, and **TRUST**. These baseline behaviors, described by SASB as friendly and moderately enmeshed and moderately differentiated, are called the attachment group (AG). Normal people internalize these benevolent ways of relating to themselves and others. Severely disturbed patients, like Mary, are more likely to have lived with baselines of **IGNORE**, **ATTACK**, and **BLAME**, called the disaffiliative attachment group (DAG) of behaviors. Like Mary, they internalize hatred of self and/or others.

The core issue in treatment planning in IRT therapy is to lock on to the motivation that is maintaining the copy processes that implement the problem patterns. Why are the copy processes sustained? For example, why does Mary continue her mother's norm of attacking herself? IRT's answer to the question is that it is for love. Every psychopathology is a gift of love. The "Gift of Love" hypothesis holds that behaving according to the "rules" of the internalized representation of the attachment figures, called important persons and their internalized representations (IPIRs), is an attempt to seek "psychic proximity." Doing things his or her way offers psychic security in the same way that the toddler is reassured by returning to the mother for a hug. This perspective is named the developmental learning and loving (DLL) theory of psychopathology. The fact that people will maintain patterns from childhood despite their enormous cost in adulthood is evidence of the stunning power of early figures in the development of the psyche.

It follows that if the problem patterns reflect early learning through copy process maintained by the gift of

love, then the treatment plan must target that attachment. Somehow, the patient must give up the organizing wishes to rewrite history, or to wreak revenge (followed by reconciliation). The heart of reconstructive change will involve grieving what has been lost and what can never be. The patient must see and accept that childhood cannot be relived better and "righter." Letting go of those wishes is not easy. Tragically, the less secure and the more damaged the person, the more likely he or she is to cling to old fantasies of rescue or restitution. It takes good security and a solid psychological base to be able to let go of old patterns and move on to friendly independence.

IRT attempts to facilitate the development of new bases so that the patient can have the courage to let go and live differently and better. The therapy relationship is part, but not all, of the process of building a new base. Sometimes the parenting figure himself or herself can best serve this role.² The IRT therapist is quite active in helping the patient choose and maintain current relationships that are based in the normal (AG) range of behaviors. This is easier said than done, for there are powerful forces³ that call the patient back to the familiar domain of DAG.

In the effort to transform the gift of love, every intervention in IRT is supposed to comply with three requirements: (1) It must conform to the case formulation, already discussed; (2) in addition, an intervention must implement one or more of five therapy steps; (3) finally, a good intervention implements the core algorithm.

The five therapy steps are (a) collaboration; (b) learning what your patterns are, where they are from, and what they are for; (c) blocking maladaptive patterns; (d) enabling the will to change; and (e) learning new patterns. Each of these five steps can be facilitated by any and all interventions known to the domain of psychotherapy. Therapy techniques are classified in two subgroups depending on whether they facilitate (a) experiencing or (b) self-management. In general, techniques from psychodynamic therapies encourage experiencing (e.g., discovery of ancient patterns and buried feelings through free association). Those from

² This requires that the parent is currently not defensive and, more important, that the therapist is not blaming. The assumption is that the pathology stems from the internalized representation, not the "reality."

³ Complementarity with current figures is one such force for stasis. Most threatening, however, is the fact, that when people give up old patterns, they lose their identity. "I don't know who I am if I am not what I have been." This undefined state can be quite terrifying, and one resolution is to go back to the old ways.

behavioral therapies (e.g., learning and practicing skills in assertiveness) are more likely to invoke self-management techniques. Both domains of intervention are required in IRT: (1) The patient has to experience how it was and is to engage the will to change; (2) once he or she decides to change, learning better self-management can follow. According to IRT, the main difference between psychodynamic and behaviorally oriented therapies is in their relative emphases on (1) and (2).

When choosing an intervention, it often is helpful to think of the patient as, in effect, two people. The part that comes to therapy and hopes to change to function and feel better is called the growth collaborator (GC) or the "Green." The part of the person that wants to remain loyal to old ways is the regressive loyalist (RL), or the "Red." The conflict between the Green and the Red is everpresent and can be understood only after the case formulation is clear. In Mary's case, for example, the Red was often furious when someone showed signs of rejecting her; she was likely to react with self-destructive behavior. The Green, by contrast, would reflect carefully on why Mary was so panicked and angry about being left, and how her behaviors encouraged her husband to avoid her (step 2). For someone still in a problem relationship, these insights can help the patient contain the actions that alienate the spouse (step 3). Later, the patient can consider ways of relating to the spouse that might be more successful (step 5). Unfortunately, the Green cannot do much until the Red has had her say and the patient is truly sick of repeating the pattern. That decision to give up the ancient ways (step 4) is the most critical and most elusive part of therapy. It is facilitated if the therapist can minimize interventions that support the Red, and maximize those that encourage the Green. This can be altogether tricky. For example, after a fight with her husband, therapist efforts to encourage better patterns (help the Green) could easily be seen by Mary as blaming her (excite the Red). By using carefully chosen words informed by SASB codes of the therapy process and the case formulation, the therapist can make interventions that are perceived mostly as Green.

Finally, the core algorithm requires that the clinician extract from the therapy narrative a current episode that reflects the presenting problems. In Mary's case, for example, anything involving rejection, attack, or blame would be highly relevant. The clinician makes sure that each episode is fully explored in terms of (1) input, (2) response, and (3) Impact on self. A second feature of the core algorithm is to remember to attend to three domains, called the ABCs (affect, behavior, and cognition). The third feature of the core algorithm is that the clinician should try to enhance

the Green and minimize the Red. For example, if Mary reports an episode of raging and crying when her date does not show up for lunch, it is appropriate to conduct a verbal walk through her morning up to the point where the rage erupted. This includes consideration of input (what set her off); response (rage and despair); and impact on self ("Nobody will ever love me"). The therapist encourages Mary to describe not only the situation and her behavior (B), but also her feelings (A) and her thoughts (C) about it. This could take most of a session. It would be excellent if the discussion also could contribute to her program of learning about how her repetition of patterns of rejection and abuse is related to the residuals of her attachment to her mother. (Her sexually abusive father also is an important part of Mary's story, but cannot be developed here.) After substantial repetition and lots of support, Mary eventually can "get the picture" emotionally and behaviorally as well as cognitively. That, of course, is the most difficult and challenging step for both patients and therapists. Various additional specific procedures to facilitate that realization and enhance the decision to let go are discussed in Benjamin. When the old wishes are given up, Mary and other IRT patients can give up the quest and the associated repetitions of the family scenario.

II. THEORETICAL BASES (CONCEPTUAL UNDERPINNING)

Bowlby argued that having reliable access to a supportive primary caregiver provides basic security required for independence. He emphasized that security is not the direct result of receiving food or the satisfaction of other needs. Harlow confirmed Bowlby's view of attachment by showing that baby monkeys gained more security and willingness to explore from having a huggable terry cloth laboratory mother that did not provide milk, than from a bare wire mother that did. Harlow suggested that contact comfort is a key component of attachment. Bowlby further proposed that children organize their behavior around internal working models derived from experience with their attachment persons. Copy process theory draws directly on Bowlby's concept of internal working models. Describing an individual's patterns in terms of the SASB model simply makes more explicit the nature of the internal models and their connection to the problem behaviors. Bowlby's work with attachment as a primary drive was revolutionary. Today's burgeoning literature continues to show that early attachment has a profound impact on mental and physical health.

IRT combines the fundamental principles from attachment theory with behavior theory. From behavior theory comes the idea that what works is likely to be repeated. Therapy must therefore identify and change the rewards. Attachment theory provides the definition of what “works.” In other words, psychic proximity is the main “reward.” IRT’s focus on attachment demotes traditional “drivers” such as anger, rage, power, superiority, and the like. These human traits are very much a part of IRT, but they are not considered to be the primary targets of intervention. IRT centers instead on love for an important person and his or her internalized representation (IPIR). Once the loyalty to that internal representation is transformed,⁴ the patient is free to learn and implement an entirely new and better way of living.

III. EMPIRICAL STUDIES

There have been many published studies of the methodological and clinical validity of the SASB model. There have been no formal published studies on the validity of IRT. However, IRT has repeatedly been successfully applied in a difficult-to-treat population, illustrated by Mary. The main measures have been in “testimonials” and in dramatic reductions in numbers of hospitalizations and suicide attempts. Scattered sets of before and after measures using Intrex questionnaires and symptom scales also are encouraging. However, with these severely disordered individuals, treatment may have to last for 2 or more years to achieve definitive and stable remission. The present hope is to conduct formal clinical trials at the University of Utah Neuropsychiatric Institute and possibly with colleagues at the University of Pittsburgh.⁵

IV. SUMMARY

IRT seeks to treat “nonresponders” by directly identifying and transforming the underlying motivations for the interpersonal and intrapsychic problems. The presenting problems are linked specifically to relationships with early caregivers in the form of three types of copy process: be like him or her; act as if he or she is still there and in control; treat yourself as did he or she. The

⁴ It is assumed that the neurologically based templates that have been implementing the problem patterns must be transformed by the new learning.

⁵ Paul Pilkonis and Jennifer Skeem have teams of clinicians engaged in preliminary trials to gather pilot data preparatory to applying for grant support.

motivation for copy process is to implement the rules or values of the persons being copied in order to provide testimony to their beliefs and to achieve reconciliation with them. The treatment implication of this “Gift of Love” hypothesis is that these now impossible wishes must be recognized, grieved, and given up. Then, personality reconstruction can begin. To reach that goal, IRT draws from any and every school of therapy as long as an intervention can achieve one of five therapy steps, use the core algorithm, and fit the case formulation. Assessment of patterns, copy links, therapy process, therapy content, and the effectiveness of therapy steps are greatly facilitated by clarity and explicitness provided by the SASB model and its associated technology.

GLOSSARY

autonomous ego functions *Primary*: Inborn functions that follow a development timetable that unfold sequentially, so long as the environment does not interfere. Includes processes such as cognition, perception, and language. *Conflict free*: Refers to primary autonomous ego functions that arise without precondition of conflict. *Secondary autonomy*: Ego functions that arise out of conflict but become independent of such conflict.

compromise formations The balance of superego injunctions and id demands created by the ego and manifested in fantasies, symptoms, dreams, character traits, etc.

condensation A process whereby a sole idea represents several associative changes and is part of the functioning of the id.

displacement The process employed by the id in which an idea's emphasis, interest, or intensity is detached and passed onto other ideas.

drive derivatives The surface and conscious representation of id drives.

drives Psychic representation of instinctual and biological needs and urges.

ego The psychic structure posited by the structural theory developing out of the id, which functions as a synthesizing agency between the demands of the superego and the pressure for expression in the id. Functions include self preservation, perception, motility, learning, memory, cognition, language, reality testing, and the synthetic function.

ego psychology An offshoot of structural theory developed by Heinz Hartman and David Rapaport emphasizing the role of the ego in mental life.

id Identical to the earlier concept of the System Unconscious. The id is, in the structural theory, the reservoir for psychic representation of the two instinctual drives of libido and aggression.

infantile sexuality The idea that infants and children have sexual intentions, aims, and motivations.

intrapsychic conflicts Conflicts between intentions of the person, both conscious and unconscious, in conflict with the demands of external prohibitions.

libido The instinctual drive oriented towards merging, and is generally thought to be the basis of sexuality.

pleasure principle The economic concept of the organization of the mind under the structural theory that posits the motivating drive as the discharge of excitations, experiences, pleasure.

primary process A type of logic employed by the id in which the pleasure principle guides the direction of behavior. It is a timeless process that modifies distinctions in order to create representations and opportunities for pleasurable discharge.

reality principle The manner in which the ego carries out its work based on a perception and measurement of social reality demands.

resistance A defense aimed towards keeping the unconscious material activated by analysis or psychotherapy from reaching consciousness.

secondary process thinking The mode used by the ego that is based on logic, linear thinking, and time orientation.

structure A group of psychological functions or processes that are organized hierarchically and have a slow rate of change.

superego The psychological structure that represents the internalization of the parents' values and prohibitions and consequently those of the larger social cultural world.

topographical model An early model of psychoanalytic theory developed by Sigmund Freud which characterized mental phenomenon as being unconscious or conscious in postulated functions in a relationship to these qualities of mental life. This thinking included the ideas of systems unconscious, preconscious, and conscious.

I. LIMITATION OF THE TOPOGRAPHIC MODEL

Structural theory, sometimes referred to as the structural model or the tripartite model, refers to Freud's final and ultimate model of the mind that he first introduced with his book, *The Ego and the Id* in 1923, and elaborated in *Inhibitions, Symptoms, and Anxiety* in 1926. This shift in conceptualizing the workings of the mind away from the topographic model that had organized his thinking for over 20 years was prompted by Freud's realization that his topographic theory had too many theoretical inconsistencies to remain viable, and that it could not account adequately for a variety of clinical phenomena, most notably unconscious guilt. Freud came to see that understanding the workings of the mind, particularly the intrapsychic conflicts that give rise to most mental phenomena, needed to be based on something other than the relationship of mental contents and functions to consciousness. Thus, he changed his metaphors for understanding the mind away from the notion that mental contents moved from the depths to the surface. To accomplish this goal and to ensure that his new model more adequately explained the complexity of the psyche necessitated the relinquishing of his constructs of the systems Unconscious, Preconscious, and Conscious.

II. STRUCTURAL THEORY

These layers or stratas of the mind were replaced by what he first called agencies and later called structures—the id, the ego, and the superego. The term

structure is an ambiguous one in psychoanalysis, although most analysts adhere to the definition of David Rapaport that the term refers to a group of psychological functions or processes that are organized hierarchically and have a slow rate of change. The id, ego, and superego are certainly not the only mental structures that comprise the mind. But they are thought to be its superordinate structures, leading Merton Gill to refer to them as macrostructures. It is assumed by most psychoanalysts that the mind is composed completely of these three superordinate structures, each of which can have substructures. The interrelationships within and between these three structures, particularly intrapsychic conflict, are what give rise to most mental phenomena and all psychologically mediated behavior.

Freud did not abandon all of the key concepts that he had developed during his topographic era of model building when he replaced it with the structural theory, however. His important concepts of infantile sexuality, libidinal and aggressive drives, unconscious mental functioning, and internal conflict remained as did more dubious concepts such as psychic energy. But these concepts were modified and integrated into structural theory with varying degrees of conceptual clarity and success. For example, the concepts of unconscious, preconscious, and consciousness were retained. But these concepts now became adjectives, used merely to describe whether any particular mental content or process was within the individual's conscious awareness or not. The terms no longer retained any structural or systemic implications. Despite this fundamental reconceptualization, it is not uncommon, even today, to hear psychoanalysts speak of the Unconscious as though it were a structure, to imply that unconscious mental phenomena are somehow deeper and more primitive than conscious mental phenomena, or to talk about the technical need to make the Unconscious conscious. Such analysts seem not to realize that such ways of thinking about analytic matters are outdated and at odds with how we have come to understand the workings of the mind.

III. THE ID

Nonetheless, conceptual overlap between the earlier topographic model and the later structural one remains important in understanding the intricacies as well as the necessity for utilizing structural theory in clinical situations. Perhaps the clearest overlap between the two models involves how Freud formulated the id. The id is virtually identical with the earlier concept of the system

Unconscious. Thus, it is the reservoir for psychic representations of the two instinctual drives, libido and aggression. As such its contents revolve around the basic, pleasure-seeking urges of mankind. It operates according to the pleasure principle and is organized according to the logic (or lack thereof) of the primary process. Freud retained his concept of psychic energy when he developed the structural model and he used differences in the nature of psychic energy to explain differences between structures of the mind. Psychic energy was thought to be mobile and its discharge rapid in the id, allowing for the clinical manifestations of primary process thinking—condensation and displacement. Drives were thought to be relatively unfused in this structure. Freud was drawn to the analogy of the id as a wild, untamed horse that had to be broken by the rider, the ego. Thus, he saw the ego as developing out of the id so that the individual could adapt to reality rather than run amok as the id's drives were given free rein. Freud viewed the contents of the id as dynamically unconscious; that is, they were defended against so as not to reach conscious awareness and cause unpleasure. He thought that they could only be known through their surface manifestations—what came to be called drive derivatives. More recent theorists such as Charles Brenner have questioned this dichotomy, arguing that the concept of drives is a purely theoretical and abstract one. To the degree that drive derivatives are the real clinical phenomena encountered, their availability to consciousness is a graded one. It is simply at odds with clinical experience to speak of completely unconscious drives.

IV. THE EGO

The ego is generally accepted as the most important structure of the mind in understanding the ability of humans to adapt and to survive in the world. In fact, it is so important that psychoanalytic thinkers such as Heinz Hartmann and David Rapaport developed an offshoot of structural theory, called ego psychology, between the late 1940s and the early 1960s. Their ideas are generally subsumed under the rubric, structural theory, today. But their wish to highlight the importance or even preeminence of the ego among the structures of the mind is worth noting. As will be described later, it has major implications for the clinical practice of psychoanalysis. Freud described the ego as developing out of the id because of the necessity to mediate between the drive wishes of the id and the demands and restrictions of external reality. As development proceeds, the ego comes to balance superego injunctions

along with these other pressures. Thus, it is the source of compromise formations manifested in fantasies, symptoms, dreams, character traits, and so on. The ego accomplishes this complex task of mediating between the id, superego, and external reality according to the reality principle and through the use of secondary process thinking. The ego psychologists emphasized that the ego's structure was so complex and its mode of organization so substantially different than that of the id that it seemed more likely that both structures evolved out of an originally undifferentiated psychic matrix. This model of the mind developing through progressive differentiation is far more in keeping with modern concepts of developmental psychology than is Freud's metaphor of the rider ego.

Regardless of how one understands its origins, the ego remains understood as the "coherent organization of mental processes" that Freud described. Its most important clinical function is that of defense. That is, the ego monitors the conscious awareness and/or expression of id impulses and uses a wide array of defense mechanisms to keep them from arousing excessive unpleasure or causing danger to the individual. The ego does not just defend against the id, however. Defenses are just as readily deployed against the superego or against perceptions of external reality.

Defense is also not the only ego function. In *An Outline of Psychoanalysis* Freud discussed other ego functions including self-preservation, perception, motility, and learning. Later memory, cognition, language, reality testing, and the synthetic function of the ego were described by psychoanalysts including Anna Freud, Hartmann, Kris, and Loewenstein, Bellak, Arlow, and Brenner. All agree that it is impossible to develop a comprehensive list of ego functions because the mind is so complex. Nonetheless a particularly useful delineation of 12 ego functions that can be empirically measured has been developed by Leopold Bellak and his collaborators. These 12 functions include reality testing; judgment; sense of reality of the world and of the self; regulation of drives, affects, and impulses; object relations; thought processes; adaptive regression in the service of the ego; defensive functioning; stimulus barrier; autonomous functioning; synthetic-integrative functioning; and mastery-competence. This list is neither exhaustive nor theoretically consistent. But it does demonstrate the complexity of the ego and does offer a method of quantitative research.

Many of these functions also help to clarify another reason that the ego psychologists objected to Freud's idea that the ego developed out of the id. Freud's idea carried with it the notion that all ego functions arise

out of intrapsychic conflict and are influenced by the id. Reality testing, for example, was thought to arise out of hallucinatory wish fulfillment conflicting with external reality. In contrast Heinz Hartmann argued that many ego functions are primarily autonomous. That is, they are inborn and follow a developmental time table that will unfold sequentially as long as the environment does not interfere. Processes such as cognition, perception, and language, for example, are conflict-free. Conflict was not necessary for their genesis or development. Other ego functions achieve what Hartmann called secondary autonomy. That is, certain functions or personality traits may originally develop out of conflict but over the course of development become functionally autonomous. Thus, conflict-related behaviors can become independent of their roots. This concept helps to explain the imperviousness of certain fantasies or character traits to interpretation, despite the therapist's ability to analyze and interpret all the various conflicts that gave rise to it.

V. THE SUPEREGO

The superego was the third structure of the mind in Freud's structural theory. In large part it is this structure and the clinical phenomena that it elucidates that caused Freud to develop his structural model in the first place. Prior to giving up the topographic model, Freud struggled to understand the phenomenon of unconscious guilt and its clinical manifestations, particularly the negative therapeutic reaction and issues pertaining to masochism. To explain these phenomena, he offered the concept of the superego as the internalization of the parents' values and prohibitions. He described it as developing out of the ego and becoming a full-fledged structure in its own right as part of the child's oedipal resolution. This latter point continues to be debated in the literature. Some contemporary structural theorists such as Paul Gray argue that the superego is just a specialized ego function and not a structure in its own right. In contrast some child psychoanalysts have noted the presence of a fully functioning superego far earlier than oedipal resolution and have argued that its function as a separate mental structure needs to be kept conceptually separate from the developmental level of the drives against which it is pitted. Despite these subtleties of theory, most psychoanalysts see the superego as crucial in understanding behavior. In essence it functions both as a conscience and as an internalized set of ideals, both of which are significant motivators of behavior.

VI. STRUCTURAL CONFLICT

These three structures of the mind—id, ego, and superego—function both on their own and interact in ways that determine every aspect of human behavior. But it is important to realize that calling structural theory a tripartite model is somewhat misleading. This is because external reality plays a far more prominent role in structural theory than it did in the earlier topographic model. Because the structural model stresses the importance of adaptation to an external environment, external reality is viewed as placing demands on the ego's mediating abilities just as much as the id and the superego. Thus, the compromise formations that the ego organizes to balance these sources of pressure must take into account reality's demands also.

The clinical implications of this model generally involve its role in intrapsychic conflict. Conflict between any of the structures can occur as can intrastuctural conflicts wherein subprocesses or functions of each structure conflict with each other. Examples of the former include an ego defense arrayed against an id drive or a superego injunction deployed against an id drive or an ego function. An intrastuctural conflict might involve competing ideals within the superego, for example. The fantasies, symptoms, behaviors, or character traits for which patients seek therapy are understood as compromise formations involving the ego's attempt to mediate the conflicts between these structures and external reality.

VII. TECHNICAL IMPLICATIONS

Only recently have psychoanalysts delineated a manner of working with patients that follows logically from this structural model. Fred Busch and Paul Gray are the two psychoanalysts most closely associated with a contemporary structural approach to technique. In essence, this way of working with patients emphasizes the need to expand the patient's autonomous ego functioning by teaching him or her to observe intrapsychic conflict as it becomes manifest in sessions. The patient is taught to closely observe his or her associations with a particular lookout for evidence of resistance. Resistance is monitored carefully with the analyst listening to and teaching the patient to listen for moments in the analytic process when resistance to the direct and unfettered expression of thoughts or feelings occurs. The patient learns to oscillate between being in analysis and observing the free associations that characterize the psychoanalytic process.

The goal of an analysis shifts from the topographic emphasis on making the unconscious conscious so that core unconscious fantasies can be changed to gaining mastery over them by thinking about them. Resistance analysis gains center stage in analytic technique guided by structural theory rather than being a means to an end with the end being making unconscious mental contents conscious. Self-analysis becomes a key criterion for termination, as patients master the analytic way of thinking and apply it to their own associations, particularly noticing unconscious defensive activity aimed at keeping thoughts out of awareness.

This approach to analytic technique is based on the realization that the way in which the ego handles its task of mediating the other structures and reality determines psychological health. Thus, the way in which a person thinks, and the amenability of that thinking to analytic interventions, are more important than the contents of that thinking. Oedipal, preoedipal, narcissistic, and so on refer to mental content. But structural theory, in contrast to earlier analytic models, focuses on mental structure. Analysts now try to help the patient to reestablish mental connections that have been disrupted by defense rather than to recover memories or fantasies. Structural theorists such as Busch or Gray take the ego's synthetic function seriously. Thus, insight becomes directed at understanding the workings of the patient's mind instead of at deep, hidden, mental content. New solutions to conflict emerge as a result of bringing the conflict between unconscious wishes and defenses or superego under the scrutiny of the autonomous ego.

Toward this end, vicissitudes of conflict are addressed by the analyst as they appear in sessions. Busch points out that the ego is regressed when in the midst of conflict so that thinking becomes preoperational and concrete. Thus, interventions by the analyst must be concrete and immediate in order to be grasped by the patient's regressed ego. Conflict, as it occurs in the associational processes, can be seen more readily by the patient than unconscious content, which is more abstract, and less immediately visible. Furthermore, interpretations of deep unconscious content as practiced under the topographic model risk analytic change occurring on the basis of identifying with the analyst's authority rather than on any expansion of the ego's ability to perceive and master conflict. Finally, the structural model postulates that the ego defends against unconscious id contents because they would stimulate excessive anxiety or guilt if they became conscious. To address these contents directly without first exploring and modifying the anxieties that motivate the defense will only increase the patient's anxiety and resistance.

Although such technical implications may seem obvious, they have only been elucidated over the past 15 years. Until then psychoanalysts practiced according to an implicitly topographic perspective despite their belief that they were operating from a structural orientation. This state of affairs was due primarily to Freud's writings on technique having been published during his topographic era of theorizing. He never returned to the theory of technique after formulating his structural model. Thus, too many psychoanalysts clung to outdated ways of working or of formulating their work because of their wish to remain true to Freudian technique. Even today it is not uncommon to hear analysts interpret unconscious anger, for example, before they have interpreted and understood the patient's reluctance to be aware of his or her anger. Furthermore, psychoanalysts of orientations other than Freudian have continued to misunderstand structural theory so that their critiques of so-called Freudian technique seem appropriate to technical concepts of the topographic era and not relevant to a truly structural approach to psychoanalytic practice. Modern day or contemporary structural theory offers a model and way of working with patients that is the most comprehensive and integrative of psychoanalytic approaches today. It is capable of integrating the clinical findings of self-psychology or object relations theory while retaining all of Freud's brilliant insights into the organization of the mind and the way in which this organization affects behavior.

GLOSSARY

community reinforcement approach Interventions based on learning theory that are designed to rearrange significant aspects of local communities, such as vocational, family, and social activities, to differentially support a non-substance-using lifestyle.

disease model approach Interventions that help the individual who abuses substances accept that they have an illness or disease and surrender by acknowledging that there is hope for sobriety through accepting the need for help from others and a higher power. A major goal is fostering active participation in self-help groups (e.g., AA, NA, CA).

methadone maintenance A pharmacological approach to the treatment of opioid dependence in which the individual who abuses opioids is maintained on an agonist, methadone, that has action similar to that of the abused drug but is considered to be less harmful.

substance abuse (DSM-IV criteria) A maladaptive pattern of substance use not due to dependence leading to significant impairment or distress that is characterized by one or more of the following occurring at any time in a 12-month period: recurrent substance use resulting in failure to fulfill major role obligations at home, work, or school; recurrent substance use in physically hazardous situations; recurrent

substance-related legal problems; continued use despite having persistent or recurrent interpersonal or social problems exacerbated or caused by the effects of using.

substance dependence (DSM-IV criteria) A maladaptive pattern of substance use leading to significant impairment or distress that is characterized by three or more of the following occurring at any time in a 12-month period: tolerance; withdrawal; taking the substance in larger amounts or for longer periods than intended; expressing a desire to cut down on use or unsuccessful efforts to cut down or stop using; spending large amounts of time obtaining the substance, using, or recovering from the substance's effects; important social, occupational, or recreational activities have been given up or reduced because of the substance use; and continued use despite recurrent physical or psychological problems that is made worse or caused by the use.

therapeutic community An intervention that supports the individual's submission to group ideology of abstinence from substances. Every aspect of the individual's daily life is regimented often through confinement, structure, and daily work assignments.

Given the place of this article in a volume describing a variety of psychotherapeutic approaches, this article focuses on those aspects of individual and group therapy that are unique to the treatment of substance dependence. This article presents guidelines on therapy applicable to those both dependent on alcohol as well as those dependent on other drugs.

I. DESCRIPTION OF TREATMENT

Some form of psychotherapy or behavioral therapy is usually considered as a treatment option for virtually all patients seeking treatment for substance use disorders. Treatment seekers typically represent the more severe end of the spectrum of community members who meet criteria for current substance use disorders. Most of those who seek treatment do so only after numerous unsuccessful attempts to stop or reduce substance use on their own. The alternatives to psychotherapy are either pharmacological or structural limitations from access to drugs and alcohol such as in residential setting. Both these alternatives have limited effectiveness if not combined with psychotherapy or counseling. Removal from the substance-using setting is a useful and, sometimes, necessary part of substance treatment but is seldom sufficient, as is shown by the high relapse rates typically seen from residential detoxification programs or incarceration during the year following the patient's return to the community.

The major strategy that is now common to all currently practiced psychotherapies for individuals who abuse substances is to place primary emphasis on controlling or reducing substance use, while pursuing other goals only after substance use has been at least partly controlled. This means that either (a) the therapist employs techniques designed to help the patient stop substance use as a central part of the treatment, or (b) the therapy is practiced in the context of a comprehensive treatment program in which other aspects of the treatment curtail the patient's use of substances (e.g., methadone maintenance, disulfiram for alcoholics, residential treatment). Because people who abuse substances frequently react to increased anxiety or other dysphoric affects by resuming substance use, anxiety-arousing aspects of treatment are typically introduced only after a strong therapeutic alliance has been developed or within the context of other supportive structures (e.g., inpatient unit, strong social support network, methadone maintenance) that guard against relapse to substance use when the patient experiences heightened anxiety and dysphoria in the context of therapeutic exploration.

Psychotherapy to treat substance abuse can occur in a variety of settings. For example, individuals who are severely dependent remain unsuccessful at achieving abstinence may become inpatients or be admitted to a detoxification program. While in the detoxification program, the individual may receive brief directed psychotherapy that focuses mainly on controlling the impulse to use. In partial hospitalization or residential

treatment programs, psychotherapy offered is typically longer in duration, and not only focuses on the impulse to use, but also includes a greater representation of managing and changing behavioral aspects that contribute to or maintain the person's substance use. In outpatient treatment settings, psychotherapeutic treatments often include all the components previously mentioned as well as an opportunity to engage in longer-term treatment that can address broader issues in the patient's life that may indirectly play a role in the individual's ability to remain abstinent.

Beyond setting differences, psychotherapy for substance use disorder may be delivered in a range of different modalities, such as group or individual. Major advantages to group substance treatment are: (a) cost savings, (b) given the social stigma attached to having lost control of substance use, having group members who acknowledge similar problems can provide comfort, (c) group members who have longer periods of abstinence can model that attempting to stop using is not a futile effort, (d) group members can act as social supports, and (e) the public nature of the group can provide powerful incentive to avoid relapse. Principal advantages to individual substance treatment are: (a) privacy for members whose careers or reputations may be damaged from more widespread knowledge of their substance use, (b) increased flexibility to address problems that are uniquely relevant to that patient, (c) easier resolution of logistics surrounding therapist caseloads where often there are not enough substance abuse clients to form a group or deterrent from individuals having to wait to engage in treatment until the group is formed, and (d) therapists may use the one-to-one relationship to explore relational elements not possible in group treatment.

II. THEORETICAL BASES

The history of individual psychotherapy for substance abusers has been one of importation of methods first developed to treat other conditions. Thus, when psychoanalytic and psychodynamic therapies were the predominant modality for treating most mental disorders, published descriptions of dynamics of substance abuse or of therapeutic strategies arose from using this established general modality to treat the special population of individuals who abuse substances. Likewise, with the development of behavioral techniques, client-centered therapies, and cognitive-behavioral treatments, earlier descriptions based on other types of patients were followed by discussions of the special modifications needed to treat substance abuse.

Although always present as a treatment option, individual psychotherapy has not been the predominant treatment modality for substance abusers since the 1960s, when inpatient 12-step informed milieu therapy, group treatments, methadone maintenance, and therapeutic community approaches came to be the fixtures of substance abuse treatment programs. In fact, these newer modalities derived their popularity from the limitations of dynamically informed ambulatory individual psychotherapy when it was used as the sole treatment for substance abusers. Many reported problems with dynamic treatment. Some of the difficulties reported for this form of treatment were premature termination, reaction to anxiety-arousing interpretations with resumption of substance use, erratic attendance at sessions, difficulties posed by attending sessions while intoxicated, and failure to pay fees because money was spent on drugs and alcohol.

Most schools of therapy, with widely varying rationales and strategies, have been adapted for potential use to treat substance abuse. Rather than focus on specific techniques associated with the different approaches, this article focuses on two topics that can guide substance abuse therapy within a variety of different schools: (a) specialized knowledge needed to apply psychotherapy to treat substance abuse, and (b) common goals and strategies that must be addressed by psychotherapists.

A. Areas of Specialized Knowledge to Treat Substance Abuse

1. Understanding the Effects of Using

The principal areas of knowledge to be mastered by the beginning therapist are the pharmacology, use patterns, consequences, and course of addiction for the major types of abused substances. For therapy to be effective, it is useful not only to obtain the academic knowledge about frequently abused substances, but also to become familiar with street knowledge about drugs (e.g., slang names, favored routes of administration, prices, availability) and the clinical presentation of individuals when they are intoxicated or experiencing withdrawal from the different abused substances. This knowledge has many important uses in the course of individual therapy with individuals who abuse substances.

First, it fosters a therapeutic alliance by allowing the therapist to convey an understanding of the addicted person's problems and the world in which he or she lives. This is an especially important issue when the therapist is of a different background from the patient who abuses substances. In engaging the patient, it is

important to emphasize that the patient's primary presenting complaint is likely to be substance abuse, even if many other issues are also likely to be amenable to psychotherapeutic interventions. Hence, if the therapist is not comfortable and familiar with the nuances of problematic drug and alcohol use, it may be difficult to forge an initial working alliance. Moreover, by knowing the natural history of substance abuse and the course of drug and alcohol effects, the clinician can be guided in helping the patient anticipate problems that will arise in the course of initiating abstinence. For example, knowing the typical type and duration of withdrawal symptoms can help the individual recognize their transient nature and to develop a plan for successfully completing an ambulatory detoxification.

Second, knowledge of substance actions and withdrawal states is crucial for diagnosing comorbid psychopathology and for helping the person who is addicted to understand and manage dysphoric affects. Most abused substances such as opioids or cocaine are capable of producing constellations of symptoms that mimic psychiatric syndromes such as depression, mania, anxiety disorders, or paranoia. Many of these symptomatic states are completely substance induced and resolve spontaneously when substance abuse is stopped. It is frequently the therapist's job to determine whether or not presenting symptoms are part of an enduring, underlying psychiatric condition or a transient, substance-induced state. If the former, then simultaneous treatment of the psychiatric disorder is appropriate; if the latter, reassurance and encouragement to maintain abstinence are usually the better course. Over the last decade, co-occurrence of psychoactive substance use disorders with other psychiatric disorders have become much more widely recognized and are of common occurrence in most treatment facilities.

Third, learning about drug and alcohol effects is important for detecting when patients have relapsed or have come to sessions intoxicated. It is seldom useful to conduct psychotherapy sessions when the patient is intoxicated, and when this happens the session should be rescheduled for a time when the patient can participate while sober.

2. Understanding Treatment Philosophies

A second area of knowledge to be mastered by the psychotherapist is an overview of treatment philosophies and techniques for the other treatments and self-help groups that are available to patients who abuse substances. As noted earlier, the early experience of attempting individual psychotherapy as the sole treatment of the more severe types of substance abuse was

marked by failure of an early dropout. Hence, for many individuals who abuse substances, individual psychotherapy is best conceived of as a component in a multifaceted program of treatment to help them overcome a chronic, relapsing condition.

Another major function of knowing about the major alternative treatment modalities for substance abusers is to be alert to the possibility that different treatments may provide contradictory recommendations that may confuse the patient or foster the patient's attempts to sabotage treatment. Unlike a practitioner whose treatment is likely to be sufficient, the individual psychotherapist does not have the option of simply instructing the patient to curtail other treatments or self-help groups while the treatment is taking place. Rather, it is vital that the therapist attempt to adjust his or her own work to bring the psychotherapy in line with the other treatments. It is also important to note that many treatments with high levels of empirical support are not the treatments most widely used clinically.

B. Common Goals and Strategies for Substance Abuse Psychotherapy

This section reviews issues presented by persons who abuse substances that should be addressed, if not emphasized, by any type of individual or group psychotherapy that is likely to be effective. As noted in reviewing the difficulties encountered by early psychodynamic practitioners, the central modification that is required of psychotherapists is always to be aware that the patient being treated is a substance abuser. Hence, even when attempting to explore other issues in depth, the therapist should devote at least a small part of every session to monitoring the patient's most recent successes and failures at controlling or curtailing substance use and being willing to interrupt other work to address slips and relapses when and if they occur.

Implicit in the need to remain focused on the patient's substance use is the requirement that psychotherapy with these patients entails a more active therapist stance than does treatment of patients with other psychiatric disorders such as depression or anxiety disorders. This is related to the fact that the principal symptom of substance abuse, compulsive use, is at least initially gratifying, and it is the long-term consequences of substance use that induce pain and the desire to stop. In contrast, the principal symptoms of depression or anxiety disorders are inherently painful and alien. Because of this key difference, substance abuse psychotherapy typically requires both empathy and structured limit setting, whereas the need for limit

setting is less marked in psychotherapy with patients who are depressed or anxious.

Beyond these key elements, this section also elaborates on key tasks that are common to most approaches to psychotherapy for substance use: enhancing motivation to stop substance use, teaching coping skills, changing reinforcement contingencies, fostering management of painful affects, and improving interpersonal functioning. Although different schools of thought about therapeutic action and behavior change may vary in the degree to which emphasis is placed on these different tasks, some attention to these areas is likely to be involved in any successful treatment.

1. Enhancing Motivation to Stop Substance Use

Even at the time of treatment seeking, which usually occurs only after substance-related problems have become severe, patients usually can identify many ways in which they want or feel the need for drugs or alcohol and have difficulty developing a clear picture of what life without substances might be like. To be able to achieve and maintain abstinence or controlled use, individuals who abuse substances need a clear conception of their treatment goals. Several investigators have postulated stages in the development of ones' thinking about stopping use, beginning with precontemplation, moving through contemplation, and culminating with determination as the ideal cognitive set with which to get the most out of treatment.

Regardless of the treatment type, an early task for psychotherapists is to gauge the patient's level of motivation to stop substance use by exploring the treatment goals. In doing this, it is important to challenge overly quick or glib assertions that the patient's goal is to stop using substances altogether. One way to approach the patient's likely ambivalence about treatment goals is to attempt an exploration of the patient's perceived benefits from abused substances or perceived needs for them. To obtain a clear report of the patient's positive attitudes toward substance use, it may be necessary to elicit details of the patient's early involvement with drugs and alcohol. When the therapist has obtained a clear picture of the patient's perceived needs and desires for abused substances, it is important to counter these exploring advantages of a substance-free life.

As noted earlier although virtually all types of substance abuse psychotherapies address the issue of motivation and goal setting to some extent, motivational therapy or interviewing makes this the sole initial focus of treatment. Motivational approaches, which are usually quite brief, are based on principles of motivational

psychology and are designed to produce rapid, internally motivated change by seeking to maximize patients' motivational resources and commitment to abstinence.

2. Teaching Coping Skills

One enduring challenge of treating substance abuse is to help the patient avoid relapse after achieving an initial period of abstinence. A general tactic for avoiding relapse is to identify sets of circumstances that increase an individual's likelihood of resuming substance use and to help the patient anticipate and practice strategies (e.g., refusal skills, recognizing and avoiding cues for craving) for coping with these high-risk situations. Examples of approaches that emphasize the development of coping skills include cognitive-behavioral approaches such as relapse prevention, in which systematic effort is made to identify high-risk situations and master alternative behaviors and coping skills intended to help the patient avoid substance use when these situations arise.

3. Changing Reinforcement Contingencies

As substance abuse worsens, it can take precedence over concerns about work, family, friends, possessions, and health. As compulsive substance use becomes a part of every day, previously valued relationships or activities may be given up so that the rewards available in daily life are narrowed progressively to those derived from substance use. When substance use is brought to a halt, its absence may leave the patient with the need to fill the time that had been spent using drugs or alcohol and to find rewards that can substitute for those derived from use.

An example of an approach that actively changes reinforcement contingencies is the approach developed by Steve Higgins and colleagues that incorporates positive incentives for abstinence into a community reinforcement approach (CRA). This strategy has four organizing features that are grounded in principles of behavioral pharmacology: (a) substance use and abstinence must be swiftly and accurately detected, (b) abstinence is positively reinforced, (c) substance use results in loss of reinforcement, and (d) emphasis on the development of competing reinforcers to substance use.

4. Fostering Management of Painful Affects

Dysphoric affects are the most commonly cited precipitant for relapse, and many psychodynamic clinicians have suggested that failure of affect regulation is a central dynamic underlying the development of compulsive substance use. To foster the development of mastery over dysphoric affects, most psychotherapies include techniques for eliciting strong affects within a

protected therapeutic setting and then enhancing the patient's ability to identify, tolerate, and respond appropriately to them.

5. Improving Interpersonal Functioning and Enhancing Social Supports

A consistent finding in the literature on relapse to substance abuse is the protective influence of an adequate network of social supports. Gratifying friendships and intimate relationships provide a powerful source of rewards to replace those obtained by drug and alcohol use, and the threat of losing these relationships can furnish a strong incentive to maintain abstinence. Typical issues presented by individuals who abuse substances are: (a) loss of or damage to valued relationships occurring when using substances was the principal priority, (b) failure to have achieved satisfactory relationships even prior to having initiated substance abuse, and (c) inability to identify friends or intimates who are not, themselves, abusing substances. For some types of psychotherapy, working on relationship issues is the central focus of the work (e.g., interpersonal therapy, supportive-expressive treatment), whereas for others, this aspect is implied as a part of other therapeutic activities such as identifying risky and protective situations.

Again, although most approaches address these issues to some degree in the course of treatment, an approach that strongly emphasizes the development of social supports are traditional counseling approaches, 12-step facilitation, and other approaches that underline the importance of involvement in self-help groups. Self-help groups offer a fully developed social network of welcoming individuals who are understanding and, themselves, committed to leading a substance-free life. Moreover, in most urban and suburban settings, self-help meetings are held daily or several times weekly, and a sponsor system is available to provide the person in recovery with individual guidance and support on a 24-hour basis, if necessary. For psychotherapists working with substance abuse, encouraging the patient to become involved in a self-help group can provide a powerful source of social support that can protect the patient from relapse while the work of therapy progresses.

III. EMPIRICAL STUDIES

In general, the existing literature on behavioral treatment for substance dependence suggests the following:

1. To date, most studies suggest that psychotherapy is superior to control conditions as treatment for substance

abuse. This is consistent with the bulk of findings from psychotherapy efficacy research in areas other than substance use, which suggests that the effects of many psychotherapies are clinically and statistically significant and are superior to no treatment and placebo conditions.

2. No specific type of behavioral treatment has been shown consistently to be superior as a treatment for substance abuse or for other types of disorders as well. However, behavioral and cognitive-behavioral therapies may show particular promise.

3. The studies examining the differential impact of effectiveness of psychotherapy on those who abuse substances with and without coexistent psychopathology indicate with some consistency that those therapies shown to be generally effective were differentially more effective with patients who presented with high levels of general psychopathology or depression.

4. The effects of even comparatively brief psychotherapies appear to be durable among substance users as they are among other populations.

A. Specific Psychotherapy Approaches

In the following section we briefly describe some of the most promising behavioral therapies for substance use that have at least a minimal level of empirical support from randomized clinical trials. Although this is not exhaustive, many of these approaches are making their way into the field.

B. Contingency Management Approaches

Perhaps the most exciting findings pertaining to the effectiveness of behavioral treatments for cocaine dependence have been the recent reports by Higgins and colleagues discussed briefly earlier in the article. In this approach, urine specimens are required three times weekly to systematically detect all episodes of drug use. Abstinence, verified through drug-free urine screens, is reinforced through a voucher system in which patients receive points redeemable for items consistent with a drug-free lifestyle that are intended to help the patient develop alternate reinforcers to drug use (e.g., movie tickets, sporting goods). Patients never receive money directly. To encourage longer periods of consecutive abstinence, the value of the points earned by the patients increases with each successive clean urine specimen, and the value of the points is reset when the patient produces a drug-positive urine screen.

A series of well-controlled clinical trials demonstrated (a) high acceptance, retention, and rates of abstinence for patients receiving this approach relative to standard 12-step-oriented substance abuse counseling, (b) rates of abstinence do not decline substantially when less valuable incentives are substituted for the voucher system, (c) the value of the voucher system itself (as opposed to other program elements) in producing good outcomes by comparing the behavioral system with and without the vouchers, and (d) although the strong effects of this treatment decline somewhat after the contingencies are terminated, the voucher system has been demonstrated to have durable effects.

Moreover, the efficacy of a variety of contingency management procedures (i.e., including vouchers, direct payments, and free housing) has been replicated in other settings and samples, including cocaine-dependent individuals within methadone maintenance, homeless substance abusers, and freebase cocaine users. The use of contingency management procedures has also been effective in reducing substance use in individuals with schizophrenia and substance disorders in addition to individuals who may be homeless.

These findings are of great importance because contingency management procedures are potentially applicable to a wide range of target behaviors and problems including treatment retention and compliance with pharmacotherapy (i.e., including retroviral therapies for individuals with HIV). For example, in 1996, contingency management may be used effectively to reinforce desired treatment goals (e.g., looking for a job) in addition to abstinence.

However, despite the very compelling evidence of the effectiveness of these procedures in promoting retention in treatment and reducing cocaine use, these procedures are rarely implemented in clinical treatment programs. One major impediment to broader use is the expense associated with the voucher program; where average earnings for patients are about \$600.

Recently developed low-cost contingency management (CM) procedures may be a promising approach to bring these effective approaches into general clinical practice. For example, Nancy Petry and colleagues have demonstrated that a variable ratio schedule of reinforcement that provides access to large reinforcers, but at low probabilities, is effective in retaining participants in treatment and reducing substance use. Rather than earning vouchers, participants earn the chance to draw from a bowl and win prizes of varying magnitudes. In a study of 42 alcohol-dependent veterans randomly assigned standard treatment or standard treatment plus CM, 84% of CM participants were retained in treatment throughout

an 8-week period compared to 22% of standard treatment participants. By the end of the treatment period, 69% of those receiving CM had not experienced a lapse to alcohol use, but only 39% of those receiving standard treatment were abstinent. A controlled evaluation of this promising approach for the treatment of cocaine dependence is ongoing.

C. Cognitive Behavioral/Relapse Prevention Therapy

Another behavioral approach that has been shown to be effective is cognitive-behavioral treatment (CBT). This approach is based on social learning theories on the acquisition and maintenance of substance use disorders. Its goal is to foster abstinence through helping the patient master an individualized set of coping strategies as effective alternatives to substance use. Typical skills taught include: (a) fostering resolution to stop drug use through exploring positive and negative consequences of continued use, (b) functional analysis of substance use, that is, understanding substance use in relationship to its antecedents and consequences, (c) development of strategies for coping with craving, (d) identification of seemingly irrelevant decisions that could culminate in high-risk situations, (e) preparation for emergencies and coping with a relapse to substance use, and (f) identifying and confronting thoughts about substance use.

A number of randomized clinical trials over the last decade with several diverse cocaine-dependent populations have demonstrated: (a) compared with other commonly used psychotherapies for cocaine dependence, CBT appears to be particularly more effective with more severe cocaine users or those with comorbid disorders, (b) CBT is significantly more effective than less intensive approaches that have been evaluated as control conditions, and (c) CBT is as or more effective than manualized disease model approaches. Moreover, CBT appears to be a particularly durable approach, with patients continuing to reduce their cocaine use even after they leave treatment.

D. Motivational Approaches

For individuals with severe dependence who deny the seriousness of their involvement, a course of individual therapy in which the patient is guided to a clear recognition of the problem may be an essential first step toward more intensive approaches. Motivation enhancement treatment (MET) sets out to accomplish this in a brief therapy approach (i.e., 2–4 sessions). In-

cluded in these sessions are typically emphasis on personal responsibility for change with advice and change options, objective feedback of impairment, therapist empathy, and facilitation of patient self-efficacy.

MET has been used to treat a variety of substance disorders, including marijuana dependence. Although marijuana is the most commonly used illicit substance, treatment of marijuana abuse and dependence is a comparatively understudied area to date, in part because comparatively few individuals present for treatment with a primary complaint of marijuana abuse or dependence. Currently, no effective pharmacotherapies for marijuana dependence exist, and only a few controlled trials of psychosocial approaches have been completed. In 2000, Robert Stephens and associates compared a delayed treatment control, a 2-session motivational approach, and the more intensive (14-session) relapse prevention approach and found better outcomes for the two active treatments compared with the delayed-treatment control group, but no significant differences between the brief and the more intensive treatment.

E. Family Therapy

Early intervention with individuals who abuse alcohol has historically been approached in some settings by addressing past crisis caused by the alcohol abuse into one dramatic confrontation by family and friends. This therapeutic approach is designed to combat denial by having family and individual close to the person present the negative effects of the individual's use in attempts to move the individual to agree to get treatment.

Moving beyond initial confrontation, others have included family in ongoing aspects of treatment. Edward Kaufman has identified three basic phases of family involvement in treatment: (a) developing a system for establishing and maintaining a drug-free state, (b) establishing a workable method of family therapy, and (c) dealing with the family's readjustment after the cessation of drug abuse. Where these three stages may vary is based on the substances abused, stage of the addiction, family reactivity, and gender of the individual.

M. Duncan Stanton and William Shadish in 1997 conducted a meta-analysis across 1,571 cases reviewing drug abuse outcome studies that included family couples therapy. Family therapy was seen as more beneficial than individual counseling, peer group therapy, and family psychoeducation. In addition, family therapy had higher retention rates than non-family therapies and was seen as a cost-effective adjunct to methadone maintenance.

F. Manualized Disease Model Approaches

Until very recently, treatment approaches based on disease models were widely practiced in the United States, but virtually no well-controlled randomized clinical trials had been done evaluating their efficacy alone or in comparison with other approaches. Thus, another important finding emerging from recent randomized clinical trials that has great significance for the clinical community, is the effectiveness of manualized disease model approaches. One such approach is 12-step facilitation (TSF). It is a manual-guided, individual approach that is intended to be similar to widely used approaches that emphasize principles associated with disease models of addiction and has been adapted for use with cocaine-dependent individuals. Although this treatment has no official relationship with Alcoholics Anonymous (AA) or Cocaine Anonymous (CA), its content is intended to be consistent with the 12 steps of AA, with primary emphasis given to Steps 1 through 5 and the concepts of acceptance (e.g., to help the patient accept that they have the illness, or disease, of addiction) and surrender (e.g., to help the patient acknowledge that there is hope for sobriety through accepting the need for help from others and a “higher power”). In addition to abstinence from all psychoactive substances, a major goal of the treatment is to foster active participation in self-help groups. Patients are actively encouraged to attend AA or CA meetings, become involved in traditional fellowship activities, and maintain journals of their self-help group attendance and participation.

Within Project MATCH, TSF was found to be comparable to CBT and motivational enhancement therapy in reducing alcohol use among 1,726 individuals with alcohol dependence; the findings from these studies offer compelling support for the efficacy of manual-guided disease model approaches. However, it is critical to recognize that the evidence supporting disease model approaches has emerged from well-conducted clinical trials in which therapists were selected based on their expertise in this approach and were trained and closely supervised to foster high levels of adherence and competence in delivering these treatments, and it remains to be seen whether these approaches will be as effective when applied under less-than-ideal conditions.

G. Combined Treatment Approaches

1. Combining Psychotherapies

At times it can be useful to combine different psychotherapies to treat patients who have ongoing spe-

cialized needs such as in the case of co-occurring disorders or if they are at a point in their treatment where they can benefit from combined approaches that address specific areas of concern. An example of the latter would be individuals in the initial stages of treatment receiving MET in conjunction with relapse prevention to address early treatment issues of decreased motivation to stop using that often occurs initially due to the uncertainty of how life would be without substances.

An example of the former would be combined treatments for posttraumatic stress disorder (PTSD) and substance dependence. Many women receiving substance treatment also meet the criteria for current PTSD. This may often cause the individual to experience a greater severity in the course of their illness than those who have only one of these. Other examples of combined treatments for patients who have co-occurring diagnoses include relapse prevention and exposure therapy for individuals who also have obsessive-compulsive disorder and relapse prevention and motivational long-term approaches for individuals who also have psychotic disorders.

2. Combining Psychotherapy with Pharmacotherapies

At times psychotherapy may be combined with pharmacotherapies to enhance adherence to the pharmacotherapy or synergistically enhance the effects of both treatments. Even when medications have been proven to be effective, dropout from treatment and compliance have still been a problem. Moreover, there has been no study that has demonstrated that the addition of psychotherapy did not help the medication effect.

The most powerful and commonly used pharmacologic approaches to substance abuse are maintenance on an agonist that has an action similar to that of the abused substance (e.g., methadone for opioid addicts, nicotine gum for cigarette smokers), use of an antagonist that blocks the effect of the abused substance (e.g., naltrexone for opioid addicts), the use of an aversive agent that provides a powerful negative reinforcement if the substance is used (e.g., disulfiram for alcoholics) and use of agents that reduce the desire to use the abused substance (e.g. naltrexone and acamprosate for alcoholics). Although all of these agents are widely used, they are seldom used without the provision of adjunctive psychotherapy, because, for example, naltrexone maintenance alone for opioid dependence is plagued by high rates of premature dropout and disulfiram use without adjunctive psychotherapy has not been shown to be superior to placebo.

Several studies have evaluated the use of contingency management to reduce the use of illicit drugs in addicts who are maintained on methadone. In these studies, a reinforcer (reward) is provided to patients who demonstrate specified target behaviors such as providing drug-free urine specimens, accomplishing specific treatment goals, or attending treatment sessions. For example, methadone take-home privileges contingent on reduced drug use is an approach that capitalizes on an inexpensive reinforcer that is potentially available in all methadone maintenance programs. Maxine Stitzer and George Bigelow, in 1978 and 1986, did extensive work in evaluating methadone take-home privileges as a reward for decreased illicit drug use. In a series of well-controlled trials, this group of researchers has demonstrated (a) the relative benefits of positive (e.g. rewarding desired behaviors such as abstinence) compared with negative (e.g., punishing undesired behaviors such as continued drug use through discharges or dose reductions) contingencies, (b) the attractiveness of take-home privileges over other incentives available within methadone maintenance clinics, and (c) the relative effectiveness of rewarding drug-free urine screens compared with other target behaviors. More recently in 1998, Andrew Saxon and colleagues further demonstrated that take-home doses of methadone serve as a reinforcer for abstinence among methadone maintenance program participants by showing fewer restrictions on their availability make them even more effective.

In 1996 and 1998, Kenneth Silverman and colleagues, evaluated a voucher-based CM system to address concurrent illicit drug use, typically cocaine, among methadone-maintained opioid addicts. In this approach, urine specimens are required three times weekly to systematically detect all episodes of drug use. Abstinence, verified through drug-free urine screens, is reinforced through a voucher system in which patients receive points redeemable for items consistent with a drug-free lifestyle that are intended to help the patient develop alternate reinforcers to drug use (e.g., movie tickets, sporting goods). In a very elegant series of studies, the investigators have demonstrated the efficacy of this approach in reducing illicit opioid and cocaine use and producing a number of treatment benefits among this very difficult population.

IV. SUMMARY

Psychosocial treatments should be considered as a treatment option for all patients seeking treatment for

substance use disorders. The treatment itself can take place in a variety of settings including inpatient, residential, partial hospitalization, or outpatient treatment. In more controlled settings the frequency and duration of sessions increases.

Through our review of the literature, it becomes evident that individuals who abuse substances are a heterogeneous group reflecting much diversity. To address this diversity in treatment, it is useful to consider multidimensional outcomes. Consequently, no one form of treatment or psychotherapy is typically seen as universally effective across all substance disorders. However, one major strategy common to all currently practiced psychotherapies is to place primary emphasis on reducing substance use, while pursuing other goals only after substance use has been at least somewhat controlled.

The history of individual psychotherapy to treat substance abuse arose from using already established therapeutic strategies adapted for use to treat a special population of individuals who abuse substances. Most schools of therapy that have been adapted to address substance-related problems share common knowledge and common goals or strategies that must be addressed to provide successful treatment to substance-using populations.

The main areas of knowledge to be mastered by the beginning therapist are pharmacology, use patterns, consequences, and the course of addiction for the major types of abused substances. It is important to go beyond textbook knowledge to street knowledge of frequently abused drugs as well as understand the clinical presentation of intoxicated individuals or withdrawal from different substances to fully understand the clinical picture and to aid alliance.

Common goals and strategies related to substance abuse psychotherapeutic treatment include enhancing motivation to stop using, teaching coping skills, changing reinforcement contingencies, fostering management of painful affects, and improving interpersonal functioning and social supports. The therapist needs to take a more active stance than in the treatment of other disorders such as depression or anxiety disorders due to the principal symptom, compulsive use, being initially gratifying until the long-term consequences of use induce pain and desire to stop.

Our review of rigorously conducted efficacy research on psychotherapies for substance abuse provides support for the use of a number of innovative approaches: individual substance counseling, and cognitive behavioral treatment for cocaine dependence; community reinforcement treatment with contingency management for cocaine dependence; and contingency

management approaches combined with methadone maintenance in the treatment of opioid dependence as well as use with a wide range of other substance use disorders including alcohol dependence. Manualized disease model approaches have been as effective to other forms of psychotherapeutic substance abuse treatments. Substance psychotherapies have been combined with pharmacotherapies to enhance adherence to pharmacotherapies or synergistically enhance the effects of both treatments. Future studies are needed to evaluate the usefulness of combined psychotherapy approaches and further investigate less rigorously studied treatments.

GLOSSARY

operant conditioning The process of increasing or decreasing the frequency of a behavior by altering the consequences that follow the performance of that behavior.

reinforcement Consequences that increase the likelihood that a behavior will increase.

systematic desensitization A therapeutic technique for anxiety reduction in which anxious clients are relaxed and exposed to an incremental, graded series of anxiety-provoking elements that approximate the ultimate event feared by the clients.

Successive approximations are responses that gradually increase in resemblance to the final behavior that is being shaped as part of a therapeutic program to develop new behavior. Shaping is the process of reinforcing responses that successively approximate the final desired behavior. Responses are reinforced that either resemble the final behavior or that include components of the final behavior. As new approximations are reached successfully and reinforced, the earlier ones in the sequence are allowed to extinguish.

I. DESCRIPTION OF USE

Before using successive approximations, a shaping program must be established. The shaping program consists of the following sequence: (1) a determination of the goal behavior and the criteria for successful performance; (2) a determination of the elements that resemble the goal behavior in gradually increasing steps (successive approximations) and a decision about the size of the intervals between steps; (3) a determination of the reinforcers to be given contingently as the incremental behavior is produced; (4) the application of the program. The goal behavior may be anything that the organism is physically capable of producing. It should be clearly specified in ways that may be unambiguously measured. In determining the elements that approximate the goal behavior, it is important to find a beginning point that has some resemblance to the final behavior. The beginning point may be as elementary as raising a hand, turning a head in a particular direction, or making a mark on paper. Progressive sequences of responses leading to the goal behavior and the intervals between the responses must also be determined. These are the successive approximations. The intervals between responses must be small enough so that the organism is able to succeed more often than not, for reinforcement is not given for failed responses. The interval must not be so small, however, that the organism becomes bored or inattentive. The organism may be reinforced at the same step for a short period of time in

order to practice the response, but the demands for performance must be gradually increased sequentially so that the organism does not stop altogether at one step before reaching the goal.

II. THEORETICAL BASES

The procedure of response shaping by successive approximations was developed in the laboratories of Charles Ferster and B.F. Skinner in 1957, where pigeons were trained to peck at a response key. The birds were reinforced at first when their heads moved forward and ignored for all other behaviors. Once the forward movements occurred at a high rate, additional movements in the desired direction of the final goal of key pecking were reinforced. Reinforcements were withheld until the birds moved their heads in gradually increasing distances. Finally, the birds were reinforced for moving their heads in a position directly across from the response key. The pecking response could not fail to occur and the birds were reinforced only for pecking the key, the final desired behavior.

This technique is derived from the operant conditioning theoretical perspective, which holds that when rewarding consequences immediately follow the performance of a particular behavior, that behavior will increase in frequency. The principles of operant conditioning describe the relationship between behavior and environmental events, called antecedents and consequences, that influence behavior. This relationship is called a contingency. Antecedent events are those stimuli that occur before a behavior is exhibited, such as instructions, sounds, and gestures. Behaviors include actions made by an organism in response to the antecedent events. Consequences are those events that follow the performance of the behavior. For a consequence to affect behavior it must be contingent or dependent on the occurrence of that behavior.

In 1958 Joseph Wolpe reported on his work in the development of methods to reduce the laboratory-created experimental neurosis (anxiety) of cats. Wolpe gradually exposed the animals to a series of rooms that successively approximated the features of the room in which the anxiety had originally occurred. When the animals displayed a slight reduction in anxiety in the other rooms, Wolpe encouraged them to eat, reasoning that if the animals could engage in responses that competed with the anxiety response, the anxiety would be overcome. This systematically applied procedure was successful.

Using this information from the laboratory, Wolpe conceptualized the effects of the procedure from the viewpoint of classical conditioning in which environmental cues are said to elicit anxiety or fear responses. Anxiety may then be eliminated by conditioning an alternative response that is incompatible with it. For humans Wolpe used deep muscle relaxation as the competing response to anxiety. While relaxed, anxious clients were exposed to anxiety-producing stimuli, either in imagination or in real life. The stimuli were presented in gradually increasing intensity and resemblance to the original anxiety stimuli (i.e., successive approximations to the original event). As relaxation becomes associated with the anxiety events, the anxiety is reduced. Wolpe called this procedure "systematic desensitization."

III. EMPIRICAL STUDIES

Successive approximations is not a clinical technique per se, but a way of presenting material within a number of procedures. There has been no research on successive approximations independent of the clinical techniques in which it is embedded. The procedures of shaping and systematic desensitization have, however, been extensively reviewed and are presented elsewhere in this book.

IV. SUMMARY

Successive approximations are responses that gradually increase in resemblance to the final behavior that is being shaped as part of a therapeutic program. They are an element in the operant conditioning procedure of shaping and in the classical conditioning procedure of systematic desensitization.

self-system The envelope of all the security operations.

transference The distortion of present experience by past experience as reflected in the patient toward the therapist.

I. INTRODUCTION

GLOSSARY

counter-transference The personal reaction of the therapist to the patient including distortions that the therapeutic training helps him or her restrain.

field of awareness The content of the therapist's conscious attention to the interaction with the patient.

modifying the introject The therapist uses insight to modify by understanding the specific content he or she is experiencing directly from the patient.

object relations theory Within the traditional psychoanalytic framework W.R.D. Fairbairn introduced object relations to refer to the relations between the patient and a significant other person.

preverbalization Thoughts and feelings that give rise to specific language.

schizophrenia A term introduced by Bleuler to replace the term dementia praecox, referring to cognitive and emotional disturbances of a severe degree. Now a term designating a set of syndromes characterized by severe disturbances in thinking and reality perception.

security operations Verbal and nonverbal efforts of many kinds to prevent or ward off anxiety.

selective inattention Perceptions not attended to because they might arouse anxiety.

Harry Stack Sullivan's technique of psychotherapy was strongly influenced by his exquisite sensitivity to any sign of a patient's distress or discomfort in interaction with a therapist—himself or other. His theory of interpersonal psychiatry was the foundation for his practice of psychotherapy. He called his method of psychotherapy participant observation because the significant data included the psychiatrist's thoughts and feelings as well as those of the patient. Although Sullivan expressed an appreciation of Freud's work, it had little influence on his own thinking, which was firmly based on the philosophy of experience.

Sullivan was first and foremost an American psychiatrist, as Helen Swick Perry has brilliantly documented in her book *Psychiatrist of America*. However respectful and sensitive, he was firm, vigorous, and well-disciplined in his approach—contrary to the opinion of his critics who accused him of being too protective of his patients.

Sullivan had an extensive correspondence with Alfred Korzybski who, together with Kurt Lewin, organized their observations to a theoretical field in which many vectors of different force operated simultaneously with their counterparts in interpersonal transactions. Therefore, some part of a personality would

enhance parts of another personality while other parts might diminish or suppress aspects of the other person. This could be elaborated with topological diagrams to clarify the ideas.

II. THEORETICAL BASES

Early in his career, Sullivan published a paper in his journal *Psychiatry* authored by Albert Dunham describing the important work of the American philosopher Charles S. Pierce and comparing it to the European philosophers on the nature of human responses. Pierce's three categories of experience, firstness, secondness, and thirdness, are logically parallel to Sullivan's prototoxic, parataxic, and syntactic modes of experience.

The prototoxic mode of Sullivan is more or less equivalent to the Firstness of Pierce—that is, immediate, instant, forever, here and everywhere, with no differentiation before or after—"unione mystica." With differentiation and past, present, or future, here and there, we have the category of Secondness and the early part of the Parataxic mode, which includes myth, superstition, dreaming, and metaphor. Thirdness includes the logical, consensually validated, or scientific—which is the Syntactic mode of Sullivan.

Sullivan introduced the term interpersonal for the first time in psychiatry in order to emphasize that the treatment, the work that was being done, was something that was done between two people, the patient and the psychiatrist, and not something that was being done to the patient by the psychiatrist. This was also emphasized in his term participant observation, which refers to the psychiatrist and the patient working together on the patient's difficulties in living in order to clarify them and to help the patient develop insight and better ways of coping more effectively.

The purpose of psychiatric treatment is to enhance the development of the syntactic mode of experience, including the range of communication by word, gesture, and movement, between persons—interpersonal processes. In that way the problems of living that are contributing to the patient's distress and/or disablement can be clarified and addressed. Sullivan avoided the terms unconscious, preconscious, and conscious for their lack of precision and consistent meaning. He preferred to use the field of awareness, which ranged in content from unavailable to marginal to focal in its spectrum. This field spectrum can become wider or narrower with specific interactions, verbal or otherwise, blocked or opened up, as the interpersonal area

changes, including the illusory or projected personification of "good me," and "bad me," "not me," as well as those of "good other," "bad other," and "non-other." In this context the psychiatrist or other mental health expert must manifest a precise sensitivity to nuances of speech and subtlety of movement. In this way the psychiatrist could avoid provoking anxiety that interfered with communication while eliciting information that was associated or accompanied by some anxiety. This has been described by others in the literature as coping with the mechanisms of defense. It is described later by Anna Freud in her well-known work *The Ego and Mechanisms of Defense*. Although Sullivan advocated various measures to minimize anxiety he vigorously opposed fraudulent reassurance or falsehood in any form. In his work with the severely mentally ill, he would sometimes use alcohol or mild sedation to help open up channels of communication.

III. THERAPEUTIC RANGE

Sullivan used the term parataxic for the phenomenon of transference and counter-transference—that is, generalizations from past experience that may not be appropriate to the present encounter, and may contribute to distressing interactions with others. As a participant observer, the therapist may reinforce some projections and diminish others. The content of this field of interaction was called the social geography or social landscape by Leston Havens. Sullivan insisted on obtaining detailed and precise descriptions of feelings and context—in one instance having a patient describe the New York subway system.

Sullivan also liked to set some distance by referring to a third party. He said that it is much easier for patients to tell the therapist what is important and unimportant, even about the therapist, if they talk about a third party. Sullivan objected to the patient lying on a couch with the therapist sitting behind the patient. Sullivan preferred to sit alongside the patient at an angle, which is the way I practiced analysis for 25 years, as did Clara Thompson, my training analyst. Sullivan referred to the content of transferences carried by the patient as false expectations, projections, and misconceptions.

For example, Sullivan said:

If a patient says to me "You must think I'm terrible" and I don't feel that is just hysterical drama, but means something, I am apt to say, quite passively "about what?" as if I had not heard anything about such a

notion. Quite frequently, just because my reaction seemed so astonished and annoyed, they tell me, and to that extent I have gotten somewhere.

Thereby he reduces the transference.

Sullivan was more interested in therapeutic change than he was in cognitive insight. This could be seen as deconditioning or in object-relations theory as modifying the introject. In some ways Sullivan's method is analogous to play therapy, with the transference projected onto the narrative or the world "out there."

In addition to correcting the transferences in a profoundly collaborative way, he used what can be called counterprojective statements. These statements talk about the important figure in the patient's life, which draws attention and projection to them. Sullivan may then join the patient in expressing appropriate feelings toward these persons such as desperation and rage. Sullivan was remarkably and dramatically effective with paranoid patients. The first step was establishing empathy with the paranoid person's rage and expressing it. At the same time Sullivan would avoid a direct face-to-face confrontation but would sit alongside the patient, joining the patient in a collaborative effort to look at the world from the patient's side. Third, he would cite some experiences of his own at distressing institutional behavior. However, this must be authoritative and not susceptible to being experienced by the patient as patronizing or false.

Sullivan examined and treated a variety of patients, but his central focus was always on schizophrenia and, to a lesser degree, obsessive-compulsive disorder. He saw conversion hysteria as a substitutive disorder wherein physical symptoms substituted for achievement in promoting an enfeebled self-esteem, and preventing anxiety, that is, the type of anxiety caused by a threat to one's sense of being a worthwhile human being.

Sullivan described the three most basic requirements for the effective psychotherapy of persons with schizophrenia. First, the therapist must review with the patient a survey of his or her conflicted growth and adaptation as skillfully as possible. Second, the therapist must provide some type of healthy "corrective" experiences in the patient's living of his or her life. Lastly, there is collaboration of the patient with an enlightened physician skilled in penetrating self-deceptions with the goal of improving the patient's self-esteem and social competence.

In assessing Sullivan's remarkable success at Sheppard Pratt Hospital it is important to note the linkage to the type of onset: Out of 100 patients who had slow insidi-

ous onset only two went on to a full recovery. Of 78 who had an acute onset, 48 showed marked improvement with most others experiencing a full recovery, according to (Sullivan in 1962.) In the Sheppard Pratt program Sullivan did very little psychotherapy directly with the patients but worked through a staff that he carefully selected, personally trained, and closely supervised.

Sullivan became interested in the criminal mind, the psychopath or sociopath, that had no empathy for fellow human beings, and no concern for anyone's welfare except their own. He expressed an opinion that they were not quite human, and that they should be studied by a method of studying animal behavior. However, he never developed this idea any further.

