About a quarter of the planetary systems detected by the radial velocity method are multiple systems. Some of the orbits in these multiple systems show clear evidence for mean-motion resonances. A mean-motion resonance exists if the ratio of the orbital periods of the two objects are commensurable (equal to the ratios of two integers, e.g. 2:1 or 5:3). This could be explained by the early dynamical evolution of these systems where migration captured the planets in resonances, similar to the resonance belt in the Kuiper belt. A certain number of multiple systems were found to have orbits just near mean-motion resonances but exactly in a resonant configuration.

The overall mass function of radial velocity planets showed a steep rise toward masses of 1 Jupiter mass or less. Thus, although less massive planets are much harder (or impossible) to detect by the radial velocity technique, we expected them to be quite frequent. On the other hand, very massive objects with masses of 10–20 Jupiter masses are very easy to detect with the radial velocity method and therefore seem to be quite rare.

About 10% of the stars surveyed by long-term radial velocity programs have detectable giant planets. The majority of these planets orbit stars of similar spectral type (i.e. effective temperature and mass) as the Sun. They usually have orbital separations less than 5 AU; in fact, about half of them reside within 1 AU from their host star. But these results also reflect strong observational biases.

As already mentioned, the radial velocity technique is more sensitive to close-in planets, and it takes a monitoring timescale of over a decade to discover planets beyond 5 AU. Also, stars hotter and more massive than the Sun are not suitable for the radial velocity technique because they tend to have higher rotation rates and much fewer spectral features, which can be used to measure the velocity. Stars less massive than the Sun are intrinsically fainter, and

large-aperture telescopes are needed to collect enough photons to ensure a sufficient data quality. Therefore, combined with the prior knowledge that at least one solartype star, our Sun, produced a planetary system, early radial velocity surveys traditionally focused on Sun-like stars. As radial velocity programs extend their time baselines and expanded their target samples to fainter and lower as higher mass stars, these initial observational biases became somewhat less important.

Main sequence stars with the spectral classification M ("M dwarfs") are smaller and fainter than the Sun. They have masses ranging from roughly 55% to about 0.8% solar masses. Despite the fact that M dwarfs comprise the majority of stars in our galaxy, they formed only subsets in the large target samples of radial velocity surveys, due to their faintness. Based on the data accumulated for a few hundred M dwarfs (compared to >1500 solartype stars) it seems that they host fewer giant planets with small orbital separations than Sun-like stars. This could indicate that the formation efficiency of giant planets is really a function of disk mass, as the protoplanetary disks around M dwarfs are presumably less massive than for bigger stars. But a few systems with M dwarf giant planets have been discovered. The star Gliese 876 was found to have a planetary system of two Jupiter-type companions in a 2:1 mean-motion resonance with periods of 30.12 and 61.02 days. More recently, a third lower mass planet with a 120-day orbit was detected in this system. With this additional third planet (which is also in resonance) the Gliese 876 system now resembles the resonance configuration of the Galilean satellites, Io, Europa, and Ganymede. Studies have also shown that this system is dynamically full, which means that no other planet can exist in this system (the same is true for the solar system). Because of its close proximity to the Sun (15 light years), Gliese 876 is an ideal target for astrometric follow-up. In 2002, highly precise measurements obtained with the Fine Guidance Sensors on board the HST successfully revealed the astrometric signature of the 60-day planet. By combining the ground-based radial velocity data with the space-based astrometric data, a true mass of 1.9 Jupiter masses was determined for this planet. Another interesting multiplanet system containing several low-mass planets was discovered orbiting the nearby M dwarf Gliese 581 (this system will be discussed in Section 3.2.1)

The radial velocity technique was also used to detect many planets orbiting giant stars. Giants stars are more evolved than solartype stars, and their cooler atmospheres have a spectral signature rich in absorption lines. These stars are thus suitable targets for the radial velocity technique. The progenitor stars (i.e. before they evolve into their current giant status) of most giant stars are more massive than the Sun and the successful detection of planetary companions around them is evidence that planet formation can also occur around more massive stars. This is not a big surprise because several dense dust disks have already been observed around progenitor stars. We shall also see later that the first massive planets were imaged around stars more massive than the Sun (Section 3.3.2).

Another interesting correlation for solartype stars (with spectral types of F, G and K) emerged from the radial velocity results: their detectability is a strong function of the metallicity of the host star. Astronomers call every element heavier than helium a metal. **Stellar metallicity** thus means the abundance of all chemical elements in a star besides hydrogen and helium. In general, the element used for the metallicity determination is iron. By measuring the stellar metal content, we can probe the primordial chemical composition of the gas and dust cloud, out of which the star (and presumably its companions) has formed. It was found that the mean value of the metallicity distribution of planet host stars is offset with respect to the mean metallicity of stars in the solar neighborhood. On average, giant planets are more frequently detected around host stars that have a higher iron to hydrogen abundance ratio ([Fe/H]) than the solar neighborhood mean [Fe/H] value. This can be seen as evidence for the core accretion model for the formation of gas giants. The efficiency of this model is sensitive to the abundance of heavier elements in the protoplanetary disk (more heavy elements → more efficient core formation → more gas giants). Alternatively, this might also be regarded as evidence that orbital migration is a function of the metal content of the planet-forming disk, because close-in planets are easier and faster to detect by radial velocity surveys.

3.2.1. Hot Neptunes & Super-Earths

In 2004, the first radial velocity planets with masses below the gas giant range were discovered. These planets have $m \sin i$ values comparable to the masses of the icy giants of our solar system, Uranus and Neptune (14 and 17 Earth masses). Their very short orbital periods give detectable radial velocity signals despite their low mass. Thus, they have been dubbed hot Neptunes. One of the very first hot Neptunes that were found orbits the M dwarf star Gliese 436. Although the planet has only a minimum mass of 21 Earth masses, it induces an Radio Velocity (RV) perturbation in its host star because the star is much less massive than a solartype star.

With further improvement of the precision of radial velocity measurements to the submeter per second level, it was just a matter of time that the first planets with minimum masses approaching the mass of Earth were found. Planets that have a minimum mass below 10 Earth masses are called "super-Earths". Very precise RV programs have detected several of these low-mass planets in the solar neighborhood, most of them with short orbital periods. One of the most interesting systems that was found orbits

another M dwarf: Gliese 581. This system consists of one hot Neptune, and at least two, if not three more, super-Earths. The existence of an additional fifth planet in this system is still controversial. In 2012, the detection of a planet with a minimum mass of only 1.1 Earth masses in a 3.2-day orbit around our close neighbor alpha Centauri B was announced. The detection is based on 4 years of radial velocity measurements of this star using the HARPS spectrograph. After a complex procedure to account and compensate for the signals introduced by the star itself, a weak 3.2 residual signal was found that the discovery team attribute to a very low mass planet orbiting our neighboring star. This, of course, would be the nearest exoplanet detected so far, and also one with the lowest mass. This important result clearly needs confirmation by other groups. Indeed, an independent analysis that used the same data set calls this planet into question.

3.3. Results from Transit Searches

With the discoveries of more and more hot Jupiters, it was just a matter of time until one of them would have a near edge-on orbit so that the planet transits in front of the star. The hot Jupiter companion to HD 209458 was the first transiting extrasolar planet. The planet itself was initially discovered by the radial velocity method, but in this case the photometric follow-up observations revealed—for the first time—the characteristically shaped light curve of a transiting planet (Figure 45.4). With the viewing angle known ($i = 86°$) the $m \sin i$ value transformed into a true mass for the planet of 0.69 Jupiter masses. The depth of the dip in the light curve yielded a radius for the companion of 1.4 Jupiter radii. With a known mass and a known radius, a mean density of 0.31 g/cm^3 was derived. This is an even lower mean density than Saturn, the planet with the lowest mean density in the solar system. The discovery of the HD 209458 transiting planet represented a major milestone in the field of extrasolar planet detection: It demonstrated that the companions discovered by the radial velocity surveys were indeed gas giant planetary companions and not more massive (even stellar) companions seen at a very unfortunate viewing angle i.

The very first planet discovered by the transit method was Optical Gravitational Lensing Experiment (OGLE)-TR-56 (HD 209458 b, the first transiting planet, had been detected by radial velocities before the photometric transit was observed). The OGLE is a precise photometric survey of millions of stars to search for gravitational lensing and planetary transit events. OGLE is a project from astronomers from Warsaw and Princeton and operates a 1.3-m telescope at Las Campanas Observatory in Chile. The companion to OGLE-TR-56 has a mass of 1.4 Jupiter masses and a radius of 1.2 Jupiter radii. The planet has an extremely short orbital period of only 1.2 days or 29 h, and the orbital separation is only 0.023 AU. This is even closer to the host star than the hot Jupiters found by radial velocity surveys.

In order to survey a sufficiently large number of stars, ground-based photometric transit search programs commonly use small-aperture telescopes with a wide field of view. Most of the stars included in these searches are far more distant and thus fainter than the stars included in

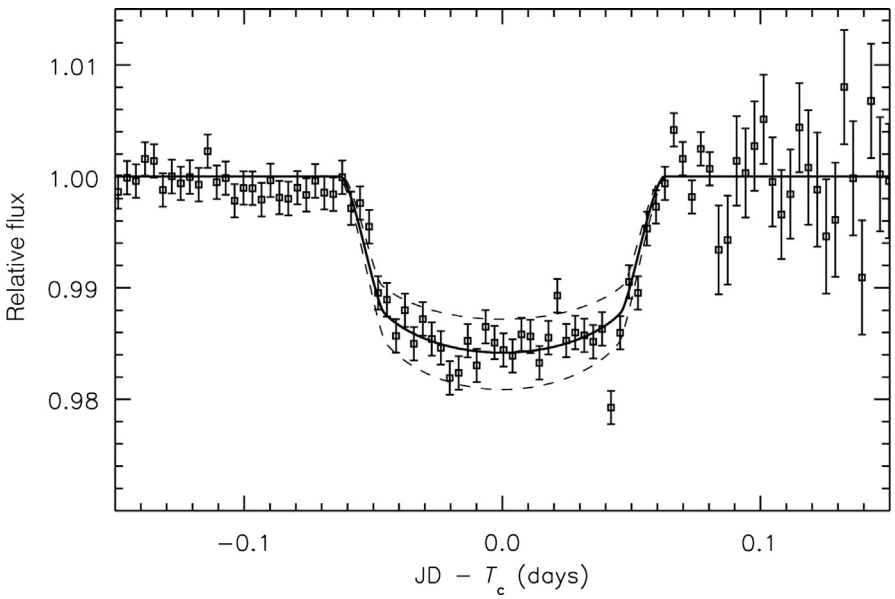

FIGURE 45.4 The light curve of the star HD 209458 showing the reduction in stellar flux by 1.5% due to the transit of its hot Jupiter. From the depth of the transit light curve, a radius of 1.4 Jupiter radii was derived, and combined with the planetary mass—determined from radial velocities—a low mean density of 0.31 g/cm^3 was found for this planet. JD = Julian Date, T_c = Time of center of transit.

typical radial velocity surveys. This makes the spectroscopic follow-up observations more time consuming. Sometimes, the largest telescopes, like the 10-m Keck telescope in Hawaii or the 8-m Very Large Telescope in Chile are necessary for this task. There are many astrophysical phenomena that can mimic the photometric signal of a planetary transit. Thus, in order to determine whether a transiting object is indeed a planet, it is necessary to obtain spectroscopic follow-up observations to rule out false positives, such as eclipsing binary stars in the background, or a giant star with a smaller secondary star or simply binary systems undergoing grazing eclipses. Once a false positive is ruled out, further follow-up observations are done to characterize the host star and, if possible, perform radial velocity measurements to derive a mass for the planetary companion.

In recent years, ground-based transit search programs have started to use entire networks of telescopes distributed over the globe. These networks, like the Trans-Atlantic Exoplanet Survey (TrES) or the Wide Angle Search for Planets (WASP and its successor SuperWASP) have uncovered over a hundred transiting hot Jupiters. Many of these planets share the characteristic of an inflated radius with the prototype case, HD 209458b. The energy source for this large radius is still under debate.

Another advantage of transiting planets is our ability to measure the angle between the stellar spin axis and the orbital plane of the planet. For this purpose astronomers use observations of the so-called Rossiter–McLaughlin (RM) effect, an apparent deviation in the radial velocity of the star from the Keplerian RV orbit due to the planet. This happens when the opaque disk of the planet blocks the blue- and redshifted sections of the rotating stellar surface during the transit. By examining the shape of the RM effect, one can determine if the planet orbits in the same direction as the star spins and if its orbital plane is aligned with the stellar equator (which both is approximately true for the solar system planets). This, of course, would be expected for planets that formed inside the rotating circumstellar disk and then subsequently have migrated inward by exchange of angular momentum with the disk. But again, the results for exoplanets were surprising. While roughly half of the transiting planets are well aligned in prograde orbits, the rest appears to have strongly inclined orbits and some of them were even found with retrograde orbits. This is usually seen as evidence that, at least for these systems, the inward migration was dominating and/or followed by gravitational scattering due to interactions with other planets rather than by mere disk-driven migration.

In December 2006, the French space agency Centre national d'études spatiales (CNES), together with the ESA and other international partners, launched the Convection, Rotation and planetary Transits (CoRoT) spacecraft. CoRoT consists of a telescope with 27-cm aperture and 4 CCD detectors to perform precise photometry. A major part of the science mission of CoRoT was the detection of planetary transits from space. By avoiding the atmospheric noise effects and by being able to monitor a star field for nearly half a year (when the telescope needs to rotate to avoid the Sun), CoRoT had the capability to find much shallower transit signals, and hence smaller planets, than traditional ground-based telescopes could. This was successfully demonstrated with the discovery of CoRoT-7b, the first transiting super-Earth. CoRoT measured a radius of 1.7 Earth radii, while the mass of about 8 Earth masses was determined using the HARPS spectrograph. The orbital period of this super-Earth is just 0.85 days, so it is very close to the parent star and has a high surface temperature. The mass determination of CoRoT-7b was complicated by the fact that the star itself is moderately active and that the RV data revealed the signals of two more low-mass (but not transiting) planets. Another interesting discovery from CoRoT is a 21 Jupiter mass companion with a radius of 1 Jupiter radii. This object is either a supermassive giant planet (as it is located in a typical hot Jupiter orbit with a period of 4.3 days) or a brown dwarf (an object that formed similar to a star but with insufficient mass to start hydrogen fusion in its core). CoRoT-9b was the first transiting giant planet with an orbital period longer than a few days. This planet orbits its host star every 95 days. The superior precision of the photometry from CoRoT allowed very precise radius determinations for these transiting objects and clearly showed the advantages of planetary transit photometry from space.

Ground-based programs also started to find smaller planets, in particular, around smaller stars. The transit signal of a given planet increases if the stellar radius decreases (the transit depth depends only on the surface area ratio of the two bodies involved). The first small transiting planet that was found by ground-based photometry was the radial velocity-detected hot Neptune around the M dwarf Gliese 436. The measured radius turned out to be very similar to the radius of Neptune. Figure 45.5 shows one of the most valuable scientific diagrams that we can only produce for transiting exoplanets: the mass–radius diagram. By placing a planet with measured radius and mass into this diagram, we can compare its location to theoretical models for the internal composition of the planet. Figure 45.5 clearly demonstrates that we can clearly discern between exoplanets that are gas giants, such as Jupiter, and smaller icy giants, such as Neptune, or even rocky planets similar to the Earth.

Another very interesting transiting planet around an M dwarf is GJ 1214b with a radius of 2.7 Earth radii and 7 Earth masses. This super-Earth was discovered by the

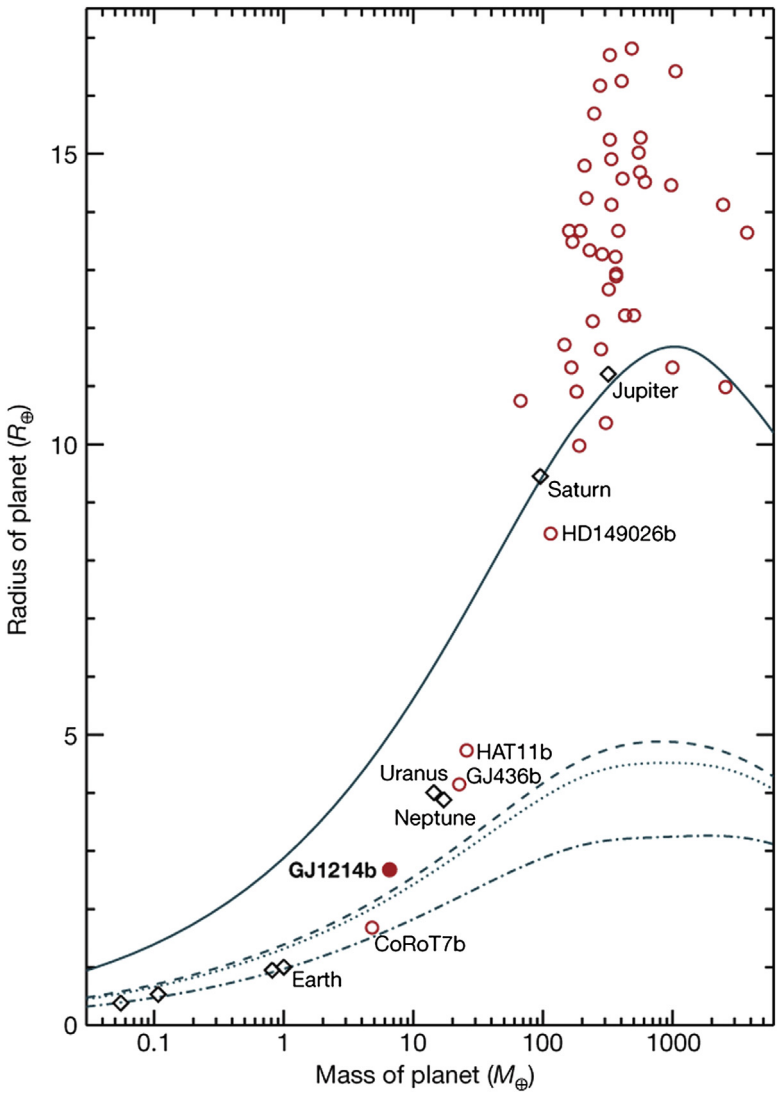

FIGURE 45.5 The mass-radius diagram for some transiting extrasolar planets (red circles). The Solar System planets are shown as black diamonds. Four models for the composition are also displayed: pure H/He (solid blue line), pure H_2O (dashed line), a water-dominated planet (75% H_2O, 22% Si and 3% Fe core; dotted line) and Earth-like (67.5% Si mantle and a 32.5% Fe core; dot-dashed line). This diagram allows us to distinguish between Jovian gas giants, icy giants like Uranus and Neptune and planets with a more Earth-like composition. *From Charbonneau et al. (2009).*

MEarth project that specifically targets small M dwarf stars to exploit the increased transit depth of small planets around this type of star. The host star itself is a cool M dwarf with a radius of only 0.2 solar radii and an effective temperature of 3000 K. Although the orbital period of GJ 1214b is only 1.6 days, the planet could be relatively cool, with an estimated equilibrium temperature of 400−550 K.

By using the Canadian *Microvariability and Oscillations of STars* (*MOST*) satellite and NASA's *Spitzer* space telescope, two independent groups discovered that the super-Earth planet in the ρ^1 Cancri (55 Cnc) system, planet e with an orbital period of only 0.74 days, also transits its star. ρ^1 Cnc e has a radius of 2.2 Earth radii, a mass of 8 Earth masses, and a mean bulk density of 4.5 g/cm^3. In the mass−radius diagram, this object is located outside the models for pure solid, rocky compositions and requires a significant amount of volatiles, e.g. water. This is the only small transiting planet around a star that is visible to the naked eye. Clearly, this planet will allow a much more detailed characterization in the near future.

3.3.1. Results from Microlensing Surveys

In the summer of 2003, the two microlensing surveys, OGLE and Microlensing Observations in Astrophysics (MOA), independently detected a microlensing event toward the galactic bulge. During the close monitoring of this event, a strong 1-week-long deviation from a single-lens light curve was discovered (see Figure 45.6). Careful modeling of the combined photometric data sets showed that the light curve of the OGLE 2003-BLG-235/MOA 2003-BLG-53 event is best described by a

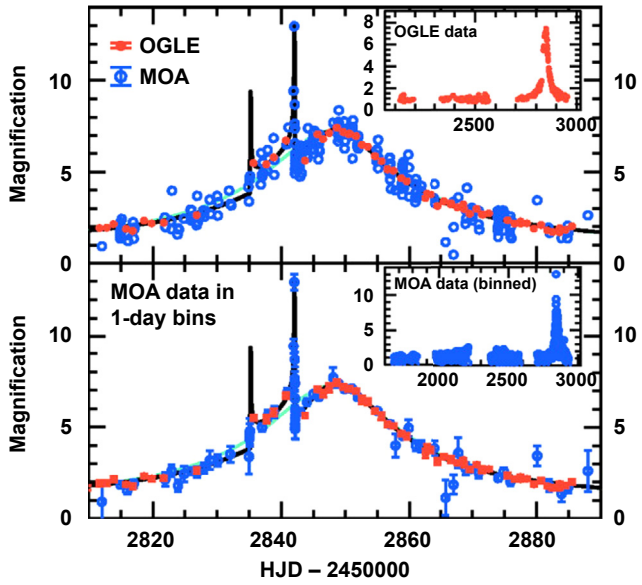

FIGURE 45.6 The first observed planetary microlensing event. Two photometric data sets (MOA survey in blue and OGLE survey in red) were combined to produce this light curve. The best-fit binary lens model is shown as solid black line. The planetary companion causes the strong double-peaked and 1-week-long deviation from the broader microlensing light curve due to its host star. HJD = Heliocentric Julian Date.

binary lens model with an extremely small mass ratio of 0.004. In the probable case that the primary lens is a normal star, the secondary lens would be a ~1.5-Jupiter-mass planet orbiting at ~3 AU. Thus, this event is regarded as the first demonstration of the discovery of an extrasolar planet by microlensing. A better characterization of the star/planet system that caused this lensing event has to await next-generation ground-based or space telescopes, which will be powerful enough to resolve the lens.

Microlensing is a very elegant technique to find exoplanets and it also has the added advantage that the Einstein radius (the lensing zone around a central mass) projects to roughly 1 AU for stars between us and the center of the galaxy. This means that this method is in particular sensitive to planets in or near the habitable zone for solartype stars. The drawback of this method is the complicated shape of the signal that could be fit by several different models with nearly the same goodness of fit. Moreover, the parameters for the planet rely often on statistical arguments on the properties of the lensing star.

About 15 planets have been announced by different groups using the microlensing technique. These surveys derived global statistics from the frequency of particular planetary lensing events compared to the total numbers of lensing events. From these studies, we know that giant planets around M dwarfs are rare and that cold Neptunes (at larger separations) could be relatively common.

3.3.2. The First Direct Images of Extrasolar Planets

Imaging searches for extrasolar planets have yielded the first candidates for successful detections. In these cases, faint companions were found in deep, high-contrast optical or infrared images taken either with powerful AO system, combined with a coronagraph, at large-aperture telescopes on the ground, or with the *HST*. Fainter background sources, mimicking companions, can be ruled out by the fact that these objects are comoving with the central star and are thus likely to be gravitationally bound to it.

One of the first imaging candidates was found near a young "failed" star, a brown dwarf, which itself is not massive enough to start thermonuclear reactions in its core. The central object (called 2MASSWJ 1207334−393254) has only ~25 times the mass of Jupiter and is located at a distance of approximately 230 light years. Its location also gives away its age: the brown dwarf lies within a young star-forming region, the so-called TW Hydrae association. This region contains young stars that are estimated to be only 8 million years old. The fainter (and thus presumably much less massive) companion was detected 0.8 arcsec away from the brown dwarf. At the distance to the brown dwarf, this transforms to a projected separation of 55 AU. First low-resolution spectra of the companion were also obtained. But is it a planet? This is the tricky part to decide. The observed brightness, colors, and spectral information can be compared to theoretical models for young planets. Such a comparison yields a mass of ~5 Jupiter masses for the fainter companion, a mass value placing the object firmly within the range of planets. However, some caution remains because the theoretical models for young planets are not calibrated and their uncertainties are difficult to assess. Moreover, the large separation of (at least) 55 AU raises the question that how massive the protoplanetary disk around a 25 Jupiter mass object must have been to form such a massive planetary companion so far away from the center.

Another candidate for a directly imaged extrasolar planet is the companion to the star GQ Lupi. This time the central object is really a star similar to the Sun, albeit a lot younger. The age of GQ Lupi is estimated to be between 100,000 and 2 million years. These very young ages for the imaging candidates are due to an observational selection effect: imaging searches specifically target young stars because young planets are much brighter at these early evolutionary stages. The companion appears 0.7 arcsec to the west of GQ Lupi, which translates into a projected separation of ~100 AU. A careful comparison of the discovery images with archived images revealed that the companion is indeed a co-moving object (they share the same motion in the plane of the sky, which rules out a background object). Therefore, it can be assumed that it

has formed at the same time as the star GQ Lupi has. In this case, comparison of the available photometric and spectral data with models for young planets yielded a mass between 1 and 3 Jupiter masses for the companion. But again, the remaining uncertainties in the values derived from models are large, and it is difficult to distinguish young planets from low-mass brown dwarfs. If GQ Lupi b has indeed formed like a gas giant planet, then it was probably transported from the denser interior of the protoplanetary disk, where sufficient planet-forming material can be found, to its present location of about 100 AU away from the star.

The year 2008 was a milestone in the field of exoplanet imaging. Basically at the same time, two teams announced to have directly imaged planets around two nearby stars. And this time there was additional evidence that supported the planetary status of the candidates in these images. One group presented images from the HST Advanced Camera for Surveys of the star Fomalhaut. These images were taken years apart and show a planet candidate apparently moving according to the expected orbital motion interior to the dense dust ring around this star (see Figure 45.7). In the case of Fomalhaut b, one can calculate an upper mass limit of $\sim$3 Jupiter masses, as the dusty disk appears unperturbed by the companion. The planet orbits the star at a very large orbital separation of 119 AU.

The other directly imaged exoplanets were found using ground-based telescopes. High-contrast images obtained with the Keck and Gemini telescope revealed even three companions to the star HR 8799. It is very interesting that a multiplanet system was found; this supports the notion that these companions formed in the circumstellar disk of gas and dust that surrounded the star when it formed. The orbital separations of the three planets around HR 8799 are 24, 38, and 68 AU. It appears to be a scaled-up version of the outer solar system. The two sets of images that were taken 3 years apart even show that these planets all orbit in the same direction, as expected for a planetary system. The masses of these planet are estimated to be between 8 and 13 Jupiter masses. In 2010, the discovery team of the HR 8799 multiplanet system added another planet to the ensemble: HR 8799 e orbits interior to the three already known planets, with a separation of 14.5 AU.

The similarities between the HR 8799 and the Fomalhaut planets are striking: both stars are more massive and younger than the Sun, both are surrounded by a dense dust disk, and both have massive planetary companions at large orbital separations. It was thus not entirely surprising that a planet was also detected by direct imaging, orbiting the prototype of star with a dense debris disk, beta Pictoris, a year following the HR 8799 and Fomalhaut detections.

The basic properties of these first directly imaged exoplanets are quite different to the planets found by the radial velocity or transit technique: they are located at very large orbital separations and are very massive (of course, there is a strong selection effect: these are the planets that we *can* take images of). With the standard giant planet formation model, the core accretion model, it is difficult to explain how such high-mass planets could have formed so far out in the disk. This makes the imaged extrasolar planets good candidates for alternative formation models such as the disk instability model scenario in which giant planets form rapidly from gravitationally unstable and collapsing clumps in a massive disk.

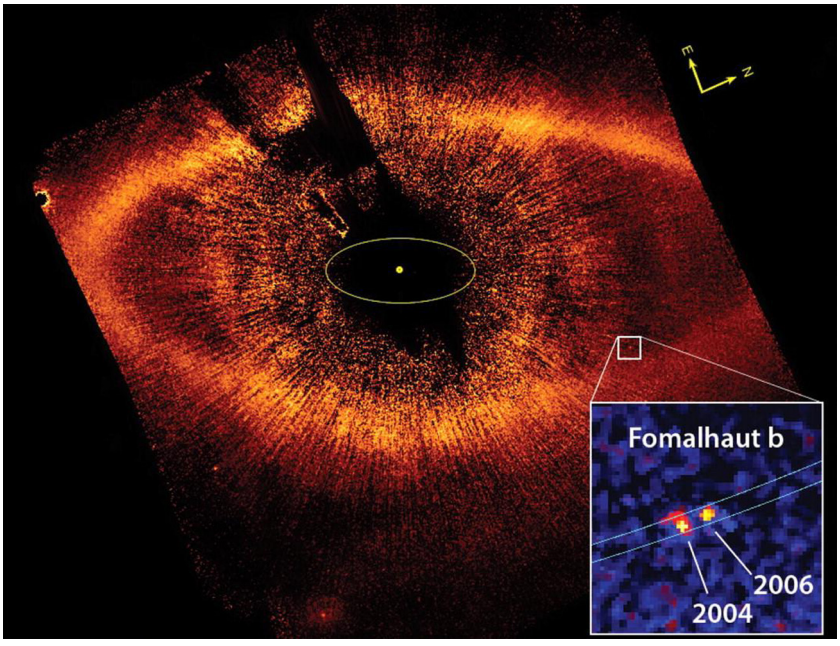

FIGURE 45.7 The directly imaged planet around the star Fomalhaut. Images taken with the Advanced Camera for Surveys camera onboard the Hubble Space Telescope reveal a planetary companion just interior to the massive dust belt around this star. The inset displays the apparent motion of the planet as seen in images taken 2 years apart. *Figure from Kalas et al. (2008).*

3.4. The Atmospheres of Extrasolar Planets

Transiting planets give us the unique opportunity to probe the atmosphere of exoplanets. During a transit one can observe the starlight that passes through the atmosphere of the planet and measure any absorption or scattering that is caused by the planet's atmosphere. With high-resolution spectroscopy we can discern certain chemical elements or molecules that are present. One can also compare the total flux that is received in the infrared in and out of transit to determine the temperature of the exoplanet's atmosphere.

Transmission spectroscopy was first performed with the HST to detect the atmosphere of HD 209548b, the first transiting planet. The *HST* spectra taken during the planetary transit showed a stronger sodium absorption line than the spectra observed without the planet in front of the star. This additional absorption is caused by the sodium in the planet's atmosphere. However, the amount of atmospheric sodium was less than expected from theoretical models, urging the astronomers involved in this study to speculate that a thick cloud cover prevents us from seeing deeper into the planet's atmosphere. Later, sodium absorption was also detected in other hot Jupiters using ground-based facilities.

In another *HST* observation of the HD 209458 planet, it was possible to measure hydrogen escaping from the heated upper layers of the planet's atmosphere. The escaping hydrogen gas forms a kind of cometary coma and tail around the planet and is blown away by the radiation and particle wind of the close-by star.

With the launch of NASA's infrared space telescope Spitzer, a new and very interesting spectral window for observations of extrasolar planets became available in the far infrared, where thermal emission dominates the radiation coming from a planet (as shown in Figure 45.2). Although Spitzer lacks the spatial resolving power to detect planets, its high sensitivity in the infrared can be used to discern between radiation from a star and its planet.

Two independent teams planned basically the same Spitzer observations to observe a transiting extrasolar planet during (and out of) secondary eclipse (the time when the planet is directly behind the star and hidden from view). If the amount of infrared radiation measured by Spitzer during the eclipse is less than that outside the eclipse, then this difference is the radiation coming from the planet itself. This effect was indeed successfully measured for the two transiting planets HD 209458 b and TrES-1 b. The amount of planetary infrared radiation was used to estimate a "surface" temperature for these two planets. The visible upper atmosphere of HD 209458 b has a temperature of 1130 ± 150 K, and for TrES-1 b the respective value is 1060 ± 50 K. Both values are in good agreement with the expected temperature of a giant planet's upper atmosphere heated by the intense irradiation of the nearby host star. The exact timing of the secondary eclipse of HD 209458b also demonstrated that its orbit is indeed circular and that tidal heating cannot be the explanation for its abnormally large radius. Interestingly (and quite ironically, because the information is obtained by the *lack* of photons during eclipse), these observations also represented the first unambiguous detections of photons emitted by extrasolar planets.

Transmission spectra for several transiting extrasolar planets have been obtained using space- as well as ground-based telescopes. Figure 45.8 shows an example of the transmission data for the hot Jupiter XO-1b that were obtained with the NICMOS instrument on the HST. The spectrum is rich on spectral information, showing deep absorption features due to molecules in the atmosphere of the planet. The best-fit atmospheric model contains H_2O, CH_4, and CO_2.

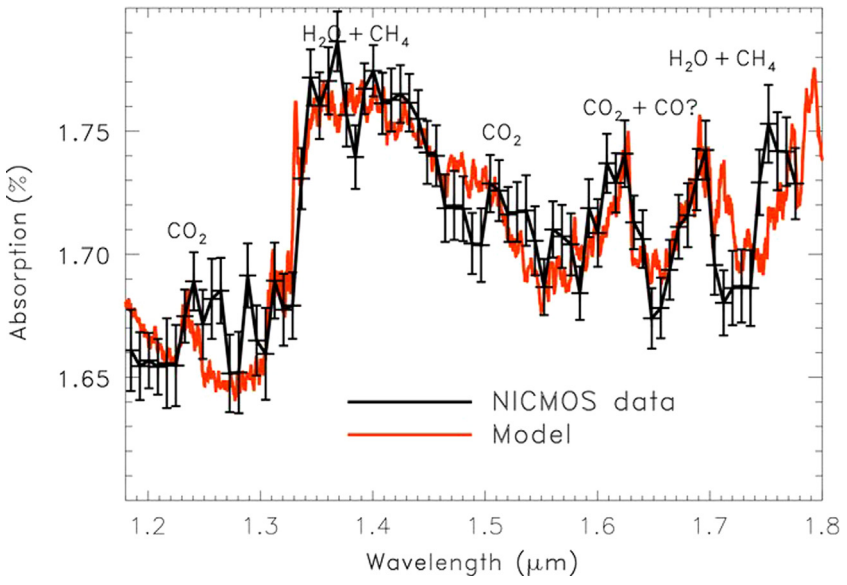

FIGURE 45.8 Near-infrared transmission spectrum of the hot Jupiter XO-1b obtained with HST/NICMOS. The best-fit atmospheric model contains significant amount of H_2O, CH_4, and CO_2. *Figure from Tinetti et al. (2010).*

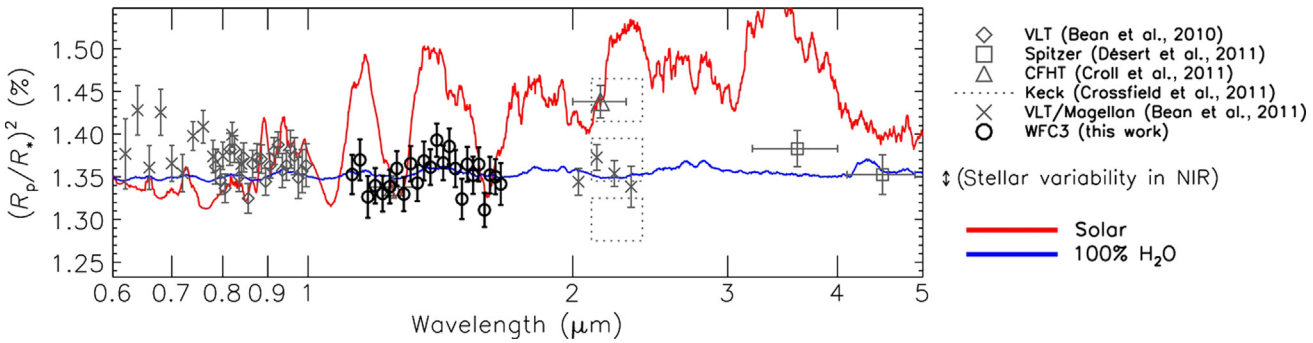

FIGURE 45.9 Transmission spectrum of the nearby super-Earth GJ 1214b, observed in the optical (0.6−1.0 μm) and infrared (>1 μm). The data are far better described by an atmospheric model rich in H_2O (blue line) than by a hydrogen-rich model (red line). NIR, near infrared. *Figure from Berta et al. (2012).*

More recently, similar techniques were used to probe the atmospheres of nearby super-Earths. Figure 45.9 shows the transmission spectrum of the small planet GJ 1214b measured with various instruments covering optical and infrared wavelengths. The very flat spectrum is best explained by an atmosphere rich (>40%) in H_2O, while a solar composition model (i.e. hydrogen rich) is clearly ruled out by the data. In the not so far future, we will be able to use these observational techniques to study small transiting planets and even search for so-called biosignatures in their atmospheres.

4. THE *KEPLER* MISSION

In March 2009, the NASA *Kepler* spacecraft was launched into its own orbit around the Sun. The primary scientific goal of *Kepler* is the determination of the frequency of Earth-size planets near and inside the habitable zone of Sun-like stars. The spacecraft consists of a wide-angle telescope with a mirror of 1 m diameter (Figure 45.10) and 42 CCD detectors to collect the light and perform very precise photometry. *Kepler* is using the transit method to detect extrasolar planets.

An Earth-size planet around a star of the same radius as the Sun produces a transit with a depth of only 84 ppm. Such a small transit signal is completely washed out by the variability of Earth's atmosphere, which is the reason why a transit telescope looking for Earths has to be in space. To achieve the goal to estimate the frequency of Earths, *Kepler* continuously monitors nearly 160,000 stars in a field of 100 square degrees (located roughly between the constellations Lyra and Cygnus).

A large part of the *Kepler* mission consists of the ground-based follow-up program to validate and confirm the *Kepler* planetary candidates. As in the case of ground-based transit searches, one cannot rely on the photometry alone to claim a planet detection. The *Kepler* follow-up observations are not only performed to rule out false positives but also to characterize the host star and, in the best cases, to measure the mass of the transiting planet by using precise radial velocity.

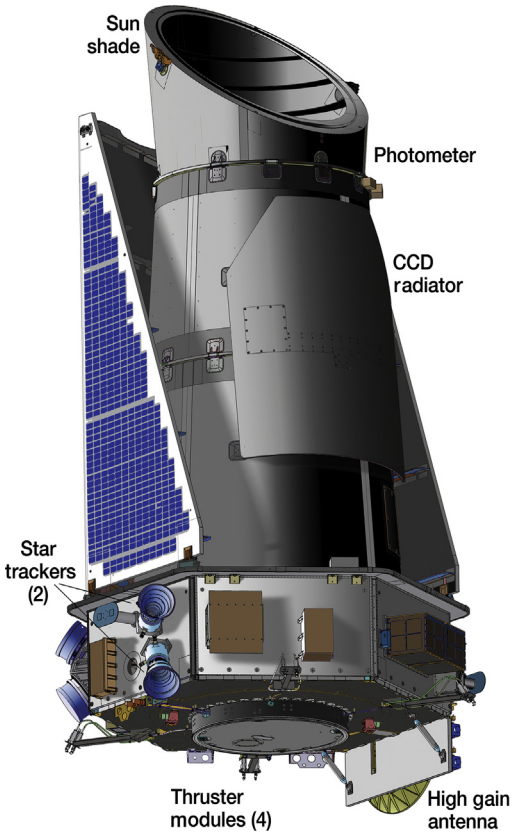

FIGURE 45.10 Artist's conception of the Kepler photometer and spacecraft. A 1-m Schmidt telescope that monitors nearly 160,000 stars in the Cygnus region for planetary transits since March 2009. Results from this mission revolutionized our current understanding of the structure and evolution of planetary systems. *Image courtesy NASA Kepler project.*

Of course, *Kepler* produces candidates much faster than confirmed planet detections. A look at the global properties of these candidates already teaches us a lot about the underlying planet population that creates these candidates. Some fraction of these candidates will be false positives but

the vast majority of them are true planets. Over the first 3 years of the mission, some very interesting trends appeared in the parameters of the *Kepler* candidates. These trends truly revolutionized our picture of the extrasolar planet landscape. *Kepler* discovered a large population of small-radii planets with a radius of less than 4 Earth radii, which clearly outnumber giant planets at least for orbital separations less than 1 AU (Figure 45.11). Moreover, it found several surprisingly compact multiplanet systems which resemble more the resonant architecture of the Galilean satellite system than our own solar system. *Kepler* also found circumbinary planets. These are planets orbiting an inner stellar binary, where the stars orbit each other with periods much smaller than the orbital period of the planetary companions. As most stars exist in binary or multiple systems, this tells us that planet formation is quite robust. Planets can also form in the protoplanetary disk around a stellar binary despite the dynamical perturbations caused by the two stars. This also means that the total number of planetary systems in the galaxy may be much larger than previously estimated.

The planets in some of the multiplanetary systems that Kepler discovered are sufficiently close to interact gravitationally with each other. This leads to variations in the orbital parameters of these planets that appear in the transit photometry as changes in the times of the transits of these planets. This effect is called transit timing variations (TTVs). Once TTVs are detected for a system, one can construct a dynamical model, including the masses of the planets, that reconstructs these interactions and the observed TTVs. This method was successfully applied to the compact Kepler-11 six-planet system to constrain the masses (and thus densities) of the planets, without the need of precise radial velocities.

A new data analysis method was developed for the *Kepler* mission, the so-called BLENDER algorithm. BLENDER is used to validate *Kepler* planet candidates in those cases where a mass determination or planet confirmation by other means is not possible. BLENDER constructs light curves for a large variety of possible false-positive scenarios, such as background eclipsing binaries. It then compares these false-positive models with the actual light curve and uses all available information on the field around the target star to estimate the probability that the light curve is produced by a transiting planet orbiting the target star as compared to a false-positive scenario. If the probability for a false detection is very low, the planet is regarded as validated.

Another advantage that the *Kepler* mission has is that the precise *Kepler* light curves can also be used to perform an asteroseismological study of the planet host star. The stellar parameters derived from seismology are more precise than spectroscopically obtained values. And these improved stellar parameters (e.g. the radius of the star) subsequently improve the planetary parameters as well (since the measured depth of the transit is proportional to the radius ratio of the bodies).