IV. TECHNIQUE

In his own psychotherapy practice Sullivan preferred to work indirectly with as much collaborative style as could be achieved. By sitting alongside or at an angle to the patient the two together could look at the "social geography" of the patient's life, examining the important relationships therein. In Sullivan's language this would "loosen or attenuate" the parataxes, or in object-relations theory modify the introjects. A corollary of this would be the counterprojective statements that would move the transference (parataxes, distortions) back to the original figures from the patient's past. In doing so Sullivan might not only refer to the significant figure (parent, sibling, etc.) and point it out, but also supply the appropriate feeling of hurt, anger, or rage in a corrective emotional experience.

Sullivan's verbal psychotherapeutic interventions could be described in four categories: interrogative, imperative, rhetorical, and declarative. Although the interrogative direct questions are obviously necessary, the imperative is only subtly apparent in the fundamental rule of free association—the verbal expression of empathy is rhetorical as it communicates the imaginative projection of one's own consciousness into the consciousness of another person. Declarative statements usually are made to clarify or interpret, but Sullivan used them also to direct attention elsewhere, away from the patient and therapist to the social field of other people. This is similar to doing play therapy with children. Thus these counterprojective statements move attention away from the patient; they point to the critical figures, and express appropriate feelings by the therapist toward those critical figures, setting an example for the patient. These counterprojective statements are

especially useful in treating a paranoid patient or a psychotic transference. Again this is analogous to using play objects in treating children. Sullivan, in speaking of reconstructing the past, said, "What I would have seen if I had been there." The advantages gained are a clearer perspective on the past, differentiation of the structure (family, teacher, friend) internalized from the past, and best of all, freedom from the past.

In the beginning of this work, and in fact throughout the course of therapy or participant observation, the emphasis and direction were always on the concrete sharing of feelings and experiences in which the feelings and thoughts of the therapist were as important to share when appropriate as were the patient's. However, the therapist's only gratification from this experience was exercise of their competence and the pay that was received. He or she would not pursue friendship, gratitude, prestige, or anything else.

Sullivan never accepted general, vague, or speculative statements at face value. He would always try to pin down specifically and concretely what the patient was referring to, and that way the patient might become more aware of something that previously he or she had not paid attention to. Naturally, this required a very intense concentration on the part of the therapist, and a very disciplined approach to paying attention to what the patient meant by what was said. Therefore, theoretical hypotheses, structures, and jargon are completely avoided in accumulating very accurate and precise information. Therefore, Sullivan advocated questions that would be more productive than the interpretations. He also recommended attention to nonverbal communication of feelings such as a facial expression, tilting of the head, or a raising of the eyebrows that would communicate something to the patient that would be helpful in bringing out more useful data. In confronting delusional ideas that were communicated by the patient the therapist can show his or her puzzlement or questioning but should never flatly contradict or show a nonacceptance of this. The therapist should never pretend that he or she understands something when he or she does not. It is much better to say frankly that he or she does not understand and to ask for clarification or further explanation. In asking such questions the therapist might prefer indirect questions as they are less likely to be anxiety provoking, and they may yield more information than a direct question does. Indirect questions might also bring more attention to the interpersonal aspects of what was going on in the interaction between the two people referred to, rather than an attribute of somebody. Of course, at all times with either direct or indirect inquiry such questions for seeking more useful

information and helping the patient should not in any way undermine the patient's self-esteem.

Sullivan was also very active as a therapist. He was opposed to the more traditional psychoanalytic position of passively listening to whatever the patient brings out. Instead, the therapist pursues data, striving for more details and more precise information until the issue is very clear and the patient understands it, and can go on to the next thing. Sullivan not only tended to avoid interpretations but he even objected to the word interpretation, which has an authoritarian aspect to it. Instead of using the word interpret he would employ words like comment, inquire, point out, indicate, and so on. There is a difference of viewpoint. He also recommended when pointing out particular aspects or data to a patient that the therapist should not try to do too much all at once but rather pace oneself properly so the patient has time to assimilate it, and express his or her own reaction to it. The therapist thus allows the interaction between the two of them to be productive, rather than to cut it short by overloading the patient with too much information at one time.

The thrust of the patient's work with the therapist is to become more aware of what goes on between himself or herself and other people, particularly the ones who are most significant in their life. To the extent that he or she can formulate this in words and share it with another person, namely the therapist, he or she is able to be in better health, and to be more effective in dealing with his or her problems in living. Therefore the work of therapy very often consists of paying attention to many small details that help the patient become more aware and to be able to use this awareness more effectively.

Sullivan believed very strongly that there was an innate movement toward health in the person and this thrust toward mental health would be more active as the barriers to it were removed in the collaboration between the therapist and the patient. Therefore, the therapist was never seen as curing the patient or making the illness go away; the therapist was seen as helping the patient be healthier and more competent in handling the emotional and personal problems of their life.

Sullivan uses the term anxiety in a way that is different from its general use in medicine and everyday life. He uses it as a category of all kinds of emotional anguish such as fearfulness, tenseness, guilt, inferiority feelings, shame, self-loathing, eerie feelings of personality change, and all other forms of emotional distress. Anxiety can vary in degree from a scarcely noticeable fear to incapacitating panic. There has to be some anxiety in order to know that you are getting somewhere, doing something useful; therefore, it is important for the therapist to (as it were) keep the

finger on the pulse of anxiety to keep it manageable and constructive rather than interfering.

Sullivan was very skeptical about the value of direct reassurance. He saw that many schizoid and obsessional patients were able to respond to direct reassurance by having no response whatsoever and not allowing it to have any impact on them. Therefore indirect assurance was the only kind of assurance that would be effective. Sullivan was also very skeptical about the expression of admiration, gratitude, and affection from the patient. He did not believe that patients had enough feelings for themselves to be able to afford to appreciate him much. He believed patients may feel worthwhile only because this wonderful person is interested in them, but that is not very clinically useful and is not going to do them much good in their lives. It is much better that they discover how more effective and competent they are than they thought; and if that means disappointment in the therapist, that is beneficial. Being disappointed in themselves and feeling more inadequate is not of benefit, and indicates that their therapy is not going too well.

Sometimes the therapist can pick up anxiety that is blocking the patient by listening carefully to the pauses, missing data, and distortions in an account that the patient is giving them. The anxiety tends to block out an awareness of events, and things happening in the event, so by paying close attention, one may pick up on what is missing, and then find out what the anxiety was, and what it was all about. Rather than giving empty reassurance to the patient's anxiety, it is better for the therapist to specify the nature of the anxiety and the context in which it arose. For example, if the patient is feeling very angry with his parents it may make him feel guilty to point that out. It might be helpful for the person to be oriented to where he is emotionally because the anxiety interferes with the process. It may seem like stating the obvious, but when a person is in the midst of a breakup of a relationship, it may be useful to simply spell out the distress that the person is experiencing in the context of the breakup and how natural and normal it is to suffer such distress. Some people feel ashamed and embarrassed that they are a patient seeking help from a mental-health expert for their problems. This can be spelled out with the patient and put into its proper context. In doing such explorations with a patient, Sullivan was particular in adhering to objective data taking place in real time and a real place, and to not encourage the patient to go off into descriptions of fantasies. This is something he did not encourage and did not think was valuable. He believed it might even encourage unrealistic thinking; daydreaming might be present at times but it does not solve any problems.

Sullivan used the term security in a much broader sense to mean the opposite of anxiety: a sense of personal adequacy, or personal worth, personal value, or strong self-esteem and a complete lack of the negative feelings of worthlessness and other emotional distress. He saw the polar opposites of anxiety and security as being in a continual state of movement, trying to balance against each other like opposite ends of a see-saw. The ways of enhancing security and avoiding anxiety were called security operations by Sullivan and they could be either healthy or unhealthy. A healthy security operation increased a person's effectiveness and emotional health, and an unhealthy one could impair the interpersonal relationship. They are different from the Freudian notion of defense because the notions of defense occur in a hypothetical mind-structure and are not observable, whereas the security operations of Sullivan are behavioral.

Sullivan's whole system might be called a cognitive behavioral system. One of the unhealthy or sometimes healthy security operations is selective inattention. This occurs when individuals observe only a part of what is happening in their environment between them and authorities so that they pay attention to some things and avoid paying attention to others. This is analogous to Freud's concept of repression. Selective inattention is always an ongoing activity between two or more people whereas repression can be something between a person and himself in his mind. Sullivan was a fairly rigorous taskmaster in keeping the patient focused on the matter at hand, and not letting the patient go off into empty discussions of trivial subjects that were not particularly relevant to the basic problems for which help is being sought. Sullivan also discouraged pseudo-compliance wherein a patient becomes very eager to please and agrees with everything the therapist says without really confronting his or her issues. It is a way of dismissing the whole investigation with faint praise. Another way of avoiding confronting something that is painful or distressing is to get angry about something that is not to the point, and in the angry exchange the therapist may be put on the defensive unless he or she realizes what is happening.

The self-system is not exactly the same thing as the ego of psychoanalytic theories. The self-system that Sullivan refers to is what is characteristic of the individual and what defines that individual as a person that is known. Thereby the self-system protects patients against distress and enables them to live as comfortably as possible so that they can feel (that is, identify) who they are, and that they are worthwhile and recognized as such. The self-system is not something that exists as a thing in

time and space. The self-system is simply a verbal convenience, a phrase to refer to an envelope of protective movements and ethics that the patient makes to avoid distress. The therapist must therefore use his or her skill to enable the patient to feel more worthwhile, and safer, and with more self-esteem while exploring relationships and experiences that might provoke embarrassment, shame, or other kinds of distress.

Sullivan paid great attention to this aspect of giving a kind of reassurance that was not sentimental, false, or difficult for the patient to assimilate. He would indirectly always provide a way for patients to see themselves with greater dignity and self-respect. Nonetheless, as Sullivan rigorously pursued the details of the patients' experiences with the important other persons in their life, it would provoke some distress. Sullivan was very careful to note this distress and to try to be helpful with it. Sometimes he would suggest a healthier, more constructive, way of dealing with a problem situation that the patient had never considered. When the patient is presented with the novel approach it must be something reasonable and practicable for the patient to follow.

Behavior and feeling patterns that recurrently characterize interpersonal relations—the functional interplay of persons and personifications, personal signs, personal abstractions, and personal attributions—make up the distinctively human sort of being. Sullivan characterized the manifestations in the interpersonal relations of activities as integrating, disjunctive, or isolative. He sometimes referred to the zones of interaction in which behavior takes place in interpersonal relationships, such as the oral zone, genital zone, anal zone, muscular activity zone, and so on. But he rarely referred to these zones.

In the course of treating very seriously ill persons Sullivan noticed that they sometimes manifested what he called a malevolent transformation. This occurs when the therapist or another person has shown a greater manifestation of tenderness and expression of a caring closeness to the patient than the patient is able to bear in his own experience of himself. Therefore the patient manifests a sense, or a feeling of hatred and hostility, and may even attack the person who is being tender and loving to him.

Sullivan did pay some attention to dreams but he never referred to it as dream interpretation. He would pick out salient features of the dream and then present them to the patient to ask the patient what the patient thought of it. For example, there was a dream of a Dutch windmill that the patient had in which everything was rack and ruin and when the patient finished reporting the dream Sullivan picked out two details,

that the windmill was beautiful, active on the outside but utterly dead and decayed within, and the patient responded, "My God, my mother." Although this might be seen by others as interpretation it actually was presenting some details to the patient in such a way that the patient was able to use the dream, and use these details to get some insight into the relationship with his mother that he had not seen before. Sullivan not only showed a great respect for dreams and their content but he also showed much respect for the fantasies a patient might present. He objected strongly to the dismissal of these fantasies as mere wish-fulfilling fantasies. He insisted that they might actually provide some creative foresight and planning for the future.

The therapist needs to be aware of what he or she is communicating nonverbally to the patient as well as what the patient is communicating to him or her consciously or otherwise. Sullivan was against the idea of the therapist sitting behind the patient where he or she could not be seen, which reduces nonverbal communication to some extent, but of course it did not eliminate it. Sullivan was very much aware of the particular meanings that vary from one language or culture pattern to another. When therapists are not familiar with the language, or the cultural context of the patient, they may be misled by words or gestures from the patient. Because of Sullivan's experience with anthropology he was able to bring a much more sensitive cross-cultural awareness to his work.

In a case seminar with Dr. Kvarnes, an associate at Chestnut Lodge, Sullivan brought out the importance of looking at the apparent devotion and love of the patient's parents for him and seeing what there was in it that could be constructive for the patient. It could also be harmful in being overprotective. Sullivan was exquisitely sensitive not only to overprotective movements and gestures by significant people in the patient's life but also to overindulgence, which can be equally sabotaging of the patient's self-esteem.

A personified self is the whole fabric of how the patient presents himself and sees himself in relation to other people. He may mean that when important people around him are upset he retreats and withdraws. If they upset him, also, that may mean that he cannot stand stress very well. However, he might mean that he has much inner emotional calm and secure self-respect that will enable him to cope with stress in a very effective manner.

Another area that is useful to explore is what the patient imagines about his future. It is good to encourage the patient to speculate about what he will be doing 3 years or 5 years or 10 years from now. However, if this arouses undue feelings of despair and hopelessness, one

should not permit that to go on. In every case, in all categories of illness and types of patients, Sullivan was rigorously pursuing the precise and exact data of the patient's experience: What did occur, when did it occur, where did it occur, who was there, what did they say, what did they do, and so on. Sometimes the patient gets upset without the therapist knowing what the upset was triggered by, and what it is all about; one cannot let that pass. The therapist must investigate it and find out what has upset him, and what can be done about it.

Sullivan sometimes used what he called preverbalization when things were not going well with a patient; this is not the same thing as Freudian free association. Free association is usually employed as a method of therapy over a period of months or a year, whereas Sullivan used preverbalization as a tool for alleviating a block or a difficulty in communication. When there has been stagnation, he asked the patient to tell him everything that came to his mind about this particular aspect of his life. In the course of the interview in clarifying and straightening out misunderstandings, and the events and experiences of the patient's life, it was important for him to not only avoid any jargon himself but also to discourage the patient from using technical terms such as psychosis, complex, and so on. That way he could get down to the "nitty-gritty" and not be bogged down in terms of which neither person knew exactly the meaning.

Sullivan felt very strongly that the patient should get a summary of the important content of the interview or the course of treatment at some point. This could be done just before saying goodbye. The course of treatment could be summarized after each session. The therapist could give a summary of what was noteworthy in the session, and an anticipation of what will be looked for in the next meeting. In the course of such summaries the therapist may repeat the fact that he or she is a skilled person who has special training and knowledge; that the therapist is there to help clarify the problems that the patient has, and to help resolve them. This helps to keep the therapist/patient relationship on a professional level and reminds the patient of what he or she is about, and not to get lost in various distortions of what the therapist would like or fears or other anticipations that are not grounded.

Sometimes a patient who is grateful toward the therapist may experience a sexual urge to show his gratitude by submitting to a sexual experience, to giving the therapist sexual pleasure. In such cases the therapist needs to simply express an appreciation, and point to the fact that such an experience would be destructive to the therapeutic relationship. The professional nature of their relationship must be preserved so that work

can go on, and the patient can get the most benefit from the relationship.

Sullivan was very familiar with the phenomenon of loneliness and stressed the important and powerful role it could play, referring to it as a driving force.

Sullivan had considerable experience of loneliness in his childhood and adolescence. He emphasized very strongly the importance of intimacy, and the devastating character of its lack from infancy throughout development to early adult life. He called loneliness or the need for intimacy one of the major integrating tendencies of life. He carefully separated it from other needs such as the need for satisfaction of lust.

Sullivan was very interested in the subtle and sometimes minute consequences of personal statements made to a patient. For instance, when a nurse told him some information about a patient, he was careful not to invade the patient's privacy by frankly communicating this to him. Instead he would do it indirectly so that the patient did not feel that people were spying on him. He did not want to undermine the patient's sense of confidence in the nurse's interest and her communication with him. He expected that their privacy would be fully respected. For example, the patient might confide something to the nurse that Sullivan felt was important to investigate and so Sullivan might say to the patient that he did not know how the nurse got this idea but he was glad that she was interested enough to speak to him about it. He would then ask the patient what he thought about it and what it was all about. In that way he got into it without violating the confidentiality of the nurse/patient relationship and at the same time he was able to explore this important information.

V. SUMMARY

In conclusion, it must be emphasized that Sullivan avoided jargon, theoretical systems, and language pertaining to such. He was very compassionate and at the same time very vigorous in collecting significant data from the patient that would be useful and helpful to the patient in living his or her life. Sullivan said that growth is still possible for the fortunate ones: If they are fortunate the growth goes on and on, they observe, formulate, and validate more and more; at the same time foresight continues to expand so that they can foresee their career line, not as it inevitably will be, but in terms of expectation and probability, perhaps with provisions for disappointment. Sullivan viewed a human as an enduring pattern of human relationships and also as a whole person, unique and alone. To him

the structure of our human being and the core of our self-esteem is one with the continuity of specific kinds of relationships. The integrity of the self is one with the integrity of relating to others; reality of the self is one with the reality of the relationship, the "I am" of identity with the "you are" of identity—the enduring patterns of relatedness, with the whole person, alone in his uniqueness, related in his humanness.

GLOSSARY

evaluation Feedback in supervision allows the therapist to take distance from the therapy and is a form of ongoing evaluation.

parallel process The therapist re-creates the therapy in the supervision. This parallel process provides a guide to understanding the therapy.

supervision A relationship between a supervisor and a therapist to help the therapist more effectively engage in a purposeful relationship with a patient.

supervisor An individual experienced in psychotherapy and teaching.

therapist An individual engaging in helping patients with psychological problems.

ticeship to learn the craft of psychotherapy. A hermeneutic model provides an understanding of this process. The model holds that supervision is concerned with the meaning found in the supervisor–student interaction about patient-related issues. This is craft learning that as Alan R. Tom notes implies “an inexhaustible rule structure” because the “application of routinized skill sequences often fail to bring about desired results.” The skilled therapist has the ability to analyze situations and has a broad range of therapy strategies that are then applied to a specific situation. In supervision, the student provides data about what occurred, and new knowledge is constructed in the supervisory interaction. Issues cluster around problems, which are analyzed by supervisor and student who then revise strategies for dealing with them. Over time there is an increasing understanding of problems, and the focus is on new concerns. The supervisory interaction provides new ways of framing problems and strategies to deal with them. The supervision process allows for the resident to take distance from psychotherapy and provides a method of ongoing evaluation of the psychotherapy.

I. CONDUCT OF SUPERVISION

A basic task of the supervisor is to provide a trusting relationship in which the student therapist can openly discuss work with the patient. An accepting and non-judgmental attitude provides the context for the therapist

to share unique concerns raised by the patient in an atmosphere of safety. Indeed, the alliance with the supervisor is at the center of supervision experience. So valued is this relationship that many former trainees view supervision as one of the most important elements of training. The supervisor allows the therapist's story about the therapeutic encounter to develop. Indeed, the identification and the tracking of the therapist's central and affectively charged concerns about the patient are essential elements of supervision. Different terms describe the therapist's concerns: blind spots, conflicts, difficulties, dilemmas, impasses, issues, lack of mastery, lead or main themes, problems, troubles, worries, and from the educational literature, messes.

A focus on the therapist's immediate experiences and an orientation to the specifics of the material are also essential to supervision. Indeed, therapist's concerns should be dealt with in the context of the material. Inquiry should be kept within the parameters described by therapist staying close to the understanding of the moment. For example, recommendations for interventions should be linked to issues presented by the therapist. Seemingly general questions should be reframed to focus on specific issues raised in the session. Similarly, each session is taken on its own understanding. Themes from previous sessions should be acknowledged in the changing context of current material. This is disciplined behavior on the part of the supervisor.

An accurate view of the patient using data provided by the therapist has the effect of affirming the therapist's observational and reporting skills. Even what is not discussed is perceived as an affirmation that the therapist's conduct with the patient is adequate.

Early, the novice therapist has to learn how to handle the data of the psychotherapeutic interaction and to maximize the production of new information. They learn over time how to discern problems and be able to share them with the supervisor. The task of the supervisor is to facilitate such discussion. In addition, a language of discourse develops between teacher and student about the patient interaction. The student's language and conceptual framework best guide this development.

Technical comments and jargon terms are used sparingly and in the context of the therapist's data. In addition, theoretical discussions are generally infrequent. This is in keeping with an early report by Joan Fleming and Theresa Benedict of the supervision of psychoanalytic candidates who called these discussions "surplus learning." Although scientific data and theory enhance reflection, such discussion should be also tied to the specifics of the material presented by the therapist.

The downside of not being in touch with the student therapist's concerns and not exploring underlying issues as well as interfering with the development of the therapists' story is to leave the novice therapist without direction or insight into the care of the patient. This leads to the therapist feeling discounted, devalued, and resentful.

Different methods of presentation of material from therapy sessions yield different information and are suitable for different tasks. Videotapes as well as audiotapes of actual sessions minimize distortion of what goes on in the therapy session. Videotapes have particular value early on in the supervisory experience. Discussion of videotaped data can alert the student therapist to the complexities of the interaction and are useful in group supervision. Audiotapes and detailed notes of the therapy (called process notes because they are filtered through the therapist) are more commonly used in supervision. In part, the use of each is a matter of personal preference. Audiotapes require a review of the tape by the therapist before the supervisory session. This allows the therapist to be an active participant. A downside of audiotapes as well as videotapes is that they are inefficient. For instance, observation of supervision using audiotapes reveals that considerable time is spent listening to the tape with minimal interaction between supervisor and therapist. Here, both supervisor and therapist are observed looking at the tape recorder as if it were the patient. Some supervisors base their discussion on the therapist's free-flowing summary of the session. Although this method addresses the therapist's understanding of the therapy it may be more suited to supervision of experienced therapists who have learned the complexities of therapeutic interaction. Notes drawn from an actual session force the therapist to capture the interaction and focus on problems raised in the interaction.

A. Focus of Comments: Parallel Process

The therapist recreates his or her view of the therapy in the supervision. In this sense, the therapist's data parallels what goes on in the therapy. An awareness of this parallel process provides a guide for the supervisor to help the therapist understand the therapy and is at the heart of supervision. The various levels of feedback implicitly use the parallel process strategy.

In terms of frequency, comments made by supervisors are directed at four levels:

1. Understanding the patient
2. Relationship of patient to therapist

3. Relationship of the therapist to patient
4. Relationship of therapist to supervisor in the context of understanding the patient

1. Understanding the Patient

The bulk of supervisory comments are directed to helping the therapist further understand the patient's actions, thoughts, and feelings. This is done through reframing the therapist's understanding of the patient. Questions about the meaning of a patient's comments should have continuity with the material and be asked in an open-ended manner. This leads the therapist to develop a broader understanding of the patient and the interaction.

Special attention is necessary for highly charged clinical dilemmas. These often involve the therapist's concerns about safety for themselves or for patients who are self-destructive, suicidal, angry, or violent. Guidance about dealing with these situations helps defuse the therapist's sense of helplessness. However, supervision based solely on management of difficult patients is better suited for supervision of more structured clinical experiences such as patients who are seen in an emergency center.

2. Relationship of Patient to Therapist

The most frequent relationship comments are directed to helping the therapist understand the patient's view of therapy or that relationship to the therapist.

3. Relationship of Therapist to Patient

Less frequent, although highly valued by therapists, are comments directed to deepening the therapist's understanding of concerns about his or her role in the interaction. The supervisor can reframe the interaction to help the therapist understand the role in the interaction. The highest praise is for the supervisor who uses a strategy of helping the therapist understand responses to the patient. This is a strategy for deepening the therapist's understanding that is particularly useful when the therapist feels immobilized. This level of discussion catches deeper levels of vulnerabilities and encourages the therapist to be more appropriately direct and active. Moreover, such concerns are highly personal. They can take many years to fully professionalize and can remain active for a considerable period of time after training.

Supervisors of developing professionals often acknowledge therapist's concerns about the impact of personal life experiences on the care of their patient. These concerns can involve poignant and emotionally intense experiences. Some are coincident with similar experi-

ences in the patient's life. These include the impact on treatment of their own depression, transition to chief residency, impending marriage, divorce, pregnancy, and adoption of a child, or grief over the death of a loved one. Former therapists remain thankful for such discussions years after the supervisory experience and rate these supervisors as among the best of their training.

An adult developmental perspective is useful for understanding therapists' interest in discussing personal issues that affect their work. For therapists, the domain of work and caring for patients is at forefront of their lives. Usually, one other domain, perhaps two, are also operative in therapists' lives. The other domains include intimate relationships, family, religion, and community. Activity in these domains allows for the expression and gratification of deep values and needs. An important element in the professional developmental process involves integrating work with the other domains. This is a highly personal process that can involve considerable emotional conflict.

4. Relationship of Therapist to Supervisor

A discussion of the therapist-patient relationship in the context of the supervisory relationship can highlight issues in the therapy but has to be easily integrated with the therapist's data. This level of discussion is used infrequently but can be quite helpful in dealing with therapist's issues.

II. TERMINATION

Novice therapists worry about how well they are doing with their patients and how their patients will do after termination. Many worry that they have failed their patients and feel guilt over possible inappropriate termination plans. Some have unrealistic expectations of outcome and what can reasonably be accomplished. Discussion of expectations of outcome should be ongoing rather than just at termination. In addition, discussion of termination should focus both on clarification of the therapists' expectations of outcome as well as patient outcome.

III. EVALUATION

The feedback provided by the supervisor is a form of ongoing evaluation. This is called formative evaluation and is in contrast to the evaluation given at the end of a teaching period called summative evaluation. Here the

supervisor summarizes what has occurred over the course of the supervision and provides recommendations for ongoing learning.

IV. CHARACTERISTICS OF THERAPISTS

The novice therapist's lack of experience in the conduct of psychotherapy can result in considerable emotional intensities. Indeed, the intensity of concerns about competence is easy to underestimate. Such concerns involve a sense of inadequacy to the task, feeling at a loss of how to conduct oneself with patients, and that others can do better. These underlying concerns can be acknowledged but do not need to be a major focus of discussion. Rather, the value of a sympathetic supervisor who acknowledges personal concerns provides a framework for helping the therapist achieve a sense of mastery. Indeed, development into a mature therapist takes years after training. With time, the student develops a personal style.

The ability among therapists to discuss and deal with problems varies considerably and guides the supervisor in the level of discussion. Indeed, supervisors adapt to the pace of the therapist's learning and adjust their discussion to the level of the therapist. Indeed, once a supervisory relationship is established, because of the variation in therapist abilities, it is difficult to discern the year of training by the level of sophistication of the presentation or the discussion. The range of therapist abilities mitigates against stage theories of learning supervision. Such theories posit stages of development as a psychotherapist based on year of training. These theories do not emphasize the personal development of the therapist.

V. LEARNING TO BE A SUPERVISOR

Discussing supervisory dilemmas with experienced colleagues is useful. This can be done in an ongoing group and is helpful for supervisors at all levels of experience. This discussion can aid the supervisor in understanding whether the problem is specific to the interaction, or a general problem that the therapist has with other supervisors. For instance the therapist may not be able to be open about discussing concerns about

the patient. Such discussion can empower the supervisor to make appropriate interventions and also replicates the supervision process. Reading papers and texts on supervision is useful in orienting the supervisor to the conduct of supervision. However, they are often general and need to be applied to a specific situation.

Learning to be a supervisor is a matter of experience with a number of different therapists. Most supervisors initially model their behavior on their supervisory experiences during their training. They draw from these relationships until they develop a distinct supervisory style of their own. This also takes years to develop. Interestingly, supervisory behaviors become relatively stable even with different therapists.

VI. OUTCOME OF SUPERVISION

The intended outcome of the supervisory interaction is the transfer of new understanding to the patient encounter along with the transfer of patterns of interaction to other psychotherapeutic encounters.

empirically validated treatments Treatments that are designated as effective because of their relative performance in comparative treatment studies.

meta-analysis A collection of data across many studies that is summarized quantitatively.

researcher's allegiance The belief of a researcher in a treatment's efficacy—the bond between researcher and treatment.

GLOSSARY

alliance The concept of the therapeutic alliance, which refers to the positive bond that develops between patient and therapist.

blinding The use of controls on human judgments where the judges are restricted from access to information that could contaminate them.

cognitive-behavioral therapy A well-known form of psychotherapy that is built on the concepts of belief systems and consequent dysfunctional attitudes.

core conflictual relationship theme (CCRT) A method of formulating the essence of the relationship pattern between patient and other people, including the therapist. It is derived from the repetitions of the themes across the narratives in the sessions.

correlation A statistic in which the level of association of one item with another is computed.

dynamic A well-known theory of psychotherapy based on Sigmund Freud. It involves an assessment of both conscious and unconscious aspects of behavior and the concept of conflicts among the patient's wishes and other behaviors.

empirical As used here, it refers to the inclusion of a reliance on quantitative methods for data analysis.

I. DESCRIPTION OF TREATMENT

Supportive-expressive (SE) dynamic psychotherapy is now a standard form of psychotherapy. It was developed in the early 1940s at the Menninger Foundation and it has continued to be practiced there and in many other places around the world. In 1984, I published a book on supportive-expressive dynamic psychotherapy explaining the principles, procedures, and empirical supports for doing that psychotherapy.

The attractions to therapists for practicing this form of psychotherapy are multiply based: (1) it is a dynamic psychotherapy, (2) it is adaptable in terms of treatment length and applicability to patients with a wide range of severity and wide spectrum of diagnoses, and (3) it has the convenient capacity to be able to mix supportiveness and expressiveness so that the more severely sick patients are treated by greater supportiveness and lesser expressiveness and vice versa for less severely ill patients.

My books describe the two main formats of SE: time open-ended and time-limited psychotherapy. In 1998, Howard Book dealt with time-limited treatment and gave

an unusual example: a verbatim complete case as treated by SE short-term psychotherapy. For most treatments the decision about the use of short-term versus open-ended treatment can be made even before the treatment starts, or sometimes in the early sessions. Most commonly, the time open-ended treatment is the preferred choice because with that the length of treatment tends to be a function of the patient's needs and wishes. When time-limited psychotherapy is the option chosen, it tends to be based on considerations of the limited time available, or considerations of the needs of a research protocol or of the preferred practice in a particular treatment setting.

A. How to Begin a Supportive-Expressive Psychotherapy

1. Treatment Arrangements

In the opening phase of psychotherapy, usually in the first session, treatment arrangements must explicitly be made. They include the frequency of sessions (usually one or two per week), the cost of each session, the method of payment, the handling of missed sessions, and a guide for the patient's style of speaking—the patient should speak about whatever is on the patient's mind, as well as the patient can.

2. Setting Goals

In the early phase of treatment, the setting of goals is essential. In the early sessions, and throughout the treatment, the patient should specify what it is that he or she wishes to change. That is a crucial first step because it can lead to achievement of the goals and to changes in the patient's goals. Both the patient and the therapist should be working toward the achievement of the same goals, and progress is gauged in terms of the achievement of these goals.

3. Development of the Therapeutic Alliance

The hope of both patient and therapist is that in the early sessions, and certainly as the treatment goes on, a relationship will be formed between patient and therapist of greater trust, rapport, and alliance. As examined by Safran, Muran, and Samstag in 1994 at times there is an oscillation between movement toward a rupture in the alliance that is usually followed by a movement toward reestablishing a positive relationship.

4. Focusing Interpretations around the Core Conflictual Relationship Theme

Starting early in the treatment, the therapist, and then the patient, will be able to understand and

respond more effectively to the patient's problems. The therapist, by following the Core Conflictual Relationship Theme (CCRT) method described in 1998 in Luborsky and Crits-Christoph, will be able to formulate the central relationship problem. It is this pattern that will help the therapist to focus interpretive responses on aspects of the central relationship pattern and it is this focus that helps the therapist to shape the treatment into a focal treatment. The word "focal" means that the treatment is based on the gradually greater understanding of the main relationship pattern, which continues throughout the treatment and thereafter. There are likely to be major changes in understanding and behavior in the course of the treatment, but mostly there is a broadening, deepening, working through, and a mastering of the central theme.

B. Supportive Procedures and Principles

According to the dynamic theory of psychotherapy, a supportive relationship is vital.

1. Sigmund Freud in 1913 advised that the therapist's basic attitude should be as a sympathetic listener. Most comparative studies of psychotherapies actually have similar amounts of supportiveness, as shown in 1983 in Luborsky, Crits-Christoph, Alexander, Margolis, and Cohen. The most necessary supportive component, of course, is that the therapist is there to be helpful and to help the patient achieve the patient's goals and that the patient recognizes this.

2. In most psychotherapies a rapport with the patient is developed, which, in turn, develops into a therapeutic alliance. The alliance tends to improve when progress has been made and is recognized; in turn, the alternative sequence can also be that when progress has been made the alliance tends to improve, as shown by Tony Tang and colleagues in 2000.

3. A variety of measures of the alliance have been developed. These measures include two main types: self-report measures (for example, for self-ratings of the helping alliance), and the observer-judged alliance measures as developed by Luborsky in 1976 and 2000.

4. Paradoxically, the joint search for understanding can be classified under supportiveness as well as under expressiveness, for it can be both—the giving of interpretations can be experienced by the patient as supportive and the giving of interpretations also provides the patient with understanding.

C. Expressive Procedures and Principles

The other broad category of technique besides supportiveness is expressiveness. Expressiveness refers to the state of the patient that permits the patient to express his or her thoughts and feelings as fully as possible. The therapist then uses what is expressed by the patient to frame interpretations of the main relationship themes that are drawn from aspects of the CCRT as described by Luborsky, a theme that is reevaluated by the therapist in each session. The patients then use the therapist's responses, as well as their own knowledge of themselves to advance in mastery of their relationship conflicts. This sequence is essentially what is done in dynamic psychotherapies and in psychoanalysis.

The therapist tries to help patients to be free enough to share thoughts about themselves and their main problems in several ways:

1. Within each session, the therapist often responds to the patient by offering facets of the CCRT. The therapist should not try to encompass the entire CCRT in each of the few interpretations given, but instead, presents the separate components from time to time, so that the patient has a chance to build up a concept of the broader pattern of the relationship themes.

2. In the course of each treatment, there will be times in the sessions in which the patient's alliance moves toward a near-rupture, as noted earlier. These alliance shifts tend to occur when the patient experiences the relationship with the therapist in terms of a major negative pattern in the patient's CCRT.

3. Some expressions of the components of the CCRT can be thought of as a test of the relationship with the therapist. It has been shown in Weiss and Sampson and their research group in 1986 by examination of patients' responses that it is helpful for the treatment that the therapist pass the test.

4. The movements toward mastery are an important aim in psychotherapy. In the course of the sessions, most patients will succeed in achieving improved mastery of the relationship conflicts as shown by Brin Grenyer in 1996.

D. Ending Treatment

Both in time open-ended and in time-limited treatment, as the treatment ending approaches, the patient and therapist remind each other of when the termina-

tion will take place, so that they will be prepared. If a reference to termination does not happen spontaneously from the patient's side, the therapist will often bring it up.

Treatment endings tend to correspond to the achievement of the patient's goals; patients tend to complete treatment when they have achieved at least some of their goals, and even in a time-limited treatment some of the goals tend to be achieved.

A common event toward the end of treatment is the resurgence or reemergence of the initial symptoms. This event typically implies that the patient experiences the anticipation of not seeing the therapist at a time when the patient does not recognize that he or she has enough of a reliable internalized image of the therapist and the treatment. Usually, even a brief review by the therapist of the meaning of such recurrence of initial symptoms tends to bring back the patient's level of control.

II. THEORETICAL BASES

My 1984 book on the principles of psychotherapy explained and exemplified the principles for doing supportive-expressive psychotherapy. These principles were mostly based on Sigmund Freud's 1912 and 1913 writings on dynamic psychotherapy and on SE adaptations of Freud by Robert Knight in 1945 and other collaborators, including Karl Menninger.

III. APPLICATIONS AND EXCLUSIONS

One of the attractions of SE psychotherapy is its broad applications in terms of degrees of severity and varieties of diagnoses. Even the most severely ill patients can be treated through modifications of the method in terms of increased supportiveness and decreased expressiveness of SE psychotherapy, whereas the reverse is feasible for less severely ill patients.

IV. EMPIRICAL STUDIES

There are about 50 studies dealing with the uses and the effectiveness of supportive-expressive psychotherapy. Some representative studies are given in the Further Reading section of this article and in the books by Luborsky.

These are two typical examples of empirical studies: (1) Supportive-expressive psychotherapy for depression has been frequently studied, as reviewed in the 1984 book, the SE patients performed well. One of these studies is a comparison of patients diagnosed with major depression versus with chronic depression; there were no significant differences in outcomes in these two groups; (2) in the National Institute for Drug Abuse study of cocaine addiction four treatments were compared: supportive-expressive psychotherapy, cognitive-behavioral psychotherapy, drug counseling, and group psychotherapy. The results were that the supportive-expressive and cognitive-behavioral groups were not significantly different in their outcomes, but the most effective of the four in this study was the drug counseling.

It is also worth noting that the comparisons of one form of psychotherapy with another form of psychotherapy tend to show nonsignificant differences between them. This was true for supportive-expressive psychotherapy as well as for other psychotherapies. To cite some examples: In 1983, Woody, Luborsky, McLellan, and colleagues found nonsignificant differences between supportive-expressive psychotherapy and cognitive-behavioral psychotherapy for opiate addicts. In the psychotherapy for cocaine abuse, supportive-expressive and cognitive-behavioral therapies were not significantly different in their outcomes and also were not as effective as drug counseling, as reported by Crits-Christoph, Siqueland, and colleagues in 1999.

A meta-analysis summarizing the results of comparisons of different psychotherapies, such as Paul Crits-Christoph's in 1992, showed nonsignificant differences were most common. In 1993 analysis by Lester Luborsky and Louis Diguier showed a similar nonsignificant tendency.

In conclusion, there is not a lot of reliable consistent evidence for the special advantages of any one psychotherapy over another. In fact, the major positive evidence from comparative treatment studies is marred by a major limitation, that is, treatment comparisons are not done blindly by the researchers and perhaps cannot even be done blindly. The probable effect of this is that the differences in researcher's allegiance to forms of psychotherapy correlates very highly with the differences in outcomes of the treatments—the correlation is .85, according to a study by Luborsky, Diguier, and Seligman in 1999! Until such findings have appeared, the research field has been involved in a highly enthusiastic search for what are called “empirically

validated treatments.” The outcomes of these treatment comparisons have, in fact, even become part of advertisements as the “winners” of these comparisons. Unfortunately, the facts are that the field has to recognize the ambiguity of comparative treatment results, as just stated.

In summary, in practice it has become clear that the “empirically validated treatment comparisons” are ambiguous in their implications. The combination of the ambiguity introduced by the researcher's allegiance effect, as well as of the older problem of nonsignificant differences among the treatments compared, means that the field has a distance to go in terms of generating a trustworthy set of comparisons of one form of psychotherapy with another.

V. CASE ILLUSTRATIONS

Howard Book in 1998 offered a vivid, complete, and highly instructive book including a case illustration of a supportive-expressive psychotherapy in a generally well-functioning patient who developed a very positive alliance with her therapist.

Another example explains in greater detail the operation of the CCRT. Mr. EH, age 18, was a college student with problems of guilt, anxiety, sporadic pain in his penis, difficulty in dealing with a new girlfriend, and resentment of his parents. As a youngster he had never felt close to his father but had felt very close to his mother. He often felt he could not experience closeness from others. The seriousness of his conflicts were difficult to evaluate. They seemed either a worsening of normal adolescent development with intense guilt over sex or there was a thought disorder involved with his wishing to be an exalted spiritual leader. The start of his treatment also showed that he had difficulties in being assertive and becoming separate from his family.

The relationship episodes in his session 3 contained six condensed examples. These six relationship episodes are followed here by a CCRT formulation in which the most frequent components are summarized: He wishes to be close, the other person rejects him, and he feels rejected, ashamed, and upset. What follows below are brief summaries of the six relationship episodes that he told during session 3 of his psychotherapy and the CCRT scoring of each one. This CCRT, as is usual, formed the basis for the interpretations given by the therapist:

CCRT Scoring	Precis of First Six Relationship Episodes
	<i>Mother #1</i>
W: To get info about sex (W1): To get closeness RO1: Rejection RS1: Feel rejected RS2: Shame RS3: Upset	This might have been a dream. Mother says it didn't happen. Up until we moved, when I had questions about sex, mother would explain to me. One day I asked and she said, "Sorry E. we can't talk about that anymore. You're getting to that age." Bothered me 'cause my young sister went into fits of laughter.
	<i>Mother #2</i>
W: Get in bed with parents (W1): To get closeness RO1: Rejection RS1: (Rejected)	Mother said this never happened: we, brother and I—before sister was born—when it was really cold, would sleep with parents. Parents took my brother in bed with them and they wouldn't take me.
	<i>Therapist #3</i>
W: To get rapport (W1): To get closeness RO1: Rejection RS1: Feel blank (empty)	T: What's happening now? P: I feel generally unresponsive. I'm getting a headache, tense, been thinking all week about relating all this stuff to what I was 10 years ago (sigh) and not getting any—I mean, nothing comes out ... like groups of guys who have embarrassing silences. It proves no perfect rapport exists. I feel blank.
	<i>Mother #4</i>
W: To kiss mother RO1: M. criticizes him RO1: Rejection, kissing stopped RS1: Rejected, out in the cold	Before I went to school I always used to kiss mother. I'm not sure it was a big thing, but it was a big thing when it stopped. She made a big thing about how I didn't want to kiss her anymore. I was suddenly out in the cold again.

(W1): Closeness to girlfriend RO: Doesn't like me RO1: Rejection, broke off RS2: Self-blame RS1: Rejected ("severed") RS3: Upset	<i>E (girlfriend) #5</i> I'm beginning to feel a lot of resentment to E (girlfriend). I went with her for a couple of years. It's just been severed. I'm fearful of seeing her and feeling something for her. She just doesn't give a damn. Bothered me I used to be so screwed up about her.
(W1): To get a response RO1: Rejection RS: Resentment RS1: Rejected	<i>Mother #6</i> One thing that started my resentment against my parents. I told her about E (girlfriend) that everything was cut off. I said E's not writing and it upsets me. She said, "Well, I'm sure about you and you aren't sure about her." That really cut me up because she ... she ... a ... assumes between us is like between E and me.
<i>N</i>	<i>Total CCRT Formulation</i>
6 Wish 1 6 Response from other 1 6 Response from self 1 2 Response from self 2 2 Response from self 3	W1: To be close RO1: Rejection RS1: Feel rejected RS2: Shame RS3: Upset, anxious

VI. SUMMARY

Supportive-expressive psychotherapy is a common form of dynamic psychotherapy. Its main principles are basically derived from Sigmund Freud's as these were shaped by clinicians at the Menninger Foundation, starting around 1940. In each session the therapist allows the patients to express themselves in their own way and to choose their own goals. A main technique for helping the patient is provided by the therapist who formulates the patient's main conflictual pattern of relationships in terms of the Core Conflictual Relationship Theme. It is the patient's main pattern of relationships, especially those that are conflictual; this pattern of relationships is derived from narratives about relationships that the patient tells during each session. The treatment is called

supportive-expressive because supportiveness and expressiveness are the two main techniques that the therapist uses. When the treatment conditions are more supportive, the therapist provides support when needed; when the help is more expressive, the therapist provides help with understanding by using what the patient expresses in interpretations. The length of the treatment is either time open-ended or time-limited. The treatment comes to a close when the main goals have been achieved and there has been sufficient occasion to work through the meanings of termination in order to optimize the retention of the gains.

Symbolic Modeling

Michael A. Milan

Georgia State University

- I. Description
- II. Theoretical Basis

- IV. Summary
- Further Reading

instruction manuals, and books. Silent reading, as well as imagining a model or one's self engaging in behavior, are considered covert forms of symbolic modeling.

GLOSSARY

- imitation** The behavior of an observer that is similar to that of a model and that occurs subsequent to the observation of modeling.
- model** The individual or character who is observed and demonstrates the behavior that is to be imitated.
- modeling** (1) The act of demonstrating the behavior that is to be imitated and (2) the general term describing the treatment procedure.
- observer** The individual who observes and imitates the behavior of the model.

Symbolic modeling is one of two general forms of modeling: live and symbolic. In live modeling, the model is actually present and models behavior "live." In symbolic modeling, the model is not actually present but instead is pre-recorded, drawn, or described. Symbolically modeled behavior is typically presented on videotape or film; in animated or still cartoons; and in narratives read aloud by another, listened to on audiotape, or read silently to one's self from printed handouts,

I. DESCRIPTION

In its most basic form, symbolic modeling is a process in which one individual sees, hears, or reads a depiction of the behavior of a real or fictional individual or character and then engages in behavior that is similar to the behavior that was observed. Although the initial research on modeling focused on overt motoric behavior, more recent research has also explored the effects of modeling on covert affective and cognitive behaviors. The results of that research confirmed that modeling is indeed an important contributor to the acquisition and modification of both overt and covert behaviors, and that the manner in which modeling produces its effects is generally the same for both overt and covert behavior.

Although symbolic modeling alone can have powerful effects, it is often a part of multicomponent programs designed to teach social skills, such as assertiveness, anger management, and self-control. It is also often a component of programs designed to treat anxiety disorders, such as social phobias, agoraphobia, and animal phobias. Symbolic modeling can serve five general functions: It can teach a new behavior or skill that is demonstrated by a model; it can reduce anxiety by depicting a model

engaging in a feared activity or making contact with a feared situation with no untoward consequences; it can encourage or disinhibit behavior by depicting positive consequences following modeled behavior; it can discourage or inhibit behavior by depicting negative consequences following behavior; and it can elicit or facilitate behavior by serving as a prompt to engage in the behavior at a particular time or place.

II. THEORETICAL BASIS

Since first recognized and studied by psychology, what is now typically referred to as modeling has been known by a variety of other terms, including observational learning, vicarious learning, identification, copying, matching-to-sample, and contagion. In their efforts to understand the modeling process, researchers have examined several theoretical issues raised by modeling and imitation, four of which will be discussed here. The first issue is whether the ability to imitate is innate or acquired. The general consensus among scientists in the field now is that the ability to imitate a broad range of behaviors modeled by a variety of both live and symbolic models is primarily an acquired skill.

The second issue involves the role of operant conditioning in modeling and imitation. Researchers have concluded that operant conditioning plays an important role in the acquisition and modification of overt, motoric behavior, as when a mother reinforces an infant when the infant produces a vocal sound similar to that the mother has made and as a result is more likely to imitate that and other vocalizations, or a child observes other children behaving aggressively and then does so as well.

The third issue involves the role of respondent conditioning. Again, researchers have concluded that respondent conditioning is primarily involved in the acquisition and modification of covert, emotional behavior, as when a child is terrified by a filmed depiction of a traumatic event happening in a dark room and as a result is fearful of dark rooms. Conversely, symbolic exposure to fear-producing stimuli can contribute to the deconditioning or extinction of anxiety responses in the treatment of anxiety disorders.

The fourth issue involves the adequacy of operant and respondent conditioning in the explanation of the full range of modeling and imitation phenomena. Cognitive theorists claim that conditioning theories ignore central processes. The cognitivists in general, and ad-

vocates of a social learning theory explanation in particular, postulate that a consideration of the action of a variety of intervening variables, such as anticipation, symbolic coding, and cognitive organization is necessary for an adequate understanding of the effects of modeling.

III. EMPIRICAL FINDINGS

Both live and symbolic modeling have long been accepted as an important contributor to the acquisition and modification of behavior. The major advantages of live modeling are that it typically allows more participatory learning and greater individualization of the content, pacing, and repetition of the modeled material to maximize its impact on the observer than does symbolic modeling. The major advantages of symbolic modeling are that it typically allows the modeling of behavior in situations that cannot be either practically or safely created live, it permits the widescale dissemination and cost-effective utilization of the modeling materials in a variety of settings, and it enables the assignment of homework or "self-study" modeling experiences as part of the course of treatment.

Several guidelines for the effective use of modeling have been identified. They address the characteristics of the observer, the characteristics of the model, and how modeling is conducted. The findings most relevant to the design of modeling programs will be noted here. The observer must have an adequate repertoire of imitation skills. If an assessment of the strengths and weaknesses of the observer indicates that the observer has not mastered the ability to imitate, imitative behavior must be taught.

The observer must attend to both the model and to the relevant aspects of the modeled behavior. Again, if assessment indicates that the observer does not have these skills, they must be taught; if the observer has these skills but does not use them, prompts must be provided and/or contingencies must be arranged to foster their utilization. Finally, the observer must imitate the modeled behavior. If the observer does not, impediments must be identified and eliminated and/or contingencies must be analyzed and altered to foster imitation.

To maximize the effects of modeling, the model should be similar to the observer and/or have high status or prestige for the observer. The modeled behavior should be expected to result in naturally occurring positive consequences for the model, such as the granting

of a request, rather than arranged consequences, such as the award of a token. Modeling should portray a naturally occurring positive outcome for the model as a result of the modeled behavior. Models should be portrayed as coping successfully with the problems or tasks confronting them rather than achieving complete mastery and/or exhibiting flawless performance. To the degree possible, a variety of models using a number of variations of the skills being taught should be shown dealing with a range of problems or tasks in an array of settings appropriate to the observer.

The difficulty or complexity of the modeled behavior should be matched to the characteristics and abilities of the observer. More difficult or complex behavior should be broken down into components or approximations and taught in sequence. Self-instructions should be taught in order to assist observers to guide themselves through expected performances and deal with impediments to successful outcomes if they arise. Observers should be taught to evaluate their behavior, identify the strengths and weaknesses of their performances, and then self-reinforce for the strengths and determine how the weaknesses may be remediated. The modeled behavior should be actively practiced by the observer after it is modeled, and the practice should include feedback, reinforcement, and correction. Finally, arranged prompts and reinforcement that have been used to foster acquisition and performance of the modeled behavior should be faded out during the course of training to maximize the likelihood that the behavior will occur and maintained under natural conditions.

IV. SUMMARY

Symbolic modeling consists of a recording, depiction, description, or imaginal portrayal of behavior. The person demonstrating the behavior is termed the model; the actions of the model are termed modeling; the person observing the model is termed the observer; and the subsequent behavior of the observer that is similar to the modeled behavior is termed imitation. Explanations of symbolic modeling and imitation rely on operant conditioning, respondent conditioning, and cognitive social learning processes. Modeling has been shown to be effective in the teaching of overt behavior, such as social skills and anger management,

and in the treatment of covert behaviors, such as fear and anxiety.

Successful modeling programs should include an assessment of the observers' strengths, weaknesses, and natural environment. The program should then be matched to observers' strengths, weaknesses, and the characteristics of their natural environment. Factors to be considered include the attributes of models, and the complexity and natural consequences of the modeled behavior. A variety of models, situations, and behaviors resulting in successful outcomes should be presented. Coping rather than mastery should be emphasized, and ample opportunities to practice and refine imitative performance should be provided. Prompts and reinforcement should be used as necessary to facilitate learning and performance and then faded out to foster success in the natural environment.

GLOSSARY

conditioned inhibition In the learning theory of Clark L. Hull the repetition of a learned response is accompanied by the buildup of a fatigue-like tendency to not respond called reactive inhibition. Stimuli present at the time of reactive inhibition become conditioned stimuli for inhibition or conditioned inhibitors.

counterconditioning An approach to learning associated with the theory of Edwin R. Guthrie; a relevant stimulus is maintained intact while a substitute response is practiced in its presence.

exposure technology Associated with Isaac Marks; refers to a therapeutic orientation according to which prolonged exposure to fear cues is the sole requirement for treatment success, and no interest is shown in how or why exposure produces beneficial outcomes.

extinction Associated with Ivan P. Pavlov's learning theory; denotes the repeated presentation of a conditioned stimulus in the absence of any unconditioned stimulus. Sometimes refers to the response decrement that follows from repeated presentations of a conditioned stimulus alone.

habituation The decrement in a response due to repeated, predictable presentations of a stimulus. Sometimes habituation is said to be limited to unconditioned responses. Usually habituation refers to decrements in the neural substrate of behavior.

hierarchy As used in behavior therapy; a listing of verbal scenarios that describes situations in which a fearful person gradually confronts fearsome objects and/or events.

progressive relaxation training An approach to learning how to relax developed by Edmund Jacobson. Different groups of muscles are repeatedly tensed and relaxed in sequential order "up" or "down" the body while the different feedback from tense versus relaxed muscles is contemplated and deeper relaxation is suggested.

reciprocal inhibition The physiologist C. S. Sherrington's term that denotes the inhibition of neuronal activity by the activation of other, reciprocally inhibiting, neuronal activity. As used by Joseph Wolpe reciprocal inhibition refers to the inhibition of sympathetic activation by parasympathetic dominance.

spatiotemporal hierarchy A hierarchy for systematic desensitization in which increasing the fearsomeness of successive scenarios is accomplished by reducing the times and/or distances separating the patient from the frightening encounter.

SUD scaling The patient is taught to assign numbers from 0 (calm) to 100 (terrified) that reflect the level of fear or subjective units of discomfort (SUDs) associated with targeted activities or objects.

thematic hierarchy A hierarchy for systematic desensitization in which increasing the fearsomeness of successive scenarios is accomplished by increasing the clarity or poignancy of focal themes such as "being watched," "being criticized," "suffocating," "being confined."

Systematic desensitization is a venerable behavior therapy technique developed by Joseph Wolpe for the treatment of fear- and anxiety-related disorders. Systematic desensitization includes three basic procedural elements. The patient is taught to relax his or her voluntary musculature using a procedure known as progressive relaxation training. Concurrently the patient and therapist develop detailed descriptions of realistic encounters with the objects and/or events that provoke fear or anxiety, and arrange those descriptions in order of fearsomeness. Finally the patient is guided to visualize the scene descriptions in increasingly fearsome order while taking care to maintain a relaxed muscular state. In addition, treatment based on systematic desensitization often entails encouragement to rehearse the targeted encounters in real life after they have been visualized calmly. Systematic desensitization helped launch the behavior therapy movement and was the first psychological treatment that produced behavioral improvement reliably.

I. DESCRIPTION OF TREATMENT

A. Relaxation Training

As noted above one basic procedure in the use of systematic desensitization is training the patient to relax the voluntary musculature. Usually the training is done according to the “progressive relaxation” techniques that were developed by Edmund Jacobson during the 1930s. Ideally relaxation training is done using a procedural guide and detailed transcripts such as those in the manual provided by Douglas A. Bernstein and Thomas D. Borkovec in 1973 and in the book provided by Marvin R. Goldfried and Gerald C. Davison in 1976. Ordinarily the available transcripts for relaxation training provide the following: (1) a subdivision of the skeletal musculature into a number of muscle groups, usually 16; (2) a set of instructions that will produce tension in each of the muscle groups; and (3) another set of instructions that focus attention on the different sensations that arise from tense versus relaxed muscles. In the widely used manual of Bernstein and Borkovec there are transcripts also that subdivide the muscles into eight and four separate groups.

The 1976 book by Goldfried and Davison contains valuable information about how to set the stage for relaxation training, including information about such things as the purpose of relaxation training and how being deeply relaxed will feel. After the stage is set ac-

ording to those or similar guidelines the therapist is ready to begin. The first step in relaxation proper is to demonstrate various exercises that will be used, exercises that create discernible tension in several groups of muscles. The second step is to encourage the patient to seek clarification about the exercises and, as needed, to repeat one or more of the demonstrations. In the third step the therapist reads the relaxation transcript with a few points in mind: (1) A training “trial” for a muscle group is a tension-relaxation cycle. After instructions for tensing a specific muscle group have been read, 10 seconds or so are allowed for maintaining the tension. At that time instructions for relaxing or “letting go” are read, after which another 20 seconds or so are allowed for relaxing and for attending to feedback differences from tense versus relaxed muscles. (2) Each muscle group is used for at least two consecutive trials. (3) The muscle tension should be easily discernible but not extreme. (4) The muscle groups will be relaxed in some progression (i.e., from the feet to the head-neck).

Some therapists provide patients with tape-recorded relaxation instructions and encourage them to practice relaxing at home. There is evidence that “live” relaxation is better than taped relaxation. Hence, taped relaxation is best viewed as an adjunctive procedure. If home practice of relaxation is important, then the patient should be instructed to record and submit regularly a diary of when, where, and how well he or she relaxed on each occasion.

B. Hierarchy Construction

Relaxation training usually takes from five to seven sessions. During this time the therapist and patient can construct what is known as a “desensitization hierarchy” provided that care is taken to construct the hierarchy when the patient is not relaxing. Behavioral assessment will have provided the information necessary to begin hierarchy construction. The information will include a complete and detailed listing of the various cue-stimuli for fear as well as a tentative arrangement of the fear stimuli according to groups. Each group of fears that has a common thread will ultimately be arranged into a single hierarchy or increasingly fearsome listing of targeted scenarios.

The most common types of desensitization hierarchies are spatiotemporal hierarchies and thematic hierarchies. In spatiotemporal hierarchies, increasing the fearsomeness of successive scenarios is accomplished by decreasing the times and/or distances that separate the patient from targeted encounters. For example, the

times and distances separating a socially phobic student from a dreaded classroom speech can be reduced systematically from days, to hours, to minutes. In thematic hierarchies, increasing the fearsomeness of successive scenarios is accomplished by increasing the clarity or poignancy with which the scenario captures the fearsome theme. Given the same socially phobic student, for example, the successive scenarios in a public-speaking hierarchy could entail increasing scrutiny and/or increasing likelihood of failure. Choosing between spatiotemporal and thematic hierarchies is not always straightforward, nor is grouping disparate fears to form thematic hierarchies. The most common approach to the problem of grouping is to use traditional phobia categories. Wolpe, for example, arranged 14 “different” fears into four hierarchies: acrophobia, agoraphobia, claustrophobia, and fears related to illness.

The most common procedure for constructing desensitization hierarchies was developed by Wolpe and is called SUDs scaling. In this procedure, the patient is first taught to assign a numerical value of 0 subjective units of discomfort (SUDs) to reflect absolute calmness, and to assign a numerical value of 100 SUDs to reflect the most extreme fear imaginable. Each potentially useful scenario in a given hierarchy is then assigned a SUDs rating and the scenarios are ordered in terms of increasing fearsomeness. Then scenarios are dropped and new ones added until the first scenario (hierarchy item) is rated near 0 SUDs, and the zenithal scenario is rated near 100 SUDs. As is described later, each hierarchy of fearsome scenarios provides for systematic “exposure in imagination” to attenuated, then intermediate, than maximally fearsome forms of the cue stimuli for fear. Each successive scenario should be more fearsome than the last but the difference should not be over 10 SUDs at any point in the hierarchy and should be quite small toward the upper end of the hierarchy. The scenarios incorporated into the hierarchy should sample comprehensively the objects, events, situations, or themes that cue fear responses. Each scenario should be relatively complete and, where possible, relatively concrete. Initial hierarchies can be modified as desensitization proceeds and response to treatment can be monitored.

C. Systematic Desensitization

Systematic desensitization proper typically is performed in one of two ways. In the “orthodox” procedure the patient is first exposed to abbreviated relaxation training. (Abbreviated relaxation training is

accomplished, after thorough training, by using fewer than 16 muscle groups, for example 8 or 4 groups as described by Bernstein and Borkovec.) Next the therapist instructs the patient to visualize for 10 to 15 seconds the least aversive hierarchy scenario and to signal by elevating an index finger if the visualization is accompanied by discomfort or fear. If the patient does not signal the presence of fear, then he or she is instructed to relax and, later, to visualize the scenario again. If the visualization occasions no fear on this second trial, then a 30 to 60 second period for relaxing follows and the next scenario on the hierarchy is presented for visualization. This process is repeated again and again as progressively more fearsome scenarios are visualized. Should the patient signal that fear is present, he or she is instructed to stop visualizing and relax. After time for relaxation the scenario is visualized again. If the fear signal recurs, then the therapist repeats the previously desensitized scenario and, after relaxation, repeats the troublesome scene. If the patient still signals the presence of fear, then the therapist and patient construct, on the spot, a new scenario that stands between the troublesome scenario and the last one that was successfully negotiated. Orthodox imaginal desensitization is complete when the most fearsome scenarios are visualized without fear signals.

Joseph Wolpe introduced the “improved” procedure for systematic desensitization in 1973. Here again treatment begins with abbreviated relaxation practice. Then the patient is instructed to visualize the appropriate scenario and to signal, by raising an index finger, when the imagery is clear. The therapist allows 10 to 15 seconds after a signal for the patient to continue visualizing fearsome material, then instructs the patient to drop the images and report orally a SUDs rating of the fear experienced during visualization. In this procedure visualization of each fearsome scenario is repeated until the patient reports 0 SUDs. “Improved” desensitization in imagination is complete when the patient visualizes the zenithal scenario(s) and reports that no fear was experienced.

Beyond the basic techniques discussed earlier there are a number of important considerations at the level of procedure. Discussions of specific procedures are available in Wolpe’s various books and in the book by Goldfried and Davison. The following subset of those recommendations shows the flexibility of the approach.

1. The therapist should view any hierarchy as tentative and should be prepared to add, modify, or delete exact scenario descriptions as needed.

2. Multiple hierarchies should be dealt with simultaneously; no more than three or four scenarios in any given hierarchy should be dealt with during a given session.

3. Desensitization proper should last 20 to 30 minutes per session; sessions should occur at daily to weekly intervals.

4. Once a particularly troublesome scenario has been visualized calmly, it should be visualized repeatedly before the next one is attempted.

5. Throughout desensitization the patient should be reminded to include himself or herself as a participant in the scenarios. He or she is not merely visualizing fearsome situations, but is visualizing himself or herself behaving within the fearsome scenarios.

6. The patient should be encouraged to participate in the targeted real life scenarios after they have been imaginably desensitized; such participation should lag somewhat behind progress in imaginal desensitization.

II. THEORETICAL BASES

There are a dozen or so theories that explain how or why systematic desensitization brings about fear reduction. Many of them are only partial theories, nearly all are *post hoc* in nature. Theorizing about the causal efficacy of desensitization represents in microcosm many of the ills that have plagued general and clinical psychology for the past half century.

A. The Legacy of Learning Theory

The psychology of learning during the 1930s and 1940s incorporated several competing theoretical systems (e.g., the systems of Edwin R. Guthrie, Clark L. Hull, and Edward C. Tolman). There was not much disagreement about experimental data. The major facts of acquisition, extinction, generalization, discrimination, and the like were, for the most part, consensually endorsed. Nonetheless there was spirited argument at the seemingly basic levels of “what” was being learned, “what” was being unlearned, and so forth. Hull spoke of “habits.” Tolman spoke of “expectancies.” Guthrie spoke of S-R bonds.

Joseph Wolpe chose to articulate his explanation of desensitization effects using the language of Hull (see below). When he did so he invited rejoinders in the languages of Guthrie and Tolman. Once Joseph Wolpe’s ideas gained some notoriety, these rejoinders did not take long to appear. Guthrie’s language was used in the

assertion that systematic desensitization embodies “counterconditioning.” Tolman’s language was used in the argument that desensitization works, in part, by engendering optimistic “expectancies.”

B. The Psychotherapy Environment

The field of psychotherapy during the 1950s and 1960s also incorporated competing theoretical systems. Arnold Lazarus, for example, listed 36 psychotherapy systems in evidence as of 1967, adding that his list was incomplete. There was not much disagreement at the level of data in the psychotherapy field either. With the noteworthy exception of Carl Rogers and his followers, data did not play an important role in system development. From such a variegated and uncritical psychotherapy environment, it was inevitable that some would seize on opportunities to explain Joseph Wolpe’s impressive results by recourse to their own preferred explanatory constructs. Thus, the beneficial effects of desensitization were said to depend on “the therapeutic alliance,” on fortuitous psychodynamic accompaniments of desensitization treatment, and the like.

C. Empirical Problems

During the late 1960s and early 1970s scores of articles appeared that were intended to provide experimental answers to the theoretical questions made outstanding by the legacies of learning theory and the environment of psychotherapy. For one example, the outcomes of experiments on systematic desensitization with and without muscular relaxation were styled as evaluating “counterconditioning” versus “extinction” as explanatory vehicles. Unfortunately, the substantive yield from the many papers was confusing and contradictory; theorists remained free to “pick and choose” experimental support for the various explanations afforded by learning and psychotherapy theories.

D. Theories of Fear Reduction from Systematic Desensitization

By and large theories of the active mechanism(s) of systematic desensitization have not been theories at all. Rather, they have been uniformly *post hoc* (and often vacuous) claims that desensitization effects represent something else such as extinction, habituation, counterconditioning, deconditioning, and the like. Furthermore, these and similar concepts have been used

uncritically, even interchangeably, as if the early behavior therapist acquired the lexicon of animal learning but little else.

1. Reciprocal Inhibition and Habituation

According to the reciprocal inhibition theory, systematic desensitization reduces anxiety by causing the cues for the anxiety to become cues for anxiety inhibition. Anxiety is composed of conditioned sympathetic responses. The occurrence of sympathetic responsivity during aversive imaging can be reciprocally inhibited by the parasympathetic underpinnings of concurrent muscular relaxation, provided that the imaging is graduated in fearsomeness. When reciprocal inhibition of the sympathetic response occurs during aversive imaging, the act of imaging acquires an anxiety-inhibiting function. This happens via a mechanism known as conditioned inhibition. Hence systematic desensitization reduces anxiety via conditioned inhibition based on reciprocal inhibition.

According to the habituation theory, systematic desensitization reduces anxiety due to habituation of sympathetic responses to clinically targeted stimuli. Sympathetic responsivity during aversive imaging is made to habituate over repeated imaging trials in much the same way that an orienting reflex habituates over the course of exposure to repeated novel stimuli. Theoretical accounts of habituation differ in minor ways and these differences appear in different renditions of how habituation is produced by systematic desensitization. Muscular relaxation plays a significant role by hastening or facilitating the rate of sympathetic response habituation.

2. Counterconditioning and Extinction

According to a theory based on counterconditioning, systematic desensitization reduces anxiety by causing the cues for anxiety-related behaviors to become cues for other behaviors. The display of emotional behaviors during conditioned aversive stimulation is prevented by rehearsing competing behaviors. (Relaxation is customary but any nonanxious behavior would suffice in principle.) In due course the conditioned aversive stimuli call forth the competing behaviors instead of the anxiety-related behaviors. Muscular relaxation plays a role by providing the substitute behaviors.

Throughout much of the early behavior therapy literature, clinically focal fears were regarded as conditioned emotional (Pavlovian) respondents. Accordingly, systematic desensitization was said to work by promoting respondent extinction. The role of muscu-

lar relaxation, in tandem with graduated exposures, was that of arranging for presentations of fear signals to be unreinforced.

3. A Variant of Exposure Technology

Beginning with Isaac Marks in the mid 1970s, most contemporary writers describe systematic desensitization as a variant of exposure technology. On the surface that characterization is not unreasonable because imaginal exposure is a prominent aspect of the procedure, and *in vivo* exposure is recommended adjunctively. However, characterizing systematic desensitization as a variety of exposure flies in the face of well-known history and does nothing to explain how systematic desensitization works.

4. Cognitive and Social Reinforcement Theories

Albert Bandura and Wallace Wilkins have both offered theories that explain the beneficial effects of systematic desensitization. Initially during the 1970s Albert Bandura developed his broadly applicable idea that “a sense of self-efficacy” is fundamental to success in psychological therapy. Relatively high self-efficacy influences successful outcomes by promoting persistent and vigorous self-change efforts. According to Albert Bandura systematic desensitization operates by increasing self-efficacy; the stronger self-efficacy promotes continued self-change efforts, and so forth.

In 1971 Wilkins offered a fairly elaborate theory explaining the beneficial effects of systematic desensitization. Among Wilkins’ assertions are that systematic desensitization works because the therapist fosters an expectation of therapeutic success; because feedback during treatment affords information that the patient is improving; and because systematic desensitization teaches one how to control the onset and offset of fearsome imagery.

5. Other Theoretical Approaches

The notions that systematic desensitization effects arise from the therapeutic alliance and from fortuitous psychodynamic processes were alluded to earlier. Others have argued that systematic desensitization effects might rest on covert modeling of fearless behavior, or on social reinforcement of motoric approach responses, or on reinterpretations of the meanings of fearsome images. There is also the plausible notion, based on the contemporary work of Peter J. Lang, that systematic desensitization works by modifying the bioinformational import of fearsome imaging.

III. APPLICATIONS AND EXCLUSIONS

Over the past three decades creative clinicians have found numerous applications for relaxation-based fear treatments such as systematic desensitization and its variants. The most common applications have involved various specific phobias and social phobia. But applications to other anxiety-related disorders are not rare. Among the specific phobias with which systematic desensitization has been used are those related to death, injury, disaster, illness, water, storms, animals, birds, reptiles, airplanes, automobiles, injections, ambulances, sanitary napkins, and childbirth. Applications related to social phobia have included "social situations," heterosexual interactions, and authority figures. Among the other anxiety-related disorders treated heretofore with systematic desensitization are asthma, recurring nightmares, repetitive cleansing, chronic diarrhea, and urinary urgency.

For the past two decades clinicians have been opting for *in vivo* treatments that, in the aggregate, are called exposure technology. Hence, the first choice point in deciding to use systematic desensitization for any phobia or anxiety-related disorder is to establish that *in vivo* techniques are not feasible.

After a decision is made to consider using systematic desensitization there must be a relatively thorough assessment of the controlling stimuli for fear and the details of fearful responsivity. (Assessment of the sort used for diagnosis and for exposure treatment is rarely adequate.) Such specific assessment will afford answers to four important questions. (1) Can the cue-stimuli for fear be described in fairly concrete terms? (2) Does the patient show four or fewer different sets of fears? (3) Does the patient report clear imagery related to the fear cues? (4) Does the patient report or manifest fear, arousal, or discomfort while visualizing the relevant fear scenes? Affirmative answers to these questions prompt consideration of treatment via systematic desensitization.

Wolpe has written extensively on complications that arise from attempting systematic desensitization with inappropriate patients. Some patients simply cannot learn to relax. Others display what might be called a fear of relaxing or of "letting go." Still other patients do not seem to be able to conjure up the requisite imagery or to picture themselves as part of the targeted scenarios. Problems at these levels should prompt reconsideration of whether it is possible to use some sort of *in vivo* exposure procedure.

IV. EMPIRICAL STUDIES

Early reports about the successes of systematic desensitization did much to promote behavior therapy and the conditioning formulation of psychopathology on which behavior therapy was based. However, the tenor of those early reports was influenced by the Protestantism of that era; the subsequent four decades have witnessed some moderation of those early claims and no small amount of controversy.