Some of the most interesting individual systems that were found by *Kepler* include: the Kepler-9 system, the first system of transiting planets that exhibits TTVs; Kepler-10b, a very hot super-Earth with a radius of 1.4 Earth radii and a high density of 8.8 g/cm^3 (similar to CoRoT-7b); and the Kepler-11 system of six transiting planets, one of the flattest and most compact systems that we know. The planet in the

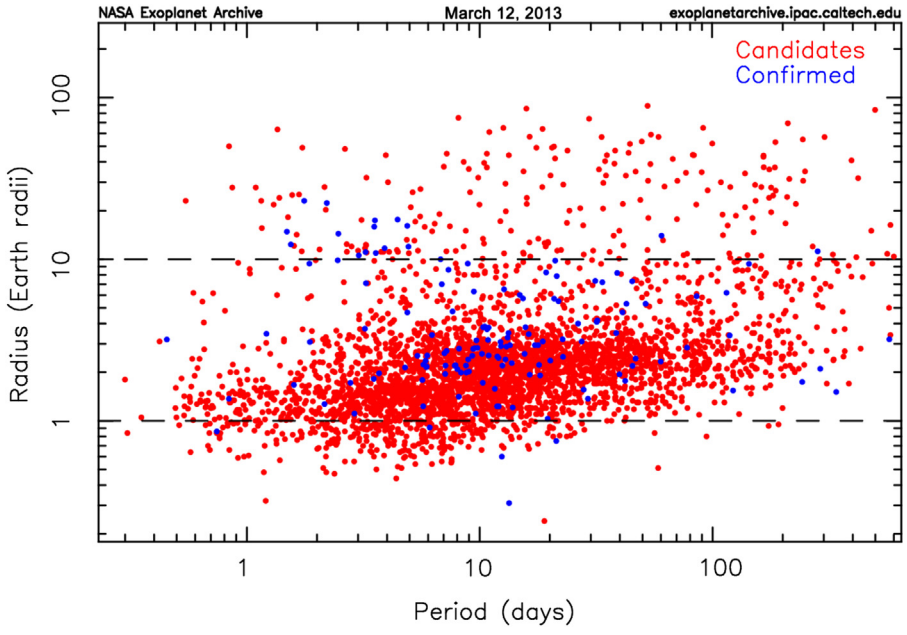

FIGURE 45.11 The distribution of the nearly 3000 Kepler planet candidates (red) in radius versus orbital period. The majority of candidates are smaller than 4 Earth radii. The blue dots show the confirmed Kepler planets. *Image courtesy of NASA Exoplanet Archive: http://exoplanetarchive.ipac.caltech.edu/.*

Kepler-16 system was the first circumbinary transiting planet. The inner binary consists of a K- and an M-type star that orbit each other every 41 days, while the Saturn-sized planet has an orbital period of 229 days. In summer 2012, *Kepler* announced the Kepler-47 system, the first circumbinary multiplanet system with at least two planets, one even in the habitable zone (Figure 45.12). This is further evidence that planet formation appears to be a robust mechanism and that also multiple star systems can host systems with several planetary companions.

Kepler also found small transiting planets inside the habitable zone of their (single) parent star. The first one found, Kepler-22b has a radius of only 2.4 Earth radii and a period of 290 days. Precise RV measurements cannot measure a mass in this case, but they set an upper mass limit, at the 1σ level, of 36 Earth masses. Two planets in the five-planet Kepler-62 system have orbital periods that place them in the habitable zone and measured radii of 1.6 and 1.4 Earth radii.

Despite the fact that the nearly 4000 planet candidates from *Kepler* are not all bona fide planets (a certain percentage are false positives), we can now derive first global statistical properties of the planet population that produces these candidates. From the total numbers of planet candidates of a given size we see immediately that smaller planets, in particular planets smaller than $\sim$3 Earth radii, dominate the planet sample. A new study by the team that developed the BLENDER method estimates that the global false-alarm rate for Kepler candidates is $\sim$10%. So 90% of the 4000 candidates are very likely to be real planets! The same study presented planet occurrence rates for orbital periods less than 85 days based on the current *Kepler* data and corrected for the false-alarm rate in the different planet size bins. The result is shown in Figure 45.13. We see that there is a sudden jump in the frequency of planets around 3 Earth radii and a relatively flat distribution down to 1 Earth-radius. For planets smaller than that and orbital periods longer than 85 days, the *Kepler* results are still too incomplete to estimate planet occurrence rates. Nevertheless, based on these first estimates, we can say that $\sim$17% of the stars in the *Kepler* field have at least one Earth-sized planet with a period of less than 85 days!

Another surprising result that emerged from the global analysis of the *Kepler* photometric data was the realization that using the photometric variability of our Sun as a benchmark, and as an expectation for the average variability of the stars in the *Kepler* field, underestimated the true variability of the *Kepler* target stars. The average *Kepler* star is $\sim$50% more variable than our Sun. This makes very shallow transit signals more difficult to detect, due to the higher noise level in the light curve. In order to find the transits of true Earth-size planets, several more transits need to be combined to get a significant detection. It thus became necessary to extend the mission by several years to assure sensitivity for Earth-size planets in the

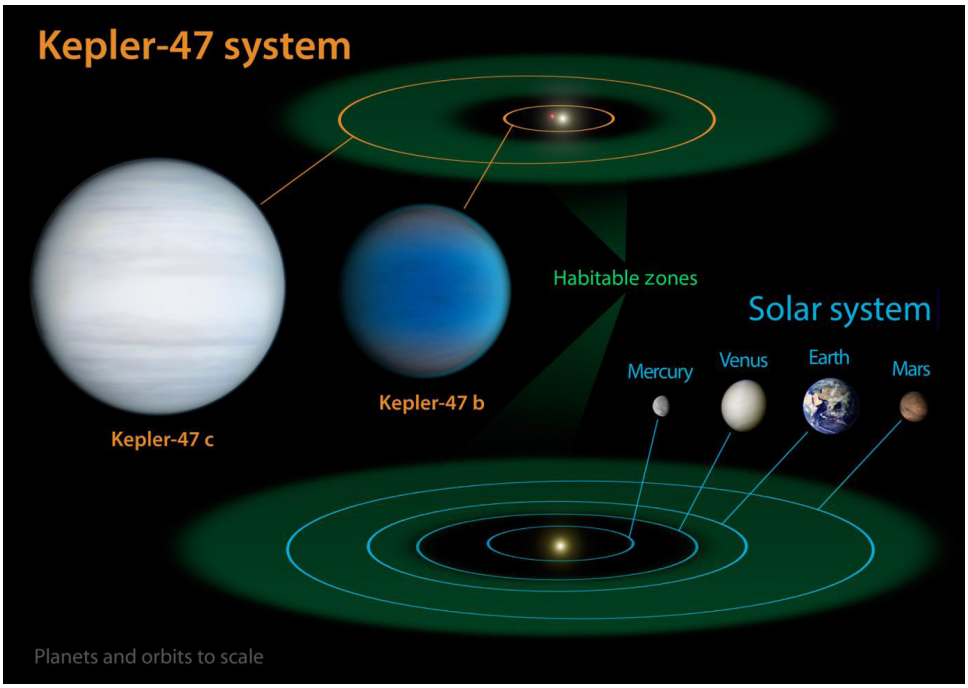

FIGURE 45.12 The Kepler-47 system of circumbinary planets compared to our solar system. The binary star consists of a solartype star and a small red dwarf star that orbit each other every 7.5 days. The two planets have orbital periods of 50 and 303 days, respectively. The inner planet is 3 times larger than the Earth and the outer one has a radius of 4.6 Earth radii and orbits within the habitable zone of this system. *Image courtesy of NASA Kepler mission.*

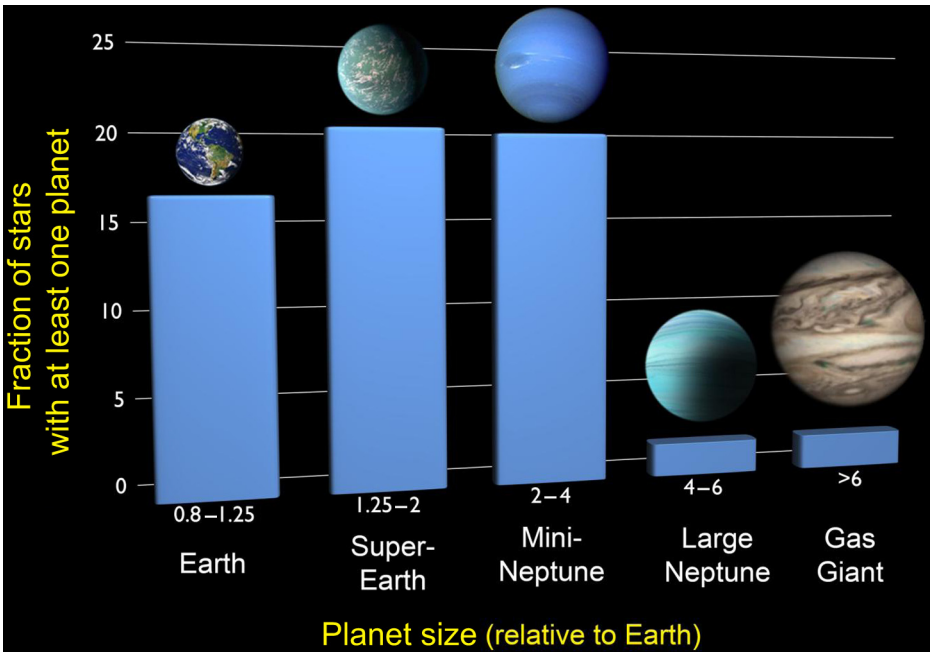

FIGURE 45.13 The planet occurrence rate as measured by Kepler for orbital periods less than 85 days. The primary goal of the extended mission of Kepler is the determination of the frequency of Earth-size planets in or near the habitable zone of Sun-like stars, so for periods close to 1 year. *Figure from Fressin et al. (2013).*

habitable zone (as these planets transit only about once per year). In 2012, NASA decided to extend the mission until 2016, but this extended mission ended prematurely in early 2013 due to a spacecraft malfunction. The final analysis of the entire 4 years of highly precise *Kepler* photometry will likely allow a first estimate of the frequency of Earth-size habitable zone planets, albeit with a larger uncertainty.

5. SUMMARY AND OUTLOOK

We truly live in the golden age of studying extrasolar planets. Detection programs using ground-based telescopes will continue to improve their sensitivity and to extend their search spaces, while space telescopes will play a more important and likely even dominant role in this field in the coming years.

The extrasolar planetary systems discovered so far demonstrate that a surprising variety of planetary systems exists in our galaxy. Although we now know that other stars also have planetary companions, and that planet formation is not unique to our star, many of them have characteristics different from the planets in our solar system. But this is primarily a result of the observational selection effects that are inherent to the techniques used to find these planets. A new kind of planet, the so-called super-Earths, was found to exist in other star systems.

The radial velocity technique was the first successful method that revealed a large number of planetary systems with giant planets on orbits unlike our solar system. These systems have had a much more dynamic past than our planetary system. The gas giant planets found at small orbital separations are probably a result of orbital migration, while the quasirandom distribution of orbital eccentricities might be caused by more violent and frequent interactions between planets in the early evolutionary stages. The fact that the overall mass function of extrasolar planets detected by RV surveys was steeply rising toward lower masses was an early indication that smaller and less massive planets are abundant in the galaxy. We also know today that the metallicity of the star- and planet-forming nebula has an impact on the structure of planetary systems. Most of the radial velocity planets are found around stars that are richer in heavier elements than the Sun. This is strong support for the core accretion model of giant planet formation. The lowest mass planets found around other solartype stars using very precise RV data already approach the mass range of the terrestrial planets.

The results from ground-based transit searches revealed the physical properties of a large number of hot Jupiters (and a few hot Neptunes). For the first time, one was able to determine the bulk density of these planets. Transiting planets helped to move the field from pure detection to a more detailed characterization of exoplanets. By using transmission spectroscopy we probed the atmospheres of these planets.

Microlensing surveys discovered several interesting planetary systems and the global results from these programs deliver important statistics on the galactic population of planets.

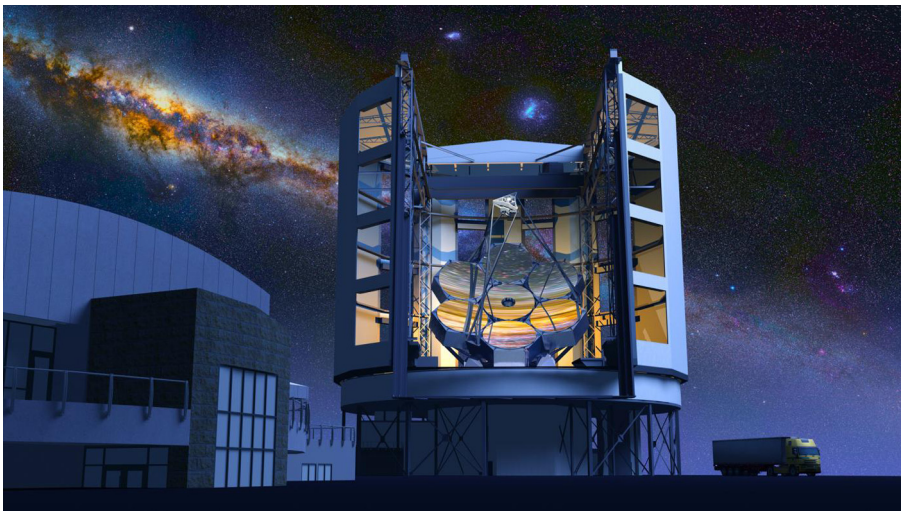

FIGURE 45.14 Artist conception of the future Giant Magellan Telescope. It consists of seven 8.4-m mirrors that have an equivalent light-collecting area of a 24.5-m telescope. With these extremely large telescopes like the GMT, the Thirty Meter Telescope, and the European Extremely Large Telescope, scientists will be able to detect and study nearby Earth-like planets and possibly even search for chemical signatures of life. *Image courtesy GMT project.*

The first exoplanets around nearby stars have been directly imaged. These are massive giant planets at large orbital separations that are currently difficult to explain by standard models of planet formation.

Space missions play an increasingly important role in exoplanet research. The European mission CoRoT was the first mission devoted to exoplanets. It found the first transiting super-Earth, CoRoT-7b.

In recent years, NASA's *Kepler* mission really helped to lift the field to the next level. It demonstrated that smaller planets dominate the population of planets. Despite the premature end of the extended mission, a very first estimate of the frequency of Earth-size planets in the habitable zone of Sun-like stars will probably arise from the *Kepler* data. This will be a truly historical result that will resonate not only in scientific circles but also in the general public as well.

But science never stops and *Kepler* is just the beginning of a new era of exoplanet research. There are several new missions and telescopes and instruments currently in preparation and planning that will greatly increase our knowledge of extrasolar planets. NASA is planning to launch the Transiting Exoplanet Survey Satellite (TESS) that will perform an all-sky survey for transiting planets. It can be expected that TESS will find some of the nearest small transiting planets that will be amendable for detailed follow-up studies. NASA's James Webb Space Telescope (JWST) will be an ideal instrument to study extrasolar planets in high detail in infrared wavelengths. The next generation of extremely large aperture ground-based telescopes with mirrors in the 30−40 m range, like the Giant Magellan Telescope (Figure 45.14), the Thirty Meter Telescope, and the European Extremely Large Telescope will allow astronomers in the coming decades to study small, possibly terrestrial, planets and their atmospheres around nearby stars. With JWST and these large telescopes on the ground, it might become possible to search for "biosignatures", chemical atmospheric tracers that are produced by an active biosphere. We are not very far away from obtaining a nearly complete census of the planet population in our galaxy, which will constrain our models of planet formation in general, and to even discover if any of these planets might be habitable.

3.5. Global Cooperation Becomes Reality 996
4. Conclusions and Outlook **996**
Bibliography **996**

1. EXPANDING HUMAN FRONTIERS INTO SPACE

Curiosity is a fundamental characteristic of the human species, which is the natural incentive for exploration. Discovering new worlds by exploring the unknown has been the stimulus to develop mankind into its present state. Starting from their origins in Africa, humans have continuously explored their near and far environment and thus settled all habitable ranges of the Earth. Mankind has explored all areas of the globe, from pole to pole, from deep in the sea to the highest mountain tops and to the uppermost levels of the atmosphere.

The challenge of today and of tomorrow is the exploration of space. Like the exploration of the seas, which followed breakthroughs in shipbuilding and navigation, distinct technological developments are a precondition for this step. The advances in rocket propulsion in the middle of the twentieth century, initiated by military research efforts in Germany, were the starting point of a rapid evolution, accelerated by the cold war in the "space race". This led to a solid technological basis for space flight, stimulating research, advanced technology, and international cooperation.

There are various definitions of the term space exploration. In the present context, we define it as follows: "**Space exploration** is the extension of human reach beyond the Earth's atmosphere using spacecraft to access unknown terrains and environments, and to acquire knowledge about space, planets, stars, or other celestial bodies by human and robotic means."

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00046-3
Copyright © 2014 Elsevier Inc. All rights reserved.

This definition does not include astronomical observations from Earth, which has given mankind insight into space and the celestial bodies since ancient times, as part of space exploration. It does, however, encompass remote observation of any object from space.

The destinations of space exploration are unlimited; however, some restrictions are imposed by the human life span, the energy available for propulsion, and the distances involved. In foreseeable future, our reach will be confined within the planetary system. Distinct constraints will be encountered for human exploration, where the major destination will be the surface of Mars, our neighbor planet.

1.1. Why Should We Explore Space?

Space exploration has started just 50 years ago, and it is a continuous process that will extend over the next centuries. So far, substantial accomplishments have been achieved through space flight that changed paradigms of our world view and improved our daily life. Numerous satellites observe the Earth's surface for a variety of purposes. They range from agricultural support to the mitigation of natural or man-made disaster events. Important evidence is derived from their data concerning the human influence on a global change of climate. A permanent human presence in **low Earth orbit** (LEO) has been established through the International Space Station (ISS), where the microgravity environment allowed for discoveries in medicine and materials science that have led to improved health care and industrial processes on Earth. Communication relies on spacecraft in geostationary orbit, and novel navigation services have become a matter of course worldwide. Industrial structures have been established on Earth through space exploration, with considerable economic impact. Our knowledge about space and the objects in our planetary system has grown substantially, and the understanding of our universe has evolved in a revolutionary way. Such progress for humanity was not expected at the early days of space flight, which were driven by military aspects and the cold war environment.

There is no limit to the exploration of space, and we may expect in future similar progress as in the past. While discoveries and novel technologies cannot be predicted, a number of benefits will undoubtedly emerge from space exploration. Among those are the following:

- *Improvement of the quality of life on Earth* is a prime objective of space exploration. This applies to progress for individuals in areas like safety, food, and health, and even more to collective advances for humanity. It will help to ensure a viable Earth for our grandchildren by mitigating global challenges. This includes the conservation of the Earth's biosphere and climate. Both are global phenomena, so global tools in space are required to monitor changes and find means of reducing negative effects.
- *Human progress and knowledge* will rely on contributions derived from space exploration. There are fundamental questions of mankind, such as

  Where do we come from? What is the origin of life in the universe?

  Are we alone? Does life exist anywhere else than here on Earth?

  Where are we going? How are humanity, the Earth, and the universe developing?

  Definitely, space exploration will deliver important contributions toward answering such questions. Moreover, it will yield a wealth of scientific opportunities that help to understand the solar system in relation to our home planet Earth and the universe as a whole.
- *Technology and economy* will advance in future through progress in space exploration. The technological demands of space are extreme, calling for new approaches in miniaturization, environmental tolerance, reliability, and energy conservation. Space developments will influence industrial processes and strengthen the competitive position of manufacturers on the international markets. Private ventures will increasingly participate in exploration, as opportunities like space tourism and planetary resource extraction emerge.

  Space exploration is an engine of progress, stimulating increased employment in the high-quality job sector. The past rapid evolution of the communication market will progress with new services from space, with the accompanying increase in novel instrumentation and consumer products. In addition, derived services on the ground making use of space assets will rapidly grow.
- *Cooperation* is a necessity in future space exploration. Major space ventures, in particular involving human space travel to distant destinations like Mars, are beyond the capabilities of any single nation. While the early beginning of space flight was dominated by national competition, culminating in the cold war between the two superpowers, in recent times the aspect of cooperation has become more and more relevant. A current example is the ISS, a cooperative venture between 14 nations that is stable since 1998. It has survived political turnover in several partner nations, severe technical and financial problems, and the world economic crisis. There is no doubt that the cooperation in a peaceful technological project of the dimension of the ISS has contributed to improved relations between the participating nations. Scientific and technical cooperation on a global scale, a precondition for

human space exploration, will contribute to peace and a better understanding between nations.

- *Inspiration* is an important feature of space exploration. The fascination of space is prompted by the mere difficulty of reaching and exploring it, and by the rewards in terms of knowledge and discovery of exotic new worlds. Human presence in space dramatically enhances public interest, a fact of utmost significance as it is this very public that carries the load of funding in its role as taxpayer. Space exploration catches the attention of the young generation and is a stimulus to aspire careers in science and technology.
- *Sustained human life beyond Earth* could open a variety of perspectives for future human development. While none of the bodies in our planetary system is directly suitable for human life, numerous planets orbiting stars are presently being identified by searches in the Milky Way (*see* Exoplanets). Some of those could be habitable or be made habitable to be destinations for expansion of the human race. Enormous technology steps are required to support human transportation to even nearby stellar systems. Alternatives such as the transfer of genetic information might be considered.

1.2. Exploration Extents into the Universe

Space is huge, and it contains a vast amount of features and objects worth exploring. Not all of them are as obvious as, for example, a planet. Of interest is "empty" space itself, where the physical properties, magnetic and electric fields, radiation environment, and stellar winds or dust particles may be the object of investigation. In fact, the first scientific satellite, Explorer 1(*see* Planetary Exploration Missions), discovered in 1958 the van Allen belts, a radiation zone around the Earth composed of solar wind and cosmic ray particles. Later this led to the discovery of the magnetosphere, which protects the Earth from hazardous radiation and particles.

Conspicuous potential destinations of exploration are the large and visible objects in nearby space, like the sun and its planets, the Moon, and various natural satellites orbiting planets. There is a vast population of smaller objects, like the **asteroids** accumulated between Mars and Jupiter, and **comets** roving around in the solar system. The latter originate from the **Kuiper belt** or the **Oort cloud**, areas crowded with small bodies, extending from Neptune's orbit to the limits of the solar system.

Most large bodies in our vicinity have been discovered in ancient times, long before the space age. New discoveries through space probes therefore are limited to several moons of the giant gas planets.

Exploration of planetary bodies is usually performed in steps. First, a flyby takes close images and measures selected physical properties. A more thorough study continues with a satellite in orbit around the celestial body, mapping most of the surface and taking detailed remote measurements. Exploration continues with landing a probe on the surface (whenever existing) to make in situ measurements, and possibly releasing a mobile element to investigate the near environment. Returning samples to the Earth for detailed analysis is the following step, before a human landing on a body in the planetary system might be considered. The final step is utilization, which could be scientific, public, or commercial.

A summary of the exploration steps of the large objects in the solar system is presented in Figure 46.1. Apparently all planets and some smaller bodies have been visited by

Objects in the solar system													
Exploration step	Moon	Mercury	Venus	Mars	Mars moons	Comets, Asteroids	Jupiter	Jovian moons	Saturn	Saturn's moons	Uranus	Neptune	Kuiper belt
Discovery	Discovered before the Space Age							Galileo		Cassini

spacecraft (*see* Planetary Exploration Missions), but only the Moon has been explored including all steps and is now awaiting utilization.

1.2.1. The Human Action Radius is Limited

While robotic spacecraft have investigated nearly the entire solar system, present-day space technology sets strict limitations on the range humans can travel in space. Crew on board is heavy; it requires facilities and consumables. Radiation in space is a hazard, with the dose increasing with exposure time. The safety demands are considerably higher than for robotic probes, and the safe return of the crew is, with the exception of a few debatable projects, a precondition.

A schematic presentation of the **human action radius** is given in Figure 46.2. Man can travel in the vicinity of Earth on various orbits and has established permanent presence in LEO by means of the ISS. The Moon has been visited as part of the Apollo project several times in the late 1980s. Using present-day technology, humans can travel toward the Sun up to about the Venus orbit. Closer to the Sun thermal conditions become very demanding. In the other direction, away from the Sun, planet Mars is the most exciting destination for human exploration. Using appropriate road maps and way stations, and particular by suitable means of **human-robotic partnership**, the human range could be extended beyond Mars and its moons, up to the inner parts of the asteroid belt.

The current human action radius appears quite limited, compared to the size of the solar system and the dimensions of the universe. However, man can be a factor to answering the main quest of exploration within his action radius. In particular, contributions to the fundamental search for the origin of life can be expected. Not all destinations are of equal value in this respect. The Moon offers a special potential as an archive of the history of the planetary system (*see* The Moon and Lunar Exploration). Without atmospheric erosion and limited geologic activity, the Moon preserves a record of almost its entire impact history of 4.5 billion years, offering important information on the processes in the early evolution of the solar system. Venus, with its hot surface and the extreme atmospheric pressure probably has not preserved much features relating far back in time. Interesting objects are small bodies like asteroids and comets. Comets, distinguished from asteroids by their coma (or tail), originate from the outer regions of the solar system. At the low temperatures prevailing there, volatiles and possible organic molecules have been preserved from the **protoplanetary nebula**, the material from which our solar system has formed. If such a body is deviated into regions close to Earth, it is a source of information about matter essentially unchanged since 4.5 billion years. Different motives stimulate human interest in asteroids, which might be a hazard to Earth. Some of them, approaching the vicinity of Earth as a "**near Earth object**", might develop into targets for commercial ventures mining precious materials for use on Earth.

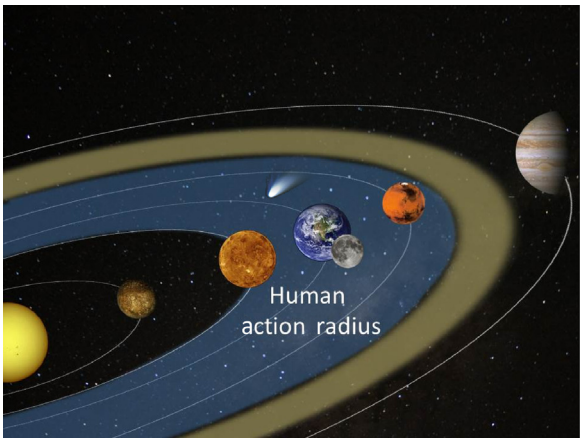

FIGURE 46.2 The human action radius in the solar system extends from the orbit of Venus to the inner part of the asteroid belt, including the Moon, Mars, near-Earth asteroids, and some comets.

1.2.2. The Special Role of Mars

Planet Mars has always inspired human fantasy. This is one of our two close neighbor planets, and it exhibits similarities to Earth. Through a telescope, even in early times, features could be identified, which change periodically with seasons. This stimulated the idea of vegetation existing on Mars. The discovery of surface structures, erroneously identified as engineered "channels" (actually due to an incorrect translation from Schiaparellis labeling as "canali", which means riverbeds) led to speculations about intelligent life on the planet.

Early exploration missions to Mars therefore had stimulated significant interest. The first images received from a spacecraft were taken by Mariner 4 in 1965. Even though the quality of the 22 pictures returned to Earth was disappointing from today's standards, the result was a sensation, but at the same time disillusioning; they showed a desolate landscape with no signs of vegetation or water. The landing of the Viking spacecraft in 1976 confirmed this impression, and its search for traces of life was rather negative, however, by no means conclusive.

Nevertheless, Mars is an intriguing planet. It is at the outer edge of the **habitable zone** of our solar system, where the existence of liquid water in principle is possible. In the early state of planetary development Mars could have been quite similar to Earth, temporarily with abundant water and a dense atmosphere (*See* Mars Atmosphere: History and Surface Interactions). It is intriguing to note that this was at

a time when life developed on Earth, about 3.5 billion years ago. Due to its smaller size, Mars has developed much faster than Earth (*see* Mars Interior). Today it is a desert planet with a tenuous and toxic atmosphere. At the Mars surface, pressure and temperature conditions are below the triple point of water, so water cannot exist in liquid form for extended periods of time. The atmosphere, consisting mainly of carbon dioxide, is highly oxidizing. Together with the radiation environment this will prevent the persistence of organic material near the surface of Mars. In spite of this hostile environment, traces of extinct or extant life could potentially be found in subsurface layers of Mars, where water exists adsorbed on grains or in the form of ice, protected from the atmosphere and radiation.

It is therefore not surprising that Mars is one of the most popular destinations for space exploration, only second to the Moon, which is so much closer. Since 1960, 42 missions have been launched to the red planet (not including swing-by maneuvers). Of these, only 22 missions have been successful, which demonstrates the difficulty in reaching our neighbor planet. A total of eight landing probes have successfully reached the surface of Mars, and four rovers have been deployed to investigate the environment.

The flight to Mars is quite challenging. The minimum energy trajectory to transport a spacecraft to the planet follows a **Hohmann transfer orbit** (Figure 46.3). This is an elliptical trajectory that has common tangents to circular orbits both at the body of departure and the destination body, with pulses of injection thrust applied at both ends. It makes use of the orbital velocity of the Earth around the Sun. The launch window is defined by the respective positions of the planets at the beginning and the end of the transfer. The Earth–Mars trajectory has a launch window every 780 days, which is the **synodic period** of Mars with respect to Earth. Due to the orbital eccentricities, optimum launch windows exist approximately every 16 years, with the last opportunity in 2003 and the next in 2018. The actual transfer flight takes about 260 days. After a landing maneuver, the window for the return trip opens about 15 months after arrival, so the total time required for a journey to Mars and back with minimum energy requirement is about 2 years and 9 months or 1000 days.

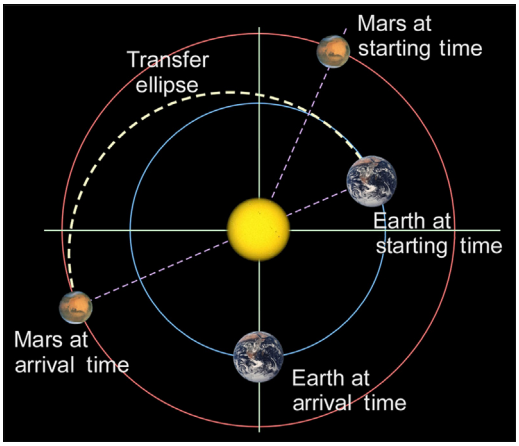

FIGURE 46.3 A minimum-energy flight to Mars relies on the Hohmann transfer ellipse, making use of the orbital velocity of Earth.

1.2.3. Exploration Beyond Mars

For destinations beyond Mars, the difficulties of spaceflight increase substantially. The distances become very large, which gives rise to transfer times in the order of decades rather than years. Simultaneously, fuel and propulsion requirements increase as the spacecraft moves further out in the solar gravitational field. Solar power becomes increasingly dilute at these distances, imposing demands on spacecraft energy supply and thermal design. The radiation exposure is high due to the long travel time, and it can become massive when approaching the radiation belts of the large planets. All these difficulties increase dramatically if transport of crew is considered.

The giant gas planets Jupiter, Saturn, Uranus, and Neptune have thick atmospheres of mainly hydrogen and helium that gradually increases in density, with possibly a rocky core inside (*see* Interiors of the Giant Planets). In contrast to the terrestrial planets, there is no solid surface at their outer boundaries, so landing a probe does not make sense. Therefore, flyby and orbital missions might possibly be complemented by balloon-like probes in the atmosphere. All the outer planets, however, have numerous moons that have solid surfaces and one of them, Saturn's largest moon Titan, even has an atmosphere. Titan has been visited by the Cassini mission and the landing probe Huygens has successfully descended through the atmosphere to land on the moon's surface.

Icy moons of gas giants have recently attracted increased attention as they may contain large reservoirs of liquid water, where primitive forms of life might exist. The three outer Galilean moons of Jupiter, namely, Europa, Ganymede, and Calisto, hold liquid water under thick surface layers of ice, kept fluid by pressure and tidal heating. It is in particular Europa (*see* Europa) that has stimulated interest due to the observations that hint at a huge ocean of salty water, buried under an ice layer with a thickness of a few kilometers up to several tens of kilometers. The potential existence of microbial life has been speculated there, similar to the hydrothermal vents ("black smokers") observed deep in the oceans of the Earth. Another candidate for the existence of liquid water is Saturn's moon Enceladus, which emits plumes of water vapor in a process of **cryovolcanism**. Different conditions exist on Titan, where lakes of liquid methane were detected. Conditions similar to those on the primordial Earth led to

the speculation of possible prebiotic compounds or even primitive microbial life forms to exist there. The Huygens lander was not equipped to search for traces of life, so no evidence exists today. It is interesting to note that these observations put the notion of a **habitable zone** around a star in perspective. This is presently defined as a circumstellar zone where planets with a sufficiently dense atmosphere can maintain liquid water at the surface and such can host life.

1.2.4. Exploration Beyond the Solar System

At the present time, four spacecraft are on the way to leave the solar system (Figure 46.4). These are Pioneer 10 and 11, launched to explore the outer solar system in 1972 and 1973, respectively, and Voyager 1 and 2, both launched in 1977 to take advantage of a favorable alignment of the planets. Voyager 1 presently travels through the heliosheath, which separates the solar system from interstellar space. In 2022, Voyager 1 will pass the **heliopause** and become the first man-made object to leave the solar system. In contrast to the Pioneer spacecraft, both Voyager probes are still partly operational and transmit data about electric and magnetic fields, solar wind, and hydrogen distribution.

Traveling at a speed of 17 km/s after four gravity assist maneuvers it will take Voyager 1 about 50 years to leave the solar system. This is an indication of the enormous distances and flight times inherent in interstellar travel. A trip to the closest star Proxima Centauri at this speed would take roughly 75,000 years. Obviously, exploration beyond the solar system requires major progress in propulsion. Novel systems including nuclear energy and continuous propulsion through, for example, electric drives will be necessary. Interstellar spaceships carrying crew are out of scope with present day technology. The problems are not only propulsion, but include the life support, which has to operate with a closed cycle, radiation protection, reliability of all systems and subsystems, and not the least the psychological problems inherent in such ventures. On the other hand, science discovers at a rapid rate **extrasolar planets**. Very likely planets with conditions similar to our home planet will be found, and some of them maybe in nearby stellar systems. It will be just a matter of time to develop technology to explore those potential future habitats for humans.

1.3. Future Space Exploration Relies on Significant Progress

Future space exploration, by its very nature, will have destinations more demanding than previous ventures. Most of them, in particular if a crew will be involved, will therefore require advanced technical developments or even breakthroughs, novel ways of project preparation and long-term planning, enhanced coordination and cooperation between nations on a global scale, and political consensus within and between all participating nations.

1.3.1. Technological Developments

Heavy launch capabilities are a precondition for ambitious exploration tasks. The present development status of chemical rockets has approached its limits. In modern launch vehicles, the structural coefficient, i.e. the ratio of structural mass to total launch mass, has reached a value of 5%. There is not much room for engineering improvements in this field.

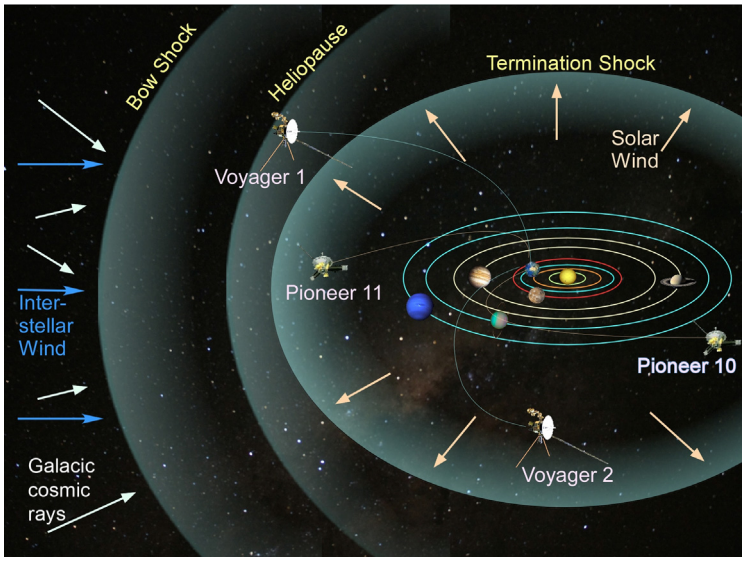

FIGURE 46.4 Schematic of the heliosphere (not to scale), the region where solar fields and particle flows dominate interstellar space. The termination shock was successfully detected by Voyager 1 in 2004 and Voyager 2 in 2007. Voyager 1, launched in 1977, is the farthest man-made object from Earth and is still active.

Various chemical propellants are in use, optimized for solid or liquid rocket motors. Adaptation to specific tasks, including exploration missions, therefore relies on scaling and staging optimization.

Major improvements in the efficiency of transport from the Earth's gravity well into space require new approaches. Several systems using air breathing engines in the first stage are presently under development. Among these are commercial ventures like the suborbital space plane "SpaceshipOne" or the "Skylone" project. Alternatives are projectiles, accelerated by chemical means or by electromagnetic rail guns. Futuristic ideas such as a space elevator will have to await advances in materials development.

For in-space propulsion, presently used systems rely on reactive thrusters, where a mass is emitted at high velocity to propel the spacecraft. Chemical systems could in future be replaced by electromagnetic or nuclear powered engines. Nonreactive propulsion systems like solar sail, magnetic sail, or electromagnetic tether depend on photon or particle flux from the Sun, or on interplanetary fields. The latter are most efficient in the vicinity of the Sun or near strong local magnetic fields like in the Jupiter system.

Novel development is also demanded in spacecraft design. Depending on the exploration destination and the strategy chosen various spacecraft for crew and cargo transport will be required, in addition to habitats, descent- and ascent vehicles, and service and support systems. All this will have to be embedded into extensive research programs on advanced materials, novel manufacturing processes, system management and simulation, and accompanied by parallel advances in instrument technologies.

1.3.2. International Cooperation in Space Exploration

Most space ventures to date are single-nation efforts or bilateral agreements. Notable exceptions are the European Space Agency (ESA), which brings together the knowledge, industrial power, and resources of 20 European nations, and the ISS, a joint effort of five partners including 14 nations. A challenging exploration effort should encompass as many nations as possible, each contributing according to its national interest, capabilities, and resources. This requires a strong and long-term coordination effort to ensure compatibility, efficiency, and to avoid duplication. A framework has to be established of interested nations, open for additional participants. This has to agree on overarching principles such as a governance system, common goals and objectives, basic principles of cooperation including work sharing, interdependency and competition, and the cooperation with commercial partners. From there, mission scenarios and technological road maps will then be developed.

1.3.3. Human-Robotic Partnership

The definition of space exploration hinged to the extension of human reach in space does not imply a priority for human spaceflight. In fact, **human-robotic partnership** will be indispensable to any exploration venture. Any human mission to a body in space will be preceded by robotic flights, investigating the environment and preparing it for human presence. Robotic precursor missions are important sources of scientific knowledge. The synergy between human and robotic action in space will not be limited to preparatory measures. Robotic components in a human space program will be necessary to reduce the risk, to ensure human safety, health, and to enhance the working efficiency. Humans may play a role for future servicing of high-value assets near Earth or Moon (following the example of the Hubble Space Telescope). A balanced use of human and robotic capabilities will be necessary to maximize the return of investment in any space exploration mission.

1.3.4. The Need for Sustainability

The Apollo program was a bold pioneering venture and very successful. It was, however, by no means sustainable. While the scientific results are still highly valuable, much of the technical and operational expertise is lost today. Apollo is neither a precursor nor a model for a future exploration program.

Sustainability refers to the need to make steady progress and continuous delivery of benefits within an affordable budget environment. In the end, the perceived benefits and investments need to be balanced. A sustainable exploration program cannot be understood as a sequence of several independent visits to various destinations, but rather as a continuous, stepwise process that finally leads to self-sufficient presence of humans in space, supported by robotic systems, and exploiting local resources. Therefore, the capability of developing **in situ resource utilization** will be an important component of exploration.

But sustainability is necessary not only in the technical domain. As a multinational effort, the international cooperation agreement signed as the basis for space exploration has to be sufficiently robust to sustain political changes, economic problems, and a temporary decline of public interest. An important ingredient of such an effort is the involvement of private industry, both in the development of an efficient space infrastructure, and in the exploitation of extraterrestrial resources. In the long run, having a sustained and self-sufficient presence in space will also allow humanity to maintain off-world repositories of knowledge and history.

1.4. The Challenge of Human Exploration

With the establishment and operation of the ISS mankind is at home in LEO. The ISS has been inhabited continuously

since the year 2000. Some astronauts have logged an extremely long stay in space, with cosmonaut Valeri Polyakov holding the record of 437 days. There are no reports about permanent impact of spaceflight on the health status of astronauts. Apparently, the effects of microgravity on the human physiology can be managed by appropriate countermeasures. These facts appear to allow the conclusion that humans can adapt to the space environment. This, however, is true only for the LEO, where the crew remains within the shield of the Earth's magnetosphere and at least a third of the cosmic radiation is blocked out by the large body of nearby Earth.

The challenges of human spaceflight beyond LEO are numerous. As the distances get large, the travel time increases due to present day limitations in space propulsion. Intermediate stations on the way to distant targets may reduce some difficulties. For destinations beyond the Moon, opportunities for emergency return within a few days diminish. This imposes stringent requirements on safety and reliability of all subsystems, as well as repair and in situ manufacturing of spare parts. In addition, the impact on human psychology should not be neglected. Medical care requires novel approaches. Provisions for in situ medical treatment have to be envisaged, supported by advanced telemedicine as developed in the course of ISS operations.

A crew member requires about 5 kg of consumables per day in the form of food, water, and oxygen. It creates an equal amount of waste in solid, liquid, or gaseous form. All systems used presently for long-time life support, e.g. on Apollo or ISS, rely on resupply from Earth. For long-duration space flight, it is a prerequisite to recycle at least part of the consumables. Ultimately, closed cycle systems are necessary. Environmental control and life support systems provide breathing air, remove carbon dioxide and contaminants, and regulate pressure, temperature, and humidity for human survival and comfort. Only partial reuse is present state of the art. The life support system of the ISS is equipped with a water recovery system that processes waste water from hygiene systems (showers, sinks etc.), urine water, and water vapor collected from the atmosphere. This water is partly recycled for drinking, and part of it is electrolyzed to produce oxygen for air revitalization. Huge development efforts are necessary to produce closed cycle life support systems suitable for long-distance space flights. There are research attempts toward in situ food production, which are still far from a closed cycle production.

1.4.1. Radiation Exposure is Most Critical

The most severe limitation for human spaceflight is the radiation environment. As a spacecraft leaves the protective shield of the Earth magnetosphere, it is exposed to the space radiation environment. This is composed of galactic cosmic rays and energetic solar particles. **Galactic cosmic radiation** (GCR) consists of about 85% high-energy protons, 15% helium (alpha particles), and highly ionized heavy nuclei (HZE particles). **Solar energetic particles** originate from solar flare eruptions, which inject energetic electrons, protons, and alpha particles into space.

The health impact of space radiation environment on the human body can be both acute and chronic. In particular heavy bursts of solar particle events (SPEs) may be lethal to unprotected crew. These events, however, are relatively rare with less than 10 per solar cycle and last only for days. The crew can be protected for these periods in a small, specially shielded shelter. GCR flux is more continuous, its intensity being inversely correlated with the solar cycle. It causes health hazard like DNA damage, increased cancer risk, and may impact the human central nervous system. An illustration of the risk of cancer death for various exposures is presented in Figure 46.5.

1.4.2. Is Shielding the Solution?

Shielding reduces the radiation flux, but its effect has limitations, mainly due to the amount of protective material that has to be transported during the space flight. Present human spacecraft uses the aluminum skin of the crew module as radiation shield. The skin of ISS reduces the radiation flux inside by about 50%. Light atoms like hydrogen are more efficient in shielding. Therefore, plastic material like polyethylene, which is rich in hydrogen, might in future be used for spacecraft skin. This material is light and can be produced with strength higher than aluminum. Liquid hydrogen, which would serve as fuel for propulsion, can be used as a temporary shield. Water carried on the spacecraft is an alternative. Especially for crew protection during SPEs, which are of limited time duration and allow for a warning time of a few hours, small sheltered areas can be created in this way.

An alternative to mass shielding is the active deflection of charged particles by magnetic fields, similar to the magnetosphere that protects Earth. A "magnetic Faraday cage" for a manned flight to Mars has been proposed by Samuel Ting, which, however, requires a total coil mass of more than 5 tons and up to gigawatts of energy.

The effects hazardous to the human body scale with the absorbed dose, which is exposure multiplied by time. This leads to typical mission radiation doses as illustrated in Figure 46.6, based on present-day space transport technology. The data reveal that a human Mars mission is at the limit of the radiation dose acceptable for an astronaut's career. Human space flight beyond Mars, exemplified for a mission to Jupiter's moon Calisto in the diagram, would far exceed this dose. As passive shielding has a heavy mass penalty, the alternative is to reduce travel time. This requires

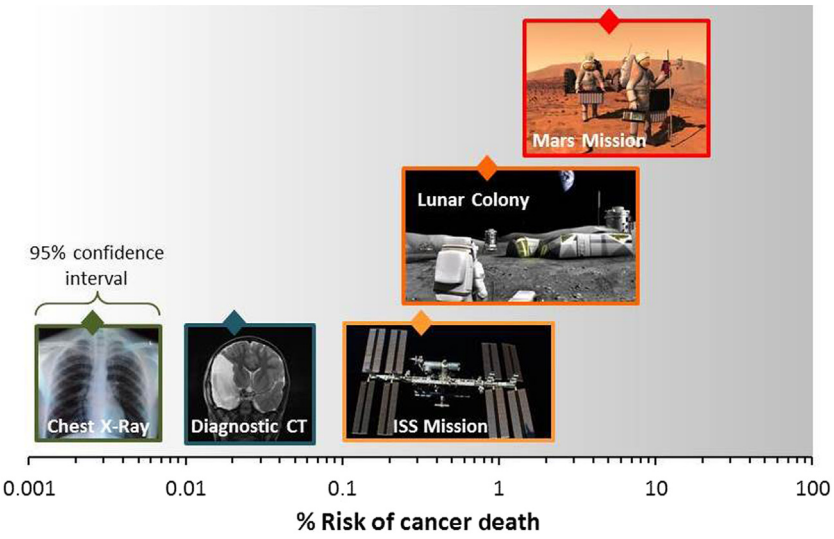

FIGURE 46.5 Risk of cancer death for various space missions, as compared to the risk from medical diagnostic tools on Earth. *Courtesy: Marco Durante.*

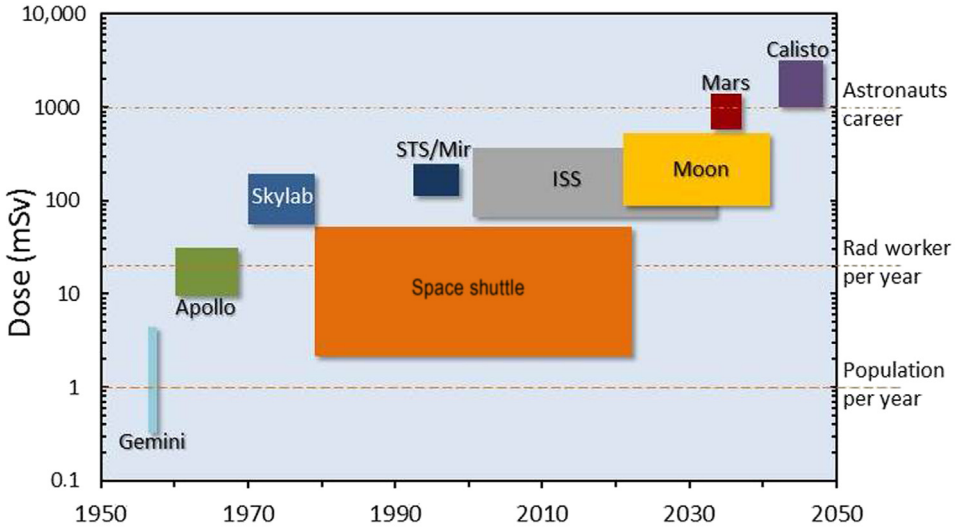

FIGURE 46.6 Radiation dose estimated for various space missions. The dashed horizontal lines indicate the limit levels for the public (lower line, corresponds approximately to the radiation background on Earth), for designated nuclear energy workers (middle), and the maximum level for an astronaut accumulated over his career. *Courtesy: Marco Durante.*

breakthroughs in propulsion technology, including continuous thrust rather than short pulses as foreseen in Hohmann transfer orbits.

2. A CASE STUDY: HUMAN EXPLORATION OF MARS

Human in situ exploration of the Mars surface represents an achievable challenge for the twenty-first century. Sending humans to the surface of Mars, working there efficiently for advancing the knowledge of the Mars system, and returning the crew safely will require long-term planning and preparation over multiple decades. Studies by the International Academy of Astronautics (IAA) (Huntress et al., 2006) and the Committee on Space Research (COSPAR) (Ehrenfreund et al., 2012) have investigated this endeavor. The capabilities required for implementing such a mission as well as knowledge gaps that have to be closed through terrestrial and space-based research are being considered in detail. The resources required for realizing a mission over such an extended period of time exceed the capabilities of any single nation. Broad international cooperation is therefore a mandatory precondition for achieving a human mission to Mars. Affordability considerations will constrain the ability to develop in parallel the large number of new technologies and systems required and therefore call for a stepwise approach. The risk areas are well identified, and significant

effort is required to adapt them to the current safety standards related to human space travel. An incremental approach will help to achieve intermediate successes and results, a necessity in a program that is depending on public support for periods of several decades.

A long-term cooperative program therefore requires in preparation a careful procedure that includes

- establishment of a cooperation framework including all nations interested,
- definition of potential benefits in science, economy, and culture,
- agreement on common strategies,
- investigation of various mission scenarios,
- definition of a global road map.

2.1. Cooperation Models

Early space exploration activities have been based on national pride and international competitiveness, driven by the Cold War. With increasing complexity of space projects, nations joined into cooperative missions on a bilateral or multilateral level to share resources and capabilities. Usually one nation is leading in such collaboration and the contributions from partners are of complementary nature.

A special kind of cooperation was created in the ESA, where several nations decided to tackle complex and costly space projects on the basis of equal partnership, each nation pursuing priorities to benefit their citizens. With 20 nations pooling their resources in an organization active for more than 40 years, ESA is a success story of cooperation.

The ISS is the first intercontinental cooperation on a single, long-term space project, which relies on public funding and coordinates national interest on the basis of complementarity and interdependency. It is based on an international treaty signed in 1998, called the ISS Intergovernmental Agreement. This provides the framework for design, development, operation, and utilization of the ISS. The agreement has governed the cooperation successful over several decades, overcoming technical problems, economic turmoil, and changing governments.

While the structure of the ISS partnership has been designed for the specific purpose of developing and operating the ISS, it represents a good basis and reference for the type of partnership required for taking on the challenge of expanding human presence to Mars. The functional needs and characteristics of the cooperation required for the latter differ from the ISS cooperation. Sustainable human exploration of Mars is a venture of several decades, with timescales extending to a century. A more flexible framework is therefore required that can evolve in line with the stepwise implementation of the mission and adapt to new or changing partners along the way. The agreement has to focus on a long-term alignment of national plans of the partners, which depend on public interest, industrial capabilities and experience, resource levels, and specific needs and priorities of their citizens. The cooperation has to include complementarity, interdependency, and competitive elements. Typical characteristics of an international cooperation agreement for human exploration of Mars therefore should be

- a definition of common goals and objectives,
- long-term committing but nonbinding agreements between partners,
- incorporation of national plans and priorities, including planned near-term investments,
- a stimulus for aligning future developments in a direction advancing the common goals,
- identification of strategic knowledge gaps and specific engineering challenges,
- a stepwise approach including intermediate results of high visibility.

In addition, a collaboration agreement on the programmatic and technical side has to be complemented by a coordination framework on the political level and should be paralleled by industrial cooperation on an international basis.

2.2. Defining and Communicating the Benefits

Institutional funding plays to date a dominant role in advancing research and development in space. Private sector investment becomes increasingly more important for the development and provision of space services. However, activities in space driven by the private sector generally exploit knowledge and technologies developed earlier through institutional funding. The bulk of investments required toward realizing human missions to Mars will have to be provided by governments. Gaining and maintaining public support is therefore a critical factor for advancing toward human Mars missions. It is essential to understand and communicate how expanding the sphere of human activity within the Earth–Moon–Mars environment is relevant to society and citizens on Earth. Public sector investments need to ultimately improve the quality of life of citizens. Delivering tangible benefits and reporting back to the investors on benefits achieved will therefore be an important aspect of managing the process toward realizing a human Mars mission. Those benefits will concentrate in the areas of innovation, culture and inspiration, and peaceful global cooperation.

It is imperative for the international consortium to communicate efficiently with political decision makers and with the public regarding socioeconomic benefits resulting from space exploration. This includes the establishment of a common benefits-related framework and vocabulary

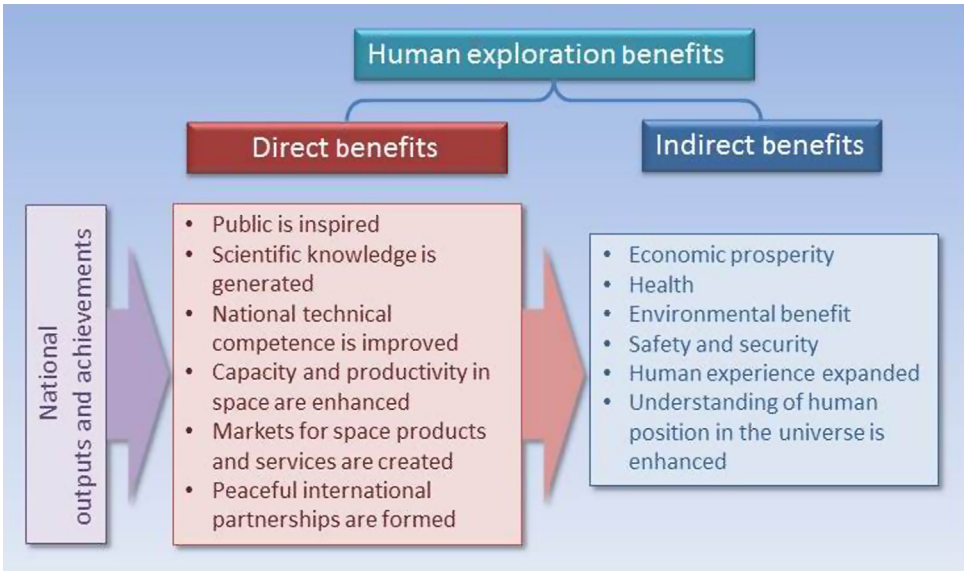

FIGURE 46.7 Logical model for describing how space exploration delivers benefit to society derived from work performed by the International Space Exploration Coordination Group. *Copyright: ISECG.*

among the partners. In this context it is helpful to distinguish between direct benefits, which emerge immediately from exploration outputs of space agencies and industry, with supporting contributions from international partners, and indirect benefits resulting over time from direct benefits (see Figure 46.7).

2.3. Focusing on Common Strategies and Intermediate Destinations

The mission of extending human presence to the Mars surface is of enormous complexity and extends over several decades. It therefore requires long-term common guidance and agreed goals and objectives. A set of guiding principles will have to be developed and agreed upon by the cooperating partners, such as

- a stepwise approach in phases based on capabilities and objectives,
- well-defined intermediate destinations generating results and stimulating public interest,
- robustness to ensure resilience to technical challenges and new developments,
- affordability based on realistic extrapolations of budget developments of the partners,
- flexibility to accommodate changes in partnership or in partner's priorities,
- emphasis on human-robotic partnership.

For the case studied here, the final destination is defined as a sustainable human presence on the surface of planet Mars. In any strategy, various intermediate way stations offer risk reduction, accumulation of experience, and valuable intermediate results. On the way to Mars the following destinations could be considered:

- **ISS**: As an existing asset in LEO, ISS can serve as a laboratory to advance capabilities in specific technologies, for gaining experience in operating critical systems over extended periods of time, for simulating deep space mission operation scenarios and conducting research for mitigating risks to human health and performance in space.
- **LEO**: Institutional and private sector funds have been invested in the development of crew and cargo transportation systems for accessing LEO. These relatively easy accessible orbits represent destinations where the economic feasibility of sustained human presence will be demonstrated first, possibly serving as model for similar activities applied later at other exploration destinations in the Earth−Moon−Mars system.
- **Cis-lunar space**: This embraces destinations beyond LEO, extending to the Moon and including the Earth−Moon **Lagrangian points** as well as high lunar orbits above 100 km.
- **Moon**: Low lunar orbits and the surface of the Moon are important destinations to gain experience and to develop capabilities required for a human mission to Mars. The Moon offers reduced risk due to easy communication to Earth with signal delays in the order of seconds, and crew emergency return to Earth in a 3−5 day time frame.
- **Near-Earth asteroids**: Those are objects from the asteroid belt with trajectories partially or fully within the Mars orbit, some of them crossing the Earth orbit. As intermediate destinations, they are of high scientific

interest and can reduce the risk for deep space exploration. Several commercial institutions have expressed interest in exploiting asteroid resources.

- **Mars system**: The Mars moons Phobos and Deimos, as well as Mars orbits, can serve as intermediate stations preceding human surface exploration of the Mars surface.

2.4. Mapping the Way to Mars

The development of a human space exploration strategy is a stepwise process. Starting on the basis of strategic mission scenarios, suitable selection processes are used to narrow down to a small number of design reference missions, which finally are used to detail a mission road map. In the following, this process is described using examples from the results of the International Space Exploration Coordination Group (ISECG).

2.4.1. Strategic Mission Scenarios

The strategies and intermediate way stations agreed jointly in the cooperating partnership serve as a basis for the development of a set of mission scenarios. These explore potential pathways to the final destination over a time scale of several decades. The missions are considered compatible with the existing capabilities and global development plans, using way stations in various configurations. They are based on consensus between the partners on principles such as affordability and value to stakeholders (see Figure 46.8). Necessarily, assumptions will have to be used in this process. Several scenarios are introduced, accompanied by studies into a suitable level of detail, which allows judgment with respect to the criteria defined by the stakeholders. In this way the number of mission scenarios is reduced.

2.4.2. Design Reference Missions

Within a selected strategic mission scenario, one or several **design reference missions** are defined. A design reference mission is a top-level description of the mission sequence and the capabilities needed to execute it. While usually being destination focused, the reference missions will include capabilities that are reused or evolved from capabilities used at other destinations. It will allow the partners to gain insight in what is required to explore the various destinations, including the capabilities needed and the basic operational concept. An example for a design reference mission developed for a human mission to the lunar surface is shown in Figure 46.9.

2.4.3. Global Exploration Road Map

Derived from the strategic mission scenarios and the design reference missions, a **global exploration road map** emerges. The road map reflects the international effort to collaboratively define technically feasible and programmatically implementable exploration mission scenarios with a common goal, agreed as sending humans to the surface of Mars and returning them safely. Figure 46.10 shows an example of a stepwise road map, starting from the ISS, advancing with readiness of the international partners for conducting human missions to Mars in the post-2030 time frame. It contains a long-term vision based on the national capabilities and priorities of the partners and serves as a nonbinding reference for the nations to inform near-term decisions related to exploration preparatory activities. A global road map will indicate the intended work sharing along the way to Mars, with existing and future capabilities of the participating nations forming a flexible, sustainable, robust, and affordable long-term plan. It

contains both robotic and human mission elements in a balanced way and ensures intermediate results of scientific or technical nature. It defines industrial niches for partner nations and allows for bilateral or multilateral partnerships between the participants.

3. SPACE EXPLORATION AND SOCIETY

An ambitious endeavor like the long-term vision of human exploration of our solar system, which relies on the cooperation of many nations of the world, requires careful preparation over an extended time span. A flexible approach in the cooperation framework is a necessity, as individual nations have different priorities and advance their technology with different paces. Diverse views will also prevail on the important question of affordability. In this context it is rewarding the see that a core of a cooperation framework has already been formed and is initiating first steps toward a global exploration plan.

3.1. Many Nations are Interested in Space

Space activities have been started by the two superpowers in the Cold War. With the proliferation of space technologies, other nations developed their own capabilities, but for quite some time space flight appeared to be the domain of rich, highly developed countries. It is only since the late 1990s that more and more nations discovered space as a tool to improve the living conditions of their citizens. This includes numerous developing or emerging economies worldwide. It is significant that 74 of a total of 193 member states of the United Nations (UN) have joined the UN Committee on Peaceful Uses of Outer Space (COPUOS), which has grown into one of the largest Committees of the United Nations. While the number of states having the technical capability to launch humans into space is still restricted to three, there are 11 capable of launching payloads into orbit. Through a network of bilateral and multilateral cooperation, at least 43 nations operate satellites in space, and there are many more that make use of data or results of space payloads for the benefit of their citizens (see Table 46.1). While most of these activities are presently concentrated on space assets looking at Earth or on communication and navigation systems, an increasing number of nations are beginning to extent their interest into space exploration. This is the basis for international cooperation in the preparation of a global effort of space exploration.

3.2. Can Nations Afford Space Exploration?

The concept of affordability is always relative. It depends on current priorities and the perception of values, which are subject to change over time. This is imminent for programs targeting far into the future, like a human mission to Mars

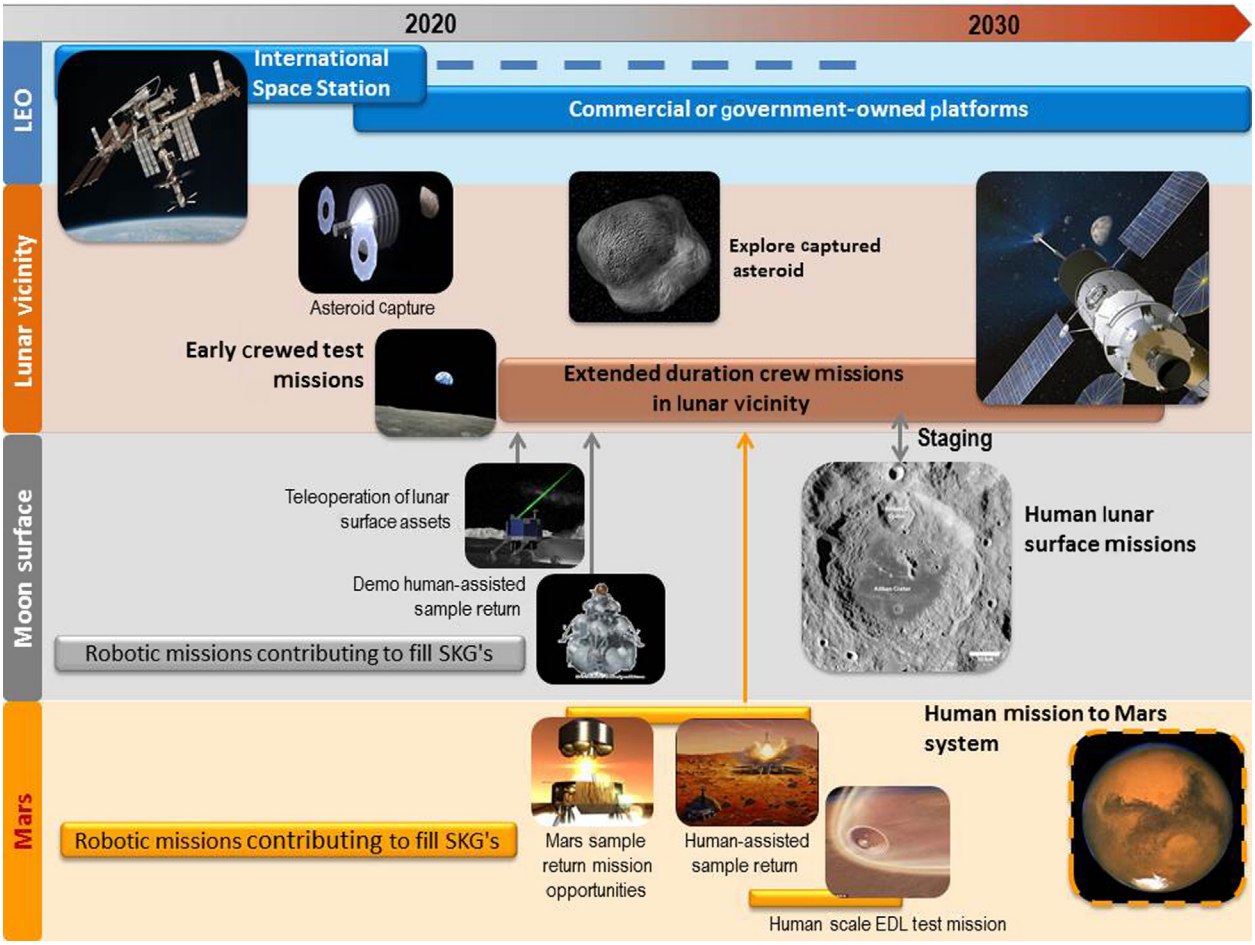

FIGURE 46.10 Overview of the international exploration mission scenario for the next two decades, driven by the long-term goals to enable human missions to Mars and showing operational (International Space Station), planned (early crewed test missions, asteroid capture), and conceptual missions on the pathway to Mars. extending over half a century. By any means space exploration is expensive. It requires numerous costly technological developments over a very long time scale. In all considerations, however, it should be kept in mind that these funds are spent on Earth on highly qualified jobs and cutting-edge technology.

Calculation of the cost of a human flight to Mars is difficult and depends on the complexity and duration of the mission considered. Most exploration studies refrain from stating potential cost figures. There is a diverging range of estimates and speculations, some of them not very well substantiated. A commercial venture claims cost of 6 billion dollars for bringing, within 10 years, a crew of four to the Mars surface to initiate a settlement, i.e. without considering a return. The National Aeronautics and Space Administration (NASA) "90 Day Study on Human Exploration of the Moon and Mars", presented to President Bush in 1989 did not give explicit cost figures. Cost estimates on the basis of this study arrived at

TABLE 46.2 Assessment of the Affordability of a Human Mission to Mars by Comparison to the Apollo Program

	Reference Year	Billion $	Ratio to GNP %
Apollo cost	1973	24.5	–
US GNP	1973	1.190	2.06
World GNP	1973	5.400	0.45
Mars mission cost	2011	450	–
US GNP	2011	14.991	3.00
World GNP	2011	70.020	0.64

The ratio of the total program cost (over several years) to the gross national product (GNP) in a single base year is used to judge affordability.

258 billion dollars for a three-decade program. This amounts to about 450 billion dollars in 2013 value. Assuming leveled expenditure over the years results in an annual spending figure of 15 billion dollars over 30 years. This is close to the total annual NASA budget of nearly 18 billion dollars, showing clearly that no single nation is able to afford a human exploration program on its own. The situation looks different if compared to the total global annual government spending on civil space programs, which amounts to 73 billion dollars in 2012. From this point of view, an exploration effort appears feasible and affordable on a global scale.

An alternative way to assess affordability is a comparison to the Apollo program. This is summarized in Table 46.2. The total cost of the Apollo project extending over the years 1961–1972 was reported as 25.4 billion dollars in 1973. In order to relate this value to the different economic conditions in 1973 and today, the ratio to the gross national product (GNP) in the relevant year is used. The ratio of the cost of a human mission to Mars in 2011 conditions to the US GNP would be about 50% higher than that of the Apollo program. On the other hand, the impact of the Mars mission cost on the world GNP is only a third compared to that of Apollo on the US GNP. Considering the fact that the Apollo project did not have a negative effect on the US economic development but in contrast contributed substantially to its growth, a global effort to extend human presence to Mars can not only be regarded as affordable, but may even stimulate global economy.

3.3. Involving Private Capital

Space exploration does by no means have to rely exclusively on government funds. In contrast, a global effort should enlarge the basis of stakeholders by including capital and capabilities of commercial entities. Private capital can be used more flexibly, but it does not necessarily reduce overall cost as it always is expected to generate revenues.

NASA has successfully initiated a commercialization of space transport to LEO in its Commercial Orbital Transportation Services program (COTS), which has been extended to crew transport in the Commercial Crew and Cargo Office (C3PO). There are several commercial initiatives aiming at tourist services in suborbital flights. Similar activities are planned for orbital flights and potentially to the Moon.

Two commercial projects have been announced that target destinations beyond the Moon. The enterprise Planetary Resources, founded in April 2012, is aiming at "bringing the natural resources of space within humanity's economic sphere of influence" by mining asteroids for precious minerals or using them as fuel depots in space. Similar intentions have been declared by the company "Deep Space Industries Inc." in January 2013.

In February 2013, the first space tourist Dennis Tito revealed his plans for a privately funded mission to Mars, sending a man and a woman on a flyby trajectory without landing, to be launched in 2018. The SpaceX Company, which successfully performed the first commercial cargo transport to ISS, proposed the "Red Dragon" landing device for Mars. The founder of SpaceX, Elon Musk, announced his intention to establish a colony on Mars on a commercial basis. With a ticket price of half a million dollars, he expects to expand in future to 80,000 colonists. A commercial venture called "MarsOne" plans to send humans to Mars and start a settlement there, to be funded on the basis of a television reality show.

3.4. Avoiding Contamination of Earth and Celestial Bodies

A potential problem in any kind of space exploration is that of contamination, usually summarized under the term **planetary protection**. It pertains to both the avoidance of contamination of celestial bodies by human action and the inverse problem of bringing potentially hazardous extraterrestrial material to Earth. There is concern about the contamination of the Moon with the increasing number of missions planned. Even more severe is the problem on Mars as this is the only planet in our solar system that holds promise of the potential detection of past or present life. This is the main scientific driver for the exploration of Mars. Any activity on Mars, be it human or robotic, carries the danger of contaminating the planet or introducing microbial life forms. COSPAR has elaborated rules for planetary protection (Rummel et al., 2002), which should be carefully observed in any mission to Mars. An early colonization, as foreseen in some concepts of commercial human flight

to Mars, is difficult to design compatible with the COSPAR rules.

3.5. Global Cooperation Becomes Reality

In 2006, 14 space agencies from different nations came together to discuss possibilities of jointly developing a vision for peaceful robotic and human space exploration, focusing on destinations within the solar system where humans may one day live and work. Considering common objectives and plans, a joint document was released in May 2007 entitled "The Global Exploration Strategy: The Framework for Coordination". The key finding in this work was the demand to establish a cooperation framework between the agencies to prepare future progress. Consequently, the ISECG was formed between the cooperating agencies as a voluntary, nonbinding international coordination mechanism to exchange information and coordinate plans. The intention is to work together on means of strengthening both individual exploration programs as well as the collective effort.

The ISECG team, consisting of representatives of the presently 14 space agencies involved, was established in November 2007 and meets since at regular intervals. It works on the key principle of an "open and inclusive" approach. The membership is open to any interested space agency. Numerous products have been achieved and published by ISECG. Various reports have been issued and papers are presented in the name of the group at international space congresses. The most important product so far is the "Global Exploration Road map", the first iteration of which has been issued September 2011. This road map reflects the international effort to define feasible and sustainable exploration pathways to the Moon, near-Earth asteroids, and Mars. Beginning with the ISS, it examines possible pathways for space exploration in the next 25 years with the aim to arrive at a single, consolidated plan.

A global coordination process on a long-term vision like space exploration can work only if it involves the political leaders worldwide. A first step in this direction has also been initiated. ESA convened high-level political representatives in Prague, 2009, stimulating an exchange to shape Europe's position in the global space exploration context. This was followed by a similar meeting in Brussels (2010). In 2011, the third International Conference on Space Exploration in Lucca convened government representatives from 28 nations, which committed to begin an open structured high-level policy dialogue on space exploration. A "High-level International Space Exploration Platform" was founded that issued a declaration recognizing the benefit of a continuing dialogue on a worldwide scale to help identify potential areas for international cooperation. The subsequent meeting was hosted by the United States in Washington, DC, in early 2014. It is expected that further discussions will cover joint missions and collaboration on research, and could lead to greater cooperation in areas such as access to space, innovation and space technologies, the use of current and future low-orbit infrastructures, and future human and robotic presence further out in space.

4. CONCLUSIONS AND OUTLOOK

Exploration of space started only some 50 years ago and it has already had profound impact on the development of society: economically, scientifically, and culturally. Progress in human exploration has been politically motivated and accomplished in major steps enabled by the development of new transportation systems. Robotic missions are and have been primarily science-driven. Future space exploration plans promote strongly the concept of human-robotic partnership and a further integration of human and robotic capabilities in space seems likely.

A human mission to Mars has been declared by various space agencies to be the driving goal for exploration within this century. Such an endeavor is technically feasible and programmatically implementable, provided it is carefully planned, executed in a stepwise manner, and realized within a broad international partnership, including members from both the institutional and private sectors. While Mars mission concepts have been studied since the days of Wernher von Braun, there are signs today that such an endeavor could actually become reality: (1) New transportation systems, under development in the United States and Russia are being designed such that they have the potential to evolve toward the capabilities required for human Mars exploration. (2) International coordination at agency level and international dialogue at political level demonstrate the commitment to cooperate toward achieving common exploration goals. Most exploration missions, robotic and human, are conducted presently within international partnerships. (3) Various initiatives in the domain of exploration demonstrate the readiness of the private entities to invest in this domain. It is therefore likely that within the next 30–50 years humans will set foot on Mars, representing what partnership, possibly between different political and economic systems, can achieve for the benefit and future prosperity of the global society.

This chapter gives a brief overview of the history of solar system research from the earliest times up to the start of the space age.

1. BABYLONIANS AND GREEKS

Many early civilizations studied the heavens, but it was the Babylonians of the first millennium B.C. who first used mathematics to try to predict the positions of the Sun, Moon, and visible planets (Mercury, Venus, Mars, Jupiter, and Saturn) in the sky. In this they differed from the Greeks, as the Babylonians were priests trying to predict the movement of the heavenly bodies for religious purposes, whereas the Greeks were philosophers trying to understand why they moved in the way they did. The Babylonians were fascinated by numbers, whereas the Greeks were more interested in geometrical figures.

The accuracy of the Babylonian predictions in the second century B.C. is remarkable. For example, their estimate of the length of the **sidereal** year was within 6 min of its true value, and that of the average **anomalistic month** was within 3 s. In addition, Jupiter's sidereal and **synodic periods** were within 0.01% of their correct values.

Pythagoras (c. 580–500 B.C.) was a highly influential early Greek philosopher who set up a school of philosophers, now known as the Pythagoreans. None of Pythagoras' original writings survive, but later evidence suggests that the Pythagoreans were probably the first to believe that the Earth is spherical, and that the planets all move in separate orbits inclined to the celestial equator. But the

Pythagorean spherical Earth did not spin and was surrounded by a series of concentric crystalline spheres supporting the Sun, Moon, and individual planets. Each had its own sphere, which revolved around the Earth at different speeds, producing a musical sound, the "music of the spheres", as they went past each other.

Hicetus of Syracuse (fl. fifth century B.C.) was the first person to specifically suggest that the Earth spun on its axis, at the center of the universe. This model was further developed by Heracleides who proposed that Mercury and Venus orbited the Sun as it orbited the Earth. Then Aristarchus (c. 310−230 B.C.), who was one of the last of the Pythagoreans, went one step further and proposed a heliocentric (i.e. Sun-centered) universe in which the planets orbit the Sun in the (correct) order of Mercury, Venus, Earth, Mars, Jupiter, and Saturn, with the Moon orbiting a spinning Earth. This was 1700 years before Copernicus came up with the same idea. Aristarchus was also the first to produce a realistic estimate for the Earth−Moon distance, although his estimate of the Earth−Sun distance was an order of magnitude too low.

While the Pythagoreans were developing their ideas, Plato (c. 427−347 B.C.) was developing a completely different school of thought. Plato, who was a highly respected philosopher, was not too successful with his geocentric (i.e. Earth-centered) model of the universe. His main legacy to astronomy was his teaching that all heavenly bodies must be spherical, as that is the perfect shape, and that they must move in uniform circular orbits, for the same reason. Aristotle (384−322 B.C.), a follower of Plato, was one of the greatest of Greek philosophers. His ideas were to hold sway in Europe until well into the Middle Ages. However, his geocentric model of the universe was highly complex, requiring a total of 56 spheres to explain the motions of the Sun, Moon, and planets. Unfortunately, many of its predictions were wrong, and it soon fell into disuse.

Hipparchus (c. 185−120 B.C.), who was the first person to quantify the **precession of the equinoxes**, was aware that the Sun's velocity along the ecliptic was not linear. This was known to the Babylonians and to Callippus of Cyzicus, but they did not seek an explanation. Hipparchus, on the other hand, in adopting Plato's philosophy of uniform circular motion in a geocentric universe, realized that this phenomenon could only be explained if the Sun was orbiting an off-center Earth. However, his estimate of the off-center amount was far too large, although his **apogee** position was in error by only 35′.

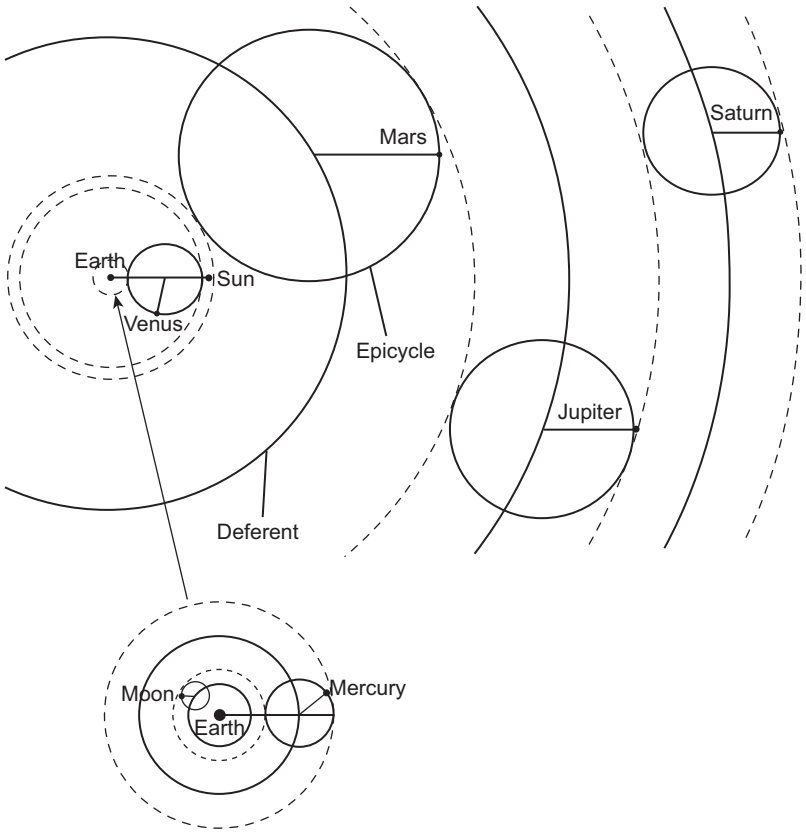

FIGURE 47.1 Ptolemy's model of the universe in which all bodies, except the Sun (and stars), describe epicycles, the centers of which orbit the Earth in deferents. He assumed that there were no gaps between the circle enclosing the furthest distance of one planet, and that just touching the epicycle of the next planet out from the Earth.

The mathematician Apollonius of Perga (c. 265−190 B.C.) appears to have been the first to examine the properties of epicycles. These were later adopted by Ptolemy (c. A.D. 100−170) in his geocentric model of the universe. In Ptolemy's scheme (Figure 47.1), the Moon, Sun, and planets each describe a circular orbit called an epicycle, the center of which goes in a circle, called a deferent, around a nonspinning Earth. Because the inferior planets, Mercury and Venus, each appear almost symmetrically on both sides of the Sun at maximum **elongation**, he assumed that the centers of their epicycles were always on a line joining the Earth and Sun. For the superior planets he assumed that the lines linking these with the center of their epicycles were always parallel to the Earth−Sun line. Unfortunately, this simple system did not provide accurate enough position estimates, and so Ptolemy introduced a number of modifications. In the case of the Moon, he made the center of the Moon's deferent describe a circle whose center was the Earth. For the planets he introduced the concept of an equant, which was a point in space equidistant with the Earth from the center of the deferent (Figure 47.2). The equant was the point about which the planet's angular velocity appeared to be uniform. Other modifications were also required, but by the time he had finished, he was able to make accurate position estimates for all but the Moon and Mercury. In addition, assuming that there were no gaps between the furthest part of one epicycle and the nearest part of the next, he was able to produce an estimate for the size of the solar system of about 20,000 times the radius of the Earth (or about 120 million km). Although this was a gross underestimate, it gave, for the first time, an idea of how large the solar system really was.

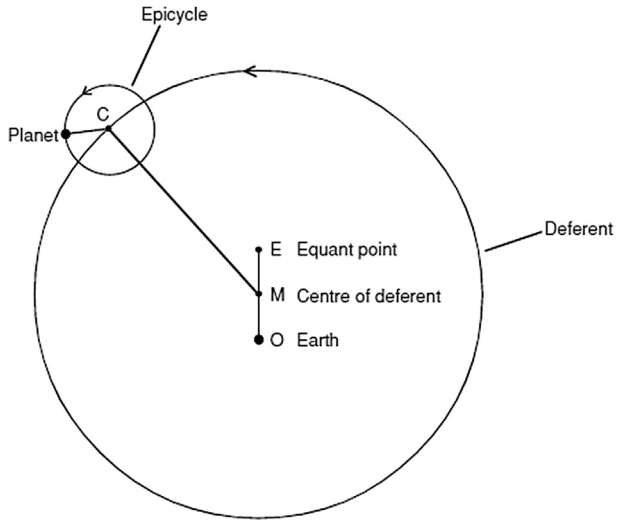

FIGURE 47.2 Ptolemy modified his epicycle theory for the superior planets by moving the Earth O from the center M of the deferent, and by defining an equant point E such that the distance $EM = MO$. He then assumed that the angular velocity of C, the center of the epicycle, is uniform about the equant point E, rather than about the center M of the deferent.

2. COPERNICUS AND TYCHO

There was virtually no progress in astronomy over the next 1000 years, and during this time many of the Greek texts had been lost in Europe. But in the twelfth century Arab translations found their way to Europe, mainly via Islamic Spain. Then in the fourteenth century Ibn al-Shātir (1304−1375), working in Damascus, improved Ptolemy's model by modifying his epicycles and deleting his equant. Interestingly, al-Shātir's system was very much like Copernicus' later system, but with the Earth, not the Sun, at the center.

Copernicus' heliocentric theory of the universe (Figure 47.3) was published in his *De Revolutionibus Orbium Coelestium* in 1543, the year of his death. Interestingly, in the light of Galileo's later problems with the Church, the book was well received. This is probably because of the Foreword, which had been written by the theologian Andreas Osiander and explained that the book described a mathematical model of the universe, rather than the universe itself.

Copernicus (1473−1543) acknowledged that his idea of a spinning Earth in a heliocentric universe was not new, having been proposed by Aristarchus. In addition, Copernicus' theory was based on circular motion and still depended on epicycles, although he deleted the equant. But he had resurrected the heliocentric theory, which had not been seriously considered for almost 2000 years, at the height of the Renaissance, which was eager for new ideas.

In the Middle Ages, Aristotle's ideas were taught at all the European universities. But now Copernicus had broken with the Aristotelian concept of a nonspinning Earth at the center of the universe. Then in 1577 Tycho Brahe (1546−1601) disproved another of Aristotle's ideas. Aristotle had believed that comets are in the Earth's atmosphere, but Tycho was unable to measure any clear parallax for the comet of that year. Finally, Tycho, in his book of 1588, rejected another of Aristotle's ideas, that the heavenly bodies are carried in their orbits on crystalline spheres. This is because, in Tycho's new model of the universe, all the planets, except the Earth, orbit the Sun as the Sun orbits the Earth. This meant that the sphere that carried Mars around the Sun would intercept that which carried the Sun around the Earth, which was clearly impossible if they were crystalline.

3. KEPLER AND GALILEO

Johannes Kepler (1571−1630) looked at the universe in an entirely different way than his predecessors. The Babylonians

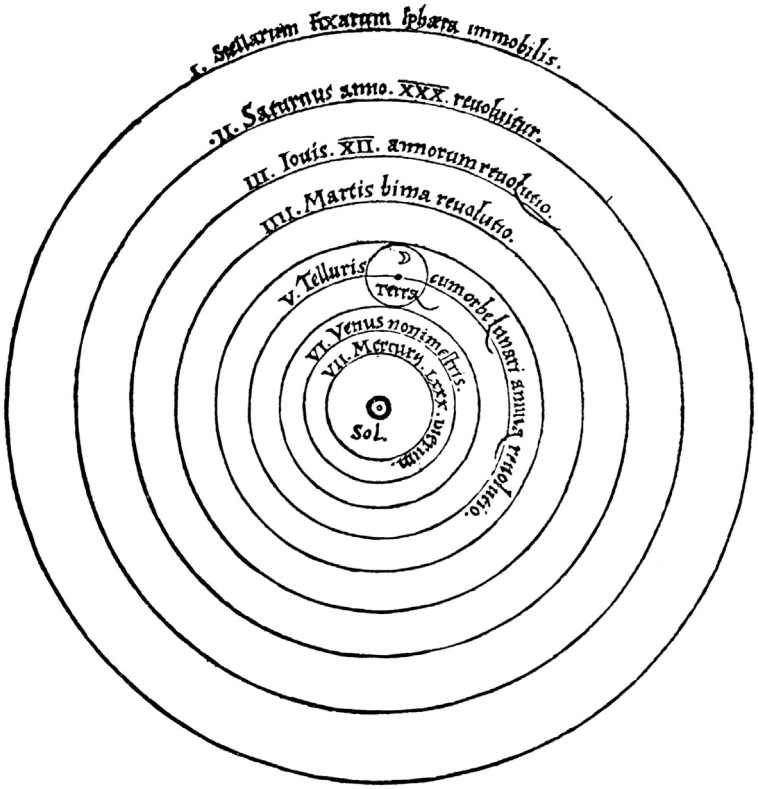

FIGURE 47.3 Copernicus' heliocentric universe, as described in his *De Revolutionibus*, in which the planets orbit the Sun (Sol) and the Moon orbits the Earth (Terra).

had examined it arithmetically, and the Greeks and later astronomers had considered it in geometrical terms. Kepler, on the other hand, tried to understand the structure of the solar system by considering physical forces.