A. Early Clinical Reports

The first reports of clinical success with systematic desensitization were reported by Joseph Wolpe via a series of papers published from 1952 to 1962. These papers were shadowed by a series of similar reports provided by Arnold Lazarus from 1957 to 1965. An extraordinarily thorough review of these and other early reports was prepared by Gordon L. Paul and published in 1969.

1. Joseph Wolpe

In his influential 1958 book, *Psychotherapy by Reciprocal Inhibition*, Joseph Wolpe reported that nearly 90% of 210 patients were either improved or much improved following treatment with his new methods. Gordon Paul pointed out later that some of those 210 patients were treated with methods other than systematic desensitization. He reanalyzed Wolpe's original reports, identified 85 patients who had been treated with systematic desensitization alone, and reported success in 78 (92%) of those 85 cases. He reported also that follow-up contacts with 21 patients after periods of 6 to 48 months yielded no report of relapse. In some cases the effects of systematic desensitization were gauged by direct observation and by reports from unbiased others. By and large, however, "success" was defined as self-reports of improved responses in the presence of previously anxiety-eliciting stimuli encountered in the natural environment.

2. Arnold Lazarus

In 1957 Arnold Lazarus and Stanley Rachman provided the first report of success when systematic desensitization was used by a therapist other than Joseph Wolpe. Through the first half of the 1960s Lazarus provided very careful case reports and summaries about a total of 220 patients with whom systematic desensitization had been used. The presenting problems were quite diverse; they included social anxieties, generalized

anxiety, panic, and numerous phobias including agoraphobia. Of these 220 diverse cases Lazarus counted 190 as successes based on therapists' Likert-type ratings of patients' functioning in several adaptively significant arenas. He also acquired corroborative reports from referral sources in 70% of his cases.

3. Other Early Reports

The successes reported by Joseph Wolpe and Arnold Lazarus prompted numerous other reports about treating anxiety-related conditions with systematic desensitization. By 1969, Gordon L. Paul was able to locate 51 separate reports of individual cases or clinic series and several reports of systematic desensitization applied in groups. Successful outcomes were not universal in these reports, but there were relatively few failures.

B. The First "Controlled" Experiments

The earliest behavior therapists sought scientific support for the efficacy of their treatments. Thus when early experimental work done by Peter J. Lang and by Gordon L. Paul provided that support it received unprecedented attention.

1. Peter J. Lang

In 1963 and again in 1965 Peter J. Lang and his colleagues reported early experiments in which snake-fearful college students were exposed to standardized forms of systematic desensitization. In the aggregate the experiments achieved impressive control over sources of unwanted variance in the dependent-variable measures; they succeeded in supporting the argument that temporal pairing of muscular relaxation and graded imaging of snake-related scenarios was specifically responsible for observed reductions in avoidance and reported reductions in fear of snakes. They also provided 6-month follow-up data supporting the specific effect of systematic desensitization. Overall, 15 participants who nearly completed the standard course of systematic desensitization improved significantly by contrast with 10 participants who did not complete the standard course of desensitization, with 10 participants exposed to a procedural control for experimental demand/placebo influences, and with 11 participants who served as untreated controls.

2. Gordon L. Paul

In 1966 Gordon L. Paul reported an experiment that remains a methodological reference point three decades

later, and that still affords the most convincing evidence available of the specific effectiveness of systematic desensitization. The participants were 96 college students most of whom would now be diagnosed as having generalized social phobia with particular problems in the domain of public speaking. After extensive assessment each of 74 participants was assigned to one of four experimental conditions that, taken together, served to compare the effects of systematic desensitization with those of insight-oriented psychotherapy under conditions that controlled for influence from experimenter (therapist) bias and from major extratherapeutic sources of variance. Fear during a standardized public speaking task was assessed by self-reports, by demonstrably reliable behavioral observation, and by pulse-rate and palmar sweat measures. The group treated with systematic desensitization improved significantly more than did any other group on fear measures in all three domains. Posttreatment differences were maintained as judged by self-reports acquired 2 years later from carefully selected respondents.

C. Analogue Experiments

The behavior therapy movement was up and running by 1970 complete with several new books, three new journals, and two new societies. In this context the early experiments reported by Peter J. Lang and his colleagues spawned scores of experiments in which pretreatment and posttreatment measures of fear of snakes among college students were used to evaluate the effects of systematic desensitization. Some of the experiments compared the effects of systematic desensitization with the effects of competing behavior-influence packages, notably implosive therapy and imaginal flooding. Most of the experiments compared the effects of systematic desensitization with those procedural variations that were germane for one reason or another. Many questions were asked. Is muscular relaxation training necessary for fear reduction with systematic desensitization? Must the imaging instructions proceed along a graded, increasingly fearsome hierarchy of scenarios? Must the participant be permitted to govern his or her own rate of progress along the scenario hierarchy?

Notwithstanding the effort and ingenuity that went into the so-called "snake desensitization studies" they afford very little by way of characterizing the clinical efficacy of systematic desensitization. This is true for at least two reasons. First, in the intellectual climate of the day the efficacy of systematic desensitization was virtually axiomatic; therefore most of the research was intended

to answer other questions, such as questions about the “active ingredients” or causal mechanism(s) that explain the success of the approach. Second, the quality of systematic desensitization research with snake-fearful participants fell off sharply very soon after Lang’s original reports; since 1972 the external validity of empirical generalizations based on orthodox “snake desensitization studies” has been very much in doubt.

D. Current Status

Throughout most of the decade of the 1960s systematic desensitization was clearly the treatment of choice for phobias and for other anxiety-related conditions. That popularity was based on the reports of clinical cases and series noted earlier and, in part, on the zeitgeist in which Joseph Wolpe’s formulations appeared. Toward the end of the decade the work of Albert Bandura and his students began to receive attention also; phobia treatments such as graduated participant modeling began to compete with systematic desensitization. During the middle 1970s Isaac Marks began arguing persuasively that exposure to fear signals is the common element of the successful phobia treatments and that *in vivo* or real-life exposure is all that is needed for clinical success. Thus was born the approach known as “exposure technology.”

One outcome of the competing efforts of Albert Bandura and Isaac Marks was an abrupt decline of interest in systematic desensitization. Thus when reports of experiments on the systematic desensitization of snake-fearful (and test-anxious and shy) college students disappeared suddenly from the mainstream literature in 1972 there was nothing about systematic desensitization to take their place. For the past 28 years the empirical literature has contained only episodic case reports about unusual or otherwise interesting applications of the procedure.

Because of the dearth of new data for a quarter century and the widely suspect external validity of “analogue” studies, there are essentially two ways to attempt answering questions about the efficacy of systematic desensitization. One can study and evaluate polemic papers, including papers based on meta-analytic studies, that include statements about clinical outcomes and/or one can retreat to information found in the early clinical series and experiments reported by people such as Joseph Wolpe, Arnold Lazarus, Peter J. Lang, and Gordon L. Paul. The polemics have occurred mainly between Joseph Wolpe and Isaac Marks who have championed the causes of systematic desensitization and exposure technology, respectively. The early clinical series and ex-

periments were, as noted earlier, reviewed in painstaking detail, by Gordon L. Paul in 1969.

V. CASE ILLUSTRATION

The narrative that follows describes the treatment of a 45-year-old, married, white female (Helen) who had severe dental phobia. Behavioral interviewing revealed a clear history of aversive conditioning that involved both pain and ridicule during her extremely rare dental visits. The patient’s goal in seeking treatment was to tolerate many sessions of restorative dental treatment. (She could more easily have been a candidate for dentures than for full-mouth restoration; she resisted dentures citing the implication of old age.)

A. Assessment

Early on Helen flatly refused to try direct exposure to dental care under any conditions. Systematic desensitization was then considered as a preparation for subsequent real-life exposure, provided that assessment data supported the use of systematic desensitization.

Initially a suitable dentist was contacted and together Helen and I visited the dentist’s office in order to promote concrete imagery during the upcoming assessment. (The visit required a promise that no interaction with the dentist other than a “hello” would be expected.) Time was taken for Helen to get sufficient information for detailed mental pictures of the sights and sounds of that specific environment, and to tell that dentist about her fear.

A widely used structured interview produced diagnoses of claustrophobia and social phobia. (Usually fear of pain or of other oral discomfort plays a central role in dental fear and avoidance; the picture for Helen was surprising, especially given an apparent history of pain-related aversive conditioning.) Questionnaires, role-plays, and imaginal rehearsals were used to pinpoint the kinds of events that made Helen anxious and to describe her fear in three-channel terms. (For example, a questionnaire about the details of claustrophobia established that she was concerned with confinement but not with suffocation.) Helen was identified as a candidate for systematic desensitization in imagination based on the criteria in Joseph Wolpe’s 1990 book. Importantly she reported clear imagery and considerable discomfort, including perceived heart-rate increase, during imaginal rehearsals of selected dental-visit scenarios. The kinds of events that made Helen anxious did, indeed, have more to do with confinement and with criticism than with pain.

B. Relaxation and Hierarchy Construction

An eight-session course of relaxation training was undertaken twice weekly using transcripts from the 1973 manual of Douglas A. Bernstein and Thomas D. Borkovec. During the last two sessions four muscle groups were used in order to set the stage for systematic desensitization. In general four repetitions of tension-relaxation cycles were used. Helen had no means of playing tape-recorded relaxation instructions. She was encouraged to relax at home when possible but no records were kept.

During several of the eight visits, at times when Helen was not relaxing, two initial hierarchies for systematic desensitization in imagination were prepared. The hierarchies were developed with an orthodox SUDs-scaling procedure based on scenarios initially provided by both of us. There was difficulty developing separate hierarchies for confinement and for devaluation/criticism that had the necessary gradations in SUDs. After considerable work we decided to begin with one hierarchy that contained scenarios related both to confinement and to devaluation/criticism. In addition we imbedded scenarios of both kinds in a spatiotemporal sequence that began 4 weeks before the first dental visit and that ended in the dental operator. In the end the hierarchy included 21 scenarios that were at or near 5 SUDs apart from one another. Representative items include "Thinking about the dental visit one week away," "The assistant telephones to remind you two days before the appointment," "The dentist looks startled and asks you if you have ever brushed your teeth," "Reclining in the dental chair with tubes in your mouth so you cannot move."

C. Systematic Desensitization

Systematic desensitization occurred over 12 weekly visits. Each time it was preceded with 8 minutes of four muscle-group relaxation training. Then imaginal rehearsals of the hierarchical scenarios were begun. By and large the procedure involved "orthodox" systematic desensitization as described earlier. In general the actual desensitization trials lasted between 15 and 18 minutes. Each scenario was visualized calmly four times in succession before going to the next. No more than three scenarios were completed in any single session. Care was taken to end the trial on a successful item. On five occasions a scenario prompted repeated anxiety signals and a new, intervening scenario was used.

Beginning in the third week Helen was instructed to begin real-life practice of the spatiotemporal and behavioral aspects of the visualized scenarios. She was encouraged to not go too fast; to practice a week or so behind her progress along the imaginal gradient. As systematic desensitization progressed the dentist participated as an *in vivo* partner; various, long-duration *in vivo* exposure visits were added to the imagined scenarios.

VI. SUMMARY

Systematic desensitization is a venerable behavior therapy for fear and anxiety. Usually it entails remaining deeply relaxed while visualizing a series of increasingly fearsome scenes in which the patient confronts targeted events or situations. There are many theories about how systematic desensitization reduces fear; most "theories" are *post hoc* claims that systematic desensitization instantiates some other training regimen or process such as respondent extinction, habituation, counterconditioning, or self-efficacy augmentation. Joseph Wolpe's original theory of how systematic desensitization works appeals to learned inhibition of anxiety that is based on parasympathetic inhibition of sympathetic activation. Criteria have been developed to identify good candidates for systematic desensitization (e.g., there are four fears or fewer, there is evidence of a capacity for clear imagery, there is evidence of emotional discomfort while imaging frightening material). Scores of case studies and reports of clinical series attest to the efficacy of systematic desensitization. Several now classic experiments show the efficacy of systematic desensitization also. Much research on the outcomes of systematic desensitization was done in a way that renders it of little value. By and large research on the effects of systematic desensitization disappeared from the literature when exposure technology replaced systematic desensitization as the treatment of choice for phobic complaints. However, the earliest case studies and clinical series suffice to support the claim that systematic desensitization is effective and should be considered when *in vivo* exposure is not feasible or is initially refused. A case is described in which a 45-year-old female is treated for dental phobia that was based on claustrophobia and on social phobia.

the other end incoming analogue data are converted back to digital. Download speed, which is variable at best is 50 kbps, and upload is 33 kbps.

satellite Speeds are on par with DSL and cable. Requires a rooftop dish.

videoconferencing Long distance meetings occurring with both picture and sound transmitted between two or more locations. Ideally transmission occurs in real time and there is perfect synchronization of voice and sound.

GLOSSARY

bandwidth Data transfer speed for telecommunication data.

cable The widest pipes and the fastest but speed will vary. Pipelines are shared with neighbors, and are not dedicated lines like DSL. The maximum theoretical download speed is 27 gigabits per second. Upload speed may be 128 to 384 kbps.

chat rooms Virtual containers for instant e-mail correspondences from disparate locations.

DSL A digital subscriber line has no standard speed. Speeds vary from 256 kbps to 1.5 Mbps and thus are considerably faster than ISDN.

e-mail Electronic mail sent via the Internet.

fixed wireless Requires an antenna on the roof; download speed 1 to 2 mbps, and upload 256 kbps.

ISDN Integrated services digital network begins with a guaranteed 64 kbps, or two lines at 128 kbps, or four lines at 256 kbps or higher. Data can be compressed as well to speed transmission.

POTS Plain old standard telephone has the slowest speed. Data are transmitted in analogue wave form. A computer modem converts outgoing digital data to analogue and on

I. INTRODUCTION

Tele is a prefix from the Greek *tele* meaning at a distance, or far off. Thus, tele-psychotherapy is simply a term for psychotherapy conducted at a distance instead of taking place in the usual office setting with all participants physically present in one room. Tele-treatment is usually assumed to include new technology, either videoconferencing or e-words.

Videoconferencing technology has advanced sufficiently to deploy psychotherapeutic services that can span the globe, or even transmit to a space vehicle. At the present time, researchers funded by NASA are planning the psychological and medical care for a Mars probe planned for the end of this decade. Treatment will soon be supported from one end of our solar system to another. Truly, psychotherapy has been liberated from the office!

There is nothing new in psychotherapy occurring long distance. Letters have always been sent by surface mail from patient to therapist and vice versa, and

should be considered a valid part of treatment. The telephone, as well, has routinely been used for brief consultation or full scheduled visits. Certainly, the initial call that plans the first visit and introduces the participants to each other is a form of tele-psychotherapy, although rarely recognized as such.

Telephone psychological support services have a long history, and provide much needed round-the-clock services sometimes with a more user-friendly interface than traditional medical settings. While suicide hot lines may be staffed by nonprofessionals, the ready access to a sympathetic voice has often sustained the troubled through difficult times.

Students who go off to be educated at a distant locale frequently remain in telephone relationships that are well established and proven salutary. Face-to-face visits are held at vacation times. Many adult patients who are attached to their therapists move, and choose to remain in a well-known trusted helpful partnership, rather than start over again with someone new. These patients should, and often do, have an occasional live office visit.

A colleague in psychoanalysis explained that at the beginning of the week she traveled to a city 3 hours away for an evening session, stayed overnight in a hotel, and had a visit the following morning, and then participated in two more telephone visits before the weekend. While this is unusual, it is not unheard of. Other patients traveling for work or pleasure, or simply too busy to commute to the therapist in the midst of a day of activities, will opt to keep a therapy appointment by phone, if the therapist is agreeable. This is more likely in the west than in the east. There are numerous surreptitious stories of telephone treatments. However, until now, the practice of telephone psychotherapy has always been utilized within treatments that began in a traditional office setting.

Today our new technology allows for treatments to begin outside an office container. What should we make of this psychotherapeutic brave new world? This article will introduce you to tele-psychotherapy: good or bad, safe or risky.

There is much reason for optimism: As new standards for telecare are written, and new regulatory law is encoded, good treatments will prevail, not wild teletherapies, and new, effective and improved telepsychotherapies will be developed. We are at the point that quality care can be universal, if only we will share our resources.

II. TECHNOLOGY: VIDEO

Top-quality telephone or computer-driven videoconferencing has images that are similar to television or

movies. The transmission of separate pictures is not detectible, and lip synchronization is perfect. Often there is little or no delay caused by distance, and communication flows easily. From the wide array of videoconferencing tools, equipment can be utilized with a guaranteed verisimilitude, the ideal, or for the most modest investment, inexpensive video that is unreliable, and/or so poorly reproduced that it is nearly useless. The quality of images relates to one factor: cost. The more money spent on equipment, software for computer applications, and transmission links, the better the result.

Videophones are now available that are simply telephones that can be plugged into a standard phone jack and produce excellent pictures. The image may appear on a lightweight portable phone screen that easily fits into an ample pocket or purse, or on a larger stationary telephone unit's screen, or displayed on a computer screen, or at the most lifelike projected on a television screen. These phones may have regular or plain old telephone system transmission links (POTS), or ISDN phones that utilize linkages two to four times as wide as POTS telephones. The best of them, often bought by the government to be used by the CIA, FBI, or military, cost well over a thousand dollars. The advantage of POTS videophones is ubiquity. The best videophones scramble information so privacy is almost guaranteed, hence their utility for the government.

Videoconferencing can also be conducted between computers with no telephones involved. When the widest pipe lines (known as broadband) are sending digital information, excellent images result. The cost of an individual long distance phone call is not incurred with every meeting, which is considerable when the videoconference lasts for a standard psychotherapeutic hour and crosses one or more oceans. The users pay a monthly fee for renting the broadband attachment (e.g., cable, ISDN, or DSL) to the local phone line. Such private stable computer linkages are often established between hospitals and satellite clinics. These networks may be set up by one of the large videoconferencing companies who sell their own connecting software or done more simply by downloading videoconferencing software off the web to go with a single PC.

Small clinics that cannot underwrite such expensive private networks can turn to the Internet for video transmission help. At least two companies will now permit downloading of videoconferencing software without charge into a PC/Windows based personal computer: CUSeeMe from White Pine and Microsoft's Netmeeting. With the addition of a 70 dollar videocamera on both ends, and an attachment to a high speed

link like cable or DSL, without the addition of special software of equipment sold by the top videoconferencing companies, reliable intermediate quality images will result. For a military clinic in Hawaii with patients on a tiny island thousands of miles away, some video is far better than none, and improves care well above that done with mere sound.

Lower cost computer-driven video and low end videophones are, of course, available for pure POTS transmission, although diminishing expense is unfortunately correlated with decreasing quality. This would occasionally allow a therapist to receive video alongside audio, but the images are most likely to be delayed, and are prone to breaking up or fragmenting into component data, and transmission most often cannot be guaranteed, as crowded Internet lines prevent the flow of data at peak times. Thus, when a subject moves, the image conveyed breaks up into tiny parts or fragments. This is a disconcerting experience to view. The intermittent distorted weird displays are unsettling, and are not conducive to serious psychotherapeutic work.

How does videoconferencing compare to a real office visit? Is it nearly as useful? How much evaluative data are lost when a therapy patient is seen in only two dimensions? What happens when scent/olfaction is lost as a sensory cue? How much do we rely on intuition, whatever that is, as an evaluative measure and how much is it dependent on the actual sharing of physical space? How long will it take a generation of computer savvy people to process the mysteries of each other with a virtual contact? We have much to learn, but this should not hold us back.

III. TECHNOLOGY: E-WORDS

In the beginning, the portal of entry to the web was a computer. Access today can be instantaneous with a mere handheld wireless device that can fit in one small palm, even a child's. Alternatively a modestly priced electronic gadget designed only to link to the Internet equipped with a keyboard and large screen will do. The Internet's transmission of words, pictures, and other data is astonishing; the effluent is rapidly changing our civilization. Information of serious or dubious value is readily available for global consumption. The latest news can be read almost as it happens with the flick of a switch on a tiny unit. Nearly anyone can search the most knowledgeable medical databases from nearly anywhere. Sophisticated patients may know as much or more than their doctors about their illnesses as chat groups or bulletin boards run by victims of illnesses

often provide the best information for dealing with disease. The Internet world has spun us topsy-turvy, replaced some pomposity with humility, and occasional ignorance with knowledge, and allowed a cave in a wilderness to headquarter a global terrorist war. The facile flow has brought all of us closer together, for good and for evil.

Groups, sometimes patients, can meet in real time in chat rooms that include participants from all over our planet. At the present time, these virtual settings allow only verbal messages, but in the near future, when broadband and POTS are near equally priced, and information that creates images races along, these virtual rooms will have multiple video-streams, one from each source. A dyad, or therapy pair, can now talk via instant messaging and share live real time e-conversation, usually typed and sometimes spoken.

E-mail is ubiquitous: The good news is the telephone has not deleted the written word, indeed letter-writing has returned in spite of television usurping hours spent on reading; the bad news is that much e-mail, whether spoken or typed, like much surface mail, is junk.

Amidst the deluge of e-correspondences, however, are useful interactions between therapists and patients. E-mail contact has a bad reputation because of the exploitation of cyberspace for felonious "activities". However, imagine the gain for a fragile person who can send a letter (albeit an e-letter) to a therapist at any time of night or day. In the loneliest hours when most are asleep, this may make the difference between life and death.

Properly used, the Internet will alter psychotherapy practice for the benefit of patients. Today, cyberspace is the "wild west," anything goes. Rest assured, this will not last.

IV. TELE-PSYCHOTHERAPY TODAY

A spare room in a centrally located community building can quickly be converted into a satellite psychotherapy clinic with the simple addition of a videoconferencing system, a scheduling administrator, and the requisite broadband link to a clinic with available psychotherapy staff. The earliest utilization of tele-psychotherapy has been the most natural: The technology has enabled the development of satellite clinics providing care in communities that cannot support full mental health clinics themselves.

The psychiatric and psychological sections of meetings for telemedical professionals have nearly always included clinical presentations from countries and states

with large remote areas with low population density including Australia, Newfoundland, Norway, Alaska, Arizona, Michigan, and New Mexico, as well as other more exotic locales. These papers recount the benefit and efficacy of tele-treatments. The presentations are inspirational and usually have scenic photographs: one side of the videolink may be a well-known center of excellence, while the other is a few huts in the wilderness sometimes surrounded by reindeer and locked in by snow and ice. The patients, if depicted, are overwhelmingly grateful that care is available at long last for conditions that heretofore have gone neglected. The tele-psychotherapeutic visits are presumed to be almost as good as the real thing, and are justified as providing virtual care where real office care cannot exist.

A secondary proliferation of tele-psychotherapeutic services has been to prisons that are intentionally built far from population centers. A videoconferencing link allows for flexibility of delivery of services that could not be supported by importing mental health staff or exporting prisoner-patients with the requisite guard staff and a driver.

The United States Department of Health and Human Services Commission endorses long-distance treatment as the legitimate embrace of new technology by creating the first reimbursement codes for tele-psychotherapy, although in rural areas only. The preference for rural telemedicine and telepsychotherapy is echoed as well by the governmental agencies that fund telemedical programs: They are only willing to support programs in rural settings. Urban clinicians need not apply.

The military, of course, uses tele-treatments for troops and support staff who are stationed routinely in remote locations. The earliest implementation of the most sophisticated equipment would be allocated toward saving lives, hence tele-psychological services would be supported only when physical health needs are fully deployed. It is not yet widely accepted that providing adequate psychological support after the horror of battle and injury, if possible, speeds recovery from medical injuries.

Tele-treatments are slow in developing outside remote areas. There is little research on the potential exploitation of this new technology to improve delivery of care for patients who require the careful purview of a vigilant therapist with some exceptions. A project from Massachusetts General evaluates videoconferencing for OCD by Lee Baer and colleagues. A researcher from London, Paul McLaren, studies the use of videoconferencing in psychiatry in urban settings by inpatient units seeking specialty consultation at other hospitals.

Medical schools in and outside the United States show enormous zeal for developing consultation programs that bring in patients from distant locales. Many of these projects are developing to bring income into institutions facing funding cuts while they are simultaneously finding new and improved models of patient care. The comparative indifference to exploring the potential benefit of this new technology for local use seems shortsighted and overly cautious. In general, the prevailing opinion of tele-psychotherapy is that it is a second-rate alternative to in-the-flesh real care. Still, there is a surprising lack of creative effort for planning new techniques for conducting psychotherapy using this technology. Perhaps one explanation of this relative indifference is that grant money for pure clinical work is difficult to find. Much psychiatric research is drug company based, hence scientific research devoid of pharmaceuticals is more difficult to support. If this technology promises to bring relief of suffering to patients, and this opinion is popularized, scientific scrutiny is certain to ensue, although this seems not likely to occur soon. Today's adolescents have rich social lives in virtual settings sometimes all over the world, but the adult scientist generation is not yet ready to mine these virtual settings for clinical gain.

Psychotherapy in cyberspace or e-therapies are developing quickly. A web search will find a variety of dotcoms selling web treatments, and more added each day. The preponderance of e-psychotherapies are offered by nonmedical clinicians, and it is often difficult to evaluate the credentials of the practitioners. A minority of these web clinics include telephone conversations alongside e-mail chat. E-mail treatment is inexpensive but many clinicians believe it is of dubious value, hence you get what you pay for. How can words alone be beneficial to patients? If e-mail help is limited to informational help, rather than counseling or treatment, and goals are limited, and conceptually understood, it seems feasible that some useful parameters for e-service could be defined. If a life is saved by a well-timed persuasive e-comment, how would we discover this unknown benefit? The rapid condemnation of all e-services without exploring individually what each is doing seems hasty and gratuitously cautious.

Many psychotherapists exchange e-mail with patients. When this mail is sent within an active clinical exchange, the interaction is similar to a voice mail message, and is simply a new component of treatment. E-dialogue is another way for our patients to reach us, to confess secrets hard to admit face to face, to let us know more of aspects of a distraught inner self, and

therefore provide more grist for the mill of an ongoing therapy.

V. IMPEDIMENTS, CONTROVERSIES, AND CAVEATS

Why hasn't tele-psychotherapy been embraced far and wide by practitioners with technical savvy when it seems such a logical extension of office treatment? The primary obstacle is probably money. As yet, there are no reimbursement codes for billing tele-psychotherapeutic videoconferencing visits unless your clinical work is done in rural areas. The managed care companies that underwrite much psychotherapy in the United States have not yet discerned that tele-psychotherapeutic visits are likely to save considerable funds when conducted in rural and urban settings. The studies demonstrating this have simply not been done yet.

There is also no reimbursement for e-mail correspondence, rural or otherwise. When clinicians permit e-mail correspondence, they either have to do this as a gift of time, or a billing arrangement must be agreed on with the individuals involved. When the patient's psychotherapy coverage is within a managed care program, the clinician is breaching the managed care contract by charging for e-mail treatment time. The concerned clinician is faced with an unpleasant dilemma when supplementing office visits for a fragile patient with an e-mail correspondence. If this exchange is done without fee, does this generosity have a tinge of self-sacrifice by the clinician? How would this effect the treatment over time? Alternatively, if a billing arrangement is set behind the back of managed care rules, what message does this give the patient about the therapist's ethics? There is no good solution given today's managed care contractual agreements for clinicians.

The solution might be to limit e-mail correspondence to self-pay patients. A policy of this sort would enhance the development of tiered mental health services with the best care given to the wealthiest patients who can afford to self-pay out of discretionary funds. This seems an unfortunate division of services for discerning who gets the most flexible treatment. Another solution might be to create public sector services for everyone offered by one government agency instead of our current complex system. We are a long way in the United States from a unitary mode.

In countries with government health care coverage for all citizens, it will probably prove easier to establish tele-psychotherapeutic practice. The complex chal-

lenges of finding liability coverage for clinicians for novel tele-treatments would be dealt with by a central authority, and reimbursement for telecare for all citizens could be efficiently planned. In the United States with its complex health care apparatus, each independent clinician will have to struggle to find tele-treatment liability coverage usually through a professional society. At the time of this writing there is scant malpractice liability coverage sold for tele-psychiatry by psychiatric insurers. The American Psychiatric Association is unfortunately not likely to make this available anytime soon even as an add-on to the usual malpractice package. Teletreatment programs operating out of medical schools and graduate psychology and social work departments that self-insure the malpractice of staff clinicians will have more flexibility.

The logical way to bill for e-mail time is by bytes of time or minutes. Just as lawyers charge for varying lengths of time, psychotherapists might do the same. But the reimbursement system in American medicine (and psychotherapy falls into this category) is by service code, roughly but not precisely based on time. How long will it take to convert the standard procedure code system to a more flexible scheme for tele-psychotherapeutic care that above all else should have flexibility for session lengths whatever the method of delivery? Since this constitutes a radical change in reimbursement structures, it is likely to be slow in coming. Another more novel approach for payment of e-mail correspondence might be a monthly set fee for e-mail privileges.

The regulatory barriers to tele-psychotherapy are enormous, and are likely to be more complicated in the future, not less. In the United States, licensures for psychotherapeutic practice is issued by state. Clinicians are credentialed to practice locally. Tele-psychotherapy would be confined to a geographic area when large clinics establish satellites, but how are clinicians to be licensed when the primary clinic is in one state and the satellite(s) in another? The medical-legal issues are compounded even more when the treatment is between two nations or several. The European Union is establishing guidelines for telemedical care that will enhance the flow of treatment within these countries. The World Health Organization has a larger global focus as it seeks to establish telemedical rules for all nations. It too is working on guidelines for telemedical practice. Ultimately, the nations of the world will have global pacts for telemedical and tele-psychotherapy treatments, protection of patient privacy regulations, conventions for flow of medical data, and even, one hopes, global pharmaceutical rules so patients who travel may

easily get telemedical treatment and medications whenever they happen to be.

Today, whenever a therapist conducts tele-treatment with a patient in another country, or another state or province, the clinician is already operating in a legal gray area. Videoconferencing and telephone sessions held interstate or between national jurisdictions are not always clearly legally permissible, although they are also not quite against the law. For instance, does the clinician require a license to practice where the patient is located, however distant? Some would argue that an affirmative reply is correct, others not.

The G8 telemedical study group has members roughly comparable to the top eight global industrial powers. One of their strong recommendations is that when telemedical treatment is done, the license and governance in the location of the medical clinician should govern the transaction. Thus, clinicians will only require licenses, malpractice liability, and liability releases in one jurisdiction, not every location they are treating patients. It is not known, as sensible as this notion is, whether local governments will go along with such rules. How will chauvinism restrain itself from rearing its ugly head and launching protective turf battles? How will psychotherapy regional societies sit back and allow distant clinical intruders to compete for their available patient pool? Neither seems likely, although the alternative possibilities are dismal.

Who will be responsible for monitoring long distance treatments? Will this be done by the medical/psychotherapy societies in the clinician's jurisdiction or in the patient's? There is little agreement so far on what is considered adequate care utilizing videoconferencing, and even less of a consensus regarding e-word or text-based treatment. Standards of care must be determined, but given the paucity of scientific data on tele-psychotherapy, how will these be set? Interest in tele-treatment is not adequate yet for sufficient research to be funded to make these assessments. When agreement is finally reached, will it be possible to allow enough flexibility so creative clinicians can continue to generate new and exciting techniques and methods? Alas, in psychiatry, practice guidelines geared to protect patients and guarantee a high standard of care are being established that may eliminate deviation from a strict conservative norm. So in the short term patients are protected, at grave risk of an overall atrophy of creativity in the field.

The privacy issue has evoked much concern. When videoconferencing networks with a few private linkages are established, it is easy to create encryption of

data and sufficient firewalls around the database server so the patients are as close to guaranteed privacy as is possible. But when the Internet is used for videoconferencing, or for e-mail, for modestly funded programs or treatments, how will privacy of data be promised if it flows between many servers that cannot be regulated by clinician or patients?

In the United States, extensive standards governing both privacy and security of health information are being developed and implemented under HIPAA (the Health Insurance Portability and Accountability Act of 1996). This law threatens high fines and even criminal penalties for unauthorized release of information. The security requirements will mandate some form of access control or encryption to protect electronic data traveling over a communications network. Other countries are enacting similar legislation. But how will every psychotherapist know these rules and follow them when the available unregulated Internet is so seductive?

The issue about which there is the most controversy is the entire matter of cyberspace psychotherapy or treatment by e-mail. Is it simply bad treatment and therefore negligent only designed to make a fast buck for its purveyors? Or are there circumstances when e-care might be appropriate or necessary? If so, what are these? Robert Hsiung, M.D., at the University of Chicago, is editing a book on e-therapy. He is well suited to do this as he runs a message board for patients with a million hits per month that he monitors himself, clearly not an easy task. Dr. Hsiung believes that e-care should not be carelessly relegated to tele-psychotherapeutic malpractice without a careful exploration of its salutary potential. But how will we decide what e-care is helpful and what is not in the face of the paucity of evidence-based clinical research to allow these determinations to be made based on scientific data?

Horror stories exist of Internet fraud: self-appointed therapists with no training setting up shop on the web. Who should regulate such practice? Should there be monitoring for consumer, or in this case, patient protection? Is this monitoring an invasion of privacy? Who will decide? No doubt, in time government commissions will develop to scrutinize web businesses, including all psychotherapeutic transactions, but if both parties have encryption and firewalls, this will not be an easy task.

One caveat: If you are going to utilize e-mail in your existing psychotherapeutic practice, make sure your patients know how often you read your letters. You do not want a new patient or anyone to send you an e-note full of suicidal ideation, homicidal yearnings, confessions of

horrific crimes, or any other shared desperate feelings that you should have acted on but instead missed with dire consequences, because you had not had sufficient time to review your mail.

We have so much to discover and learn about tele-psychotherapy. The best of us is only an e-treatment toddler awkwardly staying up and finding the correct path.

VI. CLINICAL TALES AND THE ISSUE OF TELE-TRANSFERENCE

Patient confidentiality has been protected by eliminating or altering identifying data.

A. Case History I

Thomas is a tall, elegant, middle-aged man with a large brood of interesting tow-headed children. He has had two brief courses of psychotherapy with me several years apart each involving e-technology. He came to his first visit with great reluctance, and arrived incredibly late to underscore that sentiment. He had always taken great pride in his competence and independence, and like many people, stigmatized psychiatric illness, and felt any need for treatment was an embarrassing weakness. His father had service-connected bipolar disease related to battle experiences during World War II; he viewed this man with both sympathy and pity. He sought help from me when he realized he was losing control of his most valuable commodity, time, and had given up any hope of remedying the situation himself.

His first treatment occurred when Internet access was considered quite precious and was sold by the minute, and was usually a privilege for the wealthy or a perk of academia. Thomas was neither. He described how he sat in his office at the end of a grueling day of back-to-back meetings, and signed on to the web to relax. Soon he found himself in chat rooms where he easily found women offering delightful e-company. Conversations would go on for hours, and were quite expensive. He found himself lying to his wife about his unusual long evening hours at the office. He was horrified by his dissembling, and the huge expense for his e-habit. He felt addicted to the web and its chat rooms, and his self-reproach for this loss of control was enormous. He believed he loved his wife and did not understand his incessant web flirtations.

In the past he had had several serious episodes of depression that he waited out; all of these had a seasonal

component. His usual state was mildly ebullient: He needed little sleep, and his productivity was impressive. His only impulsive behavior in the past was with food; to his chagrin his weight went up and down. He exercised long hours to control his girth given his tendency to eat too much.

During several months of treatment, which involved an extraordinary number of cancellations, which he easily rationalized away as due to urgent situations at work, we discussed his marriage, its strengths and weaknesses. While it was apparent to me that Thomas was lonely in what appeared to be a faltering marriage, he had not allowed himself to acknowledge this. He saw his addiction to the web as analogous to overeating; and just as his weight would go up and down, so would his Internet time.

Thomas is a highly intelligent fellow. He enjoyed the opportunity to explore his past, his marriage, his parents' commitment to each other, and the nature of their relationship to him, and even our cautious study of his relationship with me. In time, he acknowledged how disappointed, sad, and bored he felt with his wife. His web friendships, which developed into romances, were thrilling.

One day he announced he was done with therapy, although he had just made a plan to meet one of his web girlfriends across the country during a business trip. He had never before considered infidelity and given his lapsed Catholicism, he would not abandon the sacrament of marriage without much soul-searching. Apparently he was not to do that with me as an accomplice.

Years later, Thomas contacted me again. He was now involved in a real love affair and was considering leaving his wife, and no, he had never met his cross country date when last we met. He was becoming increasingly depressed, and anxious about his confusing situation. His lover was pressuring him to end his marriage so she could leave her annoying husband, but he found himself reluctant to tear apart his children's family while they were still quite young. He enjoyed their company enormously and did not want to give up daily contact with them. Leaving his wife would be easier, though even this would be daunting.

At first his anxiety was nearly incapacitating and required the aggressive use of a tranquilizing SSRI antidepressant. When both his wife and his lovers' husband learned of the affair, not surprising given the frequent mid-day and evening assignations, he became deeply suicidal. Despite this, he refused to come in for office visits with the frequency his serious illness required, claiming work obligations. This explanation had already

seemed a convenient cover for his avoidant behavior, which had not responded to interpretation.

I knew him well enough to understand his need to distance himself, even at a time when he felt extremely fragile, could not be altered. This very private man had to maintain his boundaries with me, no matter what the cost, including the risk of suicide. He was unwilling to plan telephone visits claiming an absence of privacy on all his phones; he was terribly worried that someone would listen in. (This treatment was before personal cell phones.)

So I turned to the web to supplement his visit schedule as the only alternative to having information from him about his level of potential lethality, and thus a site for titrating his medications frequently, and a place to nurture him with well-chosen words. I insisted he maintain an e-mail correspondence with me, daily when necessary at a frequency determined by me, so I could follow the depth of his suicidal ideation. His treatment consisted of a weekly visit and for a month near daily e-mail notes. During this time, he decided to end his affair and concentrate on improving his marriage. When his suicidal depression improved, we slowly weaned his e-mail nurturance.

He continued his treatment with decreasing frequency while he described the benefits of his newly discovered focus on his marriage. His wife was now experienced as his long lost best friend. The privacy each partner needed to sustain a long commitment did not allow for intimate lovemaking, and he adjusted to the lost thrill of his love affair versus the reliability of his marriage.

One day he cancelled a visit for what seemed like a spurious reason. A nonjudgmental inquiring e-mail went unanswered. Once again, his real and virtual treatments ended abruptly.

Thomas' second treatment could have been fore-shortened when he became acutely suicidal but refused to allow me to determine the appropriate pace of our office meetings given his life-threatening illness. It was obvious that any attempt on my part to challenge or control him would have met with complete resistance, and the likely premature disruption of his treatment. My suggestion that we turn to a virtual conversation allowed for an ongoing discourse that could not be held elsewhere. Had we only had a weekly office visit with no supplementation, I would have never known if Thomas was safe. He could not be counted on to contact me if he became dangerously low. Plus I knew he could be overwhelmed by urges he could not control as he had been with spectacular binges of sweets. We both recognized that he might have become overwhelmed with suicidal impulses. The virtual conversations al-

lowed for daily care, which he needed, without what for him would have been an overwhelming intensity of intimate real office dialogue. Thank goodness there was e-mail. It may have kept him alive.

B. Case History 2

Anna lives in Hong Kong with her husband and children. Her spouse has a lucrative and interesting job that pulled the family from a much appreciated community on the east coast. Anna's oldest daughter has just hit menarche, the youngest is still in diapers, and there are a few sons in between. Anna feels she should be content with the opportunity to live in a fabulous city especially with her recent affluence. Instead she is miserable. Her mother-in-law contacted me for help.

Anna, like many expatriates, is homesick and misses her family, her home, her language, and her culture. She speaks eloquently about her many travails, but she believes she should be happy. She is pensive about the origin of her gloom, offers biological and philosophical explanations, and also is deeply ashamed.

There are no English-speaking psychiatrists in her Asian city that she can find despite a circle of expatriate friends. She does not know the local language so cannot utilize local care. I agreed to have telephone consultations with her only if she had office visits with me regularly when she returns to the states on visits.

That was 6 months ago and since then she has sometimes been quite ill. One serious downswing reminded her of a postpartum illness when she stayed in bed for a month and had both infanticidal and suicidal thoughts. She often has high energy spells with racing thoughts and not infrequent fabulous shopping sprees at the many terrific stores.

I have arranged to have medication sent abroad to her but only products with a wide margin of safety. I have told her she needs more effective but riskier pharmaceuticals, but am waiting to prescribe mood stabilizers until we have videoconferencing visits. I hope this caution makes sense to her; I have explained that I need to see her if I am giving her a medicine that can be toxic. Voice alone will not give me adequate diagnostic cues.

We are planning a video link soon, so more aggressive care is imminent. In the meantime, she is feeling euthymic right now, though she doubts this will last long.

Anna's telephone psychiatric consultations will soon be enhanced with the addition of videoconferencing. She is likely to be my only transcontinental patient until telepsychiatric liability is available for long-distance care. Her telecare is untraditional but given her circumstances, it seemed the most reasonable alternative.

C. Case History 3

Maureen at 50 is finally happily married, though little else about her life is pleasurable. She sought my help about a year ago when her last psychiatrist moved away and she felt perilously close to a suicide. She did not want to do this to her beloved spouse, though she cared little for her own life.

She was often morbidly ill as a young woman and her arms are covered with innumerable scars from self-mutilation. She now will not wear clothing that shows her arms as she is so ashamed of these revealing white lines. So she hides beneath hand-woven fabrics in an interesting palette. Her overeating, always a problem, has recently gotten completely out of control. She has doubled her weight. An all too familiar feeling of deadness will not abate and she wonders, without any tears, if she will ever feel alive again, not that she cares much.

Recently a pain in her abdomen turned out to be the result of rare benign tumors in both kidneys. The largest was embolized, but her extreme discomfort continues and it seems likely that surgery will be necessary. During her weekly psychotherapy visits, she cracks black comedic jokes, and converses with my two French mastiffs, but says little to me.

Early on in her care, she accepted my invitation to send e-mails with reports of her food intake. We were not able to successfully curb her binge eating, though she described her struggles with control, and other critical emotional events. Recent notes are of visits with this specialist and that. She also in e-writing reveals her fears, her despair, and her anguish, all of which cannot be spoken. As her mood disorder does not respond to pharmaceuticals, we rely on therapy, real and virtual, to control her demons and one hopes, slowly heal her many wounds. She is witty and talented, and I am determined to enliven her—this will require ingenuity on both our parts, but luckily we have an abundance of patience. She has done so well in the past in overcoming her slicing impulses, there is room for optimism.

Maureen's e-mail correspondence is much like Thomas'. Her letters allow for self-revelation that is impossible to achieve face to face. She can accept warmth and kindness from me in writing that would seem disingenuous in my consulting room where she spends her time amusing me. Her e-treatments sometimes seems like the most useful treatment but I know she values our meetings as well. I like and respect her and recognize her talents that too often have been ignored. Our shared pleasant hours are salutary given the abuse in her childhood.

Many therapists will eventually use videoconferencing or e-mail in a similar fashion. Patients will insist on this

flexibility, and therapists will comply. Teletreatments will be common, and will be understood to be nothing more or less than traditional care expanded by technology.

The relationship between patient and therapist will be equally available for scrutiny as an office treatment. Transference is a term that describes our predilection for misinterpreting relationships due to prior experiences usually in our childhoods. Thus an adult neglected in childhood will too easily find adult insult and injury. Tele-relationships will take longer to develop intensity but despite this attenuation, the full panoply of emotions will ensue. To be sure: tele-treatment will have transference aspects, despite the altered venue.

VII. TWO PRELIMINARY STUDIES

By early 1999, the web was suddenly abuzz with exciting activity. America Online was selling inexpensive global connectivity, and Amazon.com was selling books. How could this new technology be a potential source of benefit to my patients? The answer was not obvious.

After attending my first telemedicine conference in the fall of 1999, I decided to try out the technology in my practice to reduce the stress of separation at the time of my holidays, which seemed overwhelmingly distressing for some of my most fragile and dependent patients. These accounts are strictly anecdotal, there was never any plan to produce verifiable data. I was simply trying out what might be helpful in the most preliminary way. If my conclusions were positive, scientific studies might be warranted later.

A. Study 1: January 2000

The editor of a prominent telemedical journal suggested that low-cost videophones might suffice for long distance telepsychiatric treatment. Shortly before a trip to London for a conference sponsored by this colleague, I ordered six such videophones. Five were handed out to five fragile patients most likely to find the break in treatment troubling. The sixth phone went to England with me.

1. Results

2/5 Patients acted out by not appearing for their scheduled tele-visits.

3/5 had televisits with images appearing at a sluggish frame rate that had no semblance of reality. Voice and picture were poorly synchronized, not only did image lag way beyond sound, but the picture itself fragmented with movement creating a psychedelic effect.

1/5 A bipolar male used to long distance telephone treatment declared the video of no benefit.

1/5 A paranoid schizophrenic woman would not look at the camera, though her husband enjoyed the unique experience of a trans-Atlantic video-conversation

1/5 A bipolar woman was delighted with her video-talk with me and believed seeing me defused her anguish.

2. Conclusion

Low end videoconferencing is minimally better than telephone without video. Clinically useful videoconferencing should approximate real time with well synchronized movement and sound.

B. Study 2

I had announced a holiday to Nepal and invited patients to e-mail me if necessary during my lengthy absence. My practice would be covered by a local psychiatrist during this hiatus, but e-mail greetings were available during recuperative stays in Kathmandu between treks.

1. Results

Eighteen patients wrote, five more than once. No patient required a single visit with another psychiatrist during my holiday, or needed a day hospital or inpatient stay.

2. Conclusion

An e-mail during a long break in treatment may obviate the need for an office visit by another clinician. Such e-mails may alleviate suffering due to separation anxiety as well. Reimbursement for such e-mail correspondence might save on the overall cost of treatment.

VIII. TELE-PSYCHOTHERAPY TOMORROW

Today we are nearly at launch position for tele-psychotherapy (to use the space exploration metaphor again). Our current treatment model, except in rural areas, presumes patients will come to our offices for visits. In the not too distant future, the usual visit will be virtual. This will enable patients to access care from anyplace they happen to be that has appropriate telecommunication links.

In the case of a disaster, whether natural or man-made, health care relationships will be established almost immediately by bringing in videoconferencing

and other telemedical equipment, if necessary, linked by remote satellite. When counseling is available immediately for victims, posttraumatic stress disorder will be prevented or diminished in at-risk populations.

Videoconferencing equipment will soon be on airplanes to calm nervous passengers, or support flight attendants handling challenging situations. Internet in real time will allow patients with phobias to find support as they fly. Such equipment will be on board ships, and even on space crafts!

Troops in combat will wear dog tags with lifetime medical histories; medics will carry small terminals to transmit this information to ships nearby, or to consultants across the ocean. Just as medically compromised patients will have access to improved immediate treatment, tele-psychotherapies will soon be supported for many emergencies.

Group therapies will be held with streaming video from disparate sites. Imagine the AA meeting with members from all seven continents.

If managed care has damaged the relationship between therapist and patient, tele-psychotherapy will promote healing of the wounds. Tele-treatment will restore the therapy relationship to the primacy it deserves, while the utmost of patient privacy will be guaranteed with encryption.

Someday we will have global conventions on licensing and global pacts on pharmaceutical distribution for people on the move.

Of utmost importance, should we develop and share our resources generously, is that rich and poor alike all over the globe could have access to the wisdom of our best clinicians. At last, worldwide excellent treatments are potentially an achievable goal, if only we make this our priority.

GLOSSARY

termination The end of psychotherapy.

All therapeutic relationships come to an end. This chapter discusses theoretical formulations and empirical findings concerning psychotherapy termination.

I. OVERVIEW

The ending of psychotherapy is commonly referred to as termination. The 1994 ethical standards of the American Psychological Association (APA) specify that therapists should terminate treatment with a client when the client does not require further therapy, or the client is not benefiting or is being harmed by continued service. Ideally, client and therapist make a mutual decision to discontinue therapy when the goals of treatment have been met.

In reality, however, the termination sometimes occurs because just one of the parties decides that it is time to

end treatment. Client and therapist do not always agree on when termination should occur. Termination is sometimes forced on both client and therapist. Neither party may wish to terminate, but one of them may be moving to a new location or agency, insurance policies may limit therapy to fewer sessions than client and/or therapist view as sufficient, or agencies may have a rigid session limit.

The APA ethical standards require therapists to discuss termination with their clients and to provide “appropriate pretermination counseling.” The nature of this pretermination counseling is not specified in the standards, but therapists are instructed to provide referrals for clients when appropriate. In 1994, Mathilda Canter and other colleagues who helped to construct the APA standards suggested that termination discussions should at least summarize the treatment and plan for the future. Oftentimes this future planning includes provision of referrals to other therapists and/or invitations to return to therapy in the future should the client encounter further difficulties.

II. THEORETICAL BASES

In 1993, Stephen Quintana summarized the major theoretical formulation of termination. He indicated that termination has been conceptualized from a psychoanalytic perspective as having two components—loss and development. The loss component was

hypothesized to sometimes reach crisis proportions. It has received some attention with researchers such as Hans Strupp and Jeffrey Binder stating in 1984 that therapists must work to ensure that clients do not suffer a relapse of symptoms because of the loss of their relationships with their therapists. Therapists are also hypothesized to be affected by their loss of relationship with clients. In 1981, Rodney Goodyear argued that therapists who had not grieved past losses sufficiently were most likely to be disproportionately saddened by termination with clients. Quintana stated that some theorists even believed that anxiety surrounding termination has led many researchers to avoid studying the process of termination altogether.

In 1933, Freud conceptualized that the loss triggered by psychotherapy termination facilitates the formation of an internal representation of the lost person (i.e., the therapist). The client compensates for the loss of the therapist by developing his or her own internal resources to replace what the therapist provided. Thus, termination is also viewed as a time of personal development. The client is viewed as maturing under the careful direction of the therapist much in the same manner that a child matures under parental guidance. When the client terminates therapy, he or she carries important internalized aspects of the relationship with the therapist that will facilitate the formation of new relationships with others.

Quintana updated this developmental conceptualization of termination to focus greater attention on the client's contribution to the therapeutic progress. He indicated that therapy is a process of continuing maturation of the client, and that termination is a time to call attention to the client's growth and the therapist's support of the client's progress. Quintana believed that termination is an opportunity to review the client's role in the therapeutic progress. In this way, the client clarifies what he or she did to facilitate change, and should problems arise after termination, the client may use these techniques to handle them. Finally, Quintana endorsed a conceptualization of termination as a sad time because of the loss of the relationship with the therapist that is tempered by the knowledge that the client has outgrown the relationship. Thus, termination represents a time to bid farewell to therapy and move on to new relationships. Quintana compared termination to graduation.

III. EMPIRICAL RESEARCH

Even though termination occurs in all therapy relationships very little research has been conducted on the

termination process. Simon Budman and Alan Gurman suggested in 1988, that for many clients, therapy is an ongoing activity in their lives. They presented evidence that the majority of clients have had previous therapy, and 50 to 66% of clients who terminate will return to therapy within a year. This would tend to dampen the loss felt at termination, because therapy would not really be terminated in the sense that most clients return for further help in the future.

In 1985, Judith Marx and Charles Gelso asked 72 former clients at a university counseling center to indicate the most common behaviors and feelings surrounding their therapy terminations. Over 70% of the sample stated that they and their therapists summarized the therapy, assessed goal attainment, and planned for the future. Contrary to expectations, clients indicated significantly more positive than negative emotions surrounding termination. Clients also reported that more termination work was done when loss had been a theme of therapy, when the client had a closer relationship with the therapist, and when there had been more therapy sessions. The results supported a developmental view of termination rather than a conceptualization of termination as a crisis or loss.

In 1992, Stephen Quintana and William Holahan extended Marx and Gelso's research to therapists by asking 85 therapists what termination activities they engaged in and having them rate their clients' reactions to termination. Each therapist was asked to choose two recent short-term therapy cases—a case in which the therapy outcome was successful and a case where the therapy outcome was unsuccessful. Like Marx and Gelso, Quintana and Holahan found that clients' reactions (as rated by their therapists) to therapy termination were significantly more positive than negative. Not surprisingly, in unsuccessful cases, clients were significantly more likely to devalue therapy. The ranking of termination activities by therapists corresponded closely to client rankings of activities in the Marx and Gelso study. In successful cases, however, therapists were more likely to discuss the course of counseling, client affective reactions to termination, and the end of counseling than in unsuccessful cases. This research suggested that therapists did a more complete job of discussing termination issues with clients from successful therapy cases than from unsuccessful cases.

In 1993, Susan Boyer and Mary Ann Hoffman tested the hypothesis that therapists' reactions to termination would be affected by the impact of previous losses in their lives and their perceptions of clients' sensitivity to loss. They asked 165 licensed psychologists each to

think of a client that they had seen for a minimum of 25 sessions. Therapists rated how sensitive they perceived these clients were to loss. Therapists also answered questions about their own grief reactions to past and present losses as well as questions about their perceptions and feelings surrounding termination with the client. They found that therapists' past grief reactions, present grief reactions, and perceived client loss predicted therapists' anxiety surrounding termination. Therapists' loss and perceived client loss, however, were unrelated to therapists' feelings of satisfaction with termination.

IV. SUMMARY

Termination is the capstone of psychotherapy. It should be a time when all that has gone before is discussed and solidified before the client leaves. Yet we know little about the process of termination. The results of the few studies of termination process suggest that for most clients and therapists psychotherapy termination is a relatively positive event rather than a traumatic loss. These findings support Qunitana's notion that termination serves a developmental function in which clients bid farewell to a relationship that they have outgrown. Loss appears to play a role in termination particularly when client and/or therapist have suffered past or present losses. In these cases, therapists are frequently more anxious about terminating, and loss is an important part of client-therapist termination discussions.

Study results show that most termination discussions cover what transpired during treatment, participants' feelings, and plans for the future. This seems to be particularly true when the outcome of therapy has been positive. When therapy has not been as successful, however, there is less discussion of the end of therapy, clients' reaction to termination, the course of therapy, and the client-therapist relationship. Thus, unsuccessful therapy is mirrored in a less thorough termination experience.

Much more research on the psychotherapy termination process is needed. Many variables need to be explored relative to termination. In particular, it is important to study client and counselor characteristics as they relate to the termination process.

spiritual therapy A form of treatment based on six tenets of transcendence of soul and spirit—love of others, love of work, love of belonging, belief in the sacred, belief in unity, and belief in transformation.

GLOSSARY

analytic (or psychodynamic) therapy A primarily long-term, in-depth treatment concerned with conflictual intrapsychic forces, especially early libidinal urges and repressed childhood memories, which are uncovered and worked through via the interpretation by the analyst of the meaning of the patient's verbalizations.

behavior therapy (or behavior modification) Techniques of conditioning, shaping, and/or training—usually active, structured, time-limited, and directive—for the alteration of maladaptive symptoms and behaviors.

cognitive therapy A form of behavior therapy that addresses irrational beliefs and distortions of thinking, based on the fundamental idea that how a person perceives and structures the world determines personal feelings and behaviors.

existential approach (or analysis) A form of therapy that posits that a person's decisions, commitment, and responsibility for "choosing the future" give meaning to life, whereas choosing the past leads to boredom, meaninglessness, and despair.

interpersonal therapy A form of treatment that focuses on current life events—especially grief, developmental transitions, role disputes, and social deficits—based on the fundamental thesis that disorders are the result of unsatisfactory relationships and social maladaptation, the consequence of the individual's attempts to adapt to surroundings.

I. INTRODUCTION

In an attempt to comprehend therapeutic factors in the total range of psychological treatments, one needs to differentiate the nonspecific elements that all psychotherapies are presumed to share, and the specific elements that may distinguish one school from the others. This article discusses the former under the headings of affective experiencing, cognitive mastery, and behavioral regulation, and the latter under the headings of analytical, behavioral, and experiential schools, each with its own variations. The therapeutic aspect of the therapist–patient relationship is discussed in its various forms: transference and working alliances, and teacher–pupil and person-to-person relations. In clinical practice, these therapeutic factors are not categorical distinctions, but overlapping phenomena. An integration of past and present therapeutic factors is proposed.

II. NONSPECIFIC THERAPEUTIC FACTORS

The following features have been repeatedly cited as basic to all psychotherapies: an emotionally charged,

confiding relationship; a therapeutic rationale (myth) that is accepted by patient and therapist; the provision of new information, which may be transmitted by precept, example, and/or self-discovery; the strengthening of the patient's expectation of help; the provision of success experiences; and the facilitation of the arousal of one's emotions. In their 1980 comprehensive analysis of the benefits of psychotherapy, Mary Lee Smith, Gene V. Glass, and Thomas I. Miller concluded that the weight of the evidence that now rests in the balance so greatly favors the general factors interpretation of therapeutic efficacy that it can no longer be ignored. Thus, above and beyond (or in addition to) the specific features of major modalities that technically differentiate them from one another, a number of universal conditions of therapeutic change have been hypothesized that unite all forms of treatment.

Aside from equivocal research findings from extensive comparison studies of outcome, other lines of support have been cited for a universality thesis. These include cross-cultural, historical, and religious examinations of the recurrent nature of healing agents, particularly the "placebogenic" roles of suggestibility, persuasion, trust, and hope, in changing or curing patients throughout the ages; the paucity of proof that special technical skill, type of training, theoretical orientation, or professional discipline is significantly related to therapeutic results; and, within the past decade, controlled studies of some commonly shared ingredients of successful outcome.

A. Affective Experiencing

Some form of strong emotional arousal was probably the primary tool in the psychotherapeutic cures of primitive man. Often seances were conducted in the presence of a select group of individuals (the psychotherapists of their day), and emotional excitement was induced through smoking, drinking, drugs, and rhythmic music. Such affectively charged situations facilitated patient regression and eased the confession of sins. This type of affective purging process was the prototype for the earliest known structured psychotherapeutic attempt to deal with man's problems.

The specific Freudian version of this was the now-classic "cathartic method," whereby abreaction occurred, with the emergence of repressed memories through the technique of free association. Behavior therapies have also had their affective counterparts in reproducing anxiety-evoking stimuli in imagination or *in vivo* (with or without the accompaniment of relaxation techniques for purposes of systematic desensitization).

Flooding and implosion procedures, for example, re-create high-intensity exposure to feared objects or situations, with the expectation that patients will experience their anxiety as fully as possible and, exhausted with fear and relief, will no longer respond as they used to. Similarly, aversion therapy, by presenting an unpleasant and sometimes painful stimulus, at least temporarily disrupts emotional equilibrium as a precursor of change through reconditioning.

By far the most extensive resurgence of the therapeutic use of emotional arousal and release occurs in the "experiential" approaches. Reichian therapy, Lowenian bioenergetics, and Rolfian structural integration aim to express the affect trapped in the body posture not by analyzing defensive character armor as Wilhelm Reich originally did, but by physically manipulating the muscles that underlie it. Psychodrama enacts the expression of feelings through dramatic improvisations, while uninterrupted lengthy marathon sessions seek emotional access through the by-products of physical exhaustion. Comparably, primal scream and Morita use prolonged isolation and sensory deprivation to lower resistance and break down cognitive defenses—the former expressed in a sobbing, screaming, seizurelike episode to recapture the pain of the primal past, the latter by activating anxiety and distress as a preparatory step toward the creation of a state of spiritual readiness for rediscovering the beauty of life. A basic rationale for such diverse methods is that they aim to facilitate therapeutic change by producing excessive cortical excitation, emotional exhaustion, and states of reduced resistance or hypersuggestibility.

Emotional arousal is one of the major effective ingredients of successful psychotherapy. Following a strong abreaction, there occurs a period of exhaustion that produces heightened acceptance in which the patient appears bewildered, dependent, and eager to find a comforting solution from the therapist. Three experiments by Rudolf Hoehn-Saric in 1978 showed that heightened arousal made patients more receptive to suggestion and therefore more willing to change attitudes than they were under low-arousal conditions. Arousal combined with cognitive confusion yielded even better results than arousal in patients with undisturbed cognitive functions. Heightened arousal under conditions of cognitive disorganization helped to "unfreeze" attitudes necessary for change. Thus, affective experiencing—as a universal change agent in the psychotherapies—may be globally defined as arousing excitement and responsiveness to suggestion: unfreezing and expression of feelings.

The major roles and functions of affective experiencing thus are to set the emotional state for receptivity to

change, to ease the cathartic release of repressed material, and to facilitate patient accessibility by reducing resistance and breaking down defenses. In short, the patient, through the dislodging of persistent chronic attitudes, is made more available for a new cognitive paradigm. However, Hoehn-Saric's results also reflect the finding (often observed clinically) that intense emotional arousal, however profound and necessary to set the stage for therapeutic change to occur, is difficult to sustain. Attitude changes that occurred were short-lived, and repeated interventions were required for such change to be established into a more stable new position. This observation parallels Sigmund Freud's earlier acknowledgment of the limitations of the cathartic method and his significant theoretical transition from release of repressed affects and traumatic memories to their systematic exploration and understanding, that is, from catharsis to insight as the ultimate aim of therapy. It is also consistent with the research conclusion that although heightened arousal under conditions of cognitive organization helps to unfreeze an attitude, it does not necessarily lead to a new solution unless it is followed by cognitive learning.

That is, perhaps the major role of affective experiencing is to emotionally prepare the patient for new cognitive input. Indeed, pure catharsis is considered most effective only in certain limited psychiatric conditions. Moreover, "peak experiences," which may offer attractive opportunities for rapid change, often do not carry over beyond the immediate encounter. In fact, when three therapy groups of differing duration were compared, the curative value of catharsis appeared to diminish in the longest-term group. Thus, some form of affective experiencing appears to be universally applicable, but perhaps largely as a preliminary stage of treatment. Ideally, this means that it should be succeeded by, or combined with, other therapeutic agents that have complementary roles and functions, to maximize or prolong its effectiveness.

B. Cognitive Mastery

All therapies, in some measure, provide the patient with cognitive mastery, whether they offer the classical, well-timed interpretations of Freudian psychoanalysis or, as in Albert Ellis's rational-emotive therapy, have the therapist "sing along" with the patient a litany of the patient's irrational false beliefs. Cognitive mastery thus refers to those aspects of treatment that use reason and meaning (conscious or unconscious) over affect as their primary therapeutic tools, and that attempt to achieve

their effects through the acquisition and integration of new perceptions, thinking patterns, and/or self-awareness. A prototype of a cognitive change agent is the therapeutic application of insight, defined as the process by which the meaning, significance, pattern, or use of an experience becomes clear—or the understanding that results from this process.

Historically, primitive faith healing and the early stages of psychotherapy were very much alike in that neither initially attempted to provide insight. However, while faith healing continued only to maximize suggestion (essentially through affective experiences), Western psychotherapy became distinctive in departing from the primitive mode by moving into a second state—to correct problems by explaining them rationally. Going somewhat farther along this line, although the foundation of all therapies is the phenomenon of therapeutic suggestibility, primitive therapies are based almost entirely on irrational belief and dependency, whereas Western scientific therapies are more often founded on rational insight and independence.

Insight (through free association and interpretation) has been considered a *sine qua non* of the psychoanalytic process, yet all psychotherapies provide opportunities for change through cognitive channels—by means of explanation, clarification, new information, or even confrontation of irrational and self-defeating beliefs. Behavior therapies, once considered the antithesis of an insight-oriented approach, have increasingly incorporated cognitive learning techniques into their repertoire. Over time the behavioral model of treatment has radically changed from that of conditioning to social learning and information processing. The behavioral technique of thought stopping developed by David Wolpe, a cognitive variation of classical conditioning methods to extinguish anxiety, can be considered an early example of this change in approach. Albert Ellis's rational-emotive therapy, William Glasser's reality therapy, and Aaron Beck's cognitive therapy all share in direct attempts to correct stereotyped, biased, or self-defeating thinking patterns and dysfunctional attitudes and values, whereas others, like Victor Frankl's logotherapy and William Sahakian's philosophical therapy, are directed to the most profound cognitive reappraisals of life and its meaning. Even the most actively experiential therapies use cognitive techniques; for example, Gestalt "experiments" can be considered cognitively as a structured interpretation.

Thus, cognitive mastery as a universal therapeutic agent may be defined as acquiring and integrating new perceptions, thinking patterns, and/or self-awareness,

whether this is effected through interpretations, explanations, practical information, or direct confrontation of faulty thoughts and images. In contrast to affective experiencing, it serves as a rational component of treatment—to inform, assess, and organize change and to establish or restore ego control. Despite their therapeutic utility in providing a new perspective, meaning, or way of thinking, cognitive approaches are not always sufficient as change agents. Put succinctly, not all change is attributable to insight and not all insight leads to change.

In the final analysis, the criteria for attaining lasting insight must be judged by its personal and social consequences. In short, new thinking (or insight) that has been achieved in therapy must be worked through and incorporated into one's actions and behavior in everyday life; it must be transferred from the structured and safe confines of the therapist's office and put into active practice in the real world outside treatment. Thus, cognitive mastery, like affective experiencing, needs to be complemented by other therapeutic change agents. More specifically, although an affective experience may prepare the patient for cognitive learning, the latter requires gradual assimilation and behavioral application of new input, if therapeutic effects are to endure.

C. Behavioral Regulation

Behavior modification approaches have directly sought behavioral change as an active goal, and learning to self-regulate or control one's habitual responses has become the thrust of their therapeutic efforts. Methodologically, this has meant the use of an extensive repertoire of reinforcement and training techniques based on research in experimental animal and human social learning laboratories—from classical conditioning to explicit rewards and punishments, to shaping and modeling methods in imagination and *in vivo*.

Nonetheless, as already implied, behavioral regulation as a major change agent is no longer limited to the classical confines of a conditioning model; nor is it restricted to the immediate territory of the behavior therapies. Even psychoanalysis, which has been considered relatively weak as a model for behavioral change, and whose therapists must ideologically refrain from direct suggestion or deliberate manipulation, is by no means exempt from the use of behavioral regulation, at least implicitly. All therapies, albeit in less systematic and sometimes unintentional ways, use methods of behavioral reinforcement, feedback, and modeling. Analytic interpretation influences behavior by labeling, defining a problem, providing permission, implying a course of action, facilitating foresight, and the like. Indeed, re-

search has experimentally demonstrated that subtle cues can shape the responses of patients. Examination of actual excerpts of Carl Rogers's so-called nondirective therapy confirmed that even incidental nods or "hmmms" by the therapist positively reinforced client responses. On a more inaccessible level, unconscious identification with the therapist is considered an essential aspect of shaping and modeling the patient's behavior. In the final analysis, all therapy may be a matter of emotional, cognitive, and behavioral learning.

III. SPECIFIC THERAPEUTIC FACTORS

Although universal features undoubtedly exist, this does not mean that we must *ipso facto* minimize differences in psychotherapy. There are comparative conceptual studies of various forms of psychotherapy that typically cite striking contrasts among them. More recently, experimental studies of different schools have lent some scientific support to the separatist stance. Exemplary of such findings are the systematic studies of analytically oriented psychotherapy versus behavior therapy, supporting the view that these are highly contrasting styles of treatment. Moreover, the treatment procedures created, developed, and chosen in one society or within the context of a particular belief system, may not be transposable to another. This is especially evident in attempts at cross-cultural psychotherapy.

The current state of the art attests to the lack of clarity and lack of resolution of the specificity versus non-specificity controversy in explaining what is the quintessence of the therapeutic cure. This conflicting state of affairs is further compounded by comparative studies of various psychotherapies, which suggest that one's espoused theoretical orientation regarding the nature of the healing process may not always be synchronous with one's actual practices. In a comparison research study of Freudian, Kleinian, Jungian, and Gestaltist therapists, descriptive ratings of the different approaches in action did not differentiate the respective schools of thought, the investigators (and, no doubt, the proponents themselves) naturally expected.

A. Analytical Schools

For the analytic therapist the ultimate task, in its most parsimonious and famous form, is to make conscious the unconscious. The ongoing therapeutic charge is to facilitate the emergence and comprehension of unconscious content. That is, such a therapist seeks to

undo the repressed material of the patient and to overcome the patient's natural resistances to this endeavor. The therapist attempts to accomplish this by means of a slow and scrupulous unraveling of the largely historical meanings of mental events and the characteristic ways in which they may serve to ward off the underlying conflicts through defensive camouflage. Understandably, the analytic goal is thereby a long-range one, perhaps even interminable. At best this concept of cure means opting for total personality reorganization in the final resolution of neurotic conflicts. The most crucial manifestation of this is the resolution of the Oedipal conflict, which is traditionally regarded as requisite for a healthy personality. This ultimate integration of personality would translate itself into final mastery of ego over id impulses or, as classically stated by Freud, "where id was, there ego shall be."

There are believed to be four successive stages in attaining therapeutic insight: (1) preparation, which is characterized by frustration, anxiety, a feeling of ineptness, and despair. It may be accompanied by much trial-and-error activity relevant to the solution of a certain problem and the falling into habitual patterns or ways of thinking, foreseeing no apparent solution to the problem; (2) incubation or renunciation, in which one desires to hide or escape from the problem and is resistant or unmotivated in therapeutic or insightful efforts; (3) inspiration or illumination, in which the whole problem becomes illuminated, and a solution or solutions suggest themselves (often there is a flood of vivid ideas and a sense of finality accompanied by a conviction in the truth of the insight); and (4) elaboration and evaluation, in which the validity of the insight is checked against external reality.

Furthermore, insight is most therapeutic when it meets all of the following specifications: (1) consistency, whereby the deductions based on the original insight are stable and logically sound, regardless of the truth or falsity of the particular content of the insight; (2) continuity, whereby insights must take place within some existing theoretical framework or stream of tradition in which the insight can be tested; (3) personal consequences, whereby the insight must be judged by the fruit it bears in terms of the ultimate use to which the insight is put; and (4) social consequences, whereby the acquisition of insight should allow the person to interact with others in a more honest and meaningful manner.