Kepler conceived of a force emanating from the Sun that pushed the planets around their orbit of the Sun such that planetary movement would stop if the force stopped. The magnitude of his force, and hence the linear velocity of the planets, decreased linearly with distance. This should have resulted in the period of the planets varying as their distance squared, but Kepler made a mathematical error and came up with another relationship. Fortuitously, however, his analysis produced remarkably accurate results.

Although Kepler was having some success with this and other theories, he thought he could improve them if he had access to Tycho Brahe's accurate observational data. So Kepler went to see Tycho; a visit that ended with him joining Tycho and eventually succeeding him after his death.

Tycho had initially asked Kepler to analyze Mars' orbit, a task that he continued well after Tycho's death. Kepler published his results in 1609 in his book *Astronomia Nova*, in which he reintroduced the equant, previously deleted by Copernicus. In Kepler's model, all the planets orbited the Sun in a circle, with the Sun off-center, but he could not find a suitable circle to match Mars' observations, even with an equant. So he decided to reexamine the Earth's orbit, as the Earth was the platform from which the observations had been made.

Copernicus had proposed that the Earth moved around the Sun in a circle at a uniform speed, with the Sun off-center. So there had been no need for an equant. But Kepler found that an equant was required to explain the Earth's orbit. However, even adding this, he could not fit a circle, or even a flattened circle to Mars' orbit. And so in desperation he tried an ellipse, with the Sun at one focus, and, much to his surprise, it worked.

Kepler now considered what type of force was driving the planets in their orbits, and concluded that the basic circular motion was produced by vortices generated by a rotating Sun. Magnetic forces then made the orbits elliptical. So Kepler thought that the Sun rotated on its axis, and that the planets and Sun were magnetic.

Initially, Kepler had only shown that Mars moved in an ellipse, but in his *Epitome* of 1618–1621 he showed that this was the case for all the planets, as well as the Moon and the satellites of Jupiter. He also stated what we now know

as his third law, that the square of the periods of the planets are proportional to the cubes of their mean distances from the Sun. Finally, in his *Rudolphine Tables*, he listed detailed predictions for planetary positions and predicted the transits of Mercury and Venus across the Sun's disc.

Galileo Galilei (1564–1642) made his first telescopes in 1609 and started his first telescopic observations of the Moon in November of that year. He noticed that the **terminator** had a very irregular shape and concluded that this was because the Moon had mountains and valleys. It was quite unlike the pure spherical body of Aristotle's cosmology.

Galileo undertook a series of observations of Jupiter in January 1610 and found that it had four moons that changed their positions from night to night (Figure 47.4). Galileo presented his early Moon and Jupiter observations in his *Sidereus Nuncius* published in March 1610. By 1612, he had determined the periods of Jupiter's moons to within a few minutes.

Galileo's *Sidereus Nuncius* created quite a stir, with many people suggesting that Galileo's images of Jupiter's moons were an illusion. Kepler, who was in communication with Galileo, first saw the moons himself in August 1610 and supported Galileo against his doubters. The month before, Galileo had also seen what he took to be two moons on either side of Saturn, but for some reason they did not move. Finally in late 1610 he observed the phases of Venus, finally proving that Ptolemy's structure of the solar system was incorrect. As a result, Galileo settled on the Copernican heliocentric system.

Sunspots had been seen from time to time in antiquity, but most people took them to be something between the Earth and Sun. Although Thomas Harriot and Galileo had both seen sunspots telescopically in 1610, it was Johann Fabricius who first published his results in June 1611. He concluded that they were on the surface of the Sun, and that their movement indicated that the Sun was rotating. This was completely against Aristotle's teachings that the Sun was a perfect body.

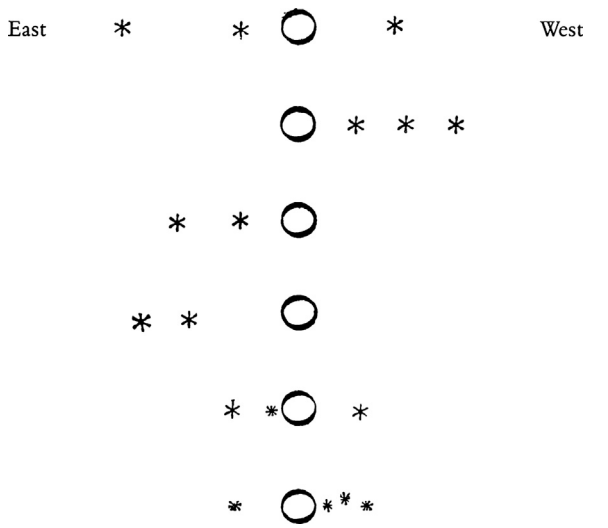

FIGURE 47.4 Galileo's observations of the moons of Jupiter on consecutive nights from 7 to 13 January (excluding 9 January) 1610, as shown in his book *Sidereus Nuncius*.

In the meantime, Galileo had visited the Jesuits of the Roman College to get their support for his work and, in particular, their support for Copernicus' heliocentric cosmology. His reception was very warm, and he was even received in audience by the pope. But, although the Roman Catholic Church did not argue with his observations, outlined above, there was considerable unease at his interpretation. Initially, the Church was prepared to tolerate Galileo's support of the Copernican cosmology, provided he presented this cosmology as a working hypothesis, rather than as a universal truth. But Galileo was stubborn and tried to take on the Church in its interpretation of theology. In this he could not win, of course, and the Church put him on trial, where he was treated very well. Nevertheless, he was forced in 1633 to recant his views and was then placed under house arrest for the remaining 9 years of his life.

4. SECOND HALF OF THE SEVENTEENTH CENTURY

4.1. The Moon

Thomas Harriot (1560–1621) was the first astronomer to record what we now know as the libration in latitude of the Moon, which has a period of 1 month. This occurs because the Moon's spin axis is not perpendicular to its orbit. A little later Galileo detected a libration in longitude, which he thought had a period of 1 day. In fact, it has a period of 1 month and is caused by the eccentricity of the Moon's orbit.

Although Galileo thought that the Moon has an atmosphere, he concluded that there was very little water on the surface as there were no clouds. His early telescopes were not sufficiently powerful, however, to show much surface detail. But over the next few decades, maps of the Moon were produced by a number of astronomers. The most definitive of which were published in 1647 by Johannes Hevelius (1611–1687). They were the first to show the effect of libration.

By mid-century, it was clear that there were numerous craters on the Moon, and in 1665 Robert Hooke (1635–1703) speculated on their cause in his *Micrographia.* He undertook laboratory-like experiments and noted that if round objects were dropped into a mixture of clay and water, features that resemble lunar craters were produced. But he could not think of the source of large objects hitting the Moon. However, he also found that he

TABLE 47.1 Key Solar System Discoveries and Observations, 1630–1700

Sun–Earth distance	
1672	Richer, Cassini, and Picard deduce a solar parallax of 9.5 min of arc from observations of the parallax of Mars. John Flamsteed independently deduces a similar value. This implied a Sun–Earth distance of about 22,000 earth radii, or 140 million km.
Moon	
See main text	
Mercury	
1631	First observation of a transit of Mercury by Gassendi, Remus, and Cysat—all independently. It occurred on the date predicted by Kepler.
1639	Phases of Mercury first observed by Zupus.
Venus	
1639	First observation of a transit of Venus by Horrocks and Crabtree.
1646	Fontana observes that Venus' terminator is uneven, attributing the cause to high mountains. (This is now known to be incorrect; Venus is covered in dense clouds.)
1667	Cassini deduces a rotation period of about 24 h (This is now known to be incorrect).
Mars	
1659	Huygens observes Syrtis Major and deduces a planetary rotation period of about 24 h.
1672	Huygens first unambiguously records the south polar cap.
Jupiter	
c. 1630	Fontana, Torricelli, and Zucchi independently observe the main belts.
1643	Riccioli observes the shadows of the Galilean satellites on Jupiter's disc.
1663	Cassini deduces a Jupiter rotation period of 9 h 56 min.
1665	Cassini observes a prominent spot that may be an early appearance of the Great Red Spot.
1690	Cassini observes the differential rotation of Jupiter.
1691	Cassini observes Jupiter's polar flattening, which he estimates to be about 7%.
Saturn	
See main text	

could produce crater-like features if he boiled dry alabaster powder in a container. As a result, he concluded that lunar craters are produced by the collapsed blisters of warm viscous lava.

4.2. Saturn

Christiaan Huygens (1629–1695) and his brother Constantyn finished building a state-of-the-art telescope in early 1655. Shortly afterward Christiaan discovered Saturn's first moon, Titan, which he announced in his *De Saturni* of 1656. The next four moons of Saturn were discovered by Gian Domenico Cassini (1625–1712); Iapetus in 1671, Rhea in 1672, and both Tethys and Dione in 1684.

Huygens had also mentioned in *De Saturni* that he had solved the problem of Saturn's two "moons" observed by Galileo. In fact, the behavior of these moons had been very odd, as they had both completely disappeared in November 1612, reappearing again in mid-1613. Since then, their shape had gradually changed. In 1650, Francesco Grimaldi discovered Saturn's polar flattening, but still the behavior of the moons, then called ansae, was unexplained. Finally, Huygens announced, in his *Systema Saturnium* of 1659, that the ansae were actually a thin, flat solid ring, which was inclined to the ecliptic, and so changed its appearance with time. Then in 1675 Cassini noticed that Saturn's ring was divided in two by a dark line, now called the Cassini Division, going all the way around the planet. Cassini speculated that the two rings were not solid but composed of swarms of small satellites.

Other major observational discoveries of this period are listed in Table 47.1.

4.3. Newton

Kepler had thought that the planets were being pushed around their orbits by a vortex emanating from the Sun but attributed the tides on Earth to the combined attraction of the Sun and Moon by a gravitational force. It seems strange to us that he did not think of this attractive force as having some effect on the orbits of the planets.

René Descartes (1596–1650) also developed a vortex theory to explain the motion of the planets. In his theory, the vortices are in the ether, which is a frictionless fluid filling the universe. In his *Principia* of 1644, Descartes stated that each planet had two "tendencies": one tangential to its orbit and one away from the orbit's center. It is the pressure in the vortex that counterbalances the latter and keeps the planet in its orbit.

In 1664, Isaac Newton (1642–1727) started to consider the motion of a body in a circle. In the following year, he proved that the force acting radially on such a body is proportional to its mass multiplied by its velocity squared, and divided by the radius of the circle (i.e. mv^2/r). From this, he was able to prove that the force on a planet moving in a circular orbit is inversely proportional to the square of its distance from the center. Newton realized that this outward centrifugal force on a planet must be counterbalanced by an equal and opposite centripetal force, but it was not obvious at that time that this force was gravity.

At this time, it was known that gravity acted on objects on the Earth's surface, but it was not known how far from Earth gravity extended. To get a better understanding of this, Newton devised his so-called Moon test. In this test, he compared the force acting on the Moon, because of its motion in a circle, with the force of the Earth's gravity at the Moon's orbit and found that they were not the same. The difference was not large, but it was sufficient to cause Newton to stop work on gravity. In fact, at that time, Newton appears to have thought that the centripetal force was a mixture of the gravitational force and the force created by vortices in the ether, so he may not have been too surprised by his result.

Newton was finally prompted to return to the subject of gravity by an exchange of letters with Robert Hooke in 1679. In the following year, Newton proved that, assuming an inverse square law of attraction, planets and moons will orbit a central body in an ellipse, with the central body at one focus. Then in 1684 he finally rejected the idea of ethereal vortices and started to develop his theory of universal gravitation.

It was during this period that the comet of 1680 appeared. At that time, most astronomers, including Newton, believed that comets described rectilinear orbits. John Flamsteed (1646–1719), on the other hand, believed that comets described closed orbits, and he suggested, in a letter to Edmond Halley (1656–1742), that the 1680 comet had passed in front of the Sun. Newton, who had been sent a copy of this letter, thought, like a number of astronomers, that there had been two comets, one approaching the Sun and one retreating. Further communications between Flamsteed and Newton in 1681 did not resolve their disagreements, causing Newton to drop the subject of cometary orbits. Eventually, Newton returned to the subject, and by 1686 he had changed his position entirely, as he proved that cometary orbits are highly elliptical or parabolic, to a first approximation. So the 1680 comet had been one comet after all. Newton now felt, having solved the problem of cometary orbits, that he could complete his *Principia*, which was published in 1687.

TABLE 47.2 A Comparison of Newton's Results (Relative to the Sun) with Modern Values

	Mass		Density	
	Principia	Modern Value	Principia	Modern Value
Sun	1	1	100	100
Earth	1/169,282	1/332,980	400	392
Jupiter	1/1067	1/1047	94.5	94.2
Saturn	1/3021	1/3498	67	49

Newton developed his universal theory of gravitation in his *Principia*, which ran to three editions. For example, he used Venus to "weigh" the Sun, and planetary moons to weigh their parent planets, and by the third edition he had deduced the masses and densities for the Earth, Jupiter, and Saturn relative to the Sun (Table 47.2).

Newton realized that if gravity was really universal, then not only would the Sun's gravity affect the orbit of a planet, and the planet's gravity affect the orbit of its moons, but the Sun would also affect the orbits of the moons, and one planet would affect the orbits of other planets. In particular, Newton calculated that Jupiter, at its closest approach to Saturn, would have about 1/217 times the gravitational attraction of the Sun. So he was delighted when Flamsteed told him that Saturn's orbit did not seem to fit exactly the orbit that it should if it was only influenced by the Sun. Gravity really did appear to be universal.

Richer, Cassini, and Picard had found evidence in 1672 that the Earth had an equatorial bulge. Newton was able to use his new gravitational theory to calculate a theoretical value for this **oblateness** of 1/230 (modern value 1/298). He then considered the gravitational attraction of the Moon and Sun on the oblate Earth and calculated that the Earth's spin axis should precess at a rate of about 50″.0 per annum (modern value 50″.3). This explained the precession of the equinoxes.

5. THE EIGHTEENTH CENTURY

5.1. Halley's Comet

Halley used Newton's methodology to determine the orbits of 24 comets that had been observed between 1337 and 1698. None of them appeared to be hyperbolic, and so the comets were all clearly permanent members of the solar system. Halley also concluded that the comets of 1531, 1607, and 1682 were successive appearances of the same comet as their orbital elements were very similar. But the time intervals between successive perihelia were not the same; a fact he attributed to the perturbing effect of Jupiter. Taking this into account, he predicted in 1717 that the comet would return in late 1758 or early 1759.

Shortly before the expected return of this comet, which we now called Halley's comet, Alexis Clairaut (1713−1765) attempted to produce a more accurate prediction of its **perihelion** date. He used a new approximate solution to the three-body problem that allowed him to take account of planetary perturbations. This showed that the return would be delayed by 518 days due to Jupiter and 100 days due to Saturn. As a result, he predicted that Halley's comet would reach perihelion on about 15 April 1759 ± 1 month. It did so on 13 March 1759, so Clairaut was just 33 days out with his estimate.

5.2. The 1761 and 1769 Transits of Venus

James Gregory (1638−1675) had suggested in 1663 that observations of a transit of Mercury could be used to determine the **solar parallax**, and hence the distance of the Sun from Earth. Such a determination required observations from at least two different places on Earth, separated by as large a distance as possible. In 1677, Edmond Halley observed such a transit when he was on St. Helena observing the southern sky. But, when he returned, he found that Jean Gallet in Avignon seemed to have been the only other person who had recorded the transit. Unfortunately, there were too many problems in comparing their results, which resulted in a highly inaccurate solar parallax.

In 1678, Halley reviewed possible methods of measuring the solar parallax and suggested that transits of Venus would produce the most accurate results. The problem was, however, that these occur in pairs, 8 years apart, only every 120 years. The next pair were due almost 100 years later, in 1761 and 1769.

Joseph Delisle (1688−1768) took up Halley's suggestion and tried to motivate the astronomical community to undertake coordinated observations of the 1761 transit. After much discussion, the French Academy of Sciences sent observers to Vienna, Siberia, India, and an island in the Indian Ocean, while other countries sent observers to St. Helena, Indonesia, Newfoundland, and Norway. Unfortunately, precise timing of the planetary contacts proved much more difficult than expected, resulting in solar parallaxes ranging from 8″.3 to 10″.6. Interestingly, several observers noticed that Venus appeared to be surrounded by a luminous ring when the planet was partially on the Sun. Mikhail Lomonsov (1711−1765) correctly concluded that this showed that Venus was surrounded by an extensive atmosphere.

The lessons learned from the 1761 transit were invaluable in observing the next transit in 1769. This was undertaken from over 70 different sites, and analysis of all the results eventually yielded a best estimate of 8″.6 (modern value 8″.79) for the solar parallax.

5.3. The Discovery of Uranus

On 13 March 1781, William Herschel (1738−1822), while looking for double stars, noticed what he thought was a comet. Four days later, when he next saw the object, it had clearly moved, confirming Herschel's suspicion that it was a comet. He then wrote to Nevil Maskelyne (1732−1811), the Astronomer Royal, notifying him of his discovery. As a result, Maskelyne observed the object on a number of occasions, but he was unsure as to whether it was a comet or a new planet.

Over the next few weeks a number of astronomers observed the object and calculated its orbit, which was found to be essentially circular. So it was a planet, now called Uranus. It was the first planet to be discovered since ancient times, and its discovery had a profound effect on the astronomical community, indicating that there may yet be more undiscovered planets in the solar system.

A few years later Herschel discovered the first two of Uranus' satellites, now called Titania and Oberon, with orbits at a considerable angle to the ecliptic.

5.4. Origin of the Solar System

Immanuel Kant (1724−1804) outlined his theory of the origin of the solar system in his *Universal Natural History* of 1755. In this he suggested that the solar system had condensed out of a nebulous mass of gas, which had developed into a flat rotating disc as it contracted. As it continued to contract, it spun faster and faster, throwing off masses of gas that cooled to form the planets. However, Kant had difficulty in explaining how a nebula with random internal motions could start rotating when it started to contract.

Forty years later, Laplace (1749−1827) independently produced a similar but more detailed theory. In his theory, the mass of gas was rotating before it started contracting. As it contracted, it spun faster, progressively throwing from its outer edge rings of material that condensed to form the planets. Laplace suggested that the planetary satellites

formed in a similar way from condensing rings of material around each of the protoplanets. Saturn's rings did not condense to form a satellite because they were too close to the planet. At face value, the theory seemed plausible, but it became clear in the nineteenth century that the original solar nebula did not have enough angular momentum to spin off the required material.

5.5. The First Asteroids

A number of astronomers had wondered why there was such a large gap in the solar system between the orbits of Mars and Jupiter. Then in 1766 Johann Titius (1729–1796) produced a numerical series that indicated that there should be an object orbiting the Sun with an orbital radius of 2.8 **astronomical units** (AUs). Johann Elert Bode (1747–1826) was convinced that this was correct and mentioned it in his book of 1772. However, what is now known as the Titius–Bode series was not considered of any particular significance, until Uranus was found with an orbital radius of 18.9 AU. This was very close to the 19.6 AU required by the series.

In 1800, a group of astronomers, who came to be known as the Celestial Police, agreed to undertake a search for the missing planet. But before they could start Giuseppe Piazzi (1746–1826) found a likely candidate by accident in January 1801. Unfortunately, although he observed the object for about 6 weeks, he was unable to fit an orbit, and wondered if it was a comet. But Karl Gauss (1777–1855) had derived a new method of determining orbits from a limited amount of information, and in November of that year he was able to fit an orbit. It was clearly a planet, now called Ceres, at almost exactly the expected distance from the Sun. But it was much smaller than any other planet. Then in March 1802 Heinrich Olbers (1758–1840) found another similar object, now called Pallas, at a similar distance from the Sun. At first Olbers thought that these two objects may be the remnants of an exploded planet. But he dropped the idea after the discovery of the fourth such asteroid, as they are now called, in 1807, because its orbit was inconsistent with his theory.

6. THE NINETEENTH CENTURY

6.1. The Sun

Sunspots were still an enigma in the nineteenth century. Many astronomers thought that they were holes in the photosphere, but because the Sun was presumably hotter beneath the photosphere, the Sunspots should appear bright rather than dark. Then in 1872 Angelo Secchi suggested that matter was ejected from the surface of the Sun at the edges of a sunspot. This matter then cooled and fell back into the center of the spot, so producing its dark central region.

In 1843, Heinrich Schwabe found that the number of sunspots varied with a period of about 10 years. A little later Rudolf Wolf analyzed historical records that showed periods ranging from 7 to 17 years, with an average of 11.1 years. Then in 1852, Sabine, Wolf, and Gautier independently concluded that there was a correlation between sunspots and disturbances in the Earth's magnetic field. There were also various unsuccessful attempts to link the sunspot cycle to the Earth's weather. But toward the end of the century, Walter Maunder pointed out that there had been a lack of sunspots between about 1645 and 1715. He suggested that this period, now called the Maunder Minimum, could have had a more profound effect on the Earth's weather than the 11-year solar cycle.

In 1858, Richard Carrington discovered that the latitude of sunspots changed over the solar cycle. In the following year, he found that sunspots near the solar equator moved faster than those at higher latitudes, showing that the Sun did not rotate as a rigid body. This so-called differential rotation of the Sun was interpreted by Secchi as indicating that the Sun was gaseous. In the same year, Carrington and Hodgson independently observed two white light solar flares moving over the surface of a large sunspot. About 36 h later, this was followed by a major geomagnetic storm.

Astronomy was revolutionized in the nineteenth century by Kirchoff's and Bunsen's development of spectroscopy in the early 1860s, which, for the first time, enabled astronomers to determine the chemical composition of celestial objects. Kirchoff measured thousands of dark Fraunhofer lines in the solar spectrum and recognized the lines of sodium and iron. By the end of the century, about 40 different elements had been discovered on the Sun.

Solar prominences had been observed during a total solar eclipse in 1733, but it was not until 1860 that they were proved to be connected with the Sun rather than the Moon. Spectroscopic observations during and after the 1868 total eclipse showed that prominences were composed of hydrogen and an element that produced a bright yellow line. This was initially attributed to sodium, but Norman Lockyer suggested that it was caused by a new element that he called helium. This was confirmed when helium was found on Earth in 1895.

6.2. Vulcan

Newton's gravitational theory had been remarkably accurate in explaining the movement of the planets, but by the nineteenth century there appeared to be something wrong with the orbit of Mercury. In 1858, Le Verrier analyzed data from a number of transits and concluded that the perihelion of Mercury's orbit was precessing at about 565″/century, which was 38″/century more than could be accounted for

using Newton's theory. As a result, Le Verrier suggested that there was an unknown planet called Vulcan, inside the orbit of Mercury, causing the extra precession. A number of astronomers reported seeing such a planet, but none of the observations stood up to detailed scrutiny, and the idea was eventually dropped.

Einstein finally solved the problem of Mercury's perihelion precession in 1915 with his general theory of relativity. No extra planets were required.

6.3. Mercury

There was considerable disagreement among astronomers in the nineteenth century on what could be seen on Mercury. Some thought that they could see an atmosphere around the planet, but others could not. Hermann Vogel detected water vapor lines in its spectrum, and Angelo Secchi saw clouds in its atmosphere. However, Friedrich Zöllner concluded, from his photometer measurements, that Mercury was more like the Moon with, at most, a very thin atmosphere.

A number of astronomers detected markings on Mercury's disc in the middle of the nineteenth century and concluded that the planet's period is about 24 h. On the other hand, Daniel Kirkwood maintained that it should have a **synchronous rotation** period because of tidal effects of the Sun on its crust. In the 1880s, Giovanni Schiaparelli confirmed this synchronous rotation observationally, and in 1897 Percival Lowell came to the same conclusion. So at the end of the century, synchronous rotation was thought to be the most likely.

6.4. Venus

In the eighteenth century, Venus was thought to have an axial rotation rate of about 24 h. In fact, a 24-h period was generally accepted until in 1890 Schiaparelli and others concluded that it, like Mercury, has a synchronous rotation period.

Spectroscopic observations of Venus yielded conflicting results in the nineteenth century. A number of astronomers detected oxygen and water vapor lines in its atmosphere; however, W. W. Campbell, who used the powerful Lick telescopes, could find no such lines.

6.5. The Moon

The impact theory for the formation of lunar craters was resurrected at the start of the nineteenth century, after the discovery of the first asteroids and a number of meteorites. There now seemed to be a ready source of impacting bodies, which Hooke had been unaware of when he had abandoned his impact hypothesis. But both the impact and volcanic theories still had problems. Most meteorites would not hit the lunar surface vertically, and so the craters should be elliptical, but they were mostly circular. Also, as Grove K. Gilbert pointed out, the floors of lunar craters are generally below the height of their surrounding area, whereas on Earth the floors of volcanic craters are generally higher than their surroundings.

Edmond Halley had discovered in 1693 that the Moon's position in the sky was in advance of where it should be based on ancient eclipse records. This so-called secular acceleration of the Moon could be because the Moon was accelerating in its orbit, and/or because the Earth's spin rate was slowing down. In 1787, Laplace had shown that the observed effect, which was about $10''/\text{century}^2$, could be completely explained by planetary perturbations. But in 1853, John Couch Adams included some of Laplace's second-order terms, which Laplace had omitted, so reducing the calculated figure from $10''/\text{century}^2$ to just $6''/\text{century}^2$. Charles Delaunay suggested that the missing amount was probably because of tidal friction, but it was impossible at that time to produce a reasonably accurate estimate of the effect. In the early twentieth century, Taylor and Jeffreys produced the necessary calculations, showing that Delaunay was correct.

In 1879, George Darwin developed a theory of the origin of the Moon. In this the proto-Earth had gradually contracted and increased its spin rate as it cooled. Then, when the spin rate had reached about 3 h per revolution, it had broken into two unequal parts: the Earth and the Moon. After breakup, tidal forces had caused the Earth's spin rate to slow down and the Moon's orbit to gradually increase in size.

A major problem with this theory was that the Earth would have had a tendency to break up the Moon shortly after separation. It was not clear whether the Moon could have passed through the danger zone before this could have happened.

6.6. The Earth

Karl Friedrich Küstner undertook precise position measurements of a number of stars in 1884 and 1885 from the Berlin Observatory. When he analyzed his results, however, he found that the latitude of the observatory had apparently decreased by about $0.20''$ in a year. Intrigued, the International Commission for Geodesy (ICG) decided to organize a series of observations around the world to define the effect more precisely. These results indicated that the Earth's spin axis was moving, relative to its surface, with a period of about 12 or 13 months.

Seth Chandler had also noticed slight variations in the latitude of the Harvard College Observatory, at about the same time as Küstner was making his measurements, but Chandler had not taken the matter further. Galvanized by Küstner's and the ICG's results, however, he undertook a

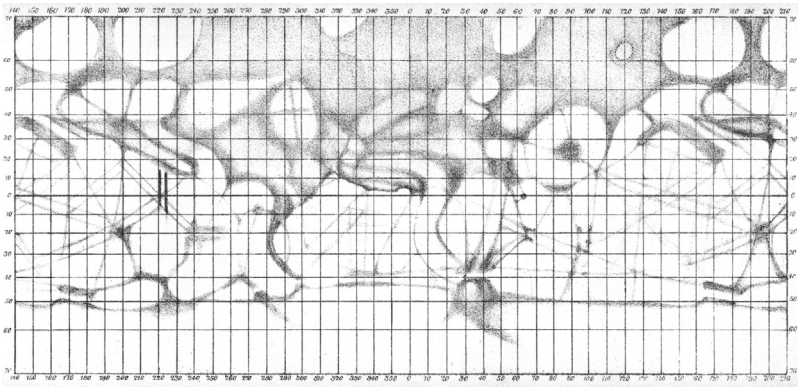

FIGURE 47.5 Schiaparelli's map of Mars produced following the 1881 opposition. A large number of *canali* are seen, many of them double. *From Ball, R. (1897).*

thorough review of all available data. As a result, he concluded that the observed effect had two components. One had a period of 14 months, and was because of the nonrigid Earth not spinning around its shortest diameter. The other, which had a period of a year, was because of the seasonal movement of water and air from one hemisphere to the other and back.

6.7. Mars

The first systematic investigation of Mars' polar caps had been undertaken in the eighteenth century by Giacomo Maraldi, who found that the south polar cap had completely disappeared in late 1719, only to reappear later. William Herschel suggested that this was because it consisted of ice and snow that melted in the southern summer.

At the end of the eighteenth century, most astronomers thought that the reddish color of Mars was because of its atmosphere. But in 1830, John Herschel suggested that it was the true color of its surface. Camille Flammarion, on the other hand, hypothesized that it was the color of its vegetation.

It was generally believed by astronomers in the mid-nineteenth century that there must be some form of life on Mars, even if it was only plant life, because the planet clearly had an atmosphere and a surface that exhibited seasonal effects. The polar caps were apparently made of ice or snow, and there were dark areas on the surface that may be seas.

Schiaparelli produced a map of Mars, following its 1877 **opposition**, that showed a network of linear features that he called *canali.* This was translated incorrectly into English as canals, which implied that they had been built by intelligent beings. Schiaparelli and others saw more *canali* in subsequent years (Figure 47.5), but other equally competent observers could not see them at all. Percival Lowell then went further than Schiaparelli in not only observing many canali, but interpreting them to be a network of artificial irrigation channels. At the end of the century, the debate as to whether these *canali* really existed was still in full swing.

Spectroscopic observations of Mars in the late nineteenth century yielded conflicting results. Some astronomers detected oxygen and water vapor lines, whereas Campbell at the Lick Observatory could find none. There was also a problem with the polar caps: Calculations showed that the average temperature of Mars should be about −34 °C, yet both polar caps clearly melted substantially in summer, which they should not have done if they had been made of water ice or snow. In 1898, Ranyard and Stoney suggested that the caps could be made of frozen carbon dioxide. But there appeared to be a melt band at the edge of the caps in spring, yet carbon dioxide should sublimate directly into gas on Mars.

Two satellites of Mars, now called Phobos and Deimos, were discovered by Asaph Hall in 1877. Their orbits were extremely close to the planet, and the satellites were both very small. As a result, they were thought to be captured asteroids.

6.8. Jupiter

The Great Red Spot (GRS) was first clearly observed in the 1870s. Then in 1880 an unusually bright, white equatorial spot appeared; it rotated around Jupiter over 5 min faster than the GRS. This gave a differential velocity of about 400 km/h. But the rotation rates of both the white spot and the GRS were not constant, indicating that neither could be surface features as some astronomers had supposed.

White and dark spots were continuously appearing and disappearing on Jupiter, suggesting that they were probably clouds. But the GRS was completely different because, although it changed its appearance and size over time, it was still there at the end of the century. This longevity led astronomers to wonder if it could really be a cloud system.

In 1778, Leclerc, Compte de Buffon, had suggested that rapid changes in Jupiter's appearance showed that it had not completely cooled down since its formation. In the

nineteenth century, Jupiter's differential rotation and low density, which were both similar in nature to those of the Sun, caused some astronomers to go even further and wonder if Jupiter was self-luminous. Although this was considered unlikely, the idea had not been completely ruled out by the end of the century.

William Herschel had concluded in 1797 that the axial rotation rates of the four Galilean satellites were synchronous. However, it was not until the 1870s that Engelmann and Burton independently confirmed this for Callisto and the 1890s that Pickering and Douglass confirmed it for Ganymede. The rotation rates of Io and Europa were still unclear.

In 1892, Edward Barnard discovered Jupiter's fifth satellite, now called Amalthea, very close to the planet, when he was observing Jupiter visually through the 36-in. Lick refractor. Amalthea was very small compared with the four Galilean satellites. It was the last satellite of any planet to be discovered visually.

6.9. Saturn

In 1837, Johann Encke found that the A ring was divided into two by a clear gap, now called the Encke Division. Then in 1850 W. C. and G. P. Bond discovered a third ring, now called the C ring, inside the B ring. The new ring was very dark (Figure 47.6) and partly transparent. In 1867, Kirkwood pointed out that any particles in the Cassini Division would have periods of about one-half that of Mimas, one-third that of Enceladus, one-quarter that of Tethys, and one-sixth that of Dione. He concluded that these resonances had created the Cassini Division, which would be clear of particles.

The true nature of Saturn's rings had been a complete mystery in the eighteenth century. Cassini had thought that they may be composed of many small satellites, and Laplace had suggested that they were made of a number of thin solid rings. Others thought that they may be liquid. But in 1857, James Clerk Maxwell proved mathematically that they could not be solid or liquid. Instead, he concluded that they were composed of an indefinite number of small particles.

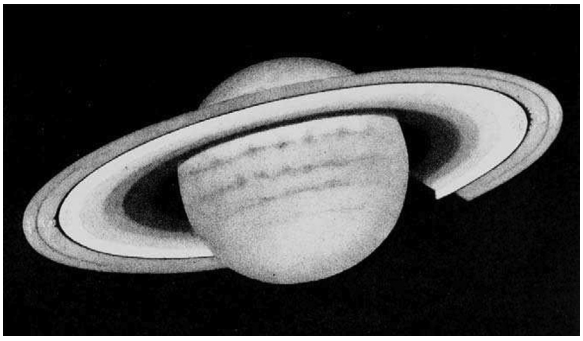

FIGURE 47.6 Trouvelot's 1874 Drawing of Saturn. It clearly shows the dark C ring extending from the inner edge of the B ring to about half-way to the planet. *From Ledger, E. (1882).*

Two new satellites were found in the nineteenth century: Hyperion by G. P. Bond in 1848 and Phoebe by William Pickering 50 years later. Phoebe was the first satellite in the solar system to be discovered photographically. It was some 13 million km from Saturn, in a highly eccentric, **retrograde** orbit. So it appeared to be a captured object.

6.10. Uranus

Little was known about Uranus in the nineteenth century. William Herschel had noticed that Uranus had a polar flattening, its orientation indicating that its axis of rotation was perpendicular to the plane of its satellites. But observations of apparent surface features produced very different orientations. Uranus' spectrum appeared to be clearly different from those of Jupiter and Saturn, but it was very difficult to interpret. There was even confusion about the discovery of new satellites. It was not until 1851 that William Lassell could be sure that he had discovered two new satellites, now called Ariel and Umbriel within the orbit of Titania. He had, in fact, seen them both some years before, but his earlier observations had been too infrequent to produce clear orbits.

6.11. The Discovery of Neptune

In 1821, Alexis Bouvard tried to produce an orbit for Uranus using both prediscovery and postdiscovery observations. But he could not find a single orbit to fit them. The best he could manage was an orbit based on only the postdiscovery observations; he published the result but admitted that it was less than ideal. However, it did not take long for Uranus to deviate more and more from even this orbit. One possible explanation was that Uranus was being disturbed by yet another planet, and if the Titius-Bode series was correct it would be about 38.8 AU from the Sun.

In 1843, the Englishman John Couch Adams set out to try to calculate the orbit of the planet that seemed to be disturbing the orbit of Uranus. By September 1845, he had calculated its orbital elements and its expected position in the sky, and over the next year, he progressively updated this prediction. Unfortunately, these predictions varied wildly, making it impossible to use them for a telescopic search of the real planet. In parallel, and unknown to both men, Urbain Le Verrier, a French astronomer, undertook the same task. He published his final results in August 1846 and asked Johann Galle of the Berlin Observatory if he would undertake a telescope search for it. Galle and his assistant d'Arrest found the planet within an hour of

starting the search on 23 September 1846. There then followed a monumental argument between the English and French astronomical establishments on the priority for the orbital predictions. But much of the evidence on the English side was never published, and an "official line" was agreed. That evidence has recently come to light, however, and it is currently being analyzed to establish the exact sequence of events. What is clear, however, is that when Neptune's real orbit was calculated, it turned out to be quite different from either of the orbits predicted by Le Verrier or Adams. So its discovery had been somewhat fortuitous.

Less than a month after Neptune's discovery, William Lassell observed an object close to Neptune, which he thought may be a satellite. It was not until the following July that he was able to confirm his discovery of Neptune's first satellite, now called Triton. Triton was later found to have a retrograde orbit inclined at approximately 30° to the ecliptic.

6.12. Asteroids

The fourth asteroid, Vesta, had been discovered in 1807, but it was not until 1845 that the fifth asteroid was found. Then the discovery rate increased rapidly so that nearly 500 asteroids were known by the end of 1900. As the number of asteroids increased, Kirkwood noticed that there were none with certain fractional periods of Jupiter's orbital period. This he attributed to resonance interactions with Jupiter.

All the early asteroids had orbits between those of Mars and Jupiter, and even as late as 1898 astronomers had discovered only one that had part of its orbit inside that of Mars. But in 1898, Eros was found with an orbit that came very close to that of the Earth, with the next closest approach expected in 1931. This could be used to provide an accurate estimate of solar parallax.

In 1906, two asteroids were found at the Lagrangian points, 60° in front of and behind Jupiter in its orbit. They were the first of the so-called Trojan asteroids to be discovered.

6.13. Comets

Charles Messier discovered a comet that passed very close to the Earth in 1770. Anders Lexell was the first to fit an orbit to it, showing that it had a period of just 5.6 years. With such a short period it should have been seen a number of times before, but it had not. As Lexell explained, this comet had not been seen because it had passed very close to Jupiter in 1767, which had radically changed its orbit. In the late nineteenth century, Hubert Newton examined the effect of such planetary perturbations on the orbits of comets and found that, for a random selection of comets, they were remarkably inefficient. Lexell's comet appeared to be an exception.

Jean Louis Pons in 1818 discovered a comet that, on further investigation, proved to have been seen near previous perihelia. In the following year, Johann Encke showed that the comet, which now bears his name, has an orbit that takes it inside the orbit of Mercury. When the comet returned in 1822, Encke noticed that it was a few hours early and suggested that it was being affected by some sort of resistive medium close to the Sun. In 1882, however, a comet passed even closer to the Sun and showed no effect of Encke's medium. Then in 1933, Wolf's comet was late, rather than early. The problem of these cometary orbits was finally solved in 1950 when Fred Whipple showed that the change in period was caused by jetlike vaporization emissions from the rotating cometary nucleus.

The first successful observation of a cometary spectrum was made by Giovanni Donati in 1864. When the comet was near the Sun, it had three faint luminous bands, indicating that it was self-luminous. Then 4 years later, William Huggins found that the bands were similar to those emitted by hydrocarbon compounds in the laboratory.

Quite a number of cometary spectra were recorded over the next 20 years. When they were first found, they generally exhibited a broad continuous spectrum like that of the Sun indicating that they were scattering sunlight. As they got closer to the Sun, however, the hydrocarbon bands appeared. Then in 1882 Wells' comet approached very close to the Sun. Near perihelion its bandlike structure disappeared to be replaced by a bright double sodium line. In the second comet of 1882, this double sodium line was also accompanied by several iron lines when the comet was very near the Sun. As the comet receded, these lines faded and the hydrocarbon bands returned.

6.14. Meteor Showers

A spectacular display of shooting stars was seen in November 1799, and again in November 1833. They seemed to originate in the constellation Leo. In the following year, Denison Olmsted pointed out the similarities between these two meteor showers and a less intense one in 1832. These so-called Leonid meteors seemed to be an annual event occurring on or about 12 November. Olmsted explained that the radiant in Leo was because of a perspective effect (Figure 47.7). A similar effect was then observed for a meteor shower on 8 August 1834, which appeared to have a radiant in Perseus. Shortly afterward, Lambert Quetelet showed that these were also an annual event.

In 1839, Adolf Erman suggested that both the Leonid and Perseid meteor showers were produced by the Earth passing through swarms of small particles that were orbiting the Sun and spread out along Earth's orbit. But it was still unclear as to the size of the orbit. In 1864, Hubert Newton found that the node of the Leonids' orbit was

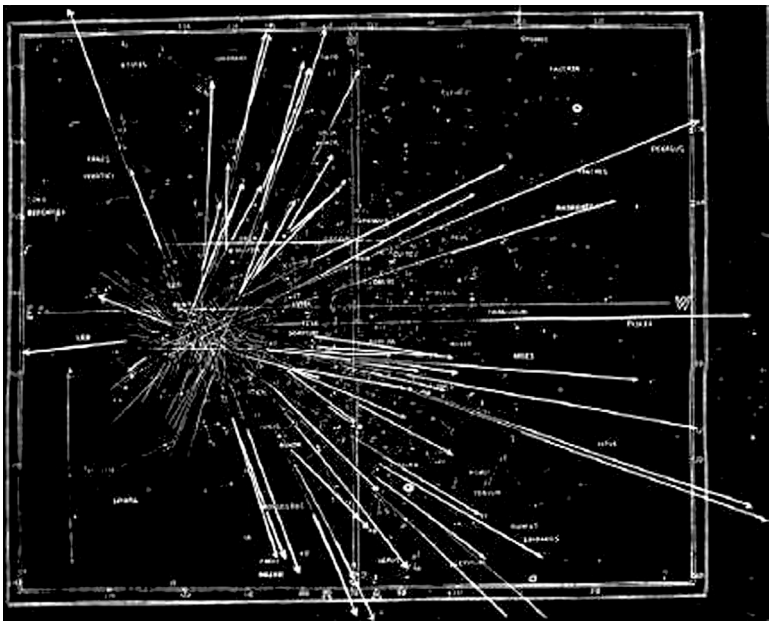

FIGURE 47.7 Paths of the Leonid meteors showing their apparent origin from a common radiant due to parallax. *From Newcomb, S. (1898).*

precessing at about 52″/year. John Couch Adams then showed that only a particle in a 33.25-year orbit would have this nodal precession. So the Leonids were orbiting the Sun in a diffuse cloud every 33.25 years, which explained why the most intense showers occurred with this frequency. The stragglers all around the orbit explained why we saw the Leonids on an annual basis. In 1867, Carl Peters recognized that the source of the Leonid meteor stream was a periodic comet called Tempel–Tuttle. This was just after Schiaparelli had linked the Perseids to another periodic comet, Swift–Tuttle.

7. THE TWENTIETH CENTURY PRIOR TO THE SPACE AGE

7.1. The Sun

In the nineteenth century, most physicists had thought that heat was transported from the interior to the exterior of the Sun by convection. But in 1894, R. A. Sampson suggested that the primary mechanism was radiation. Then, 30 years later, Arthur Eddington used the concept of radiative equilibrium to calculate the temperature at the center of the Sun and found it to be about 39 million K. At about the same time, Cecilia Payne showed that hydrogen and helium were the most abundant elements in the stars. Although this idea was initially rejected, it was soon accepted for both the Sun and stars. As a result, in 1935 Eddington reduced his temperature estimate for the center of the Sun to 19 million K.

However, Eddington's calculations made no assumption on how the Sun's heat was produced, which was still unknown at the time. Earlier, in 1920, Eddington himself had proposed two alternative mechanisms. The heat could be produced either by the mutual annihilation of protons and electrons or by the fusion of hydrogen atoms into helium atoms in some unknown manner. There were other mechanisms suggested by other physicists, but the issue could not be resolved at the time because nuclear physics was still in its infancy. The breakthrough came in 1938 when Charles Critchfield explained how energy could be produced at high temperatures by a chain reaction starting with proton–proton collisions and ending with the synthesis of helium nuclei. Hans Bethe then collaborated with Critchfield to develop this idea. But Bethe also examined an alternative mechanism that relied on carbon as a catalyst to produce helium from hydrogen, in the so-called carbon cycle. Carl von Weizsäcker independently developed this same scheme. Which mechanism was predominant in the Sun depended crucially on temperature, and it was not until the 1950s that it became clear that the proton–proton chain is dominant in the Sun.

In the nineteenth century, the **corona** had been found to have a faint continuous spectrum crossed by Fraunhofer absorption lines, but the conditions in the corona were unclear. Of particular interest was a bright green emission line in the coronal spectrum; Young and Harkness found it in 1869 and originally attributed it to iron. In 1898, however, it was found to have a slightly different wavelength than the iron line. Because no known element generated the required line, it was attributed to a new element called coronium.

At that time, it was assumed that the temperature of the Sun and its corona gradually reduced from the center

moving outward. But in the early part of the twentieth century, competing theories were put forward, one for a low-temperature corona and another for a high-temperature one. In 1934, Walter Grotrian analyzed the coronal spectrum and concluded that the temperature was an astonishing 350,000 K. A few years later Bengt Edlén, in a seminal paper, showed that coronal lines are produced by highly ionized iron, calcium, and nickel at a temperature of at least 2 million K. The "coronium" line, in particular, was the product of highly ionized iron. How the temperature of the corona could be so high, when the photosphere temperature is only of the order of 6000 K, was a mystery, which has not been completely resolved even today.

Charles Young discovered in 1894 that, at very high dispersions, many absorption lines in sunspot spectra appeared to have a sharp bright line in their centers. In 1908, George Ellery Hale and Walter Adams found that photographs of the Sun taken in the light of the 656.3-nm hydrogen line showed patterns that looked like iron filings in a magnetic field. This caused Hale to examine sunspot spectra in detail. He found that the Young effect was actually caused by Zeeman splitting of spectral lines in a magnetic field, which was of the order of 3000 G. So sunspots were the home of very high magnetic fields.

Hale then started to examine the polarities of sunspots, and found that spots generally occur in pairs, with the polarity of the lead spot, as they crossed the disc, being different in the two hemispheres. This pattern was well established by 1912 when the polarities were found to be reversed at the solar minimum. They reversed yet again at the next solar minimum in 1923. So the solar cycle was really 22 years, not 11.

Walter Maunder found in 1913 that large magnetic storms on Earth start about 30 h after a large sunspot crosses the center of the solar disc. Later work showed that the most intense storms were often associated with solar flares. In 1927, Chree and Stagg found that smaller storms, which did not seem to be associated with sunspots, tended to recur at the Sun's synodic period of 27 days. Julius Bartels called the invisible source on the Sun of these smaller storms, M regions. Both the so-called flare storms and the M storms were assumed to be caused by particles ejected from the Sun. In 1951, Ludwig Biermann suggested that, to explain the behavior of cometary ion tails, there must be a continuous stream of charged particles emitted by the Sun. Then in 1957, Eugene Parker proposed his theory of the solar wind, which was later confirmed by early spacecraft.

Marconi noticed in 1927 that interference with radio signals in September and October of that year coincided with the appearance of large sunspots and intense aurorae. In the late 1930s, Howard Dellinger carried out a detailed examination of the timing of shortwave radio fade-outs, at numerous receiving stations, and solar flares. He found a reasonable but by no means perfect correlation. The fade-outs seemed to start almost instantaneously after the flare was seen, and they only occurred when the receiving station was in daylight. So Dellinger concluded that they were caused by some form of electromagnetic radiation from the Sun, rather than particles.

7.2. Mercury

The synchronous rotation period of Mercury was gradually accepted as a fact in the twentieth century. But in 1962, W. E. Howard found that Mercury's dark side seemed to be warmer than it should be if it were permanently in shadow. Then 3 years later, Dyce and Pettengill found, using radar, that Mercury's rotation period was not synchronous, but represented two-thirds of its orbital rotation period.

7.3. Venus

There was considerable confusion in the first half of the twentieth century about Venus' rotation period. All sorts of periods were proposed between about 24 h and synchronous (225 days). Then in 1957 Charles Boyer found a distinctive V-shaped pattern of Venus' clouds that had a 4-day period. In 1962, however, Carpenter and Goldstein deduced a period of about 250 days retrograde using radar, which was modified to 243 days in 1965 for the rotation period of Venus' surface. So Venus has a 243-day period, while its clouds have a period of about 4 days, both periods being retrograde.

In 1932, Adams and Dunham concluded that there was no oxygen or water vapor on Venus, but carbon dioxide was clearly present. A few years later, Rupert Wildt calculated that the greenhouse heating of the latter could produce a surface temperature as high as 400 K. Then in 1956, Mayer, McCullough, and Sloanaker deduced a surface temperature of about 600 K by analyzing Venus' thermal radio emissions. The suggestion that Venus' surface temperature could be so high was naturally treated with caution. Shortly afterward, Carl Sagan estimated that the surface atmospheric pressure was an equally incredible 100 bar.

7.4. The Moon

The idea that there may be life on the Moon had fascinated people for centuries. Even respected astronomers like William Herschel had thought that there would be "lunarians" as he called them. But by the start of the twentieth century, it was thought that the most complex life-forms would be some sort of plant life. However, by the 1960s, when the Americans were planning their lunar landings, even this concept had been rejected. Nevertheless, it was thought that there may be some sort of very elemental life, like bacteria, on the Moon.

Bernard Lyot had concluded in 1929, from polarization measurements, that the Moon was probably covered by volcanic ash. Then in the 1950s, Thomas Gold suggested that the Moon may be covered with dust up to a few meters deep. If this was so, it would have provided a major problem for the manned *Apollo* missions.

At the end of the nineteenth century, the key objection to the impact theory for the formation of lunar craters had been that the craters were generally circular, when they should have been elliptical, because most of the impacts would not be vertical. However, after the First World War it was realized that the shape of the lunar craters resembled shell craters. The shell craters were formed by the shock wave of the impact or explosion, so a nonvertical impact could still produce a circular crater. Nevertheless, not all lunar craters have the same general appearance. So, by the start of the space age it was still unclear if they had been produced by volcanic action, meteorite impact, or both.

7.5. The Earth

It was known in the nineteenth century that temperatures in deep mines on Earth increased with depth. That, together with the existence of volcanoes, clearly indicated that the Earth has a molten interior. Calculations indicated that the rocks would be molten at a depth of only about 40 km.

In 1897, Emil Wiechert suggested that the Earth has a dense metallic core, mostly of iron, surrounded by a lighter rocky layer, now called the mantle. A little later, Richard Oldham found clear evidence for the existence of the core from earthquake data. Then in 1914, Beno Gutenberg showed that the interface between the mantle and the core, now called the Wiechert−Gutenberg discontinuity, is at about $0.545r$ from the center of the Earth (where r is its radius).

A little earlier, Andrija Mohorovičić had discovered the boundary between the crust and mantle, now called the Mohorovičić discontinuity, by analyzing records of the Croatian earthquake of 1909. The depth of this discontinuity was later found to vary from about 70 km under some mountains to only about 5 km under the deep oceans.

A number of theories were proposed to try to define and explain the internal structure of the Earth. In particular, Harold Jeffreys produced a theory that assumed that all the **terrestrial planets** and the Moon have a core of liquid metals, mostly iron, and a silicate mantle. But it could not explain how those planets with the smallest cores could have retained a higher percentage of lighter material in their mantles. In 1948, William Ramsey solved this problem when he proposed that the whole of the interior of the terrestrial planets consists of silicates, with the internal pressure in the largest planets causing the silicates near the center to become metallic. Unfortunately this idea became unviable when Eugene Rabe found in 1950 that Mercury's density was much higher than originally thought. It was even higher than that of Venus and Mars, which were much larger planets.

In the mid-twentieth century, most astronomers believed that the planets had been hot when first formed from the solar nebula, but in 1949 Harold Urey suggested that the nebula had been cold. According to Urey, the Earth had been heating up since it was formed because of radioactive decay. Internal convection had then started as iron had gradually settled into the core. Urey believed that the Moon was homogenous because it was relatively small.

At the turn of the nineteenth century, it was thought that radio waves generally traveled in a straight line. So it was a great surprise when Marconi showed in 1901 that radio waves could be successfully transmitted across the Atlantic. Refraction could have caused them to bend to a limited degree, but not enough to cross the ocean. In the following year, Heaviside and Kennelly independently suggested that the waves were being reflected off an electrically conducting layer in the upper atmosphere.

The structure of what we now call the E or Heaviside layer, and of other layers in the ionosphere, was gradually clarified over the next 20 years or so. The 80 km high D layer was found to largely disappear at night, and the higher E layer was found to maintain its reflectivity for only 4 or 5 h after sunset. In addition, it was found that solar flares can cause a major disruption to the ionosphere (see Section 7.1). However, it was not until after the Second World War that the cause of these effects could be examined in detail by first sounding rockets and then by spacecraft. The first major discovery was made by Herbert Friedman in 1949 when he showed that the Sun emits X-rays, which have a major effect on the Earth's ionosphere.

7.6. Mars

There was a great deal of uncertainty about the surface of Mars in the first half of the twentieth century. It was thought unlikely that the linear markings called *canali* really existed, but they were still recorded from time to time by respected observers. In addition, some astronomers thought that the bluish green areas on Mars were vegetation, while others thought that they were volcanic lava.

There was also considerable uncertainty about the spectroscopic observations of Mars. Some observers recognized water vapor and oxygen lines, whereas others found none. But in 1947 Gerard Kuiper clearly found evidence for a small amount of carbon dioxide, and in 1963 Audouin Dollfus found a trace amount of water vapor. Estimates of the surface atmospheric pressure varied from about 25 to 120 mbars. Then in 1963, shortly before the first spacecraft reached Mars, a figure of 25 ± 15 mbars was estimated by Kaplan, Münch, and Spinrad.

It seemed clear that the yellow clouds seen on Mars were dust. In 1909, Fournier and Antoniadi found that they appeared to cover the whole planet for a while. Later Antoniadi found that they tended to occur around perihelion when the solar heating is greatest, and so appeared to be produced by thermally generated winds. Thirty years later, De Vaucouleurs measured the wind velocities as being typically in the range of 60−90 km/h when the clouds first formed.

7.7. Internal Structures of the Giant Planets

It was known in the nineteenth century that the densities of Jupiter, Saturn, Uranus, and Neptune were similar to that of the Sun, and were much less than that of the terrestrial planets. At that time, it was thought that Jupiter, and probably Saturn, had not yet fully cooled down since their formation. As a result, they were probably emitting more energy than they received from the Sun.

In 1923, Donald Menzel found that the cloud top temperatures of Jupiter and Saturn were about 160 K. This compares with temperatures of 120 and 90 K for Jupiter and Saturn, respectively, that would be maintained solely by incident solar radiation. Three years later, Menzel produced modified observed temperatures of 140, 120, and 100 K, for Jupiter, Saturn, and Uranus. So any internally generated heat would be rather low.

In 1923, Harold Jeffreys pointed out that the ratio of the densities of Io and Europa, the innermost of Jupiter's large satellites, to that of Jupiter, was about the same as the ratio of the density of Titan, Saturn's largest satellite, to that of Saturn. He then assumed that the density of the cores of Jupiter and Saturn were the same as these their large satellites. In that case, the thickness of the planetary atmospheres would be about 20% of their radii.

In the following year, Jeffreys included consideration of the moments of inertia of Jupiter and Saturn in his analysis and concluded that their atmospheres would have depths of $0.09R_J$ and $0.23R_S$, respectively (where R_J and R_S are the radii of Jupiter and Saturn, respectively). He assumed that beneath their atmospheres there was a layer of ice and solid carbon dioxide, which in turn surrounded a rocky core.

Various schemes were then produced by a number of physicists, of which those of Rupert Wildt in 1938 and William Ramsey in 1951 were probably the most significant. Wildt, who was particularly interested in internal pressures, wanted to find out if matter at the core of the large planets was **degenerate**. His calculations indicated that it was not. Ramsey, on the other hand, developed his theory assuming that the giant planets were made of hydrogen. He then added helium and other ingredients until their densities and moments of inertia were correct. On this basis, he concluded that Jupiter and Saturn were composed of 76% and 62% hydrogen, by mass, respectively, with central pressures of 32 and 6×10^6 bar. At these pressures, most of the hydrogen would be metallic.

The structures of Uranus and Neptune were a problem in Ramsey's analysis because the heavier planet, Neptune, was the smaller. So their constituents could not be the same. Then in 1961 William Porter produced a model that seemed to fit; in this model, Neptune had 74% ammonia and 26% heavier elements, whereas Uranus had less heavy elements and a small amount of hydrogen.

7.8. Atmospheres of the Giant Planets

Vesto Slipher undertook a detailed investigation of the spectra of Jupiter, Saturn, Uranus, and Neptune in the early decades of the twentieth century. He recorded numerous bands for all the planets but had trouble interpreting them. In 1932, Rupert Wildt deduced that a number of the bands in all four planets were due to ammonia and methane. However, subsequent work by Mecke, Dunham, Adel, and Slipher showed that some of the lines had been misattributed, so there was no ammonia in the atmospheres of Uranus and Neptune. This was, presumably, because it had been frozen out at their lower temperatures. Adel and Slipher also concluded that the methane concentration reduced in going from Neptune to Uranus to Saturn to Jupiter.

7.9. Jupiter

In 1955, Burke and Franklin made the unexpected discovery that Jupiter was emitting radio waves at 22.2 MHz. Subsequently, it was found that Jupiter emitted energy at many radio frequencies. Some of it was thermal energy, with an effective temperature of 145 K, but some was clearly nonthermal. The latter was taken to indicate that Jupiter had an intense magnetic field, with radiation belts similar to those that had, by then, been found around the Earth.

Our knowledge of Jupiter's Galilean satellites changed little in the twentieth century before the space age. In 1900, Barnard had observed that the poles of Io appeared to be reddish in color. Then in 1914 Paul Guthnik showed that all four Galilean satellites exhibited synchronous rotation. In the nineteenth century, it was thought that all four satellites probably had atmospheres, but this was considered more and more unlikely as the twentieth century progressed.

7.10. Saturn

A prominent white equatorial spot had been observed on Saturn in 1876. Then in 1903 Edward Barnard discovered another temporary prominent white spot at about 36° N, but its rotation period around Saturn was some 25 min slower. Another equatorial spot that had a similar period to the

1876 equatorial spot appeared in 1933, and another spot that had a similar period to the 1903 spot was observed at about 60 °N in 1960. The velocities of these spots showed that there was an equatorial current on Saturn, similar to that on Jupiter. But the one on Saturn had a velocity of about 1400 km/h, compared with just 400 km/h for Jupiter. It was unclear why Saturn, which is farther from the Sun, and so receives less heat than Jupiter, should have a much faster equatorial current.

Markings on Saturn's rings were seen by a number of observers in the late nineteenth and early twentieth centuries, including the respected observers Etienne Trouvelot and Eugiéne Antoniadi. In 1955, Guido Ruggieri noticed clear radial streaks at both ansae of the A ring, but after further investigation he concluded that they were an optical illusion. It is unclear whether any of these observations were early observations of spokes, of the sort discovered by the *Voyager* spacecraft on the B ring, or not.

In the winter of 1943−1944, Gerard Kuiper photographed the spectrum of the 10 largest satellites of the solar system and found evidence for an atmosphere on Titan and possibly Triton. He could find no such evidence for the Galilean satellites of Jupiter, however.

7.11. Uranus and Neptune

In the nineteenth century, Triton had been found to orbit Neptune in a retrograde sense, and it was unclear at the time whether Neptune's spin was also retrograde. But in 1928 Moore and Menzel found, by observing the **Doppler shift** of its spectral lines, that Neptune's spin was **direct** or **prograde**. So Neptune's largest satellite was orbiting the planet in the opposite sense to the planet's spin. This phenomenon had not been observed before in the solar system for a major satellite.

Kuiper discovered Uranus' fifth satellite, now called Miranda, in 1948. It was orbiting the planet in an approximately circular orbit inside that of the other four satellites. Then in the following year he discovered Neptune's second satellite, now called Nereid, orbiting Neptune in the opposite sense to Triton. Nereid was in a highly elliptical orbit well outside the orbit of Triton. So Nereid was the "normal" satellite in orbiting Neptune direct or prograde, whereas the larger Triton, which was nearer to Neptune in an almost circular orbit, appeared to be the abnormal one.

7.12. The Discovery of Pluto

The discoveries of Uranus and Neptune made astronomers realize that there may well be planets even farther out from the Sun. As Neptune had only been discovered in 1846, and as it was moving very slowly, its orbit was not very well known in the second half of the nineteenth century. However astronomers had much better information on Uranus' orbit, and so they reexamined it to see if there were any unexplained deviations that might indicate the whereabouts of a new planet. Such deviations were soon found, and a number of possible locations for the new planet proposed by various astronomers, including Percival Lowell. A photographic search for the new planet was started at Lowell's observatory, but this was abandoned when Lowell died in 1916.

In 1929, Vesto Slipher, the new director of Lowell's observatory, recruited Clyde Tombaugh to undertake a search for the new planet using a photographic refractor that had been specifically purchased for the task. Tombaugh photographed the whole of the zodiac, and used a blink comparator to find objects that had moved over time. The task was very tedious, but he discovered Pluto in February 1930 after working for 10 months. However, although the planet's orbit was very similar to that predicted by Lowell (Figure 47.8), it was far too small to have perturbed Uranus in the way that Lowell had estimated.

Over the years, the estimated mass of Pluto has gradually reduced from 6.6 M_E (M_E is the mass of the Earth) predicted by Lowell, to 0.7 M_E (maximum) at the time of its discovery, to 0.002 M_E now. Its orbit is highly eccentric, and it has the largest inclination of the traditional planets.

In 1955, Walker and Hardie deduced a rotation period of 6 day 9 h 17 min from regular fluctuations in Pluto's intensity. Little more was known about the planet when the space age started.

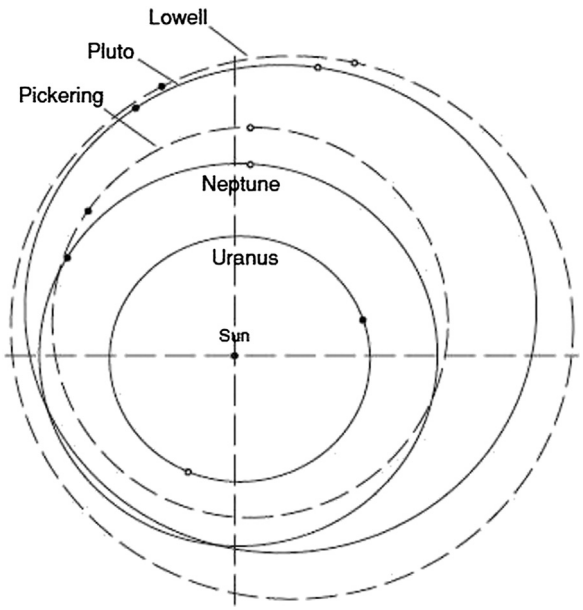

FIGURE 47.8 A comparison between the true orbit of Pluto and that predicted by Lowell and Pickering. Although Lowell's orbit was reasonably close to that of Pluto, the agreement was fortuitous. (The open circles show the positions of the planets in 1900, and the closed circles represent those in 1930.)

7.13. Asteroids

In 1918, Kiyotsugu Hirayama identified families of asteroids based on their orbital radius, eccentricity, and inclination. Initially, he identified three families, Themis (22 members), Eos (21 members), and Koronis (13 members). Hirayama suggested that the three families were each the remnants of a larger asteroid that had fractured. This resurrected, in modified form, the theories of Thomas Wright and Wilhelm Olbers, in the eighteenth and nineteenth centuries. They both believed that there had been a planet between the orbits of Mars and Jupiter that had broken up.

In the nineteenth century, Eros had been discovered with a perihelion of 1.13 AU. In 1932, another asteroid, now called Amor, was found that had an orbit that came even closer to that of the Earth than Eros. Then, just 6 weeks later, the first asteroid, now called Apollo, whose orbit crossed that of the Earth, was discovered. The names of Amor and Apollo have now been given to families of asteroids with similar orbital characteristics.

7.14. Comets

Huggins had shown in the nineteenth century that there were hydrocarbon compounds in the heads of comets, but he was not able to specify exactly which hydrocarbons were involved. Molecular carbon, C_2, was first identified in the head of a comet just after the turn of the century, and by the mid-1950s C_3, CH, CN, OH, NH, and NH_2 had been found in the heads of comets.

Molecular bands were observed in the tail of Daniel's comet by Deslandres, Bernard, and Evershed in 1907 and in the tail of Morehouse's comet by Deslandres and Bernard the following year. These bands were later identified by Alfred Fowler was those of ionized carbon monoxide, (CO^+) and N_2^+. Later CO_2^+ was also found in the tail of a comet.

In the 1930s, Karl Wurm observed that many of the molecules found in comets were chemically very active, and so they cannot have been present there for very long. He suggested, instead, that they had come from the more stable so-called parent molecules $(CN)_2$, H_2O, and CH_4 (methane). In 1948, Pol Swings, in his study of Encke's comet, concluded that the parent molecules were water, methane, ammonia (NH_3), nitrogen, carbon monoxide, and carbon dioxide, all of which had been in the form of ice before being heated by the Sun.

In 1950 and 1951, Fred Whipple proposed his icy-conglomerate model (better known as his dirty snowball theory) in which the nucleus is composed of ices, such as methane, with meteoric material embedded within it. Unfortunately, some of the parent molecules were highly volatile. But in 1952 Delsemme and Swings suggested that these highly volatile elements would be able to resist solar heating better if they were trapped within the crystalline structure of water ice, in what are known as clathrate hydrates.

It was difficult to determine the orbits of long-period comets because they were only observed for the fraction of their orbit when they were close to the Sun. However, a survey of about 400 cometary orbits observed up to 1910 showed that only a tiny minority appeared to be hyperbolic. Strömgren and Fayet then showed that none of these comets had hyperbolic orbits before they passed Saturn or Jupiter on their approach to the Sun. So the long-period comets appeared to be members of the solar system.

In 1932, Ernst Öpik concluded, from an analysis of stellar perturbations, that comets could remain bound to the Sun at distances of up to 10^6 AU. Some years later, Adrianus Van Woerkom showed that there must be a continuous source of new near-parabolic comets to explain the relative numbers observed. Then in 1950 Jan Oort showed that the orbits of 10 comets, with near-parabolic orbits, had an average **aphelion** distance of about 100,000 AU. As a result, he suggested that all long-period comets originate in what is now called the Oort cloud about 50,000 to 150,000 AU from the Sun.

7.15. The Origin of the Solar System

In the early decades of the twentieth century, theories of the origin of the solar system generally focused on the effect of collisions, and close encounters of another star to the Sun. But all the theories were found to have significant problems, so Laplace's theory of a condensing nebula was reconsidered.

Laplace's theory had been rejected in the nineteenth century because the original solar nebula did not appear to have had enough angular momentum. However, in the 1930s, McCrea showed that this would not be a problem if the original nebula had been turbulent.

In 1943, Carl von Weizsacker produced a theory where cells of circulating convection currents, or vortices, formed in the solar nebula after the Sun had condensed. These vortices produced planetesimals that grew to form planets by accretion. Unfortunately, as Chandrasekhar and Kuiper showed, the vortices would not be stable enough to allow condensation to take place. Kuiper then produced his own theory, as did Safronov and others, with the common theme of planetesimals merging to form planets, but none was fully satisfactory.

1. INTRODUCTION

The usually defined range of X-ray photons spans $\sim$0.1−100 keV. Photons in the lower (<5 keV) end of this energy range are termed soft X-rays. In space, X-ray emission is generally associated with high-temperature phenomena, such as hot plasmas of 1 million to 100 million K and above in stellar coronae, accretion disks, and supernova shocks. However, in the solar system, X-rays have been observed from bodies that are much colder, $T < 1000$ K. This makes the field of planetary X-rays a very interesting discipline, where X-rays are produced from a wide variety of objects under a broad range of conditions.

The first planetary X-rays detected were terrestrial X-rays, discovered in the 1950s. The first attempt to detect X-rays from the Moon in 1962 failed, but it discovered the first extrasolar source, Scorpius X-1, which resulted in the birth of the field of X-ray astronomy. In the early 1970s, the *Apollo* 15 and 16 missions studied fluorescently scattered X-rays from the Moon. Such X-rays originate when energetic photons or particles remove an inner electron from atoms in the irradiated material. When the atom relaxes by filling the resulting gap with an outer shell electron, an X-ray photon with a characteristic energy is emitted. At low X-ray energies, this photon is usually produced by the transition of an $n = 2$ to the $n = 1$ shell electron, and is termed a Kα transition. A Kβ transition would be for an $n = 3$ to $n = 1$ electron, while an Lα photon would be produced by an $n = 3$ to $n = 2$ transition, etc.

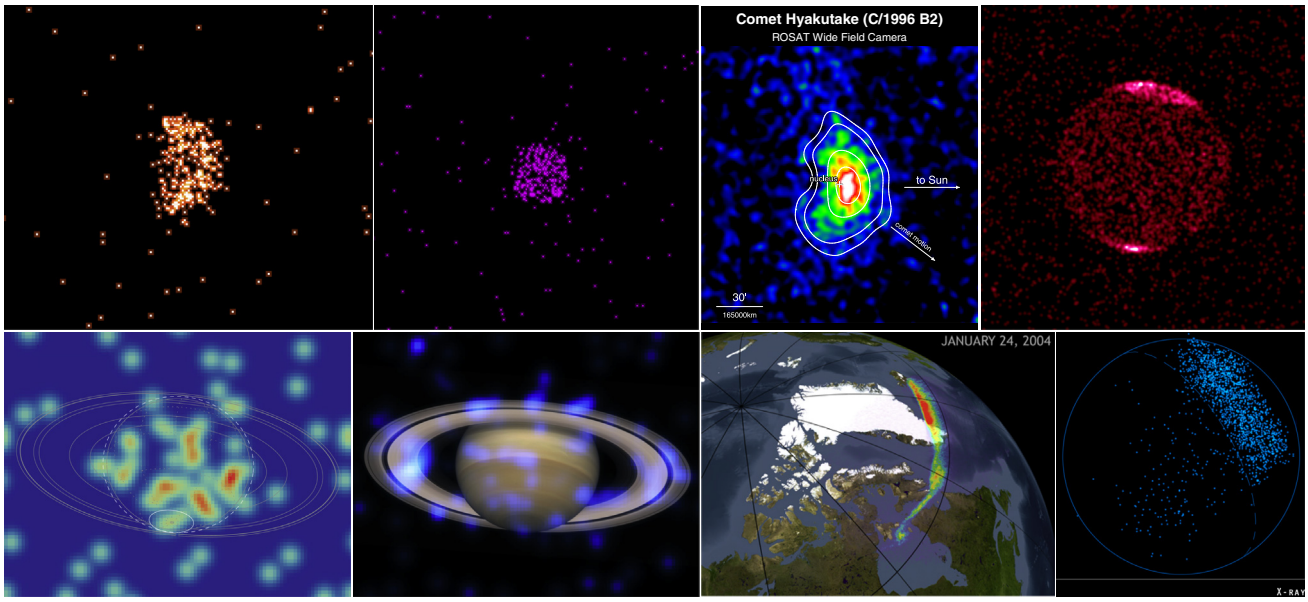

FIGURE 48.1 *Chandra* montage of solar system X-ray sources. Upper panel, from left to right: Venus, Mars, Comet Hyakutake (C/1996 B2), Jupiter (aurora + reflected disk emissions). Bottom panel, from left to right: Saturn, Saturn rings, Earth (auroral emission), Moon (sunlit side emission).

When Kα X-rays are produced in an oxygen atom, it is called oxygen Kα or O-Kα photon.

Launch of the first X-ray satellite *Uhuru* in 1970 marked the beginning of satellite-based X-ray astronomy. The subsequently launched X-ray observatory *Einstein* discovered, after a long search, X-rays from Jupiter in 1979. Before 1990, the three objects known to emit X-rays (in addition to the Sun) were Earth, Moon, and Jupiter. In 1996, *ROSAT* (*Röntgensatellit*) made an important contribution to the field of solar system X-rays by discovering X-ray emissions from comets. This discovery revolutionized the field of solar system X-rays and highlighted the importance of the solar wind charge exchange (SWCX) mechanism in the production of X-rays in the solar system, which will be discussed in this chapter in various sections.

Today, the field of solar system X-rays is very dynamic and in the forefront of new research. During the past one decade or so, our knowledge about the X-ray emission from bodies within the solar system has significantly improved. The advent of higher resolution X-ray spectroscopy with the *Chandra* and X-Ray Multi Mirror Mission (*XMM*)-*Newton* X-ray observatories, followed by the next-generation *SWIFT* and *Suzaku* observatories has been of great benefit in advancing the field of planetary X-ray astronomy. Several new solar system objects are now known to shine in the X-ray (Figure 48.1). At Venus, Earth, the Moon, Mars, Jupiter, Saturn (including its rings), and asteroids, scattered solar X-rays have been observed. The first soft X-ray observation of Earth's aurora by *Chandra* showed that it is highly variable, and the Jovian aurora is a fascinating puzzle that is just beginning to yield its secrets. The X-ray emission from comets, the exospheres of Venus, Earth, and Mars, and the heliosphere are all largely driven by charge exchange between highly charged minor (heavy) ions in the solar wind and gaseous neutral species.

This chapter surveys the current understanding of X-ray emission from the solar system bodies. We start our survey locally, at the Earth, move to the Moon and the nearby terrestrial planets, and then venture out to the giant planets and their moons and rings. Next, we move to the small bodies, comets and asteroids, found between the planets, and finally we study the X-ray emission from the heliosphere surrounding the whole solar system and possibilities of X-rays from extrasolar systems. An overview is provided on the main source mechanisms of X-ray production from each object. For further details, readers are referred to the bibliography provided at the end of the chapter and references therein.

2. EARTH

2.1. Auroral Emissions

Precipitation of energetic charged particles from the magnetosphere into Earth's auroral upper atmosphere leads to ionization, excitation, dissociation, and heating of the neutral atmospheric gas. Deceleration, or braking of precipitating particles during their interaction with atom and molecules in the atmosphere, results in the production of a continuous spectrum of X-ray photons, called **bremsstrahlung**. This is the main X-ray production mechanism in the Earth's auroral zones, for energies above ~3 keV; therefore, the X-ray spectrum of the aurora has been found to be very useful in studying the characteristics

of energetic electron precipitation. In addition, particles precipitating into the Earth's upper atmosphere give rise to discrete atomic emission lines in the X-ray range. The characteristic inner-shell line emissions for the main species of the Earth's atmosphere are all in the low-energy range (nitrogen Kα at 0.393 keV, oxygen Kα at 0.524 keV, argon Kα at 2.958 keV, and Kβ at 3.191 keV). Very few X-ray observations have been made at energies at which these lines are emitted.

While charged particles spiral around and travel along the magnetic field lines of the Earth, the majority of the X-ray photons in Earth's aurora are directed normal to the field, with a preferential direction toward the Earth at higher energies. Downward-propagating X-rays cause additional ionization and excitation in the atmosphere below the altitude where the precipitating particles have their peak energy deposition. The fraction of the X-ray emission that is moving away from the ground can be studied using satellite-based imagers (e.g. AXIS on *Upper Atmosphere Research Satellite (UARS)* and PIXIE on the *POLAR* spacecraft).

Auroral X-ray bremsstrahlung has been observed from balloons and rockets since the 1960s and from spacecraft since the 1970s. Because of absorption of the low-energy X-rays propagating from the production altitude (∼100 km) down to balloon altitudes (35−40 km), such measurements were limited to >20 keV X-rays. Nevertheless, these early omnidirectional measurements of X-rays revealed detailed information of temporal structures from slowly varying bay events to fast pulsations and microbursts.

The PIXIE instrument aboard *POLAR* is the first X-ray detector that provides true two-dimensional global X-ray images at energies >3 keV. In Figure 48.2 two images taken by PIXIE in two different energy bands are presented. The auroral X-ray zone can be clearly seen. Data from the PIXIE camera have shown that the X-ray bremsstrahlung intensity statistically peaks at midnight, is significant in the morning sector, and has a minimum in the early dusk sector. During solar substorms, X-ray imaging shows that the energetic electron precipitation brightens up in the midnight sector and has a prolonged and delayed maximum in the morning sector due to the scattering of magnetic-drifting electrons and shows an evolution significantly different than that when viewed in the ultraviolet (UV) emissions.

During the onset/expansion phase of a typical substorm, the electron energy deposition power is about 60−90 GW, which produces 10−30 MW of bremsstrahlung X-rays. By combining the results of PIXIE with the UV imager aboard *POLAR*, it has been possible to derive the energy distribution of precipitating electrons in the 0.1−100 keV range with a time resolution of about 5 min (see Figure 48.2). Because these energy spectra cover the entire energy range important for the electrodynamics of the ionosphere, important parameters like the Hall and Pedersen conductivities and the amount of **Joule heating** can be determined on a global scale with larger certainties than parameterized models can do. Electron energy deposition estimated from global X-ray imaging also gives valuable information on how the constituents of the upper atmosphere, like NO_x, is modified by energetic electron precipitation.

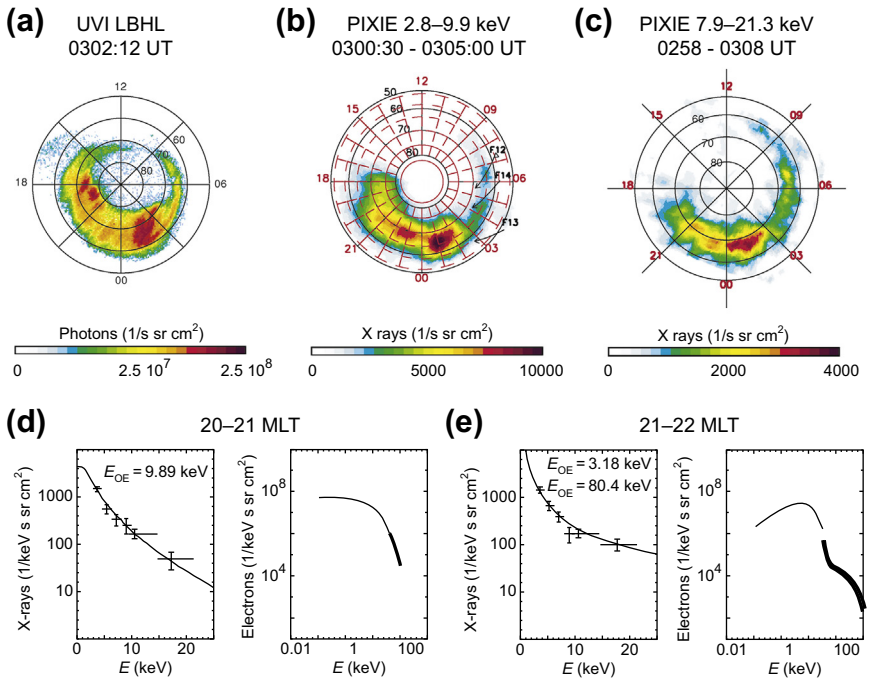

FIGURE 48.2 Earth's aurora. *POLAR* satellite observation on July 31, 1987. (a) UVI and (b, c) PIXIE images in two different energy bands. (d) Left: Measured X-ray energy spectrum. An estimated X-ray spectrum produced by a single exponential electron spectrum with e-folding energy 9.89 keV is shown to be the best fit to the measurements. Right: The electron spectrum derived from UVI (thin line) and PIXIE (thick line). Both plots are averages within a box within 20−21 magnetic local time (MLT) and 64−70° magnetic latitude. (e) Same as (d) but within 21−22 MLT, where a double exponential electron spectrum is shown to be the best fit to the X-ray measurements. *From Østgaard et al. (2001).*

Limb scans of the nighttime Earth at low- to midlatitude by the X-ray astronomy satellite High Energy Astronomy Observatory-1 (*HEAO-1*) in 1977, in the energy range 0.15−3 keV, showed clear evidence of the Kα lines for nitrogen and oxygen sitting on top of the bremsstrahlung spectrum. The High-Resolution Camera (HRC-I) aboard the *Chandra* X-ray Observatory imaged the northern auroral regions of the Earth in the 0.1- to 10-keV X-ray range at 10 epochs (each ∼20 min duration) between December 2003 and April 2004. These first soft X-ray observations of Earth's aurora (see Figure 48.3) showed that it is highly variable (intense arcs, multiple arcs, diffuse patches, and at times absent). Also, one of the observations showed an isolated blob of emission near the expected cusp location. Modeling of the observed soft X-ray emissions suggests that it is a combination of bremsstrahlung and characteristic K-shell line emissions of nitrogen and oxygen in the atmosphere produced by electrons. In the soft X-ray energy range of 0.1−2 keV, these line emissions are ∼5 times more intense than the X-ray bremsstrahlung.

2.2. Nonauroral Emissions

The nonauroral X-ray emission above 2 keV from the Earth is almost completely negligible except for brief periods during major solar flares (Figure 48.4). However, at energies below 2 keV, soft X-rays from the sunlit Earth's atmosphere have been observed even during quiet (nonflaring) Sun conditions. The two primary mechanisms for the production of X-rays from the sunlit atmosphere are: (1) Thomson (coherent) scattering of solar X-rays from the electrons in the atomic and molecular constituents of the atmosphere and (2) the absorption of incident solar X-rays followed by the resonance fluorescence emission of characteristic K lines of nitrogen, oxygen, and argon. During flares, solar X-rays light up the sunlit side of the Earth by Thomson and fluorescent scattering (Figure 48.4); the X-ray brightness can be comparable to that of a moderate aurora.

Around 1994, the Compton Gamma Ray Observatory (*CGRO*) satellite detected a new type of X-ray source from the Earth. These are very short-lived (1 ms) X-ray and γ-ray bursts (∼25 keV−1 MeV) from the atmosphere above thunderstorms, whose occurrence is also supported by the more recent Reuven Ramaty High Energy Solar Spectroscopic Imager (*RHESSI*) observations. It has been suggested that these emissions are bremsstrahlung from upward-propagating, relativistic (megaelectronvolt) electrons generated in a runaway electron discharge process above thunderclouds by the transient electric field following a positive cloud-to-ground lightning event.

2.3. Geocoronal Emissions

In the Earth's exosphere (geocorona), SWCX with neutrals can produce X-rays. This process is now understood as a contribution to the soft X-ray background and to its long-term enhancements (LTEs) seen in the *ROSAT* all-sky survey. The LTEs in the *ROSAT* all-sky survey data are well correlated with the solar wind proton flux, suggesting that SWCX with H in the geocorona is the source of the LTEs. *Chandra* observations of the Moon are particularly interesting because they have cleanly separated

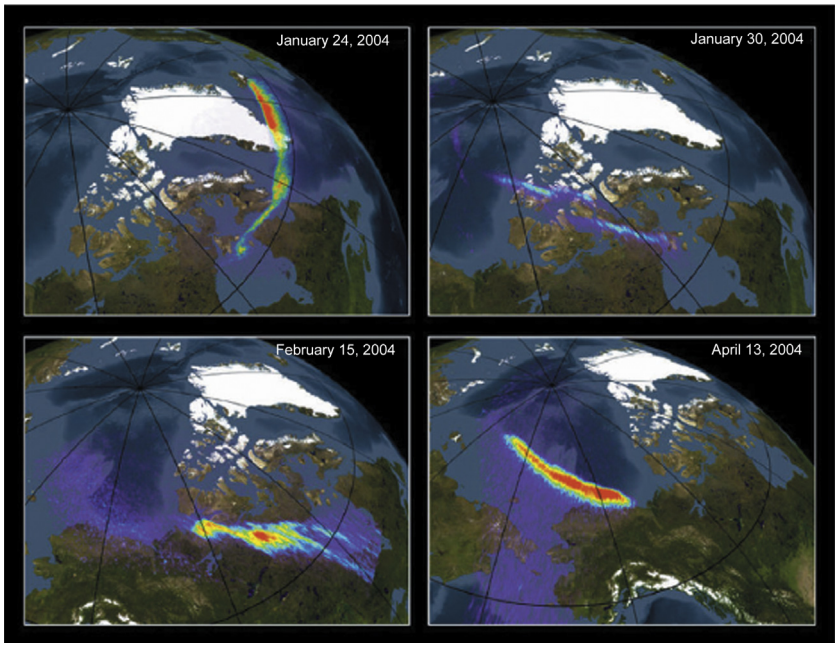

FIGURE 48.3 Four Earth's aurora X-ray images (shown on the same brightness scale) of the north polar regions obtained by *Chandra* HRC-I on different days (marked at the top of each image), showing large variability in soft (0.1−10 keV) X-ray emissions from Earth's aurora. The bright arcs in these *Chandra* images show low-energy X-rays generated during auroral activity. The images are superimposed on a simulated image of the Earth. *From Bhardwaj et al. (2007b).*

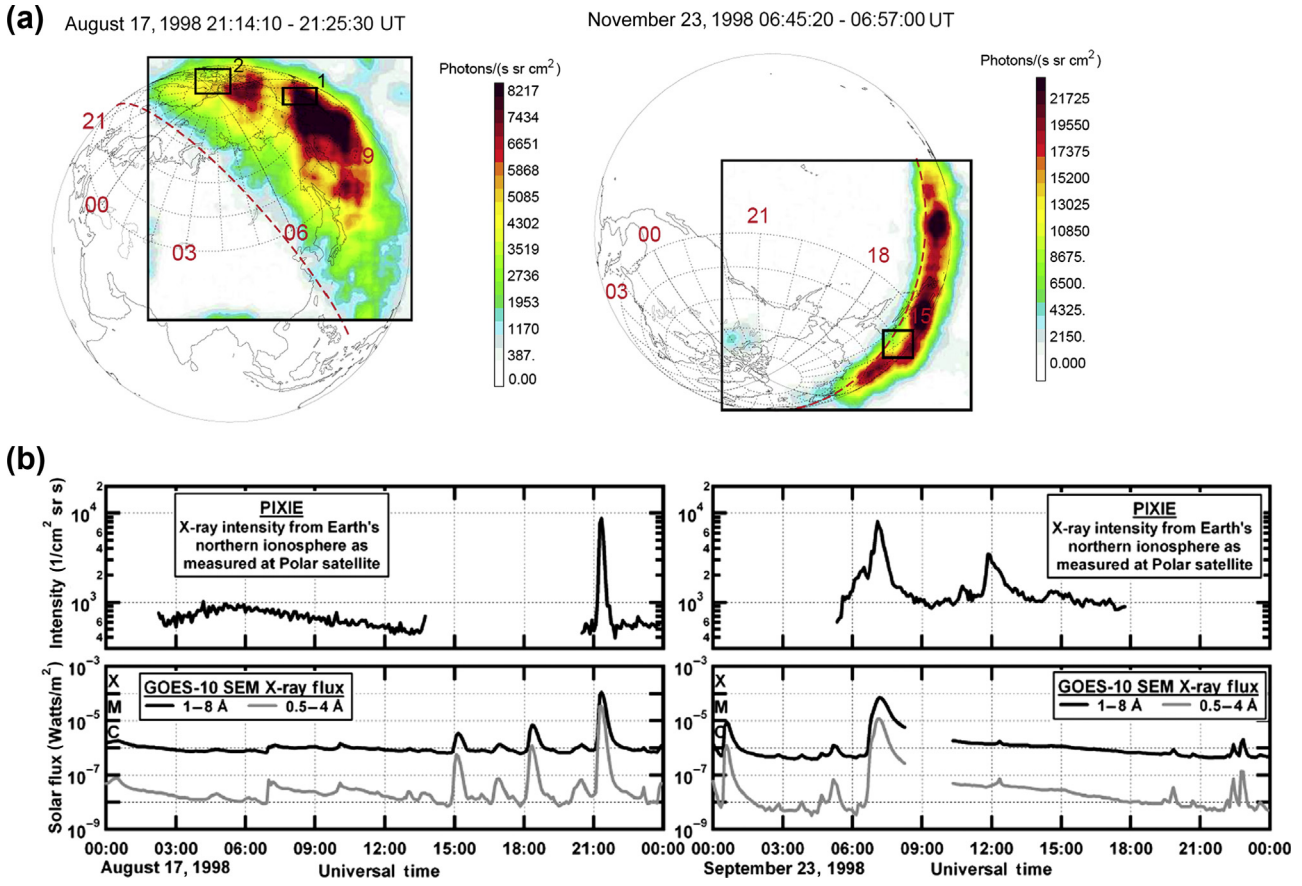

FIGURE 48.4 (a) X-ray images of the Earth from the *POLAR* PIXIE instrument for the energy range 2.9−10.1 keV obtained on August 17, 1998, (left) and November 23, 1998, (right), showing the dayside X-rays during a solar X-ray flare. The grid in the picture is in corrected geomagnetic coordinates, and the numbers shown in red are magnetic local times. The terminator at the surface of the Earth is shown as a red dashed line. *From Petrinec et al. (2000).* (b) Left: a sudden increase and subsequent decrease in X-ray intensity were observed on August 17, 1998, shortly after 21 UT while the PIXIE instrument was observing the Earth's northern hemisphere. This spike in X-ray intensity coincided with an X1 solar X-ray flare, as measured by *GOES-10*. Right: the occurrence of an M7 solar flare at ∼07 Universal Time (UT) resulted in a sudden increase and decrease in X-ray flux from the Earth on September 23, 1998. A later increase in the X-ray emissions from the Earth's ionosphere (shortly before 12 UT) was due to increased auroral activity. *From Bhardwaj et al. (2009).*

geocoronal from heliospheric charge exchange emissions and all other contributors to the soft X-ray background and have shown correlation of geocoronal X-rays with the flux of highly charged oxygen ions in the solar wind. *XMM-Newton* and *Suzaku* have observed correlations of the X-ray intensity from the Earth's vicinity with the solar wind flux on timescales of about half a day, and also short-term (∼10 min) variations. The correlated variability of X-ray intensity with solar wind, and the lack of correlation with solar X-rays, suggests that the production of SWCX-induced X-rays is taking place in the Earth's magnetosheath.