1. Variations on the Analytical Theme

The prototypic embodiment of the psychoanalytic or psychodynamic theme is, of course, classical psychoanalysis. The variations on the dynamic theme reflect

overt and covert modifications of theoretical conceptualizations as well as methodological and technical applications in practice. These include attempts to partially or completely transcend the biological focus of Freud with more interpersonal, social, ethical, and cultural considerations (e.g., Alfred Adler, Karen Horney, Harry Stack Sullivan, Erich Fromm, Frieda Fromm-Reichmann, and Alfred Meyer); to extend or enhance the ego with earlier or more adaptive endowments (e.g., Federn and Melanie Klein); to enlarge man's temporality with a time focus on his primordial past (e.g., Jung), his present and/or his future (e.g., Adler, William Stekel, Otto Rank, and Rado); to expand treatment procedures by altering the range and goals of treatment (e.g., Otto Rank, Franz Alexander, Helena Deutsch, and Albert Karpman); to shift from ego to self psychology (e.g., Heinz Kohut), to narcissism as a character disorder (e.g., Otto Kernberg) to develop guidelines for short-term psychotherapy with anxiety-provoking techniques (e.g., Peter Sifneos), and even brief treatment of serious illness within the context of a single interview (e.g., David Malan); to revise the role of the therapist's personality and relationship to the patient by making the therapist a more direct, flexible, and/or active participant (e.g., Adler, Sullivan, Rank, Alexander, Stekel, Sandor Ferenczi, and Victor Rosen); to emphasize the developmental approach to diagnosis and treatment (e.g., T. Byram Karasu, James Masterson) at perhaps the opposing end of the analytic spectrum, to restore the psychophysical balance of man by focusing equally on the physical half of the psychophysical split (e.g., Sandor Rado and Jules Masserman) and/or substituting an approach to therapeutic cure from the somatic side by trading the traditional change mode of insight for a reversal back to the earlier catharsis by means of the bodily release of conflictual tensions (e.g., Wilhelm Reich).

The fundamental goals of the interpersonal approach relate to the need to maintain good interpersonal relations and social adaptability; they include reconstruction of present maladaptive relationships and, where possible, restoration of past losses. This means both coping with immediate stressful interactions and forming better or new relationships by developing problem-solving strategies and mastery in social skills. In 1984 Gerald Klerman and Myrna Weissman formulated a short-term, manualized form of interpersonal therapy (IPT), specifically applicable, but not limited to, depression.

In practice, a seasoned dynamic therapist is more broadly defined. This refers to the integration of drive, ego, object relations, and self approaches, and to the more global synthesis of conflict and deficit models.

This integrative model of psychotherapeutic practice acknowledges the joint impact on psychic structure formation of unresolved conflictual urges and wishes interfaced with early environmental deficiencies and traumas in the real-object world of the patient. In terms of treatment, it recognizes the pivotal roles of both erotic and narcissistic transferences in the therapist–patient relationship and in the respective stances and strategies of the listening and empathic presence.

B. Behavioral Schools

For the behaviorist, all problems are construed as pedagogical in nature, and therefore alterable only through direct teaching and learning of new behavioral associations, that is, stimulus–response connections. The patient must be taught new alternatives that have to be repeated and practiced within as well as outside the therapy situation. These alternative modes of functioning do not occur simply as a concomitant of cognitive or emotional understanding of one’s problems—the patient needs to rehearse the new alternatives directly. Thus, in direct contrast to the psychodynamic schools, the behavioral approaches have tended to sustain the view that insight is not only unnecessary but can hinder the treatment of deviant behavior.

One implication of the behavioral view of the mode of therapeutic action is that change can presumably occur within a short period of time. In contrast to the dynamic therapists, behaviorists generally believe that all treatment of neurotic disorders is concerned with habits existing in the present, and their historical development is largely irrelevant. Moreover, some behaviorists have even suggested that it is possible to have a situation in which symptoms have been removed, with no knowledge at all their etiology.

Although all behaviorists may be viewed as seeking change through direct conditioning, shaping, or training, the classical conditioning paradigm sees all therapeutic learning or change (not just behavior therapy) as occurring within the reciprocal inhibition framework, incorporating the substitution of relaxation for anxiety in the reduction or elimination of symptoms. However, more critically, the difference between behavior therapy and other therapeutic modalities is that in the latter, counterconditioning of relaxation over anxiety occurs indirectly unsystematically, whereas in behavior therapy this process is overt, systematic, and under the direct control of the therapist.

In Jan Ehrenwald’s 1966 words, the behavioral schools of psychotherapy actively relinquish “the methods of the

couch” and replace them with “the methods of the classroom and the pulpit.” Behavior therapists have at their disposal a large variety of conditioning, training, and other directive techniques. This repertoire may include any or all of the following: the more classical conditioning techniques of systematic desensitization combined with deep muscle relaxation, implosion, or assertiveness training; the operant techniques of positive or negative reinforcement, such as aversiveness training; shaping or modeling; and/or the direct transmission of advice, guidance, persuasion, and exhortation. The latter methods more typically reflect the means by which behavior modification has been extended recently to the teaching or conditioning of attitudes underlying specific behaviors, methods of philosophical indoctrination, or cognitive programming.

The behavioral counterpart of the psychodynamic procedure of working through is behavioral rehearsal within the confines of therapy, as well as assignments to be worked on outside of therapy; these are important parts of the total regimen. For example, the patient might be directly trained in certain social skills that may first be role-played or rehearsed within the course of therapy, and then explicitly instructed and tested out in outside, real-life situations, and reviewed in subsequent sessions.

1. Variations on the Behavioral Theme

Three broad types of behavior therapies or behavior modification are considered under the umbrella of the behavioral theme: one, based on the early classical Pavlovian paradigm, primarily uses systematic desensitization or extinction of anxiety techniques (e.g., reciprocal inhibition therapy); a second type, based on an operant paradigm, uses direct reinforcement by means of reward/punishment procedures (e.g., token economy); and a third type, based on a human social learning paradigm, is contingent on direct modeling or shaping procedures (e.g., modeling therapy). The last type extends to a variety of new systems of directive psychotherapy that expressly aim at attitudinal or philosophical restructuring, albeit using methods of the behaviorist’s laboratory. Such so-called integrity therapies share the fundamental learning or problem-solving stance, yet are usually more actively advisory and/or exhortative in their therapeutic techniques (e.g., Albert Ellis’s rational therapy, William Glasser’s reality therapy, and William Sahakian’s philosophic psychotherapy).

Another way of viewing the scope of these behavioral variations is through the evolution of their targets of change, from external to internal alterations in man’s learnings. The earlier behavior therapeutic systems

addressed overt behaviors and fears (e.g., Wolpe); the more recent systems are directed to more covert values and beliefs (e.g., Ellis). The most contemporary approaches even venture into the reaches of inaccessible and involuntary mental and physiological states and responses, such as heart rate, blood pressure, and brain waves (e.g., biofeedback).

Whereas in typical behavior modification, alterations in overt behavior are viewed as an end in themselves, with the cognitive approach they are considered a means to cognitive change. In 1979, Aaron Beck formulated a short-term, manualized form of cognitive-behavior therapy (CBT). The goals of this approach have been succinctly stated as: (1) to monitor negative, automatic thoughts (cognitions); (2) to recognize the connections between cognition, affect, and behavior; (3) to examine the evidence for and against the distorted automatic thoughts; (4) to substitute more reality oriented interpretations for these biased cognitions; and (5) to learn to identify and alter the dysfunctional beliefs that predispose the person to distort his or her experiences.

The major cognitive aims or processes of change have four successive components: recognition of faulty thinking through self-monitoring, modification of thinking patterns through systematic evaluation, empirical testing of the validity of automatic thoughts and silent assumptions, and self-mastery by means of homework and everyday practice on one's own. The initial phase of treatment, which aims at symptom reduction, emphasizes the recognition of self-destructive thoughts, whereas the subsequent phases, which aim at prophylaxis, concentrate on the modification of specific erroneous assumptions within and outside the treatment sessions. To isolate, control, and change illogical thinking—the cognitive concept of cure, treatment is organized to elicit and subject to rational examination the actual mental contents of conscious depressive ideation (current automatic thoughts, silent assumptions, attitudes, values, daydreams) and to trace their impact on dysphoric feelings and behaviors in current concrete situations. CBT has recently been applied to disorders other than depression. Its ultimate purpose is self-control and self-mastery—patients explicitly rehearse and train themselves to recognize and restructure their own faulty cognitions so that they can cope better in the future.

C. Experiential Schools

The experiential schools of psychotherapy trade intellectual cognition and insight for emotion and experi-

ence, forsaking the there and then of the distant past for the here and now of the immediate present. Experiencing is a process of feeling rather than knowing or verbalizing; occurs in the immediate present; is private and unobservable, but can be directly referred to by an individual as a felt datum in his own phenomenal field; acts as a guide to conceptualization; is implicitly meaningful, although it may not become explicitly so until later; and is a preconceptual organismic process. The many implicit meanings of a moment's experiencing are regarded not as already conceptual and then repressed; rather, they are considered in the awareness but as yet undifferentiated. Here therapeutic change occurs because of a process of experiencing in which implicit meanings are in awareness, and are intensely felt, directly referred to, and changed—without ever being put into words.

One variation of this thesis, especially applicable to Roger's client-centered therapy, reflects the underlying positive belief that every organism has an inborn tendency to develop its optimal capacities as long as it is placed in a optimal environment. The patient is offered an optimistic self-image and the understanding that the patient is basically good and full of potential. Therefore, the therapist does not need to challenge or shape the patient, only to offer a warm and understanding milieu that will enable the patient to unfold latent potentials.

Unlike transference, which is dependent on the revival of a former interpersonal relationship, experiential encounter works through the very fact of its novelty. Through encounter the therapist serves as a catalyst in whose presence the patient comes to realize his or her own latent and best abilities for shaping the self. In this behalf, there are schools of psychotherapy within the experiential theme that recoil at the idea of therapeutic technology. These schools, which are predominantly existential, renounce technique as part of their philosophy of understanding human existence. They feel that the chief block in the understanding of man in Western cultures has been an overemphasis on technique and a concomitant tendency to believe that understanding is a function of, or related to, technique. Rather, they feel that what distinguishes existential therapy is not what the therapist would specifically do, but rather, the context of the therapy. In other words, it is not so much what the therapist says or does, as what the therapist is. However, in this regard the existential schools of psychotherapy have been criticized for their vagueness about technical matters in the conduct of psychotherapy.

The experiential schools aspire to flexibility or innovation in their actual methods, as long as these methods

are useful in the therapist's attempt to experience and share the being of the patient. Here the aim of all techniques would be to enter the phenomenological world of the patient. In direct contrast to the view of the analytic therapist, the experiential therapist does not concern himself or herself with the patient's past, the matter of diagnosis, the aspiration of insight, the issue of interpretation, or the subtle vicissitudes of transference and countertransference. Unlike the behavioral therapist, the experiential therapist expressly does not set goals for the patient and does not direct, confront, or otherwise impose his or her personality on the patient with directives in the form of behavioral instructions or problem-solving preferences.

Although they share the same basic faith in the therapeutic encounter and an emphasis on feelings, schools under the experiential umbrella are often antiverbal in approach. Such schools (e.g., Gestalt therapy) view overintellectualization as part of the patient's problem, that is, a manifestation of defense against experiencing or feeling, and discourage it as part of the therapeutic endeavor. These therapies attempt to accentuate activity over reflection, emphasize doing rather than saying, or, at the minimum, aim to combine action with introspection. The goal of experiencing oneself includes developing the patient's awareness of bodily sensations, postures, tensions, and movements, with an emphasis on somatic processes. Awareness of oneself as manifested in one's body can be a highly mobilizing influence. The main thrust of therapy is therefore to actively arouse, agitate, or excite the patient's experience of self, not simply to let it happen.

Among the techniques for expressing one's self-experience in such schools is the combination of direct confrontation with dramatization, that is, role-playing and the living out of a fantasy in the therapeutic situation. This means that under the direction (and often the creation) of the therapist, the patient is encouraged to play out parts of the self, including physical parts, by inventing dialogues between them. Performing fantasies and dreams is typical and considered preferable to their mere verbal expression, interpretation, and cognitive comprehension. In variations of the somatic stance, body and sensory awareness may be fostered through methods of direct release of physical tension, and even manipulations of the body to expel and/or intensify feeling.

In yet other attempts to unify mind, body, and more especially, spirit, the immediate experience of oneself by focusing on one's spiritual dimension is sought. This is most often accomplished through the primary technique of meditation. The ultimate state of profound

rest serves to transcend the world of the individual ego, forming a higher reality or state of consciousness that the individual ego subserves. Major methods of will training and attention focused on a special word sound or mantra, for example, serve to create an egoless transcendent state.

1. Variations on the Experiential Theme

The therapeutic systems that have evolved under the experiential theme represent various approaches, each propelled by the immediate moment and geared toward the ultimate unity of man. These include the following: (1) a philosophic type, which reflects existential tenets as a basis for the conduct of psychotherapy and pivots on the here-and-now mutual dialogue, or encounter, while retaining essentially verbal techniques (e.g., Carl Roger's client-centered therapy and Victor Frankl's logotherapy); (2) a somatic type, which reflects a subscription of nonverbal methods and aspiration to an integration of self by means of focusing attention on subjective body stimuli and sensory responses (e.g., Fritz Perls' Gestalt therapy) and/or physical motor modes of intense abreaction and emotional flooding in which the emphasis is on the bodily arousal and release of feeling (e.g., Alexander Lowen's bioenergetic analysis and Janov's primal scream therapy); and, finally, (3) a spiritual type, which emphasizes the final affirmation of self as a transcendental or transpersonal experience, extending one's experience of self to higher cosmic levels of consciousness that ultimately aim to unify one with the universe. This is primarily accomplished by means of the renunciation of the individual ego. The establishment of an egoless state can occur by meditation (i.e., relaxation plus focused attention) in which one reaches a state of profound rest (e.g., Transcendental Meditation). Such a spiritual synthesis may be amplified by various techniques of self-discipline and will training, for example, practice of disidentification (e.g., Assagioli's psychosynthesis).

A most recent "variation on a theme" crosses the boundaries of the above three schools. Dialectical Behavior Therapy (DBT), originated by Marsha Linehan, Ph.D., in 1993, empirically supported multimodal psychotherapy, initially developed for chronically parasuicidal women diagnosed with borderline personality disorder (BPD). DBT blends standard cognitive-behavioral interventions with Eastern philosophy and meditation practices, as well as shares elements with psychodynamic, client-centered, Gestalt, paradoxical, and strategic approaches. DBT structures the treatment hierarchically in stages. It is based on Linehan's biosocial theory, whereby

etiology of this dysfunction lies in the transaction between a biological emotional vulnerability and an invalidating environment.

IV. THE RELATIONSHIP AS THERAPEUTIC FACTOR

The patient's relationship to the therapist embodies one of the most powerful forces in the therapeutic enterprise. Psychotherapeutic changes always occur in the context of an interpersonal relationship and are to some extent inextricable from it. In the next section, these therapeutic relations are discussed under the three headings of transference-therapeutic; teacher-pupil; and person-person. Again, they are far from being categorical distinctions. Rather, they simultaneously occur in different combinations and emphases.

A. Transference Relations and Working Alliances

Deliberate, systematic attention to the vicissitudes of the special relationship between therapist and patient is crucial to the conduct of the psychoanalytic approach. It constitutes both the subject and the object of analysis. Historically, two stances—transference versus nontransference—have been described in portraying the psychodynamic psychotherapies: the primary stance with regard to the making of the transference relationship and, more recently, the secondary stance with regard to the making of a working or therapeutic alliance. Despite increasing acceptance of combining them in the therapeutic situation, these represent dual postures, even antithetical to each other, both in their essential purposes and in the actual requirements they make of the therapist.

The primary stance reflects Freud's original recommendations: (1) that the analyst be like a mirror to the patient, reflecting only what is reflected by the patient and not bringing personal feelings (attitudes, values, personal life) into play; and (2) that the analyst follow a posture of privation or rule of abstinence, that is, technical motives must unite with ethical ones in preventing the therapist from offering the patient the "love" that the patient will necessarily come to crave. These two basic requirements are traditionally made of the analyst, if the analyst must remain relatively removed and anonymous, a deliberately dispassionate observer and reflector of the patient's feelings. Such a therapeutic relationship is necessarily asymmetrical.

Conversely, the more recent concept of a working or therapeutic alliance reflects an alternatively nonregressive, rational relationship between patient and therapist. Although still in the service of analyzing transference and resistances, it means that the therapist aims at forming a real and mature alliance with the conscious adult ego of the patient and encourages him or her to be a scientific partner in the exploration of these difficulties. The real object need of the patient, deliberately frustrated by the transference relationship, is relatively satisfied by the therapeutic alliance. This therapeutic alliance has several variations and names, that is, working alliance, holding environment, corrective relationship, and empathic relationship. For example, self psychology introduced a new concept to psychology—the self, an experiential construction, the perceiver's own experience. Here the therapist provides an empathic atmosphere to foster development of a coherent self, and facilitates not so much insight as transmuting internalization, to crystallize the self. He or she is therapeutic through contemporary self-object functions for the self within an interpretive framework.

B. Teacher-Pupil Relations

The nature of the therapeutic relationship between therapist and patient in the behavioral therapies is an essentially educative, teacher-pupil relationship. It is a deliberately structured learning alliance in which, at its best, attention is drawn to the more current and presumably constructive aspects of the patient's personality in collaborating on the course of therapy. Here the behavior therapist has been depicted as a learning technician or social reinforcement machine. Although this rubric may apply to all therapies to greater or lesser degrees, usually the behavioral therapist openly regards him or herself as an instrument of direct behavioral influence or control, one who directly and systematically manipulates, shapes, and inserts individual values in the therapeutic encounter. In a comparable context, the therapist shapes personal behavior so as to be a social reinforcer for the patient. If the therapy does not proceed smoothly or effectively, the behavior therapist revises the behavioral plan or schedule to better fit the patient to treatment.

Behavior therapy deliberately does not dwell on the therapist-patient relationship; at most, it does so secondarily, only to the extent that this is seen to be important in securing the patient's cooperation with the therapist's treatment plan. The behavior therapist's use of warmth, acceptance, and any other relationship

skills is common but relegated to the realm of secondary “relationship skills” that are not crucial therapeutic requirements for desired change to occur in the patient.

The term *collaborative empiricism* has been coined to characterize the major therapeutic relationship in cognitive therapy—CBT, a specific form of behavior therapy for treatment of depression—in which the therapist is continually active and deliberately interacting with the patient. The two participants have been further depicted as an investigative team; the content of each depressed thought is posed as a hypothesis to be tested by two scientists, who collect all the evidence to support or refute that hypothesis. Under the collaborative empiricism model, the major role of the therapist is primarily educative—to instruct and advise the patient in rational thinking and to provide active guidance during systematic reality testing, which is considered intrinsic to the cognitive approach. The therapist actively points out automatic thoughts, helps to identify cognitions from the patient’s report of recent experiences, reviews patient records, assigns homework, and provides concrete feedback. Often part of this tutorial approach is a direct problem-solving, question-and-answer format, with which the therapist and patient can jointly explore the patient’s cognitions.

Interpersonal therapy (IPT) shares elements with both the psychodynamic and cognitive approaches as it addresses four major foci or problem areas: interpersonal role disputes, especially between family members; difficult role transitions in coping with developmental landmarks or significant life events, such as getting married or divorced, having a child, changing careers or retiring from work; interpersonal deficits, including inadequate social skills; and abnormal grief reactions. It emphasizes the solving of interpersonal problems and entails supportive and behavioral strategies as well as both directive and nondirective exploratory methods—information, guidance, reassurance, clarification, communication skills education, behavioral modification, and environmental management. Didactic education techniques and environmental interventions are largely used in initial efforts to ameliorate overt symptoms, whereas support, exploration, behavioral modification, and social skills training are subsequently applied to specific interpersonal issues.

C. Person-to-Person Relations

Although methods may vary, the real here-and-now therapeutic dialogue or mutual encounter, between therapist and patient is the *sine qua non* of many of the

experiential schools. It is an emotionally arousing human relationship in which each person tries to communicate honestly, both verbally and nonverbally. These approaches to psychotherapy ideologically aspire to an egalitarian treatment model. The human alliance is not of analyst to patient or teacher to student but of human being to human being. Here the therapist is still presumably an expert; but, if he or she is not first of all a human being, the expertness will not only be irrelevant, but even possibly harmful. Rogers stated that if the patient is viewed as an object, the patient will tend to become an object. Therefore, this type of therapist says in effect: “I enter the relationship not as a scientist, nor as a physician who can accurately diagnose and cure, but as a person, entering into an interpersonal relationship.” Naturally, what one construes to fall within the domain of personal or real in a therapeutic relationship is open to interpretation. The state of the art of therapeutic factors suggests that new paradigms are necessary to combine and transcend diverse perspectives of schools. As there are transcending non-specific elements, there are also transcending dimensions to all specific therapeutic relations and techniques.

The psychotherapeutic relationship possesses certain qualities of other relationships, such as between parent–child, teacher–student, and friend–friend, but it is also quite different from them. It is not natural, induced, or intended. It seems spontaneous but is not random, in fact, calculated. It has an intuitive quality but is learned, in fact, cultivated. It seems informal, but is quite serious. There is a system to this relationship—psychotherapy requires the systematic use of the human relationship. Based on the degree of consolidation of the patient’s psychic apparatus, the therapist may modulate his or her activities to establish and maintain the relationship with the patient, no matter what technique used; and he or she may use any technique. Yet all techniques are implemented interpersonally, even prescribing of a medication.

The relationship is potentially a healthy medium in and of itself. The cumulative aspect of the interpersonal relationship was an inspiration for the emergence of the Sullivanian school. For analytically oriented therapists, their schools’ contributions of four patient–therapist relationships (transferential, therapeutic alliance, object relations, self-object) are diagnostic and formative. The analytical therapist’s first task is to establish a relationship, but the second task is to explore what that relationship reveals. For the nonanalytical practitioner, there are the patient’s relational predispositions. The therapist does not need to use the relationship as a

formative technique but must be aware that whatever technique used, these relationships will come to play.

V. AN INTEGRATION: THE PAST AND THE FUTURE

With shifting paradigms, every therapist must synchronize with the patient, not unlike meshed teeth of a cogwheel, and become a presence in the patient's psychic life. The technique evolves from such a presence. It has been said that the relationship is never sufficient. The technique alone is not feasible. The first task, the most fundamental technique, would be how to establish and maintain the therapeutic relationship. The second task is to apply any technique that is potentially useful and within the range of the therapist's competence and patient's receptivity.

Finally, we must not forget that there were "therapeutic factors" long before such a term was invented. Our professional ancestors used overarching teachings of their religions, the knowledge of their times, and their cultural myths in the service of the healing arts. Today, we can benefit from our professional ancestors by learning ways of the soul and the spirit, and by incorporating these into "spiritual psychotherapy," as recently described by T. Byram Karasu. Six tenets of transcendence incorporate the fundamental thesis that the way to soulfulness is through love—love of others, love of work, and love of belonging; and the way of spirituality is through believing—belief in the sacred (reverence for all life), belief in unity (i.e., oneness with nature and the universe), and belief in transformation (i.e., sense of the continuity and renewal of the life

cycle)—the combination of which may turn out to be the superordinate therapeutic factors.

GLOSSARY

arousal A heightened emotional or cognitive state in response to sensory input or internal neural stimuli.

attunement Alignment of the therapist and clients' emotional states so that each can experience the other's subjective world. This permits the sense of emotional communication and connection often described as "being together" and "feeling felt." The nonverbal signs of eye contact, body gestures, facial expressions, and tone of voice communicate the state of mind of each member of a dyad through the orbitofrontal cerebral cortex. Neurophysiological mechanisms use these stimuli to integrate several domains of the human experience, including emotional regulation, response flexibility, consciousness, social relationships, and the evaluation of meaning. Misattunements lead to emotional dysregulation, which require "interactive repair" through a sufficient number of beneficial interpersonal experiences for the child or adolescent to achieve or regain emotional regulation. Storytelling supports the "secure attachment" developmental state. This state tolerates arousal of excitement, interest, and enjoyment, and emotional resonance, which allows these pleasure effects to persist.

imagery The arousal of mental images through sensory neural stimuli.

resonance The mutual emotional alignment of the mental states of two individuals that persists within the mind of each individual after the direct interaction is no longer present. Secure developmental attachments allow children to tolerate the resonance of high-intensity emotional states without discomfort, while children with less secure attachments may experience affect blocking.

transitional phenomena Refers to a metaphorical dimension of living that does not belong to an external or internal reality, and a place that both connects and separates outer and inner. Donald Winnicott conceived of it as the area where cultural experience, creativity, playing, stories, and being occur. Contemporary developmental neurobiologists relate transitional phenomena to the complex neural interactions observed in attunement and resonance.

The stories that people tell are the container that holds their world together and gives meaning to their lives.

Andrew Ramer

I. DESCRIPTION OF TREATMENT

Stories within a psychotherapeutic setting can facilitate positive interpersonal interaction between therapist and client, and can provide emotional enrichment and inner cognitive resourcefulness. Either therapist or

client, in individual, family, or group therapy, may initiate the story. The setting can be a private office or an inpatient or outpatient institutional facility.

Both client and therapist often experience pleasure and camaraderie from following unwinding plots that stimulate mental images through curiosity, dilemma, suspense, delight, fear, and relief. Intimacy can occur because both therapist and client reveal much of themselves, their personal interests, values, attitudes, and playfulness. Clients may be able to speak of their issues more comfortably and indirectly in story or metaphor form than in explicit conversation. Developmental neurobiologists have suggested that metaphoric and story experiences help young people to organize emotions and integrate social experience through a process of "interpersonal neurobiology" of the developing mind.

Of particular value in therapy are young people's autogenic (spontaneous) stories, metaphors, and self-narratives, because these encode information about their developmental experiences, emotional maturity, and ability to achieve interpersonal synergy. The therapist who uses storytelling skillfully with these goals in mind can often build an alliance with young patients.

Early in the first encounter a well-chosen story may allay some of the child's natural anxiety, fear, and distrust, while energizing memory, emotion, and self-awareness. As psychotherapy progresses, stories can continue to serve treatment goals. Often the mutual exploration of an evolving spontaneous metaphor becomes the core of the helping enterprise.

One of the author's 7-year old clients enthusiastically referred to the stories in the therapy sessions as "word movies," thereby innocently naming the pleasant images he had experienced. At the start of each group session he would eagerly ask, "Will we have word movies today?"

Useful resources are increasingly available for the therapist interested in developing a storytelling approach, and customizing it to the specific client needs and clinical settings. Planning the therapist stories in advance, selecting an environment free of interruption, and orchestrating the necessary neurobiological dynamics that accompany effective storytelling, is necessary to optimize their therapeutic value. These necessary dynamic elements include attunement, resonance, imagery, modeling, transference, countertransference, social interaction, and interpretation, as shown in Table I.

TABLE I
Developmental, Neurobiological, and Dynamic Principles in Storytelling Sequence

<i>Storytelling component</i>	<i>Developmental/neurobiological correlate</i>
Private area	Allows focusing on group experience
Free of interruptions	Fosters attunement and resonance
Familiar staff members present	Provides comfort, safety, and trust
Drama, animation, stage props	Activates five senses, emotional arousal
Audience vocal participation	Activates interpersonal awareness
Vaguely mysterious storyteller persona	Excites curiosity, memories, images
Children gather around	Corporate experience is to be shared
Name recognition	Each child recognized, valued
Refocusing client's attention	Attunement gateway to rich experience
Storyteller's first story	Example of model structure to be realized
Children participate	Child plays role in enactment of model
Applause, discussion	Recognition, gratitude, challenging
Feedback from the children	Each child's peer input valued, used
Children volunteer their story	Opportunity for meaning making
	Permission to resonate and experiment
	New insights on personal self-narrative
"Storyteller hat," "storyteller seat"	Child earns status from staff and peers
	Social rewards for risk taking
Applause, discussion	Child's risk-taking is reinforced by peers
	Value of peer approval is learned
Staff attention to emotion and content	Can we decode child's emotional clues?
	What themes trigger arousal or anxiety?
Revealing autobiographical narratives	Child risks self-disclosure
"Oscar" calls	Narrative bridging object
Assessing the emotional experience	Transference, countertransference, synergy?

The mix of each of these elements varies with who is present at the storytelling session, who tells the stories, how interesting and well-told the stories are, how the group interacts socially, and many other factors. Because of the calls to memory and the unconscious, no two storytelling experiences are ever identical for an individual participant. Listening to children's after-story interpretations makes that phenomenon clear. Each child hears a unique story, and each storytelling is a unique never-to-be-repeated telling for the storyteller, because it is mysteriously nuanced by the presence and interaction of the listeners.

Knowledge of current literature and resources in storytelling presented in this article may facilitate selection, creation, and use of story techniques that can be shaped to specific client circumstances through the art of the therapist, and the use of client autogenic stories.

II. THEORETICAL BASIS

Storytelling and metaphors supplied by psychotherapists and clients are a universally recognized resource for developing rapport with children, and a technique that has a venerable reputation among psychotherapists since the early work of Helmut von Hug-Hellmuth, a Vienna psychiatrist, in 1913. He liked to make up disguised stories with young clients that might begin, "I used to know a little boy a lot like you who used to wet his bed, too, but he learned how to get over it." Over time the client would gradually begin to guess that he himself was the true protagonist, the "little boy" in the therapist's story.

Contemporary and later influential psychotherapists such as Sigmund Freud, Carl Jung, Anna Freud, Bruno Bettelheim, Milton Erickson, and Erik Erikson also advocated their own distinctive theories and treatment goals in the use of stories and metaphors, and commented on their relationship to play and dreams. David Gordon wrote in 1988, "Metaphors, in the form of fairytales, parables, and anecdotes, are consciously and unconsciously used by therapists in order to assist a client in making changes he wants to make."

Freud, through analysis of his own dreams, as well as those of his patients, gradually became aware of the resemblance of dreams to Greek tragedies and to mythology. Using the Sophocles *Tragedy of King Oedipus*, Freud made his interpretation of the Oedipus myth into one of the cornerstones of his scientific psychological system. He came to believe that the "Oedipus complex" was a critical key to the understanding of the history and evolution not only of social interaction, morality, and reli-

gion, but of normal and abnormal child development as well. As he put it, the Oedipus complex, with its unconscious guilt of imaginary patricide and incest, was "the kernel of neurosis." Carl Jung carried his teacher's ideas even further. He observed early in his psychoanalytic training that the powerful revelational emotional reactions and remembered experiences that occurred through the language of dreams, stories, metaphors, and childish play might relate to the presence of universal unconscious archetypes or archaic symbols that operated in the unconscious. Because of his theory that in the unconscious of modern man existed a vestige of the active mind of primitive man that was overtaken by later concessions to logic and written language, he later referred to archetypes as natural symbols or primordial images. The extensive findings of similar archetypal themes in his investigation of primitive cultures and myths from around the world, and in studies of medieval alchemy symbols, reinforced the validity of Jung's concept of archetype.

This wider cultural anthropological theme was further developed by Jung's friend Joseph Campbell, whose *The Hero with a Thousand Faces* in 1968 popularized Jung's concept of a universal subconscious archetype by showing the remarkable similarity of myths and legend themes from many unconnected cultures of the present and past. Not surprisingly Campbell's favorite lifelong venue was the New York Museum of Natural History.

Freud, Jung, and Campbell also called attention to important gender themes in human development. Myths and fairy stories frequently depict conflicts between maternal and paternal imperatives metaethically encoded in matriarchal and patriarchal social systems. These powerful archetypal images arouse both conscious and unconscious emotions. Homer's *Odyssey* provides us good examples in the protagonists Odysseus and Penelope. Penelope, the matriarch, embodies love, fidelity, care, and nurture and protection of children. She values ties to her (and Odysseus's) bloodline, ties to the earth (a live tree branch grows through the marital bed), universality, tolerance, acceptance of natural phenomena, longing for peace, and tender humanness. The woman's womb may produce many brothers and sisters to every human being, and all should have a chance to thrive. Meanwhile, Odysseus, the patriarch, embodies the archetype of adventurousness and risk-taking, obedience to divine authority, and a hierarchical order in society. In place of the feminine concept of equality of offspring and impartiality toward each, with Odysseus we encounter the concept of the favored son. Odysseus is as sexually promiscuous as his wife is

chaste. He is crafty and ruthless in combat and takes the lives of many mothers' sons in order to win honor and fame for himself. He pillages cities, takes his enemies' treasure and his enemies' wives and children as slaves or concubines, and desecrates nature by killing bulls, cutting down trees, making bonfires, and raising elaborate buildings. Through recklessness and offense to the gods he loses all his comrades, ships, and plunder, and returns home alone to desolated families, leaving a trail of corpses behind. He arrives home just in time to slaughter all of Penelope's suitors, thereby keeping his honor and winning more fame. Having no womb to make children, the patriarchal archetype makes words, fame, commerce, theology, waste, and war.

In the Judeo-Christian Scriptures God is envisioned as a patriarch and patron, whose preexistence and authority mysteriously emanated from "the Word." The Gospel of St. John begins with the patriarchal vision, "In the beginning was the Word, and the Word was with God, and the Word was God." These gender themes preserved since the dawn of the human record continue to be relevant to the world we now inhabit, and are alluded to in a recent genre of gender psychology books that began with John Gray's *Men Are from Mars, Women Are from Venus*.

David Hicks, Headmaster at Darlington School, in Rome, Georgia, commented in a homily in 2001 on the persistence of metaethical archetypal themes, "Now, the influence of the world and the mind runs both ways. The world ultimately reflects the minds of those who inhabit it. At the same time, our minds mirror the world we inhabit" (and, we might add, the stories that reinforce these archetypes).

Using storytelling and metaphor allows the therapist access to a domain of childhood usually off limits to adults because storytelling can bypass both client anxiety and emotional resistances.

Richard Kopp in 1995 classified these resistances as both those known to the client (secrets actively avoided) and not known to the client (unconsciously avoided), both of which can be a barrier to learning the issues that prevent "living a free and full life." Because it specifically avoids confronting resistances, storytelling to and by children is usually more successful than direct questioning in assessing a child's attitudes, emotional intelligence, moral intelligence, assumptions, inner drives and conflicts, and the child's developing self-narrative. With children in groups, important information about the social interaction with peers and caregivers can also be assessed. Storytelling is also compatible and used with every major discipline of psychotherapy, and many psychotherapists use stories routinely.

III. APPLICATIONS AND EXCLUSIONS

The author conducts a regular weekly storytelling group for children ages 5 to 12 at a 300-bed child and adolescent psychiatric facility in Westminster, Colorado. One group of clients is inpatient, one is a day hospital group, and another a public school day-hospital group. Group size varies from 5 to 15. In addition, the author regularly uses selected storytelling along with autogenic autobiographical poems and fairy tales in a weekly adolescent values group with 10 to 20 clients ages 12 to 18. Because the ability to fathom abstract ideas and to activate the imagination is a necessary part of understanding metaphor and stories, young clients who suffer from, for example, developmental disability, obsessive-compulsive disorder, psychosis, or profound sedation from psychotropic drugs may not be able to benefit from storytelling. These children may have such a limited vocabulary or a concrete or unimaginative perception that the point of proverbs and metaphors may be a complete mystery to them. In fact, in every storytelling group the ability of children to attune, resonate, focus, engage, and interact varies, depending on many factors, including their developmental level, their degree of anxiety, their psychoactive medication, their underlying behavior disorder, and their ability to be playful.

For these reasons advance consultation with unit staff in planning a group helps the storyteller therapist understand each child's handicaps as well as to avoid distractions and logistical missteps. Children who are oppositional, acting out, or completely somnolent due to medication are best excluded from the storytelling activity group until their behavior permits their ability to participate and not distract others. On the other hand even some children who speak slowly or have speech impediments, are shy, or have other difficulties, should be allowed and encouraged to tell their stories if possible, and the therapist leader should help the other group members to be patient and respectful of the handicapped individual. This models the social values of tolerance and compassion. The presence of familiar unit staff members to calm or redirect children who are inattentive or who "act out" during a group is essential, since the storyteller is engaged and cannot take time out to deal with unexpected individual behavior. Fortunately the enthusiasm carried over by children and staff from week to week often makes the storytelling group familiar, popular, eagerly awaited, and fun. Because children are aesthetically discriminating, quality stories may help children overlook distractions. Both

children and adolescents prize stories that are imaginative, dramatic, novel, subtle, intricate, and well told. Not infrequently children will request repetition of a story that they liked from the previous week.

IV. EMPIRICAL STUDIES

The quest for identifying the exact neurobiological pathway(s) by which storytelling and metaphor connects with development, consciousness, and unconscious goes back as far as Friederich Nietzsche, who coined the term “the third ear” in *Beyond Good and Evil* in 1886. Nietzsche proposed that with this imaginary extra ear we are able to hear and recognize the metaphorical language of our intuition.

J. L. Despert and H. W. Potter in 1936 reached the following conclusions from their clinical experience in therapeutic storytelling:

1. The story is a form of verbalized fantasy through which the child may reveal his or her inner drives and conflicts.
2. A recurring theme generally indicates the principal concern or conflict, which in turn may be corroborated with other clinical evidence (e.g., dream material).
3. Anxiety, guilt, wish fulfillment, and aggressiveness are the primary trends expressed.
4. The use of stories appears to be most valuable when the child determines the subject of the story.
5. The story can be used as both a therapeutic and an evaluation device. These observations are still valid.

Donald Winnicott wrote in 1971 of a “third area” of reality, as a dimension in which cultural experience is located between interior and exterior reality. He speculated that in this third area the young person experiences play, humor, metaphor, and stories as “transitional phenomena.” Winnicott believed that the role of the child psychiatrist was to help the child who was unable to play attain the state of being able to play, and that “psychotherapy takes place in the overlap of two areas of playing, that of the patient, and that of the therapist.”

Winnicott also described his experience with finding an unconscious meeting ground with children. He wrote of a “sacred moment” in the initial interaction of client and therapist when the child, aided by storytelling, believes that he or she is being understood in a common metaphorical language. He noted that the function of this sacred moment could either be to allow deep work

during the first interview or serve as a “prelude to longer or more intensive psychotherapy.”

Bettelheim, like Winnicott, was also highly aware of the “enchanted moment and place” phenomenon that stories could provide. He pointed out in 1975 an important subtlety of Grimms’ and other traditional fairy tales: “The unrealistic nature of these tales ... is an important device, because it makes obvious that the fairy tale’s concern is not useful information about the external world, but about processes taking place in an individual.” Milton Erickson, who was himself a gifted and creative storyteller and metaphor artist, theorized in 1979 on the basis of extensive hypnotherapy experience that the location of the “third ear” of Nietzsche or “third area” of Winnicott was a specialized neuroanatomical site in the right cerebral hemisphere containing the primary process locus for processing not only metaphorical language but psychosomatic symptomatology as well. Erickson believed that this anatomical localization could account for the more rapid improvement in psychosomatic complaints when metaphorical and hypnotherapy rather than standard psychoanalytical approaches were employed.

Neurobiological research with infants by Daniel Siegel in 1999 and by Alan Schor in 2001 and the earlier work of Daniel Stern has identified primary processing in human preverbal and verbal stages of development that correlates with the appearance of symbolic and metaphoric thought, often described as nonlinear, nonsequential, metaphorical, and nonlogical. This neurofunctional distinction was made to contrast it to cognitive thought, which is said to be linear, sequential, nonmetaphorical, and logical. S. Engle in 1999 theorized that this primary processing helps explain the objective basis by which self-composed stories may serve as the “most essential symbolic process” for reflecting on and describing experiences. Siegel, a developmental neurobiologist, described findings that the mind encodes internal and external experiences represented in different forms and creates a sense of continuity across time by linking past, present, and future perceptions is within the narrative process. The autobiographical self-narrative is a key evolving integrative process that influences the nature of interpersonal relationships, and is central to secure attachment relationships, and to how one constructs reality. These and other developmental findings about childhood and adolescence suggest ways to use neurobiologically advantageous strategies for storytelling with young clients suffering from mental or behavior issues.

In case there has been any doubt about the significant role of storytelling, Siegel stated that from the developmental neurobiological standpoint, “Storytelling

becomes a proxy to the damaged or missing attachment relationships that are causing emotional despair and rebellion.”

The hospital setting for a child away from family and among strangers and peers with behavioral problems may not seem so hospitable or safe. Consequently the therapeutic storyteller must make efforts to create a safe, comfortable, quiet environment so that each child can process as much sensory experience and emotion from the stories as possible, and feel free to contribute autogenic stories. The identification and timing of neurobiological factors, as well as psychodynamic concepts that can optimize the storytelling and autogenic narrative process, are summarized in Table I. The observation that adults outside the mental health setting also benefit from directed storytelling suggests that the effect is perennial and universal. Business leaders have recently written about the benefits of storytelling in the workplace to promote morale and teambuilding.

Theologians in recent years have reemphasized the narrative structure of the Scriptures and recommended narrative technique for homilies and teaching. More recently the U.S. Military Academies Academy Character and Leadership Divisions have adopted the practice of bringing in distinguished retired military officers to tell young cadet classes their personal stories of moral leadership struggles. For mentoring, small groups of cadets are given the opportunity to team with these elders.

The foregoing data support the author's belief that therapeutic storytelling facilitates the development of beneficial interpersonal relationships between client and therapist. Although each person experiencing a story has a unique psychic experience, stories activate important emotional and cognitive neural pathways that promote emotional enrichment and inner cognitive resourcefulness. Clarissa Pinkola Estes, the Jungian psychotherapist, poetic storyteller, and author of *Women Who Run With the Wolves*, once commented that we humans come not only from dust, but from stardust as well.

For children and adolescents whose brief life history has often been filled with grievous injustices such as parental neglect, physical and sexual abuse, violence, rejection, arrests, and pain, the redemptive personal attention, respect, ability to win peer approval, and the chance to develop a self-narrative through storytelling sessions may reopen an area of development and relationships that had been sealed. By approaching a side door rather than the main door, psychic resistance can often be bypassed so clients can willingly enter into a health-restoring personal psychotherapy program, the goal of which is to promote social and emotional maturation and healthy personal autonomy.

V. CASE ILLUSTRATIONS

Therapeutic storytelling preparation begins with finding and using or reworking story sources. Each therapist probably has at least a few and perhaps many favorite stories, and we encounter new stories daily in the various media. In general, little of the available children's story literature is immediately appropriate for psychotherapy storytelling. However, many of the following resources have been useful to the author in understanding, selecting, and working with a broad spectrum of storytelling options and psychotherapeutic approaches.

Jack Zipes' retranslation of classical folktales and his astute commentary on their archaic and modern cultural context, including feminist revisions, has enhanced their usefulness to psychotherapy. His books, such as *The Oxford Companion to Fairy Tales* in 2000, provide the therapist with a good background analysis of the genre. The Zipes references, taken in chronological order published from 1989 to 2000, make a thorough introduction to storytelling, as well as reviewing the state of academic "fairytale-ology." Bruno Bettelheim, who was intrigued by fairy tales and used them in therapy with adolescents, took off a year on sabbatical to write a book discussing his application of Freudian analysis to selected Grimms' (and other) fairy tales, and his 1975 publication *The Uses of Enchantment*, has been well received. Bettelheim's opinion was that fairy tales attract us because they permit our vicarious wish fulfillment in a seemingly perfect enchanted world. At the same time he said they help to affect sexual drives in a positive way, thus aiding resolution of oedipal tendencies and sibling rivalry.

Zipes, a nonpsychologist, disagreed with Bettelheim's analysis, writing that the appeal of the stories was more likely due to our desire to deal indirectly with repressed modern issues such as parental abuse, neglect, brutality, and our parental desire to abandon our children. Zipes wrote in 1995 that traditional fairy stories were originally written in raw detail for adults, and that the substitution of happy endings in order to dilute them for children was a travesty.

Ronald Murphy, a Jesuit priest and professor of German, pursued the religious themes in Grimm's fairy tales. Murphy journeyed to Germany for a detailed study of personal books, manuscripts, annotated personal Bibles, and other Grimm family items. In *The Owl, The Raven, and the Dove* in 2000, Murphy reconstructed from notations and background material in these original sources, the influences of Christian theology, oral culture, and German pagan mythology, choosing five selected fairy tales edited by Wilhelm Grimm.

William Bausch, another Catholic priest, published an extensive anthology of multicultural stories in several books (1996 to 1999), including *The Wizard of Oz*, with commentaries, which are potentially useful in psychotherapy, religious education, and homily composition. Recently other concerned educators have compiled story anthologies directed toward moral education of young people.

A recurrent dilemma in preparing traditional folktales or stories so that they are age appropriate and suitable for young mental health clients is how to maintain the charm and feel of the stories while making them more contemporary for young listeners. Ideally one should aim to preserve the authenticity, flavor, and meaning of the archaic story, as much as possible, although finding ways to deal with brutality, anti-Semitism, and sexual offenses may be a struggle.

John Stephens and Robyn McCallum in their 1998 *Retelling Stories, Framing Culture: Traditional Story and Metanarratives in Children's Literature*, showed how in traditional folktales and legends the encoded metaethics might impact the hearer on a deep moral or social level. They summarize the not-so-obvious cultural and ethnic baggage directed at the original audience, which they term the metanarrative in epics such as *The Arabian Nights*. In their opinion such ancient tales may transmit "implicit and usually invisible ideologies, systems, and assumptions that operate globally in a society to order knowledge and experience." Obviously the psychotherapist needs to consider these cultural and ethical overtones carefully for their positive or negative impact on today's clients.

Several resources have targeted specific children's behavioral health problems, such as kidney failure, bedwetting, and chronic illness, and the stresses from disruption of family life by divorce, useful for therapists who prefer modern stories. George Burns in his *101 Healing Stories: Using Metaphors in Therapy* in 2001 ranks high on the list of useful resources. Burns not only provides numerous engaging therapy stories, but he comprehensively discusses how to identify story resources from our own life experiences, from our patients, and from the secular world. He gives detailed, thought-provoking advice on how-to, and how-not-to develop and use stories with clients, and how to select and shape stories for specific client needs. Unlike other literary presentations, he comprehensively lists and discusses his interpretation of the psychodynamic themes in each of his healing stories from a psychoanalytic standpoint.

Lee Wallas in 1985 contributed 19 lively stories that she developed spontaneously in her Ericksonian hyp-

notherapy practice. She examines her personal experiences and insights about how she happened to hit upon these themes and develop the stories in the course of treating clients with various neuroses.

Richard Gardner in 1993 published his mutual storytelling techniques, *Storytelling in Psychotherapy with Children*, in which he relies upon autogenic (spontaneous undirected) stories told by the client, sometimes involving hypnotherapy. Gardner's therapeutic technique evolves from intense involvement with the client in therapy and, like Wallas, using reflections about the client's clinical problem as the kernel of a new story within the same metaphor and with the same characters used by the client. The therapist then tells the unique "new story" to the client in a way that suggests alternative methods for the client to deal with the problem issue(s). Gardner elaborates on further innovations including dramatized mutual storytelling, storytelling games, and bibliotherapy (the use of books in the therapeutic process).

Gardner's colleague, Jerrold Brandel in *Of Mice and Metaphors* in 2000, described his personal experience and his own modifications of Gardner's reciprocal storytelling technique. Brandel used the term "re-visioning" for his method of modifying struggling youngsters' own stories therapeutically and then "bouncing them back" to the client with the remedial editing and interpretation as part of a dynamic storytelling game. He might inquire of the client, for example, "How would you like this story to end?"

In 1997 Carlissa Pinkola Estes compiled a collection of deep and thought-provoking feminist fairy tales, *Women Who Run With The Wolves*, in both print and audiotape. She has used these in Jungian psychotherapy and hypnotherapy. Her tapes, published by the Sounds True Company in Boulder, Colorado, are a fascinating resource for grasping the immense possibilities of psychotherapeutic storytelling. Her audio performance of Hans Christian Anderson's *The Red Shoes* is an excellent example. She follows the story with a detailed and valuable interpretation of the Jungian insights of the fable. This author has found this story compelling in sessions with adolescent clients, who unerringly relate the theme of self-destructive obsession to their own life situation.

Ellen Wachtel in her 1994 *Treating Troubled Children and their Families*, wrote about helping parents compose and tell stories to their child at home as part of his or her therapeutic program, especially when there is poor clinical progress with conventional treatment methods. She reminds us of the immense pedagogical and spiritual value of parental life anecdotes that satisfy the child's developmental need to assimilate family

tradition and parental role modeling as part of a healthy attachment and evolving self-story.

Personal storytelling tutorials, for example Nancy Shimmel's 1992 *Just Enough to Make A Story*, offer useful guidelines and some prime examples. Her title story highlights human persistence and thrift, and the underlying purpose of stories. It is about a tailor who buys a bolt of cloth to make himself an overcoat. When the overcoat begins to wear out he cuts it into a jacket, after further wear he pares it down into a vest, then a hat, and finally there is only enough to make a button. When the button is worn out there is "only enough left to make a story."

Zipes, in *Creative Storytelling: Building Community, Changing Lives* in 1995, offers novel ideas and model tales for telling, although he shares his skepticism about using stories for psychotherapeutic goals. Several authors, including Gianni Ronardi in *The Grammar of Fantasy* in 1973 have given memorable advice on inventing stories for telling.

Internet resources are considerable, and include "The Storytelling Ring," a popular site with a variety of public domain story resources (e.g., the interesting Southern mystery stories at www.themoonlitroad.com or www.storyteller.net). Friends, relatives, and community members, and especially senior citizens, often have poignant or funny anecdotes that can be creatively reworked.

Therapists may wish to seek out community storytelling groups in order to observe presentation techniques and content. Even more useful is the easily obtained opportunity to volunteer as a storyteller at a local library or elementary school. Another resource is the Storytelling Magazine and the live storytelling festival audiotapes of the National Storytelling Network.

A. Immediate Preparation

Ideally, the therapist should review the story list prior to the session. Preparation includes memorizing newly adapted stories, rehearsing, and developing an agenda on the evening before a group. When only one story is to be used the author selects it to fit a specific topic and proverb for that day. For example, if the group topic is coping with adversity, a story of the "Rapunzel" genre might fit.

B. Running the Group

A comfortable and private office is favorable for individual client stories during a treatment session. Storytelling with a group in a mental health center is more logistically demanding. One needs to find a

space free of interruptions and arrange for familiar staff to be present.

Drama, animation, stage props, and audience participation enhance the choreography of this activity, while activating sensory and emotional pathways in the participants. Token costume items like a Turkish hat or cowboy jacket, according to the therapist's taste and intentions, can help the drama effect. The children gather around in chairs or sit on the floor with name cards in front of them so that the storyteller can identify and address each child by name. The first action of the group session is to refocus the children's attention by various techniques such as group singing, or asking the children to quietly listen to and identify various white noise sounds such as a down-pour in a rainforest or a faraway train. These sounds can come from an inexpensive electronic generator operated by the storyteller. Alternatives might include juggling or harmonica playing by the storyteller.

Once attention is refocused, the storyteller begins, choosing first a story in which the children participate by repeating phrases, assuming roles, or making sounds to accompany the narrative. For example, in a story about a train trip designated children provide the sound effects of the "All aboard!," others the train wheels sound, and still others the train whistle at the appropriate times.

When the first story and applause are through, the storyteller asks for feedback from the children. What were their impressions and feelings during the story? What did the story mean to them? How did they feel when they were hearing it? Were they surprised or puzzled by some story element? Each child usually interprets the story somewhat differently. If a child is reluctant to share a personal interpretation, asking the child to briefly repeat the story aloud may be useful.

Next three children are recruited sequentially to tell an autogenic story. Offering the child a special "storyteller hat," and allowing the child to occupy a special "storyteller seat" can enhance the honor of this selection. Following each child's story there comes applause and feedback comments from the peers about each story. The staff and the therapist pay attention to the body language, facial expressions, emotion, and content of each child's story and the social interactions of others in the group. When clients tell revealing autogenic stories, their body language tends to become busier than usual. Sometimes a "poorly functioning" child surprises everyone with dramatic and sensitive stories, or with the ability to repeat someone else's story verbatim even though he appeared not to be paying attention.

Occasionally between stories the therapist's cellular phone "rings," because "Oscar" is phoning. The therapist explains that Oscar (the mythical caller and narrative continuity object) is a wizened old storyteller with a gruff voice. He "calls" to ask about the children's stories and describes where he is located geographically, and what his activities are. Recently Oscar reported that he was riding on a porpoise's back in the Bahamas.

The children are charmed but skeptical about Oscar. In every group meeting, and even in the cafeteria or while crossing the campus, the more experienced children ask the therapist whether Oscar will call in that day.

After three rounds of therapist and children's stories the author concludes the group by asking each child one-by-one to step up directly in front of him, hand the storyteller his or her name card, look the storyteller in the eye, and state which "word movies" he or she enjoyed. In that final moment of eye contact the therapist attempts to assess the magnitude, richness, and meaning of the emotional experience that child and the storyteller have shared during the hour, and to look for any signs of emotional upset.

VI. SUMMARY

Therapeutic stories generated by both therapist and client are valuable tools in individual and group therapy with children and adolescents. When used as part of any psychotherapeutic approaches they enhance the ability of the clients' developing minds to make beneficial alliances with staff and therapists, and to further develop their personal self-narrative. Developmental neurobiologists believe that storytelling acts as a substitute for unhealthy attachment relationships that are at the root of many behavioral disorders in children and adolescents. Taking advantage of the neurobiological and social mechanisms that occur during storytelling helps the therapist optimize the setting and choreography of storytelling.

In an era of cost-cutting pressure on behavioral health care providers, and an increasing reliance on psychoactive drugs, therapeutic storytelling as described in this article may be one of the truest forms of psychotherapy still being practiced. An important bonus to the use of stories is that they are a lively and enjoyable activity. Stories encourage children to share their experience and redevelop its meaning in an environment of human warmth, safety, trust, and curiosity.

GLOSSARY

counterconditioning A method to remove the original association between fear and the trigger for the fear and to replace it with a new trigger that is incompatible with fear.

covert sensitization A procedure in which an inappropriate response to a stimulus (e.g., a sexual response to children in an adult male) is broken by attempting to associate the stimulus with a new incompatible response (e.g., associating children with discomfort that may be produced by a puff of air in the eye).

escape conditioning A noxious stimulus is paired with anxiety/fear to terminate the fear and a more appropriate response is put in place (e.g., repeatedly pairing an intrusive thought with an electric shock. Over time the intrusive thought declines because of its association with the electric shock).

obsessive-compulsive disorder (OCD) An anxiety disorder that is characterized by the presence of obsessions and/or compulsions. Obsessions are defined as repetitive, unwanted, senseless thoughts, images, or impulses that may be repugnant or horrific. Compulsions are defined as overt behaviors or mental acts that are typically done in response to the obsession and function to decrease the anxiety. They

are time consuming, excessive, and senseless. Persons are often aware that they are unnecessary but cannot stop themselves.

Thought stopping (TS) is a behavioral technique used to minimize the distress associated with unwanted intrusive thoughts. Clients are asked to sit with their eyes closed and verbalize a typical sequence of problematic thoughts. During this time the therapist suddenly shouts, "Stop!" The therapist then highlights that the thoughts did stop and proceeds to repeat the procedure several times until the client is able to subvocally disrupt the maladaptive thoughts.

I. OVERVIEW AND DESCRIPTION OF THOUGHT STOPPING

Joseph Wolpe describes TS as useful in the elimination of undesirable thoughts that are unrealistic, unproductive, and anxiety producing. Although used frequently by behavior therapists in the 1970s and early 1980s, TS has received relatively little rigorous empirical attention. Uncontrolled case studies and anecdotal reports of TS are generally favorable when used as both a stand-alone procedure or in conjunction with other cognitive and behavioral techniques. Our purpose is to summarize this work and draw conclusions about the usefulness of TS as a therapeutic technique.

Last, we will introduce a cognitive alternative to TS that has produced some initial success for clients with obsessive-compulsive disorder.

TS was introduced by James Alexander Bain and J. G. Taylor under the premise that thought control is important for positive mental health. Although TS is often viewed as an overly simplistic technique, it actually requires a thorough behavioral analysis. In 1977, Joseph Cautela and Patricia Wisocki suggest that the behavioral analysis should include a client's comprehensive list of disturbing and uncontrollable thoughts with particular importance placed on any overt or covert behaviors that have harmful societal implications (e.g., thoughts of seeking revenge).

Target thoughts are agreed on and the rationale for their elimination is discussed. Cautela recommends that clients be asked to close their eyes and raise their finger once deliberately thinking of the target thought(s). When the client raises a finger, the therapist loudly shouts "Stop!" that typically produces a startle response. The therapist explains that one is unable to think of two things at the same time (stop and the target thought[s]) and proceeds to teach the client the procedure for his or her own use by encouraging the client to subvocally yell "Stop!" These rehearsals continue in-session for approximately 10 min or for 20 trials until the procedure is learned. Therapists emphasize that with the repeated and daily use of TS, the target thought(s) will gradually decrease in frequency until they disappear altogether. Subsequent sessions might allot 5 min for TS rehearsals including variations of the procedure (e.g., snapping a rubber band on the wrist instead of yelling "stop," substituting another word for "stop," visualizing a stop sign instead of yelling "stop").

II. THEORETICAL BASES

The theoretical underpinnings of TS are vague and sparse. Indeed, since the early 1970s, reservations concerning the adequacy of supporting theoretical arguments for TS have been expressed. Wolpe and Taylor did not discuss a conceptual basis for TS, however, Cautela and Wisocki suggested that the more likely interpretations include escape conditioning and counterconditioning.

Within the escape conditioning paradigm, TS functions to replace an inappropriate discomforting response with an appropriate alternative. In 1943, C. L. Hull contended that behaviors that reduce discomfort,

such as anxiety, are associated with establishing a habit. Avoidance also strengthens a habit because it prevents clients from experiencing anxiety.

An anxiety-provoking thought is triggered by an internal or external cue. Counterconditioning is thought to function by replacing the old response with a new response in the face of the identical trigger. For example, once trained in progressive muscle relaxation, clients are instructed to think of the anxiety-provoking trigger while relaxed. The rationale behind this technique is that it is impossible to feel fear and relaxation at the same time. In 1958, Wolpe used a counterconditioning procedure and called it systematic desensitization. Cautela and Wisocki hypothesized that TS could be used to assist in the development of the new response.

III. EARLY EMPIRICAL STUDIES

Historically, TS was used in the treatment of obsessions, however, the technique has been used as an intervention for a variety of different disorders including smoking cessation, drug and alcohol dependence, psychosis, depression, panic, agoraphobia, generalized anxiety, and body dysmorphic disorder. Although numerous uncontrolled single case studies concluded that TS is a viable behavioral technique, there is little methodologically sound research with larger sample sizes to support the use of TS. After a thorough review of the literature in 1979, Georgiana Tryon concluded that the effectiveness of thought stopping had not been demonstrated. Another limitation preventing stronger conclusions about the efficacy of TS is the lack of a standard procedure when using TS. Many studies provide minimal detail regarding the procedure and use a variety of TS procedures in conjunction with various other techniques such as relaxation and self-monitoring.

TS is often used to treat obsessional difficulties. For example, in 1974 Raymond Rosen and Betty Schnapp reported that TS was helpful for a man who was ruminating about his wife's infidelities. In 1971, by instructing patients to snap a rubber band on their wrist in response to an obsessional thought, Michael J. Mahoney decreased the frequency of obsessive ruminations. In 1971, Toshiko Yamagami had success reducing color obsessions with four variations of TS. In 1982, Helen Likierman and Stanley Jack Rachman compared TS and habituation training for 12 individuals with obsessions and found little therapeutic benefit for both procedures. Of the six individuals in the TS group, four improved, one became worse, and, with one it was unclear.

TS has also been used in smoking cessation treatment. In 1974, Wisocki and Edward Rooney compared the effectiveness of TS, covert sensitization, and attention placebo in decreasing the number of cigarettes smoked. Initially, TS and covert sensitization significantly reduced smoking, however, this difference disappeared at 4-month follow-up. Another study conducted by Yves Lamontagne, Marc-Andre Gagnon, Gilles Trudel, and Jean-Marie Boisvert in 1978, compared four different treatments, including TS, group discussion, and wearing a badge, all with self-monitoring compared to self-monitoring alone. All treatments initially reduced the frequency of smoking; however, it was TS and self-monitoring that maintained a significant decrease at 6-month follow-up.

In another class of problems, Makram Samaan in 1975 reported that TS was successfully used to treat auditory and visual hallucinations in one client who did not experience a relapse 20 months after treatment. In 1979, John O'Brien applied TS to two cases of agoraphobia with no relapse at 1-year follow-up. However, the efficacy of TS is difficult to determine because the client received 1 year of treatment that included self-monitoring and some cognitive therapy. In 1978, John Teasdale and Valerie Rezin compared TS to placebo control for 18 individuals with symptoms of depression. TS had little effect in reducing the frequency of depressive thoughts or the intensity of depressed mood.

The previous paragraphs suggest that the efficacy of TS is based on single cases but its general usefulness is in question. Rachman and Padmal de Silva may have inadvertently discovered one reason why TS is not helpful as a strategy. In a survey of people who lived in the general community, these researchers found that over 90% reported a multitude of intrusive thoughts, images, and impulses. The results of these and related studies suggest that experiencing unwanted intrusive thoughts is a completely natural, normal phenomenon. If so, the elimination of these thoughts through TS or other deliberate suppression attempts may be futile, at best, and harmful, at worst.

IV. THE IMPACT OF THOUGHT SUPPRESSION

Recent work in the area of thought suppression has confirmed that attempting to distract, ignore, or suppress thoughts may serve to increase their frequency. Dan Wegner's investigations on the effects of thought suppression have revolutionized the understanding of

disorders characterized by persistent unwanted thoughts. In a series of two experiments, Wegner demonstrated that subjects who were asked to not think of a white bear during a 5-min time period actually thought of a white bear more frequently than another group of subjects who were told that it was okay to think of a white bear.

In a review of the literature in 1999, Christine Purdon indicated that thought suppression has now been identified as both a causal and/or maintaining factor in generalized anxiety disorder, specific phobia, posttraumatic stress disorder, obsessive-compulsive disorder (OCD), and depression. According to this line of research, purposely suppressing thoughts is associated with an unexpected and surprising increase in their frequency. For example, Paul Salkovskis and his colleagues in Great Britain have suggested that active and deliberate thought suppression in the form of neutralization is critical in the development of obsessions. Students who experienced frequent unwanted intrusive thoughts that they felt necessary to neutralize had their intrusive thoughts recorded and were asked to either neutralize the thought or distract themselves from it. Those students who neutralized the thought reported significantly more anxiety and a greater urge to neutralize when the thought was presented a second time.

V. A COGNITIVE ALTERNATIVE TO THOUGHT STOPPING

The work of Wegner, Salkovskis, and Purdon has demonstrated that thought suppression increases the frequency of the target thought(s). TS can be considered a form of thought suppression or control and will thus likely serve to increase the frequency of the thoughts. For example, if clients have a belief that they must be in control of their thoughts and emotions at all times, experiencing an unwanted thought (which we know from the work of Rachman and de Silva is a normal, natural phenomenon) will produce anxiety and the need to try to control the thought. Attempts at thought control often involve ignoring, distracting, or suppressing the thought. These strategies serve to increase attention to the thought process, likely making the thoughts more noticeable and seemingly more frequent. The apparent increase in the frequency of the unwanted thoughts likely serves to further heighten anxiety, attention to the thought process, and precipitate additional attempts at thought control. A vicious circle can quickly develop.

As part of recent developments in cognitive behavioral treatments for OCD, Maureen Whittal and Peter McLean have described a process coined “come and go.” Clients are encouraged to experience the intrusive unwanted thought and not try to control it (i.e., do not try to ignore, suppress, distract or anything else that will serve to get rid of the thought). Rather, clients are instructed to let the thought leave naturally, typically when another thought logically takes its place. Clients are instructed to practice this “come-and-go” strategy and their usual style of thought control on alternate days and predict their anxiety and the frequency of intrusive unwanted thoughts on each of the days. Clients invariably predict that letting thoughts come and go will result in higher levels of anxiety and more frequent intrusive thoughts. They are often surprised that letting go of their efforts at thought control (i.e., letting thoughts come and go) lessens the anxiety and typically lowers the frequency of the target thought(s).

To date to the best of our knowledge, this “come-and-go” strategy has been tested only with clients with OCD. However, it is likely that it would also be helpful for other disorders that feature repetitive unwanted thoughts (e.g., eating disorders, impulse control disorders, and body dysmorphic disorder).

VI. SUMMARY

Thought stopping (TS) is a behavioral procedure used to minimize the distress and anxiety associated with unwanted intrusive thoughts. Clients are asked to sit with their eyes closed and verbalize a typical sequence of problematic thoughts. During this time the therapist suddenly shouts “Stop!” The therapist then highlights that the thoughts did stop and proceeds to repeat the procedure several times until the client is able to subvocally disrupt the maladaptive thoughts.

Although used frequently by behavior therapists in the 1970s, TS has received relatively little rigorous empirical attention. Uncontrolled cases studies and anecdotal reports of TS are generally favorable when used as

both a stand-alone procedure or in conjunction with other cognitive and behavioral techniques. The few studies utilizing rigorous empirical methodology in their investigations of the efficacy of TS have been equivocal.

Recent empirical studies with thought suppression have demonstrated the paradoxical increase in thought frequency. TS can be considered a form of thought suppression or control and will, thus, likely serve to increase the frequency of the thoughts. With this in mind, Whittal and McLean developed a cognitive alternative to TS termed “come and go” that has shown success in treating individuals with OCD. The authors suggest that letting thoughts come and go will also be helpful with other problems that feature repetitive, unwanted thoughts (e.g., eating disorders, impulse control disorders, other anxiety disorders).

Acknowledgments

The authors wish to express their appreciation to S. Rachman, Ph.D. and Simon Rego, Psy. M. for providing comment on earlier versions of this manuscript.

GLOSSARY

attachment theory Pertains to how children become comfortable or anxious in relationship to their caregivers' behavioral and emotional responses; such attachment patterns are presumed to carry over into adult relationships.

behavioral A therapeutic approach that emphasizes that behaviors are learned (according to learning principles such as reinforcement and extinction) and therefore can be modified using these same principles.

case formulation The process of diagnosing problems for psychotherapeutic intervention. Case formulation differs from diagnosing psychopathological categories. Rather than producing a diagnostic label, case formulation seeks to create a minitheory linking current presenting problems with recurrent problem patterns and underlying core-ordering processes.

cognitive A therapeutic approach that emphasizes that how one interprets events in the world determines an individual's behavior and feelings; interventions therefore focus on changing the way one thinks and evaluates.

manualized treatment A psychotherapy with principles and techniques that have been specified in a written manual developed to specify the treatment variable in research contexts. Manualized treatments usually include associ-

ated psychometric instruments for measuring therapist's adherence to the precepts of the manual.

metacommunication Refers to communications in which the process of communication or the relationship between the communicators becomes the topic of conversation. In psychotherapy, metacommunication functions as a form of interpretive intervention focused on clarifying the ongoing interpersonal process between the patient and the therapist.

psychodynamic A therapeutic approach that emphasizes unconscious processes, the influence of early experiences, conflict, transference/countertransference, and resistance.

schema Stable, enduring, often unconscious, cognitive structures for screening, coding, evaluating, and organizing stimuli into patterns.

transference The tendency to reenact experiences and relationship patterns from past relationships in the therapeutic relationship.

working models A mental framework of what can be expected from others derived from both observation and inner schemas.

Time-limited dynamic psychotherapy (TLDP) is an interpersonal, time-sensitive approach for patients with chronic, pervasive, dysfunctional ways of relating to others. This article will present TLDP theory, assumptions, goals, formulation, intervention strategies, a clinical illustration, and empirical findings. The goal of TLDP is to help patients change their dysfunctional, interpersonal patterns by fostering new experiences and

new understandings that emanate from the therapeutic relationships.

I. DESCRIPTION OF TREATMENT

A. Definition

Despite proponents dating to the 1920s, for decades the general response of the psychoanalytic establishment to short-term therapies was unreceptive. However, intense interest in brief dynamic therapy resurfaced in the 1970s and early 1980s, and by the 1990s brief intervention had become a treatment of choice for most patients. Confidence in the basic viability of brief therapy was buttressed by empirical research demonstrating that the majority of patients who benefit from psychotherapy do so within the first 6 months, and that success rates are not necessarily dependent on treatment duration.

Time-limited dynamic psychotherapy was developed with the intention of helping clinicians have more successful outcomes when treating patients with self-defeating interpersonal behaviors—the so-called difficult patient—seen in brief treatment. It was designed to target the specific subgroup of patients whose symptomatic problems (anxiety, depression, etc.) are embedded in underlying core patterns of recurrent dysfunctional interpersonal relationships and whose enactment of these dysfunctional patterns generalizes into the therapeutic relationship. When originally conceived, a liberal time limit of 25 to 30 hours was proposed. Currently the time frame is in the 15 to 20 session range, with the therapist maintaining a time-sensitive or focused approach rather than emphasizing a stipulated number of fixed sessions. The focus is not on symptom reduction per se, but rather on altering the way one relates to others and the self. More ambitious or perfectionistic goals, such as extensive personality reconstruction or plumbing the unconscious origins of experience, are generally inappropriate for TLDP.

Consistent with a general trend toward manualizing therapies for research purposes, the principles of TLDP were originally set forth in a manual published in 1984 under the title *Psychotherapy in a New Key*, authored by Hans Strupp and Jeffrey Binder with collaboration from Thomas Schacht. A subsequent volume produced a decade later by Hanna Levenson provides an updated perspective on TLDP. Levenson's approach places more emphasis on change through experiential learning, whereas the 1984 manual stresses insight through interpretation.

B. Assumptions Essential to TLDP Treatment

There are three core assumptions underlying the practice of TLDP.

1. Maladaptive interpersonal patterns acquired early in life underlie many presenting complaints of symptomatic distress and functional impairment.

Early experiences with parental figures inform the child as to what can be expected from others and what is necessary to maintain connectedness with them. These experiences from the building blocks in the mind of the child of what eventually become mental representations or working models of relationships in general.

2. Maladaptive interpersonal patterns acquired early in life persist and are maintained in current relationships, including reenactment in the therapeutic relationship.

Although one's dysfunctional style is learned early in life, according to the TLDP model, the individual's way of seeing the world must be supported in the person's present adult life for interpersonal difficulties to continue. For example, if one's parents were harsh and demanding, it would be understandable if such a child grew into a placating, deferential adult. Displaying such a subservient manner, such a person might inadvertently and unconsciously pull for others to respond in controlling ways—echoing the behavior of the parents.

This recursive focus is consistent with a systems-oriented approach, which holds that if you change one part of the system, other parts will shift as a result. In this manner, "pathology" does not exist solely within the individual, but rather resides in the totality of the interpersonal system that maintains the behavior. From a time-limited viewpoint, this emphasis on the present enables the therapy theoretically to be completed in a shorter amount of time, because the focus is on what is happening in the current interpersonal world of the individual rather than on an archeological dig into one's past.