3. THE MOON

X-ray emissions from the Earth's nearest planetary body, the Moon (see also "The Moon"), have been studied in two ways: close-up from lunar orbiters (e.g. *Apollo 15* and *16*, *Clementine, SMART-1, Kaguya*, and *Chandrayaan-1*), and more distantly from Earth-orbiting X-ray astronomy telescopes (e.g. *ROSAT* and *Chandra*). Lunar X-rays result mainly from fluorescence of solar X-rays from the surface, in addition to a low level of scattered solar radiation. Thus, X-ray fluorescence studies provide an excellent way to determine the elemental composition of the lunar surface by remote sensing, since at X-ray wavelengths the optical properties of the surface are dominated by its elemental abundances. Elemental abundance maps produced by X-ray spectrometers (XRSs) on the *Apollo 15* and *16* orbiters were limited to the equatorial regions but succeeded in finding geochemically interesting variations in the relative abundances of Al, Mg, and Si, such as the enhancement of Al/Si in the lunar highlands relative to the mare. The D-Compact X-ray Spectrometer (D-CIXS) instrument on

SMART-1 has obtained abundances of Al, Si, Fe, and even Ca at 50-km resolution from a 300-km altitude orbit about the Moon. XRSs capable of higher spatial and spectral resolution have been flown on *Kaguya* and *Chandrayaan-1*. The X-ray charge-coupled devices on *Kaguya* suffered severe radiation damage en route to the Moon and could not perform well. C1XS on *Chandrayaan-1* provided new data sets on composition of Mg, Al, Si, Ca, and Fe at scales of 50 km, which indicates regions that may be richer in the sodic variety of plagioclase than previously thought. These recent experiments also suggest that particle-induced X-ray fluorescence could also contribute to the signal. Future X-ray experiments such as CLASS on *Chandrayaan-2* aim at global elemental mapping with better spatial resolution (∼12−25 km) and wider elemental overage (including direct detection of sodium) and will use refined

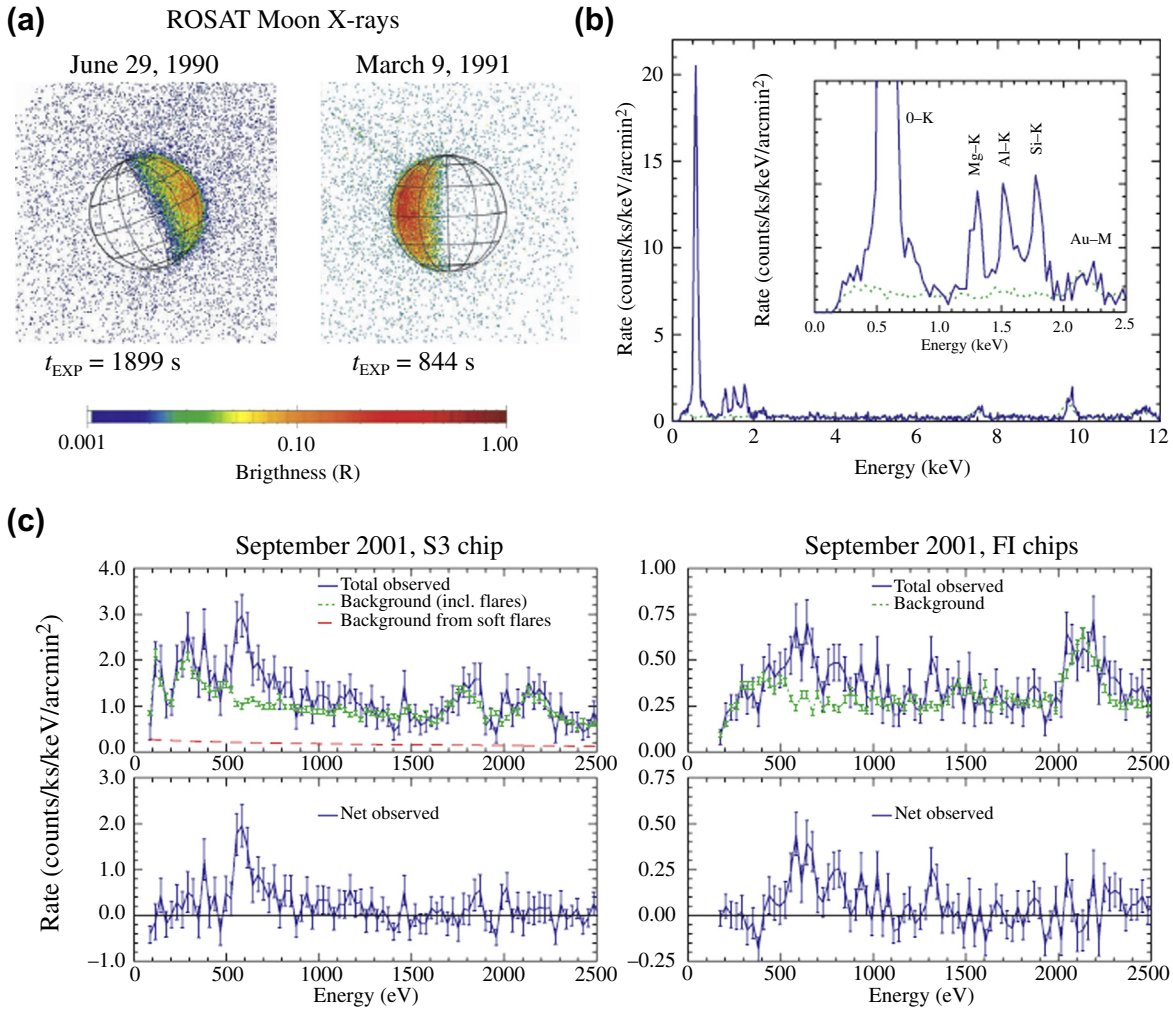

FIGURE 48.5 The Moon. (a) *ROSAT* soft X-ray (0.1−2 keV) images of the Moon at first (left side) and last (right side) quarter. The dayside lunar emissions are thought to be primarily reflected and fluoresced sunlight, while the faint nightside emissions are foreground due to charge exchange of solar wind heavy ions with H atoms in the Earth's exosphere. The brightness scale in R assumes an average effective area of 100 cm^2 for the ROSAT Position Sensitive Proportional Counter (PSPC) over the lunar spectrum. *From Bhardwaj et al. (2007a).* (b) *Chandra* spectrum of the bright side of the Moon. The green dotted curve is the detector background. K-shell fluorescence lines from O, Mg, Al, and Si are shifted up by 50 eV from their true values because of residual optical leak effects. Features at 2.2, 7.5, and 9.7 keV are intrinsic to the detector. *From Wargelin et al. (2004).* (c) Observed and background-subtracted spectra from the September 2001 *Chandra* observation of the dark side of the Moon, with 29-eV binning. The left panel is from the back-illuminated Advanced CCD Imaging Spectrometer - Spectroscopic Array 3 (ACIS-S3) CCD, while the right panel shows the spectrum obtained with the front-illuminated (FI) ACIS-I Advanced CCD Imaging Spectrometer - Imaging Array (ACIS-I) CCDs, which have higher spectral resolution, but lower sensitivity. Oxygen emission from charge exchange is clearly seen in both spectra, and the energy resolution in the FI chips is sufficient that emission from M-L shell transitions of O^{7+} ions is largely resolved from L-K transitions of O^{6+} ions. Emission lines from transitions of what is likely Mg-Kα around 1340 eV, Al-Kα at about 1550 keV, and Si-Kα at approximately 1780 keV are also apparent in the FI spectrum. *See also Ewing et al. (2013).*

methodologies to take into account signals from PIXE, enabling observations even during lunar night. These global maps will be complemented by rovers on the planned missions *Selene-2* as well as *Chandrayaan-2* which are expected to carry alpha particle spectrometers to study local surface chemistry through in situ quantitative analysis.

Early lunar X-ray observations from Earth orbit were made with *ROSAT*. A marginal detection by the Advanced Satellite for Cosmology and Astrophysics (*ASCA*) is also reported. Figure 48.5(a) shows the *ROSAT* images of the Moon; the right image is data from a lunar occultation of the bright X-ray source GX5-1. The power of the reflected and fluoresced X-rays observed by *ROSAT* in the 0.1−2 keV range coming from the sunlit surface was determined to be only 73 kW. The faint but distinct lunar nightside emissions (100 times less bright than the dayside emissions) were originally interpreted as being produced by bremsstrahlung of solar wind electrons of several hundred electronvolts impacting the nightside of the Moon on its leading hemisphere. However, this was before the GX5-1 data were acquired, which clearly show lunar nightside X-rays from the early trailing hemisphere as well. A new, much better and accepted explanation is that the heavy ions in the solar wind charge exchanges (SCWX) with geocoronal and interstellar H atoms that lie between the Earth and Moon result in foreground X-ray emissions between *ROSAT* and the Moon's dark side. This was confirmed by *Chandra* Advanced CCD Imaging Spectrometer (ACIS) observations in 2001 (see Figure 48.5(c)).

The July 2001 *Chandra* observations also provide the first remote measurements that clearly resolve discrete K-shell fluorescence lines of O, Mg, Al, and Si on the sunlit side of the Moon (see Figure 48.5(b)). The observed oxygen Kα (O−Kα for short; which means K-shell emissions from oxygen (O) atoms) line photons correspond to a flux of 3.8×10^{-5} photons/s/cm^2/arcmin^2 (3.2×10^{-14} erg/s/cm^2/arcmin^2). The Mg−Kα, Al−Kα, and Si−Kα lines each had roughly 10% as many counts and 3% as much flux as O−Kα line, but statistics were inadequate to draw any conclusions regarding differences in element abundance ratios between highlands and maria. Later *Chandra* observations of the Moon used the photon counting, high spatial resolution HRC-I imager to look for **albedo** variations due to elemental composition differences between **highlands** and **maria**. The observed albedo contrast was noticeable, but very slight, making remote elemental mapping difficult.

4. MERCURY

Being too close to the Sun, Mercury (see also "Mercury") cannot be observed by any X-ray observatory orbiting around the Earth. Launched on August 3, 2004, the *MESSENGER* (MErcury Surface, Space ENvironment, GEochemistry, and Ranging) spacecraft conducted its first flyby of Mercury on January 14, 2008, followed by two subsequent encounters on October 6, 2008, and September 29, 2009, prior to Mercury orbit insertion. On March 18, 2011, it became the first probe to orbit the planet Mercury. The XRS onboard *MESSENGER* has observed X-ray fluorescence emission from Mercury—thereby providing important information on the elemental composition of its surface. The XRS spectra have revealed Mercury's surface to differ in composition from those of other terrestrial planets and the Moon.

The XRS has also observed electron-induced X-ray emission from the dark side of Mercury. These X-ray fluorescence emissions are produced by interaction of ~1- to 10-keV electrons with Mercury's surface and the abundance results derived from this technique for Mg, Si, and Al are found to be consistent with those derived from solar-induced X-ray fluorescence. In fact, electron-induced X-ray fluorescence has been used to derive the spectrum of electrons precipitating onto the Mercury surface, which is in agreement with the *MESSENGER*'s Energetic Particle Spectrometer (EPS)-measured spectrum. This showed that both the dayside and the nightside of an airless planetary body can be mapped by X-ray fluorescence—while on the dayside solar photons produce fluorescence and on the nightside its electrons. The XRS has also been used to study astrophysical objects during *MESSENGER*'s flybys of Mercury.

In future, the Mercury Imaging X-ray Spectrometer (MIXS) aboard the European Space Agency−Japan Aerospace Exploration Agency *BepiColombo* mission will help further investigate Mercury's X-rays and look for even solar wind-induced charge exchange emission, since the strength of solar wind flux is very high at Mercury.

5. VENUS

The first X-ray observation of Venus was obtained by *Chandra* in January 2001. It was expected that Venus would be an X-ray source due to two processes: (1) charge exchange interactions between highly charged ions in the solar wind and the Venusian exosphere and (2) scattering of solar X-rays in the Venusian atmosphere. The predicted X-ray luminosities were ~0.1−1.5 MW for the first process, and ~35 MW for the second one, with an uncertainty factor of about 2. The *Chandra* observation of 2001 consisted of two parts: grating spectroscopy with Low Energy Transmission Grating (LETG)/Advanced CCD Imaging Spectrometer - Spectroscopic Array (ACIS-S) and direct imaging with ACIS-I. This combination yielded data of high spatial, spectral, and temporal resolution. Venus was clearly detected as a half-lit crescent, exhibiting

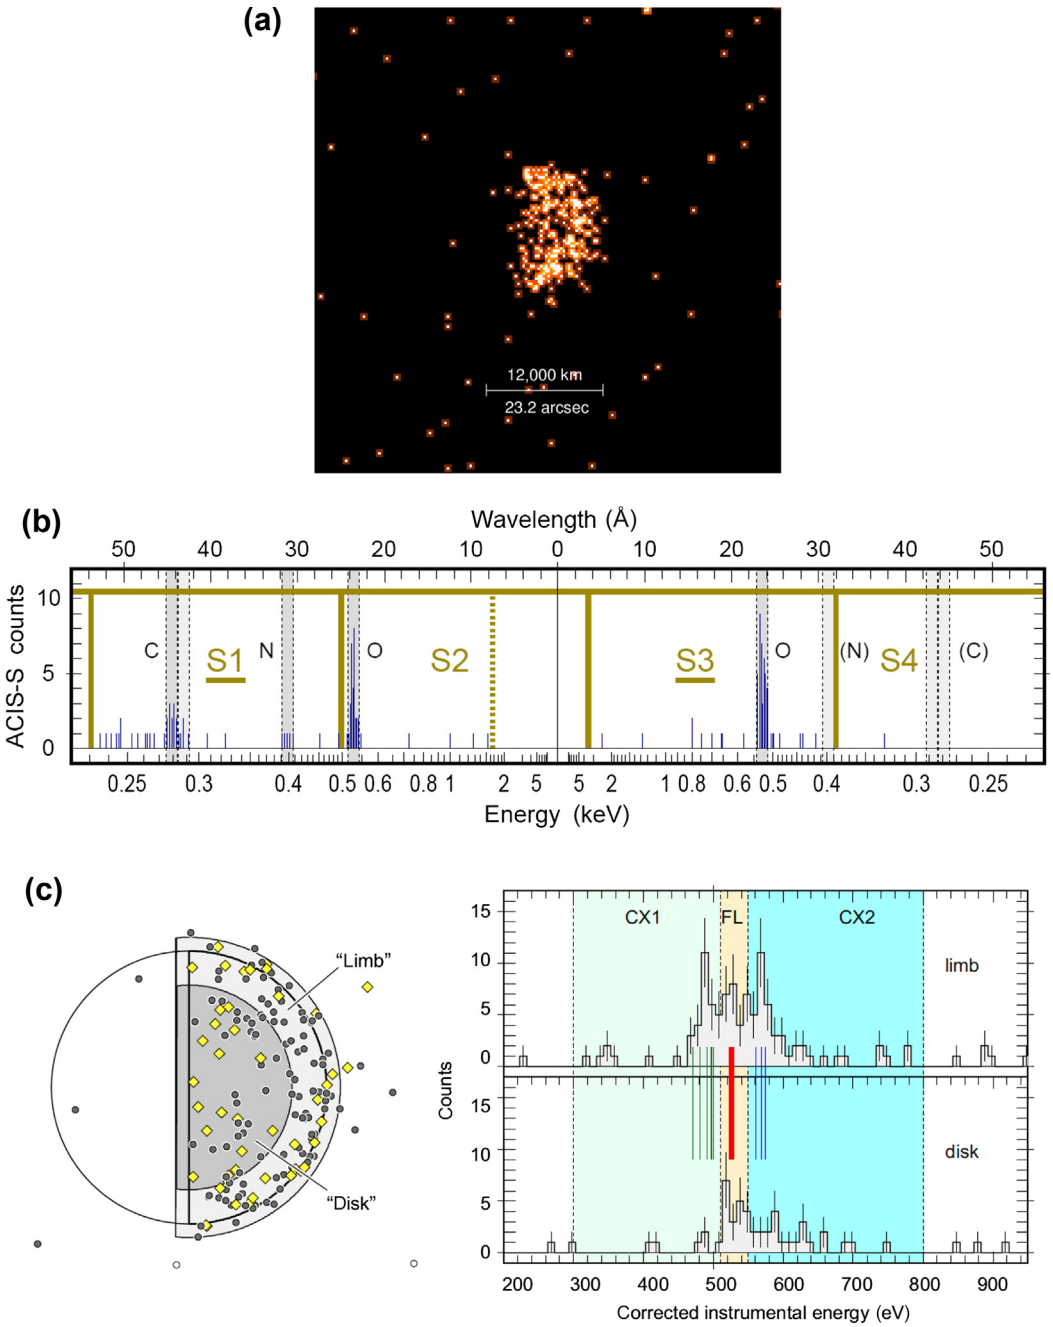

FIGURE 48.6 Venus. (a) First X-ray image of Venus, obtained with *Chandra* ACIS-I on January 13, 2001. The X-rays result mainly from fluorescent scattering of solar X-rays on C and O in the upper Venus atmosphere, at heights of 120−140 km. In contrast to the Moon, the X-ray image of Venus shows evidence for brightening on the sunward limb. This is caused by the fact that scattering takes place on an atmosphere and not on a solid surface. (b) Spectral scan. Scales are given in kiloelectronvolts and angstroms. The observed C, N, and O fluorescent emission lines are enclosed by dashed lines; the width of these intervals matches the size of the Venus crescent (22.8″). *From Dennerl, Burwitz, Englhauser, Lisse, and Wolk (2002).* (c) Spatial and spectral distribution of X-ray photons from Venus, obtained on March 27, 2006 with Chandra. Left: Distribution of the X-ray photons in the energy range 0.3−0.8 keV. Photons in the fluorescence band FL are marked with bright diamonds, and those in the charge exchange bands CX1 and CX2 with dark circles. The extraction regions for the limb and disk spectra are superimposed on light and dark gray, respectively; the circle indicates the geometric size of Venus. Right: X-ray spectra for the limb (top) and the disk region (bottom), with the energy bands CX1, FL, and CX2 marked. The spectrum of the limb region is dominated by two emission lines in the CX1 and CX2 bands. These lines are almost absent in the disk spectrum, which is dominated by emission in the FL band. The energies of characteristic lines expected for charge exchange and fluorescence are marked by vertical lines. *From Dennerl (2008).*

considerable brightening on the sunward limb (Figure 48.6); the LETG/ACIS-S data showed that the spectrum was dominated by K-shell fluorescence of oxygen and carbon (O−Kα and C−Kα), and both instruments indicated temporal variability of the X-ray flux. An average luminosity of 55 MW was found, which agreed well with the theoretical predictions for scattered solar X-rays. In addition to the C−Kα and O−Kα emission at 0.28 and 0.53 keV, respectively, the LETG/ACIS-S spectrum also showed evidence for N−Kα emission at 0.40 keV. An additional emission line was indicated at 0.29 keV, which might be the signature of the C 1s → π* transition in CO_2. The observational results are consistent with fluorescent scattering of solar X-rays by the majority species in the Venusian atmosphere, and no evidence of the 30 times weaker charge exchange interactions was found. Simulations showed that fluorescent scattering of solar X-rays is most efficient in the Venusian upper atmosphere at heights of ∼120 km, where an optical depth of 1 is reached for incident X-rays with energy 0.2−0.9 keV.

The second *Chandra* observation of Venus in March 2006 showed clear signature of charge-exchanged X-rays from the exosphere (Figure 48.6), which was marginally detected again in the October 2007 *Chandra* observation. The bright emission feature is O^{6+} emission near 565 eV, which is also an important feature in X-ray spectra of comets and the Martian exosphere.

The appearance of Venus is different in optical light and in X-rays. The reason for this is that the optical light is reflected from clouds at a height of 50−70 km, while scattering of X-rays takes place at higher regions extending into the tenuous, optically thin parts of the thermosphere and exosphere. As a result, the Venusian sunlit hemisphere appears surrounded by an almost transparent luminous shell in X-rays, and Venus looks brightest at the limb because more luminous material is there. Because X-ray brightening depends sensitively on the density and chemical composition of the Venusian atmosphere, its precise measurement will provide direct information about the atmospheric structure in the thermosphere and exosphere. This opens up the possibility of using X-ray observations for monitoring the properties of these regions that are difficult to investigate by other means, as well as their response to solar activity.

6. MARS

The first X-rays from Mars were detected on July 4, 2001, with the ACIS-I detector onboard *Chandra*. In the *Chandra* observation, Mars showed up as an almost fully illuminated disk (Figure 48.7). An indication of limb brightening on the sunward side, accompanied by some fading on the opposite side, was observed. The observed morphology and X-ray luminosity of ∼4 MW, about 10 times less than at Venus, was consistent with fluorescent scattering of solar X-rays in the upper Mars atmosphere. A single narrow emission line caused by K-shell fluorescence emission of oxygen dominated the X-ray spectrum.

Simulations suggest that scattering of solar X-rays is most efficient between 110 km (along the subsolar direction) and 136 km (along the terminator) above the Martian surface. This behavior is similar to that seen on Venus. No evidence for temporal variability or dust-related emission was found, which is in agreement with fluorescent scattering of solar X-rays as the dominant process responsible for Martian X-rays. A gradual decrease in the X-ray surface brightness between 1 and ∼3 Mars radii is observed (see Figure 48.7). Within the limited statistical quality of the low flux observations, the spectrum of this region (halo) resembled that of comets, suggesting that they are caused by charge exchange interactions between highly charged heavy ions in the solar wind and neutrals in the Martian exosphere (corona). For the X-ray halo observed within 3 Mars radii, excluding Mars itself, the *Chandra* observation yielded a flux of about 1×10^{-14} erg/cm^2/s in the energy range 0.5−1.2 keV, corresponding to a luminosity of 0.5 ± 0.2 MW for isotropic emission, which agrees well with that expected theoretically for the SWCX mechanism.

The first *XMM-Newton* observation of Mars in November 2003 confirmed the presence of the Martian X-ray halo and allowed a detailed analysis of its spectral, spatial, and temporal properties to be made. High-resolution spectroscopy of the halo with *XMM-Newton* Reflection Grating Spectrometer (RGS) revealed the presence of numerous (∼12) emission lines at the positions expected for deexcitation of highly ionized C, N, O, and Ne atoms (Figure 48.8). The three Kα lines of O VII emission were resolved and found to be dominated by a long-lived forbidden triple to singlet transition, as expected for charge exchange but not fluorescence or collisionally induced X-ray emission. This was the first definite detection of charge exchange-induced X-ray emission from the exosphere of another planet.

The *XMM-Newton* observation confirmed that the fluorescent scattering of solar X-rays from the Martian disk is clearly concentrated on the planet, and is directly correlated with the solar X-ray flux levels. On the other hand, the Martian X-ray halo was found to extend out to ∼8 Mars radii, with pronounced morphological differences between individual ions and ionization states (Figure 48.8). The halo emission exhibited pronounced variability, but, as expected for solar wind interactions, the variability of the halo did not show any correlation with the solar X-ray flux. Mars was found to be dimmer in observations made during solar minimum, suggesting direct correlation with solar activity. *Suzaku* could not even detect Mars in X-rays in an observation in April 2008.

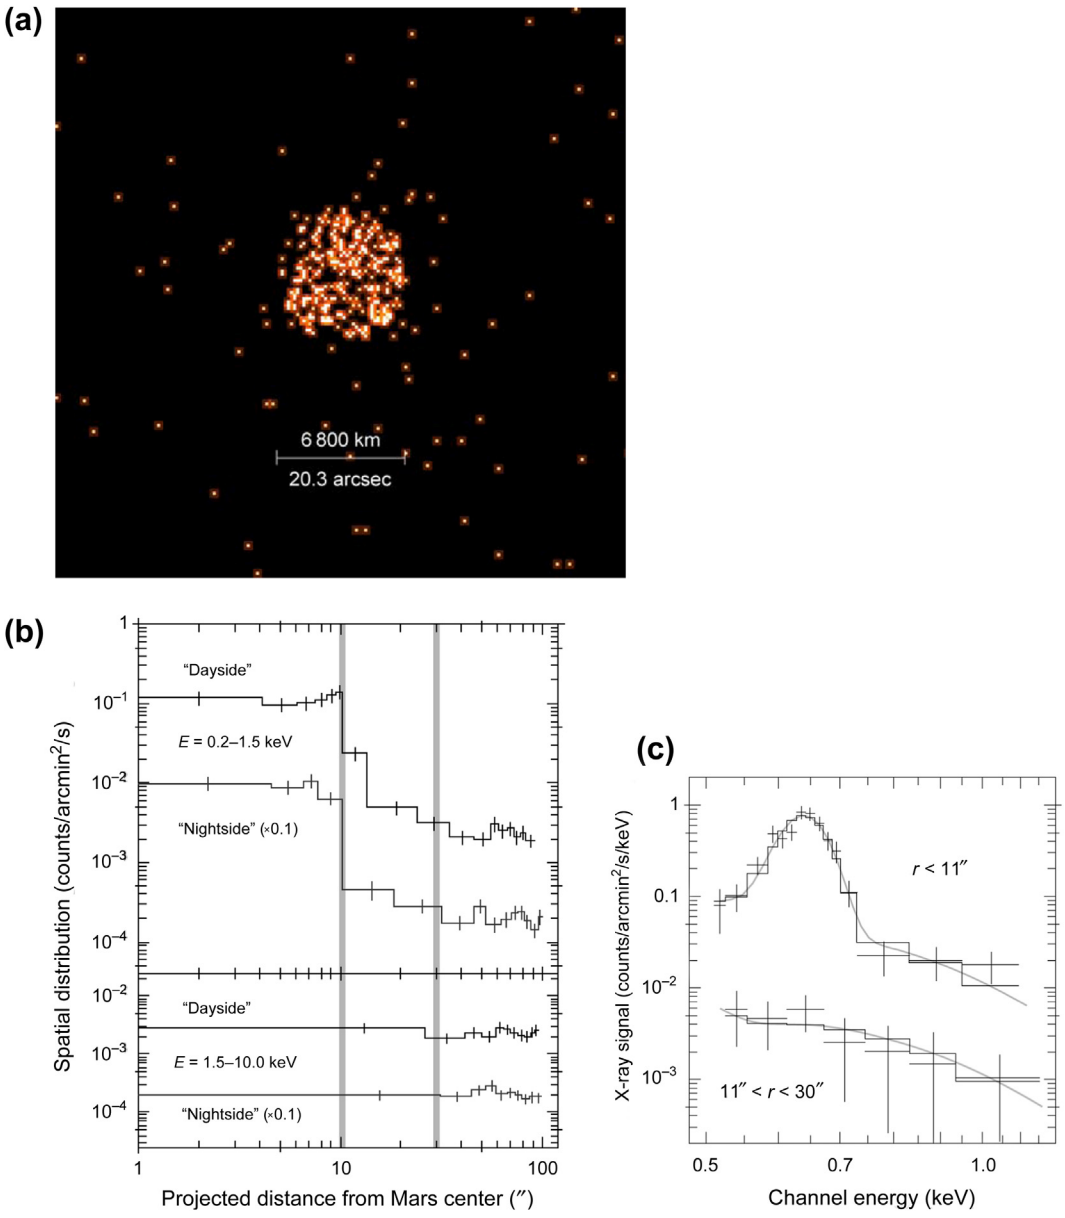

FIGURE 48.7 Mars. (a) First X-ray image of Mars, obtained with *Chandra* ACIS-I. The X-rays result mainly from fluorescent scattering of solar X-rays on C and O in the upper Mars atmosphere, at heights of 110−130 km, similar to Venus. The X-ray glow of the Martian exosphere is too faint to be directly visible in this image. *From Dennerl (2002).* (b) Spatial distribution of the photons around Mars in the soft ($E = 0.2-1.5$ keV) and hard ($E = 1.5-10.0$ keV) energy range, in terms of surface brightness along radial rings around Mars, separately for the dayside (offset along projected solar direction >0) and the nightside (offset <0); note, however, that the phase angle was only 18.2°. For better clarity, the nightside histograms were shifted by one decade downward. The bin size was adaptively determined so that each bin contains at least 28 counts. The thick vertical lines enclose the region between 1 and 3 Mars radii. (c) X-ray spectra of Mars (top) and its X-ray halo (bottom). Crosses with 1σ error bars show the observed values; the model spectra, convolved with the detector response, are indicated by gray curves (unbinned) and by histograms (binned as the observed spectra). The spectrum of Mars itself is characterized by a single narrow emission line (this is most likely the O-Kα fluorescence line at 0.53 keV; the apparent displacement of the line energy is due to optical loading). At higher energies, the presence of an additional spectral component is indicated. The spectral shape of this component can be well modeled by the same 0.2-keV thermal bremsstrahlung emission which can be used as a "technical" proxy for characterizing the basic spectral properties of the X-ray halo in an instrument-independent way. *From Dennerl (2002).*

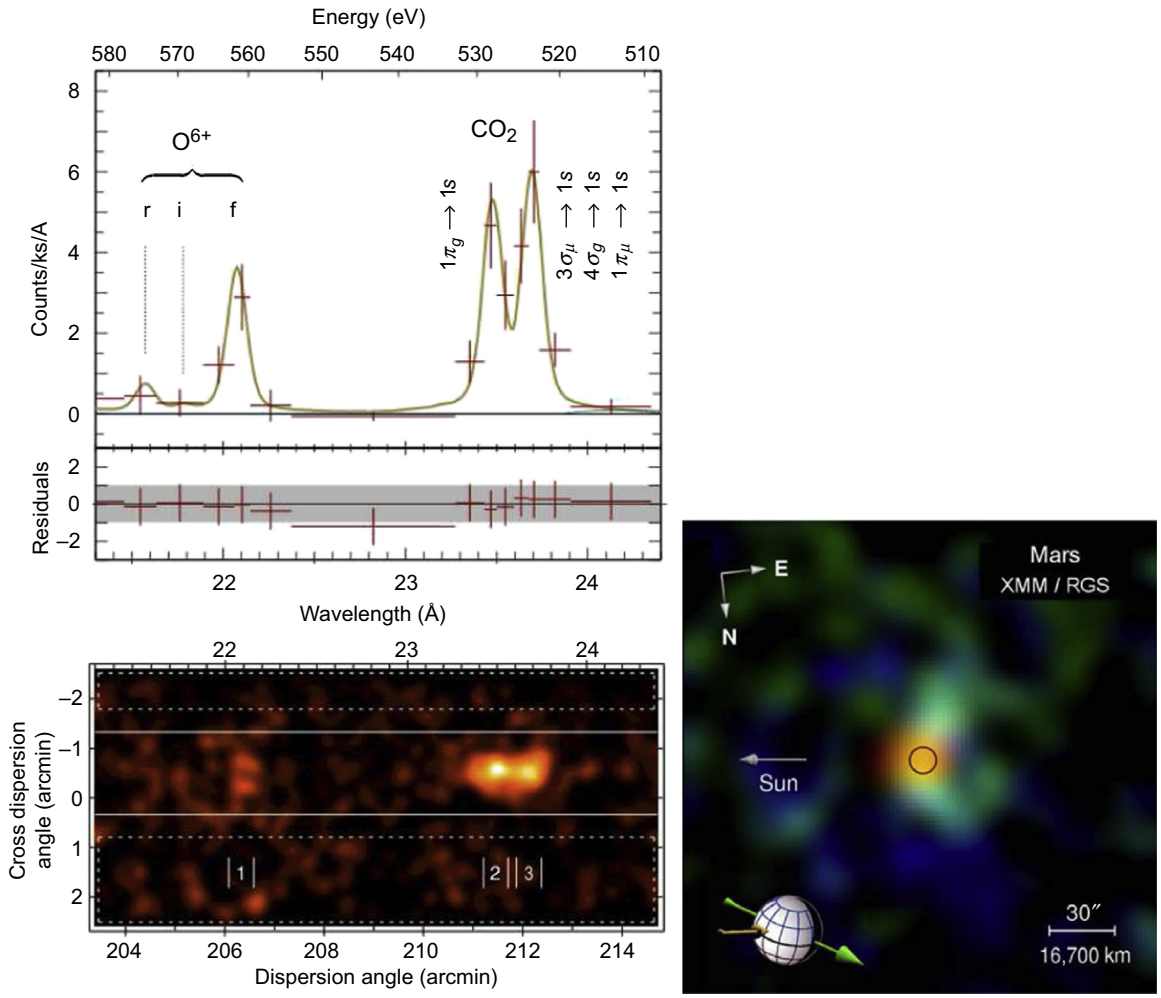

FIGURE 48.8 Mars. Imaging spectroscopy of Mars with *XMM-Newton's* RGS in November 2003 showing images of Mars and its halo in the individual emission lines of ionized oxygen and fluorescence of CO_2. (Top) RGS spectrum obtained from a 100″-wide area along the cross-dispersion direction, showing the region around the CO_2 doublet and the O VII multiplet. (Bottom) dispersed images in the same wavelength range as above. The apparent diameter of Mars during this observation was 12.2″. (Right) X-ray image of Mars in November 2003 with *XMM-Newton*/RGS in the emission lines of charge exchange (green-blue) and fluorescence of solar X-rays (orange). The black circle indicates the size of planet. *From Dennerl et al. (2006).*

7. JUPITER

7.1. Auroral Emission

Like the Earth, Jupiter emits X-rays both from its aurora and its sunlit disk. Jupiter's UV auroral emissions were first observed by the *International Ultraviolet Explorer* (IUE) and soon confirmed by the Voyager 1 ultraviolet spectrometer as it flew through the Jupiter system in 1979 (see Bhardwaj and Gladstone (2000) for review). The first detection of the X-ray emission from Jupiter was also made in 1979; the *Einstein* satellite detected X-rays in the 0.2−3.0 keV energy range from both poles of Jupiter, due to the aurora. Analogous to the processes on Earth, it was expected that Jupiter's X-rays might originate as bremsstrahlung by precipitating electrons. However, the power requirement for producing the observed emission with this mechanism (10^{15}−10^{16} W) is more than two orders of magnitude larger than the input auroral power available as derived from *Voyager* and *IUE* observations of the UV aurora. (The strong Jovian magnetic field excludes the bulk of the solar wind from penetrating close to Jupiter, and the solar wind at Jupiter at 5.2 AU is 27 times less dense than at the Earth at 1 AU.) Precipitating energetic sulfur and oxygen ions from the inner magnetosphere, with energies in the 0.3−4.0 MeV/nucleon range, were suggested as the source mechanism responsible for the production of X-rays on Jupiter. The heavy ions are thought to start as neutral SO and SO_2 molecules emitted by the volcanoes on Io into the Jovian magnetosphere, where they are dissociated and ionized by solar UV radiation, and then swept up into the huge dynamo created by Jupiter's rotating magnetic field (see also "Jupiter" and "Planetary Magnetospheres").

The ions eventually become channeled onto magnetic field lines terminating at Jupiter's poles, where they emit X-rays by first charge stripping to a highly ionized state, followed by charge exchange and excitation through collisions with H_2.

ROSAT's observations of Jupiter X-ray emissions supported this suggestion. The spatial resolution of these early observations was not adequate to distinguish whether the emissions were linked to source regions near the Io torus of Jupiter's magnetosphere (inner magnetosphere) or at larger radial distances from the planet. The advent of *the Chandra* and *XMM-Newton* X-ray observatories revolutionized our understanding of Jupiter's X-ray aurora. High-spatial-resolution (<1 arcsec) observations of Jupiter with *Chandra* in December 2000 (see Figure 48.9) revealed that most of Jupiter's northern auroral X-rays come from a "hot spot" located significantly poleward of the UV auroral zones (20−30 Jupiter's radius, R_J), and not at latitudes connected to the Io plasma torus (IPT) (inner magnetosphere). The hot spot is fixed at 60°−70° magnetic latitude and 160°−180° longitude (in "system III" coordinates rotating with the Jovian magnetosphere) and occurs in a region where anomalous infrared and UV emissions (the so-called flares) have also been observed. On the other hand, auroral X-rays from 70° to 80° S latitude spread almost halfway across the planet (starting at ∼300° and spreading through 0° out to 120° longitude). The location of the auroral X-rays connects along magnetic field lines to regions in the Jovian magnetosphere well in excess of 30 Jovian radii from the planet, a region where there are insufficient S and O ions to account for the X-ray emission. Acceleration of energetic ions was invoked to increase the phase space distribution, but now the question was whether the acceleration involved outer magnetosphere heavy ions or solar wind heavy ions.

Surprisingly, *Chandra* observations also showed that X-rays from the Jovian aurora pulsate with a periodicity that is quite systematic (approximately 45-min period) at times (in December 2000) and irregular (20−70 min range) at other times (in February 2003). The 45-min periodicity is highly reminiscent of a class of Jupiter high-latitude radio emissions known as quasiperiodic radio bursts, which had been observed by Ulysses in conjunction with energetic electron acceleration in Jupiter's outer magnetosphere. During the 2003 *Chandra* observation of Jupiter, the Ulysses radio data did not show any strong 45-min quasi-periodic oscillations, although variability on timescales similar to that in X-rays was present. *Chandra* also found that X-rays from the northern and southern auroral regions are neither in phase nor in antiphase, but that the peaks in the south are shifted from those in the north by about 120° (i.e. one-third of a planetary rotation).

The *Chandra* and *XMM-Newton* spectral and spatial observations have now established that X-rays from Jupiter's aurora are basically of two types: (1) soft (∼0.1−2 keV) and (2) hard (>2 keV) X-rays (Figure 48.9).