The relationship that evolves between therapist and patient can be understood as a microcosm of the interpersonal world of the patient. The patient relates to the therapist in ways that are characteristic of interactions with significant others (i.e., transference), and hooks the therapist into responding in a complementary fashion (i.e., countertransference). Although this reenactment of interpersonal difficulties in the therapeutic relationship poses difficulties for the alliance, it is inevitable and also provides the opportunity to transform the therapeutic relationship into a specialized context for reflecting on and changing interpersonal patterns. In

such a manner, the therapist has the opportunity to see the maladaptive interactions evolve in the therapeutic relationship and to discern dysfunctional patterns. Because such patterns are presumed to be sustained through present interactional sequences, the therapist can concentrate on what is happening in the session to alter the patient's experience and understanding.

As pointed out earlier, the therapist in attempting to relate to the patient is unwittingly enlisted into a reenactment of the patient's dysfunctional pattern; in other words, in addition to observing, the therapist becomes a participant in the interaction or a participant observer. The therapist is pushed and pulled by the patient's style and responds accordingly. The therapist's transactional reciprocity and complementarity are not viewed as a "mistake," but rather as a form of interpersonal empathy or role responsiveness. Eventually, the therapist must realize how he or she is replicating this interpersonal dynamic with the patient, and use this information to change the nature of the interaction in a healthier direction.

3. TLDP focuses on one chief problematic relationship pattern.

The emphasis in TLDP is on the patient's most troublesome and pervasive interactive pattern. Although other relationship patterns of less magnitude and inflexibility are important, in a time-limited format pragmatics dictate focusing on the most central interpersonal schema.

C. Goals

1. *New Experience*

The first and major goal is for the patient to have a series of new experiences through which he or she develops a different appreciation of self, of therapist, and of their interaction. These new experiences provide a foundation of experiential learning through which old patterns may be relinquished and new patterns established. The formulation of each particular case (see later) determines what specific types of new experiences will be most helpful in disconfirming the patient's interpersonal schemata and thereby undermining his or her maladaptive style. The concept of a corrective emotional experience described more than 50 years ago by Alexander and French is relevant. They suggested that with experiential learning individuals could change even without insight into the etiology of their problems. It is our current thinking that experiential learning broadens the range of patients who can benefit from a brief therapy format, leads to greater generalization to the outside world, and permits therapists to use a

variety of techniques and strategies in addition to traditional insight-promoting clarification and interpretation. For example, with the placating individual mentioned earlier, the goal might be for him to experience himself as more assertive and the therapist as less punitive within the give and take of the therapeutic hours.

2. *New Understanding*

The second goal of providing a new understanding focuses on helping patients identify and comprehend the nature, etiology, and ramifications of their dysfunctional patterns. To facilitate such an understanding, the TLDP therapist can point out repetitive patterns as they have manifested with past significant others, with present significant others, and with the therapist in the here-and-now of the sessions. Metacommunication occurs when the ongoing process of interpersonal transaction between the patient and therapist becomes the content of the therapeutic dialogue. Therapists disclosing their own reactions (i.e., interactive countertransference) to the patients' behaviors can be of benefit in this regard. In this way, patients can begin to recognize relationship patterns and discern their role in perpetuating the very dysfunctional interaction they wish to change.

D. Patient Suitability

TLDP may be helpful to anyone for whom adequate descriptions of their interpersonal transactions can lead to a dynamic focus. It is designed, however, for people who have lifelong interpersonal difficulties. Table I contains the five major selection criteria and four major exclusionary criteria for ascertaining a patient's suitability for TLDP.

E. Formulation

1. *The Cyclical Maladaptive Pattern*

In long-term treatments, therapists may rely on the patient's spontaneous organizing abilities to bring coherence, over time, to the tacit themes and patterns of their difficulties. However, a time-limited therapy requires a more systematic approach, a core theme or dynamic focus, which acts as a guiding beacon to direct and organize therapeutic activity. In TLDP this core theme is the repetitive dysfunctional interactive sequence that is both historically significant and also a source of current difficulty. This cyclical maladaptive pattern (CMP) provides a framework for deriving a dynamic, interpersonal focus for TLDP. It forms an organizational structure for the various components that contribute to the idiosyncratic vicious cycle of reciprocal interactions. By creating

TABLE I
Selection Criteria for Time-Limited
Dynamic Psychotherapy

Inclusionary

1. Patient is sufficiently uncomfortable with his or her feelings and/or behavior to seek help via psychotherapy.
2. Patient is willing and able to come regularly for appointments and talk about his or her life.
3. Patient is willing to consider the possibility that his or her problems reflect difficulties in relating to others.
4. Patient is open to considering the possibly important role that his or her emotional life plays in interpersonal difficulties.
5. Patient evidences sufficient capacity for relating to others as separate individuals so that identifiable relationship predispositions can be enacted in the therapeutic relationship and then collaboratively examined.

Exclusionary

1. Patient is not able to attend to the process of a verbal give-and-take with the therapist (e.g., patient has delirium, dementia, psychosis, or diminished intellectual status).
2. Patient's problems can be treated more effectively by other means (e.g., patient has specific phobia or manic-depressive illness).
3. Patient cannot tolerate the active, interpretative, interactive therapy process, which often heightens anxiety (e.g., patient has impulse control problems, abuses alcohol and/or substances, or has a history of repeated suicide attempts).
4. Patient's problems are primarily due to environmental factors (e.g., social oppression, imprisonment, poverty).

Adapted from Strupp & Binder (1984) and MacKenzie (1988).

a narrative that incorporates the elements of the CMP, the clinician is guided in developing a treatment plan. A successful CMP should describe the nature and extent of the interpersonal problem, lead to a delineation of the goals, serve as a blueprint for interventions, enable the therapist to anticipate reenactments, and provide a way to assess if the therapy is on track.

2. Constructing the CMP

To derive a TLDP formulation, the therapist uses four categories to gather, organize, and probe for relevant information.

1. Acts of the self. These acts include the thoughts, feelings, motives, perceptions, and behaviors of the patient of an interpersonal nature. "I enjoy social gatherings because I am the life of the party!"

2. Expectations of others' reactions. This category pertains to how the patient imagines others will react to him or her in response to some interpersonal behavior (Act of the Self). "I expect that if I go to the party, everyone will want to talk with me."
3. Acts of others toward the self. This third grouping consists of the actual behaviors of other people as observed (or assumed) and interpreted by the patient. "When I went to the party, people were so concerned with making a big impression on the host, that no one spoke to me."
4. Acts of the self toward the self. In this section belong the patient's behaviors or attitudes toward oneself. "When I left the party, I told myself that it was their loss and felt better."

By linking information in these categories together, a narrative is formed from which emerges themes and redundancies in the patient's transactional interactions. This narrative forms the CMP describing the patient's predominant dysfunctional interactive pattern. The therapist then sets the goals for the treatment by considering what specific types of experiential interactions and new understandings would help weaken the strength, rigidity, and repetitiveness of the patient's CMP.

F. TLDP Strategies

Implementation of TLDP does not rely on a fixed set of techniques. Rather it depends on therapeutic strategies that are seen as embedded in a therapeutic relationship. The Vanderbilt Therapeutic Strategies Scale (VTSS) was designed to measure therapists' adherence to TLDP principles. The 10 items that contain TLDP specific strategies are included in Table II.

In general these therapeutic strategies emphasize clarification and understanding of actions and experiences in the here-and-now rather than excavation of the patient's past. Although a search for historical antecedents may help to clarify current events, archeological exploration of the patient's life history is subordinate to a thorough reconnaissance of present experiences, behaviors, and circumstances. In TLDP the patient and therapist collaboratively "make" the patient's life story, as contrasted with the traditional unilateral "taking" of a life history.

II. THEORETICAL BASE

Historically, TLDP is based in an object-relations, interpersonal framework with roots in attachment theory.

TABLE II
Vanderbilt Therapeutic Strategies Scale

TLDP Specific Strategies:

1. Therapist specifically addresses transactions in the patient–therapist relationship.
2. Therapist encourages the patient to explore feelings and thoughts about the therapist or the therapeutic relationship.
3. Therapist encourages the patient to discuss how the therapist might feel or think about the patient.
4. Therapist discusses own reactions to some aspect of the patient's behavior in relation to the therapist.
5. Therapist attempts to explore patterns that might constitute a cyclical maladaptive pattern in the patient's interpersonal relationships.
6. Therapist asks about the patient's introject (how the patient feels about and treats himself or herself).
7. Therapist links a recurrent pattern of behavior or interpersonal conflict to transactions between the patient and therapist.
8. Therapist addresses obstacles (e.g., silences, coming late, avoidance of meaningful topics) that might influence the therapeutic process.
9. Therapist provides the opportunity for the patient to have a new experience of oneself and/or the therapist relevant to the patient's particular cyclical maladaptive pattern.^a
10. Therapist discusses an aspect of the time-limited nature of TLDP or termination.

Reproduced with permission from Butler, S. F., & Center for Psychotherapy Research Team. (1995). Manual for the Vanderbilt Therapeutic Strategies Scale. In Levenson, H. *Time-limited dynamic psychotherapy: A guide to clinical practice*. pp. 243–254. New York: Basic Books.

^a Item written by H. Levenson.

According to object relations theory, people are innately motivated to maintain human relatedness. Basic tenets of interpersonal theory hold that, all else being equal, people learn to treat themselves in a manner that is complementary to how they are treated by others. Therefore, images of the self and others are considered to be products of social interactions. This relational view contrasts with that of classical psychoanalysis, which holds that drives for sex and aggression and their derivatives take preeminence. From a relational perspective, psychopathology results when recurrent dysfunctional interactions cause the individual to engage in patterns of maladaptive behavior and negative self-appraisal. Although recent applications of TLDP are grounded in psychodynamic theory, they also incorporate cognitive, behavioral, and systems approaches.

III. EMPIRICAL STUDIES

A series of studies done at Vanderbilt University in the 1970s found that therapists have difficulty being therapeutically effective when their patients are negative and hostile; in fact, the therapists themselves can often become hooked into responding with negativity, hostility, and disrespect. These findings led Hans Strupp and colleagues to develop TLDP.

Time-limited dynamic psychotherapy does not belong to the new research paradigm of the so-called empirically validated therapies (EVTs). Rather, TLDP was created to support a long tradition of basic research into the elementary processes distinguishing effective psychotherapy from interventions that are less effective or even harmful. Whereas the EVT concept furthers the idea that it is the technique of treatment that is most important, TLDP, in contrast, stems from a research tradition that underscores the importance of so-called common factors such as the personal qualities of the therapist, the interpersonal nature of the therapeutic relationship, and the quality of the therapeutic alliance. Thus, rather than producing an empirically validated “treatment” per se, TLDP research has sought to validate underlying generic therapeutic principles. TLDP was constructed to provide a fertile arena for investigating these principles, but it is by no means the only therapeutic environment in which similar research could be or has been conducted.

Although the primary emphasis of research has not been to demonstrate that TLDP is effective for particular disorders, many patients in studies involving TLDP have improved. Research on TLDP outcomes found that a majority of patients at a Veterans Administration outpatient clinic achieved positive interpersonal or symptomatic benefit, with almost three-quarters feeling that their problems had lessened by termination. Long-term follow-up of these patients revealed that patient gains were maintained and slightly bolstered, with 80% feeling helped. Other analyses indicated that patients were more likely to value their therapies the more they perceived that the sessions focused on TLDP-congruent strategies such as trying to understand their typical patterns of relating to people. A study examining relational change found that following TLDP, patients significantly shifted in their attachment styles (from insecure to secure) and significantly increased in their secure attachment themes. Other empirical studies have found that patients' images and treatment of themselves are a reflection of the way they were treated by their therapists, and that these internalizations are associated with better outcomes.

With regard to case formulation, empirical research suggests that the TLDP-CMP is a reliable and valid procedure. CMPs from patients who had completed TLDP were read by five clinicians unfamiliar with the cases. Based only on these CMPs, the clinicians' independent ratings showed high levels of interrater agreement with regard to the patients' interpersonal difficulties. Further analyses indicated that there was considerable overlap in problems the raters said should have been discussed with those that actually were discussed. Also the therapies were found to have better outcomes the more they stayed focused on CMP relevant topics. Another study found that themes derived from CMPs corresponded to themes obtained from another psychodynamic formulation method.

With regard to training in TLDP, research has demonstrated that although a programmatic effort to train experienced therapists in TLDP was successful in increasing therapists' use of TLDP strategies, many of the therapists did not reach an acceptable level of TLDP mastery within the training period. Further inquiry into the data also revealed some unintended and potentially untoward training effects. For example, after training the therapists were more willing to be active and as a consequence made more "mistakes," inadvertently becoming less supportive and delivering more complex communications to patients.

In another training study, psychiatry residents and psychology interns changed their attitudes and values about brief therapy in a more positive direction as a result of a 6-month seminar and group supervision in TLDP. In a multisite investigation, similar attitudinal shifts have been found with experienced clinicians who attended 1-day TLDP workshops.

IV. CASE ILLUSTRATION

Ms. R. was a professional woman in her early forties, married for 15 years with three children. She sought psychotherapy for chronic symptoms of depression and anxiety that had been present for several years. Exploration of the interpersonal context of the presenting complaints indicated that Ms. R. frequently experienced others as emotionally distant or uncaring. She responded with complementary interpersonal distancing. For example, she felt that her husband had been unsupportive with child rearing and during a past time of physical illness but rather than expressing her concerns and wishes to him, she concealed her resentment and withdrew from sexual relations without explanation. Ms. R.'s description of her family of origin mir-

rored her current marital relationship. She did not feel close to her siblings. Her relationship with her father was notable for unrequited wishes for greater closeness and involvement. In a prior attempt at psychotherapy, Ms. R. found herself wishing for more time with the therapist, but could not bring herself to reveal this, ultimately choosing instead to discontinue therapy.

From the opening moments of the first interview, her TLDP therapist focused on Ms. R.'s current problems, especially as they were reflected in relationships with others and in concerns and expectations regarding the therapist. The beginning of the therapeutic relationship was a primary source of clues for a focal theme. Ms. R. expressed concern about the cost of treatment and added that she had not felt able to discuss this with her husband. She indicated that she was having second thoughts about therapy, and wondered if treatment would be a mistake. The therapist invited associations that eventually linked Ms. R.'s descriptions of uncomfortable affective states to accompanying interpersonal contexts. A search for similarities in patterns across contexts clarified how Ms. R.'s ambivalence about therapy stemmed from a fear that participation in treatment would disturb her marriage. In response to a comment from the therapist inviting associations to her apparent anger and resentment, Ms. R. reported a fear that her husband would perceive her seeking therapy as a rejection of him. She then wondered if therapy might also represent an indirect act of aggression toward him. Such early clarifications and interpretations allowed the therapist to assess Ms. R.'s capacity to participate in collaborative inquiry and probed her response to the work of therapy.

In emphasizing the interpersonal context of Ms. R.'s presenting complaints, the therapist set the stage for identification of a focal theme. In Ms. R.'s case, a theme was identified the essence of which was: "If I ask for what I want, I will be disappointed and will feel useless and worthless. If I don't want to be hurt or abandoned, I must always be polite and must do what others want. I must avoid standing up for myself and must never express anger toward men and must always subordinate my wishes to theirs. If something goes wrong in my relationships, it must be my fault and I am responsible for correcting the situation." Consistent with this theme, Ms. R. often perceived others as withholding what she wanted or needed, and as unresponsive to issues of relationship fairness that were important to her. Although the superficial expression of this theme takes the form of a subdued and unemotional exterior, there is a subtextual theme of covert hostility that finds indirect expression in complementary withholding, in withdrawal, or in subtle or passive forms of aggression.

The therapist used this theme as a heuristic to guide construction of organizing questions and comments designed to stimulate the patient's curiosity and foster collaborative effort. Even as Ms. R. was discussing her husband, other comments, behavior, and perceptions suggested that she often felt similarly toward the therapist. For example, she expected that the therapist would criticize her for her reluctance to tell her husband about seeking psychotherapy. Ms. R. expressed a fear that she would run out of things to say, and that the therapist would respond judgmentally and would refrain from helping her, leaving her cruelly tongue-tied. Similarly, when the therapist agreed to accept her into a time-limited 25-session treatment immediately following the initial interview, she did not experience this as a helpful gesture, but rather perceived the offer of help as a form of coercive pressure, as if the therapist had said: "You can be my patient, but only on my terms and my schedule, and you must choose now." The potential for such transference enactment was continuously in the background of the therapist's awareness.

As treatment progressed, Ms. R. and the therapist reencountered examples of the enactment of this focal theme in narratives about primary childhood relationships, other current family relationships, romantic relationships including her current marriage, and her relationship with the therapist. Within a few sessions, this dynamic focus was sufficiently salient that the therapist proposed to Ms. R. that working on the manifestations of this theme become a primary goal for their continuing sessions.

In future sessions, Ms. R.'s primary task was to verbalize whatever came to her mind. However, she often began her sessions with an awkward silence and an aloof stare that most likely reflected the vigilance associated with ingrained expectations that others will be displeased with her. At the beginning of therapy, as expected according to the principles of interpersonal complementarity, the therapist alternately felt bored, irritated, or subtly dismissive in response to Ms. R.'s criticality and withdrawn stance. For example, in the third session, the therapist, annoyed with the patient's indirect criticism of him, began to think about a highly successful intervention he had made with a previous patient. As he was in the midst of this self-congratulatory reverie, he lost track of what Ms. R. was saying. His emotional distance echoed the behavior of Ms. R.'s husband (and others in her life) and in fact was a reenactment of the very CMP that had become the focus of the therapeutic work.

Ms. R., hurt by her therapist's inattention, started to berate him and then trailed into a series of self-deni-

grating statements with sullen affect. The therapist, reflecting on this transactional process in the moment, realized that he had been countertransferentially responding to Ms. R.'s behavior and attitude. Rather than defensively denying his inattentiveness, the therapist admitted his lapse, and helped Ms. R. to express directly her disappointment and anger toward him. Together they explored the interactional sequence leading up to their mutual disconnect. The therapist did not punish Ms. R. or excuse his own dismissive behavior, but rather welcomed hearing her feelings, thereby providing her with a reparative interpersonal experience. As other such reenactments were therapeutically addressed, they became fewer and farther between.

For much of the therapy the therapist was able to support, clarify, elaborate, and link Ms. R.'s concerns to the core theme. Connections between Ms. R.'s current experience and the past helped to clarify Ms. R.'s perception of her circumstances, while also highlighting their anachronistic character and underscoring elements of distortion associated with transference experience. Exploration of the past was important, but clearly subordinate to the therapist's endeavors to stay close to the patient's emotional experience. To this end, the therapist used simple evocative language and avoided complex constructions or abstract interpretations that were likely to move the patient away from her affective experience. Redundant encounters with the focal theme provided repeated opportunities for discussion and corrective emotional experience derived from the contrast between Ms. R.'s transference expectations and what actually occurred with the therapist. In this portion of the work, both the process and the content of the therapeutic dialogue had a healing impact. Indeed, the therapist's behavior often spoke more loudly than his words. A verbal profession of support for Ms. R.'s autonomy would have been of little value if the therapist's conduct simultaneously expressed criticism or infringed on that same autonomy.

Numerous examples of such corrective emotional experiences occurred as the therapy progressed. The therapeutic dyad encountered numerous variations on the focal theme, each a different facet of the theme's pervasive presence in Ms. R.'s life. Around the 20th session, Ms. R.'s concerns turned urgently to the impending termination date. She pressed the therapist for reassurance that therapy would not really have to stop at the agreed time. In response, the therapist maintained the same exploratory stance that had carried the relationship forward from the beginning. Thus, the therapist expressed curiosity about the patient's emotional experience and

her wishes and fears associated with the anticipated end of the therapeutic relationship. The therapist did not attempt to reassure Ms. R. that everything would be OK or that the treatment had accomplished enough. Instead, he treated her responses to termination in the same manner as all other material that Ms. R. had brought to the therapy—as expressions of her central relationship issues.

As termination approached, Ms. R. initially pressed the therapist with rational arguments, protesting that while she had become much more aware of her automatic interpersonal predispositions, she needed much more therapeutic time to master alternative responses. When these arguments failed to elicit the desired amendment to the scheduled termination, Ms. R. then regressed temporarily, sarcastically stating that the therapist was putting her through hell and then withholding further disclosure by refusing to discuss her feelings. Despite Ms. R.'s provocative conduct, the therapist managed not to respond with complementary intensity or negative reaction, but instead maintained a gentle, receptive, and supportive curiosity. The therapist acknowledged Ms. R.'s experience of loss, empathized with her perception that she felt like a helpless child being summarily dismissed by an unfeeling parent, and clarified this fear of rejection and abandonment as a recapitulation of earlier traumas as expressed in the focal theme. The therapist also pointed out the realistic limitations of the therapy, emphasizing what Ms. R. had gained rather than what she imagined she may have foregone by terminating treatment at this time. In this way, the termination phase continued the primary work of the therapy, while also assisting the patient in a corrective emotional experience, namely experiencing the loss of the therapist via normal grief and mourning, rather than as a maladaptive resentment from perceived deprivation.

At their last session, Ms. R. indicated acceptance of the termination and reported that she felt "ready." She framed the termination positively via a metaphor of graduation, rather than negatively via analogy to divorce, abandonment, or ex-communication as would have been expected based on her focal theme. She verbalized comfort in the knowledge that further therapy was possible in the future if she encountered difficulties that she could not master on her own. She and the therapist parted with a sincere and warm good-bye.

V. SUMMARY

TLDP was developed to help therapists treat difficult patients within a brief therapy format. In TLDP, problems are defined in terms of a dynamic focus that formulates dysfunctional interpersonal patterns. The treatment process includes development and maintenance of a therapeutic alliance in the face of the patient's dysfunctional patterns and the therapist's own interpersonal proclivities. Therapeutic strategies include observing the inevitable reenactment of those patterns in the therapeutic relationship, metacommunicating about them, and providing opportunities for experiential learning.

This article will further define the concept of timeout, suggest typical methods for successful implementation of the timeout procedure, discuss the theoretical bases on which the technique relies, and identify several empirically supported variations of the technique.

GLOSSARY

functional analysis Assessing a set of circumstances (e.g., through observation, interview, collection, and analysis of data) to identify and target variables that are influencing problematic behavior.

operational definition (of a behavior) A clear, specific description of a behavior so that it can be more easily targeted for change. For example, rather than targeting general “non-compliance,” it is easier to target more specific “refusal to comply with direct instructions provided by an adult.”

positive reinforcement (or reward) A situation or event, often pleasant in nature, which, when delivered contingent on the occurrence of a behavior, results in an increase in frequency of that behavior.

punishment An event following a behavior that thereby decreases the likelihood that the behavior will recur in the future.

Timeout is a punishment technique such that, following an act of negative behavior, a child spends a brief period of time in an environment less reinforcing than that in which the behavior originally occurred.

I. DESCRIPTION OF TREATMENT

Timeout is a disciplinary technique that, when used correctly and consistently, can be quite effective in reducing maladaptive behavior patterns of children. Although several major principles of behavior modification may be involved with the use of timeout, the procedure is in its most basic form a punishment procedure, because it denies a child access to activities or situations that are sources of positive reinforcement. Thus, the term “timeout” suggests that a child is shifted from being in a reinforcing environment to being in an unpleasant or less reinforcing environment. It is important to note that timeout appears to be most effective when used in combination with other techniques, such as rewarding appropriate behaviors, and therefore encouraging greater frequency of positive behavior.

A. When to Use Timeout

The use of timeout can be effective for children from toddlerhood through adolescence, and in some cases even for adults, and can be used in many different

settings. Schoolteachers often find the technique quite useful in handling classroom disruptions. The procedure is also valuable in working with individuals with developmental delays, inpatient residents in psychiatric settings, children who are aggressive toward siblings or peers, or in families with children who are defiant or noncompliant. Timeout can reduce behaviors such as tantrums, aggression, inattention, refusal to follow directions, inappropriate social comments or actions, or self-injurious behavior.

B. Functional Analysis

Before considering the use of timeout on a consistent basis, a functional analysis should be conducted to identify typical patterns of problematic behavior. A functional analysis can be conducted through the use of both formal and informal methods. Formal methods might include a distinct written operational definition of the target behavior, noting when and where the behavior does and does not occur (e.g., percentage of the time, duration of incidents, number of occurrences per time period). The graphing or charting of trends might be helpful both before and after starting the timeout strategy so that changes in patterns of behavior are easily evident. More informal methods of functional analysis might involve making notes on a calendar or simply being more attentive to potential triggers of behavioral outbursts. Jill Taylor and Michelle Miller provide several classroom case examples illustrating how a thorough functional analysis can lead to successful timeout implementation, or can help identify why the procedure is not producing desired results.

Whether formal or informal methods are used, the goal of the functional analysis is to determine typical antecedents and consequences of the child's actions. Determining the contingencies that could be reinforcing the undesired behavior can help the adult anticipate under what circumstances the behavior is likely to occur. In addition, this information can be used in setting realistic goals for timeout. It is important to set a clear goal (e.g., decrease the behavior by a certain amount) and to recognize and reward the child as positive changes happen and when goals are met.

C. Type of Timeout

Jennie Brantner and Michael Doherty defined three major categories of timeouts: isolation, exclusion, and nonexclusion. Isolation timeout is one in which a child is taken to a solitary, non-reinforcing area, separate in location from where the inappropriate behavior oc-

curred. At home or at school, this might be a hallway or other specified room (where the adult can monitor the child, but without reinforcers present). Alternately, exclusion timeout means that the child is not actually removed from the room where the behavior occurred, but is also not allowed to participate in or view ongoing activities. An example of this would be having the child sit in a chair facing the wall. Russell Barkley suggests a modification of these ideas for use in public places, such that the child can be placed in a quiet corner facing the wall or can be taken to the car for a timeout.

The third category of timeout is nonexclusion, meaning that the child is able to view ongoing activities but the child's participation is restricted for a period of time following undesired behavior. Brantner and Doherty identified three further variations of non-exclusion timeout. The first variation, titled contingent observation, requires the child to sit on the periphery of activities and watch what is occurring, which might include observing others continue to receive reinforcement. Another variation is removing reinforcing materials, or giving a "timeout" to the television, toys, games, or stereo being used by the child. This seems particularly effective for older children or adolescents. A third variation of non-exclusion time-out is simply ignoring the child, so that reinforcement is not being provided for a period of time. This could include turning away from the child or refusing to interact for a period of time.

To choose which type of timeout will be most effective, one must consider the disruptiveness of the behavior itself, the age, and developmental level of the child (i.e., a very young child may be far less receptive to an isolation timeout), whether or not the behavior occurred in a group setting, and any potential reinforcers in the setting where the behavior occurred (e.g., peer attention). Charles Wolfgang offers several examples of charts useful for record keeping if timeout is to be implemented in a school or group setting, and emphasizes the importance of implementing timeouts without allowing ridicule or social reinforcement from peers. Russell Barkley offers suggestions for training parents to use the technique, such as modeling the procedure for parents and dealing with frustration commonly experienced when implementing a new timeout program. Barkley also offers several adaptations in the procedure, such as incorporating a token economy system and taking additional measures to deal with a child's noncompliance with timeout.

D. Duration of Timeout

There has been considerable debate among researchers and behavior modification experts regarding

the appropriate duration of timeout. The effectiveness of different lengths of time has been empirically tested and has produced varying results. Therefore, there is no absolute standard regarding how long a child should remain in a timeout. Some experts suggest a range of 1 to 5 min, whereas others suggest lengths of up to 20 min for older children. A typical rule of thumb is to require 1 min for each year of a child's age (e.g., a 5-year-old should receive a 5-min timeout). This rule seems logical, because a younger child will likely possess less patience than will an older child. However, this should not be an inflexible standard, because a child's developmental level should also be considered. For example, a 8-year-old who is developmentally delayed might receive beneficial effects from a timeout much shorter than 8 min in duration. For any child, use of a kitchen timer or buzzer can avert arguments or incessant questioning about when timeout has ended.

In determining appropriate timeout length, each child should be considered on an individual basis. The importance is to achieve the aversive and punishing nature of the timeout. That is, too short a timeout might not be perceived as aversive, whereas too long a timeout prevents opportunities to practice other behaviors. In either case, inappropriate duration of a timeout will ultimately be less effective in achieving the ultimate goal: reducing maladaptive behavior.

E. Providing Instructions

Before implementing timeout, the child must know ahead of time what the rules are and what consequences to expect when they are broken. R. Vance Hall and Marilyn C. Hall provide guidelines for explaining timeout to an individual. The adult must first explain to the child the specific target behaviors that will result in a timeout and convey that timeout will be enforced each and every time that behavior occurs. The length of timeout should be preestablished, and the child should know what indicates the end of a timeout. The adult should explain where the child is to spend timeout, and this designated area should be used consistently. If a "timeout chair" will be used, Russell Barkley suggests leaving the chair out for a few weeks to serve as a reminder of consequences. After explaining the entire procedure, younger children might benefit from practicing or role playing a pretend timeout, so they will know what to expect under real circumstances.

The child must also understand that certain behaviors can extend the duration of timeout. For example, screaming, arguing, leaving the timeout area, or other similar conduct should each extend the timeout (e.g., 1

minute for each infraction). The adult must enforce this rule, even if it initially leads to very long timeouts. Without enforcing this procedure, the child might manipulate his or her way out of the consequences and likely attempt that same tactic in later timeout sessions.

When a child's behavior actually warrants a timeout, the adult must deliver consequences in a calm, neutral manner. Russell Barkley suggests redirecting the behavior, waiting a 5 sec count, then warning the child that a timeout will occur if compliance with the request does not occur, waiting another 5-sec count, and if the child fails to respond appropriately, then direct the child to the timeout area. Many variations on this sequence can occur, depending on the child and the infraction. On the end of timeout, the child should be required to resolve the issue or behavior which necessitated timeout in the first place (e.g., if the timeout was for refusing to put away his toys, the child should put away his toys immediately following timeout). Otherwise, the child might begin using timeout as an escape from responsibilities. Consistent rewards, positive attention, and praise should be offered when the child demonstrates positive behavior following a timeout. In starting a new timeout program, the adult should initially expect resistance from the child, particularly if tantrums have been an effective ploy in the past. However, the adult must be willing to enforce timeouts in the same manner each time the behavior occurs. Without consistency, the technique will not be effective and will end up being more work for the adult than it is designed to be when used correctly.

F. When Timeout Does Not Work

If timeout seems ineffective, several factors could be the cause. Perhaps the target behavior is too vague, and the child is having difficulty understanding what behaviors are appropriate. On the other hand, perhaps the "timein" (time spent engaging in supposedly reinforcing activities) is not really rewarding. Thus, timeout might not seem so terrible an option. It could be that the child is using misbehavior and subsequent timeout as a way to gain attention or avoid being in particular environments. In addition, perhaps reinforcement is not being provided for positive displays of behavior. Adults who work to increase positive interactions with the child on a regular basis will be offering a more rewarding "timein," which builds a positive and supportive relationship and offers a little more leverage when disciplining the child.

Even if applied in a consistent and straightforward manner, some children react drastically to timeouts.

These reactions might include severe temper tantrums, physical aggression toward the adult, refusal to go to the timeout area, or leaving the timeout area before the required amount of time has been served. Adults must be prepared for these reactions so they can be dealt with accordingly. If a child is very young, he or she may be physically placed in the timeout area or restrained gently in the chair. If a child refuses to go to or repeatedly leaves the timeout area, extra time may be included or additional punishment (e.g., taking away other privileges) can be utilized.

II. THEORETICAL BASES

Timeout is based on the principle of punishment. Alan Bellack, Michel Hersen, and Alan Kazdin note that in his conceptualization of punishment, B. F. Skinner differentiated between two classes of punishment: one in which existing (often rewarding) stimuli are removed, and one in which new (often unpleasant) stimuli are introduced. A negative punishment (e.g., timeout) would fit into the first class, whereas a positive punishment (e.g., spanking) would fit into the second class. Barkley suggests that use of punishment should only be considered as an alternative after rewards or incentives fail to encourage positive behavior. He also notes that punishment usually fails to be effective when presented in a situation in which no regular positive interactions occur. Therefore, parents must accept some responsibility in finding ways to encourage positive behavior, as well as anticipating potential behavior problems. Simply reacting to negative behavior may encourage helplessness or guilt in a child, because few positive interactions are likely to occur on a consistent basis.

Karen Harris noted that the most important defining characteristic of an effective timeout is the discrepancy between "timein" and "timeout" environments. A timeout will not be perceived as a punishing event if the environment from which the child was removed was never rewarding to begin with. This idea also emphasizes the need for praise and positive social interactions between the adult and child, so that the child will value the "timein."

III. EMPIRICAL STUDIES

In considering length of timeout, Jennie Brantner and Michael Doherty reviewed timeout studies across different types of problem behaviors and in various set-

tings. They were able to conclude that short intervals of timeouts (i.e., 5 min or less) can be quite effective with many populations and in many different settings. Successful use of the timeout technique has been documented with normal children in a family setting; with individuals in inpatient psychiatric settings; with defiant, assaultive, or delinquent adolescents; and in classroom settings at virtually all age and educational levels (to treat behaviors such as noncompliance with rules or inattentiveness). Timeout procedures can also be quite effective in working with autistic children and with children, who are mentally retarded particularly in dealing with aggressiveness or to shape new behaviors such as correct toileting habits. Timeout has been proven to be effective in dealing with a variety of undesirable behaviors, such as aggression, defiance, noncompliance with rules, temper tantrums, being argumentative, inappropriate social interactions, or engaging in self-injurious behavior. A timeout can also serve as a punisher during any type of training task, if the individual already understands and is capable of the desired response.

Robert Jones, Howard Sloane, and Mark Roberts targeted aggressive behavior, comparing the effectiveness of an immediate timeout versus a "don't" instructional command, which included "don't" directives, reinforcement for compliance, a warning for noncompliance, and finally a timeout for noncompliance with the warning. The immediate timeout proved more effective in reducing aggression, possibly because the "don't" procedure offered less immediate consequences and provided more social reinforcement and attention for misbehavior.

David Reitman and Ronald Drabman described an adjustment in implementing timeouts with children who typically become verbally noncompliant. The procedure is called "Read My Fingertips" and has the adult nonverbally add additional minutes to the timeout, by touching each finger one by one, increasing the timeout one extra minute for each argumentative word spoken by the child. If the child understood the procedure ahead of time, the authors found the technique highly effective in reducing arguing that typically followed a directive to go to timeout.

R. M. Foxx and S. T. Shapiro implemented a nonexclusionary "timeout ribbon" procedure for use in a group setting with children with mental retardation. Following positive behavior, such children were given colored ribbons to wear and received edible reinforcers every few minutes for maintaining appropriate behavior. When misbehavior occurred, a timeout was issued,

meaning that the child's ribbon was removed, and the child received no reinforcement for a brief period. The procedure was found to be useful in reducing undesirable behavior, it did not noticeably disrupt the group as a whole, and the teacher was usually able to continue the procedure alone without extra staff on hand to assist.

There are countless studies and reviews (e.g., Karen Harris; Bellack, Hersen & Kazdin; Brantner and Doherty) examining specific cases and providing continued support for the effectiveness of timeout, particularly when compared with other behavior modification procedures. Although timeout may not work for every individual, there is abundant data to suggest that its use can be quite beneficial in many cases and across many settings.

IV. SUMMARY

When implemented consistently and in combination with reinforcement for positive actions, timeout can be a beneficial method for decreasing negative behavior. As a punishment technique following misbehavior, timeout prevents an individual's access to a more rewarding environment for a brief period of time. There are various subcategories of timeout, which can be adjusted depending on an individual's age, developmental level, and setting in which timeout will be used. A functional analysis can help clarify target behaviors and goals for change, as well as encourage recognition and reward for positive change. Alternate methods of discipline should be in place if timeout fails to be successful. Although timeout may not be successful for every possible situation, there is much evidence to suggest its efficacy across numerous settings and populations.

GLOSSARY

backup reinforcers Goods and privileges purchased with tokens that provide the token with its reward value.

change agent Person who administers reinforcers to a client contingent on the performance of a behavior or set of behaviors according to a prescribed plan.

extinction A reduction in the frequency of a behavior upon the cessation of its reinforcement.

generalized reinforcers Secondary reinforcers that are associated with a wide variety of reinforcing stimuli. Money is an example.

law of association by contiguity A fundamental law of learning that states that two events will come to be associated, or mean the same thing, if they are contiguous or occur together.

law of effect A fundamental law of learning that states that the frequency of a behavior is dependent on its resulting effects or consequences.

level system A supplementary system to a token economy program that involves different stages through which clients progress according to their mastery of specific behavioral competencies. Each stage, or level, is associated with more

demanding reinforcement contingencies. The goal of such level systems is often to remove the use of tokens entirely.

negative punishment (response cost) The removal of a desirable event following a behavior that serves to reduce the frequency of that behavior.

negative reinforcement Increasing the frequency of a behavior by removing aversive stimuli as a consequence of that behavior.

positive punishment (aversion) The application of an aversive event following a behavior that serves to reduce the frequency of that behavior.

positive reinforcement Increasing the frequency of a behavior by applying desirable stimuli as a consequence of that behavior.

primary reinforcers Stimuli that have an “unlearned” reinforcing value. These are things that are critical to our survival, such as water, food, and sleep.

prompts Events that initiate a behavior, which is subsequently reinforced. These include a specific instruction of the expected behavior and its associated consequence.

punishment Arranging consequences of a behavior to decrease the frequency of that behavior.

reinforcement Arranging consequences of a behavior to increase the frequency of that behavior.

secondary reinforcers Stimuli that gain reinforcing value after being associated with primary reinforcers.

social reinforcers Social stimuli, such as attention, facial expressions, and verbalizations, that come to have a reinforcement value after being associated with other reinforcers.

stimulus sampling Procedure whereby clients are permitted to try a variety of reinforcers at no cost to generate interest and increase the likelihood that they will purchase the reinforcer with tokens once the sampling period is over.

time-out from reinforcement Removal of the client from all sources of reinforcement for a specified period of time to reduce the frequency of a particular behavior. Usually takes place in an isolated room or quiet area.

token Any symbolic material that can be exchanged for backup reinforcers. Tokens often consist of coins, poker chips, or cardboard squares.

I. DESCRIPTION

A token economy program (TEP) is a system whereby clients earn tokens in exchange for engaging in designated target behaviors. In some TEPs, clients will also lose tokens or be “fined” in response to engaging in inappropriate behaviors.

Just as we use money to buy the things we want, clients in a TEP exchange their tokens for a variety of desirable backup reinforcers, including food, beverages, magazines, toiletries, CDs, potted plants, toys, crayons, school supplies, and other desirable goods. Clients in residential settings may be given the opportunity to purchase a private bedroom, room furnishings, or home passes. Persons in TEPs in correctional settings often spend tokens to buy the privilege to wear their own, rather than institutional, clothes.

Backup reinforcers are available to the clients at specified times during the day, often through a well-stocked “token store” that functions like a small convenience store. In addition, other things purchased with tokens include time to watch TV or play a video game, trips to town for movies or other leisure events, and other desirable privileges. Because most people engage in such behaviors at a high rate when given the opportunity, these high-frequency behaviors are often used as reinforcers in TEPs. Improving the selection of backup reinforcers available, instituting time-limited sales, and holding auctions of highly desirable items all enhance token spending and associated client performance.

Tokens are disbursed by a change agent (e.g., psychiatric aide, educator, or parent) contingent on the performance of desired behaviors by the client. Change agents play active roles in TEPs, including informing the client of the contingencies for earning, spending, and/or losing tokens, and providing prompts as needed. In addition, as the goal of token economy programs is often for a behavior or set of behaviors to take place and be reinforced in the “natural” environment, token reinforcement and prompts are often withdrawn once consistent rates of the desired behaviors have been achieved. Change agents therefore deliver social

reinforcers in addition to tokens to help maintain behavior when tokens are withdrawn. In addition, the transfer from a token economy back to a natural environment may include a transition from tokens to more abstract credit vouchers and eventually to money. This transition may be facilitated by a level system, whereby clients demonstrating the acquisition of certain competencies are “promoted” to a higher level that has more demanding contingencies associated with the client’s improved functioning. The highest level of such a program could include elimination of tokens.

II. THEORETICAL BASES

B. F. Skinner’s pioneering work in operant conditioning is generally credited with providing the theoretical foundation for the development of token economies. It is assumed that basic laws of learning account for the occurrence of behaviors, whether adaptive or maladaptive, and these same laws can be extended to change these behaviors through the thoughtful engineering of environmental events.

Two major laws synthesize theories of learning and have been validated by a body of basic and applied research. The law of effect states that the frequency of a behavior is dependent on the resulting consequences, or effects. Thus, behavior is strengthened or weakened by what follows it in the environment. In fact, a consistent finding has been that the more immediately a consequence follows a behavior, the greater effect it will have. Reinforcement always has the effect of increasing the likelihood or recurrence of behavior. In positive reinforcement this is done by adding a positive or desirable event (e.g., tokens) to the environment when a behavior occurs. In negative reinforcement, it is accomplished by removing an unpleasant or aversive event from the environment after a behavior occurs. A patient who utters threatening comments in a therapy group that she dislikes will have this behavior negatively reinforced if she is subsequently asked to leave the group (removal of an aversive event) and can be expected to make such statements with greater frequency to avoid that group.

Decreasing the frequency of a behavior is accomplished by removing reinforcement, or extinction. For example, some research shows that self-injurious behavior (e.g., head banging, hair pulling) in children with disabilities generally results in attention from caregivers (e.g., verbalizations of concern, physical intervention). Often, this attention positively reinforces

the self-injurious behavior. Brian Iwata and colleagues have repeatedly demonstrated that when such attention is withdrawn, a marked decrease in self-injury ensues.

Behavior can also be decreased by use of punishment. In positive punishment, this consists of applying an aversive event (e.g., spanking a child) following the target behavior, whereas in negative punishment the consequence involves removing a desirable event (e.g., removing a child's privileges). Punishment is most effective when used for brief periods and in combination with reinforcement for desirable behaviors. It is not recommended for use by itself.

The second law of learning is the law of association by contiguity. It states that two events will come to be associated if they are contiguous or occur together. Thus, things that are not reinforcing in and of themselves can become reinforcing by pairing them with things that are. By pairing tokens with a primary reinforcer such as food, the tokens become secondary reinforcers. Eventually, through association with a variety of primary and secondary reinforcers, tokens will become generalized reinforcers.

III. APPLICATIONS AND EXCLUSIONS

Because the operant conditioning principles on which TEPs are founded apply to all behavior, it is not surprising that TEPs have been developed to deal with a large variety of populations and target behaviors. They have been found to be effective in increasing exercise regimens in chronic pain patients; reducing cigarette smoking in psychiatric outpatients; improving outpatient therapy attendance and participation; reducing alcohol consumption and illicit drug usage in outpatient alcohol and substance abusers; increasing dietary compliance for individuals with diabetes or renal problems; promoting weight loss; improving word finding and decreasing misarticulations in aphasic patients; reducing temper tantrums, teasing, and other "acting out" by children in the home; eliminating thumb sucking; increasing self-care skills, social interaction, and exercise in geriatric patients; reducing stuttering; eliminating enuresis and encopresis; decreasing chronic nail biting; and improving marital satisfaction.

Token economy programs have also been applied to broader social issues, with successful implementations resulting in increased bus use at a major university, increased safety practices (and reduced injuries) at a pit mining operation, increased seat-belt use in young-

sters, and increased litter control at a residential facility for individuals with mental retardation.

As should be apparent by now, participants for TEPs are not identified by focusing on psychological syndromes or diagnostic categories. Rather, the focus of the TEP is on the frequency and intensity of target behaviors. Thus, a TEP in a psychiatric hospital may focus on increasing grooming and hygiene, basic conversational skills, and vocational skills, and on decreasing assaultive and other maladaptive behaviors. It does not focus on treating "schizophrenia." Similarly, the social skills and academic skills of youth residing in correctional facilities may be addressed by a TEP. The TEP is not, however, used to treat "delinquency." In fact, although this article appears in the *Encyclopedia of Psychotherapy*, a TEP is not a "psychotherapy" or "treatment" per se. Rather, it is an extremely flexible organizational system used to deliver a wide range of plans for changing behavior. As Gordon Paul and Robert Lentz explained in 1977, the treatments delivered by two TEPs may be no more related to each other "than the action of heroin is related to that of penicillin, even though both are administered by injection."

IV. EMPIRICAL STUDIES

The bulk of the research on TEPs focuses on four populations: psychiatric patients, individuals with mental retardation, schoolchildren, and correctional populations. Although it is certainly possible to apply diagnostic labels to these groups, it is important to reiterate that the focus of TEPs is on identifiable behaviors and not syndromes. Common targets across these populations include enhancing "motivation," increasing social and adaptive behaviors, and decreasing maladaptive and dangerous behaviors.

A. Psychiatric Patients

The first TEP for psychiatric inpatients with severe disabilities was implemented at Anna State Hospital in Illinois in the 1960s by Teodoro Ayllon and Nathan Azrin. Their research demonstrated that changes in the patients' off-ward job choices and increased performance of the non-preferred jobs resulted through use of token reinforcers. In another TEP at a VA hospital, John Atthowe and Leonard Krasner reported that previously catatonic, withdrawn, or isolated patients demonstrated a significant lessening of apathy indicated by requesting and receiving overnight passes with family,

going to the canteen, and engaging in a variety of social interactions on the ward such as playing pool or card games (where betting was done with tokens).

Other target behaviors addressed by early TEPs with psychiatric patients included grooming and hygiene, bedroom care, attendance and participation in group activities, general cooperativeness with ward rules, and social functioning. Scores of publications show patient improvements in all of these areas, as compared to either their own pre-TEP behaviors, or to behaviors of patients on non-TEP wards.

In addition to these increases in appropriate and adaptive behaviors, psychiatric patients in TEPs have shown decreases in inappropriate and maladaptive behaviors as well. Some of these reductions occurred without being directly targeted, apparently as side effects of improvements in adaptive areas of functioning. Other TEPs have directly targeted such behaviors, generally by withholding reinforcement or using token fines. Results over the years show reductions in screaming, ritualistic behaviors, mannerisms, responsiveness to hallucinations, and the frequency of delusional talk. In addition, TEPs have shown dramatic decreases in threatening and assaultive behaviors, with corresponding reductions in use of seclusion and restraint with patients. Research shows that decreases in PRN or "as needed" medication usage as well as reductions in dosage of routine medications is common for TEP patients. In fact, some studies show that behavioral interventions such as the TEP are effective with psychiatric patients even in the absence of medications. Gordon L. Paul and colleagues reported that patients diagnosed with schizophrenia in a social learning program, which included a TEP, were able to be withdrawn from all psychiatric medications without a deterioration in functioning.

Finally, although discharge from inpatient settings and subsequent community tenure are affected by a number of political, financial, and social factors, TEP patients have nevertheless demonstrated decreased lengths of inpatient stay, increased rates of discharge, and decreased numbers of readmissions in comparison to non-TEP patients.

B. Individuals with Mental Retardation

Token economy programs for individuals with mental retardation (MR) have had similar results to those for psychiatric inpatients. Bathing, grooming, toileting, bed making, feeding, tooth brushing, and washing/combing hair have all been shown to increase for individuals with MR in TEPs. Improvements are also seen in voca-

tional skills (punctuality and attendance, production rates, task quality) and academic skills (test preparation, study behaviors). Some TEPs even permit banking of tokens and will teach check-writing skills to their clients with MR to access tokens saved in this manner. Social behavior has also been affected, from behaviors such as making eye contact and asking questions to more complex skills like proper noun-verb agreement, correct grammar, appropriate use of articles or pronouns, and even speech volume and dysfluencies. For younger individuals, increases have been shown in cooperative and competitive play in comparison to solitary or parallel play.

Inappropriate behaviors of individuals with MR have been targeted as well. Research has demonstrated that aggression, rocking behaviors, and self-injury are responsive to treatment programs using token reinforcement, time-out from reinforcement, extinction, and token fines.

C. School Children

Schools have been a popular setting for TEPs, with participants including "normal" children as well as children with a variety of problems including learning disabilities, attention deficit hyperactivity disorder, and emotional disturbances. Participants have spanned the age range from elementary through high school and beyond.

A large TEP undertaking reported by Howard Rollins and colleagues in 1974 included more than 700 inner-city students in Grades 1 through 8. Students in the 16 TEP classrooms demonstrated increased attentiveness and superior improvements in IQ and academic achievement measures than students in the 14 non-TEP control classrooms. Other researchers have obtained similar results, including improved completion of homework and increased basic academic skills as measured by task completion, accuracy, and grades. These improvements are reported in "normal" children as well as those who demonstrate learning disabilities, hyperactivity, and emotional difficulties. In addition, TEPs have been successfully used to improve articulation in children with speech disorders and have even been successful in enhancing writing skills as measured by use of different adjectives, verbs, and story beginnings, and as rated by outside blind reviewers.

A comparison of multiple methods for controlling disruptive behaviors in the classroom was reported by K. Daniel O'Leary and colleagues, who examined the effects of rearranging the structure of the class periods, posting and reviewing of behavior rules, using praise

and extinction, and finally adding a token economy. All methods were generally ineffective until the TEP component was added. Similarly, Marcia Broden and colleagues decreased disruptive behaviors as well as improved study behavior through use of a simple timer and a TEP. The timer went off at random intervals, at which time students who were quiet and in their seats received tokens. This and other research finds TEPs to be effective in reducing relatively minor disruptions (talking in class, being out of one's seat, interrupting, arguing), as well as more serious disruptive behaviors, such as threats and verbal or physical assaults.

As an alternative or supplement to individual contingencies, many classroom TEPs make use of group contingencies. In such an arrangement, it is the behavior of the entire group or class rather than the individual student that determines how much reinforcement each student receives. The "Good Behavior Game," developed by Harriet Barrish and colleagues, divides students into groups or teams, with each team earning or losing points depending on the behavior of the group's members. The team with the best score at the end of a specified time period receives reinforcement. Research using this game has successfully demonstrated its use to reduce disruptive behavior in the classroom. Variations on group contingencies in TEPs were examined by Ronald Drabman and colleagues. In different conditions, tokens were earned individually based on individual performance, or by the entire group based on the behavior of the best behaved child, the worse behaved child, or a randomly chosen child. Disruptive behavior decreased in all conditions, with no significant differences between them. Other research comparing individual versus group contingencies has reported similar results.

Although medications are often used to treat hyperactivity and disruptive behaviors in children, some researchers have found TEPs to be equally effective in controlling these behaviors. TEPs also have the added benefit of improving academic performance, a result not typically found with medication alone.

D. Correctional Populations

Token economy programs with youth engaging in criminal behaviors have also yielded favorable results, although these programs are generally conducted in institutional settings and not traditional classrooms. TEPs have resulted in improved self-care skills, conversational skills (including use of proper grammar), social functioning, classroom behaviors, academic skills, and vocational skills. Some programs, such as the Achievement Place program described by Elery Phillips

and colleagues, involve using a client as a change agent to dispense tokens, levy fines, and assign jobs and other tasks. This innovative feature results in improved performance of target behaviors. In addition, decreases in aggressive and threatening behaviors have been reported, often through the adjunctive use of time-out from reinforcement and token fines.

Token economy programs in adult prisons have met with varying degrees of success. An effort in Missouri focused on the state's most problematic prisoners and involved a tiered token/point system. Prisoners initially earned tokens for lack of threatening or assaultive behaviors and for cooperating with the rules and could purchase privileges such as increased opportunities to shave and shower, exercise, and possess personal items. Improvement in behavior resulted in advancement through a level system and eventually a switch to points instead of tokens, with greater opportunities to access backup reinforcers such as visits to the commissary, outside phone call privileges, and paid "vacation" days from work. Plagued with legal problems throughout its existence, including charges of violating prisoners' rights, the program generally failed to meet its goals of returning its difficult prisoners to the general population and was closed after two years.

Less ambitious prison TEPs have been successful in improving compliance with basic prison routines (getting up on time, keeping cell neat, performing cellblock chores) and increasing academic skills in prisoners, including earning GEDs. Backup reinforcers in some innovative programs have included offering appointments with parole board officers, and even opportunities to go fishing or visit a women's prison.

E. Failures of TEPs

In spite of the success indicated here, research consistently shows that a small number of individuals fails to respond to TEPs. This may be due to individual differences in responsiveness to the contingencies arranged in a particular TEP. For example, providing cigarettes as a backup reinforcer to a non-smoking client is not likely to be very motivating. Similarly, offering reinforcers to a client who is unfamiliar with them may not generate much interest. Teodoro Ayllon and Nathan Azrin addressed this through the use of stimulus sampling. By permitting patients to "sample" new or unfamiliar backup reinforcers (e.g., attending a local fair or a concert) at no cost, they were able to increase interest in those reinforcers once token charges were reinstated.

Other TEP clients may not respond because they lack the skills necessary to perform the target behavior, or because they do not understand the relationship between the target behavior and the reinforcement. Devising individualized contingencies and personalized reinforcers can improve responsiveness in a TEP.

Finally, inadequate implementation of the TEP can attenuate client responsiveness. Some research shows that client change is related to the accuracy with which staff adhere to the planned contingencies. Inadequate training and/or oversight of the TEP can lead to poor results.

F. Generalization

Research indicates that gains made in TEPs do not always last after the token reinforcement has ended. Generalization of gains made in TEPs typically requires some advance planning and should not be expected to simply happen. Strategies for accomplishing this include a gradual rather than sudden cessation of token usage combined with a corresponding increase in naturally occurring reinforcers such as social praise. Other strategies include lengthening the delay between the behavior and the reinforcement, and providing reinforcement in a variety of settings so that the behavior is not limited to a narrow range of cues.

V. CASE ILLUSTRATION

Joe, 33, has spent most of his adult life in state psychiatric facilities. Periodically he gains discharge, only to be readmitted within a period of months. His current hospitalization has lasted over 3 years.

Joe typically spends his day in his bedroom. He rarely talks to anyone and only ventures out for coffee, cigarettes, and meals. He goes weeks without bathing, requiring strong staff encouragement or assistance on those occasions that he does bathe. Joe responds to auditory hallucinations and can frequently be heard talking and yelling at "Uncle Ed," his abusive and now-deceased uncle whom Joe believes is the source of his voices. At times, Joe assaults staff members and other patients in response to directives from "Uncle Ed."

On March 1, Joe is admitted to the hospital's TEP with identified goals of increasing socialization, improving self-care skills, decreasing responsiveness to hallucinations, and reducing/eliminating aggressive behaviors. Program staff orient Joe and explain the TEP to him, inducing a discussion of how to earn and spend tokens. Joe immediately begins a period of stimulus sampling, whereby all backup reinforcers are available to him free

of charge so that he may be exposed to a wide variety of things that he may later wish to purchase with tokens. The free availability of backup reinforcers is gradually reduced over the next few days, and by March 5th Joe must have tokens to access his coffee and cigarettes. At first, Joe becomes angry when he does not receive a free cup of coffee and assaults a staff member. He receives a token fine for his behavior, which must be paid before he can purchase backup reinforcers for himself. Joe has similar incidents over the next few days but eventually realizes that assaulting others will not get him a cup of coffee, and by March 10th Joe is engaging in some simple behaviors to earn tokens. He starts attending a few scheduled treatment groups and begins to shower a couple of times a week. However, Joe doesn't use soap or shampoo while showering and only stands under the water for about 1 min. A decision is therefore made to individualize Joe's target behavior for showers. The next day, Joe earns a token for staying in the shower for 3 min. Eventually, he must use soap and then shampoo to earn his token. The change agents work closely with Joe to help him develop these skills. Slowly, over the course of about 2 weeks, Joe's showering skills advance to the point that he is taking full showers, with good use of soap and shampoo. His hygiene and grooming have improved immensely, and Joe smiles when staff compliment him on his appearance.

As Joe spends more time out of his room, he begins to notice other patients leaving the ward for vocational activities. He expresses an interest in this, but learns that he must be at Level 2 in the TEP to work, and he needs to participate in semistructured social activities to reach that level. Joe reluctantly begins showing up at a couple of the evening card games scheduled on the ward. When he discovers that he cannot earn tokens if he talks to his hallucinations, he angrily retreats to his room. Eventually, after this behavior costs him tokens in a number of activities, Joe begins to reduce the frequency of responding to hallucinations. By April 14th, Joe is promoted to Level 2 and starts attending work. Token payment for work activities is delayed at this Level, and patients are paid in a lump sum at the end of the week as the first step in gradually weaning them off the token economy.

While walking to and from work each day, Joe notices the Recreation Center on campus, as well as some of the gardens and nearby benches. His attendance and participation in other treatment groups starts to improve, as Joe tries to earn additional tokens to spend on grounds passes. An aggressive incident at work on May 10th results in a token fine and the loss of Level 2. Joe is frustrated and becomes sullen and withdrawn for a few days. Staff once again hear him speaking to "Uncle

Ed.” However, after 3 days Joe shows up for the morning exercise group where he earns a token and receives a good bit of social praise from the staff. Joe focuses on regaining Level 2, and succeeds on May 22nd.

By late June, Joe rarely isolates himself in his bedroom. His aggressive behaviors are well under control, and he no longer talks to “Uncle Ed.” Improvements in his group attendance and work performance result in a promotion to Level 3 on June 30th. Joe now receives a large weekly deposit of tokens into his “bank account,” instead of receiving physical tokens at the time he performs each target behavior. He must learn to budget his token supply for an entire week, because no new token deposits will be received before the next week. Joe struggles with this for a few weeks, and often runs out of tokens after only 3 to 4 days, but with some teaching he learns to manage his funds for the entire week.

By late July, Joe is ready to make brief visits to local group homes in preparation for discharge. He continues to participate in treatment at the hospital during the day but starts engaging in evening and weekend leisure events at the group home where he wants to live. There are no tokens at the group home, and this is an additional step in helping Joe move from the token economy back to the community. When Joe is promoted to Level 4 on August 5th, he starts carrying money again and is taken off the token economy entirely. Staff continue to provide Joe with lots of social praise for engaging in positive and adaptive behaviors. By September 8th, Joe is ready for discharge.

VI. SUMMARY

Leonard Krasner once described TEPs as “the most advanced type of social engineering currently in use.” Since their inception in the early 1960s, TEPs have been used to improve basic hygiene and grooming, social functioning, and vocational skills, and reduce agitation,

assaultiveness, and other maladaptive behaviors. They have improved academic skills and have reduced classroom disruptions in schoolchildren. Individuals in correctional settings show improved social skills and rule compliance. Most participants respond favorably to TEPs, but poor implementation, including inadequate training or oversight, will reduce their effectiveness. In addition, people respond differently to reinforcement contingencies, and this will also affect the effectiveness of the TEP. Finally, planning for generalization can help ensure that client improvement continues after the token reinforcement has ended. Forty years after its inception, the token economy remains a powerful tool for changing an enormous array of behaviors with a wide range of populations in a variety of different settings.

GLOSSARY

backup reinforcer The positive reinforcers for which tokens are exchanged.

Premack principle The finding that the opportunity to engage in high-probability activities will serve as a reinforcer for engaging in lower probability activities.

radical behaviorism Based on the work of B. F. Skinner, it is the theoretical orientation that posits that behavioral principles provide an explanation and understanding of the full range of human behavior, thought, and emotion.

target behavior A desirable or undesirable behavior to be increased or decreased in the token economy program.

token The item earned or lost when desirable or undesirable target behavior occurs and which is exchanged for backup reinforcers.

I. HISTORICAL ANTECEDENTS OF THE TOKEN ECONOMY

Token economies have a long history. Perhaps the earliest description of what would now be considered a token economy was provided by Alexander Maconochie in the mid-1800s. While warden of the Norfolk Island,

Australia prison, Maconochie concluded that the punitively oriented, torturous methods of inmate management common at that time did nothing to prepare offenders for a productive life in the community but instead increased the likelihood that they would return to their criminal ways when released. In an effort to bring humane management practices and meaningful rehabilitation programs to his prison, Maconochie developed a mark (token) system in which inmates earned marks for appropriate behavior and lost marks for inappropriate behavior. The inmates, in turn, used marks to purchase food, clothing, and privileges. Promotion through a levels system within the prison and even eventual release from prison were also determined by the number of marks accumulated.

It was not until the mid-20th century work of Ayllon and Azrin with severely disturbed psychiatric patients on one ward of a large state hospital and the work of Arthur Staats and his colleagues with children in a preschool setting that the token economy found acceptance and widescale use in modern psychology. Their work is a pioneering example of the extension of basic research conducted in the tradition of Skinner's radical behaviorism into applied settings.

II. OVERVIEW OF THE TOKEN ECONOMY

Stuve and Salinas provide a detailed description of the token economy in their contribution to this encyclopedia.

Our contribution therefore begins with only a brief overview of the token economy. We then offer a number of suggestions or guidelines for the operation of token economies that are based on both a consideration of published works in the area and our personal experience operating token economies in applied settings.

As Stuve and Salinas indicate, a token economy is a reinforcement-based motivational program that is used to encourage desirable, adaptive behaviors and to discourage undesirable, maladaptive behaviors. It differs from other reinforcement programs in that an artificial or contrived reinforcer (the token) is introduced to mediate the relationship and bridge the delay between behavior and more natural reinforcing consequences, such as extra recreational activities or special foods. Desirable behaviors are followed by the award of tokens, which are then exchanged for the natural reinforcers. Similarly, undesirable behavior is followed by the loss of tokens, which reduces or prevents access to the natural reinforcers. Token economies are typically employed with groups of individuals, such as all students in a classroom, all persons with developmental disabilities in a sheltered workshop, all psychiatric patients in a hospital ward, all delinquents in a group home, or all prisoners in a cell block. However, token reinforcement programs can also be used with individual children, adolescents, or adults. When this is done the program is usually referred to as a token or point system rather than as a token economy.

III. ESTABLISHING AND OPERATING A TOKEN ECONOMY

Token economies should be predominantly, if not exclusively, positive rather than punitive. That is, the target behaviors that lead to token award should far outnumber those that lead to token loss, and the participants should earn access to far more backup reinforcers than they are denied. Similarly, tokens should be awarded when earned by engaging in desirable target behaviors rather than given at the start of a day, for example, and taken away as punishment when desirable target behaviors are not exhibited. By emphasizing positive consequences for desirable behavior and for behavior that is incompatible with undesirable behavior, the token economy fosters cooperation and a sense of community among clients and staff while preventing the alienation and resistance that often is seen in punitively oriented programs. By so doing, the token economy fosters a positive attitude about the token economy, active participa-

tion in the token economy, and constructive relationships with those who carry it out on a day-to-day basis. Punitively oriented token economies tend to do just the opposite and explain much of the alienation and resistance commonly seen in such programs.

The major components of the token economy are the target behaviors, the tokens, and the backup reinforcers. In addition, the token economy includes the schedules relating target behaviors to the award or loss of tokens and the exchange of tokens for the acquisition of backup reinforcers. The token economy also includes provisions for the training and monitoring of staff, the use of behaviorally based methods for the development of the target behaviors to be reinforced, and procedures to ensure that behavior change is maintained as the client leaves the token economy. Finally, all aspects of the operation of the token economy and the progress of clients are monitored on a regular basis.

A. Target Behaviors

The token economy exists to increase and maintain desirable behaviors and to decrease and eliminate undesirable behaviors. In general, targeted desirable behaviors are those that contribute to or result in successful community adjustment and the living of a satisfying and productive life. Targeted undesirable behaviors are those that interfere with or prevent those outcomes. Quite often, the positive character of the token economy may be enhanced by targeting the desirable incompatible opposite behavior of an undesirable behavior for token award, rather than targeting the undesirable behavior for token loss.

The target behaviors should be in accord with the mission and goals those settings have established for themselves and their clients. A program for persons incompetent to stand trial that targets the signs and symptoms of mental illness, for example, is inadequate unless it also targets or even emphasizes the skills necessary to competently stand trial. Some behaviors may be targeted for all clients in the token economy. The target behaviors should also be based on an assessment of the strengths or abilities and the problems or deficiencies of the individual clients. As a result, clients may have several target behaviors in common, as well as several target behaviors that are unique to themselves or a small number of other clients.

The target behaviors or, in some instances, the products of the target behaviors should be described in unambiguous terms that make them observable and countable by a second party. This serves several

important functions that advance the treatment effort. First, the clients know exactly what is expected of them and act in a manner that will earn tokens or avoid their loss. The staff also know exactly what is expected of the clients and can accurately award or deduct tokens accordingly. In addition, the objective definition of target behaviors reduces conflict between clients and staff about the occurrence or nonoccurrence of target behaviors that typically occurs when more subjective criteria are employed. Similarly, the clear specification of target behaviors fosters consistency in the manner in which different staff, often on different shifts, work with clients. Finally, the more objectively defined the target behaviors, the less likely it is that clients will be effective in manipulating staff by arguing, for example, that a staff member is discriminating against them by treating them more harshly than other staff members.

B. Tokens

Tokens should be awarded as quickly as possible, if not immediately, following a desirable target behavior and taken away as quickly as possible, if not immediately, following an undesirable target behavior. The tokens themselves should be tangible, durable, portable, counterfeit-proof, and personalized in a manner that allows their accumulation by participants. In a very real sense, a country's financial economy is a token economy, and the characteristics of these tokens are a good model for the tokens in any token economy. In general, the nickels, dimes, and quarters of the United States' economy are tangible, durable, and portable. These coins can be accumulated in considerable numbers, and are virtually counterfeit-proof. They can also be easily carried by staff and can be awarded to clients immediately following a desirable behavior. Perhaps the greatest problem the currency in the United States' economic system poses is that it is not personalized and as a result individuals can and do acquire these tokens through theft and other means without engaging in appropriate and desirable target behaviors.

Rather than use "real" money, of course, token economies typically employ other items as tokens. What is used as a token in a token economy is limited only by the ingenuity of the staff of the program. One example is the poker chip or similar item, perhaps personalized with a number or letter to discourage illegitimate acquisition through theft or coercion. Another example is the daily punch card on which staff punch holes in circles as clients earn tokens and cross off punched-out circles as clients spend tokens. At the end of the day the cards are

collected by staff who determine the number of unexpired tokens, punch that number into the next day's cards, and distribute the individualized cards at the start of the next day. Still another example is a checkbook banking system in which clients are told to add tokens to their account as they earn tokens and write checks as they spend tokens. At the end of the day staff balance each account and inform the clients of their balance at the start of the next day.

The tokens in the three representative examples range from concrete or tangible to abstract or intangible. Where along that continuum the token should fall is dependent on the characteristics of the client population. Young preschool children should be provided more concrete or tangible tokens, whereas older adult offenders would most probably function well with more abstract or intangible tokens. When making that decision, one should keep in mind that one cannot err in the direction of using tokens that are too concrete or tangible.

C. Backup Reinforcers

The backup reinforcers are the natural reinforcers that give value to the tokens. The token economy should not deprive any clients of anything to which they are entitled by the Constitution or by statute. The backup reinforcers therefore are additions to these legally mandated minimums. They may involve access to additional amounts or enhancements of entitlements, such as additional exercise time or special foods, as well as anything to which the client is not legally entitled. In general, backup reinforcers fall in several categories. These consist of edibles or consumables, such as special food or drink; activities, such as extra recreational or computer game time; material objects, such as special athletic shoes or posters; and independence, such as reduced supervision or movement through progressively less restrictive levels in a structured levels program. Each can be considered a to-be-earned privilege.

A number of strategies may be used to identify backup reinforcers. The most straightforward consists of asking the clients what they would like and would work for. Another is based on the Premack principle and involves observing clients during free or unstructured time to identify the things they are most likely to do. These may then be used as backup reinforcers for the typically lower probability target behaviors. Finally, the staff can be asked what they believe will serve as backup reinforcers for their clients. It is important to note, however, that the information gathered through these strategies results only in the identification of

potential backup reinforcers. The reinforcing properties of the potential backup reinforcers must be tested to determine whether they are true backup reinforcers. This is done by assessing whether clients will engage in target behavior to earn tokens and then exchange the tokens for the potential backup reinforcers.

What is reinforcing to one client may or may not be available to another client. The token economy must therefore offer a variety of backup reinforcers to ensure that there are sufficient reinforcers for all participants. Although some backup reinforcers may motivate most or all clients, additional backup reinforcers that function as such for only a few or, perhaps, only one client should also be made available to ensure that the unique interests of all clients are addressed. The backup reinforcers should be available to clients on a regular basis. Some should be available several times a day, others several times a week, and perhaps still others several times a month or only on a monthly basis. The schedule of availability of backup reinforcers is dictated, in part, by the characteristics of the clients, and a token economy cannot err in the direction of making backup reinforcers too frequently available to clients. Finally, the backup reinforcers must be available only through the token economy. The availability of "bootleg" backup reinforcers, that is, backup reinforcers that may be obtained through other means, will dilute or negate the reinforcing properties of backup reinforcers and should be prevented.

D. Additional Considerations

The token economy should be fair or balanced. That is, the backup reinforcers should be commensurate with the target behaviors. This is accomplished, in part, by ensuring there is a rich and variable array of backup reinforcers available to the clients, and by ensuring that the number of tokens earned is in accord with the nature of the to-be-rewarded target behaviors and the number of tokens expended are in accord with the nature of the to-be-purchased backup reinforcers. These ratios should be adjusted as participation in the token economy dictates. Clients should be included in the decision-making process to both better ensure fairness is maintained and to offer them the therapeutic benefit such involvement brings to the treatment setting. The token economy should also be as simple or straightforward as possible so that the relationship between target behaviors, point award or loss, and backup reinforcers is clear to all clients. Conditions, exceptions, and qualifications that obscure the direct relationship between target behavior, tokens, and backup reinforcers will work to dilute the effects of the token economy.

Although the token economy itself may provide experiences that foster a structure and an appreciation of the quid pro quo relationship between privileges and responsibilities that prepare individuals for life in the community, its greater power lies in its ability to motivate clients to participate in therapeutic and rehabilitative programs and activities. These should be identified while developing the target behaviors of each client's individualized treatment program. Staff require training to carry out the token economy and its treatment programs, or to support the staff that do. The general skills necessary to carry out a token economy include, among others, how to shape behavior, the use of prompting to increase desirable behavior and redirection to decrease undesirable behavior, how to use social reinforcement when awarding tokens and backup reinforcers, and the use of behavioral momentum, differential reinforcement, and chaining to further encourage appropriate behavior or discourage inappropriate behavior. Training in specific therapeutic skills is necessary to carry out the treatment programs called for by the characteristics and special needs of the client population. These should be in accord with the profession's movement toward the identification and adoption of empirically based treatments.

A monitoring system is an important part of the token economy. Not only should clients' progress be monitored and assessed on a regular basis, but the performance of the staff in carrying out the token economy should also be monitored and assessed on a regular basis. When the monitoring of clients indicates that their progress is not as is expected, changes in both the clients' individualized treatment plan and the design or implementation of the token economy should be considered and implemented as called for. When the monitoring of staff indicates that their performance is not as is called for, retraining and more intensive supervision should be considered and implemented as called for. More important, however, staff should participate in a positive organizational behavior management program to sustain high levels of work performance and morale.

Special procedures should be implemented to phase out the token economy when clients are eligible to move to another treatment setting or into the community. The general strategy to be followed is to give clients progressively more responsibility for the management of their own behavior. This may be done by moving clients through a structured levels program or by moving from the token economy to self-management in the absence of levels. One might begin, for example, by relaxing a requirement that staff evaluate clients' performance and award tokens as clients assume more responsibility for

evaluating their performance of their target behaviors and awarding or deducting their tokens accordingly. Similarly, the next phase might involve the clients assuming responsibility for exchanging tokens for backup reinforcers. Finally, the tokens might be eliminated and clients assume full responsibility for continuing to engage in their target behaviors and, in exchange, have full but reasonable access to backup reinforcers. Staff should continue to monitor clients throughout this process to ensure that performance is sustained. Transitional programs should ensure that improvements are maintained as clients leave the token economy setting. These programs range from training those who will work with the clients in the additional behavioral skills employed by the token economy staff to training them to continue token economy procedures, if such prosthetic arrangements are deemed necessary.

IV. EFFECTIVENESS OF THE TOKEN ECONOMY

Maconochie's anecdotal reports indicate that the recidivism rate for inmates released from his program on Norfolk Island was markedly lower than that for other prisons in the British colonies. More recent empirical research provides general confirmation of the effectiveness of properly designed and implemented token economies. Perhaps the most influential of the empirical studies is Paul and Lentz's thorough-going experimental comparison of milieu therapy and social learning therapy with a severely disturbed psychiatric population in a large state hospital. They defined the milieu approach as consisting of increased social interaction and group activities, expectancies and group pressure directed toward normal functioning, more informal patient status, goal-directed communication, freedom of movement, and treatment of patients as responsible people rather than custodial cases. The social learning approach was described as the systematic extension of principles and techniques derived from basic research on learning to clinical problems, specification of specific behaviors for change, emphasis on response-contingent consequences, and the use of token economy programs.

In general, Paul and Lentz found the token economy to be superior to the milieu program in terms of both in-hospital improvement and then postrelease adjustment

during a year and a half follow-up period. It was also found to be the more cost effective of the two approaches. The milieu approach, in turn, was found to be superior to routine hospital care for both the in-hospital and postrelease indices of program effectiveness. Findings such as these ensured that the token economy would become an important component of many treatment programs for persons with mental illness as well as in educational settings, training schools, and prisons.

V. SUMMARY

The token economy employs a conditioned reinforcer to mediate between clients' behavior and its more natural positive reinforcement. It is an effective motivational system to encourage desirable behavior and discourage undesirable behavior. It is also effective in ensuring clients' participation in individually prescribed treatment programs. Although simple in concept, it requires sophistication in implementation as well as staff training and continued monitoring to ensure its effectiveness.

GLOSSARY

defense The methods used by the ego to master and control id impulses or superego injunctions.

drives Another term for Freud's instincts. Two drives were postulated by Freud—sexual and aggressive. These were the major factors motivating the operation of the mind in his topographic model. They continue to be considered important but not the only motivating factors by modern psychoanalysts.

libidinal wishes Wishes infused with affectionate or sexual urges thought to be ubiquitous in human functioning.

libido The hypothetical psychic energy attached to the sexual instincts.

narcissism Love for the self. Modern-day psychoanalysts use the term primarily to refer to issues of self-esteem. Narcissistic defenses refer to defenses designed to protect or enhance self-esteem, for example.

object relations Refers to relationships to other people. In psychoanalysis, it is the internal representations of self and others that are important in motivating and mediating interpersonal interactions. A developmental distinction is often made between dyadic and triadic object relations. The former refer to relationships modeled on preoedipal

experiences where the major goals of the child revolve around need satisfaction by the mother. Triadic relations are seen as more mature, implying oedipal engagement and the increasing mental complexity implicit in being aware of needs and wishes toward one parent vis-à-vis the other parent.

psychic determinism The tenet that all mental acts have meanings and causes. Psychoanalysis assumes that such causes have to do with mental phenomena that preceded the act in question.

resistance The manifestation of defense within the treatment process whereby the patient opposes the analyst's interventions.

transference The process by which the patient displaces onto the therapist or analyst feelings, impulses, attitudes, or defenses derived from important interactions in the past.

Topographic theory refers to Freud's second phase in developing his psychoanalytic model. It lasted from 1897 until he introduced his structural model in 1923. This phase was marked by rapid, significant evolution in psychoanalytic theory and technique. Many key concepts from it continued to inform psychoanalytic theory and practice including drives, unconscious mental functioning, defenses, unconscious conflict, object relations, and narcissism. Dream analysis, the importance of transference and resistance, and the importance of insight in bringing about psychoanalytic cure stem from Freud's interest in delineating the topography of the mind.

I. SEXUAL TRAUMAS

The most decisive clinical finding that led Freud to abandon his previous affect-trauma model and to develop his topographic one was his finding that the sexual traumas remembered by his hysterical patients thought to cause their symptoms had often not happened. He came to this startling conclusion when he realized that every patient blamed her problems on perverse actions of her father. The likelihood of such pervasive sexual abuse seemed too great to accept as Freud gained more experience with his new talking cure. Furthermore, he himself developed similar memories in his self-analysis. Yet he knew definitively that such actions had not truly happened. These realizations left Freud with the problem of how to account for the existence of such false memories as seemingly a part of the human condition. Puzzling over this problem, he realized that such memories were actually fantasies, fantasies from which he deduced the existence of sexual drives. The concept of defense was brought in to explain the patient's distortion of fantasies into memories. Thus was born the notion of intrapsychic conflict.

II. TOPOGRAPHIC THEORY

But Freud went far beyond the concepts of unconscious libidinal fantasies conflicting with defenses as he tried to understand a host of normal and pathological human characteristics during this stage of his thinking. In order to explain dreams, jokes, slips of the tongue, various types of psychopathology, and aspects of clinical technique he found it necessary to map out the terrain or topography of the mind. His topographic theory differentiated areas of the mind and mental characteristics according to their relationship to consciousness. A spatial metaphor of proceeding from the depths to the surface of the mind was used. Three regions or systems in the mind were delineated: (1) the system Unconscious; (2) the system Preconscious; and (3) the system Conscious. The mental contents of the system Unconscious, instinctual drives and wishes, were thought to be continually pushing to be discharged into the system Conscious. But the unpleasant affects anticipated were they allowed to emerge into consciousness gave rise to defenses that attempted to maintain them in the system Unconscious or to distort their expression so that only partial and disguised discharge was allowed into the system Conscious. This model of mental functioning, thought to give rise to the neurotic symptoms

that Freud treated in his patients, led to the technical dictum of that era—make the unconscious conscious. Thus, Freud advocated that analysts impart insight of their patients' unconscious mental contents, and that this insight would lead to symptom relief.

The spatial metaphor that Freud relied on during this stage of his thinking was most clearly delineated in the seventh chapter of the *Interpretation of Dreams*, which he published in 1900. The model of the mind as composed of three systems or regions that he constructed was based on the concept of the reflex arc. This model held that mental contents had to proceed from the system Unconscious through the system Preconscious before becoming accessible to conscious awareness in the system Conscious. Each of these systems or regions of the mind had distinct characteristics, all of which combined to make mental functioning highly complex. Boundaries were thought to exist between each system, although the rigidity of the boundaries varied. When the mind was in a state of equilibrium or harmony, the boundaries between the regions were thought to be vague, but the dividing lines became quite defined during episodes of conflict.

III. SYSTEM UNCONSCIOUS

The system Unconscious was the most important system in this model. Indeed, the idea of unconscious mental functioning remains central to psychoanalytic understanding of normal and abnormal behavior to this day despite the concept of the system Unconscious having been eliminated. The idea that all behavior and psychological functioning have unconscious determinants remains central to psychoanalysis. Joseph Sandler and his colleagues have pointed out that this hypothesis assumes that the greatest portion of the mind operates outside conscious awareness. It follows from the assumption that most psychological adaptation occurs unconsciously. The principle of psychic determinism, so important in psychoanalytic theory, applies to unconscious mental functions and contents as well as conscious ones.

Perhaps the most noteworthy aspect of the system Unconscious are the contents that Freud thought it contained—the instinctual drives. The overall structure of the mind during this stage in his thinking was thought to occur so that instinctual drives from the system Unconscious could be controlled and expressed in a way that took into account both external reality and the need to allow drive gratification, albeit in disguised

and attenuated forms. These contents of the system Unconscious were emphasized to play a dominant role in the individual's development and ultimate psychological functioning. Freud described the concept of instinctual drives as "a concept on the frontier between the mental and the somatic" in his 1915 paper, *Instincts and Their Vicissitudes*. He seemed to see the concept as a mental representation of somatic stimuli. Initially he emphasized only libidinal drives although aggression in the form of the death instinct was eventually added to psychoanalytic theory later in his life. But the aggressive drive has never been formulated as clearly as the libidinal one despite the indisputable importance of aggressive impulses in mental functioning.

Four components of the libidinal drive were described by Freud. The first was the pressure of the drive, by which he meant the degree to which it pressed for discharge. Freud was struck by the peremptory quality of libidinal urges; they seemed to exert a degree of pressure to act far more compelling than most other human urges. The aim of the instinctual drive was satisfaction. Satisfaction could only be obtained at the source of the instinct. The source referred to the part of the body from which the instinct was thought to derive. Oral impulses, for example, derived from the oral cavity and so could only be satisfied at that source. Finally the object of the drive is that person or object through which satisfaction is obtained. These objects can be part of one's own body. The wide range of perversity known to the human condition demonstrates how variable this component of instinctual drives can be.

The system Unconscious was postulated by Freud to be characterized by a number of unique processes. Perhaps the most important was what he called the primary process in contradistinction to the secondary process, which he saw as characterizing the systems Preconscious and Conscious. Underlying this concept of the primary process was Freud's economic model wherein he believed that a special form of energy, psychic energy, contributed to all mental functioning. Freud believed that the energy in the system Unconscious was freely mobile so that instinctual energy could shift between separate ideas, parts of ideas, memories, and so on, without consideration of logic or time. Thus, ideas could be combined or shifted in ways that the conscious mind would be unable to understand or accept. As a result unconscious thinking is often characterized by displacement or condensation. The former allows one idea to stand for another in the system Unconscious whereas the latter involved a fusing of two ideas that might not be logically compatible. These two

primary process mechanisms—displacement and condensation—are what made dream analysis so complicated and interesting a task for Freud. In order to make the unconscious conscious, the analyst needed to decipher the unconscious mental contents that were disguised by these two primary process mechanisms.

Other unique characteristics of the system Unconscious were also described by Freud. Thus, he described its timeless nature. Temporal considerations were thought to be irrelevant in this system. Furthermore, it operated on the basis of the pleasure principle with no regard for reality constraints or logic. No distinction between memories of real or imagined experiences occurred in the system Unconscious. Furthermore, contradiction did not exist nor did negation. In this way opposites could be experienced as identical in the system Unconscious. Finally words (symbols) and that which they symbolized were experienced as identical in this system according to Freud.

IV. SYSTEM PRECONSCIOUS

The second deepest system or region of the mind according to Freud was the system Preconscious. It was defined as lying between the systems Unconscious and Conscious with its major task being to protect the system Conscious from being inundated by the instinctual drives of the system Unconscious. Freud's topographic model hypothesized that the system Preconscious developed gradually from the influence of both unconscious instinctual wishes and external reality. Over the course of childhood it was thought to become increasingly differentiated from the systems Unconscious and Conscious. Helping in this differentiation was the development of defenses that Freud first called censorship and later repression in this stage of his model development. Thus, the system Preconscious formed a censorship at its boundary with the system Unconscious in order to prevent the instinctual wishes from gaining direct access to the system Conscious. It is important to note that this defensive or censoring function of the system Preconscious was thought to operate unconsciously. But this type of unconscious was descriptive in nature, in contrast to the dynamically unconscious contents of the system Unconscious. That is, functions and contents in the system Preconscious were said to be capable of becoming conscious were attention directed at them. In contrast, the contents and functions of the system Unconscious are actively maintained as unconscious by the energetic force (counter

cathexis) that the preconscious censorship directs against them. This distinction between descriptively and dynamically unconscious content and functions remains relevant today.

Unlike the system Unconscious's operation according to the pleasure principle, the system Preconscious was postulated to adhere to the reality principle. Thus, the unconscious wishes that it allowed to pass through into the system Conscious were closely examined and modified to ensure that they would facilitate the individual's self-preservative needs and could be integrated with the individual's moral-ethical ideals. Secondary process thinking characterized the system Preconscious in order to ensure these adaptational needs also. Causality, logic, and temporality characterize the secondary process wherein language becomes the most important vehicle for harnessing the instinctual drives. The psychic energy assumed to characterize secondary process thinking was described as bound energy by Freud. Sandler and his colleagues have emphasized the multiple and complex functions the system Preconscious was thought to include: (1) unconscious scanning of thoughts and feeling states; (2) censoring of instinctual wishes and their derivatives; (3) formation of organized memory systems; (4) reality testing; (5) binding of psychic energy; (6) control of access to consciousness and motility; (7) affect modulation and development; (8) defensive functioning; (9) fantasy production; and (10) symptom formation.

V. SYSTEM CONSCIOUS

Freud described the system Conscious as being on the mind's surface. Unlike the two deeper regions, its contents were all conscious. Nonetheless the limitations of attention prevented all contents from being the focus of conscious attention at any one time. This system received input from both the system Preconscious and from stimuli of the external world. Thus, its contents were described as sliding back easily into the system Preconscious when conscious attention was completely removed from them. Accordingly, conscious contents are more fleeting than contents of the other systems. Self-preservation requires that the individual always be open to new perceptual experiences. Thus, attention cathexis was thought to be an important part of this system. It was described as based on psychic energy that had been neutralized of sexual or aggressive qualities. Otherwise the system Conscious was similar to the system Preconscious in its underly-

ing structure. The reality principle dominated as did secondary process functioning.

VI. IMPORTANCE OF TOPOGRAPHIC MODEL

The topographic model remains important theoretically because all of Freud's papers on clinical technique were written during this stage in his thinking. Thus, it has continued to exert a prominent influence on psychoanalytic technique despite having been replaced with the structural model in 1923. Paying attention to transference and resistance, studying dreams as the royal road to the unconscious, and interpreting the unconscious content inherent in transference and resistance manifestations came to characterize the psychoanalytic process during this era. As mentioned above, the major curative factor was thought to involve making the unconscious conscious. These technical prescriptions are likely to still sound accurate to many today despite being based on an outdated theoretical model. In fact, Paul Gray has lamented what he calls a developmental lag in the psychoanalytic theory of technique wherein analysts have been slow to realize that the technical implications of the structural model call for a very different technique than that described earlier. Working in a topographic manner leads analysts to interpret unconscious mental content without analyzing the defenses that keep such content unconscious. This approach ignores the need to understand the motives for the defense. Failure to do so renders the patient vulnerable to maintaining these defenses. Also, interpretations that ignore defense can increase the patient's anxiety and, hence, resistance. Gray and his adherents have delineated the different technical implications of the structural model. Nonetheless, many contemporary analysts practice in a topographically informed manner without realizing that they are doing so or that such ways of working are outdated. Thus, it remains important to understand the topographic model as it may be some time before it becomes no longer used.

Furthermore, aspects of the topographic model remain important, even to those analysts whose theoretical understanding has been updated. Certainly the distinction between unconscious and conscious phenomena remains clinically relevant, as does the concept of psychic conflict. Unconscious, preconscious, and conscious are now used as adjectives describing mental processes and not as nouns depicting regions of the mind. The topographic concepts of instinctual drives also remain relevant. These concepts have been revised in an at-

tempt to make them more scientifically viable. Furthermore, psychoanalysts have expanded the number of motivational factors that impel human behavior beyond sexual and aggressive impulses. Nonetheless, sexual and aggressive wishes remain quite important clinically and need to be addressed and analyzed in psychoanalytic treatment.

A major contribution of the topographic model not discussed earlier, but one that is quite important on the modern-day psychoanalytic scene, is that of object relations. The idea that individuals build up a subjective world of mental representations of self and important others, and that this representational world is a crucial component of the psyche is explicit in almost every variant of psychoanalytic theory adhered to today. Recognition of this fact has led analysts to a new acceptance of the inevitability of countertransference enactments. Such enactments are now thought to provide useful understanding about the patient rather than indicating psychopathology in the analyst or therapist. Object relations models have led to new ideas about what is curative in psychoanalytic treatment and to new technical prescriptions including the judicious use of self-disclosure on the part of the treater.

Many fail to recognize that Freud's key papers, *On Narcissism* and *Mourning and Melancholia*, written at the height of his topographic thinking, contain the seeds of all subsequent object relations models. Both these papers involve his explicit delineation of the importance of object relations in understanding psychopathology and in deriving treatment strategies. In those papers he laid out the importance of developing representational boundaries between self and other as well as the role of internalization in giving rise to important emotional states. Thus, the topographic model continues to exert a modern influence.

Joseph Sandler, one of the most prominent psychoanalytic thinkers of the last four decades, has argued for a more direct viability of the topographic model, albeit in a modified form. He believed that the transition from the topographic to the structural model left gaps and inconsistencies in conceptual understanding and in clinical technique; he believed that these could be overcome by a modification of the topographic model—what he called the three box model. He used this three box model to highlight the necessity for conceptualizing a second censor between the second and the third box or system of the mind. This censor gives the second box or system depth, acknowledging the clinical reality that unconscious ego activities have a

range of closeness to consciousness. Even more important, this second system or box is oriented to the present, not to the past. It creates current unconscious fantasies and thoughts as ways of maintaining psychic equilibrium and helping to defend against the infantile, preemptory, and potentially disruptive fantasies of the first box as they push toward actualization.

The second censorship occurring between the second and third systems attempts to avoid shame, embarrassment, and humiliation. In essence it is a narcissistic defense. The contents of the third box are surface or conscious expressions of second system thoughts, impulses, wishes, and fantasies. Sandler believed that the technical importance of this model is to distinguish between the past Unconscious of the first box and the present Unconscious of the second. It is the present Unconscious content that lies behind the second censorship and is closest to consciousness. Sandler believed that his model would help analysts to avoid the topographic era strategy of interpreting deep or past unconscious content before having dealt with less deep, present unconscious content. He advocated that the analyst listen for current unconscious content that was being censored. Thus, his modification of the topographic model is an attempt to deal with the same sort of technical problems as that of contemporary structural theorists such as Paul Gray or Fred Busch. Their approaches are currently gaining greater acceptance than Sandler's three box model. Nonetheless, his efforts do highlight the continued attraction of topographic theory to many contemporary psychoanalytic practitioners.

GLOSSARY

culture-bound-syndrome (CBS) Term coined by P.-M. Yap (1967/1974) as pertaining to only locally spread diseases in opposition to current psychiatric diagnoses. Today they are seen as strongly culturally influenced diseases, finding their explanatory roots in folk medical beliefs. Examples include koro/suoyang, paleng, amok, latah, susto, brain-fag, and ogba nje.

emic Culture-specific understanding; research by an insider; emphasized by the new cross-cultural psychiatry, comparing cultural aspects (e.g., A. Kleinman, B.J. Good, R. Littlewood, M. Lipsedge).

ethnopschoanalysis Term, first used by G. Devereux in 1972, for a kind of work initiated by G. Róheim in 1932 and continued separately by P. Parin, G. Parin-Matthèy, and F. Morgenthaler in 1963. According to Devereux psychological and sociocultural explanations must be used separately. Modern interpretations of his ideas are controversial.

ethnopsychiatry Study of psychiatric diseases in other cultures. The term was first used by Devereux around 1950. He saw one of its tasks as being to create a culturally neutral psychotherapy.

etic Useful for global generalizations; a culture transcending view, as opposed to emic; research by an outsider.

immigrants first generation—5 phases Initially (1) the preparation for and (2) the act of migration. Communication barriers because of language problems are predominant. Overcoming many psychological problems by excessive effort, that is, (3) overcompensation occurs. However, this can have a negative impact, and (4) decompensation, occurs, especially on retirement. (5) Adaptation takes more than one generation.

immigrants second generation Mostly well-spoken new language, frequently hiding the problem of different meanings and losing their parents' language. Torn between traditional values of the family and place of origin and modern values of the new surrounding.

immigrants third and later generations On the surface mostly well adapted if belonging to a more educated social class, but—often unconsciously—still influenced by the family's cultural heritage. If belonging to a lower social class, they still might have difficulties in learning the new language sufficiently, while also not learning their original language well enough.

interpreters Should be neutral persons, not family members, trained in being translators without commentaries or cotherapeutic interventions.

qigong A therapeutic combination of movement, breathing, and hovering awareness as one example of therapeutic methods in traditional Chinese medicine (in addition to herbs, acupuncture, etc.). Many traditional medicines are used in diagnosis and treatment by their respective immigrants, often without mentioning it. Their traditional explanations of their disease might play an important role in Western psychotherapy.

shaman A traditional healer, found in most traditional cultures. He uses altered states of consciousness (ASC) if he is a real initiated healer.

transcultural psychotherapy (a) Using traditional methods from other cultures in Western psychotherapy. (b) Concerning all the sociocultural problems involved in the psychotherapeutic treatment of immigrants or refugees, deriving from the encounter of the two (or more) respective cultures. Often an interpreter is necessary.

I. INTRODUCTION

Mental health services rely not only on the physical body but also on the psyche, brain, mind, and soul. The body itself with its different physical afflictions, diagnoses, and treatments is viewed quite differently depending on the cultural context, according to Payer in 1996. Mental problems and sociocultural factors are so closely interrelated that they cannot be viewed separately, as discussed by Westen in 1996. With an ever-growing worldwide multiculturalism, it is imperative to integrate the results of international research. This concerns all theories of psychoanalytic, behavioral, humanistic, and other psychodynamic counseling and psychotherapy. To improve our understanding of transcultural psychotherapy I will introduce historical perspectives. Some of the main factors to be considered are aspects of migration and transcultural contexts. Short case studies, each emphasizing a particular facet, will illustrate this point.

II. THE HISTORICAL PERSPECTIVE

The foundation of transcultural psychotherapy is based on Middle European psychiatry. Known and unknown variations of familiar "mental illnesses" were discovered in distant and "exotic" countries. The scientific founders were Van Brero, who worked in the 1890s, and Emil Kraepelin in 1904. Their comparative psychiatric works dealt with mental disorders in Indonesia. Bronislaw Malinowski's work in 1924 on *Mother-Dominated Family and Oedipus Complex* represented a milestone in which he refuted Sigmund Freud's hypothesis on the general validity of the Oedipus complex by recording his observations on the Trobriand tribe in the Pacific. He was able to show that the complexes arising within the family core were a consequence of the social structure of the tribe or people. Nevertheless, he recognized the significance of Freud's attribution to the influence of the early childhood years. In 1957 Erik H.

Erikson followed with his studies on *Childhood and Society*, a comparison between the North American Indian Yurok and Sioux tribes. Margaret Mead did her research with a scientific and objective point of view and described the customs and traditions of different races. In 1959 Mead introduced *Gender and Temperament in Primitive Societies* and was primarily interested in how children were raised within these societies. She was known as a representative of "Culture-Gestalt-Psychology," and her results are considered controversial.

Paul Parin, Golda Parin-Matthey, and Fritz Morgenthaler investigated African cultures according to psychoanalytical criteria. In the 1950s Georges Devereux coined the expression "ethnopsychiatry," and in 1972 he published the book *Ethnopsychanalysis*. According to his ethnological studies, stress is traumatic when, within the respective culture, defense mechanisms are absent. He understood culture as a system of defense mechanisms. In 1982 he stated that shamans were mentally disturbed. The fact that in 1996, Asian shamans and African medicine men were invited to speak at the first World Congress of the "World Council for Psychotherapy," in Vienna, shows that today this situation is seen quite differently. Devereux's aim in 1970 was "the introduction of teaching and practice of cultural neutral psychotherapy," as described in 1982. This kind of psychotherapy should not be based on the attributes of any particular culture, but should be "comparable to affective neutral psychoanalytical therapy." Since this originated only in Devereux's culture, it is actually a contradiction in itself.

Jeanne Favret-Saada, a psychoanalyst and ethnologist like Devereux, introduced epochal standards to her field of research by participating in conversations and witchcraft ceremonials with the natives. These "natives" were not even "exotics" but a rural group of people from the western part of France. Favret-Saada allowed herself to become personally involved, and in doing so, pioneered a new scientific approach. Thus, in 1977, she added a third method of research. In 1966, R. Pike derived the already familiar "etic" approach, from linguistics, to be applied to ethnology. This meant gaining more culture-general information from scientific studies, in contrary to the rather culture-specific "emic" approach, which enabled a better understanding of the cultural aspects from the natives' point of view. Favret-Saada, as an insider among these "natives," was able to put herself into the position of examining the culture from both points of view, changing dialectically from inside to outside. These aspects were also considered by psychiatrists such as Christian Scharfetter, who, in 1987, published the book

Ethnopsychotherapy. His ideas were based on his own experiences with the Theravada-Buddhism method of meditation, and many discussions concerning altered states of consciousness (ASC). Thomas Heise used a similar method. He studied traditional Chinese medicine (TCM) for more than 2 years in China, and, in 1996, published the book *China's Medicine in Germany*, which also covered a broader view of "psychiatric-psychotherapeutic" aspects of TCM. Another book by Heise, published in 1999, dealt with *qigong* in the People's Republic of China, its historical development, theory, and practice. Michael Harner in 1972, 1973, and 1980 and Roger Walsh in 1990 also based their scientific books about shamanism and healing on their own experiences and participation. Similarly, Stanislaw Grof, in his works since the 1970s, investigated many traditional therapies in order to find common roots. He made the workings of the various subconscious layers and ASC more intelligible and understandable.

Eric Wittkower, Wolfgang Jilek, and Louisa Jilek-Aall influenced transcultural psychiatry in many ways. Wittkower in 1978 described its aim as the "identification of quantitative and qualitative differences when comparing mental illnesses in the various cultures, the investigation to determine these differences and the application of this knowledge for the treatment and prevention of mental illnesses." In 1980 he was concerned with the cultural and transcultural aspects of psychotherapy. On the one hand he placed emphasis on the introduction of foreign cultural methods to the West, such as yoga and Buddhist meditation, and on the other hand, on the use of Western psychotherapy outside the Western culture complex.

Based on his experiences in Taiwan in 1980, Arthur Kleinmann did research on the way in which cultural symbols and meaning influence the perception and expression of symptoms and therapeutic mechanisms. In 1985, he emphasized the theme in *Culture and Depression*. Wolfgang Pfeiffer concentrated on the analysis of dialogue and migration problems as well as on the contact between various medical systems. Having lived in Indonesia, he dealt in particular with those of Asia. His first work, *Transcultural Psychiatry*, published in 1971 and revised in 1994, is a phenomenological collection of culturally influenced expressions, corresponding to the various psychiatric groups of diagnoses. Erich Wulff, who worked in South Vietnam for 7 years, studied the methods of comparative psychiatry, and emphasized the social requirements for these methods, and thus their historical significance and subjectivity. Karl Peltzer, who spent many years researching in different parts of Africa, supported these ideas and coined the expression

"postanalytical ethnopsychological research." In 1994 he published *Psychology and Health in African Cultures: Examples of Ethnopsychotherapeutic Practice*.

On the whole we can see in the historical development of transcultural understanding a start with a rather Eurocentric and limited approach. Scientists looked for the well known in foreign countries. The second step showed a deeper involvement into different cultures, but no change of scientific ideology, which only began with the third step. Here the dialectical switch between subjective involvement during field research and more objective scientific evaluation gave rise to new ideas. These are not limited to pure psychoanalytical or behavioral thinking and are more sincerely tolerant and humanistic, grounded on interdisciplinary cultural studies.

III. MIGRATION

Another pragmatically important topic concerns immigrants. They arrive for different reasons in historically varying waves, and experience specific stages of more or less successful adaptations to their problems. In Germany, for example, early research on the mentally related illnesses of foreign workers (*Gastarbeiter*) at the end of the 1970s was abandoned and thereafter temporarily forgotten. Other countries with a colonial or immigrant history were confronted with this problem to a greater degree. In the past two decades, in England and the United States, this has led to a growing literature on counseling. These perspectives on counseling apply to therapy as well. In past years the geriatric ailments of the "foreign workers" in Germany, the second and third generation of immigrants, and the increasing inflow of new immigrants and political refugees produced an escalation of problems in mental health and psychotherapy. It was found that for refugees suffering from posttraumatic stress disorder (PTSD) it is of utmost importance to assess the preflight personality, the circumstances that caused the flight, its conditions, and coping abilities. Around 20 years ago, *Counseling Across Cultures* was published by Paul. B. Pederson and colleagues. It deals not only with the specific ethnic groups in North America, but also with international students and refugees, gender conflicts, ethics, and cultural empathy. In 1989, Patricia D'Ardenne and Aruna Mahtani published the book *Transcultural Counselling in Action*, which demonstrated practical aspects of the transcultural therapist-patient relationship. That same year, Colleen Ward issued the volume *Altered States of Consciousness and Mental Health: A Cross-Cultural Perspective. Handbook of Multicultural Counseling* by Joseph G. Ponterotto

and co-workers discusses theoretical and practical statements. A book series on multicultural counseling covers themes such as *Preventing Prejudice* by Ponterotto, *Improving Intercultural Interaction* by Richard Brislin and Tomoko Yoshida, *Assessing and Treating Culturally Diverse Clients* by Freddy Paniagua, *Overcoming Unintentional Racism in Counseling and Therapy* by Charles Ridley, and *Multicultural Counseling with Teenage Fathers* by Mark Kiselica. Colin Lago and Joyce Thompson compiled the book *Race, Culture and Counseling* and Suman Fernando published *Mental Health in a Multi-Ethnic Society*. The latter two books deal particularly with the problems of biological and cultural racism and the different, often multiprofessional management of inpatient and outpatient institutions for the care of mentally disturbed foreign citizens.

One prominent French author, Tobie Nathan, published such works as *The Madness of Others: An Essay on Clinical Transcultural Psychiatry* in 1986, and *The Influence That Cures* in 1994. Initially, he held the opinion that the ethnopschoanalytical background was of prime importance. Later, however, he changed his mind and stated that patients could also be healed using the therapeutic means of their respective cultures. In 1998, Marie Rose Moro, who worked especially with immigrant children emphasizing the aspect of family therapy, published a book on these topics. In the Netherlands, in 1996, Joop De Jong developed, among other things, a handbook on transcultural psychiatry and psychotherapy. A number of German books show, by their titles alone, that there are numerous problems in the search for better solutions: Heribert Kentenich, Peter Reeg, and Karl-Heinz Wehkamp, 1990, *Between Two Cultures: Why Does a Foreigner Become Ill?*; Horacio Riquelme, 1992, *Other Realities—Other Approaches*; Eckhardt Koch, Metin Özek, and Wolfgang M. Pfeiffer, 1995, *Psychology and Pathology of Immigration: German-Turkish Perspectives*; Peter Möhring and Roland Apsel, 1995, *Intercultural Psychoanalytical Therapy*; Jürgen Collatz, Ramazan Salman, Eckhardt Koch, and Wielant Machleidt, 1997, *The Medical Report with Special Emphasis on Transcultural Issues: Quality Safeguarding of Social-Legal and Social-Medical Reports for Working Immigrants in Germany*; Thomas Heise, 1998, *Transcultural Psychotherapy: Helping to Treat Foreign Citizens*; and Heise, 2000, *The Situation of Transcultural Counseling, Psychotherapy and Psychiatry in Germany*.

Traumatization can occur as a result of ethnic, religious, sexual, or economic pursuit, if the preflight personality cannot cope. These differences must be taken into account when determining therapy, which varies for immigrants in the various generations. Each subjective

reality is based on the individual's identity, perceptions, and experiences. Neglecting its relation to culture, diagnosis may be inadequate, the patient does not feel accepted personally, and therapy is likely to fail. For evaluating the five phases of migration (see Glossary) important issues include reflecting on the cultural influence of one's own behavior; being able to investigate another person's cultural background, if necessary with interpreters; reflecting on one's own prejudices and the cultural and historical relativity of values; understanding each other sufficiently; and being able to find acceptable solutions in a multicultural teamwork. According to Sluzki in 1996, the therapist must help the migrant to prepare to accept times of feeling lonely, to encourage him or her to learn the new language and new customs as quickly as possible, to get as much new information as necessary, and in order not to lose continuity, to remain in contact with compatriots and enhance the personal environment with pictures from the past or other symbols.

IV. TRANSCULTURAL CONTEXTS

There are many cultural barriers to communication and we are only aware of some of them. Less evident are attitudes toward one another; nonverbal behavior; customs and traditions of greeting and meeting; personal theories of communication; political differences; fear, perception, and expectations of one another; systems of belief and ethics; view of personal and institutional power; notions of acceptable and unacceptable behavior; patterns of interpersonal relationships; ways of learning, working, and living; and views of illness and disease as well as of therapy regarding meaning for oneself and others. In 1980 Geert Hofstede determined some main criteria in 40 different nations and distinguished between small and large "power distance" (the acceptance of the distribution of power in society), weak and strong "uncertainty avoidance," collectivist and individualist, and feminine and masculine dimensions.

In approaching different philosophical assumptions, as Lago and Thompson showed in 1996, general views of the world will be compared.

The Western system emphasizes a material ontology, appropriating a high value to the acquisition of objects. External knowledge derived from counting and measuring is assumed to be the basis of all knowledge. The logic of this conceptual system is dichotomous (either-or), like the basis of computer technology and other technological processes that are repeatable and reproducible. In consequence, identity and self-worth tend to be based on external criteria, such as status symbols.

In the Asian conceptual system, the ontology of a cosmic unity, as taught in Buddhism, Taoism, Shintoism, and Hinduism, is of the highest value, emphasizing the cohesiveness of the group and traditionally the interplay with nature. Thus the Asian logic does not separate the body, mind, or spirit. Harmony is necessary to make the internal and external cosmos, in their interrelatedness, a balanced model of unity. In consequence identity and self-worth are based on being and an internal and external reality.

The African system emphasizes both a spiritual and a material ontology, valuing above all the interpersonal relationship between women and men. Self-knowledge is assumed to be the basis of all knowledge. One acquires knowledge through symbolic imagery and rhythm. The logic is based on co-unity, and through this process, everything in time and space is interrelated through human and spiritual networks. In consequence identity and self-worth are intrinsic.

For the sake of brevity, these views of the world indicating such tendencies may seem somewhat simplistic. Transcultural psychotherapy should try to be aware of these different processes, cosmologies, and values and their consequences.

V. APPLIED TRANSCULTURAL PSYCHOTHERAPY

According to findings by Fernando in 1996, ethnic minorities are more often diagnosed as schizophrenic, compulsorily detained under the Mental Health Act, given high doses of medication, and not referred to psychotherapy. A research survey conducted on behalf of the Royal College of Psychiatrists in 1991 and reported by Lago and Collins in 1996, showed that 85% of the 2000 respondents believed that depression was caused by life events and that psychotherapy, not antidepressants, was the most appropriate form of assistance. A study by Bebbington and colleagues of 297 randomly selected women demonstrated a significant excess of marked life events in acute cases of psychiatric disorders (50%) compared to chronic cases (16.7%) and noncases (27.9%). The effect of chronic social difficulties was even more pronounced (33.3%) than, and independent of, the effects of life events. Here psychotherapy would be helpful.

We should keep in mind that we must not be intimidated by this subject, since a good education in psychotherapy equips one with all the tools necessary and can be effectively applied here. One must simply be more eager, more neutral and tolerant, more open minded and more empathetic, and display these atti-

tudes in various ways. Patients want our help and will give us every possible assistance, if asked for, in understanding them in their cultural background. Let us use their cultural expertise by asking "What does this mean to you?" If they do not speak our language fluently, a neutral interpreter is needed and not an emotionally involved family member. If after the translating job we ask the interpreter separately for some commentaries, most of them will recognize our interest and be glad to help us. In order to broaden this point of view I will provide additional important aspects followed by short case histories, in full reported by Heise in 1998.

The term transcultural psychotherapy contains two aspects that are expressed in the prefix "trans." The monocultural aspect of illness should be transcended with regard to the diagnosis and also to the manifestation of the illness itself as a dis-ease. This kind of mental illness may arise in certain individuals as a result of the encounter of two different cultures. This fact must be taken into account in an empathetic and unprejudiced manner. A neutral attitude toward affect and culture and feigned objectivity as shown in the classic psychoanalysis with its rules of abstinence is not adequate.

In medical reports and testimonies the pathogenetic and therapeutic differences between political refugees with either acute depressive decompensation or posttraumatic stress disorders are of great importance. The task of the physician, as sometimes opposed to that of official authorities, may be challenging in the case of foreigners.

Case History 1: Pathogenetic and Therapeutic Differences between Two Kurdish Refugees with Acute Depressive Decompensation

A young Kurdish patient, accompanied by his father and older brother, was brought for examination. He suffered persistent abdominal pain and had already undergone unsuccessful surgery. The dependence on his family, who after 3 years were still awaiting political asylum, due to predominantly economic reasons, resulted in a conflict with his wish to return to his relatives in Turkey. No inpatient treatment was required for this case. The doctor treating the patient sent a letter recommending that the boy return to Turkey. The second case concerned a Kurdish female from Iraq, an accepted political refugee. Her husband, who as a physician had treated Kurdish rebels, was therefore killed by the Iraq authorities. She, due to administrative and domestic problems, had attempted to kill herself along with her little son. This case required inpatient treatment with client-centered therapy with the help of an interpreter.

The patient received support regarding her social problems, and finally gained enough self-confidence to cope alone with her difficulties. The medical role had to be determined regarding contact between the patient and the authorities for foreign citizens.

Some patients feel bewildered because of the foreign land and people, and have even more problems discussing their difficulties and emotions. Here, the use of guided affective imagery therapy according to Hanscarl Leuner, art therapy, Gestalt-therapy, or bodily oriented methods are helpful to understand, for example, depressive disorders followed by psychosomatic complaints. In addition it helps to introduce the "talking cure."

Case History 2: Guided Affective Imagery Therapy as the Turning Point in the Psychotherapy of a Russian Female with Chronic Reactive Depression

A Russian immigrant came for psychiatric help with acute suicidal thoughts and admitted to suffering from headaches and depression for 2 years. With the help of an interpreter, she was able to build up a sufficient basis of trust during client-centered psychotherapy, according to Carl Rogers, to give an account of her rape incident. She was raped by an unknown person after her arrival in Germany and had not yet summoned the courage to inform her husband of this event. As she had great difficulty in coming to terms with negative feelings or even to speak of them, the guided affective imagery therapy was invoked twice to help her express her feelings and thoughts. Only two themes (flower and mountain) were necessary to give her access to her split feelings. Of particular interest were the specific transference relation, the recalling of the situation, the confrontation with her feelings, the catharsis, and the reaction toward the symbolic image. Talking about the two images helped her to visualize her partnership conflict. After painting them she tried to speak about solutions, first in therapy and later with him.

This procedure proved effective and the patient was then able to relate the whole story to her husband. Finally, she succeeded in improving her newly found verbal abilities so that she was able to carry out a constructive discussion with her husband concerning their relationship, and also to take part with him in partner discussions. She was seen in the outpatient clinic for 8 more months. In these partner discussions her resistance to "talk" started again. The therapist introduced breathing and relaxation exercises that the

patient could manage with increasing ease. Three months later, she indicated she was ready to take up the discussions once more.

The topic "guilt" brought back the accusation of her husband that she was also guilty as she had not offered enough resistance to her rapist. It then became evident that for the Jewish family of the husband, the topic "guilt" with reference to "why didn't they kill us like the others?", played a major role in association with the persecution of the Jews in Russia.

Before this admission to the psychiatric department, the patient had already experienced three occasions when she had tried to talk about these same problems with Russian-speaking therapists without success. During the first phase of her illness, she was treated by a neurologist in Moscow in order to find the organic reasons for her symptoms. The diagnosis offered was a psycho-vegetative complaint with labile personality traits, while symptoms increased again on the way to Germany. She later consulted a Russian guest doctor (not a psychotherapist or a psychiatrist) and here misunderstandings arose in the communication between him and the doctor treating her for her psychiatric symptoms, most likely due to incorrect translation. Finally, she was treated as an outpatient by a Russian psychiatrist practicing in Germany who, on the one hand, showed a preference to administering medication and, on the other, forgot about the mutual influences of the involved cultures, and never spoke to her without her husband. Therefore, in this part of the therapy, the "trans" cultural element was disregarded. To avoid any similar retraumatizations, transcultural sensibility training should be introduced to medical and, in particular, psychotherapeutic and psychiatric education.

Problems of translation, interpreters, a mono- or bi-cultural approach, and a change in the therapeutic procedures (verbal – nonverbal) were discussed. This shows that language, ethnicity, and culture are not identical. All conscious or unconscious processes, interactions, and experiences are culture related, family related, and individual related. These can be clarified to make therapy successful.

The diversity of so-called schizophrenic manifestations is transculturally even more obvious. Therefore, diagnosis and therapy must take into account both the individual and the cultural diversity. Other cultures might even present a more adequate way to cope with psychotic experiences. In the delusion of being possessed the understanding of the patient's bio-socio-psycho-spiritual world view is paramount. This, in addition to the application of client-centered psychotherapy according to Carl

Rogers and the inspiration by transpersonal psychology, may prove more helpful in transcultural psychotherapy. An understanding of the cultural “differences” of the patient helps to build up the patient’s self-esteem.

Case History 3: A Korean Patient’s Delusion of Being Possessed

A Korean priest of a Christian sect was responsible for inflicting a patient of the same nationality with short-term exogenous psychosis by means of a syncretistic atmosphere and deprivation of sleep. This led to an attempted suicide. Mutual trust between patient and doctor was developed by therapeutic intervention according to Roger’s client-centered therapy. Further anamnestic details were obtained, particularly in connection with the dead grandmother who was a *mudang* or shaman priestess. Knowledge of the patient’s cultural background explained her reaction of feeling possessed by a bad spirit, and we, by showing a neutral respect for this particular culture, including the involved shamanism, presented the patient with a favorable prognosis for successful therapy. The conclusions resulted in a transcultural–transpersonal portrayal for diagnosis and treatment; it became obvious that there were syncretistic factors, but no real shamanistic transformation act or traditional healing process involved.

The second “trans” aspect concerns, on the one hand, the intracultural cooperation between the indigenous medical system of the immigrant and the Western medical system. On the other hand, it deals with intercultural cooperation. This may be in the form of influence or inclusion of aspects and methods from traditional medical systems together with our Western medical system. Some patients have better access to psychotherapeutic measures from other cultures. The use of foreign and archaic instruments in music therapy or therapeutic means from traditional Chinese medicine or Indian ayurvedic or Arab unani-tibb medicine may prove effective.

Case History 4: Treatment of Hallucinatory Psychosis with Complementary *qigong* Exercises

Taiji quan (T’ai Chi Ch’uan) “shadow boxing” and *qigong* (Ch’i Kung) meditative “breathing exercises” are therapeutic methods based on traditional Chinese medicine (TCM), like herbal medicine or acupuncture. There are several forms of exercises, some of which are becoming more popular in the Western sphere. At first glance only the movements bear a vague resemblance

to our established forms of gymnastic exercises, but the exercises based on TCM are, in fact, far more advanced. By means of a balanced form of movement according to the *yinyang* concept, the meridians are harmonized and the activated subtle energy *qi* also contributes to balancing the associated functional organic system. According to TCM theory, certain emotions and mental conditions are associated with specific organs, and with the help of these exercises, a psychotherapeutic effect is obtained. It was shown in a recent study by Heise in 2002, that *qigong* reduces in psychosis significantly state anxiety after each session and trait anxiety on the long term (STAI) and depression and psychoticism (SCL-90-R), increases relaxation and ability for enjoyment, helps exhaustion and achievement, and diminishes cenesthesia (case histories).

The 40-year-old patient complained of hearing voices for 4 years. The physical problems in his arms and legs and his headaches had persisted for 3 years and were induced by voices with their lips on his body. He initially tried to block out the voices by “drowning” them with beer, then gave up drinking, and since one year, had only consumed limited amounts of alcohol. The patient could for the first time be convinced of the advantage of persistent high-potency neuroleptics while undergoing day clinic therapy. Organic causes were ruled out and analgesic medication reduced. During the group therapies he demonstrated an aggressive inhibition with withdrawal tendencies on confrontation with conflicts. In addition, he took part in 5 of the above mentioned *qigong* therapy group sessions, and then a further 11 sessions on an outpatient basis following discharge. During day clinic therapy, the patient appeared to be considerably more relaxed, more lively, and more socially active with increasing clarity of mind, and experienced reduced physical pain and fewer headaches with weaker and less aggressive auditory hallucinations. It was noted on *qigong* therapy that even at the beginning he was able to rapidly develop the special “*qi*-feeling.” On discharge from the day clinic he reported that immediately after the *qigong*, the voices disappeared for an hour and the headaches became less frequent. He felt an inner calm. Up to the 6th session he admitted to changes in his condition with regard to the voices and the “headaches,” showing a slight improvement. The physical pains disappeared completely. He executed these exercises independently twice a week, and continued to do them when followed-up for research purposes 1 month and then 4 months later, as he found they helped to combat the

more aggressive voices, which now appeared about two times each week. He then received his third kind of a typical neuroleptics, and although he was unable to differentiate between these medications, he was aware that they had a certain beneficial effect on his condition, but less so than the *qigong* exercises, which he would practice whenever needed.

In order to deal with ethnocentric feeling and thinking, new solutions are required for the basic points of transcultural psychotherapy. These are not yet statistically validated, but need further investigation in this rather new field of research. Special issues are the question of value and purpose (“honor”) regarding self-responsibility and self-realization in different cultures together with its role in psychotherapy. For example, a supervisor of the same foreign culture in an analytically oriented self-experience group for social and medical professionals may help to combat hostility toward foreigners. He reduces defense mechanisms, because he has overcome these troubles himself.

Weekend seminars to discuss crisis intervention with youngsters of the same culture, using the group analytical method, may be effective in reducing violence. Thus underaged refugees may have the opportunity, during this session, to discuss, in an appropriate manner with their peers, their traumatic experiences of leaving their parents and their native culture. Different psychotherapeutic forms such as hypnotherapeutic and cognitive-behavioral therapeutic techniques may be effective, as well as ritual techniques and eye movement desensitization and reprocessing (EMDR) developed by Francine Shapiro and published in 1997, as discussed by Foa and colleagues in 2000 and Sack and co-workers in 2001.

For therapists treating in a foreign country, in their mother tongue, with deep psychological, systemic, and behavioral therapeutic elements, transference–countertransference and the risk of regression are important factors. Sociocultural circumstances influence drinking habits and drug consumption strongly and should not be disregarded in any therapy, according to Lala and Straussner in 2001.

Systemic individual and family therapy (mono- and bicultural) is resource- and solution-oriented by means of esteemed and engaged neutrality combined with respectful curiosity, as discussed by Krause in 1998. In addition to the routine service of psychotherapeutic-sensitive trained interpreters, the patient is also an expert in his culture. This induces a paradigmatic change.

Positive psychotherapy developed by Nossrat Peshchian in the 1970s is derived from the narrative el-

ements of Middle Eastern fables. This kind of therapy judges bodily feelings, senses, achievements, social contacts, and fantasy regarding future decisions. A comparison of giving life meaning in Eastern and in Western cultures is often added in this transcultural approach, similar to other humanistic psychotherapies.

All of these therapeutic methods concentrate on the way each individual interacts with his or her environment. The respective cultural background is responsible for influencing and molding the senses of perception and sensitivity of each human being. Culture is a term incorporating the material cultural relics and daily customs, everything that language makes “producible,” “approachable,” and “conceivable.” This includes specific conditionable senses of perception (particularly apparent in the Yogis and Masters of the hard *qigong*) and metaphysical experiences, speakable and unspeakable expectations, and constructed models. All of these are attitudes that are more or less “culture-bound,” without calling them a “culture-bound-syndrome.” However varied the climate and the people they originate from may be, common denominators may remain with regard to the same generation, gender, spirituality, (un-) employment, wish for a better life of one’s children, and so on.

All of these points need to be considered within the complete context of therapy—consciously or unconsciously. Certainly it would be more beneficial if this were to happen consciously and thus not uncontrolled. The rationalized, verbalized, and cognitive element has prevailed in the culture of the Western world over the past 2000 years; this is understandable when one reflects on its historical development. However, domination of this kind of thinking must not be accepted to such an overwhelming extent. Therapeutically, it is significant to attempt to discover the other elements in oneself, which one has either never or rarely recognized before, or which have not had the chance to develop properly. A feeling of amazement or astonishment must be produced, which leads to a realigning of the thoughts by thinking twice. This change of “sense(s)” cannot only be achieved by verbal tactics but also by other therapeutic techniques. This change of the senses may give another sense and meaning to living. This initiates a healing process that materializes into the human system and its culturally influenced relationships toward fellow humans and the cosmos, as a whole, in an intrapersonal, interpersonal, and transpersonal way. The therapist is the catalyst of this process, acting as a mediator to promote the self-curing efficacies of the patient.

It is interesting to note what effect this has on therapists, regarding their personal and professional development in relation to their feeling toward their own native culture, when one is constantly identifying with the patients and their foreign cultures, having to distance themselves in the next moment to assume the role of the catalyst once more.

VI. SUMMARY AND OUTLOOK

Many countries are faced with an increase in multi-culturally based problems for which not only political but also specific psychotherapeutic solutions must be sought. On the basis of a bio-socio-psycho-spiritual view of humanity, there are two main tasks for “transcultural psychiatry and psychotherapy.”

1. Adequate care that is suitably based on the individual and cultural background of mentally disturbed immigrants, along with their family and other close relations, is of prime importance. This should include a necessary and learnable sensitization of the therapist to cultural diversity, complemented by the use of professional interpreters when necessary.

2. With disregard for Americo- and Eurocentrism and school disputes, the vast area of transculturally comparative therapy research is concerned with offering the best forms of therapy to suit the requirements of the patients. Clarification for the culturally diverse self-understanding of mental illnesses in patients from other countries will ensue as a matter of course.

The experiences of many psychotherapeutic measures of other traditions are becoming of increasing interest in the Western world. For thousands of years these methods have demonstrated their value. These may not only be felt bodily but may be also related in language that uses subtle energetic–functional terms (not to be misinterpreted as purely symbolic). Consequently, methods taken from other cultures that influence the psyche are playing a more significant role in an increasingly globalized and multicultural society.

The future of psychotherapy will most likely be submitted to culturally reciprocal influences, which will not only affect the diagnostic criteria and the general attitude of life but also expectations regarding psychotherapy. Discussions in China have shown that Western forms of psychotherapy are gradually becoming better known and accepted; however, many Chinese emphatically be-

lieve that the use of Western methods in conjunction with their own methods and thinking will bring about some changes in Western psychotherapeutic procedures in China. In 1993, Louis Yang-ching Cheng, Fanny Cheung, and Char-Nie Chen described these mutual influences regarding practice in Hong Kong and for Chinese people in general. Sylvester Ntomchukwu Madu, Peter Baguma, and Alfred Pritz reported in 1996 the same relating to Africa. We must recognize that one culture can offer its therapeutic methods to other cultures, as discussed by Xudong in 2001 and Peseschkian in 2001. But it is up to each individual culture to decide what to accept, what to alter, and what to refuse.

GLOSSARY

personality Characteristic attitudes and behavioral reaction patterns based on temperament and experience.

resistance Unconscious defenses to psychoanalytic treatment or to the transference. Resistance is a term for defenses that are used against the treatment process or against the transference.

transference The transfer of feelings about childhood relationships onto the experience of the relationship with the analyst.

transference resistance Unconscious blocks to experiencing the development of the transference; defenses against the transference.

I. INTRODUCTION

Transference refers to feelings the patient has for the analyst. The term transference was first used by Freud

to refer to the neurotic feelings that were displaced or transferred from formative relationships in the patient's childhood. Transference is of crucial importance to psychoanalytic treatment because transference reactions help bring into consciousness the content and organization of the patient's unconscious self and object representations, and can dramatically demonstrate the effect of constituent conflicts, defenses, and compromises. Transference is the patient's experience in the present that comes closest to those formative relationships from the past.

As psychoanalysis widened its purview beyond mental symptoms to include the analysis of personality, the definition of transference was broadened to include all feelings the patient had for the psychoanalyst. This broadened definition included emotional reactions in the here and now that are basic to personality function.

II. HISTORY

The term transference was first used by Sigmund Freud, who discovered the phenomena in the course of his earliest treatments. He at first felt these transference reactions prevented easy and thorough reports of the emotional associations to symptoms connected to the patient's history. Seen perhaps most clearly in fears about a judgmental attitude in the analyst, Freud thought such transference anxieties could block the treatment by inhibiting a full report of symptoms and

associations. Therefore Freud at first felt that transferences were resistances to the treatment and were to be confronted by the psychoanalyst and consciously overridden by the patient. Later, Freud realized that these transference resistances were unconscious and were characteristic of the patient's personality defenses and adaptations. They displayed important aspects of the patient's symptoms. Freud further realized that the transference resistances often encoded and expressed the same themes as the patient's illness.

III. FUNCTION

Freud therefore began to focus on the transference and discovered that as the transference was allowed to intensify, the pathological attitudes and conflicts central to personality defenses rose to conscious intensity. This emotional intensity gave an experience of emotional validity to the treatment that was invaluable. Patients could see the emotional truth in their conflicts and compromise formations. Freud saw there was often little else that encoded so directly, so consistently, and so intensely these basic personality conflicts and compromise adaptations. When these compromise formations are part of personality attitude, the transference and personality disorder coincide. Analysis therefore more and more focused on transference, which became a hallmark of psychoanalytic treatment.

IV. TYPES

The emotional content of transference material may vary. The dominant theme of the content of the emotional transference is then used as a label to categorize different types of transference reactions.

The maternal transference involves the emotional experience of the analyst as a mothering figure. Conflicts about dependency needs and frustration, usually mobilizing intense conflicts between aggression and tender care, comprise the typical conflicts of this type of transference. Often associated with the personality features of the primary mothering figure, together with the child's reaction to the maternal personality, the two combine to form the projections onto the analyst, and the reactions to these projections, that form the maternal transference.

There is a similar transference possible to issues of authority and competition, often with fears of punishment. This type of material may be associated with the patient's early experiences of the father's personality. They condense together with the patient's personality

reactions and the inevitable conflicts of growth and development. Together these form the projections onto the analyst, and the reactions to those projections, that are classically labeled the paternal transference.

Of course, sibling transferences (typically of competition and aggression), grandparent transferences (typically of tender care and an absence of competition), as well as transferences from other important figures during the patient's formative years are not only possible but probable.

Transferences may also be categorized according to the dominant emotional reaction. Erotic transferences involve sexual content irrespective of the formative figure involved. Aggressive transferences involve the emotional experience of anger. Idealizing transferences involve the projection of perfection. Denigrating transferences are the projection of feelings of devaluation.

Combinations of transferences are more the rule than the exception. The particular combinations are not just mixtures but highly specific condensations that reveal basic emotional compromise formations achieved in an attempt at emotional adaptation to constituent conflicts.

Because of these strong basic emotions and their combinations, containing the transference reaction both to the treatment setting and to the capacity of the patient to experience and describe rather than enact, the analyst must take great care in both the nurturing and containing of these reactions. The method of nurturing involves interpretation of resistances to the transference and the method of containing involves interpretation of the effects of the transference intensities. This is basic to psychoanalytic technique.

One of the most intense, most difficult to manage, and potentially destructive forms of transference and transference neurosis is the negative therapeutic reaction. In this form of transference, intense negative feelings are focused either on the analyst, the patient, or both as a result of the psychoanalytic treatment. Paradoxically, the reaction happens when things seem to be going well in the treatment. The negative therapeutic reaction is a reaction to accurate interpretation by the analyst, which then triggers an intense aggressive and guilt response. The danger is that the treatment may break off before the opportunity to thoroughly analyze the triggering factors, the constituents, and the destructive compromises inherent in the negative therapeutic reaction. The destructive nature of this reaction is often operating unconsciously at a lesser intensity throughout the patient's life and experience of themselves. It is one reason for life stalemate, life failure, chronic unhappiness, and self-destructive behavior.

V. TRANSFERENCE NEUROSIS

The focus on transference manifestations led Freud to the discovery of the transference neurosis. In the transference neurosis, the entire range of the patient's personality and neurosis is displayed in the psychoanalytic treatment relationship, and focused on the analyst and the treatment. This intense emotional involvement of the patient with the analyst and with the analytic treatment can reveal in great detail the emotional conflict elements and their psychopathological compromises. The analysis of the transference neurosis may take up the better part of the middle phase of psychoanalytic treatment.

Crucial to the use of the transference neurosis is the ability to catalyze its engagement, to manage its intensity, to analyze and interpret its meaning, to progressively unfold its developmental layers, and to show its relevance to the patient's symptoms and personality dysfunctions. It is for this reason especially that psychoanalytic training is long, arduous, and involves personal analysis for the practitioner.

Because transference is such a direct and felt experience, psychoanalytic technique attempts to bring it to an optimal level of intensity. This is why patients in analysis are seen many times per week and use the couch. Frequent sessions allow the intensity to build. Use of the couch helps because normal social interaction may dilute transference emotional reactions with reality representations or with reality experiences. Placing the patient out of sight of the analyst and reducing social interaction can increase the intensity, and therefore the consciousness of the transference.

Transference occurs as a part of all relationships but is not necessarily as consistently intense, nor verbalized, nor are its antecedents studied in an attempt to change. The transference neurosis can emerge in psychoanalytic treatment because the analyst is skilled at managing intensity. The analytic setting provides a safe setting because of the dependability, confidentiality, and lack of any agenda in the analyst other than the care of the patient.

VI. PHASES OF TRANSFERENCE

The different phases of psychoanalytic treatment can be defined in relationship to the transference. In the first phase, the transference is beginning to be catalyzed and engaged through the analysis of resistances to the transference. In the middle phase the transference neurosis forms, intensifies, progresses, and is ana-

lyzed. During the middle phase a deeper understanding of the transference and its origin occurs. During this phase, the insights from the analysis of the transference neurosis are applied to the patient's problems and pathological personality adaptations and these applications are worked through. The termination phase of analysis is the phase of resolution of the transference neurosis. During this phase, because of gains made in the analysis that resulted in psychological change, the neurotic transference reaches a kind of emotional conclusion. It then becomes less intense and disengages from the reality person of the analyst.

VII. USE IN PSYCHOTHERAPY

Transference is also triggered and used in psychodynamic psychotherapy. Although the focus may not be consistently on this level of the work with the patient, emotional reactions in and to treatment are used by the therapist to understand patients' reactions to people and problems that are the focus of treatment. The transference is thus a textbook of the patient's personality reactions to be read carefully by the analyst and analyzed thoroughly in psychoanalysis. Although not necessarily analyzed so thoroughly with the patient in psychodynamic psychotherapy, the transference is as crucial to the treating psychotherapist as it is to the psychoanalyst. The problem may be that because the psychotherapy is less intense, the exact nature of the transference is unclear. However, even in less intense or briefer treatments, the transference may be strong enough to reveal itself at least partially. Even this is useful to the treating analyst, who applies the information to understanding the patient's problems even if the transference is not usually the primary focus of psychodynamic psychotherapy.

VIII. APPLICATIONS OF TRANSFERENCE

Transference is important in all medical treatment. Emotional reactions may help or impede any form of helping relationship. In medical treatments, the most common cause of noncompliance to medication is an emotional problem in the doctor-patient relationship. In psychopharmacology treatments, patients may resist their medication because of emotional relationships they have either with the treating doctor or with the medication itself. The sophisticated psychopharmacologist understands these transference reactions and interprets especially the patient's attitudes toward medication.

Psychopharmacologists psychologically sophisticated in this way achieve better compliance with medication regimens and therefore better outcomes. Likewise, the sophisticated cognitive-behavioral therapist is attuned to even nascent transference reactions to the treatment or to themselves. This is especially so where either the reactions are negative resistances to the treatment or where the reactions are so idealizing that they imply the power of change is in the therapist rather than in the patient. Cognitive-behavioral therapists are adept at either sidestepping such transferences or including the attitudes as targets for their treatment. Their treatment aims at giving patients more conscious control over aspects of these attitudes that interfere with their treatment and support their symptoms.

The role of transference in all medical care is so powerful because illness tends to trigger emotional regression in patients, as does the setting of care in which trust and hope are to be vested in someone else, a dependency situation most like early childhood. Because of its application to medical care, to teaching, to social services, and even to institutions, the concept of transference is perhaps Freud's widest contribution.

IX. SUMMARY

All schools of psychoanalysis make use of transference. Ego psychology uses it to understand mental structure, its constituent conflicts, and compromises. Object relation theorists use it to understand the contents and functions of object relations. Self psychologists use it to understand the state of empathic attunement. Transference is basic to psychoanalysis.

GLOSSARY

compromise formation Any mental phenomenon that is the product of internal conflict and expresses all components of the conflict.

conflict Opposition between mental forces. These forces can be instinctual or Freud's structures of the mind (id, ego, superego).

countertransference The analyst's feelings toward the patient. Some restrict the term to the analyst's emotional responses to the patient's transference.

defense The methods used by the ego to master and control id impulses or superego injunctions.

ego The hypothetical construct defined in Freud's structural model to enable the mind to organize its various components and to adapt to the external world.

libido The hypothetical psychic energy attached to the sexual instincts.

psychic energy Freud believed there was a quantifiable mental energy, similar to physical energy, that fueled the activity of the mind. Two major types of psychic energy were postulated—sexual energy (libido) and aggressive energy.

repression The particular defense mechanism of the ego by which a conflictual mental content or process is rendered unconscious.

resistance The manifestation of defense within the treatment process whereby the patient opposes the analyst's interventions.

structural model Freud's final model of the mind introduced in 1923 in *The Ego and the Id*. The mind was conceived of having three structures (the id, ego, and superego). Interaction between these three structures is thought to account for all mentally mediated behavior.

topographic Freud's earlier model of the mind in which its systems were defined in terms of their accessibility to consciousness. Despite the topographic model having to be discarded because of its theoretical inconsistencies and clinical failings the term *topographic* remains useful for describing mental contents and functions in regard to their degree of consciousness.

transference The process by which the patient displaces onto the therapist or analyst feelings, impulses, attitudes, or defense derived from important interactions in the past.

The phenomenon of transference neurosis is arguably the most important (and perhaps most controversial) concept in the psychoanalytic theory of technique. For almost 50 years its presence or absence has been used to determine whether a psychoanalytic treatment process is, in effect, true psychoanalysis or whether it is psychoanalytic psychotherapy. Merton Gill, in 1954, was one of the earliest psychoanalysts to differentiate psychoanalysis from psychotherapy based on whether or not the patient had developed a regressive transference neurosis in the treatment that could be resolved by interpretation. Leo

Stone, another prominent analyst of that era, concurred with Gill. But by the time of Gill's death, Gill, himself, as well as others had repudiated both his definition of transference neurosis and its centrality to the analytic process.

I. FREUD'S CONCEPT OF TRANSFERENCE

Understanding this reversal and arriving at an adequate modern-day understanding of both the concept and its role require that one study its origins in Freud's thinking. As with most of Freud's other technical concepts, the term transference neurosis predates the introduction of his structural model. Hence the concept was never reformulated or adequately integrated into Freud's new manner of thinking, leading to inconsistencies and ambiguities that continued to affect how the concept is used today. Freud first introduced the concept of transference in *Studies in Hysteria* when he discussed the "false connection" between feelings arising outside the treatment situation and those directed toward the therapist. That is, he recognized that feelings and thoughts originally experienced in regard to significant figures in the patient's life, usually from childhood, were displaced onto the analyst. Soon transference was viewed as a displacement of libidinal ties into the treatment situation.

In his *Introductory Lectures*, Freud introduced the concept of transference neurosis as a diagnostic category that included both hysterical and obsessional neuroses. Such transference neuroses were thought to be the most amenable to a successful psychoanalytic treatment because patients suffering from them were able to form a relationship with the analyst and to be influenced by their transference to the treater. Patients suffering from transference neuroses were differentiated from those suffering from narcissistic neuroses (paranoids, melancholics, and schizophrenics). Freud thought that the latter group had no capacity for a transference relationship with the therapist and, therefore, was incapable of being helped by psychoanalytic treatment.

Earlier in his thinking Freud had first understood transference as a resistance to the remembering of the past. At that stage in the evolution of his theory and technique, such resistance was quite important given that psychoanalytic cure was thought to occur when the patient was made aware of previously unconscious mental contents, usually sexual fantasies from the past. By 1912, however, Freud raised the analysis of transference to the forefront of analytic technique. He described the transference neurosis as the replacement of

the patient's clinical neurosis with an artificial neurosis "through which the patient could then be cured through the therapeutic work" in his 1914 paper, *Remembering, Repeating, and Working Through*.

The transference neurosis was described as the creation of an intermediate region between illness and real life. This newly created condition was said to contain all of the conflicts or elements of the clinical neurosis, making them amenable to therapeutic intervention. In essence, Freud came to understand the transference neurosis as a phenomenon in which the libido shifted from the original object(s) and associated internal conflicts into the transference where it became concentrated on the analyst. The original conflicts were then experienced with emotional immediacy in the relationship with the analyst. The analyst could then analyze these conflicts in a context of intense affectivity that allowed their historical or unconscious roots to become evident. Fresh repression was avoided, and the freed up psychic energy then became available to the patient's ego.

II. GREENSON'S CONCEPT OF TRANSFERENCE NEUROSES

This understanding of the transference neurosis held sway in American psychoanalysis into the early 1970s. It was given the greatest legitimacy by Ralph Greenson, arguably the greatest clinical analyst of his era, in his tome, *The Technique and Practice of Psychoanalysis*. Greenson made it clear that he viewed the development of a transference neurosis to be a central dimension of the psychoanalytic process. He described its phenomenology as involving an increase in the intensity and duration of the patient's preoccupation with the analyst and the analytic process. This intensified interest in the analyst is usually experienced by the patient as a mixture of love and hate as well as defenses against these emotional reactions triggered by anxiety and guilt. Reactions to the analyst were described as varying. They could be intense, explosive, subtle, or chronic; such constellations of affects become omnipresent once the transference neurosis takes hold. As the patient's preoccupation intensifies, his or her symptoms and instinctual demands revolve around the analyst while simultaneously remobilizing all the old neurotic conflicts. The transference neurosis, therefore, was described by Greenson as a repetition of the patient's past neurosis.

Greenson argued that the classical psychoanalytic attitude toward the transference neurosis must be to foster its development. The analyst has to safeguard the analysis to allow the best opportunity for a transference

neurosis to develop. According to Greenson, contaminations or intrusions into the analytic space, such as the analyst's personal characteristics or values, can inhibit or limit the development of the transference neurosis. Thus, they must be avoided. He took pains to warn that the analyst's countertransference could impede the development of a transference neurosis. For example, undue warmth was thought to risk inhibiting the patient's hostile transference whereas incomplete transference interpretations could produce a treatment stalemate.

III. LEGITIMACY CONTROVERSY

By 1987, however, the phenomenon of transference neurosis was being called into question on a variety of grounds. An entire issue of the journal *Psychoanalytic Inquiry* was devoted to the question of its legitimacy—hence the title of that issue, “Transference Neurosis, Evolution or Obsolescence.” Arnold Cooper was perhaps the harshest critic of the concept among the contributors to that volume. He argued that using the occurrence of a transference neurosis to differentiate psychoanalysis from other therapies left psychoanalysis in a difficult position because of the lack of precision in both the definition and the phenomenological recognition of the transference neurosis. Highlighting the term's conceptual ambiguity, he pointed out that those analysts who argued that the transference neurosis involved a heightened emotional experience of the analyst were at odds with Freud who had emphasized that the transference neurosis should be manifested more in memory than in enactment in the analytic situation. Cooper also quoted the writings of the early British analyst, Edward Glover, who had emphasized that transference neuroses developed only with regard to certain types of patients, generally those suffering from phobic, conversion, or obsessional symptoms. Thus, Glover did not see the occurrence of a transference neurosis as a differentiating factor for a psychoanalytic process.

Cooper also criticized the notion that the transference neurosis recapitulates the infantile neurosis. He pointed out the vagueness in defining the concept of the infantile neurosis. Some use the term to refer to the hypothetical childhood neurosis that presumably predated the adult one; others use the term to indicate oedipally based conflicts, while still others define it as concrete, observable, childhood, neurotic symptoms. To the extent that this concept is used in vague or inconsistent ways, it becomes impossible to describe the transference neurosis as a reactivation of it in any coherent fashion.

The connection between the concept of the transference neurosis and the infantile neurosis has also led to debate about the degree to which the transference neurosis is a regressive phenomenon. By the mid 1970s, some analysts, most notably Jacob Arlow, had argued that it was a fallacy to consider the analytic process and the activation of a transference neurosis as regressive. Rather than promoting regression, Arlow argued that the analytic situation created a context in which regressive aspects of the patient's mind could emerge in a clearly observable fashion. Merton Gill extended this view while pointing out that the transference neurosis did not involve the revival of the infantile neurosis. He challenged the entire thesis that an earlier developmental state could literally be reactivated. Rather, he believed that earlier developmental experiences that exert an active influence on present-day behavior did so because they remained active in the patient's personality. As such, he argued that such active influences would be manifested in patients' transferences to the analyst.