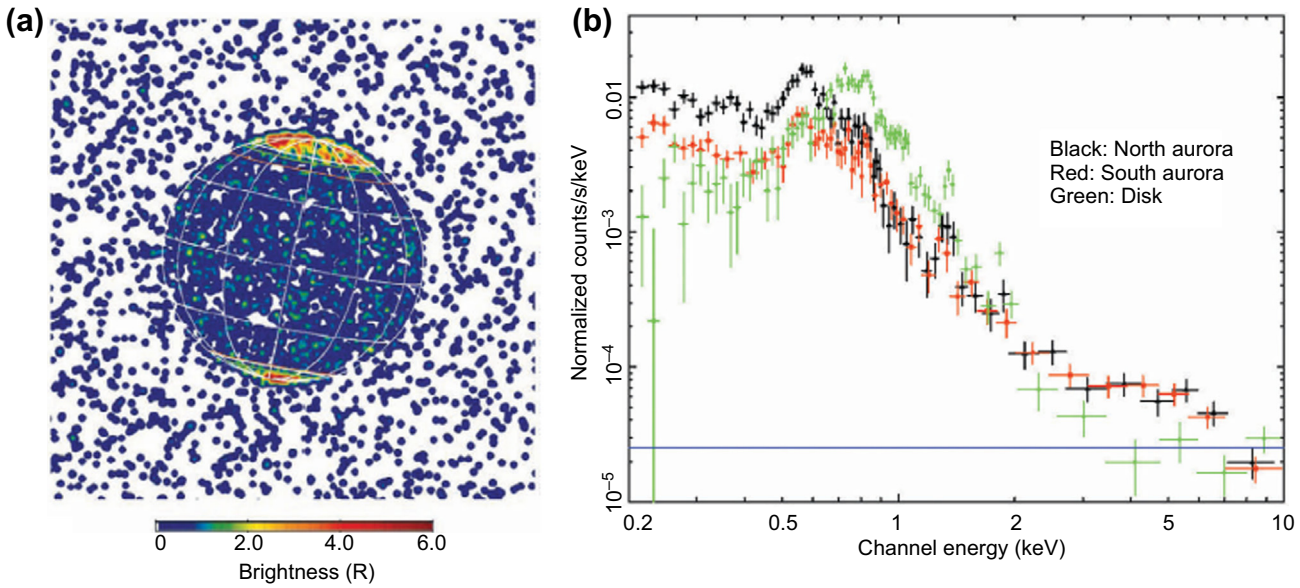

FIGURE 48.9 Jupiter. (a) Detailed X-ray morphology first obtained with *Chandra* HRC-I on December 18, 2000, showing bright X-ray emission from the polar "auroral" regions, indicating the high-latitude position of the emissions, and a uniform distribution from the low-latitude "disk" regions. *From Gladstone et al. (2002).* (b) Combined *XMM-Newton* European Photon Imaging Camera (EPIC) spectra from the November 2003 observation of Jupiter. Data points for the north and south aurorae are in black and red, respectively. In green is the spectrum of the low-latitude disk emission. Differences in spectral shape between auroral and disk spectra are clear. The presence of a high-energy component in the spectra of the aurorae is very evident, with a substantial excess relative to the disk emission extending to 7 keV. The horizontal blue line shows the estimated level of the EPIC particle background. *From Branduardi-Raymont et al. (2007).*

The soft X-rays are line emissions, which are consistent with high-charge states of precipitating heavy O and S ions from the Jovian magnetospheric that are accelerated to attain energies of >1 MeV/nucleon before impacting the Jovian upper atmosphere. There is no evidence for the role of solar wind ions due to the absence of signatures of carbon ions in the X-ray spectrum. Modeling studies which include a source of gaseous neutral atoms (Io's SiO_x and SO_x for Jupiter, Enceladus' H_2O for Saturn), solar UV photolysis and ionization (to S^+, Si^+, and O^+ for Jupiter and H^+ and O^+ for Saturn), followed by pickup, acceleration, and polar precipitation plus charge exchange of the ions at 0–2 keV energies also supports this. The higher (>2 keV) energy X-rays are basically bremsstrahlung from precipitating magnetospheric energetic electrons (see Figure 48.9) and originate from locations that spatially coincide with the Far Ultra Violet (FUV) auroral oval, suggesting that the source of both, X-rays and UV emissions, is the same. The variability on timescales of days suggests a link to changes in the energy distribution of the precipitating magnetospheric electrons and may be related to the solar activity at the time of observation.

7.2. Nonauroral (Disk) Emission

The existence of low-latitude "disk" X-ray emission from Jupiter was first recognized in *ROSAT* observations made in 1994. As for the inner planets, it was suggested that elastic scattering of solar X-rays by atmospheric neutrals (H_2 and He for Jupiter) and fluorescent scattering by the dominant multielectron atom, carbon, via carbon K-shell X-rays (mainly from methane (CH_4) molecules located below the Jovian homopause) were the sources of the disk X-rays.

A general decrease in the overall X-ray brightness of Jupiter observed by *ROSAT* over the years 1994–1996 was found to be coincident with a similar decay in solar activity index (solar 10.7 cm flux). A similar trend is seen in the data obtained by *Chandra* in 2000 and 2003; Jupiter's disk was about 50% dimmer in 2003 compared to that in 2000, which is consistent with variation in the solar activity. A *Chandra* observation in early 2008 during the *New Horizon* flyby also showed a dimmer Jupiter, consistent with a decrease in solar activity.

First direct evidence for temporal correlation between Jovian disk X-rays and solar X-rays was provided by *XMM-Newton* observations in November 2003, which demonstrated that day-to-day variations in disk X-rays of Jupiter are synchronized with variations in the solar X-ray flux, including a solar flare that had a matching feature in the Jovian disk X-ray light curve. *Chandra* observations of December 2000 and February 2003 also support this association between light curves of solar and planetary X-rays. However, there is an indication of higher X-ray counts from regions of low surface magnetic field in the *Chandra* data, suggesting the presence of some particle precipitation.

The higher spatial resolution observation by *Chandra* has shown that nonauroral disk X-rays are relatively more spatially uniform than the auroral X-rays (Figure 48.9). Unlike the $\sim 40 \pm 20$-min quasiperiodic oscillations seen in auroral X-ray emission, the disk emission does not show any systematic pulsations. There is a clear difference between the X-ray spectra from the disk and from the auroral region on Jupiter; the disk spectrum peaks at higher energies (0.7–0.8 keV) than that of the aurora emission (0.5–0.6 keV) and lacks the high-energy component (above ~3 keV) present in the latter (see Figure 48.9).

8. GALILEAN SATELLITES

The Jovian *Chandra* observations on November 25–26, 1999, and December 18, 2000, discovered the X-ray emission from the Galilean satellites (Figure 48.10). These satellites are very faint when observed from the Earth's orbit (by *Chandra*), and the detections of Io and Europa, although statistically very significant, were based on ~10 photons each! The energies of the detected X-ray events ranged between 300 and 1890 eV and appeared to show a clustering between 500 and 700 eV, suggestive of oxygen K-shell fluorescent emission. The estimated power of the X-ray emission was 2 MW for Io and 3 MW for Europa. There were also indications of X-ray emission from Ganymede. X-ray emission from Callisto seems likely at levels not too far below the *Chandra* sensitivity limit because the heavy ion fluxes of the Jovian magnetosphere are an order of magnitude lower than at Ganymede and Europa, respectively. Emissions from Io were also seen in a February 2003 *Chandra* observation, although at weaker levels.

The most plausible proposed emission mechanism is inner (K-shell) ionization of surface and near-surface atoms by incoming magnetospheric ions followed by prompt X-ray emission. Oxygen should be the dominant emitting atom either on a SiO_x (silicate) or SO_x (sulfur oxides) surface (Io) or on an icy one (the outer Galilean satellites). It is also the most common heavy ion in the Jovian magnetosphere. The extremely tenuous atmospheres of the satellites are transparent to X-ray photons with these energies, as well as to much of the energy range of the incoming ions. However, oxygen absorption in the soft X-ray is strong enough that the X-rays must originate within the top 10 μm of the surface in order to escape. Simple estimates suggest that excitation by incoming ions dominates over electrons and that the X-ray flux produced is within a factor of three of the measured flux. The detection of X-ray emission from the Galilean satellites thus provides a direct measure of the interactions of the

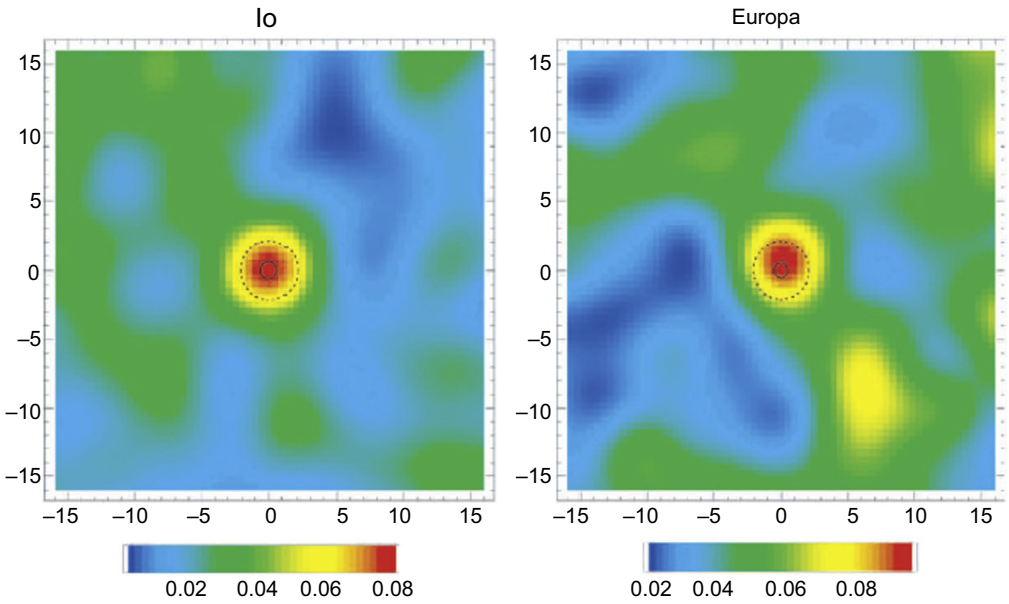

FIGURE 48.10 Galilean Moons. *Chandra* X-ray images of Io and Europa (0.25 keV $< E <$ 2.0 keV) from November, 1999 observations. The axes are labeled in arcsec (1 arcsec $\sim$ 3000 km) and the scale bar is in units of smoothed counts per image pixel (0.492 by 0.492 arcsec). The solid circle shows the size of the satellite (the radii of Io and Europa are 1821 km and 1560 km, respectively), and the dotted circle shows the size of the detect cell. *From Elsner et al. (2002).*

magnetosphere of Jupiter with the satellite surfaces. An intriguing possibility is placement of an imaging XRS onboard a mission to the Jupiter system.

9. IO PLASMA TORUS

The IPT is known to emit at extreme ultraviolet (EUV) energies and below, but it was a surprise when *Chandra* discovered that it was also a soft X-ray source. The 1999 Jovian *Chandra* observations detected a faint diffuse source of soft X-rays from the region of the IPT. The 2000 *Chandra* image, obtained with the HRC-I camera (Figure 48.11), exhibited a dawn-to-dusk asymmetry similar to that seen in the EUV. Figure 48.11 shows the background-subtracted *Chandra*/ACIS-S IPT spectrum for November 25−26, 1999. This spectrum shows evidence for line emission centered on 574 eV (very near a strong O VII line), together with a very steep continuum spectrum at the softest X-ray energies. Although formed from the same source, the spectrum is different from that of the Jovian aurora because the energies, charge states, and velocities of the ions in the torus are much lower—the bulk ions have not yet been highly accelerated. There could be contributions from other charge states because current plasma torus models consist mostly of ions with low charge states, consistent with photoionization and ion-neutral charge exchange in a low-density plasma and neutral gas environment. The 250- to 1000-eV energy flux at the telescope aperture was 2.4×10^{-14} erg/cm^2/s, corresponding to a luminosity of 0.12 GW. Although bremsstrahlung from nonthermal electrons might account for a significant fraction of the continuum X-rays, the physical origin of the observed IPT X-ray emission is not yet fully understood. The 2003 Jovian *Chandra* observations also detected X-ray emission from the IPT, although at a fainter level than in 1999 or 2000. The morphology exhibited the familiar dawn-to-dusk asymmetry.

10. SATURN

The production of X-rays at Saturn (see also "Saturn") was expected because, like the Earth and Jupiter, Saturn was known to possess a magnetosphere with energetic electrons and ions within it; however, early attempts to detect X-ray emission from Saturn with Einstein in December 1979 and with ROSAT in April 1992 were negative and marginal, respectively. Saturnian X-rays were unambiguously observed by *XMM-Newton* in October 2002 and by the *Chandra* X-ray Observatory in April 2003. In January 2004, Saturn was again observed with *Chandra* ACIS-S in two exposures, one on 20 January and the other on 26−27 January, with each observation lasting for about one full Saturn rotation. The X-ray power emitted from Saturn's disk is roughly one-fourth of that from Jupiter's disk, which is consistent with Saturn being twice as far from the Sun and the Earth as Jupiter.

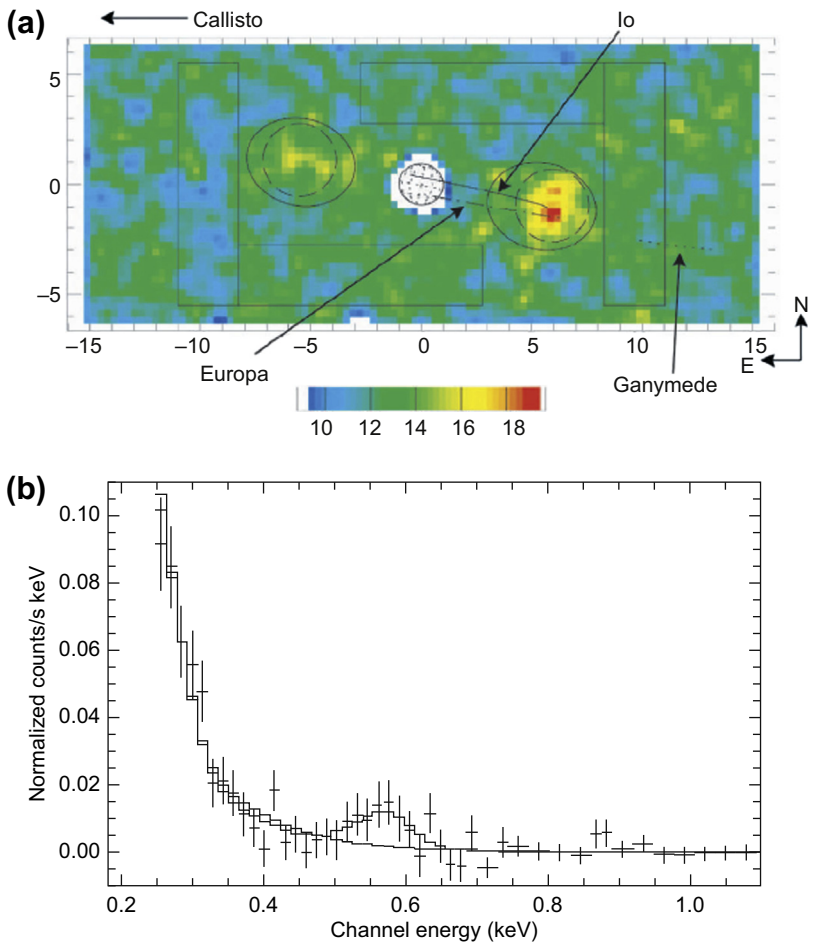

FIGURE 48.11 Plasma Torus. (a) *Chandra*/HRC-I image of the IPT (December 18, 2000). The axes are labeled in units of Jupiter's radius, R_J, and the scale bar is in units of smoothed counts per image pixel. The paths traces by Io, Europa, and Ganymede are marked on the image. Callisto is off the image to the dawn side. The regions bounded by rectangles were used to determine background. The regions bounded by dashed circles or solid ellipses were defined as source regions. (b) *Chandra*/ACIS-S spectrum for the IPT from November 1999. The solid line presents a model fit for the sum of a power law spectrum and a Gaussian line, while the dashed line represents just a pure power law spectrum. The line is consistent with K-shell fluorescent emission from oxygen ions. *From Elsner et al. (2002).*

The January 2004, *Chandra* observation showed (Figure 48.12) that X-rays from Saturn are highly variable—a factor of two–four variability in brightness over 1 week. The bright X-rays from Saturn's south polar cap on January 20 (see Figure 48.12, left panel), which are not evident in the January 26 observation (see Figure 48.12, right panel) and in earlier *Chandra* observations are an extension of the disk X-ray emission of Saturn. No evidence of auroral X-rays from Saturn has been found so far, which could be due to the limited sensitivity of current X-ray observatories.

As is the case for Jupiter's disk, X-ray emission from Saturn is due to the scattering of the incident solar X-ray flux. An X-ray flare has been detected from the non-auroral disk of Saturn during the *Chandra* observation on January 20, 2004, which, taking light travel time into account, coincided with an M6-class flare emanating from a sunspot that was clearly visible from both Saturn and Earth. This was the first direct evidence suggesting that Saturn's disk X-ray emission is principally controlled by processes happening on the Sun. Further, a good correlation has been observed between Saturn X-rays and F10.7 solar activity (see also "The Sun") index, suggesting a solar connection.

The spectrum of X-rays from Saturn's disk is very similar to that from Jupiter's disk (Figure 48.12).

11. RINGS OF SATURN

The rings of Saturn (see also "Planetary Rings"), known to be made of mostly water (H_2O) ice, are one of the most fascinating objects in our solar system. The discovery of X-rays from the rings of Saturn was made with *Chandra* ACIS-S observations in January 2004 and April 2003. X-rays from the rings are dominated by emission in a narrow ($\sim$130 eV wide) energy band of 0.49–0.62 keV (Figure 48.13). This band is centered on the oxygen Kα fluorescence line at 0.53 keV, suggesting that fluorescent scattering of solar X-rays from oxygen atoms in the surface of H_2O icy ring material is the likely source mechanism for ring X-rays. The X-ray power emitted by the rings in the 0.49- to 0.62-keV band on January 20,

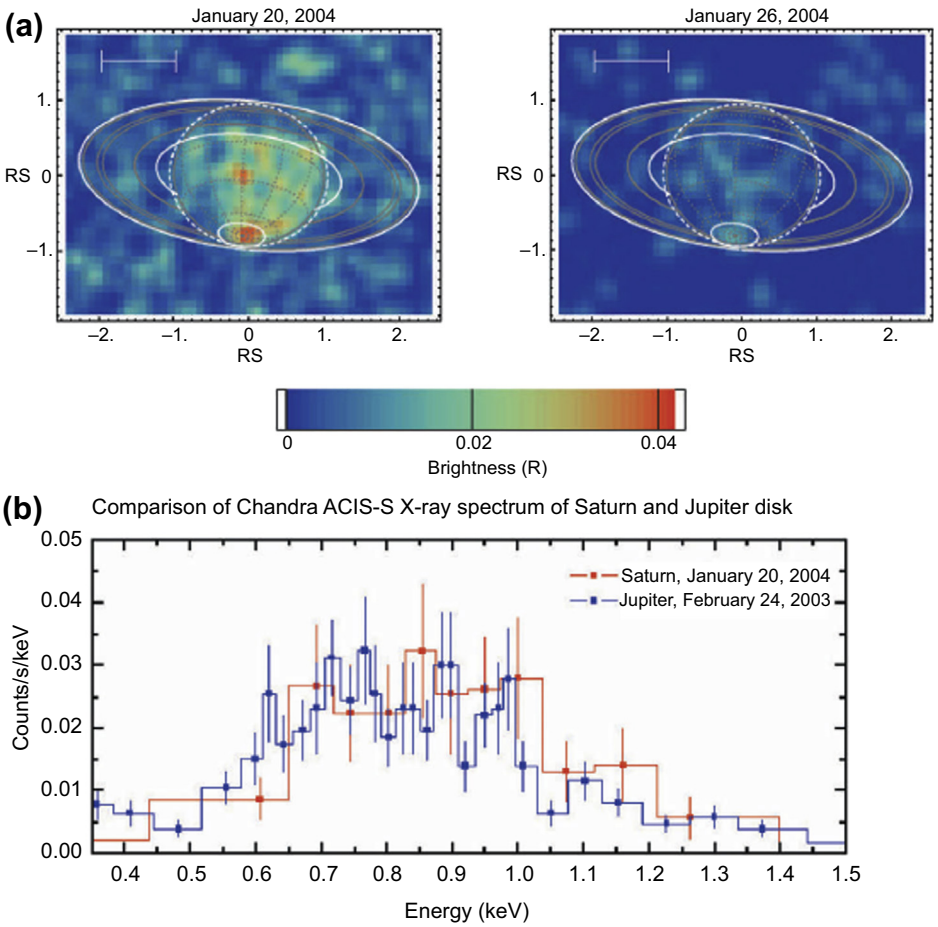

FIGURE 48.12 Saturn. (a) *Chandra* ACIS X-ray 0.24- to 2.0-keV images of Saturn on January 20 and 26, 2004. Each continuous observation lasted for about one full Saturn rotation. The horizontal and vertical axes are in units of Saturn's equatorial radius. The white scale bar in the upper left of each panel represents 10 arcsec. The two images, taken a week apart and shown on the same color scale, indicate substantial variability in Saturn's X-ray emission. *From Bhardwaj et al. (2005a).* (b) Disk X-ray spectrum of Saturn (red curve) and Jupiter (blue curve). Values for the Saturn spectrum are plotted after multiplying by a factor of 5. *From Bhardwaj (2006).*

2004, is 84 MW, which is about one-third of that emitted from the Saturn disk in the 0.24- to 2.0-keV band. The projected rings have about half the surface area of the Saturn disk, consistent with this ratio. The X-ray power emitted by the rings in the 0.49- to 0.62-keV band could vary from 30 to 150 MW depending on the observation period.

Figure 48.13 shows the X-ray image of the Saturnian system in January 2004 in the 0.49- to 0.62-keV band, the energy range where X-rays from the rings were unambiguously detected. The observations of January 2004 also suggested that, similar to Saturn's X-ray emission, the ring X-rays are highly variable—a factor of two to three variability in brightness over 1 week. There is an apparent asymmetry in X-ray emission from the east (morning) and west (evening) ansae (the apparent extremities of the rings, looking like two handles; see Figure 48.13(a)). However, when the *Chandra* ACIS-S data sets of January 2004 and April 2003 are combined, the evidence for asymmetry is not that strong. Recent study by *XMM-Newton* suggests no direct relationship between Saturn disk X-rays and ring X-rays: while disk X-rays follow solar activity, the X-rays from rings do not, suggesting the role of other processes in their production, like meteoric impact-induced spokes or lightning-induced electron beams.

12. COMETS

The *ROSAT* discovery of X-ray emission in 1996 from C/1996 B2 (Hyakutake) created a new class of cold, 10^2–10^3 K X-ray-emitting objects. Observations since 1996 have shown that the very soft ($E < 1$ keV) emission is due to an interaction between the solar wind and the comet's atmosphere (see also "Physics and Chemistry of Comets"), and that X-ray emission is a fundamental property of comets. Theoretical and observational work in the two decades since the discovery has demonstrated that charge exchange collision of highly charged heavy solar wind ions with cometary neutral species is the best explanation for the emission. In fact, of the solar system bodies with associated X-ray emission, comets are the best example of a nearly pure charge exchange emitting system, as their gravitationally unbound atmospheres (or **comae**), are tenuous and highly extended (typically 10^5–10^6 km in radius), unable to scatter

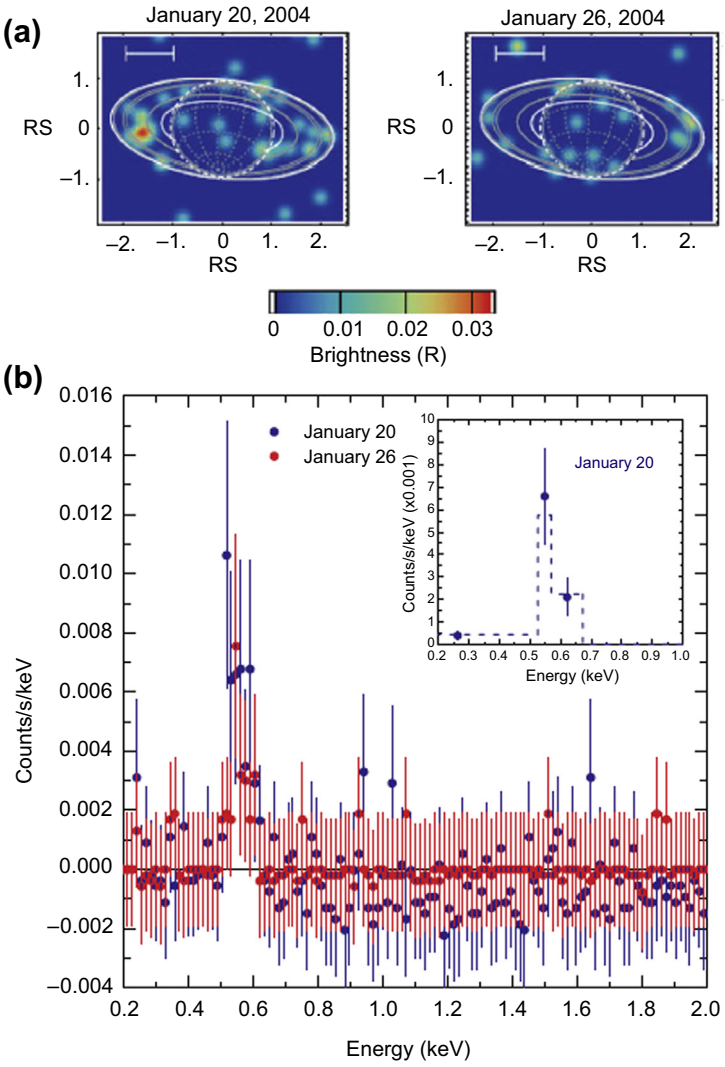

FIGURE 48.13 Saturn's rings. (a) *Chandra* ACIS X-ray images of the Saturnian system in the 0.49- to 0.62-keV band on January 20 and 26–27, 2004. The X-ray emission from the rings is clearly present in these restricted energy band images; the emission from the planet is relatively weak in this band (see Figure 48.12 (a) for an X-ray image of the Saturnian system in the 0.24- to 2.0-keV band). (b) Background-subtracted *Chandra* ACIS-S3-observed X-ray energy spectrum for Saturn's rings in the 0.2–2.0 keV range on January 20 and 26–27, 2004. The cluster of X-ray photons in the ~0.49- to 0.62-keV band suggests the presence of the oxygen Kα line emission at 0.53 keV in the X-ray emission from the rings. The inset shows a Gaussian fit (peak energy = 0.55 keV, σ = 140 eV), indicated by the dashed line, to the ACIS-observed rings' spectrum on January 20 suggesting that X-ray emissions from the rings are predominantly oxygen Kα photons. *From Bhardwaj et al. (2005b).*

many solar X-rays but highly capable of intercepting a large amount of solar wind ions as they stream away from the Sun.

Recently, X-ray emission has also been detected from a comet (C/2011 W3) flying through the lower solar corona, with the solar X-ray imager X-Ray Telescope (XRT) on-board *Hinode*. This emission is thought to arise from the ionization of cometary material in the corona.

The observed characteristics of the emission can be organized into the following four categories: (1) spatial morphology, (2) X-ray luminosity, (3) temporal variation, and (4) energy spectrum. Each of the observed characteristics depends on the nature of the comet's coma and the solar wind it interacts with. We discuss the typical nature of each of these characteristics next.

12.1. Spatial Morphology

X-ray and EUV images of C/1996 B2 (Hyakutake) made by the *ROSAT* High Resolution Imager (HRI) and Wide Field Camera (WFC) look very similar (Figure 48.14). Except for C/1990 N1, 2P/Encke, 73P/SW-3B, and C/2011 W3 (see below), all EUV and X-ray images of comets have exhibited similar spatial morphologies. The emission is largely confined to the sunward side of the cometary

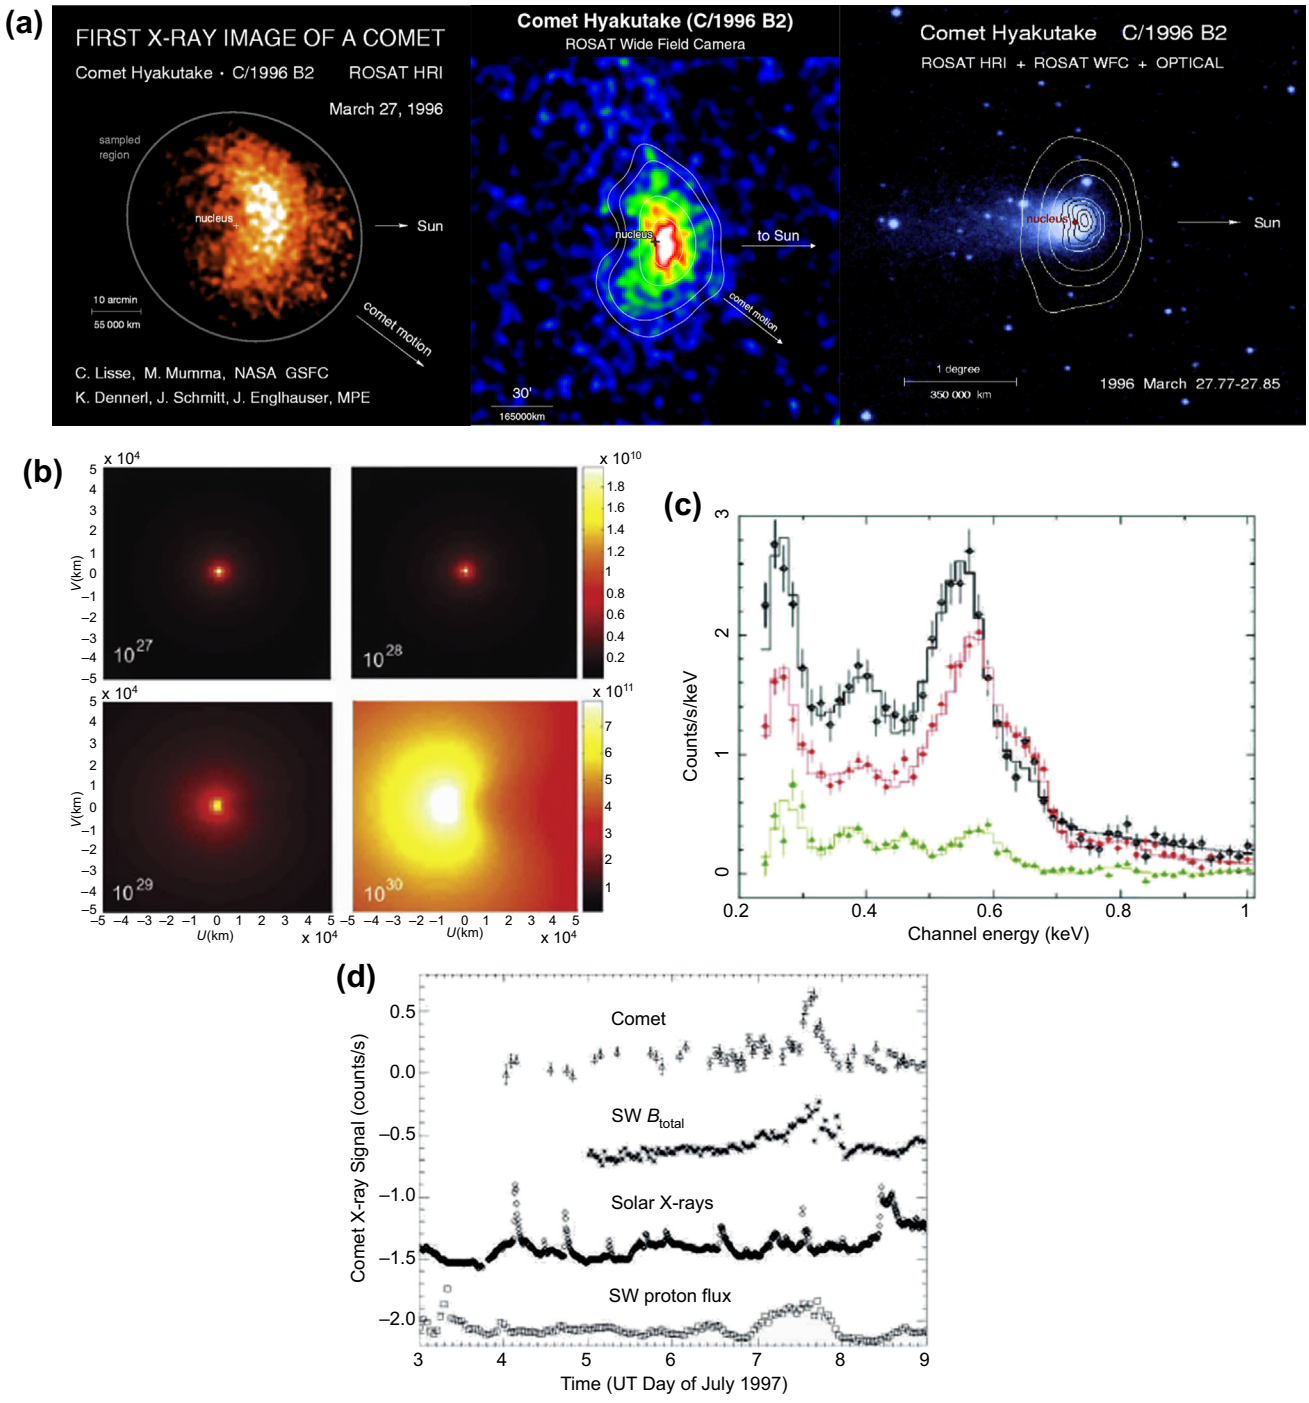

FIGURE 48.14 The rich behavior of X-ray emission seen from comets. (a) Cometary X-ray emission morphology. Images of C/1996 B2 (Hyakutake) on March 26–28, 1996 UT: *ROSAT* HRI 0.1–2.0 keV X-ray, *ROSAT* WFC 0.09–0.2 keV EUV, and visible light, showing a coma and tail, with the X-ray emission contours superimposed. The Sun is toward the right, the plus signs mark the position of the nucleus, and the orbital motion of the comet is toward the lower left in each image. *From Lisse et al. (1996).* (b) Morphology as a function of comet gas production rate (given in terms of molecules/s in the lower right of each panel). Note the decreasing concentration of model source function and the increasing importance of diffuse halo emission in the extended coma as the gas production rate increases. *From Lisse et al. (2005).* (c) *Chandra* ACIS spectra of the X-ray emission from three comets. All curves show ACIS-S3 measurements of the 0.2- to 1.0-keV pulse height spectrum, with $\pm 1\sigma$ error bars and the best-fit emission line + thermal bremsstrahlung model convolved with the ACIS-S instrument response as a histogram. Pronounced emission due to O^{7+} and O^{6+} is evident at 560 and 660 eV, and for C^{5+}, C^{4+}, and N^{5+} emission lines at 200–500 eV. Best-fit model lines at 284, 380, 466, 552, 590, 648, 796, and 985 eV are close to those predicted for charge exchange between solar wind C^{5+}, C^{6+}, C^{6+}/N^{6+}, O^{7+}, O^{8+}, and Ne^{9+} ions and neutral gases in the comet's coma. (Black) ACIS spectra of C/LINEAR 1999 S4 (circles), from Lisse et al. (2001). (Red) Comet McNaught-Hartley spectra (squares), after Krasnopolsky et al. (2003).

coma; almost no emission is found in the extended tails of dust or plasma. The X-ray brightness gradually decreases with increasing cometocentric distance r with a dependence of about r^{-1}. The emission morphology and range depend on the amount of neutral gas pouring out of the comet's nucleus. The brightness merges with the soft X-ray background emission at distances as small as 10^4 km for weakly active comets, but the most actively outgassing comets can be X-ray luminous out to 10^6 km. For the least active comets, the X-ray emission tracks the regions of densest coma gas, usually at the nucleus or along jets and shells; for the highly outgassing comets, the coma is collisionally thick to charge exchange and the region of peak emission is crescent shaped with a brightness peak displaced toward the Sun from the nucleus (Figure 48.14). The distance of this peak from the nucleus appears to increase with increasing gas production rate; for Hyakutake, it was located at $\sim 2 \times 10^4$ km.

Numerical simulations of the solar wind interaction with Hyakutake including charge exchange have been used to generate X-ray images. A global magnetohydrodynamic model and a hydrodynamic model were used to predict solar wind speeds and densities in addition to the X-ray emission around a comet. The simulated X-ray images are similar to the observed images. In the collisionally thick case, the gas production rate can be directly determined from the observed X-ray morphology, as it was demonstrated for four comets observed by *ROSAT* and *XMM-Newton*. It is also possible to deduce the location of the cometary bow shock by a tomographic analysis of the X-ray morphology. This technique was successfully applied to *XMM-Newton* data of comet C/2000 WM1 (LINEAR).

A completely different morphology—a tail-like structure—was observed from Comet Lovejoy (C/2011 W3) with XRT on *Hinode* 30 min after perihelion, when the comet was only ~320,000 km above the solar photosphere. The X-ray emission was similar to the EUV emission, but offset along the local magnetic field lines. This emission, however, is unlikely to result from charge exchange interactions but rather from direct ionization of the cometary material.

12.2. X-ray Luminosity

The observed X-ray luminosity, L_x, of comets is mainly determined by the gas production rate and the heavy ion flux in the solar wind, and also by instrumental parameters like the energy bandpass and the observational aperture. Typical values of L_x range from 0.01 to 1 GW. This is of the order of 10^{-4} of the total luminosity of a comet. For weakly active comets, with $L_x < 0.1$ GW, a roughly linear correlation between optical and X-ray luminosities is observed. For the brightest X-ray comets, a plateau or asymptote in the X-ray production is seen at a maximum value of $\sim 10^{16}$ erg/s. Particularly dusty comets, like C/1995 O1 (Hale–Bopp), 103P/Hartley 2, or 73P/Schwassmann-Wachmann 3 appear to have less X-ray emission than would be expected from their overall optical luminosity L_{opt}. This is most likely a consequence of the fact that the optical luminosity of a comet is dominated by the amount of dust, while the X-ray luminosity is controlled by the amount of gas. The peak X-ray surface brightness decreases with the inverse square of the heliocentric distance r, independent of the gas production rate.

12.3. Temporal Variation

Photometric light curves of the X-ray and EUV emission typically show a long-term baseline level with superimposed impulsive spikes of a few hours' duration, with positive excursions typically three to four times that of the baseline emission level. Figure 48.14 demonstrates the strong correlation found between the time histories of the solar wind proton flux (a proxy for the solar wind minor ion flux), the solar wind magnetic field intensity, and a comet's X-ray emission, for the case of comet 2P/Encke observed almost continuously over the course of 2 weeks in 1997 by *ROSAT* and Extreme Ultraviolet Explorer (*EUVE*) (Figure 48.14(d)). Another long-term study was conducted for comet 9P/Tempel 1 in 2005, supporting the *Deep Impact* mission. Comparison of comet luminosities with time histories of the solar wind proton flux, oxygen ion flux, and solar X-ray flux shows a strong correlation between the cometary emission and the

(Green) 2P/Encke spectrum taken on November 24, 2003, multiplied by a factor of 2. The C/1999 S4 (LINEAR) and C/McNaught-Hartley 2001 observations had an average count rate on the order 20 times as large, even though Encke was closer to *Chandra* and the Earth when the observations were being made. Note the 560-eV complex to 400-eV complex ratio of 2–3 in the two bright, highly active comets, and the ratio of approximately 1 for the faint, low-activity comet Encke. *From Lisse et al., op. cit (2005).* (d) Temporal trends of the cometary X-ray emission. Light curve, solar wind magnetic field strength, solar wind proton flux, and solar X-ray emission for 2P/Encke 1997 on July 4–9, 1997, UT. All error bars are ±1σ. D, *ROSAT* HRI light curve, July 4–8, 1997. ◇, *EUVE* scanner Lexan B light curve July 6–8, 1997, UT, taken contemporaneously with the HRI observations, and scaled by a factor of 1.2. Also plotted are the Comprehensive Solar Wind Laboratory for Long-Term Solar Wind Measurements (WIND) total magnetic field B_{total} (*), the Solar and Heliospheric Observatory *(SOHO)* Charge, Element, and Isotope Analysis System (CELIAS)/Solar Extreme Ultraviolet Monitor (SEM) 1.0–500 Å solar X-ray flux (◇), and the *SOHO* CELIAS solar wind proton flux (boxes). There is a strong correlation between the solar wind magnetic field/density and the comet's emission. There is no direct correlation between outbursts of solar X-rays and the comet's outbursts. *From Lisse et al. (1997).*

solar wind oxygen ion flux, a good correlation between the comet's emission and the solar wind proton flux, but no correlation between the cometary emission and the solar X-ray flux.

Up until 2005, the temporal variation of the solar wind dominated the observed behavior on all but the longest timescales of weeks to months. A "new" form of temporal variation was demonstrated in the *Chandra* observations of comet 2P/Encke 2003, wherein the observed X-ray emission is modulated at the 11.1-h period of the nucleus rotation. Rotational modulation of the signal should be possible only in collisionally thin (to SWCX) comae with weak cometary activity, where a change in the coma neutral gas density can directly affect the cometary X-ray flux. Imaging of the X-ray emission of comet 103P/Hartley 2, compared to optical ground-based images of the comet obtained during the *Deep Impact Extended* mission flyby of the comet, also seem to show correlated rotational modulation of the comet's X-ray emission.

12.4. Energy Spectrum

Until 2001, all published cometary X-ray spectra had very low spectral energy resolution ($\Delta E/E \sim 1$ at 300–600 eV), and the best spectra were those obtained by ROSAT for C/1990 K1 (Levy) and C/1990 N1 (Tsuchiya-Kiuchi), and by *Beppo*SAX for C/1995 O1 (Hale–Bopp). These observations were capable of showing that the spectrum was very soft. However, due to the limited spectral resolution, continuum emission could not be distinguished from a multiline spectrum, as it would result from the SWCX mechanism. It was found that thermal bremsstrahlung was a good "technical" proxy for characterizing the basic spectral properties in an instrument-independent way, given the limited spectral resolution and the lack of a more realistic model spectrum. All these spectra were consistent with bremsstrahlung temperatures kT between 0.2 and 0.3 keV. Nondetections of comets C/Hyakutake, C/Tabur, C/Hale–Bopp, and 55P/Tempel–Tuttle using the X-Ray Timing Explorer Proportional Counter Array (XTE PCA) (2–30 keV) and ASCA Solid-state Imaging Spectrometers (SIS) (0.6–4 keV) imaging spectrometers were consistent with an extremely soft spectrum.

In 2001, the first high-resolution cometary X-ray spectrum was obtained, using *Chandra* X-ray observatory measurements of the emission from comet C/1999 S4 (LINEAR) as it passed close by the Earth. Discrete line emission signatures due to highly ionized oxygen and carbon were immediately apparent. Higher resolution spectra of cometary X-ray emission are now common. Eight comets were studied with the *Chandra* X-ray observatory spectroscopy in the period 2000 to 2006, covering the transition from solar maximum to solar minimum. Figure 48.15(a) shows the (background-subtracted raw) spectra for eight of the comets, and Figure 48.15(b) and (c) show at which ecliptic latitude and phase in the solar cycle the spectra were observed. It is immediately obvious that there are spectral differences. In Figure 48.15(a), three spectral bands are indicated, dominated by emission from (1) C V, C VI, N VI ("C + N"); (2) by O VII; and (3) by O VIII ions, and the spectra are arranged so that, from top to bottom, flux is systematically shifted from lower to higher energy bands. The quantitative results of the spectral fits clearly show that the flux in the C + N band is anti-correlated to that in the O VIII band (Figure 48.15(d)), indicating that the comets were exposed to different solar wind conditions.

As can be seen in Figure 48.15(b) and (c), all the comets which were observed at high latitudes happened to be there during solar maximum, when the equatorial solar wind had expanded into these regions. This implies that, until 2006, *Chandra* had not observed any comet exposed to the polar wind. This situation changed in October 2007, during solar minimum, when the nucleus of comet 17P/Holmes experienced a spectacular outburst, which increased its dust and gas outflow and optical brightness by almost a million times within hours, from under 17 mag to 3 mag, making it by far the optically brightest comet observable by *Chandra* since its launch. At the time, comet 17P/Holmes was located at a sufficiently high heliographic latitude (19°) to be exposed to the polar wind at solar minimum. It was thus expected that this comet would exhibit considerably different X-ray properties, and in fact this was observed: 17P/Holmes became the first comet where *Chandra* did not detect any significant X-ray emission at all. The most likely explanation for this dramatic X-ray faintness is that the polar wind was so diluted and its ionization so low that only very little X-ray flux was generated by charge exchange at energies above ~300 eV. An instrumental effect, i.e. a loss of sensitivity, can definitively be ruled out, because only two months later, another comet, 8P/Tuttle, was observed with *Chandra*, and this comet, at low latitude (3°), was clearly detected in X-rays.