Such a position leads into another area of unclarity about the definition of transference neurosis. Traditionally, the concept of transference neurosis has been distinguished from the concept of transference. As mentioned earlier, the former concept has been used to distinguish a psychoanalytic process from a merely psychotherapeutic one in which many transferences develop. The latter are more fluctuating, less organized, and less intense than the sort of full-fledged transference neurosis described by Greenson. However by 1984, Gill was taking issue with this distinction. Thus, he argued that the reason for the more intense transference neurosis was not the difference in the type of treatment process involved. He believed, rather, that it was the analyst's failure to interpret earlier manifestations of transference in the treatment process that led to transferences intensifying to the point where they could not be ignored by the analyst. Thus, this sort of transference neurosis was thought by him to be a sign of poor technique, not of psychoanalytic process. For Gill there was no important clinical distinction between transference and transference neurosis. Instead he argued for early and consistent interpretation of the transference wherever it might be ferreted out in the patient's associations. Gill's technical strategy for transference interpretation has remained a minority view in psychoanalysis although his disinclination to distinguish transference from transference neurosis continues to be embraced by a number of psychoanalysts.

Charles Brenner is another prominent psychoanalyst who criticized the concept of transference neurosis. He argued, similarly to Gill, that there was nothing to be

gained theoretically or clinically by distinguishing transference neurosis from transference. Brenner argued that the term *transference* was sufficient, and that transference manifestations were compromise formations that needed to be analyzed in the same manner as any other compromise formation.

Despite these debates about the nature of the transference neurosis and its role in psychoanalytic technique, the concept continues to be valued by most theorists of analytic technique. Both editors of the *Psychoanalytic Inquiry* issue devoted to the topic concluded that transference neurosis remains a useful clinical concept and one that distinguishes psychoanalysis from psychotherapy. Nathaniel London was probably the most eloquent on the subject. He argued that the distinction between transference and transference neurosis is complex and significant, that the emergence of a transference neurosis does distinguish a psychoanalytic from a psychotherapeutic process, and that those analyses in which a full-fledged transference neurosis fails to emerge are more limited in their clinical results.

These conclusions leave psychoanalysts with the problem of defining the transference neurosis and accounting for successful clinical analyses in which one has not been manifested. A modern view is that the latter problem rests on the former. That is, many contemporary analysts believe that the apparent lack of a transference neurosis reflects a problematic definition rather than an actual failure to develop one. Too many psychoanalysts continue to think of a transference neurosis in the way that Freud did when he developed the concept. That is, it is defined as a displacement of childhood libidinal and aggressive wishes or fantasies from the parents onto the analyst in a particularly organized and emotionally intense fashion. But this definition arose from the topographic era of Freud's thinking when unconscious impulses were viewed as the explanation of most psychopathology and personality traits. The advent of the structural model in 1923 offered a more complex way of understanding transference (and, hence, transference neurosis). Freud, himself, never integrated his concepts of transference or transference neurosis with his structural model. Thus, many analysts continued to think of these concepts in a topographic manner without realizing it.

IV. STRUCTURAL BASIS

Anna Freud, in her 1936 volume, *The Ego and the Mechanisms of Defense*, offered a structurally based un-

derstanding of transference. She discussed three types of transference. It is her transference of defense that is most appropriate to a modern-day understanding. This type of transference involves the patient's projecting or externalizing significant aspects of his or her defensive structure into the analytic situation, particularly the relationship with the analyst. Thus, patients who are reported not to develop a full-fledged transference neurosis generally are found, with closer scrutiny, to be using a variation of transference of defense. Rather than displacing unconscious drive impulses onto the analyst, they externalize their defensive structure into the analytic situation and relationship with the analyst. In these instances, the defensive structure generally involves prominent defenses against feeling or becoming aware of strong emotions toward others. The apparent absence of a transference neurosis is, in actuality, an intense one whereby the analyst is treated with the same emotional detachment and/or fearfulness that characterize the patient's relationships with most important objects in his or her world, including internal representations of the parents. Thus, analysis of the transference neurosis with such patients involves the consistent confrontation, exploration, and interpretation of their distancing defenses and the reasons for them. Such work is generally quite productive but requires significant activity on the part of the analyst. Nonetheless, working in this fashion generally demonstrates the fallacy of assuming the absence of a transference neurosis and deepens the analytic work in the same way that analyzing the more obvious forms of transference neuroses do.

Those analysts who practice in this manner tend to agree that it is this work—the analysis of the transference neurosis—and all its complexity that allows for the important conflicts that cause the patient's symptoms or personality problems to be experienced and mastered by the patient in an emotionally vivid fashion. The intensity of feeling and firsthand quality of such work allows for conflict mastery far more than other nontransference elements of the analytic process. Although not scientifically demonstrated, such work does not happen in psychotherapy because the reduced frequency of sessions prevents the emergence of the sort of transference neurosis just described, although certainly transference manifestations do occur and can be worked with in a fashion that is therapeutically useful.

V. SUMMARY

In summary, the concept of transference neurosis continues to be a valuable one in psychoanalysis. It

distinguishes psychoanalysis from other forms of psychotherapy, even psychoanalytic psychotherapy. Analysis of the transference neurosis remains a crucial aspect of the analytic process, one that many continue to view as the most important in promoting mastery of conflict. Thinking in terms of the transference neurosis serves as a useful guideline for the practicing analyst. After a certain point in analysis, most analysts begin to look for the emergence of one and to attempt to understand when one is not apparent. Utilizing a contemporary structural approach to analysis allows psychoanalysts in the latter situation to more carefully observe and listen to the patient's material for evidence of the defensive aspects against deeper feelings toward the analyst, defenses that the analyst brings to the patient's awareness to analyze the reasons that the patient feels it necessary to keep the analyst at such emotional distance.

GLOSSARY

illusion A belief or experience that is based on unconscious material and is experienced as real.

objective External reality, that which is outside the individual and separate from the individual.

subjective Unconscious material such as drives, impulses, wishes, and fears that is particular to the individual and cannot be objectively defined.

transitional object An object, typically a soft toy, chosen by an infant or child. Irreplaceable, the object is imbued with the child's feelings for and experience of his or her primary caretaker. The child uses the transitional object to aid the transition from primary dependence to independence.

transitional phenomena Individual experiences characterized by the interplay of unconscious material and objective reality in forming a novel emotional experience or state.

It is not unusual for parents or caretakers to intuitively allow children the use of some kind of object, oftentimes soft and furry, less frequently hard and with

rough edges, that becomes a special kind of beloved possession of the child. Blankets, teddies, things that easily mold to the flesh, that keep a telltale smell, that survive the transition from toddlerhood into latency, ideally serve such a purpose. It is little short of miraculous how adults recognize the life-sustaining urgency of the need for the child to cling to these possessions. Such objects are often named “momma” or some such appellation that implies an understanding that the object is a stand-in for the mother, providing similar soothing and comforting, and herein lies a key paradox of childhood—the child's ability to separate from the mother begins in holding firmly to her, or at least a rendition of her. Thus, the necessary separation from primary caretaker takes place with the assistance of some symbolic object (the transitional object) that provides the continuity of closeness to the primary caretaker.

I. D. W. WINNICOTT

This paradox—that separation can come to exist only in the context of a symbolic continuity—is the sort of recognition D. W. Winnicott set about to explore in his career. A British pediatrician turned psychoanalyst, Winnicott saw thousands of infants and mothers in London during the World War II years, while developing a remarkable oeuvre that remains influential to this day. Never a systematic thinker, his uncoordinated insights into mother–child relations, the inner life of

infants and children, the relations between aggression, security, and creativity—remain the stuff to which many contemporary investigators turn for inspiration and guidance. In this article, the reader will recognize a certain allusive and poetic use of language. This is more Winnicott's than our style, for in order to grasp and communicate what Winnicott was trying to convey, one must remain true to his style of discourse.

II. TRANSITIONAL OBJECTS

In 1951, Winnicott published his classic paper "Transitional Objects and Transitional Phenomena," which investigated the relationship between symbol formation, maternal caregiving, and the development of creativity and, in fact, the mind itself. To Winnicott, the main function of a transitional object is to "start each human being off with what will always be important for them: a neutral area of experience which will not be challenged."

Winnicott provides sufficient material for a thorough understanding of transitional objects and transitional phenomena in his first paper on the topic. He presented these concepts with rich examples from infant observation and analytic work with adults. The topic appears in later articles but is only minimally refined or elaborated there. In the 1951 paper, Winnicott defines transitional objects and transitional phenomena, describes the key concepts, and identifies areas of further exploration, which have been taken up by theorists such as Paulina Kernberg, Arnold Modell, and Peter Giovacchini.

III. WINNICOTT AS THEORETICIAN

It is helpful here to say a bit about Winnicott the theoretician. Strictly speaking, Winnicott was less of a theoretician than he was a pragmatic yet intuitively driven observer. A member of the so-called middle school, his theoretical roots are both Freudian as well as Kleinian, especially in his uncanny understanding of the role of aggression in early mental life. His writings have contributed many fundamental concepts to the body of psychoanalytic thought (for example the good-enough mother, primary maternal preoccupation, the capacity for concern, and hate in the countertransference) which are not so much particular to a comprehensive theory as they are critical to what we might call the experience of being. Fogel explicates this in an article titled "Winnicott's Antitheory" wherein he explains that

Winnicott was traditionally analytic in his theoretical beliefs but obviously singular and unique in terms of his distinctive application and elucidation of the concepts that stand alongside traditional theory. Transitional phenomena and objects are good examples of this. Truly grasping what Winnicott meant is crucial in order to undertake clinical work with children or psychoanalytic work with adults yet this knowledge does not necessarily alter in any way one's theoretical foundation. Thus, it is a challenge to fully describe Winnicott's concepts of transitional objects and transitional phenomena. On the one hand, understanding what he was trying to convey makes available an intellectual and, Winnicott would hope, experiential knowledge of self and other that deepens our contact with others. On the other hand, one will not find any particular alteration to one's structural understanding of the individual or technical view of the practice of psychotherapy on the basis of the knowledge.

IV. TRANSITIONAL OBJECTS

A transitional object is an object that is chosen, or, to be more explicit, Winnicott says "created," by the infant and that stands for the breast or object (bottle, caregiver's face) of the first relationship. It is developmentally appropriate, indeed a positive indicator of a healthy maternal-child bond, typically develops first between 6 and 9 months, and lasts often into the preschool years. It is the child's first possession and original "not-me" object. By this, Winnicott means that the child is sufficiently developed to have a growing sense of object permanence and constancy (see Piaget for discussion of object permanence.) Thus, the child is able to conceive of the transitional object's separateness from himself. Object use begins with an infant's use of fist-in-mouth, then thumb, then some mixture of fingers and thumb, and finally the infant moves to the use of an object. There is a gradual progression toward the use of objects that are part of neither the mother nor the infant but represent the shared experiences of both.

Certain features mark the relationship between the transitional object and infant. Perhaps most remarkable is the infant's assumption of possession of the object and the environmental cooperation with that. Caregivers hesitate to wash well-loved transitional objects and households are collectively turned inside out when a transitional object goes missing. The transitional object is "affectionately cuddled" and "excitedly loved

and mutilated.” The transitional object possesses a reality and vitality of its own. It is cocreated by the infant’s objective perception of the object and his or her subjective projections of relating (in this case, loving and being loved) onto the object.

Winnicott talks of the “fate” of the transitional object in further defining it as well as further illustrating the depth and a particularly unique feature of his theory. Winnicott proposes a “third area” of “existing” or human life, which is where transitional phenomena grow and live. For the purposes of this article, they shall be called the first and second areas, as Winnicott did not name them. The first area is the fundamental reality of individual experience. It is the inner life, intrapsychic world, or “personal psychic world” in Winnicott’s words. Here we find the genesis of dreams, hallucinations, and the creative process. The first area of existence is our store of preferences, idiosyncrasies, and “neuroses.” The second area is the external world of the individual composed of our relations with others, standards of conscience, and the various roles we fulfill (husband, wife, worker, friend, parent, sibling). Winnicott calls this the “expanding universe which man contracts out of.”

Transitional phenomena illustrate the joining of the first and second areas of consciousness, which Winnicott calls the “cultural life of the individual.” This third area is the meeting of the objective–subjective, personal–political, internal–external realms of individual experience. Using the example of the teddy bear as transitional object, we see that the teddy is an external object (second area) real to the infant and his extended external reality (parents, siblings, etc.). Yet, the teddy also represents the material of the infant’s inner life (first area) to the extent that the teddy is a cuddling, nurturing, soothing, nonretaliatory object of his or her aggression, and a constant reliable feature of his or her existence. The infant has made the teddy with the imbuing of these unconscious features while also, for the first time, using an object outside himself to serve as a receptacle for internalized experiences. It is useful to note here Winnicott’s famous phrase that “there is no such thing as a baby.” Winnicott’s view of infant and mother are as a union, the “nursing couple” and, according to the infant’s perceptions, the mother does not exist without him or her; indeed, mother exists because of him or her. With the development of transitional objects, and by implication, the ability to live in the third area, the infant is demonstrating his or her ability to perceive the external world as separate while simultaneously giving away his or her reliance on the unconscious/first area. The use of transitional objects

demonstrates the emergence of the baby as separate from his or her primary caretaker.

The transitional object sits in the middle of the continuum between the subjective and objective. It is slowly moved more and more toward the objective as the child grasps reality, develops reality testing, and is confronted with the inevitable frustrations of external reality. Thus, the fate of the transitional object is to “fade away” but never leave. The object loses its importance in the maintenance of and elaboration of unconscious material; other mechanisms such as play, language, and interpersonal interactions serve this function. But, Winnicott argues, we see the vestiges of transitional objects and the vibrancy of transitional phenomena in the human activities of art and the appreciation of creativity and religion.

Winnicott is especially concerned with the ability to symbolize that the use of transitional objects implies. Symbolization implies a broader human activity, interesting to Winnicott, which is the use of illusion. The transitional object simultaneously serves the infant’s unconscious life of merger and union and external life of independence and self-reliance.

Here we arrive at another particular element of Winnicott’s thought and the aspect of the theory of transitional phenomena that continues to be the focus of theorists and practitioners today.

From birth and thereafter the human being is concerned with the problem of the relationship between what is objectively perceived and what is subjectively conceived of. . . . The intermediate area to which I am referring is the area that is allowed to the infant between primary creativity and objective perception based on reality testing. The transitional phenomena represent the early stages of the use of illusion, without which there is no meaning for the human being in the idea of relationship with an object that is perceived by others as external to that being.

V. ILLUSION

Winnicott’s exploration of the use of illusion was not without precedent at the time. Freud in 1920 had described his grandson’s ability to symbolize his own reality and existence through play when briefly separated from his mother. Muensterberger describes two theorists whose work predates Winnicott’s and is clearly in the same vein. Geza Roheim described the activity of filling one’s mind with thoughts of the people and relationships we are separated from as the “theory of an

intermediate object as stabilization between a trend that oscillates between clinging and going exploring.” The reference here to the “intermediate object” is very similar to Winnicott’s term the “intermediate area” and in fact, Roheim is clearly describing a transitional object (i.e., teddy bear) that helps the infant feel grounded enough to explore. Roheim later writes of the transitional phase “located somewhere halfway between the pure pleasure principle and the reality principle.” Again, this description is very similar to Winnicott’s description of the 1st, 2nd, and transitional areas of human experience. Here, Roheim is referring, in part, to an earlier work by Hermann, called seminal by Muensterberger, which is titled “To Cling—to go in Search.” Hermann’s view, very similar to Winnicott’s, is that the infant requires a link between his or her inner experience and emerging external experience. When the link is concretized, it is a transitional object. The link may also be imaginal (the memory of a connection with a significant other) in which case, the memory lives and is sustained in the transitional area.

VI. THE FUTURE

Winnicott’s concepts also provided the framework for generations of future papers. The most important aspect of his paper, in terms of the advancement of the field, is the explication of the transitional phenomena. Green states “It is easy to see that Winnicott has in fact described not so much an object as a space lending itself to the creation of objects.” Indeed, after his death his wife Clare described how Winnicott considered this one of his most important achievements and it is evident that transitional phenomena, this area of the experiential field is the groundwork for much of his more important work including primary maternal preoccupation, playing in reality, and the facilitating environment. Describing transitional phenomena is a bit like describing a fog—we can only present the outline of it against the land and sky, note its thinner aspects, and watch its movement and effect. The transitional phenomenon is in fact an experience and one further complicated by its straddling of the objective and subjective experiences of the experienter.

Winnicott described transitional phenomena as “an intermediate area of experience” and further stated “I am therefore studying the substance of illusion.” This is a most remarkable statement for Winnicott to have made. The use of illusion is at the heart of the transitional phenomena. Here, Winnicott draws our atten-

tion to the activity of the early infant in perceiving the breast (or substitute) as created by and for him or her by virtue of the good-enough mother’s repeated presentation of the breast at the moment the baby requires it—and early on, before the baby “knows” he or she requires. “The mother’s adaption to the infant’s needs, when good enough, gives the infant the *illusion* that there is an external reality that corresponds to the infant’s own capacity to create.” Our appreciation of and reliance on illusion is therefore with us from our earliest days. “From birth therefore the human being is concerned with the problem of the relationship between what is objectively perceived and what is subjectively conceived of.” Gradually, reality seeps into the infant’s sense of omnipotent control of the environment (still perceived as aspects of himself or herself) and the infant is confronted with the reality of the objective world. The good-enough mother allows the gradual impingement of reality, understanding the infant’s need to be disappointed and thereby develop reparative capacities. The place where the objective and subjective meet, where our experience is created by the interaction between our subjective material and objective reality remains and is exercised in our appreciation of the arts, practice of religion, and ability to symbolize our daily experience lives. Winnicott called it the “neutral area of experience which will not be challenged.” We do not argue with a person who cries during a soulful passage of a cello concerto or who believes in the sacrament of the Eucharist, nor do we argue with the poet who draws meaning from the curve of an arm. Only when an individual requires us to endorse the “objectivity of his subjective phenomena” do we “discern or diagnose madness.” It is when a delusional patient asks us to believe a plot involving the FBI and CIA is the true source of his or her pervasive sense of danger, importance, and isolation that we see the bullying imposition of subjective experience in the intermediate/transitional realm of experiencing.

The nature of illusion and the transitional phenomena are important to current theorists for two general reasons. First, theorists who use clinical data to expand theory have advanced the importance of illusion; second, clinicians use theory to understand clinical material. While current theorists are typically psychoanalytic theorists, because Winnicott’s theory is best applied to any two individuals conducting a relationship it is widely applicable. Clinically, researchers like Paulina Kernberg use the concept of transitional objects to identify her patients’ abilities and frustrations of mediating internal impulses and fantasies while managing

an overwhelming and confusing experience of the external world. Kernberg's most ill patients develop no transitional object use or maintain a transitional object that is cruel, rejecting, and a poor receptacle for feelings of love, hope, and forgiveness. Kernberg uses the theory of transitional objects to further clarify her patients' functioning. Peter Giovachinni in 1987 explicates the use of transitional objects and of transitional phenomena in adult borderline states from a broad clinical, phenomenological perspective. He expands the theory of the transitional object in his consideration of the borderline patient's inability to regulate affect states and adaptively use projection, thereby making impossible the use of a transitional object. Arnold Modell in 1962 detailed the idea that the adult borderline patient lives in an inner world devoid of transitional phenomena, starkly reality bound, with all the attendant harshness and abrasions of the unmitigated reality of life. In all applications, the theory of transitional objects and transitional phenomena is useful in understanding the intra- and interpersonal functioning of an individual.

Theoretically, Green tells us that Winnicott's place is in guiding any analytic work that does not strictly adhere to the tenets of classical analysis. Green states "It seems to me that the only acceptable variations of classical analysis are those whose aim is to facilitate the creation of optimal condition for symbolization." Symbolization is a transitional phenomenon. It is Winnicott's explicit assumption that reality acceptance is a never-ending task and that the intermediate area of experience, illusion, or transitional phenomena (all different names for the same, unchallenged experience) provide relief from the ongoing tension of relating internal and external reality. This experience is what many good therapists attempt to create and sustain for their patients. More precisely, therapists and patients work to cocreate this experience. The intermediate realm of experience is activated in what Winnicott termed "the holding environment," is present in unconditional positive regard, and whatever the orientation, facilitates the therapist's ability to understand his or her patient in a meaningful and intimate, beyond-language way.

Winnicott left a legacy of literature that remains vital, challenging, and inspiring. Moreover, he left detailed insights about what it means to be human, to love, to mourn, to long for, and to hope. His concept of the transitional object is one of his better known contributions. Perhaps teddy bears and blankies appeal to all of us, regardless of age. It would be a underestimation of Winnicott's contribution to characterize his

thoughts on transitional phenomena as primarily about soft cuddly toys. He described a realm of experience, never before or since captured with such elegance, wherein we have the capacity to be moved by art, find solace in religion, and use illusion in various ways to adapt and meaningfully mediate one's constant grappling with reality.

In this article, the theory of transitional objects and phenomena was presented. Additional considerations of more current applications of the theory were also presented. It is the authors' hope that the reader has been both awed and bemused by Winnicott.

GLOSSARY

exposure therapy A well-established behavioral treatment for anxiety disorders, it involves exposing individuals to feared thoughts, images, or other stimuli repeatedly and for prolonged periods in the absence of any actual threat until anxiety is reduced via habituation.

habituation A progressive decrease in the vigor of autonomic responses or behavior that may occur with repeated presentations of the eliciting stimulus.

posttraumatic stress disorder An anxiety disorder that may follow traumatic experiences (e.g., combat, physical and sexual assault), which is characterized by symptoms of re-experiencing the trauma (e.g., nightmares, “flashbacks”), emotional numbing and avoidance, and arousal (e.g., insomnia, hypervigilance, anger).

Trauma Management Therapy is a multicomponent behavioral treatment program for chronic combat-related posttraumatic stress disorder (PTSD). It is a comprehensive treatment designed to address all aspects of the clinical syndrome seen in veterans, via a combina-

I. DESCRIPTION OF TREATMENT

Trauma Management Therapy (TMT) is a multicomponent behavioral treatment program for chronic PTSD in veterans. It is a comprehensive treatment designed specifically to target various aspects of the clinical syndrome associated with chronic PTSD, particularly reducing emotional and physiological reactivity to traumatic cues, reducing intrusive symptoms and avoidance behavior, improving interpersonal skills and emotion modulation (e.g., anger control), and increasing the range of enjoyable social activities. The program is designed to incorporate exposure therapy, the PTSD psychosocial treatment approach with the most empirical support, with a social skills training component designed specifically for veterans with PTSD. It is a comprehensive treatment designed to address all aspects of the primary clinical syndrome seen in veterans, via a combination of patient education, exposure therapy, social skills training, and relevant homework assignments. It is important to note that this treatment is not merely a combination of exposure and traditional social skills training procedures. Rather, it includes strategies designed to remedy specific difficulties seen in veterans with chronic PTSD, and the particular sequencing and timing of the individual components are

thought to contribute to its overall effectiveness. The major components of TMT are described next.

A. Education

All patients are provided with a general overview of chronic PTSD, including common patterns of expression, issues of diagnosis, comorbidity of other anxiety and Axis I disorders, etiological pathways, and a review of current treatment strategies. This phase is important for ensuring that veterans not only develop a realistic understanding about treatment prognoses, but also an overall positive expectancy regarding the efficacy of behavioral treatment. Finally, this phase is used to educate veterans about the treatment they will be receiving and what will be expected from them regarding their participation in TMT.

B. Exposure Therapy

Individually administered intensive exposure therapy is included as the first active component of TMT, because it has been shown to effectively address the unique features of each patient's fear structure, allowing for a reduction in general anxiety, physiological reactivity, and intrusive symptoms. Patients are exposed imaginatively to feared or anxiety-producing stimuli in a prolonged fashion until there is a decrease in fear and anxiety (i.e., until habituation is obtained) within session. Repeated contact with the feared stimulus hastens the habituation process and, with sufficient pairings, the stimulus loses its ability to elicit the fear response. Typically, most veterans with PTSD escape or avoid feared stimuli, which functions to increase the intensity of the fear response. The goal of exposure therapy is to provide prolonged contact with the feared stimuli of sufficient duration that within session habituation occurs. Repeated pairing across a number of days also is important and hastens the habituation process. Fourteen sessions of exposure therapy are administered early in the sequence so that veterans may experience relatively quick relief from acute symptoms of PTSD, enabling them to then concentrate on developing emotional control and improving their social functioning. All sessions are terminated following a 50% reduction in within session reactivity to the traumatic cues, with reactivity monitored physiologically (i.e., heart rate) and/or by patient ratings of subjective distress. Based on our experience with PTSD, and data on behavioral treatment of other anxiety disorders, exposure sessions usually average about 90 min in duration.

C. Programmed Practice

The programmed practice component of TMT is implemented in the final seven individual exposure sessions and is a form of exposure that does not require therapist accompaniment (i.e., it is "homework"), but requires careful planning on the part of the therapist and patient together. Examples of suitable exercises focusing on traumatic combat fears include self-directed imaginal sessions at home, which may serve as an initial step toward *in vivo* activities, such as watching movies (e.g., *Platoon* or *Hamburger Hill*), visiting war memorials or museums, speaking with other veterans or loved ones about war experiences, and visiting airfields or helicopter pads. Experiences should also be devised that require the veteran to engage in other feared activities, the avoidance of which may interfere with quality of life. Examples of suitable activities include social events, shopping, attending movies, eating in a restaurant, etc.

D. Social and Emotional Rehabilitation (SER)

A highly structured group (3–5 people) social skills training component (SER) was developed to target PTSD features that are not improved by exposure therapy only. In other words, interpersonal difficulties, commonly associated with chronic PTSD, such as social anxiety, social withdrawal, excessive anger and hostility, explosive episodes, marital and family conflict are targeted via a number of specific interventions. SER includes instruction, modeling, behavioral rehearsal, feedback, and reinforcement. Following each SER session, veterans are given homework assignments to allow further practice and consolidation of newly acquired skills. A series of symptom-specific strategies were sequenced to build on one another in a cumulative fashion and are designed to serve multiple functions. One purpose is to teach veterans the requisite skill foundation for effective and rewarding social interactions. Patients with PTSD vary widely with respect to basic social skill, but most have room for improvement. In addition to general social skill, the program is divided into four components that target specific areas of dysfunction.

1. Social Environment Awareness

Social environment awareness involves teaching the nuances of when, where, and why to initiate and terminate interpersonal interactions. Veterans are taught the

verbal and nonverbal mechanics of successful social encounters, including identification of appropriate conversation topics, attentional and listening skills, and effective topic transitions.

2. Interpersonal Skills Enhancement

Interpersonal skills enhancement is devoted to teaching how to establish and maintain friendships, appropriate telephone skills, and assertive communication. This component is designed to help patients learn those skills that are necessary to engage in new and diverse social activities to increase their social repertoires and the likelihood that social interactions will become intrinsically rewarding.

3. Anger Management

Anger Management involves teaching veterans how to better manage anger and other intense emotions. It is designed to reduce temper outbursts and the problematic expression of anger. This component is designed to give patients a range of strategies for expressing their anger, problem solving, improving their emotional modulation, communicating assertively with others, so that verbal and physical violence do not continue to disrupt their relationships with others.

4. Veteran's Issues Management

Veteran's Issues Management teaches how to improve communication regarding combat trauma and military issues with nonveterans, to increase the understanding of significant others. In addition, veterans are also taught to identify and challenge negative and dichotomous thinking patterns, which limit their quality of life by reducing their involvement with others.

E. Treatment Implementation

TMT consists of 29 treatment sessions ideally administered over a period of about 17 weeks. Sessions initially occur three times a week through the Exposure phase, then twice a week at the start of SER, and then once a week for the final 10 weeks of the program (see Table 1).

II. THEORETICAL BASES

A. The Clinical Syndrome

In 1980 the American Psychiatric Association's *Diagnostic and Statistical Manual (DSM)* formally defined

TABLE 1
TMT Session Overview

Week	Session	Format	Treatment component
1	1	Individual	Education
1	2-3	Individual	Exposure
2	4-6	Individual	Exposure
3	7-9	Individual	Exposure + Prog. Practice
4	10-12	Individual	Exposure + Prog. Practice
5	13-15	Individual	Exposure + Prog. Practice
6	16-17	Group	SER: Social Environment Awareness
7	18-19	Group	SER: Interpersonal Skills
8	20	Group	SER: Interpersonal Skills
9	21	Group	SER: Interpersonal Skills
10	22	Group	SER: Interpersonal Skills
11	23	Group	SER: Anger Management
12	24	Group	SER: Anger Management
13	25	Group	SER: Anger Management
14	26	Group	SER: Anger Management
15	27	Group	SER: Veterans' Issues Management
16	28	Group	SER: Veterans' Issues Management
17	29	Group	SER: Veterans' Issues Management

and recognized the cluster of acute symptoms often seen in victims of traumatic events (e.g., combat, sexual and physical assault), naming this condition post-traumatic stress disorder (PTSD). It is defined by six basic criteria: (1) the historical antecedent of a traumatic event that involves both actual or threatened death or serious injury, and an intense response of fear, helplessness, or horror; (2) persistently reexperiencing the traumatic event through intrusive memories, dissociative flashbacks, recurrent distressing dreams, and/or psychological or physiological reactivity on exposure to associated cues; (3) the avoidance of stimuli associated with the event, or a numbing of general responsiveness, including efforts to avoid thoughts and feelings related to the trauma, efforts to avoid activities or situations that arouse recollections of the trauma, loss of interest in significant activities, social detachment, and/or reduced affect; (4) the existence of persistent symptoms of increased arousal such as hypervigilance, sleep disturbance, irritability or outbursts of anger, impaired concentration, and/or exaggerated startle response; (5) duration of the disturbance for at least 1 month; and (6) the pervasive effects of the disturbance causing clinically significant

distress or impairment in social, occupational, or other important areas of functioning.

Posttraumatic Stress Disorder is frequently chronic, and many combat veterans still suffer severe symptoms from wars fought 30 (Vietnam) or 50 (WWII) years ago. Epidemiological estimates of PTSD put the current prevalence at as high as 15% and lifetime prevalence as high as 31% for veterans exposed to war zone trauma. Given that over 3 million American soldiers served in the Vietnam war alone, and many more have served in other foreign conflicts, the potential number of veterans currently with PTSD is well above the half-million mark.

Complicating the syndrome is the fact that PTSD is typically accompanied by multiple co-occurring mental disorders, including substance abuse (73–84%), major depression (26–68%), psychotic symptoms (15–40%), and panic attacks (21–34%), among others. Furthermore, chronic PTSD is also associated with a diverse set of symptoms associated with social maladjustment, poor quality of life, sleep disturbance, medical illnesses, and general symptom severity. This includes social avoidance, memory disruption, guilt, anger, social phobia, suicide attempts, and other debilitating behavioral features, such as unemployment, impulsive or violent behavior, and family discord. In fact, it is notable that a majority (69%) of veterans seeking treatment for PTSD within VA specialty clinics seek disability payments for the debilitating occupational impairment they experience. It recently has been documented that the costs associated with PTSD are extremely high and make PTSD one of the costliest mental disorders to society.

Although PTSD symptoms currently are grouped into three primary clusters, symptoms of reexperiencing (nightmares, intrusive memories, “flashbacks”) and associated physiological reactivity, are what best distinguish PTSD from other affective or anxiety disorders. Supporting the prominence of autonomic symptoms are data from studies examining physiological responding in people with PTSD. Most notable is the finding of heightened reactivity. In these studies, combat veterans with PTSD have significantly larger blood pressure and heart rate responses during fear-relevant cue exposure than do combat veterans without PTSD.

B. Rationale for Exposure Therapy

Exposure therapy is a well-established behavioral treatment for a wide range of anxiety disorders (e.g., phobias, obsessive-compulsive disorder), which involves exposing individuals to feared thoughts, images, or other stimuli repeatedly and for prolonged periods of

time. The rationale for this treatment is based on two-factor theory. As applied to the condition of PTSD, first, stimuli (e.g., combat images or sounds) that were once paired with actual danger and horror in combat now elicit a similar autonomic response (e.g., increased heart rate) and fear. Second, as a result of this fear response, those with PTSD tend to avoid or escape from such stimuli as much as possible. Thus, habituation to the stimuli never occurs, and the maladaptive condition is maintained. Exposure therapy involves exposing individuals to feared stimuli (e.g., combat images or sounds) repeatedly and for prolonged periods in the absence of any actual threat until habituation allows for a progressive decrease in the vigor of autonomic responses (e.g., heart rate). Therefore, anxiety and fear are reduced via habituation. In the case of individuals with PTSD, such exposure is usually accomplished, at least initially, via imaginal procedures, and is often then complimented later by *in vivo*, or “live,” exposure experiences.

III. EMPIRICAL STUDIES

A. Treatment of PTSD

There are surprisingly few data available regarding treatment outcome for veterans or civilians with PTSD. To date only a relatively small number of randomized clinical trials of pharmacological and psychotherapeutic treatments have been published. Although a range of psychotherapeutic strategies for chronic PTSD have been suggested, cognitive-behavioral treatments, usually emphasizing various methods of exposure therapy, have been the most carefully studied and show the most promise.

1. Exposure Therapy for PTSD

Among civilians with PTSD, exposure has been found to be efficacious in a number of randomized, controlled trials. Exposure therapy has been found to be superior to stress inoculation training, progressive relaxation, supportive counseling, and wait-list control groups; and it is equally effective as cognitive therapy.

Among veteran samples, intensive exposure has proven partially efficacious for chronic PTSD, although the data are not as strong as for civilians. In an early trial, exposure therapy was compared to a wait-list control group using Vietnam veterans ($N = 24$). At post-treatment, the exposure group scored significantly lower than the control group on some clinical measures and received lower therapist ratings of startle responses,

memory disturbance, depression, anxiety, irritability, and legal problems. These improvements were maintained at 6-month follow-up. Significant differences were not found for emotional numbing, sleep disturbance, or any measure of social adjustment. In another study, veterans who received both “imaginal flooding” and “standard” treatment were compared to a group of yoked patients who received “standard” treatment only ($N = 14$). The exposure group showed superior outcome on patient ratings of sleep, nightmares, and intrusive thoughts, but no differences were found for heart rate, and only minimal differences were found for measures of trait anxiety, depression, and violent tendencies. Again, the treatment appears to have been only partially efficacious. Another study included the use of physiological recordings (e.g., heart rate) and self-report inventories to assess outcome in inpatient veterans treated with exposure or individual counseling. Participants receiving exposure showed modestly superior improvement across most psychological and behavioral rating measures, but no significant differences were found between the groups on physiological parameters. Further, regardless of treatment condition, those participants who showed decreased physiological responding were improved on psychological inventories at 3-month follow-up. This suggests that reductions in physiological responding was a critical element of efficacious therapy and might be a predictor of long-term treatment success. Finally, results from two uncontrolled studies support the partial efficacy of exposure for treating PTSD symptoms in veterans.

Data from these studies indicate that exposure therapy helps reduce the hallmark features of chronic PTSD and much of the general anxiety that accompanies it. In fact, according to the consensus statement on PTSD by the International Consensus Group on Depression and Anxiety exposure therapy is the psychotherapy of choice for the disorder. However, exposure does not have a significant effect on the “negative” symptoms of PTSD (e.g., avoidance, social withdrawal, interpersonal difficulties, occupational maladjustment, emotional numbing), nor on certain aspects of emotion management (e.g., anger control). This is because exposure is narrowly focused on anxiety and fear reduction and hence does not address other features of the disorder. Specifically, exposure does not address basic skill deficits, impaired social functioning, unemployment, or anger control problems. In essence, exposure therapy does not address the many problems often associated with any chronic mental disorder. Thus, many scientists have suggested that a behavioral treatment program,

targeting specific areas of dysfunction via different behavioral strategies is necessary to address the complex symptoms associated with this condition—hence, the development of Trauma Management Therapy.

2. Trauma Management Therapy

The efficacy of TMT was examined in an open trial with 15 male Vietnam combat veterans with PTSD. The veterans participating in this study had a mean severity rating of 6.09 on the 7-point rating scale of the Clinical Global Impressions scale, indicating that the sample was severely ill. Demographics were as follows: six were African American (40%) and nine were Caucasian (60%). The mean age of the sample was 47.9 ($SD = 2.1$; range = 44 to 52 years), mean education level was 12.7 ($SD = 1.2$), 8 (53%) were married, 6 (40%) were employed full-time, 5 (33%) had a prior history of arrests, 7 (47%) had a prior history of psychiatric hospitalization, 7 (47%) received some level of VA disability payments for PTSD prior to treatment, and 11 (73%) currently were seeking disability payments or increases in existing disability payments. Acute psychiatric diagnoses other than PTSD included major depression, panic disorder, social phobia, and obsessive-compulsive disorder. Personality disorder diagnoses included borderline, avoidant, and schizoid. Overall, 15 (100%) were diagnosed with a co-occurring acute psychiatric disorder, and 11 (73%) with a co-occurring personality disorder. The combination of the multiple psychiatric disorders and extreme severity ratings indicate this was a severely ill sample.

Eleven patients were included in the analyses because 4 of the 15 (27%) dropped out during the course of treatment. One veteran discontinued after a few sessions of exposure treatment without giving a reason. The remaining three dropped out after successfully completing the exposure phase and all reported benefiting from the treatment; two of these veterans dropped out because their employment took them to another city, and the other cited transportation problems for not being able to participate in the SER phase.

To summarize the results, significant pre- to post-treatment improvement on most of the outcome variables was noted (see Table 2), suggesting that TMT is a promising treatment for the chronic and multifaceted symptoms associated with combat-related PTSD. Over the course of 4 months significant improvements were made on most critical features of PTSD. Symptom reductions occurred across problematic features of sleep disturbance, nightmares, flashbacks, social withdrawal, heart rate reactivity; significant improvements were

noted on clinician ratings of general anxiety, PTSD symptoms, and overall level of functioning.

Because TMT significantly improved patients' social functioning across a number of dimensions, the outcome generally appears to be superior to findings reported for combat veterans in treatment studies using exposure therapy only or other nonexposure treatments. Furthermore, the patients' overall ratings of their treatment indicate that they considered it a credible and positive therapeutic experience, and all but one said that they would encourage other veterans with PTSD to participate in TMT. Although significant improvement was found on many measures, the clinical syndrome was not remediated entirely, which is usually the case even for most "successful" treatments of anxiety disorders and most other severe psychiatric conditions. Nevertheless, overall the new treatment strategy appears to have resulted in broad improvement across the wide symptom spectrum of PTSD in a sample of veterans typical of those in most VA settings.

For purposes of examining component efficacy, assessments were administered after completion of exposure therapy at midtreatment (Session 15), but prior to the commencement of SER. These data indicate that veterans responded with significant improvement after completion of the exposure therapy phase, but only on certain symptoms (e.g., nightmares, flashbacks, physiological reactivity, sleep, and general anxiety). Significant improvement in the frequency of social activities occurred only after the implementation of social skills

training, suggesting that this deficiency improved only after specific intervention with the SER component. This validates the need for a broad-based intervention to address the entire PTSD syndrome. Research is pending to extend these results for TMT in randomized, controlled efficacy research.

IV. SUMMARY

Posttraumatic stress disorder (PTSD) is a severe and chronic anxiety disorder that may follow traumatic experiences (e.g., combat, physical and sexual assault). The clinical syndrome is characterized by symptoms of reexperiencing the trauma (e.g., nightmares, "flashbacks"), emotional numbing and avoidance, and arousal (e.g., insomnia, hypervigilance, anger), as well as severe impairment of social functioning. Research shows that intensive exposure therapy helps reduce the hallmark features of chronic PTSD (e.g., symptoms of intrusion, physiological reactivity) and much of the general anxiety that accompanies it and is considered to be the psychosocial treatment of choice. However, exposure therapy does not have a significant effect on the "negative" symptoms of PTSD (e.g., avoidance, social withdrawal, interpersonal difficulties), nor on certain aspects of emotion management (e.g., anger control). Although exposure may reduce maladaptive arousal and fear, it does not address basic skill deficits, impaired relationships, or anger control problems. Trauma Management Therapy

(TMT) is a multicomponent behavioral treatment program for chronic combat-related PTSD designed to address all aspects of the clinical syndrome in veterans. It utilizes a combination of patient education, exposure therapy, social skills training, and relevant homework assignments. Preliminary evidence from an open trial shows that overall TMT appears to result in broad improvement across the wide symptom spectrum of PTSD, including social functioning, in veterans treated within the VA. Research is pending to extend these results for TMT in randomized, controlled efficacy research.

GLOSSARY

cathexis Freud used this term to refer to changes in direction or quantity of psychic energy. Generally it means interest, attention, or emotional investment.

hermeneutic school This approach to psychoanalysis argues that the psychoanalytic process and theory should be understood as a humanities discipline, not a natural science. Thus, it disregards concepts such as causality to focus on the coherence theory of truth. Criteria such as internal consistency, coherence, comprehensiveness, and therapeutic efficacy are more important than empirical proof.

instinctual drives Freud's two drives, sexual and aggressive, were considered to be the major factors motivating the mind. They continue to be considered important but not the only motivating factors by modern psychoanalysts.

I. INTRODUCTION

The notion that most mental processes occur outside of consciousness and that these unconscious contents

and functions exert tremendous influence on virtually all psychologically mediated behavior is perhaps the most central and long-standing of Sigmund Freud's many contributions. Although his definition and understanding of the role of unconscious phenomena have been revised and expanded, every practicing therapist who uses a psychoanalytic or psychodynamic orientation is always considering the role of unconscious psychodynamics in the symptoms and personality traits their patients want to change. Technical strategies for utilizing and working with these unconscious phenomena have evolved, but the basic idea that these phenomena are important and must receive therapeutic scrutiny has stood the test of time.

II. CONCEPT OF THE UNCONSCIOUS

The concept of the Unconscious was described in various sections of *The Interpretation of Dreams*, most notably Chapter 7, by Freud in 1900 as he delineated his topographic model wherein the regions of the mind were defined by their closeness to consciousness. But it was not until 1915 in his paper, "The Unconscious," that Freud elaborated on what he called the system Unconscious in detail. He began that paper by reviewing the justification for the inference of such a system. Thus, he pointed out what psychologists of most theoretical persuasions have come to acknowledge—that is, it is simply untenable to assume that everything that

occurs in mental life can occur in the conscious mind. Even recent cognitive and information processing models acknowledge that the conscious mind can only be aware of a fraction of the contents and processes occurring in mental life. One has only to reflect on daily phenomena such as arriving at one's destination while driving without remembering any details of stopping for traffic lights, making turns, and so on, to be struck by the evidence supporting the occurrence of unconscious mental processes.

Freud also argued that it was conceptually necessary to postulate the existence of an unconscious mind to explain the many gaps in the contents of consciousness (e.g., slips of the tongue, dreams). Such gaps were simply unintelligible using only the information provided by the conscious mind. In fact, many of the books and papers of Freud's topographic stage of thinking (1897–1923) were devoted to demonstrating the unconscious logic of these consciously illogical phenomena. Dreams, slips of the tongue, jokes, and neurotic symptoms were all studied and shown to be comprehensible once one grasped the role of the system Unconscious in their genesis and subsequent maintenance. In fact, Freud was able to argue for the legitimacy of assuming that others also had unconscious minds as he was able to make sense of their previously unintelligible behavior by illuminating its unconscious meanings.

The basic thesis of the topographic model was that the mind was organized into three systems or regions, the systems Unconscious, Preconscious, and Conscious, organized to prevent the contents of the system Unconscious from breaking into and overwhelming the system Conscious so that the individual could continue to attempt to adapt to the constraints of reality while allowing enough discharge of the contents of the Unconscious to avoid excessive frustration, unpleasure, or symptomatology. In essence, the mind's major function was one of maintaining some sort of homeostatic equilibrium between the contents of the Unconscious and the need to behave in the external world in a manner that enhanced the individual's self-preservation.

III. THE DRIVES

What made this task difficult was the nature of the contents of the system Unconscious. Most of its contents were understood by Freud to be instinctual drives—generally libidinal ones. Freud had been driven by clinical necessity to postulate the presence of unconscious sexual drives in 1897 when he realized that the sexual abuse reported by his patients generally

involved fantasies and not the actual reality that he had assumed during his previous affect-trauma stage of thinking. These sexual fantasies were theorized to derive from libidinal instincts in the system Unconscious, instincts that had a powerful, preemptory quality, always pushing the individual to discharge his or her accumulated sexual tension in the real world.

But to blindly run amok, seeking gratification of the multiplicity of sexual urges available to humanity, would place the individual at great risk for not surviving. The same could be said for the aggressive instinctual urges that Freud described later in his life. Thus, the mind needed to function so as to keep these libidinal and aggressive contents repressed, that is, in the system Unconscious. Thus, Freud hypothesized the existence of a censor at the boundary between the systems Unconscious and Preconscious. Freud always believed that some form of special energy, what he called psychic energy, provided the means by which the system worked. Each system had its own psychic energy to serve its functions. Explaining how censorship worked in his 1915 paper, he said, "there is a withdrawal of the preconscious cathexis, retention of the unconscious cathexis, or replacement of the preconscious cathexis by an unconscious one." Another form of energetic cathexis, what Freud called an anticathexis, was also used to buttress repression. In this way the mind could keep the potentially most self-destructive or unpleasurable instinctual impulses from moving into the system Preconscious, from where they could make their way into the system Conscious. Some discharge of instincts had to be allowed to prevent excessive internal tension from occurring. Discharge generally occurred through the system Preconscious disguising the contents of the Unconscious and depleting them of some intensity before allowing their derivatives to proceed into the system Conscious.

IV. THE ROLE OF PSYCHIC ENERGY

Freud also described the system Unconscious as being organized and functioning in very different ways than the other two systems. In large part these differences were due to the primary process that characterized the system Unconscious. Primary process referred to the earliest, developmentally most immature form of mental activity according to Freud. In many ways it corresponds to what cognitive psychologists call preoperational thinking. Such thinking seeks immediate and complete discharge of drive impulses by attaching psychic energy (*cathexis*) to the visual memory traces of

the object that gratified the drive in the past. Primary process mentation was characterized by the occurrence of both displacement and condensation. Displacement refers to immature thinking whereby one idea within a drive-connected associative network comes to symbolize another idea. *Pars pro toto* thinking is one example of displacement. For example, the color blond may come to symbolize the person toward whom the drive-wish was directed who had blond hair. Likewise, situations wherein the whole represents a part is another example of displacement. Condensation was the other primary process mechanism described by Freud. In condensation one mental content (idea, memory trace, etc.) can represent several others. For example, the occurrence of a church in someone's dreams might represent at the same time both wishes toward a particular figure who had been religious as well as memories of one's religious training. To account for the fluidity by which primary process thinking operated, Freud introduced the idea that the system Unconscious was characterized by mobile psychic energy that easily shifted from one mental content to another toward the goal of wish fulfillment.

V. CHARACTERISTICS OF THE UNCONSCIOUS

The system Unconscious was also said to operate according to the pleasure principle. Freud described the instinctual wishes that made up the contents of the system Unconscious as peremptory. They were so compelling that he believed they sought pleasurable discharge and the parallel reduction of unpleasurable tension at all costs. Drive stimulation was thought to arouse unpleasurable tension in what Freud called the psychic apparatus, and to push toward consciousness and motility so that satisfaction of the drive-wish could be achieved. As the wish proceeded through the other systems of the mind, its pressure for direct and immediate discharge often aroused conflict, leading the censorship between the systems Unconscious and Preconscious to transform it. If disguised sufficiently, such drive derivatives would pass into the system Conscious and provide instinctual gratification. Otherwise, they would be repressed and maintained in the system Unconscious by the censor. Thus, the contents of the system Unconscious included both the infantile sexual and aggressive drive wishes as well as their repressed derivatives that had originally been allowed into consciousness, but had subsequently aroused enough conflict that they were re-repressed.

As the individual developed, virtually all primitive sexual and aggressive wishes were said to be repressed and capable of conscious expression only after being disguised thoroughly by the system Preconscious. Repression of a drive derivative could occur at any time that it aroused unpleasure, generally in the form of anxiety, in an individual. In this way the system Unconscious was thought by Freud to be constantly changing as new repressions occurred. Strong repressions of drive wishes early on were said to serve as fixation points encouraging later repressions to regress to the fixation point.

The system Unconscious was also described by Freud as having other characteristics that differentiated it from the systems Preconscious and Conscious. First it was timeless. Mental content and processes in this system were not affected by the passage of time or the concept of time. This characteristic was necessary to explain the clinical finding that childhood instinctual derivatives continued to play such vivid roles in the psyches of adult patients. Implicit in the concept of the pleasure principle was the notion that reality was disregarded in the Unconscious. This contributed to another special characteristic—the equating of psychic reality with external reality. That is, in the system Unconscious, memories of actual occurrences were treated as no different than imagined experiences. Thus, no reality–fantasy boundary existed. Contradiction was also said not to exist in the system Unconscious. Mutually incompatible ideas could be maintained simultaneously and without conflict because of this. Negation also did not exist in the system Unconscious. Finally words were treated as things in the system Unconscious so that the symbol of a concrete thing was treated as though it were the thing it symbolized.

It is impossible to overstate the importance of the system Unconscious during Freud's topographic era of model building. Treatment was guided by the dictum that the analyst needed to make the Unconscious conscious. Helping the patient to become aware of the unconscious drive wishes that were being repressed was believed to bring about cure, in part, by releasing the psychic energy that had been dammed up, and by alleviating the unpleasant sensation of drive frustration as well by insight. Dreams were described as the royal road to the Unconscious and psychoanalysts were taught to devote particular time and energy to unraveling the disguised unconscious wishes being expressed in the dream. The primary process mechanisms described earlier were of particular importance as knowledge of them became necessary in deciphering the symbolism of the dream.

VI. CONCEPTUAL PROBLEMS

Despite the many technical and theoretical contributions of this era, clinical findings and theoretical inconsistencies led Freud ultimately to replace the topographic model with the structural one and to give up the concept of the system Unconscious. As he gained greater appreciation for the complexity of defensive functioning, particularly the fact that it, too, operated unconsciously, he realized that organizing the mind in terms of its accessibility to consciousness was no longer clinically useful. In essence, he realized that his patients' symptoms and character traits were caused by conflicts between unconscious wishes and unconscious defenses. That is, the conflicting elements were both unconscious. At this point, consciousness or the lack of it ceased to serve a differentiating function. Furthermore, he became increasingly aware of the need to deal clinically with the phenomenon of unconscious guilt. Yet there was no easy way to explain this concept in terms of topography. He needed the construct of a superego, which he described when he replaced the topographic theory with his structural one in *The Ego and the Id* in 1923. From that point, to speak of the Unconscious as a noun became theoretically anachronistic. Today it should be used only as an adjective, describing mental contents or processes that are not conscious. Some analysts fail to grasp this point, however, and still talk of an Unconscious. Unfortunately adhering to an outdated concept often leads to outdated formulations about the process of psychoanalysis or psychotherapy and how it cures.

Nonetheless, unconsciousness remains an important concept. The contents of the system Unconscious—instinctual wishes—are now thought to reside in the id, a mental structure that retains most of the structural characteristics of the system Unconscious, in particular the pleasure principle and the mechanisms of the primary process. But psychoanalytic treatment no longer is geared toward making these contents conscious as a curative approach. The discovery of unconscious defensive functioning as well as unconscious superego prohibitions has led to a therapeutic strategy whereby psychoanalysts make their patients aware of the occurrence of mental conflict as it occurs in their thoughts during treatment sessions. The patient's attention is drawn to the evidence of such conflict and whichever aspect of it is most easily accessible to the patient at any particular time. This work leads to the exploration of unconscious defenses and their motives at one time, the analysis of unconscious superego injunctions or ideals at another time, and the elaboration of unconscious wishes at still another. But the point of the strat-

egy is to expand the ego's awareness of such conflict, its elements, and the motives that cause it so that conscious ego mastery can occur. Drive satisfaction or tension reduction are no longer relevant to analytic cure, although the focus on unconscious features of mental functioning continue to remain important.

VII. THREE BOX MODEL

Joseph Sandler has also introduced what he calls the Three Box Model in which he tries to retain a place for the system Unconscious. In essence, he divides it into a Past Unconscious and a Present Unconscious in an attempt to argue the importance of interpreting the Present Unconscious content over ones from the Past Unconscious. Although most current-day analysts would support this technical dictum to interpret present before past, his theoretical modification has failed to receive widespread support. Other theoretical models, particularly the contemporary structural theories of Paul Gray and Fred Busch, offer similar technical emphases while not falling into the difficulties that describing the Unconscious as a system entail.

VIII. UNCONSCIOUS FANTASY

Another clinical arena in which the phenomenon of unconscious functioning remains salient today is the concept of unconscious fantasy. Freud first introduced the concept in *Formulations on the Two Principles of Mental Functioning* in 1911. He talked of an aspect of thinking that was split off and kept free of reality constraints. Fantasizing or daydreaming continued to operate according to the pleasure principle. Symptoms, dreams, moods, and character traits were all traced to derivatives of unconscious fantasies. Anna Freud, using the structural model, applied the concept of unconscious fantasy to explain defenses such as identification with the aggressor and denial in fantasy. Repressed masturbatory fantasies were shown to disrupt certain ego functions and to distort important object relations.

But it is Jacob Arlow who has brought this concept to current-day prominence while demonstrating its clinical utility. He pointed out that decisive conflicts during an individual's life become organized into a number of stable unconscious fantasies that provide constant stimulation to an individual's mind. In this sense they form a schema through which subjective experiences are perceived, interpreted, and reacted to. Such fantasies are organized hierarchically and group around

drive wishes, allowing for different versions of the fantasy. Arlow described such fantasies as developing early in life, but only with the resolution of the Oedipus complex. These fantasies provide what hermeneutically oriented psychoanalysts have called narratives, giving a plot to the individual's life that organizes his or her multiplicity of experiences into a few consistent and cohesive themes. Needless to say, they are important in maintaining ego identity.

Unconscious fantasies are usually the basis for neurotic symptoms and character traits. Generally the development of these clinical phenomena can be traced to an event that is reminiscent of a persistent unconscious fantasy built around a corresponding traumatic event. But equally as often unconscious fantasies lead to selective perception and responding. It is important to realize that unconscious fantasies involve the contribution of the ego and superego, and not just instinctual wishes from the id. Arlow has shown how fetishism can involve an unconscious fantasy that women have penises, which can fend off castration anxiety. Such a fantasy serves a defensive function.

Arlow has gone on to explain the technical importance of the concept of unconscious fantasy. He explained that the analyst needs to infer the presence of an unconscious fantasy from the patient's associations and to show the patient how its derivatives affect the patient's actions and mental life. An example described by Arlow was a patient who could only perform sexually if he fantasized spanking a woman. Analysis of this fantasy led the patient to realize his need to be in charge and not to see the female genital that made him anxious. Such realization allowed him to be more assertive with his wife and subsequently to have a successful sexual experience with her. Arlow has also said that the analyst's ability to empathize with and to understand the patient requires the ability to allow an unconscious fantasy to be evoked in the analyst that is similar to that of the patient's. Thus, the concept of un-

conscious fantasy remains another example of the continued importance of the concept of unconscious mental functioning in clinical practice.

It is impossible and technically unwise to ignore unconscious mental functioning when doing psychodynamic psychotherapy or psychoanalysis. Unconscious resistances are both inevitable and problematic if they are not analyzed. They lie at the core of patients described today as treatment resistant. Likewise, becoming aware of unconscious intrapsychic conflict is crucial in expanding the patient's consciousness and mastery of his or her own mind. Thus, unconscious phenomena remain as important as ever in psychodynamically oriented treatment as long as therapists are careful not to think of an Unconscious with the technical implications carried by that outdated concept.

GLOSSARY

- classical conditioning** Conditioning that is based on the association of one stimulus with another.
- continuous reinforcement schedule** A schedule in which reinforcements are given after every response.
- coping model** A model who initially performs the target behavior imperfectly or hesitantly but becomes better with repetition.
- intermittent reinforcement schedule** A schedule in which reinforcements are given fewer than once every response, according to a predetermined order. The schedules are fixed interval, variable interval, fixed ratio, and variable ratio.
- mastery model** A model who performs a target behavior perfectly and without hesitancy from the beginning.
- model** Someone who performs a target behavior and is reinforced or punished for it under observation.
- operant conditioning** Conditioning that is based on the reinforcing or punishing consequence of a behavior.
- target behavior** The behavior to be reinforced (increased in probability) or punished (decreased in probability).
- vicarious conditioning** Conditioning that occurs by an observer by watching a model perform the target behavior and being reinforced or punished for performing it. Also known as vicarious learning or vicarious reinforcement.

I. DESCRIPTION OF TREATMENT

In vicarious operant conditioning, the observer is exposed to a model who is reinforced or punished for performing a certain behavior. It is important that the model actually be observed being reinforced or punished for performing the behavior, not simply observed performing it, or vicarious conditioning will not occur. Usually it is important that the observer be repeatedly exposed to the model because conditioning may not occur after a single exposure. In addition, conditioning may not occur because the observer did not see the important features of the modeled behavior or may have no memory of it. It is helpful if the modeled behavior is symbolically represented by images or words or is mentally rehearsed. The observer, of course, must have the means to carry out the target modeled behavior.

In vicarious classical conditioning, the observer is exposed to a model who behaves fearfully when confronted with a feared object (such as a snake) or who has negative consequences occur when exposed to an object (such as being scared by a large animal or in association with that animal). As a result of making these observations, the observer may likewise learn to fear these objects or situations.

Whereas vicarious operant conditioning may require several trials and multiple models to become firmly established, vicarious classical conditioning may occur in a very few or even single trials or exposures. It is likely

that the majority of human anxiety responses are learned in this manner because most people have not had personal experiences with many of the events or people they fear.

II. THEORETICAL BASES

Vicarious conditioning is theoretically based on the modeling paradigm as developed by Albert Bandura. In modeling, individuals may show increases or decreases in various target behaviors by observing a model being reinforced (to increase target behavior) or punished (to decrease target behavior). It is not necessary that the observing individual be directly reinforced or punished for behavior change to occur. This process has been called vicarious learning, vicarious conditioning, or in some instances, vicarious reinforcement.

Vicarious conditioning is the analogous process to *in vivo* or directly experienced conditioning. According to the operant conditioning paradigm, the observing individual watches a model being reinforced for performing a certain behavior and the probability of the observer subsequently exhibiting that behavior increases as well. Observation of rewarding consequences occurring to a model for exhibiting a certain behavior, such as aggressiveness, may increase the probability of the observer performing that behavior in the future. By contrast, observation of a model being punished for exhibiting aggressive behavior may decrease the likelihood of, or inhibit the observer from performing, a similar aggressive act.

In vicarious classical conditioning, an observer watches a model becoming afraid of certain activities or animals as a result of seeing these stimuli paired with fear-producing situations. For example, the observer may see a model being bitten by a large furry dog, and subsequently fears large furry dogs without having been personally bitten. Indeed, the conditioning may generalize to a fear of large furry objects in general or to animals other than dogs.

Vicarious conditioning has been thought to be a major contributor to fear and anxiety disorders in people because people are commonly afraid of, or anxious about, situations or events that they have never experienced directly. It is also thought to account for a higher level of aggression in individuals who have not themselves been exposed to aggressive responses. Vicarious conditioning can develop through familial influences, subcultural influences, or symbolic modeling by the mass media because, for example, the latter provide ample models for violence and aggression.

Bandura has described several mechanisms or functions by which vicarious conditioning may occur. There is the informative function, in which the model's actions and response consequences provide information to observers about the probable consequences to them if they engage in similar actions. There is the motivational function, in which seeing others reinforced (or punished) can act as a motivator for the observer to perform similar actions. There is the valuation function, in which observers may come to value certain things if they see a model being reinforced for similar things. There is the influenceability function, in which observers may be influenced more by models' actions that respond positively to reinforcing consequences than by those who resist such consequences. In other words, observers tend to be more influenced by modeled responsiveness than by modeled resistance. Finally, there is the emotional learning function, in which an observer's emotional reactions are aroused by the model's emotional reactions while undergoing the rewarding or punishing consequences. This last function is essentially a form of classical conditioning in which an observer's fear responses may be enhanced or reduced by the model's fear responses or lack of them.

Observing the model gradually and perhaps hesitantly approach the feared situation or be reinforced for initially imperfect responses may be especially useful. Bandura found that a coping model, who performed the behavior gradually, imperfectly, or hesitantly was a more effective model than a mastery model, who performed the behavior perfectly, quickly, or without hesitation. People may respond better to a coping model because of perceived similarity to themselves. A coping model appears to be more like them whereas a mastery model may make them feel too inadequate and therefore not be imitated. Of course, it is important that the observers see the model as similar to themselves so that they may reasonably assume that the rewarding or punishing consequences would likely happen to them as well. For example, rewarded aggression occurring to a soldier model may not result in an increase in aggression in a civilian observer. The model and observer are not similar enough. Likewise, similarity of model and observer in such attributes as gender, age, and race may enhance the modeled vicarious conditioning effect whereas dissimilarities may reduce it. The use of multiple models may also enhance vicarious conditioning.

It should be noted that the standard laws of conditioning also apply to vicarious conditioning. For example it has been shown that conditioning that has been

established on an intermittent reinforcement schedule is acquired more quickly and established more firmly than that which has been established on a continuous reinforcement schedule. Whereas vicarious extinction may require many repeated trials, vicarious conditioning can often be accomplished in a few trials. In the case of highly intense or emotionally involving experiences, one-trial conditioning may occur.

III. EMPIRICAL STUDIES

There has been considerable research on the effectiveness of vicarious conditioning. Not only has it been found to be quite effective, it can be superior to direct reinforcement. This phenomenon is especially true if the tasks to be reinforced are more conceptual than manual. Vicarious conditioning is certainly more pervasive than direct conditioning, and likely accounts for the majority of human learning. In fact, a large number of behaviors exhibited in everyday life are probably conditioned vicariously by observing models being reinforced for performing these actions. The amount of vicarious classical conditioning has been found to be related positively to arousal level generated by psychological stress. It has been shown that the need for approval can increase the conditioning effect of vicarious reinforcement. Vicarious and instructional conditioning have been found to be major sources of childhood fears, more so than with adolescents, although they have often been combined with direct conditioning. Childhood fears have in fact been reduced or eliminated by this procedure. Vicarious conditioning has been found to be effective in eliminating maladaptive response patterns and increasing and maintaining new adaptive behaviors in children with mental retardation. It has been successfully implemented to train these children in more prosocial behaviors. It was found that children who were shown films in which a model showed either a fear response or a positive emotional response showed a lower rate of responding to the fear stimulus and a higher rate of responding to the positive stimulus. These effects were easily overridden by instructional and reinforcement conditions, however, and proved to be temporary. Only minimal cues from a model may be required for vicarious conditioning to occur as was demonstrated by one study that found that information about the model's heart rate was sufficient for it to occur. Thus, vicarious conditioning may

account for a large part of human learning and be relatively easy to implement.

IV. SUMMARY

Vicarious conditioning is theoretically based on Albert Bandura's conditioning through modeling paradigm. It is analogous to direct trial conditioning, the difference being that it occurs when an observer learns by seeing a model performing a target behavior that is reinforced or punished. It is important that the observer actually see the model being reinforced for performing the behavior, not simply observed performing the behavior. Social behaviors, such as aggression and violence, are likely learned by this process. Vicarious conditioning can also occur through the classical conditioning paradigm whereby an observer sees a model learn to be afraid by being exposed to a noxious stimulus paired with an activity or event. Most human fears have likely been acquired by the latter process. Vicarious conditioning has been shown through research to be at least as effective as direct conditioning and possibly more so. It is a highly effective method for learning under a wide variety of situations and can be flexibly adapted to many conditions. Vicarious conditioning may be especially useful in learning conceptual material as opposed to manual skills. Mastery models may be less useful than coping models. Especially with vicarious classically conditioned fear, relatively few trials may be needed for conditioning to occur.

- Further Reading

vicarious learning Learning that occurs by an observer by watching a model perform the target behavior and being reinforced or punished for performing that behavior.

I. DESCRIPTION OF TREATMENT

In vicarious operant extinction, the observer is first exposed to a model who is reinforced or punished for performing a certain behavior. It is important that the model actually be observed being reinforced or punished for performing the behavior, not simply observed performing it, or vicarious learning will likely not occur. Then, the reinforcer or punisher is removed so that the observer simply sees the model performing the behavior. As a result, the observer is less likely to exhibit the behavior (if previously reinforced) or to suppress it (if previously punished).

In vicarious classical extinction, such as is commonly used to extinguish conditioned fearful avoidance behavior, the observer is first exposed to a model who behaves fearfully when confronted with an object, such as a snake, or who has negative consequences occur when exposed to an object, such as being knocked down by a large dog. As a result of seeing the model, the observer learns to fear the objects as well. Then the model is observed approaching the object (e.g., the snake) without fear or approaching the object (e.g., the dog) without adverse consequences. As a result, the observer is likely to feel less fear and to engage in less avoidance behavior in the future.

GLOSSARY

- classical conditioning* Learning that is based on the association of one stimulus with another.
- copying model* A model who initially performs the target behavior imperfectly or hesitantly but becomes better with repetition.
- extinction* A change in behavior that occurs when it is no longer reinforced or punished.
- intermittent reinforcement schedule* A schedule in which reinforcements are delivered fewer than once for every response, according to a predetermined order. The schedules are fixed interval, variable interval, fixed ratio, and variable ratio.
- mastery model* An expert model who performs the target behavior perfectly and without hesitancy from the beginning.
- model* Someone who performs a target behavior and is reinforced or punished for it.
- operant conditioning* Learning that is based on the reinforcing or punishing consequence of a behavior.
- thin reinforcement schedule* A schedule in which few reinforcements are delivered for each response, for example, one reinforcement for every 50 responses.
- vicarious extinction* Extinction that occurs by watching a model perform a behavior that is no longer reinforced or punished.

It is important that this extinction process be repeated a number of times, sometimes a large number of times, so that the previous learning will in fact extinguish. Overlearned or traumatic learning experiences may require many extinction trials. It may also be helpful for the model to exhibit gradual approach behavior to a feared object rather than approaching it too quickly. Finally, it may be helpful to use coping models for individuals who are fearful and avoidant themselves whereas mastery models may be more useful if precise skill development is desired in the relative absence of fear.

II. THEORETICAL BASES

Vicarious extinction is theoretically based on the modeling paradigm as developed by Albert Bandura. In modeling, individuals may show increases or decreases in various target behaviors by observing a model being reinforced (to increase target behavior) or punished (to decrease target behavior). It is not necessary that the individual be directly reinforced for behavior change to occur. This process has also been known as vicarious learning.

Vicarious extinction is the analogous process to *in vivo* or directly experienced extinction. According to the operant conditioning paradigm, the observing individual, after having vicariously learned a particular behavior by watching a model being reinforced for performing that behavior, now watches the model no longer being reinforced for exhibiting that behavior. Thus, the observer's target behavior likewise diminishes over time for lack of reinforcement.

In vicarious classical conditioning, an individual may have vicariously learned from a model to fear and therefore avoid certain activities or animals (such as avoiding members of the opposite sex or avoiding dogs) by watching a model learning to fear them (perhaps by being consistently rejected or by being knocked over by the dog). In vicarious extinction, the observer no longer sees the model performing fear-producing behaviors with adverse consequences (being rejected or knocked over); in fact the observer may see the model approach the dog without problems occurring. Thus, the fear that has become associated with either stimulus is gradually extinguished as the observer learns that the activities are safe.

Observing the model gradually and perhaps hesitantly approach the feared situation without problems occurring may be especially useful. Bandura found that a coping model, who performed the behavior gradually

or imperfectly, was a more effective model than a mastery model, who performed the behavior perfectly or quickly. People may respond better to a coping model because of perceived similarity. It looks more like them whereas a mastery model may make them appear too inadequate and therefore not to be imitated.

It should be noted that the standard laws of learning also apply to vicarious learning. Therefore, the standard laws of extinction also apply to vicarious extinction. For example, it has been shown that learning that has been established on an intermittent reinforcement schedule is much more resistant to extinction than behavior acquired on a continuous schedule of reinforcement. Thus, vicarious learning that has been established on an intermittent reinforcement schedule would likewise be more resistant to vicarious extinction than that established on a continuous schedule. Likewise, a very thin vicarious reinforcement schedule would produce greater resistance to vicarious extinction than one involving a large number of reinforcers per response.

It is difficult to explain how fearful avoidance responses can be extinguished without ever being initially elicited. Bandura explains this by a dual-process theory of avoidance behavior. A conditioned aversive stimulus evokes emotional arousal that controls to some extent instrumental responding, and therefore if the arousal capacity of a fear-producing stimulus is extinguished, both the motivation and the avoidance stimulus are eliminated.

III. EMPIRICAL STUDIES

In the 1960s, there was substantial research conducted on vicarious extinction of fear and avoidance behavior, much of it conducted in Albert Bandura's laboratory. Vicarious classical extinction was found to be quite useful in extinguishing fear of certain animals in young children. Bandura and his colleagues also found that multiple models were more effective than single models in eliminating animal phobias in children, at least from posttest to follow-up. They also found that live modeling with participation (seeing an actual model perform the behavior with guided practice by the observer in performing the same behavior) was more effective than symbolic modeling (watching a film of the model performing the behavior) or systematic desensitization. Modeling appeared to account for about 60% of the behavior change and 80% of the attitude change. Guided participation accounted for the rest of the variance. Relaxation did not appear to

increase the effectiveness of symbolic modeling alone in reducing fear arousal.

Other research, including some doctoral dissertations dating from the 1970s, has been conducted on vicarious classical extinction designed to reduce fear arousal and avoidance behavior and has found it to be effective in reducing sex anxiety in women, reducing frigidity, reducing fear of dogs through films (symbolic modeling), and reducing fear of snakes. Multiple models were again found to be more effective than single models. One study comparing systematic desensitization and vicarious symbolic extinction found greater improvement for systematic desensitization. Another study comparing symbolic desensitization, symbolic modeling, and live modeling combined with guided participation (contact desensitization) found the latter to be the most effective.

IV. SUMMARY

Vicarious extinction is theoretically based on Albert Bandura's learning through modeling paradigm. It is an analogous process to *in vivo* extinction, the difference being that the former occurs when an observer sees a model performing a behavior that is no longer

reinforced, rather than not being reinforced (extinguished) directly. It was shown through research conducted in the 1960s and early 1970s to be an effective technique for extinguishing fear and avoidance behavior. It is more flexible and adaptable than *in vivo* extinction because the observer does not have to experience the extinction directly. However, live modeling combined with guided participation, which is essentially a combination of vicarious and *in vivo* extinction, was found to be more effective than other forms of vicarious extinction alone.

GLOSSARY

virtual reality A technology that enables users to enter computer-generated worlds and interface with them through sight, sound, and touch.

Virtual reality therapy (VRT) is a new modality of therapy that enables clients to confront what troubles them and deal with irrational behavior using virtual reality technology. VRT is changing deeply held concepts about how human beings can overcome psychological disorders.

I. DESCRIPTION OF VIRTUAL REALITY THERAPY

VRT brings clients face-to-face with their deepest fears in a nonthreatening environment. That is the key. Entering a computer-generated world, clients know the situation is harmless, yet the re-creation of fearful scenes is lifelike, enabling them to deal with their fears

in a realistic setting, confronting them through sight, sound, and touch.

VRT is similar to behavior therapy in its focus on exposing clients to fear-provoking stimuli. It differs from traditional behavior therapy modalities in that VRT computer graphics and various display and input technologies create real-life situations in the laboratory. These produce a sense of presence, so that the client feels immersed in the frightening scene. VRT can overcome some of the difficulties inherent in traditional treatment of psychological disorders. In traditional therapy, the therapist often has to imagine what is going on in the mind of the client. In VRT, the therapist can see how a phobic client reacts to fearful situations and is able to provide on-the-spot guidance. VRT generates stimuli of much greater magnitude than standard *in vivo* techniques can produce. It offers the added advantage of greater variety, efficiency, and economy in creating situations that might be either difficult or impossible with traditional techniques.

The centerpiece of VRT technology is a stereoscopic head-mounted video display with a head-tracking unit, along with a device that produces auditory and tactile stimuli (Figure 1). The effect can be startling, especially when the client is exposed to lifelike situations that have always produced fear. A set of VRT scenes is created before the therapy sessions begin. In the first laboratory session, which lasts approximately 20 minutes, the VRT client gets familiar with the virtual reality equipment. During this session, the client is asked to eliminate any virtual reality scenes that do not necessarily cause

FIGURE 1 A typical virtual reality system with head-mounted display and head-tracking unit for use in VRT treatment.

anxiety. The client is asked to rank the remaining scenes from least to the most threatening. For the next eight weekly sessions, which last 15 to 20 minutes each, VRT is conducted in a standard format, tailored to individual needs.

The VRT session begins with the least fearful scene. Discomfort is measured every few minutes with the Subjective Units of Disturbance (SUD) scale. Clients rate their discomfort on a scale of 0 to 10. They progress systematically through each level of discomfort, and then are exposed to the next most threatening scene. Clients control their progress through the hierarchy of scenes. However, if the SUD score is 2 or less, the therapist may urge them to move up to the next level or next scene. Each new weekly session begins where the previous session ended. In addition to client-controlled subjective measurements, such as SUD, objective measurements of discomfort are also used. For instance, a heart-monitoring device, such as EEG/EMG, can be employed to monitor physical reactions.

II. THEORETICAL BASE OF VIRTUAL REALITY THERAPY

The principal aim of VRT is to help reduce or eliminate anxiety and fear. Phobias are nearly always linked to people's reactions to specific situations. VRT focuses on re-creating those situations in a controlled environment. When people encounter these disturbing situations under nonthreatening conditions they find ways to deal with them. In VRT, they learn new responses to old disturbing situations, thus gaining more control over psychological disturbances and their symptoms.

III. EMPIRICAL STUDIES

In testing military navigation software in a virtual reality setting in 1992, Dr. Max North and Dr. Sarah North discovered that it made some of the participants very fearful. They concluded that this technology could not only trigger phobias but could be used to combat these and other psychological disorders. Since then, they have successfully conducted numerous studies of VRT applied to specific phobias, such as fear of flying, heights, being inside a dark barn, crossing a river in an enclosed bridge, and being in the presence of various animals. Fear of public speaking; obsessive-compulsive behavior, and other psychological disorders were also found to be responsive to VRT treatment. These research activities have established a paradigm that is increasingly attracting scientists from the computer science, psychology, and medical fields.

As clients looking into the VRT head-mounted video display turn their heads, the scene changes appropriately. Visual, auditory, and tactile stimuli create a virtual world, with which the client can enter and interact. This controlled environment allows the client to reexperience events that have caused any psychological imbalance, and, most significantly, it takes place in the presence of the therapist. VRT, like current imaginal and *in vivo* modalities, generates stimuli that are unusually effective in therapy. Moreover, virtual reality generated stimuli are of greater magnitude than standard traditional techniques. VRT allows successful treatment of disorders that have often been difficult or impossible to treat with traditional techniques. A classic example is treatment of the fear of flying phobia. A virtual scene makes clients feel they are actually flying over cities. As VRT treatment progresses, these clients gradually become desensitized.

A substantial number of research activities have confirmed the success of VRT in treating psychological disorders. Table I shows a sampling of these innovative applications.

Mental and physical health risks associated with VRT can be greatly minimized by taking precautionary measures, as pointed out by Stanney in 1995. Clients at risk for psychological harm are primarily those who suffer from panic attacks, those with serious medical problems such as heart disease or epilepsy, and those who are (or have recently been) taking drugs with major physiological or psychological effects. A professional screening process will help identify these risks. Questions regarding physical and mental disabilities must be a standard part of the admissions process, and persons with these

TABLE 1
A Brief Report of Prior VRT Applications

<i>Disorder to combat</i>	<i>Experiment conducted</i>	<i>Researchers</i>
Fear of flying	Several case studies involving fear of flying were successfully conducted. After clients were exposed to virtual aerial views, they were given real world tests. A virtual helicopter and virtual commercial airplanes were used to fly the clients over realistic terrain. Afterwards, when clients flew long distances in real airplanes, they reported significant reduction in anxiety levels.	North et al., 1994 North et al., 1995 North et al., 1996 North et al., 1997a Hodges et al., 1996 Wiederhold et al., 1998
Fear of heights	Virtual scenes that were created for two major controlled studies and several case studies included balconies of various heights, an elevator, a canyon, bridges, and a series of balloons. The result: Clients comfortably accomplished real-life situations involving heights.	Rothbaum et al., 1995 North et al., 1996
Agoraphobia (fear of being in certain places or situations)	A major controlled study centered on helping clients who suffer from being in places from which escape might have been either embarrassing to them or impossible. Several virtual scenes were created for this study. The scenes included a dark barn, a cat in the dark barn, a covered bridge over a river, empty room, and a few more related virtual scenes based on the request of the clients. In general, a subjective measurement showed that a majority of the clients' subjective measurements indicated their anxiety level was reduced and they became more comfortable in comparable real-life situations.	North et al., 1995, 1996
Autism	The challenge here was to create scenes of altered reality, of the kind clients were experiencing. Traditional treatments had often been ineffective for these clients. The virtual scenes closely tracked the distortion of environment that clients had personally perceived. This enabled them to gain new insight and to better understand the real situation.	Strickland, 1996
Body experience (eating disorders)	In this study, clients were exposed to a virtual environment that let them experience a modified body image. A partial reduction in negative feelings of body dissatisfaction was reported.	Riva, 1997a, 1997b
Fear of public speaking	Several case studies were conducted using a virtual auditorium with no audience initially. As treatment progressed, more audience and varieties of sound effects were introduced. Clients' symptoms reduced significantly, and they gained greater confidence in real-world speaking experiences after the therapy.	North et al., 1997b
Fear of closed spaces (claustrophobia)	Clients in several case studies were confronted with closed spaces in a virtual house. The spaces could be resized to suit the clients' progress, allowing them to gradually cope with their fear of closed spaces and significantly reduce their anxiety level.	Botella et al., 1998 Booth et al., 1992
Fear of driving	Volunteers tested the effectiveness of virtual reality technology in automobile driving situations. They were exposed to scenes that ordinary drivers might find themselves in, such as a series of stops, turns, heavy traffic, nearby buildings, and various hazards. Phobic participants significantly and consistently reported more anxiety than the nonphobic clients.	Schare et al., 1999
Posttraumatic stress disorder	In a case study, a Vietnam veteran was immersed in virtual jungle scenes, encountering thick foliage and armed combat, including machine guns and other weapons. The client reported significant decrease in symptoms as treatment progressed.	Hodges et al., 1999

(continues)

TABLE 1
(Continued)

Disorder to combat	Experiment conducted	Researchers
Obsessive-compulsive disorder	Another case study involved a young client who had trouble remembering to take supplies she needed for school each day. She was encouraged to prepare a virtual schoolbag with all the articles she would need on a particular day. After treatment she reported more confidence in remembering what to take to school each day.	North et al., 2000
Attention deficit disorder	A virtual classroom scene was created to help a client stay focused on studying. She was exposed to an increasing number of classroom distractions, as well as activities that could be seen outside the window. VRT was shown to be more effective than previous traditional treatments had been.	Rizzo, 2000

characteristics must be excluded from VRT experiences. Additionally, some otherwise healthy people experience symptoms ranging from headaches to epileptic seizures when exposed to certain visual stimuli. Clients must be closely observed by therapists at all times. Both the client and the therapist must agree beforehand to terminate quickly the virtual reality session if there is any evidence of significant physical or psychological distress. As a routine precaution, the therapist should ask clients to sit in a chair rather than stand during the VRT procedure. It is also recommended that the therapist use a modified head-mounted display so clients can partially see their physical body, choose the head-mounted display with a narrower field of view, and, most important, keep the sessions brief (between 15 and 20 minutes). This configuration reduces the degree of immersion while increasing the physical and psychological safety of the clients. There is a need for more research in this area. In the meantime, it is strongly recommended that researchers take appropriate steps to minimize client risks.

Therapists must keep in mind that symptoms of anxiety while under VRT are distinctly different from simulation sickness. Anxiety symptoms evoked under VRT are the same as real world experiences, including shortness of breath, heart palpitations (irregular or rapid heartbeat), trembling or shaking, choking, numbness, sweating, dizziness or loss of balance, feeling of detachment, being out of touch with self, hot flashes or chills, loss of control, abdominal distress, and nausea.

temporary jobs owned by a Clubhouse with the aim of helping them develop the skills and confidence required to cope with competitive employment.

vocational rehabilitation A range of interventions that aim to improve the quality of life and functional capacity of people who are subject to social exclusion by virtue of their disabilities, by providing them with the skills and attributes necessary for them to return to open paid employment.

GLOSSARY

akathisia A state of motor restlessness ranging from a feeling of inner disquiet to an inability to sit or lie quietly.

clubhouse A building run by clients and staff along egalitarian lines, where clients meet for social activity, mutual support and graded work experience.

expressed emotion Refers to a family environment characterized by hostility, criticism, or emotional overinvolvement.

individual placement and support model A type of supported employment approach.

prevocational training A form of vocational rehabilitation that advocates a period of preparation before placing clients into open paid employment.

rehabilitation Restoration of an optimal state of health and functioning by medical, psychological, social, and peer group support.

supported employment A form of vocational rehabilitation that emphasizes placing clients directly into open paid employment without any extended period of preparation.

transitional employment A form of vocational rehabilitation that involves the placement of clients in a series of paid but

The aim of vocational rehabilitation is to improve the quality of life and functional capacity of people who are subject to social exclusion by virtue of their disabilities. The main outcome is to reintegrate individuals back into open paid employment integrated into a community's economy. This article will present a psychosocial approach to this form of rehabilitation including the significance of work for people with mental health problems, the types of approaches offered, as well as the impact vocational rehabilitation has on psychopathology, self-esteem, and social relationships.

I. EMPLOYMENT AND MENTAL HEALTH

Work is central to human existence. It enables an individual to possess a valued social position and identity that has a significant influence on self-concept and relationships with others. As an important aspect of life

in today's society, work has a substantial effect on our fundamental aspects of personality and is a major contributing factor to our levels of self-esteem. In addition, work provides an opportunity for increasing social contact and improving skills while also providing income and financial security. Conversely, unemployment can produce high levels of stress, anxiety, and depression; low levels of self-worth; and decrease opportunities for self-development, autonomy, and social contact. The shift from being employed to unemployed is significantly associated with not only an increased risk of depression, alcohol dependence, anxiety states, and psychosomatic reactions, but also stigma, aimlessness, and poverty, which combine to trigger or amplify mental health problems. It appears that unemployment is associated with the conditions that substantially interfere with recovery from major psychopathology. This cycle of psychopathology, unemployment, and further distress, leading to further psychopathology, leading to further difficulty in adaptation and rehabilitation, is the vicious circle that spirals downwards in the lives of those with severe mental illness.

Unemployment is a major problem for all people regardless of their mental health status. However, for those people predisposed to mental health problems it makes sense that the effects of long-term unemployment could have a massive impact on their capacity to lead a happy fulfilled life. People who suffer from severe mental illness experience high levels of unemployment with rates estimated at 75 to 85%. Not only do these rates reflect the disability caused by severe mental illness, but also the discrimination experienced by this client group and the low priority given to employment by psychiatric services. Despite these high rates, surveys have consistently shown that psychiatric patients are strongly dissatisfied about not working and express a desire for competitive integrated employment.

II. THE ROLE OF VOCATIONAL REHABILITATION

Improving the course and management of severe mental illness involves not only the management of symptoms but also the social reintegration (or integration) of the psychiatric patient. Despite the recent advances in psychopharmacology for people with severe mental illness, medication is still unable to address the social impairment and skills deficits experienced by these groups that are a major contributing factor to high vulnerability for relapse. A comprehensive care package, therefore, would not only involve medication treatment and a psy-

chotherapy approach, but also interventions that provide patients with the social and occupational skills necessary for them to function at their optimum capacity in the community. The provision of these skills requires a comprehensive infrastructure of community services, in particular housing and employment, and a means for ensuring continuity of care.

In response to this increasing awareness of skills deficit for psychiatric patients, vocational rehabilitation has assumed increasing importance in the treatment package for rehabilitating people with severe mental illness. In the mid-19th century, the moral treatment of insanity regarded work as an effective therapeutic task that distracted patients from their psychotic preoccupations. This school of thought has evolved over the last half century, which has been witness to the development of a range of approaches to vocational rehabilitation for psychiatric patients.

The emphasis within vocational rehabilitation programs is, in the first instance, to provide patients with a structured day, and provide skills training that will ultimately enable them to secure open paid employment at a level that they will be able to manage. It is important to note that all psychiatric patients will require differing levels of input and the rehabilitation they receive must be highly individualized to their needs and capacity to work. For some patients this may take as little as a few months, in others as many as a few years. The type of rehabilitation a patient receives is dependent on the level of their "work-readiness," and is usually provided in the form of one of the two ideologies described later.

III. TYPES OF VOCATIONAL REHABILITATION

Prevocational training (PVT) and supported employment (SE) are the two main ideologies that have developed to help people with severe mental illness return to work.

Prevocational training otherwise known as the "trained and placed model," assumes that people require a period of preparation before entering into competitive employment—that is, a job paid at the market rate, and for which anyone can apply. This includes sheltered workshops, transitional employment, work crews, skills training, and other preparatory activities.

Supported employment, otherwise known as the "placed and trained model," places people directly into competitive employment without an extended period of preparation, and provides time unlimited, on-the-job support from trained job coaches or specialists. Much

work has been done in this area that has led to the development of a carefully specified variant of supported employment known as the individual placement and support (IPS) model. The IPS model is distinguished by six key principles. According to Becker in 1994, these are (1) the goal is competitive employment in work settings integrated into a community's economy, (2) clients are expected to obtain jobs directly, rather than after a lengthy period of preemployment training, (3) rehabilitation is an integral component of treatment of mental health rather than a separate service, (4) services are based on client's preferences and choices, (5) assessment is continuous and based on real work experiences, and (6) follow-up support is continued indefinitely.

In addition to these approaches, cross-fertilization between the two ideologies has led to the development of a number of hybrid models (or stepwise-eclectic models), that offer either a combination of, or all of, the services offered by both PVT and SE.

Although much research has been done on the effectiveness of prevocational models in terms of returning people to the workplace, up until the past 10 years limited evaluations have been done on supported employment programs. However, the past decade has been witness to a growth in supported employment programs and along with it has come a number of reviews of their effectiveness. These reviews have shown that SE appears to be more effective than PVT in terms of helping people with SMI obtain competitive employment.

An underlying assumption that has been related to work since the early asylum system is that "work is therapy." Work of the right type has been assumed to benefit patients in other nonvocational domains such as better controlling of psychiatric symptoms, increased levels of self-esteem and self-worth, and improved capacity for social relationships, all of which contribute to an overall improved quality of life. The relationship between vocational rehabilitation and each of these domains is outlined later.

IV. VOCATIONAL REHABILITATION AND PSYCHOPATHOLOGY

The pioneers of the early asylum movement hypothesized a direct relationship between employment and symptom alleviation. In modern times, however, the conceptual models within which psychiatry operates have not tended to include constructive activity as anything more than a mediating factor, intervening between sociodemographic or psychopharmacological variables and outcome in terms of symptom relief. With the treatment

of severe mental illness increasingly moving into the community, this attitude is beginning to change and the measurement of symptoms is often included among outcome measures as an indication of social adaptation and community living skills. Increasingly, these measures are being incorporated into evaluations of vocational rehabilitation services by measuring outcomes in terms of improvements to a person's psychopathology in addition to whether or not they have obtained employment.

Given that long-term mental health problems are commonly linked with chronic unemployment, it is not surprising that an improvement in socioeconomic status in the psychiatric patient improves psychopathology and prognosis. There are two likely explanations for this. First, the direct financial benefits of moving from an impoverished lifestyle will produce both mental and physical health gains, and second, the problem of chronic patienthood relates to social marginalization. The emphasis on employment or work, in "normalization" or "social valorization" rehabilitation theory, reflects a strategy to reverse this marginalization.

An additional latent clinical benefit of some work schemes is that they provide structured opportunities for supervision and treatment compliance. Support is often provided in the workplace for those who need it and in addition to an awareness of whether a person has taken medication or not, often an individual will not want to jeopardize their job by failing to take their medication and increasing the likelihood of relapse. A negative aspect of medication is that for many people the sedation effects and akathisia caused by medication make work tasks difficult. Therefore, until the medication regimen is stable, work would not be considered a feasible option.

Not only does employment appear to have a positive effect on psychopathology, but symptom alleviation could also be seen as a consequence of improvement in other facets of an individual's life, which again, are influenced by vocational rehabilitation. This type of rehabilitation is thought to have a significant impact on the level of self-esteem, which in turn can promote improvements in mental state.

V. VOCATIONAL REHABILITATION AND SELF-ESTEEM

Self-esteem is the evaluation people make and maintain about themselves and has been defined as evaluation of one's own worth, value, or importance. It is essential to our ability to function in a healthy way. Without the foundation of a solid sense of self-worth,

we are unable to take the risks and make the decisions necessary to lead a fulfilling, productive life. A low self-esteem has a negative effect on our relationships, careers, family bonds, and, most important, our internal sense of well-being. A high self-esteem, on the other hand, brings the high level of confidence, problem-solving abilities, and assertiveness needed to achieve what Maslow referred to as "self-actualization"—a continuous desire to fulfil potentials, to be all that you can be. Obviously this refers to everyone regardless of their mental health status; however, for psychiatric patients, this is a state that is particularly difficult to achieve. People who have positive self-esteem have healthier, stronger relationships with those with negative self-esteem. A strong sense of self-worth actually creates a type of self-fulfilling prophecy. The more people like themselves, the more they begin to act in likable ways, the more they believe they are able to achieve something, the more likely it is that they will.

The concept of self-esteem has been widely used as an outcome variable in studies of rehabilitation. This is based on the assumption that a higher level of functioning is coexistent with a higher level of self-esteem and feeling of self-worth. The sources of self-esteem are regarded as personality related and as a function of intrapersonal evaluation, individual roles, role accumulation, or early childhood experience. Self-esteem has two essential elements, social status and affirmative experience. Social status refers to an individual's position in society relative to others, and is most often measured in terms of household income, educational attainment, and occupation. As employment is a major source of social status, it may, therefore, be argued that employment in a respected occupation is a means of restoring the self-esteem of people with mental health problems that cannot be obtained in any other way. Affirmative experiences are experiences in which individuals receive positive reinforcement from others about their abilities and behavior. Affirmative experiences can usually be obtained through a variety of social encounters; however, people with mental health problems may have limited opportunities for social interaction. Hence, work in a nonstigmatized setting may enhance the self-esteem of people with mental health problems.

Goodman and colleagues in 1994 found that in psychiatric patients, low levels of self-esteem were found to be associated with higher levels of psychiatric disturbance and higher levels of external locus of control among African-American women. The potential of employment to influence self-esteem is shown by the Rosenfield model. Rosenfield's 1992 study of a Club-

house took "mastery" as a pivotal concept, defined as "a personal resource that can moderate or help in coping with the effects of stress. . . . A low sense of mastery affects subjective quality of life because it results in feelings of hopelessness and passivity." Rosenfield points out that many psychotherapists have suggested increasing a sense of mastery as the first task in psychotherapy for people with chronic mental health problems. Leading on from this she set out to explore associations among vocational rehabilitation, mastery, and quality of life. She concluded that economic resources and empowerment increased a sense of mastery and hence a better quality of life. Controlling for perceptions of mastery, she also found that having a greater time structure as imposed by work, increased people's quality of life.

Studies comparing people with mental health problems who were either in competitive employment or unemployed, found that those in competitive employment had significantly higher self-esteem than those unemployed. In addition, studies have also shown that patients working in sheltered workshops had a high level of self-esteem associated with the opinion that their job held a "valued social position."

Given the obvious importance self-esteem has on both people's capacity to lead a fulfilling life, and the type of employment they consider themselves suitable for, and able to do, rehabilitation in conjunction with psychotherapeutic interventions need to implement techniques that focus specifically on increasing levels of self-esteem.

VI. VOCATIONAL REHABILITATION AND SOCIAL RELATIONSHIPS

Our levels of self-esteem also have a significant impact on our ability to maintain social relationships. This can be seen as a self-perpetuating circumstance in that a low level of self-esteem severely disables a person's ability to interact and build social relationships. Conversely, interaction and social relationships can help build a person's feeling of self-esteem and self-worth and make them feel wanted. Social support or interaction can be seen as part of our basic need for belongingness and love and is defined as the degree to which a person's basic social needs are gratified through interaction with others.

Psychiatric patients commonly suffer deterioration of social relationships, particularly in the case of schizophrenia. Evidence for the importance of social support

in schizophrenia is growing with research showing that psychiatric service users have smaller social circles than people without mental health problems. In addition, patients with schizophrenia also perceive themselves to have fewer people offering instrumental support, and fewer social companions than those suffering with depression.

Although an understimulating social environment has been shown to be associated with clinical poverty syndrome, or institutionalization, conversely, an overstimulating one can precipitate psychotic episodes. Given that patients with schizophrenia tend to react adversely to overstimulation it is unsurprising that they withdraw from social interaction and are reluctant to enter a work environment. The emphasis here is on both the level of stimulation and the level of communication required to operate within the workplace. Obviously both of these factors need to be at a level that is suitable for each individual, while acknowledging that thresholds will be different for each person.

It is important to note here that the quality of the relationships within work is of importance. Relationships are bidirectional in that they can be seen as reciprocal or dependent. Although psychiatric patients may consider themselves dependent on a relationship in terms of receiving support, they must possess a sufficient level of social skills to maintain that relationship. Therefore, diminished social interaction may be due to the breakdown of social skills, which then places the person at a disadvantage in terms of disabling his or her capacity for beneficial social interaction.

People with mental health problems who are entering a work environment are exposing themselves to an entirely new source of social supports. These supports can be seen as “natural” (e.g., from colleagues) or “constructed” (e.g., from supervisors or job coaches). These relationships can be then further built on in order to provide both emotional and instrumental support, in some cases becoming friendships that extend beyond the workplace. The Clubhouse movement advocates this ethos in its work intervention known as transitional employment. For psychiatric patients, constructed networks derived from therapeutic settings may serve as a substitute for poor social networks outside work.

Another important aspect of employment that may facilitate improvement is removal of psychiatric patients from the home environment where their social contacts may have a high level of expressed emotion (EE). Research in EE has clearly demonstrated that medication and removal from relatives who have high EE can protect the psychiatric patient from relapse. It

therefore follows that a structured work environment to where the patient can “escape” on a regular, structured basis may serve as a protective factor. It is of obvious importance that the work setting does not replicate high levels of EE. This can be prevented by education of supervisory staff and colleagues about the concept and manifestations of EE.

VII. INTEGRATION OF VOCATIONAL REHABILITATION EFFORTS IN PSYCHOTHERAPY

Given the psychosocial aspects of vocational rehabilitation, there is a common link between this type of intervention and that of psychotherapy. Both interventions share the goal of increasing the functional capacity of the individual. The difference is that within psychotherapy, the improvement of psychopathology, self-esteem, and the capacity for social relationships are specific aims, whereas in vocational rehabilitation, they can be seen as by-products of improving an individual's capacity to work.

In terms of provision of these interventions it would be desirable to offer them within a framework where all aspects of the patient's care are provided collaboratively and communication between the services is common. Both interventions require the input of specialized individuals and it is unlikely that an individual or particular caregiver will be expert in both enough to integrate them into his or her practice. Therefore, it is often the case that both interventions will be carried out by separately trained practitioners who may not share the same views of the nature of psychopathology. They may have differing subtle and not so subtle goals and ideas about what is practical for an individual to achieve, and consequently the opportunity for conflict between the two may arise. Consequently if they are not organized out of the same agency providing care and leadership in treatment planning, they must commit themselves to a regular form of communication in which they share their ideas and assessments of individuals. Regular discussions need to take place concerning what the individual wants to achieve and whether it is feasible, what difficulties may be encountered, and perhaps most important any difficulties that may arise in their relationship with one another as they collaborate in the care of the individual. It is important to acknowledge here the existence of one such mechanism that aims to achieve treatment integration. This mechanism is known as case management, which involves a team of professionals

with a limited number of cases for each intervention, thus reducing the workload and enabling more time and commitment for patients' care. The emphasis within the team is on collaborative working, with regular meetings for discussion about patients.

Only by collaborative working between all services involved in a person's care will we be able to bring the management and rehabilitation of psychiatric patients together in an organized cohesive manner. This will enable us to ultimately provide a seamless service working closely together with the common goal of improving the overall functioning and capacity of the psychiatric patient, thus facilitating (re)integration back into the community.

GLOSSARY

gender identity The perception of oneself as being either male or female, and the acquisition of social roles culturally appropriate for that person that are gender linked.

gender role A cultural construct referring to the expectations, attitudes, and behaviors that are considered to be appropriate for a particular gender in a particular culture.

sexual orientation The sexual preference of a person based on gender, i.e. homosexual, heterosexual, bisexual.

I. INTRODUCTION

Gender is an important variable in psychotherapy. Gender can influence a patient's choice of therapist, the

"fit" between therapist and patient, and the sequence and content of the clinical material presented. It also affects the diagnosis, length of treatment, and sometimes outcome. Gender differences in experiences affect the perception and interpretation of patient material. Biologic aspects of gender must be considered from a perspective that reflects emerging data that unify brain and mind, biological, and psychosocial factors.

Evidence of gender differences in the nervous system beginning in fetal life suggests that, from birth, boys and girls may not perceive and experience the world in the same way. Gender differences in neural maturity and organization influence behavior and reactions in infants that can also affect caretakers' response, further reinforcing differences. These differences in reactions can alter the growth and development of neuronal pathways. Experience modifies the structure and function of neurons and neuronal networks, and can modify gene expression. Brain structure, metabolism, and function are also affected by psychotherapy. These findings reinforce our understanding of the plasticity of the brain and how it is affected by behavior and experience. The implications of these data underscore that the distinction between biological and psychosocial is both artificial and misleading.

In this article we focus on the relationship between gender and psychotherapy, considering psychosocial and biological variables. We will examine biological influences, developmental and life experiences, gender differences in personality styles, and the effects of stereotypes and values.

II. VALUES AND TREATMENT

Personal and social values affect standards of normality and influence the perception, diagnosis, and treatment of mental disorders and emotional problems. Although there have been changes in concepts of normality, mental illness, and the range of behaviors and attitudes that are thought to characterize each gender, evidence suggests that there continue to be differences in what is considered normal for men and women, even by therapists. Broverman and colleagues in their classic 1970s study found that when male and female psychotherapists were asked to describe a mentally healthy person, psychological health was more closely associated with descriptions of "healthy, mature, socially competent" men than with concepts of maturity or mental health of women. Although a 1990 report by Kaplan and co-workers noted that attitudes toward gender roles have changed to some extent, and that male and female psychiatrists' beliefs regarding gender-appropriate behavior had become more similar and less stereotyped, ratings derived from the Bem scale indicated that female and male psychiatrists were still more likely to choose stereotypical traits to define mental health.

Although concepts of normal masculine and feminine behavior and attitudes have shifted, these changes are not necessarily integrated into a cohesive view of normality for either men or women. Attitudinal changes may be consciously adopted by those treating a patient, but unconscious views about what is "normal" may be unchanged and can affect therapy.

Values are communicated to patients in both overt and subtle ways in the process of evaluation and referral as well as during treatment. In psychotherapy, therapists communicate values by their selection of material to respond to, by the timing of their interpretations, and by their affective reaction to the content of what is said by the patient. This subtle communication conveys the therapist's judgment. For example, the therapist may emphasize or ignore the patient's references to menstruation, to taking drugs, or to engaging in risky sexual behavior and women patients may be more reluctant to discuss these with male therapists. By responding, the therapist expresses a judgment of what is important and to whom, and consequently may misinterpret the importance of these issues for the patient.

Gender also affects treatment priorities and approaches. It has been suggested, for example, that concern about some more characteristically male behaviors, such as violence related to alcohol abuse, may lead to the development of treatment methods that are more suitable for men. These methods may also be used for

women, although there is evidence that they are less effective for them. Likewise, more attention may be paid to treating the adolescent schizophrenic or substance-abusing man, because of the threat of violence, than to treating the seriously handicapped but less threatening women with posttraumatic stress disorder (PTSD) or depression.

III. GENDER INFLUENCES AND DIFFERENCES IN EARLY DEVELOPMENT

Early influences and endowments, both biological and psychosocial, are important in the shaping of personality. In childhood, the presence or absence of continued stable care, styles of child rearing, the responsiveness and nurturance of people in the environment, physical health and illness, loss, and trauma, as well as biological endowment, are all determinants of the ultimate configuration of personality.

Complex integrative functioning, such as conceptualization and learning of language and social skills, derives from both biological and psychosocial influences. These may differ between males and females. The effects of particular cultural practices, including gender differences in child rearing, and ideas about gender-appropriate roles are also manifested very early in life and affect development. Parental behavior affects male and female roles and is a powerful developmental force.

Ideas about the determinants of gender identity have changed from the early views that the major determinants of gender development were anatomical, to a view that development and gender concerns represent a complex interplay of anatomy, genetic endowment, and environment including developmental experiences and cultural context. These include the structure of the family, the presence and roles of other siblings, the mother's other pregnancies, and many aspects of the child's relationship with extended family and others.

There seems to be a connection between early trauma and the development of personality disorders, especially borderline personality disorder, which is more commonly diagnosed in women than in men. There is evidence that developmental disruptions occur when an individual is traumatized early in life.

Gender role is a cultural construct referring to the expectations, attitudes, and behaviors that are considered to be appropriate for each gender in a particular culture. There are enormous differences in the roles and expectations of men and women in different soci-

eties. Some societies dictate more rigid and fixed roles than others. Not all value the same traits or see certain traits as gender specific in the same ways. For example, physical strength is often considered a male characteristic, but despite their smaller size and lesser physical strength women in some cultures are assigned the heavy work. The role most consistently assumed by women across cultures is early child rearing.

During early development, in all cultures, the mother remains the primary caregiver of young children. The earliest attachment is more likely to be made with her. She becomes the primary identification figure in early childhood, for both boys and girls. Therefore, for girls, the first identification is with the parent of the same sex. For boys, the first identification is with the parent of the opposite sex. As girls grow up, this same-sex identification does not have to change in order for feminine gender identity to consolidate. Thus, girls learn about being women in identifying with their mothers. Boys, on the other hand, must shift their primary identification away from their mothers in order to develop a male gender identification. Thus, they move away from their early attachment.

For girls, the continuity of attachment to their mothers, and the fear of loss of love by manifesting aggression that is disapproved of, may make it more difficult to establish autonomy and independence. Aggression, competitiveness, and anger may be difficult to manage because these affects can threaten loss of relationships. It can be difficult for women to express themselves freely, especially when they experience anger and aggression, and, at the same time to preserve relationships. This may be seen later in life in a woman's conflict about aggression, manifested in her difficulty in being appropriately assertive and in her inhibited risk-taking or autonomous behavior. Cultural values such as independence, initiative, and competitiveness have been considered positive characteristics for males, but not for females.

Because of the primacy of relational ties, women also may be more vulnerable to loss throughout their lives. One of the syndromes that has been seen as related to the conflict about autonomy and independence and the sense of vulnerability to loss is agoraphobia, which is more commonly diagnosed in women than in men. Although this syndrome has multiple determinants, it may represent anxiety about moving out into the world and feeling alone. Depression is also more frequently diagnosed in women than in men. The reasons for this are complex and unclear, but multidetermined, including conflicts about aggression and mastery, social deprecation of feminine roles, identification with depressed mothers, early loss, and biological factors.

In contrast, disturbances involving violent, aggressive behavior, and problems with impulsiveness are more often diagnosed in men. Conflicts around intimacy and socialization toward aggression and action are consistent with this picture in men. These findings raise questions about the factors affecting the process of diagnosis itself, particularly with Axis II disorders. Because these disorders more generally reflect clusters of observed personality characteristics rather than specific symptoms, incidence figures may reflect biases and sex-role stereotypes.

At times, women may also fail to act in their own best interests because of their desire to preserve relationships, even if these are abusive. This can result in behavior that may continue to put them at risk for victimization. The threat of loss then, may motivate behavior that can be interpreted as masochistic. For women, the conflict experienced about aggression can result in turning aggression inward, with excessive self-criticism and diminished self-esteem. Culturally supported passivity with consequent feelings of helplessness can be risk factors for depression. Problems in the development of self-esteem, for girls, appear to be intensified in adolescence. Gilligan found that there are gender differences in self-concept and identity in adolescence. Males generally define themselves in terms of individual achievement and work, and females more often in relational terms. Gender differences in depression, except in bipolar illness, appear to have their onset in puberty, a time when girls begin to assume adult feminine identities and roles.

IV. BODY IMAGE AND REPRODUCTION

With the beginning of puberty, girls and boys experience their reproductive identities in different ways. For girls, menarche signals a capacity for pregnancy. This change also brings a potential vulnerability for girls that is not in boys' experience. It is both a positive experience and a source of risk and anxiety. Girls develop new organs, breasts, transforming their bodies. This has no parallel in boys. For a girl, menarche is an organizer of sexual identity. It is also an undeniable physical experience, and it can be a source of pleasure and conflict about growing up and about femininity. Adolescent girls in Western cultures are bombarded with media images of women who are loved because of their physical appearance. Self-esteem and self-confidence rest heavily on physical attributes and body image especially during adolescence, for both sexes.

Conflicts around self-image and body image become more prominent during adolescence and can be expressed differently for boys and girls. Discomfort with body image and fear and ambivalence about mastery, independence, separation from family, and adulthood including sexuality, are difficult issues that are thought to contribute to the dramatic incidence of eating disorders in adolescent girls. They may literally attempt to starve themselves back into childhood and diminish female body characteristics (e.g., curves and breasts).

V. THE ROLE OF REPRODUCTIVE LIFE EXPERIENCES

Women's life cycles are closely connected to their reproductive potential. The acknowledgment of a woman's reproductive capacity is an important component of her sense of identity and femininity, regardless of whether or not she actually bears children. The knowledge that there is a finite time period for reproduction also influences her concept of time. She must make different decisions about career and family than men do. This difference can affect her emotional state, her decision to seek therapy, and the issues that will be raised in the course of therapy. With delays in the time of childbearing for contemporary women, many come to treatment as they approach 40 or in their early 40s to deal with issues around childbearing. They have not confronted their biological clocks and must deal with the issues of reproduction before it is too late.

Reproductive events, decisions, and choices may have different significance for men and women, thus affecting the process of therapy. Because reproductive issues are more likely to be addressed for female patients, male patients may find that their reproductively related concerns are not dealt with. Therapists often share the patient's reluctance to explore these issues. This avoidance may result from the conscious or unconscious conviction that exploration of a man's infertility or sexual dysfunction would be too great a threat to his view of his "masculinity."

Pregnancy as a life event marks a transition to motherhood and raises many issues for a woman, including her relationship and identification with her mother. Although pregnancy is usually experienced positively it also increases a woman's vulnerability to specific psychiatric disorders, particularly postpartum depression.

Infertility is also a different experience for men and women, and there are different issues to consider in treatment. Historically, and in some cultures today, women have been seen as the sole responsible partner when there

is infertility. A woman's pregnancy has been viewed as a confirmation of a man's masculinity and potency. Infertility can be a threatening and distressing problem for both men and woman, but in different ways, depending on how important it is to each partner and what the etiology is. Social norms have supported men's resistance to be involved in infertility workups and treatment.

Menopause is a unique marker of the life cycle for women. Stereotyped expectations about women's life cycle and the attribution of midlife symptoms to menopause have resulted in the confusion of the experiences of this time of life, including concerns about the physical and emotional aspects of aging, family changes, shifts in goals, and retirement, with the effects of the physiological event of cessation of menses. Menopause has been linked with depression and loss, but there is no evidence supporting that this is an inevitable connection. Those women who become depressed in midlife are generally those who have had depressions at other times in their lives. The peak incidence of depression in women, in fact, is in early adulthood. Responses to menopause are also strongly influenced by cultural expectations, and in many cultures, women regard the cessation of menses and childbearing with relief and sometimes with greater enjoyment of sexuality.

VI. GENDER AND CHOICE OF THERAPIST

Patients give many reasons for their choice of a therapist. These reasons have often been based on stereotyped views such as "men tend to perpetuate patriarchal values," or "women are more nurturant."

The search for a role model is often a determinant of the choice of a therapist. Women frequently feel that a woman therapist will be more responsive to their wishes for achievement, success, and self-actualization or that because she has faced similar conflicts she could empathize with them more easily. Although this idea may facilitate the development of an alliance, it does not by itself resolve the patient's difficulties.

Women may also request to see a woman because they seek permission to succeed in certain goals, particularly those involving career. Permission, explicit or implicit, can result in improvement and can enable the patient to compete and succeed, even if the issues are not taken up specifically and explicitly. Identification with a therapist is also important. Although the reasons for the choice may be based on stereotypes, without regard for the characteristics of the specific therapist, the patient's feel-

ing of greater comfort or empathy can facilitate the initial development of a positive therapeutic alliance.

A patient's gender-based choice can also derive from idealized fantasies about the characteristics and capacities of the clinician and what he or she can do for the patient. For example, if the clinician is a prominent person in the community, expectation based on this status can affect the therapeutic relationship. If the patient makes a choice because of particular political views, sexual orientation, or the cultural heritage of the therapist, treatment may begin with positive feelings, only to have these reversed if, in the course of treatment, the patient is disappointed. The recognition that the therapist is not omnipotent repeats past life experience. If there is a negative outcome it may be blamed on the therapist's gender. If the therapist is a woman who is not the fantasized omnipotent mother who can transform the patient, devalued ideas about women can be confirmed.

Choosing a therapist of a particular gender with the expectation that this will resolve the patient's problems can also be a resistance to therapy. A woman may want to see a woman for treatment because she feels unlovable and unattractive to men and can, in this way, avoid the experience of confronting her feelings or initially because she wants support, and later devalues the therapist or find herself in an angry competitive interaction, which can be a repetition of her relationship with her mother. She may be unaware of the origins of her feelings or the reasons for her choice of a therapist. Although there are conscious reasons for choices, unconscious factors or needs such as fear, anger, or a search for mothering may be important and should be considered in the initial encounter with a patient. For a woman, the choice to be treated by a woman can also represent a wish to restore the relationship with her mother or to have a better mother. A desire to see a male therapist can be based on the desire to avoid this maternal kind of relationship or the anxiety that these feelings arouse, or may reflect anxiety about the intense attachment that may be evoked by a woman.

Many support the view that women should be treated by women in order to avoid being misunderstood or treated from a male-oriented perspective. This oversimplifies the effects of gender and minimizes the necessary working through of ambivalence and conflict in the therapeutic relationship.

Concerns about sexualization and sexual relationships in treatment have become important factors in requests based on gender. For those patients who have actually been abused in previous treatment, trust can be severely damaged. It may be particularly difficult for such patients to see anyone who serves as a reminder of

that previous experience. Women therapists are often asked to see women patients who have had sexual involvements with male therapists. Although it does occur, women are less likely to become sexually involved with their patients, either male or female, than are men.

Sexual orientation has also become a consideration for many gay individuals who request therapy with gay therapists. They feel that a gay therapist will better understand and empathize with them and will be less likely to judge their sexual object choice as pathological. Although there has been controversy about the appropriateness of disclosure of the therapist's sexual orientation, some therapists believe that this disclosure can be beneficial in therapy.

Stereotypes and expectations about women affect male patients as well. A man may seek treatment from a woman therapist in order to avoid a competitive or authoritarian relationship with a man, to avoid homosexual feelings, or because he has had poor relationships with women in the past and wants to work these out with a woman. His expectations may be that a woman will provide the cure for his problems with intimacy.

VII. THE THERAPEUTIC PROCESS

Understanding the concept of transference can clarify aspects of the therapeutic relationship that may otherwise be difficult to comprehend. The attitudes and feelings brought to a relationship from past experiences with important figures such as parents are components of future interpersonal interactions. The need to please or to gain love by acquiescence or seductive behavior can be brought into the therapist-patient relationship as if it were a response of the patient to the therapist as a real person in the present. The therapist can be seen as rejecting, authoritarian, giving, preferring other patients, and so on.

The classical conceptualization of transference assumed that both maternal and paternal transference could be developed toward both male and female therapists. Thus, the therapist's gender was not a particularly salient consideration. Freud came to believe that transference responses to a male analyst differed from those to a female analyst. Subsequently, however, Horney emphasized the importance of the competitive transference with the same-sex analyst, and Greenacre stated that strong gender preferences should be respected, but also carefully analyzed because prior wishes, expectations, and fantasies could affect not only the choice but also the course of the psychoanalytic process.

Gender can affect the initial relationship and the early evolving transference, as well as the sequence in which therapeutic issues emerge, and the pace at which therapy progresses. For example, working with a woman therapist can evoke maternal transference material earlier in therapy. Transference expectations may cause some patients to fail to reveal details of sexual abuse or other sexual experiences to a male or female therapist depending on the patient's view of how the therapist might hear or react to this information. This lack of disclosure may also be related to the patient's stereotypical ideas as well as the particular characteristics of both patient and therapist.

Assessment of the kinds of transference engendered may be complicated by the countertransference of the person doing the assessing. Although an erotic transference may occur in a man's transference to a woman therapist, it is more common for women patients to develop an erotic transference to either male or female therapists. This can create problems, particularly for the inexperienced therapist. The idea that a real romantic or sexual relationship can be therapeutic to a patient can be difficult to reject if the patient passionately pursues this or demands it, particularly if she is suicidal and it may be rationalized as life-saving. Sexual relationships with patients are ethical violations, boundary violations, and leave the therapist open to legal action as well as therapeutic failures. When these become an issue in therapy, a consultation and supervision is very important.

Transference can take many forms, including cross-gender manifestations. It is possible for a woman patient to develop a paternal transference to a woman therapist. It may be difficult for the therapist to imagine himself or herself as the cross-gender person or for a man to imagine himself as a mother or a woman as a father.

Current views of transference emphasize that the therapist or analyst plays a role in the creation of the transference, even if this is not consciously recognized. Thus, recognition of the effect of the gender of both participants is important.

Change or reassignment of a therapist on the basis of gender has been widely discussed and is often recommended. Some have suggested that a change of therapist might mobilize a stalemated situation. Transfers on the basis of the therapist's gender have also been made when there is a therapeutic impasse or failure.

Unless there has been a sexual interaction, however, it is rare that gender itself is the significant variable in the majority of cases that are not successful. A transfer based on gender may be a way of avoiding responsibility for failure or dealing with the embarrassment of a negative outcome. Person suggested that women thera-

pists are often referred particularly difficult patients after these patients have failed a first therapeutic effort. Because gender affects trust and compliance in psychotherapy, change in the therapist based on gender might be helpful in some situations.

VIII. GENDER CHOICE IN COUPLES AND FAMILY THERAPY

As with all forms of therapy, gender is a consideration in the choice of a therapist for couples or families. In general, as with individual therapy, issues related to gender choice should be clarified and addressed. A couple with marital difficulties may request a female therapist because it is the wife who has made the call and it is her preference, perhaps because she feels intimidated by men or because she fears that she could be left out of the male dyad if the therapist were male. On the other hand, a husband may choose a woman or comply with his wife's choice of a female therapist because he is more comfortable and less threatened by women, because he does not take the therapy seriously, or because he has negative feelings about women. The choice of a male therapist for some couples may re-create, in the transference, a paternal or authoritarian relationship or even the fantasy of possible sexual abuse. This can be a special problem if abuse has actually occurred.

During the course of therapy, attention must be paid to bias regardless of whether the therapist is male or female. Transference issues in couples and family therapy are multiple and more complex because more people are directly involved in the therapy. For example, each partner and the couple as a unit will have different transference reactions to the therapist and to each other. If there are additional family members involved they too will add to the transference complexity.

Changes in family patterns have presented an increasing array of challenging issues for therapy. For example, the stress and demands of dual-career or commuting families, especially those with two achievement-oriented partners, can create enormous tension. This may be a greater source of conflict if the wife is earning more money, or if there is a job offer to either partner in another city. Because the husband's work has traditionally been the motivating factor in a relocation, a wife's job offer can create tensions, especially involving competition. A wife who achieves success later in life can be on a different timetable than her husband, who may wish to retire earlier.

Feminist critiques of family therapy express concern about the structural-hierarchical dominant role of

males in the family, mother blaming, assumptions about sharing power and responsibility embedded in systemic concepts, and assumptions about therapist neutrality. Family therapy has also been criticized for biased treatment of men, for example, for reinforcing the socialized limitations of male roles.

IX. GROUP THERAPY

As with couples and family therapy, there are gender issues in group therapy. When group therapy is sought or recommended, the gender of the group therapist is not frequently considered, although the gender composition of the group is often thought to be important. There are data suggesting that group behavior between group members and with the leader is affected by gender.

Women often seek women's groups because in groups of men or even in mixed groups they feel powerless, intimidated, and uncomfortable about speaking up. One need only look at classrooms, professional meetings, and business groups to recognize that women speak less often than men, and when they do speak, their comments are more often ignored or attributed to men. Women report the same experiences, regardless of professional status or income. They may feel supported and less anxious in same-sex groups, although mixed groups may be helpful in confronting these issues.

Most often single-sex groups have been used for support and consciousness-raising. Both male and female self-help groups often form around a specific focus (e.g., substance abuse, divorce, family violence) and use problem-solving approaches.

Therapy groups with both male and female leaders permit men and women to deal with transference issues, both as peers and as leaders. It is important, however, that the leaders' relationship with each other, just as with male and female therapists in family therapy, be a facilitating rather than inhibitory factor. Mistrust, competition, and anger that are not addressed in either leader or group members can be unproductive and inhibitory to group process.

X. SEXUAL ABUSE

When there is a history of early trauma, especially sexual abuse, which is more common in women, the impact of the trauma and the betrayal by parental figures or those in authority can result in psychopathology that can emerge later. It can be understood as an etiological factor in the increased likelihood that sur-

vivors of childhood abuse will be victimized as adults. Studies also report profoundly self-destructive behaviors emerging after victimization. Somatic symptoms can also develop later. The aftermath of abuse, particularly after repeated abuse, is often a residual sense of helplessness and loss of autonomy. This may intensify conflicts about dependency and stimulate self-criticism, shame, and guilt in many areas of life. Difficulty handling anger and aggression, and persistent feelings of vulnerability are also common repercussions.

For those who have been abused, the ability to form a trusting therapeutic alliance may be difficult. This is an example of a situation in which patients may not seek or continue therapy if they are not comfortable with the therapist, and in this way gender may be a variable.

Some of the responses and behaviors of those who have been victimized evoke profound countertransference reactions in those treating them. It may be difficult to work with battered and abused women, who often evoke frustration and anger because of their tendency to displace anger, their passivity and failure to follow through on suggestions, and the frequency with which they return to the abusive situation. Some therapists overidentify with these patients and may also project their own feelings, fantasies, or experiences onto their patients. These may include judgment about the appropriateness of the patient's response. Rescue fantasies may occur in both male and female therapists when they treat abuse victims and can lead to therapeutic problems such as boundary violations. The therapist may attempt to become the loving, nonabusive parent that he or she thinks the patient should have had instead of the real, abusive parent. These countertransference problems can compromise the therapeutic relationship.

XI. ALCOHOL AND SUBSTANCE ABUSE

There is less known about the epidemiology and treatment of alcoholism and substance abuse in women than in men. Pharmacological treatments have often paid little attention to the different presentations, physiology, and needs of men and women. For example, women's smaller body size, higher body fat content, and lower alcohol dehydrogenase levels contribute to higher blood alcohol concentrations in women with the same alcohol intake, and to the greater effect of smaller amounts of alcohol in women. Likewise, there are psychological and sociocultural factors affecting the behavior of those with alcohol and substance abuse. Currently, treatment approaches are similar for men and women, and do not ac-

count for gender differences. For example, treatment programs attempt to dissociate abusers from their alcohol- or drug-using peers, placing women drug and alcohol abusers at a disadvantage because they are more likely to live with partners who are also abusers and who discourage or prevent them from seeking help with threats or actual physical and/or sexual abuse.

Women respond better to relational involvement in treatment programs. They are more likely to attend and participate in women's groups. Because women's substance abuse often is less visible than it is for men, their abuse is often not recognized by family and friends so they are not encouraged to seek treatment.

XII. CONCLUSION

It is apparent that gender is an important treatment variable and that attention to the particular needs and experiences of women, together with better understanding of the complex interaction of gender and other variables, will shed light on the therapeutic process and contribute to greater therapeutic effectiveness. We have seen that gender can influence the patient's choice of therapist, the "fit" between therapist and patient, the sequence and content of the clinical material presented, the diagnosis, length of treatment, and the outcome of the treatment. Stereotyped views, expectations, and unconscious transference and countertransference fantasies about gender differences and what they will mean in the therapeutic process often persist and are influential, regardless of whether they have demonstrable validity. As more attention has been paid to the real attributes of the therapist, age, race, culture, gender, life experiences, and other variables have been understood to play an important role in the therapeutic process.

I. OVERVIEW OF THE WORKING ALLIANCE

For years, researchers conducted numerous studies to determine whether or not various psychotherapies were effective in relieving clients' problems, and if they were, which types of therapy were most effective. Large-scale reviews of these studies in 1994 by Michael Lambert and Allen Bergin, in 1986 by William Shapiro and colleagues, in 1980 by Mary Smith and colleagues, and in 1997 by Bruce Wampold and colleagues established that psychotherapy worked and that there was little difference in the effectiveness of different forms of psychotherapy. Since different types of therapy are virtually equally effective, some researchers have focused on the characteristics that all therapies have in common that contribute to client improvement. These characteristics are known as common factors, because they are procedures or processes that occur in all types of therapy regardless of the theoretical orientation of the therapist.

The working alliance refers to the collaborative relationship between therapist and client where the two establish a bond and agree on the goals of therapy and tasks to be undertaken to achieve them. It is a common factor that impacts outcome across a variety of therapies. Some theorists and researchers even believe that the working alliance is more important to outcome than the type of therapy that the therapist uses. In 1988, in an article on the integration of all forms of

GLOSSARY

- common factors* Procedures and processes that occur in all types of therapies regardless of the theoretical orientation of the therapist.
- effect size* The statistical degree to which differences or relationships between groups exist.
- meta-analysis* A statistical analysis that combines the results of several empirical studies.
- working alliance* Client–therapist bond and agreement on the goals of therapy and tasks to be undertaken to achieve them.
- Working Alliance Inventory (WAI)* A scale that enables assessment of the common alliance factors of client–therapist bond and agreement on goals and tasks of therapy. Ratings may be done by clients, therapists, and outside observers.

The working alliance is a collaborative relationship between client and therapist that is common to all types of therapies and enables therapeutic success. This article presents an overview of the theoretical foundations of the alliance and a review of research on the quality of the alliance and its relationship to therapeutic outcome.

therapy, Barry Wolfe and Marvin Goldfried called the working alliance the “quintessential integrative variable.”

II. THEORETICAL BASES OF THE WORKING ALLIANCE

The concept of working alliance originated in psychoanalytic psychotherapy that is designed to make unconscious conflicts and feelings conscious. The analytic patient relates to the analyst in a distorted manner that mirrors these unconscious conflicts. In 1912, however, Sigmund Freud also posited a positive relationship between the analyst and patient that was based in the reality of their work together. This relationship later became known as the working alliance.

To humanistic therapists who believe that people are capable of helping themselves if they are provided with a facilitating relationship, the working alliance is both necessary and sufficient for client improvement. According to Carl Rogers in 1957, the therapist was responsible for creating this facilitating relationship by demonstrating empathy, genuineness, congruence, and unconditional positive regard toward the client. Within this accepting environment, the client was then able to achieve self-acceptance and self-actualization. This relationship would then generalize to other relationships outside of therapy. Thus, for Rogers, the working relationship was directly responsible for client improvement.

Behavioral and cognitive-behavioral therapy, which are based on learning principles, did not originally address the client–therapist relationship. In 1977, however, the Association for Advancement of Behavior Therapy (AABT) published ethical principles for behavior therapists. These principles emphasized client agreement with the goals and methods of treatments that are important components of the working alliance. Thus, most behaviorists and cognitive behaviorists stress the importance of the working alliance.

The working alliance is just one term for the collaborative relationship between client and therapist. Different theorists highlight different aspects of the alliance, and as a result, it is sometimes referred to as the helping alliance or therapeutic alliance. In 1979, Bordin put all the elements of the working alliance together into one conceptualization that applied to all types of theories and therapies. He defined working alliance as a bond between client and therapist and an agreement on the goals of therapy and the tasks necessary to achieve those goals.

III. EMPIRICAL STUDIES

Interest in the working alliance as a common factor in all types of therapies has spawned considerable research. This research is primarily, but not exclusively, concentrated in three areas: assessment of the alliance, the relationship of the alliance to outcome, and changes in the alliance across time.

A. Alliance Assessment

Because different researchers emphasize different aspects of the working alliance, they have developed scales to measure the alliance that reflect their theoretical interests. For instance, in the 1980s, Lester Luborsky and his colleagues at the University of Pennsylvania developed what are now known as the Penn Scales to assess client, therapist, and observer perspectives of the helping alliance. Also in the 1980s, Charles Marmar and Elsa Marziali and their colleagues developed the Therapeutic Alliance Rating Scale (TARS), and in 1989, Marmar and colleagues revised the TARS and named the new scale the California Psychotherapy Alliance Scales (CALPAS). In 1983, D. E. Hartley and Hans Strupp developed the Vanderbilt Therapeutic Alliance Scale (VTAS), and in 1989, Stephen Saunders and his colleagues developed the Therapeutic Bond Scales (TBS).

Each of these scales was based on the different theoretical conceptualizations of the working alliance, but most also incorporated Bordin’s integrative formulations. One scale, however, was developed to specifically assess Bordin’s conceptualizations. It is the Working Alliance Inventory (WAI) and was created in 1986 by Adam Horvath and Leslie Greenberg. It allows an overall alliance score and its three scales separately assess the therapeutic bond, agreement on goals, and agreement on tasks—the three dimensions of the working alliance identified by Bordin. The original WAI is 36 items long, with 12 items in each scale. In 1990, Terence Tracey and Anna Kokotovic developed a short form of the WAI that has 12 items.

Because they were designed to assess the same thing, the various working alliance instruments have been found by researchers, such as Victoria Tichenor and Clara Hill in 1989, to be highly positively correlated. In 2000 in a statistical analysis that combined the results of 79 empirical studies, using meta-analytic strategies. Daniel Martin and his colleagues found that each of these scales is associated with good reliability. With the exception of the TARS, each of the scales also related positively and significantly to therapy outcome. Thus,

researchers investigating the working alliance could use any of these scales, with the exception of the TARS, in their inquiries with confidence. Martin and colleagues suggest, however, that the WAI is an appropriate choice for most investigations because of its applicability to all theoretical perspectives.

B. Relationship of Working Alliance to Therapeutic Outcome

The numerous studies relating the working alliance to various types of outcome (i.e., ratings of patient improvement, type of termination) are summarized by two meta-analyses. The first was a meta-analysis of 24 studies done in 1991 by Adam Horvath and Dianne Symonds. They found that the working alliance was moderately positively related to therapy outcome. The effect size, or the statistical degree to which working alliance and therapy outcome were related, was .26. Their findings applied regardless of the length of the treatment, the number of clients in each sample, and whether or not the study was published.

The recent meta-analysis in 2000 by Daniel Martin, John Garske, and Katherine Davis also found a moderate positive relationship between working alliance ratings and treatment outcomes. The effect size was .22. This meta-analysis corrected for some factors that might reduce effect size in the studies reviewed, but it did not correct for other factors (such as test reliability and validity). As a result, the effect size is an underestimate. This means that the impact of the working alliance is greater than the meta-analysis reported.

This relationship between alliance and outcome was obtained regardless of who did the alliance ratings (therapist, client, or observer), who rated the outcome (therapist, client, or observer), what outcome measure was used, the time in therapy that the alliance was assessed (earlier or later in treatment), the publication status of the research (21 studies of the 79 studies in the analysis were unpublished, 58 were published), or the type of therapy provided. Thus, Martin and colleagues' meta-analysis provided support for the inference that the working alliance is a common factor associated with outcome for all types of therapies.

C. Changes in the Working Alliance across Time

In their 1985 article on the relationship in psychotherapy, Charles Gelso and Jean Carter emphasized the importance of establishing a positive working alliance early

in treatment so that the alliance would sustain the relationships through the difficult periods in treatment. They believed that the alliance becomes disrupted in the middle phase of therapy when most intense work on behavior and attitude change is undertaken. The alliance was then assumed to recover to more positive levels later in therapy.

The 1991 meta-analysis by Horvath and Symonds provided some support for this perspective. They found a larger effect size between working alliance and outcome in studies where the assessment of the working alliance was done early in treatment session than for studies that assessed alliance in the middle phases of treatment.

The 2000 meta-analysis by Martin and colleagues did not support the formulation that successful treatment is associated with a better working alliance at the beginning and end than in the middle of treatment. The relationship between working alliance and outcome was not influenced by the time in treatment when the alliance was assessed, and, as stated earlier, the alliance–outcome relationship is also not influenced by type of therapy used. The findings of Martin and colleagues' meta-analysis support the perspective advanced by Carl Rogers that the working alliance is itself therapeutic. Thus, if a good working alliance is established, client, therapist, and external observers will perceive the client's problems as improved.

IV. SUMMARY

When clients come to therapy, they expect to find therapists with whom they can develop a close relationship. They expect that their therapists will want the same outcomes for them that they want for themselves, and they expect that therapists will suggest ways to attain these goals that they will find acceptable. These are the elements of the working alliance endorsed by most theorists and researchers—client and therapist bond and agreement on the tasks and goals of therapy. The strength of the working alliance may be assessed by giving clients and therapists any of several instruments, but the Working Alliance Inventory is recommended because it was specifically designed to assess client–therapist bond, agreement on tasks, and agreement on goals as well as the overall alliance.

Research results confirm that the working alliance is a common factor in all types of successful therapies. If the working alliance between client and therapist is positive, the outcome of therapy will be positive. If the

alliance is negative, the client will not improve and may even leave therapy before it is finished. Moreover, it could be said that the working alliance is itself a therapy. If they are part of a good working alliance, clients will improve regardless of what type of therapy is being conducted or when in therapy the alliance is assessed. These research results indicate that specific training in the establishment of positive working alliances should be done in all graduate programs regardless of the theoretical emphasis of the program.

GLOSSARY

- insight* Understanding acquired in therapy that connects general themes with particular actions and emotions.
- resistance* Term that refers to a variety of intrapsychic forces that impede the progress of therapy.
- working through* A psychoanalytic concept that describes the effort by patient and therapist of overcoming resistance and effecting change.

I. DEFINITION

The psychotherapeutic concept of “working through” originated as a psychoanalytic construct that accounted for the failure of correct interpretive work to immediately result in symptom resolution and character change. It simultaneously invokes the fact that therapy takes time and that patience and persistence on the part of the therapist must be matched by active perseverance and effort on the part of the patient. If therapy is to produce genuine changes in patterns of thinking, feeling, and behavior then a process of transformation must take place, a process that achieves both self-understanding and that neutralizes the countervailing forces of inertia and

defense. Although working through has at times seemed almost an afterthought for theorists, an epiphenomenon of the analytic work, others have viewed it as the quintessential activity that defines successful psychotherapy. Working through names the struggle to crystallize the insights gleaned from meticulous self-examination, to connect these insights not only to their putative origins, but to trace their consequences throughout one’s subjective and interpersonal experience in an effort to establish a healthier, less fettered, character. This takes time and is often an elusive and arduous goal to reach. The tendency to reenact long-established patterns is not easily undone. In other words, therapy takes work and commitment if it is to result in something more profound than glib self-awareness, which is to say substantive change.

II. FREUD’S THEORY

Freud first makes reference to the notion of “working through” in his paper on technique “Remembering, Repeating, and Working Through” written in 1914. Troubled by the mounting recognition that often a patient’s resistance persists in spite of the initial disclosures of a correct interpretation, Freud observed that the beginning analyst has

merely forgotten that giving the resistance a name could not result in its immediate cessation. One must allow the patient time to become more conversant with

this resistance with which he has now become acquainted, to work through it, to overcome it, by continuing in defiance of it, the analytic work according to the fundamental rule of analysis.

What the beginning analyst had forgotten was not always apparent even to Freud. In the early days of psychoanalysis, the work of therapy was admittedly “laborious and time-consuming for the physician” but the effort expended was directed toward bringing the pathogenic ideas to consciousness. The resistance of the patient was primarily a matter of repression; once the ideas were successfully retrieved and exposed to the light of conscious awareness symptom resolution followed in short order. Typically, this revelation was accompanied by an “abreaction” of affect associated with the offending idea. Where this failed, the affect was found to have been embedded in a series of affiliated memories and associations and only by a comprehensive “working over” of the pathogenic material could the symptoms be disposed of once and for all. This earlier term, “working over,” was a prototype for the subsequent concept of working through and signified early on the fact that analytic progress is not always straightforward, even when it seems to be going well.

Clearly, resistance plays a key role in the analytic view of therapy and it is the antinomy of working through. In Freud’s formulation working through engages the resistance once the patient has become acquainted with it. By its very nature resistance is an unconscious adversary that operates by subterfuge and stealth. It is protean in its manifestations and may appear as a failure to produce meaningful disclosures, as faulty remembering, by tenacious distortions and misconstructions, or through the distractions of a robust transference. This latter resistance was paradigmatic for Freud who was preoccupied with the dynamics of the transference throughout his papers on technique (1910–1919). Originally derived from techniques that employed suggestion, the psychoanalytic method first recognized in the transference a means of securing the cooperation of the patient and thus of facilitating the analytic work. Although there is no doubt that some degree of positive transference is indispensable to the progress of therapy, Freud learned from experience that transference is the “strongest weapon of the resistance.” As a result of this discovery, the analysis of the transference proved to be a critical step in acquainting the patient with the fact of his resistance. Freud observed:

Only when the resistance is at its height can the analyst, working in common with his patient, discover the

repressed instinctual impulses which are feeding the resistance; and it is this kind of experience which convinces the patient of the existence and power of such impulses.

In this way the patient becomes aware of the resistances and their associated impulses. Becoming conversant with these manifestations constitutes the first phase of working through proper. This phase is time-consuming because recognizing resistances requires deep understanding and an appreciation for the common themes that run through what may appear on the surface to be totally unrelated attitudes and behaviors. It is this exercise that ultimately establishes insight.

Although the resistance exhibited in the transference may have been uppermost in Freud’s thinking at the time he first wrote of working through, his subsequent deliberations on resistance called attention to the threat posed by the tendency to repeat. Freud had written variously of the “pertinacity of early impressions,” of “psychical inertia,” “fixation,” and the “adhesiveness of the libido.” All of these terms referred, in one way or another, to an obstinacy or lack of mobility on the part of the libido, its reluctance to give up its objects or to change its course. Writing of the general *modus operandi* of analytic treatment in the Introductory Lectures, Freud (1917) remarked:

The more closely events in the treatment coincide with this ideal description, the greater will be the success. . . . It finds its limits in the lack of mobility of the libido, which may refuse to leave its objects. . . .

Freud traced this obstinacy on the part of neurotic fixations to the “resistance from the id” and its manifestation he termed the “compulsion to repeat.” Even after the ego resistance has been identified and the pathogenic material rendered visible, the tendency to repeat remains. Thus, Freud observed in his *Inhibitions, Symptoms and Anxiety* in 1926:

For we find that even after the ego has decided to relinquish its resistances, it still has difficulty in undoing the repressions; and we have called the period of strenuous effort which follows after its praiseworthy decision, the phase of “working-through.” The dynamic factor which makes a working-through of this kind necessary and comprehensive is not far to seek. It must be that after the ego-resistance has been removed the power of the compulsion to repeat—the attraction exerted by the unconscious prototypes upon the repressed instinctual process—has still to be overcome. There is nothing to be said against describing this factor as the *resistance of the unconscious*.

In other words, what Freud discovered was that even after the patient has gained an awareness of his resistances and the pathogenic impulses underlying them, the perennial therapeutic imperative—"let go and move on"—is far easier said than accomplished. The resistance from the unconscious manifested by the repetition-compulsion remains to be dealt with. Overcoming this deeply mired complex of resistances represents an aspect of working through that differs from that involved in the acquisition of insight. Faced with the inherently conservative nature of the drive derivatives motivating neurotic life, the ego engaged in working through must wrest itself free from these bonds in order to foster meaningful change. The contest would appear not to be a matter of insight or of understanding, but of brute force. Knowing that one is, by nature, subject to the law of gravity does not help one to escape its influence. Only by overcoming this force can one move out of its orbit.

It is not surprising, then, that Freud in 1940 concluded the chapter on technique in his posthumously published *Outline of PsychoAnalysis* by remarking that:

We shall not be disappointed, but, on the contrary, we shall find it entirely intelligible, if we reach the conclusion that the final outcome of the struggle we have engaged in depends on *quantitative relations*—on the quota of energy we are able to mobilize in the patient to our advantage as compared with the sum of energy of the powers working against us.

This conclusion suggests that working through is nothing less than a heroic process, one that calls for overcoming, defiance, and perseverance. Indeed, the decision to continue the analytic work over and against all such forces to the contrary Freud deemed "praiseworthy." And, not inconsequentially so, for Freud conceded from the outset that working through names that "part of the work which effects the greatest changes in the patient and which distinguishes analytic treatment from any kind of treatment by suggestion."

III. PERSPECTIVES ON WORKING THROUGH

Given the obvious importance of working through to the outcome of psychotherapy it remains a curiosity that Freud devoted so little actual discussion to the problem. One explanation may be that working through is as pervasive in actual practice as it is intangible and that Freud could only invoke it as the ineffa-

ble ingredient that distinguished analysis terminable from analysis interminable. Any attempt to define it further immediately devolves into a discussion of technique, or of metapsychology.

Of course, subsequent theorists have intermittently elaborated on the concept and have generated a series of sometimes divergent positions. Not surprisingly, these elaborations typically reflect the differing approaches to technique or theory espoused by their authors. Classically, Otto Fenichel in 1945 viewed working through from the analyst's point of view, that is, as a problem in technique.

Systematic and consistent interpretive work, both within and without the framework of the transference, can be described as educating the patient to produce continually less distorted derivatives until his fundamental instinctual conflicts are recognizable. Of course, this is not a single operation resulting in a single act of abreaction; it is, rather, a chronic process of working through, which shows the patient again and again the same conflicts and his usual way of reacting to them but from new angles and in new connections.

Others such as W. Stewart in 1963 and M. Sedler in 1983 emphasized the patient's contribution to the process. P. Greenacre in 1956 conceived of working through as a "working out" of residual infantile traumas and memories that could not be adequately reconstructed or resolved solely by an analysis of current defenses. In 1991 L. Aron proposed the term "working toward" in an effort to "capture the sense of the work of both patient and analyst as co-participants in the analytic process. Patient and analyst not only work toward a new and corrective relationship, but work toward making the nuances of that relationship explicit..." Transcending such positions, Charles Brenner presented a view of working through that underscored its ubiquity in the analytic process. He argued simply that "working through is not a regrettable delay in the process of analytic cure. It is analysis. ... The analysis of psychic conflict in all of its aspects is what should properly be called working through."

Generally, there is agreement that working through is a concept made necessary in order to explain, "Why does psychoanalysis take so long?" Posing just this question, Charles Brenner in 1987 helped us perhaps to understand Freud's reticence on the subject by answering candidly, "we do not know." Brenner observed:

that such analysis takes time, all analysts know. Why it takes as much time as it does is a question which remains

as yet unanswerable. However, we also know that when analytic work proceeds favorably—when working through is successful—it results in psychic changes which are of inestimable value to the patient and which no other form of psychotherapy can achieve.

III. SUMMARY

Many of the basic truths about character pathology, neurotic symptoms, and the possibilities for meaningful change discovered in the era of psychoanalysis have been obscured by the subsequent proliferation of derivative psychotherapies. Nevertheless, the promises and predictable results of “brief therapy” cannot negate the fundamental lessons about mental life learned from our experience of psychoanalysis. Serious conflicts rooted in the soil of constitutional factors and infantile residues are not easily brought to light, and are even less easily resolved. The method of psychoanalysis is a notoriously protracted one and its results are uncertain. For these reasons its popularity and its credibility have suffered. Nevertheless, the challenges defined by working through show why it must be so: Failures, uncertainty, struggle, and hope are facts of the human condition. Technical innovations in psychotherapy are not likely to

fundamentally alter this reality. Insofar as the original meaning of “working through” has been assimilated by this psychotherapeutic pluralism, there may be a general understanding that successful therapy requires both time and hard work. At the same time, this assimilated meaning most likely designates the process only in its most generic sense, that is, as the struggle to replace one set of personal characteristics with another. In any context this is not an easy business.