12.5. Summary

Driven by the solar wind, cometary X-rays provide an observable link between the solar corona, where the solar wind originates, and the solar wind where the comet resides. They are the cleanest example of charge exchange-driven X-ray emission, and should prove to be quite valuable in understanding other astrophysical charge exchange systems found wherever cold neutral and hot ionized gases meet—e.g. in the entire heliosphere, in stellar winds, in massive star-forming regions, in the expanding

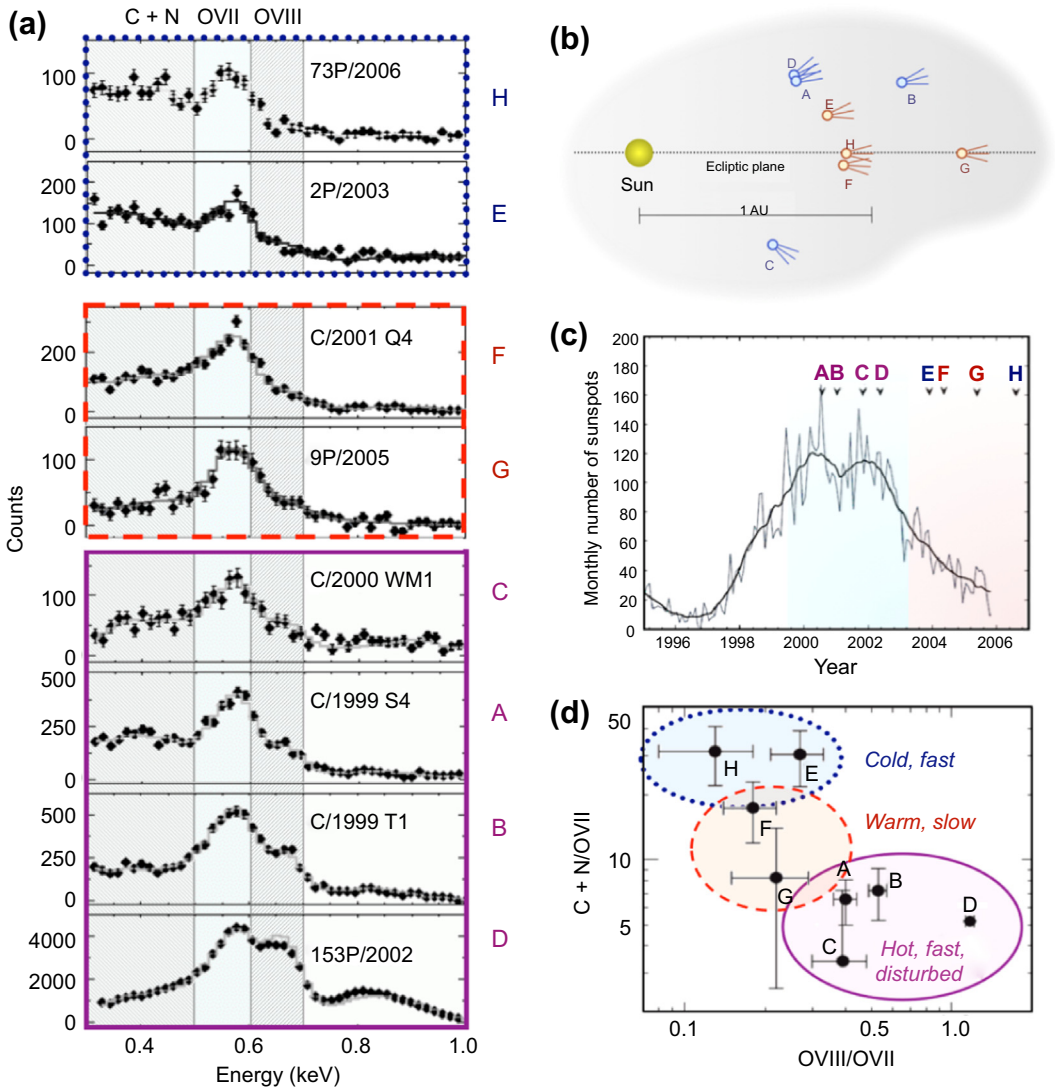

FIGURE 48.15 Summary of the spectral results obtained with *Chandra* for all the comets (denoted by A–H) which were observed from 2000 to 2006. (a) The 0.3- to 1.0-keV pulse height distributions, (b) the ecliptic latitudes, (c) phases in the solar cycle of the observed comets, and (d) the deduced information about the solar wind heavy ion content. Two comets were observed interacting with low ionization temperature but fast winds arising from the bottom of the solar corona (E, H); at least two with high ionization temperature but slow winds arising from the top of the Sun's corona (F, G, and possibly A and C); and two comets (B & D) appeared to have interacted with disturbed solar winds found during flares, coronal mass ejections, or solar sector boundary crossings. *Adapted from Bodewits et al. (2007).*

shells of supernova remnants, in active galaxies, or in clusters of galaxies. In our own solar system, once we have understood the SWCX mechanism's behavior in cometary comae in sufficient detail, we will be able to use comets as probes to measure the solar wind throughout the inner heliosphere. This will be especially useful in monitoring the solar wind in places hard to reach with spacecraft—such as over the solar poles, at large distances above and below the ecliptic plane, and at heliocentric distances greater than a few astronomical units. For example, about one-third of the observed soft X-ray emission is found in the 530- to 700-eV oxygen O^{7+} and O^{6+} lines; observing photons of this energy will allow studies of the oxygen ion charge ratio of the solar wind, which is predicted to vary significantly between the slow and fast solar winds at low and high solar latitudes, respectively.

13. ASTEROIDS

X-rays from asteroids have been studied by experiments on two in situ missions, the X-ray/gamma-ray spectrometer (XGRS) on the Near Earth Asteroid Rendezvous *(NEAR)—Shoemaker* mission to asteroid 433 Eros, and the XRS on the *Hayabusa* mission to asteroid 25143 Itokawa

(see also "Near Earth Asteroids"). The only attempt to detect X-rays from an asteroid remotely was a 10-ks, observation by *Chandra* on December 11, 2001, of 1998 WT24, but it was unsuccessful. The results of the in situ observations show X-ray emission due to fluorescence and scattering of incident solar X-rays, similar to the emission seen from the surface of the airless Moon. In fact, the best measurements were obtained during a strong solar flare, when the incident solar X-rays were highly amplified. As for the Moon, X-ray spectroscopy of resonantly scattered solar X-rays can be used to map the elemental composition of the surface.

NEAR-Shoemaker entered an Eros orbit on February 14, 2000, and completed a 1-year-long mission around it. Eros at $33 \times 13 \times 13$ km in size is the second largest near-Earth asteroid, and its "day" is 5.27 h long. Eros exhibits a heavily cratered surface with one side dominated by a huge, scallop-rimmed gouge; a conspicuous sharp, raised rimmed crater occupies the other side. The XRS part of the XGRS detected X-rays in the 1−10 keV energy range to determine the major elemental composition of Eros' surface. The XRS observed the asteroid in low orbit (<50 km) during May 2, 2000, to August 12, 2000, and again during December 12, 2000 to February 2, 2001. These observations suggest that elemental ratios for Mg/Si, Al/Si, Ca/Si, and Fe/Si on Eros are most consistent with a primitive chondrite and give no evidence of global differentiation. The S/Si ratio is considerably lower than that for a chondrite and is most likely due to surface volatilization ("space weathering"). The overall conclusion is that Eros is broadly "primitive" in its chemical composition and has not experienced global differentiation into a core, mantle, and crust, and that surface effects cause the observed departures from chondritic S/Si and Fe/Si.

Hayabusa reached the asteroid 25143 Itokawa on September 12, 2005. The first touchdown occurred on November 19, 2005. The observations made during the touchdown, a period of relatively enhanced solar X-ray flux, returned an average elemental mass ratio of $\mathrm{Mg/Si} = 0.78 \pm 0.07$ and $\mathrm{Al/Si} = 0.07 \pm 0.03$. These early results suggest that, like Eros, asteroid Itokawa's composition can be described as an ordinary chondrite, although occurrence of some differentiation cannot be ruled out.

The composition and structure of the rocks and minerals in asteroids provide critical clues to their origin and evolution and are a fundamental line of inquiry in understanding the asteroids, of which more than 20,000 have been detected and cataloged. It is interesting to note that for both Eros and Itokawa the compositions derived by remote X-ray observations using spacecraft in close proximity to the asteroid seem consistent with those found using Earth-based optical and infrared spectroscopy.

14. HELIOSPHERE

The solar wind (see also "The Solar Wind") flow starts out slowly in the corona but becomes supersonic at a distance of few solar radii. The gas cools as it expands, falling from $\sim 10^6$ K down to about 10^5 K at 1 AU. The average properties of the solar wind at 1 AU are proton number density $\sim 7/\mathrm{cm}^3$, speed $\sim$ 450 km/s, temperature $\sim 10^5$ K, magnetic field strength $\sim$5 nT, and Mach number $\sim$8. However, the composition and charge state distribution far from the Sun are "frozen-in" at coronal values due to the low collision frequency outside the corona. The solar wind contains structure, such as slow (300 km/s) and fast (700 km/s) streams, which can be mapped back to the Sun. The solar wind "terminates" in a shock called the heliopause, where the ram pressure of the streaming solar wind has fallen to that of the interstellar medium (ISM) gas. The region of space containing plasma of solar origin, from the corona to the heliopause at $\sim$100 AU, is called the heliosphere. A very small part of the solar wind interacts with the planets and comets; the bulk of the wind interacts with neutral ISM gas in the heliosphere and neutral and ionized ISM at the heliopause.

X-ray emission from the heliosphere has also been predicted from the interaction of the solar wind with the interstellar neutral gas (mainly HI and HeI) that streams into the solar system. It has been demonstrated that roughly half of the observed 0.25-keV X-ray diffuse background can be attributed to this process (see Figure 48.16). Solar and Heliospheric Observatory (SOHO) observations of neutral hydrogen Lyman-alpha emission show a clear asymmetry in the ISM flow direction, with a clear deficit of neutral hydrogen in the downstream direction of the incoming neutral ISM gas, most likely created by SWCX ionization of the ISM. The analogous process applied to other stars has been suggested as a means of detecting stellar winds. Also a strong correlation between the solar wind flux density and the *ROSAT* "LTEs," systematic variations in the soft X-ray background of the *ROSAT* X-ray detectors, has been shown. Photometric imaging observations of the lunar nightside by *Chandra* made in September 2001 does not show any lunar nightside emission above an SWCX background. The soft X-ray emission detected from the dark side of the Moon, using *ROSAT*, would appear to be attributable not to electrons spiraling from the sunward to the dark hemisphere, as proposed earlier, but to SWCX in the geocorona and the column of heliosphere between the Earth and the Moon (Section 3).

Just as charge exchange-driven X-rays are emitted throughout the heliosphere, similar emission must occur within the astrospheres of other stars with highly ionized stellar winds that are located within interstellar gas clouds that are at least partially neutral. Although very weak, in

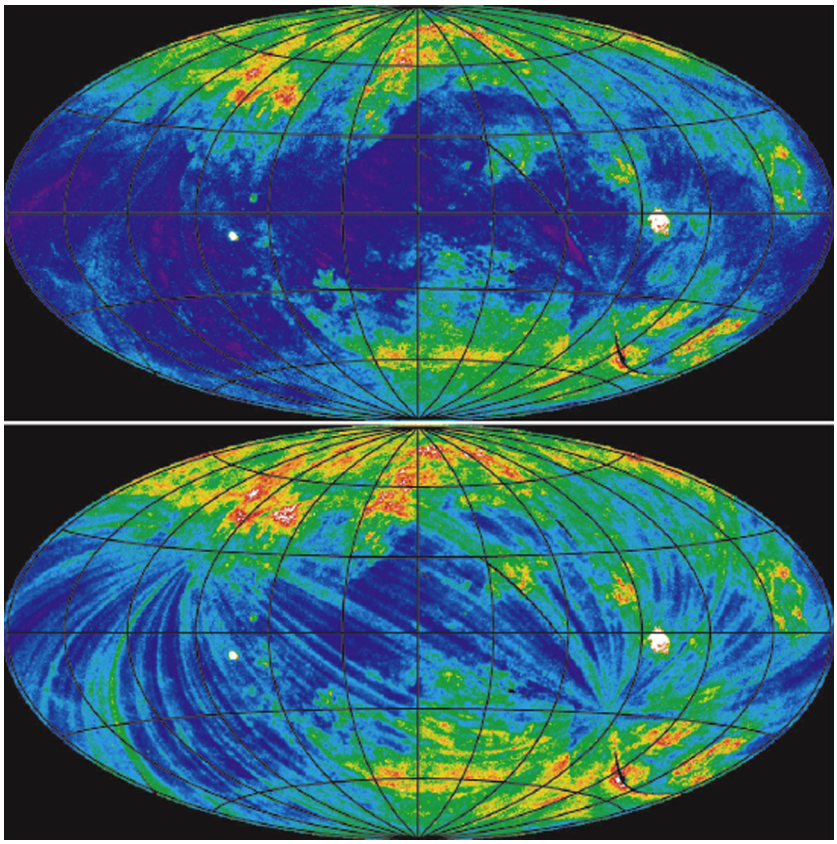

FIGURE 48.16 Heliosphere. (Upper panel) *ROSAT* All-Sky Survey map of the cosmic X-ray background at 1/4 keV. The data are displayed using an Aitoff projection in galactic coordinates centered on the galactic center with longitude increasing to the left and latitude increasing upward. Low intensity is indicated by purple and blue while red indicates higher intensity. (Lower panel) same as above except the contaminating LTEs (SWCX emission) were not removed. The striping is due to the survey geometry where great circles on the sky crossing at the ecliptic poles were scanned precessing at $\sim 1°$/day. *From Snowden et al. (1997).*

principle, this emission offers the opportunity to measure mass loss rates and directly image the winds and astrospheres of other main sequence late-type stars. Imaging would provide information on the geometry of the stellar wind, such as whether outflows are primarily polar, azimuthal, or isotropic and whether or not other stars have analogs of the slow (more ionized) and fast (less ionized) solar wind streams.

15. SUMMARY

Table 48.1 summarizes our current knowledge of the X-ray emissions from the planetary bodies that have been observed to produce soft X-rays. Several other solar system bodies, including Titan, Uranus, Neptune, and inner icy satellites of Saturn, are also expected to be X-ray sources, but they are yet to be detected. X-rays are expected from these bodies due to scattering of solar X-rays as well as SWCX and/or magnetospheric ion precipitation and electron bremsstrahlung. However, due to larger distance from Sun, and hence much reduced solar radiation and solar wind flux, the X-rays produced at these objects would be at level much lower than the detection capability of current X-ray observatories. X-rays would also be produced in extrasolar planets—through processes similar to those in our solar system. However, detecting X-rays from exoplanets would be a challenging task since the flux would be very weak due to large distances involved.

Table 48.2 lists the spacecraft missions and satellite-based observatories mentioned in the text, which have contributed to the growth of planetary X-rays and our current understanding of the processes of X-ray production. Upcoming X-ray observatories, like *Astro-H*, *eROSITA/SRG*, and *Athena*, and planetary missions (*BepiColombo*, *Selene-2*, *Chandra*yaan-2) carrying experiments are also listed, which would have better sensitivity, effective area, and resolution, thus providing better tools to significantly advance the field of solar system X-rays.

TABLE 48.1 Summary of the Characteristics of Soft X-ray Emission from Solar System Bodies

Object	Emitting Region	Power Emitted[1]	Special Characteristics	Possible Production Mechanism
Earth	Auroral atmosphere	10–30 MW	Correlated with magnetic storm and substorm activity	EB + characteristic line emission from atmospheric neutrals due to electron impact
	Nonauroral atmosphere	40 MW	Correlated with solar X-ray flux	FS by atmosphere
Jupiter	Auroral atmosphere	0.4–1 GW	Pulsating (~20–60 min) X-ray hot spot in north polar region	Energetic ion precipitation from magnetosphere and/or solar wind + EB
	Nonauroral atmosphere	0.5–2 GW	Relatively uniform over disk	RS + possible ion precipitation from radiation belts
Moon	Dayside surface	0.07 MW	Correlated with solar X-rays	FS by the surface elements on dayside
	Nightside (geocoronal)		Nightside emissions are ~1% of the dayside	SWCX with geocorona
Comets	Sunward-side coma	0.2–1 GW	Intensity peaks in sunward direction, $\sim 10^5$–10^6 km ahead of cometary nucleus and is correlated with solar wind parameters	SWCX with cometary neutrals
Comets in the solar corona	Coma plus tail		Offset from the EUV emission along magnetic field	Ionization of cometary material
Venus	Sunlit atmosphere	50 MW	Emissions from ~120 to 140 km above the surface	FS by C and O atoms in the atmosphere
	Exosphere		Emissions from region 1.2 times Venus radius	SWCX with Venus exospheric neutrals
Mars	Sunlit atmosphere	1–4 MW	Emissions from upper atmosphere at heights of 110 –130 km	FS by C and O atoms in the upper atmosphere
	Exosphere	1–10 MW	Emissions extend out to ~8 Mars radii	SWCX with Martian corona
Io	Surface	2 MW	Emissions from upper few micrometers of the surface	Energetic Jovian magnetospheric ions impact on the surface
Europa	Surface	3 MW	Emissions from upper few micrometers of the surface	Energetic Jovian magnetospheric ions impact on the surface
IPT	Plasma torus	0.1 GW	Dawn-dusk asymmetry observed	EB + ?
Saturn	Sunlit disk	0.1–0.4 GW	Varies with solar X-rays	RS + FS by atmosphere + EB
Rings of Saturn	Surface	80 MW	Emissions confined to a narrow energy band around at 0.53 keV.	FS by atomic oxygen in H_2O ice + ?
Asteroid	Sunlit surface		Emissions vary with solar X-ray flux	FS by elements on the surface
Mercury	Dayside		Emissions vary with solar flux	FS of solar X-rays by elements on the surface
	Nightside		Depends on precipitating electron spectrum	Electron-induced FS by elements on the surface
Heliosphere	Entire heliosphere	10^{16} W	Emissions vary with solar wind	SWCX with heliospheric neutrals

SWCX, solar wind charge exchange is the charge exchange of heavy, highly ionized solar wind ions with neutrals; FS, fluorescent scattering of solar X-rays; RS, resonant scattering of solar X-rays by atmospheric constituents; EB, bremsstrahlung from precipitating energetic electrons.
The question mark (?) refer to some other process(es) at work not clearly known as of now.
[1]*The values quoted are values at the time of observation. X-rays from all bodies are expected to vary with time. For comparison, the total X-ray luminosity from the Sun is 10^{20} W.*

TABLE 48.2 Satellites and Spacecraft Mentioned in the Text, Chronologically Sorted According to Launch Date

Instrument, *Mission*	Description	Category	Date	Agency, Country
Uhuru	First X-ray satellite	X-ray Astronomy	1970–1973	NASA (USA)
Apollo 15	Fourth manned lunar landing	Moon	July–August 1971	NASA (USA)
Apollo 16	Fifth manned lunar landing	Moon	April 1972	NASA (USA)
HEAO-1	High Energy Astronomy Observatory-1	X-ray Astronomy	1977–1979	NASA (USA)
UV spectrometer *Voyager 1*	Outer solar system	Jupiter, Saturn	1977–present	NASA (USA)
IUE	International Ultraviolet Explorer	UV Astronomy	1978–1996	NASA, ESA, Science and Engineering Research Council (SERC)
Einstein (HEAO-2)	High Energy Astronomy Observatory 2	X-ray Astronomy	1978–1981	NASA (USA)
PSPC, HRI, WFC *ROSAT*	Röntgensatellit	X-ray Astronomy	1990–1999	Germany, USA, UK
Ulysses	Solar Wind Observatory	Solar Wind	1990–2009	ESA, NASA
CGRO	Compton Gamma-Ray Observatory	Gamma-ray Astronomy	1991–2000	NASA (USA)
AXIS *UARS*	Upper Atmosphere Research Satellite	Earth	1991–2011	NASA (USA)
Lexan B *EUVE*	Extreme Ultraviolet Explorer	EUV Astronomy	1992–2001	NASA (USA)
SIS ASCA	Advanced Satellite for Cosmology and Astrophysics	X-ray Astronomy	1993–2001	ISAS (Japan)
Clementine	Lunar Mission	Moon	1994	Strategic Defense Initiative Organization (SDIO), NASA (USA)
WIND	Solar Wind Observatory	Solar Wind	1994–present	NASA, ESA, ISAS
CELIAS/SEM *SOHO*	Solar and Heliospheric Observatory	Sun	1995–present	ESA, NASA
PCA *RXTE*	Rossi X-ray Timing Explorer	X-ray Astronomy	1995–2012	NASA (USA)
NEAR-Shoemaker	Near Earth Asteroid Rendezvous	Asteroid 433 Eros	1996–2001	NASA (USA)
PIXIE *POLAR*	Earth Magnetosphere	Earth	1996–2008	NASA (USA)
BeppoSAX	Giuseppe Occhialini (Beppo) Satellite per Astronomia a raggi X	X-ray Astronomy	1996–2003	Italy, Netherlands
GOES-10	Weather satellite	Earth	1997–2009	NOAA/NASA (USA)
ACIS, HRC-I *Chandra*	*Chandra*sekhar X-ray Observatory	X-ray Astronomy	1999–present	NASA (USA)
EPIC, RGS *XMM-Newton*	X-ray Multi Mirror Mission	X-ray Astronomy	1999–present	ESA

ACKNOWLEDGMENTS

A large part of this chapter is based on the review article by Bhardwaj et al. (2007a), which is a collective effort of several authors, and we deeply acknowledge all the authors of that paper. We also thank the entire solar system X-ray community whose works have led to this review.

Chapter 49

The Solar System at Ultraviolet Wavelengths

Amanda R. Hendrix, Robert M. Nelson and Deborah L. Domingue
Planetary Science Institute, Tucson, AZ, USA

Chapter Outline

1. A Brief History of UV Astronomy **1047**
2. Nature of Solar System Astronomical Observations **1049**
3. Observations of Planetary Atmospheres **1049**
3.1. Mercury and the Moon 1050
3.2. Venus 1050
3.3. Mars 1051
3.4. Jupiter 1052
3.5. Saturn 1055
3.6. Uranus 1056
3.7. Neptune 1057
3.8. Pluto 1057
3.9. Galilean Satellites 1058
3.10. Titan and Triton 1059
4. Observations of Solid Surfaces **1060**
4.1. Galilean Satellites 1061
4.2. Saturnian Satellites 1063
4.3. Enceladus 1065
4.4. Uranian Satellites 1066
4.5. A Comparison of Icy Satellite Systems 1067
4.6. Pluto and Charon 1068
4.7. Asteroids and Comets 1068
4.8. The Moon and Mercury 1069
4.9. Planetary Rings 1069
5. Conclusions **1070**
BIBLIOGRAPHY **1070**

Ultraviolet (UV) imaging and spectroscopy are powerful tools for probing planetary atmospheres and surfaces. In this chapter, we review the significant contributions to our understanding of the solar system that have been made by UV observing methods. We cover results from the mid-ultraviolet (MUV, 300–400 nm), near-ultraviolet (NUV, 200–300 nm), far-ultraviolet (FUV, 122–200 nm), and extreme ultraviolet (EUV, 10–121 nm) wavelength ranges. These are shorter than visible and near-infrared (IR) wavelengths and involve photons of increasingly higher energy. UV observations therefore provide unique insight into planetary processes involving more energetic processes that cannot be studied using photons of longer wavelengths. Many of the solar system observations in the UV wavelengths have been performed by Earth-orbiting telescopes, such as the *International Ultraviolet Explorer* (*IUE*) and the *Hubble Space Telescope* (*HST*). We also review results from UV instruments on *Voyager, Galileo, Cassini,* and other spacecraft. Each planet in the solar system has been observed using UV instrumentation on Earth-orbiting telescopes and/or visiting spacecraft. Many of the larger planetary satellites, selected asteroids, and comets have also been observed. These data provide important information regarding the atmospheres and surfaces of solar system objects and the processes shaping their compositions.

1. A BRIEF HISTORY OF UV ASTRONOMY

The UV spectral region is significant to the entire community of astronomers, from those who study nearby objects such as Earth's Moon to those who probe the edge of the observable universe. From the perspective of a planetary astronomer, the UV spectral information is important for determining the composition and understanding the physical processes that are occurring on the surfaces and in the atmospheres of solar system objects.

Prior to the dawn of the space age, spectrophotometry of solar system objects at wavelengths shorter than ~300 nm had long been desired in order to complement observations made by ground-based telescopes at longer wavelengths.

However, the presence in the Earth's atmosphere of ozone, a strong absorber of UV light between 200 and 300 nm, and molecular oxygen (O_2), which is the dominant UV absorber below 200 nm, prevented astronomers of the 1950s and earlier from observing the universe in this important spectral region.

The UV wavelengths of astronomical sources became observable midway through the past century when instruments could be deployed above the Earth's atmosphere. A rocket or spacecraft provides a platform from which astronomical observations can be made where the light being collected has not been subjected to absorption from the Earth's atmospheric gases. Thus, the space revolution dramatically enhanced the ability of astronomers to access the full spectrum of electromagnetic radiation emitted by celestial objects.

In the 1950s, a series of rocket-flown instruments began to slowly reveal the secrets of the UV universe. The first photometers and spectrometers were flown on unstabilized Aerobee rockets. They remained above the ozone layer for several tens of minutes while they scanned the sky at UV wavelengths. By the early 1960s, spectrometers on three-axis-stabilized platforms launched by rockets on suborbital trajectories were able to undertake observations with sufficient resolution such that individual spectral lines could be resolved in the target bodies.

Shortly thereafter, the military spacecraft designated 1964-83C carried an ultraviolet spectrometer (UVS) into the Earth's orbit. This was followed closely by NASA's launch of the first Orbiting Astronomical Observatory (OAO) satellite in 1966. These space platforms permitted long-duration observations compared to what was possible from a rocket launch on a suborbital trajectory. By 1972, the third spacecraft of the OAO series was launched. It was designated the *Copernicus* spacecraft and was an outstanding success.

In Europe, a parallel pattern of development for exploring the UV sky was under way using sounding rockets followed by orbiting spacecraft. In 1972, the European Space Research Organization launched an Earth-orbiting spacecraft (TD-1A) dedicated to UV stellar astronomy. Such developments set the stage in the 1970s for a joint US–European collaboration, the IUE satellite.

The IUE spacecraft was launched in 1978 into a geosynchronous orbit over the Atlantic Ocean. From there it could be controlled from ground stations in Greenbelt Maryland in the United States or in Villafranca, Spain, by engineers from NASA or European Space Agency. It functioned continuously from launch until it was terminated in 1996 and its capabilities were taken over by instruments on the HST. IUE spectra were recorded in two wavelength ranges of 115–195 nm and 190–320 nm, at either high or low spectral resolution. The IUE had no imaging capability, although spatial discrimination was possible within the largest (10×20 arcsec oval) spectrograph entrance aperture.

Additional Earth-orbiting satellites with UV observing capabilities were launched in the early 1990s. These include NASA's *Extreme Ultraviolet Explorer* satellite (*EUVE*) and the joint US–European HST. HST is in a low-Earth orbit, allowing upgrades to the facilities by astronauts. However, the low orbit reduced the observational duty cycle to 50–60% of that of the IUE in high orbit. UV spectroscopy with HST has been performed with the Goddard High-Resolution Spectrograph (GHRS), the Faint Object Spectrograph (FOS), the Space Telescope Imaging Spectrograph (STIS), the Advanced Camera for Surveys (ACS), and the Cosmic Origins Spectrograph. In 1990 and 1995, the *Hopkins Ultraviolet Telescope* (*HUT*) was flown aboard the US space shuttle as part of the Astro Observatory. The *Far-Ultraviolet Spectroscopic Explorer* (*FUSE*) was launched in 1999 and has spectroscopic capabilities in the 90–120 nm wavelength range.

Many interplanetary spacecraft missions have included UV instruments in their payloads. *Pioneers 10* and *11,* which were launched in 1970 and 1973, respectively, included UV photometers among their scientific instruments. (*See* Planetary Exploration Missions.) These two spacecraft were the first to safely pass through the asteroid belt and fly by Jupiter and Saturn. *Mariner 6* and *7*, Mars flyby missions launched in 1969, and *Mariner 9,* the first spacecraft to orbit Mars, launched in 1971, all carried UV spectrometers. *Mariner 10,* which flew by Mercury three times in 1974 and 1975, carried two EUV spectrometers (an **airglow** spectrometer and an occultation spectrometer) to measure the planet's exospheric composition. *Mariner 10* also made measurements of Earth's Moon after launch. *Pioneer Venus,* which was launched in 1978, was the first US mission dedicated to the exploration of the planet Venus. It included a UVS in its instrument package. Soviet spacecraft missions *Vega 1* and *Vega 2,* launched in 1985, dropped two descent probes into Venus' atmosphere, which included a French–Russian UV spectroscopy experiment. The *Voyager* project sent two spacecraft that included UVS in their instrument payloads, both launched in 1977, to the outer solar system. *Voyager 2* was the first spacecraft to fly by all four of the Jovian planets (Jupiter, Saturn, Uranus, and Neptune). In 1989, the *Galileo* spacecraft was launched. This spacecraft was the first dedicated mission to the Jupiter system, and it included within its scientific instrument payload two UV spectrometers: the EUV (EUV spectrometer, which operated between 50 and 140 nm) and the UVS (covering the 115–430 nm wavelength range). En route to Jupiter, the *Galileo* spacecraft collected UV spectra as it flew by Venus, the Moon, and the asteroids Gaspra and Ida. The Cassini mission, launched in 1997, includes the Ultraviolet Imaging Spectrograph (UVIS) and arrived at Saturn in June 2004. The *Nozomi* spacecraft, launched in 1998,

carried two UV instruments; measurements were made of the Moon en route to Mars (Nozomi unfortunately failed to enter Mars' orbit). *Mars Express,* in orbit since December 2003, has an UV instrument called Spectroscopy for Investigation of Characteristics of the Atmosphere of Mars (SPICAM) as part of its payload. In 2011, the *MErcury Surface, Space ENvironment, GEochemistry, and Ranging* (*MESSENGER*) mission entered orbit about Mercury carrying a UV−visible (115−600 nm) spectrometer whose purpose was to observe both the surface and the exosphere of the planet. Also in 2004, Rosetta with its Alice UV instrument (covering 70−205 nm) was launched en route to comet 67P/Churyumov−Gerasimenko, set to enter orbit in 2014. The *New Horizons* mission to Pluto, launched in January 2006, carries the next-generation version Alice instrument, covering 52−187 nm. *Venus Express* has been in orbit at Venus since April 2006 and employs the Spectroscopy for Investigation of Characteristics of the Atmosphere of Venus (SPICAV)/Solar Occultation at Infrared (SOIR) UV and IR instrument for atmospheric studies. The *Lunar Reconnaissance Orbiter* (*LRO*), launched in June 2009, carries an FUV spectrometer, the Lyman Alpha Mapping Project (LAMP). LAMP is designed to peer into the Moon's polar permanently shadowed regions (PSRs) to search for water ice, using interplanetary and interstellar hydrogen emission (Lyman-alpha) as an illumination source.

2. NATURE OF SOLAR SYSTEM ASTRONOMICAL OBSERVATIONS

Most astronomers observe objects that have their own intrinsic energy source, such as stars and galaxies. However, the majority of the observations undertaken by planetary astronomers are of targets that do not emit their own radiation but are observable principally because they reflect the sunlight that falls on them or emit energy as a result of various physical processes. The measured spectrum of a body can thus reveal significant information on the composition of, and processes occurring within, planetary surfaces and atmospheres. The measured spectrum includes absorption features that can determine or constrain the composition of a surface or atmosphere, or emission features that suggest excitation processes in a gas or thermal emission from solids. The measured spectrum often displays solar features (either emission features or spectral continuum). To study the spectrum of the body itself, the solar spectrum is divided out, resulting in what is known as the spectral reflectance. The variation of the reflectance or **geometric albedo** (the reflectance at zero phase angle) as a function of wavelength is used to measure the strength of absorption features, from which the abundance of spectrally active species can be estimated.

Measuring reflected light at UV wavelengths can pose some interesting problems for instrument designers. First, the instrument's spectral sensitivity becomes weaker with decreasing wavelength and so does the Sun's energy output. The energy output of the Sun changes by a factor of 10^3 between the EUV and NUV spectral ranges, which until recently exceeded the dynamic range of UV detectors.

Second, in order to obtain the spectral reflectance of a body, a solar spectrum must be measured, which is no easy task in the UV range. Furthermore, below 180 nm, the spectrum of the Sun is variable. Therefore, a simultaneous spectrum of the Sun (or the reflection spectrum from an object whose spectrum is well understood) must be gathered at the same time that any UV observations are undertaken.

Last, particularly when performing measurements from an Earth-orbiting observatory such as the IUE or HST, solar system objects change positions against the background of stars during the course of an individual observation. In most cases, special tracking rates must be calculated prior to each observing run in order to know the change of the position of the target with time. Inaccurately calculated tracking rates can cause the observed target to drift from the instrument's field of view, thus adding noise and uncertainty to a measurement.

3. OBSERVATIONS OF PLANETARY ATMOSPHERES

With the exception of the innermost planet Mercury (which possesses a surface-bounded exosphere, similar to that observed on the Moon), all the planets in the solar system (and a few planetary satellites) are surrounded by detectable atmospheres. All the planets with atmospheres absorb UV light, and as a result UV observations provide information on the composition of, and processes that are occurring in, the object's atmosphere.

In general, the atmospheres of the terrestrial planets (Mercury, Venus, Earth, and Mars) are considered secondary atmospheres because they evolved after the primordial atmospheres were lost. However, the atmospheres of the four Jovian planets (Jupiter, Saturn, Uranus, and Neptune), because of their strong gravitational attraction and comparatively low temperatures, retained the primordial elements, particularly hydrogen and helium. From ground-based observations, methane (CH_4) and ammonia (NH_3) were identified in the atmospheres of the giant planets and therefore atmospheric processes were suspected of producing a host of daughter products that can be detected at UV wavelengths. (*See* Atmospheres Of The Giant Planets.)

Sunlight entering a planetary atmosphere can experience or initiate a wide variety of processes that contribute to the total energy emitted by the object and observed by an astronomical facility. The objects described previously all possess atmospheres that contribute significantly to their spectral behavior. Astronomical observations of such

bodies search for and measure the depths of absorption bands in the spectrum or emission bands due to atmospheric interactions with both solar photons and energetic particles that originate from the solar wind or the planet's magnetosphere. These bands are unique to specific gases; thus, it is possible to identify or eliminate particular gases as candidate materials in the atmospheres of these objects. The interpretation of an UV spectrum can be an arduous task, given that the bands and lines observed in the spectrum may arise from a combination of processes. These include:

1. Single and multiple scattering of photons by aerosols such as haze and dust (**Mie scattering**) and gas (**Rayleigh scattering/Raman scattering**) in the planetary atmosphere.
2. Absorption of the incident UV solar light by atmospheric species.
3. Stimulation of an atmospheric gas by incident sunlight and emission by **fluorescence**, chemiluminescence, or resonant scattering.
4. Photoionization and photodissociation reactions that produce a reaction product in an excited state.
5. Excitation of gas by precipitation of magnetospheric particles.

Each of these processes is associated with a well-understood physical mechanism, the details of which are beyond the scope of this chapter. The reader is referred to the bibliography and other chapters in this book.

Two significant methods of studying atmospheres at UV wavelengths are stellar occultations (observing a star as a body passes in front of the star and measuring the stellar flux as it is diminished) and reflection/airglow measurements (measurements of the backscatter of the solar continuum either by Rayleigh−Raman atomic/molecular scattering or by Mie scattering from atmospheric aerosols). The atmospheric species and density can be constrained by studying the occulted stellar spectrum as it passes through the atmosphere. Limited wavelength facilities can identify some but not all the constituents present and processes ongoing in a planetary atmosphere. The UV data from Earth-orbiting satellites have been used in combination with ground-based observations at other wavelengths and with observations by other spacecraft (including flyby missions) to develop an understanding of the atmospheres of planetary objects. The following discussion summarizes the results of those bodies in the solar system that possess atmospheres.

3.1. Mercury and the Moon

Both Mercury and the Moon have very tenuous atmospheres that are often referred to as surface-bounded exospheres. The atoms in these atmospheres do not collide with each other; rather, they bounce from place to place on the surface. The *Mariner 10* UV airglow experiment detected hydrogen, helium, and oxygen atoms as constituents of Mercury's exosphere. No molecules were detected. The pressure of Mercury's atmosphere was determined to be about 10^{-12} bar (compared to the 1 bar atmospheric pressure at sea level on Earth). Ground-based telescopic observations in the visible region have identified resonant scattering emission features attributed to sodium and potassium and calcium as well. Observations of Mercury's exospheric sodium demonstrate that it is spatially and temporally variable and the variability is not solely related to interactions with the solar environment. Sources for the known exospheric species include impact vaporization, ion sputtering, thermal- and photon-stimulated desorption, crustal outgassing, and neutralization of solar wind ions. The relative importance of these production mechanisms has been debated, and they will only be resolved by careful study of the spatial and temporal variations of the exospheric species. Many of these production mechanisms predict the existence of several species (such as Ar, Si, Al, Mg, Fe, S, and OH) that have not been detected in ground-based observations. The MESSENGER spacecraft carries a UVS as part of the Mercury Atmosphere and Surface Composition Spectrometer (MASCS) instrument package. This spectrometer operates from 115 to 600 nm and its goal is to map the constituents of the atmosphere and provide information to relate them to specific source and production mechanisms. MASCS has detected sodium, potassium and calcium in addition to discovering magnesium (Mg) in Mercury's exopshere. While in orbit about Mercury, this instrument has been mapping the spatial and temporal distribution of these species in addition to searching for other predicted species.

The lunar atmosphere is extremely tenuous and was first detected using instrumentation on *Apollo 17*. The known lunar atmospheric species present in detectable abundances are Ar, He, Na, and K. So far, only upper limits on other species have been set using UV wavelengths. The *Apollo 17* UVS provided upper limits on the number density of H, H_2, O, C, N, and CO. More recently, HST FOS NUV observations of the region away from the surface of the Moon resulted in upper limits on OH, Al, Si, and Mg abundances. LRO LAMP measurements have provided new, lower upper limits on many species and have detected He.

3.2. Venus

For more than half a century, the very dense Venus atmosphere (surface pressure of roughly 90 bar) has been known to be composed principally of carbon dioxide (CO_2) based on the existence of strong spectral absorption features in the

near-IR spectrum. Several layers of clouds many kilometers thick composed of sulfuric acid completely cloak the surface. Although these clouds obscure the surface at visual and UV wavelengths, the *Magellan* spacecraft used radar to construct maps of the volcanic surface. Atmospheric measurements in the UV region have been performed by sounding rockets and spacecraft, including the IUE, the *Pioneer Venus* orbiter, and the HUT. A UV image from Pioneer Venus is shown in Figure 49.1. The UV images of Venus' atmosphere show distinctive cloud patterns; in particular, a horizontal "Y"-shaped cloud feature (discovered by Mariner 10 Venus scientists in 1974) is visible near the equator. This feature may suggest atmospheric waves, analogous to high- and low-pressure cells on the Earth. Bright clouds toward Venus' poles appear to follow latitude lines. The polar regions are bright, possibly showing a haze of small particles overlying the main clouds. The dark regions show the location of enhanced sulfur dioxide near the cloud tops.

Within a few years of launch, the IUE identified several important trace constituents, including nitric oxide (NO), and confirmed the presence of several others, such as sulfur dioxide (SO_2). The Vega 1 and 2 probes measured local UV absorptions due primarily to SO_2 and aerosols. UV reflectance spectra obtained during two sounding rocket observations in 1988 and 1991 found that SO_2 is the primary spectral absorber between 190 and 230 nm and that sulfur monoxide (SO) is also present in Venus' atmosphere. The EUV instrument aboard the Galileo spacecraft observed Venus in the EUV wavelength range (55−125 nm) during its flyby. It detected emissions due to helium, ionized oxygen, atomic hydrogen, and an atomic hydrogen−atomic oxygen blend. In 1994, an extreme ultraviolet spectrograph (EUVS) was launched aboard a sounding rocket to observe the Venusian atmosphere from 82.5 to 11 nm. The EUVS identified several species, including N I, N II, N_2, H I, O I, and O II. The results of the EUVS measurements are consistent with earlier observations by the IUE, Pioneer Venus, *Venera 11* and *12,* and the Galileo EUV spectrometer. The EUVE provided the first full EUV (7−76 nm) spectrum of Venus in 1998 and made brightness measurements on the He **I** (58.4 nm) and O II (53.9 nm) lines. The FUV spectrum of Venus is dominated by the CO fourth-positive band system, as well as by neutral oxygen and carbon features, and has been measured by HUT (82−184 nm) in 1995 and by Cassini UVIS.

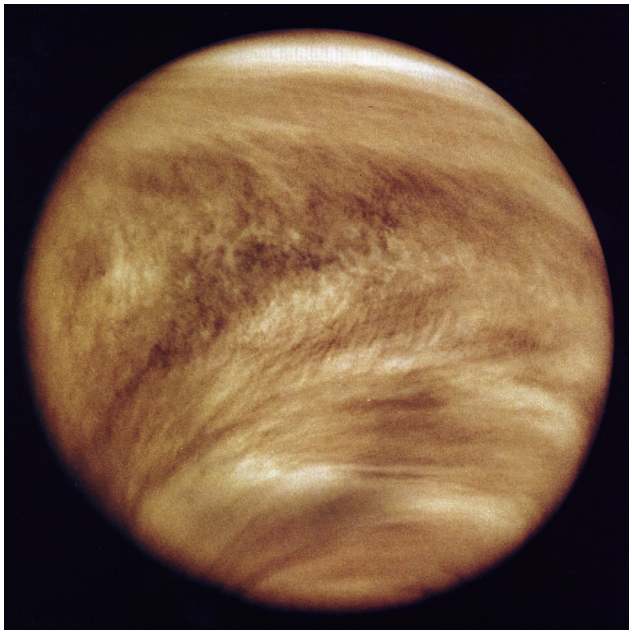

FIGURE 49.1 Pioneer Venus Orbiter cloud photopolarimeter image of Venus at 365 nm.

The IUE spectra of the Venus dayside and nightside obtained while Venus was near elongation displayed SO_2 absorptions at 208−218 nm, which when combined with the **column densities** reported by the Pioneer Venus orbiter and with ground-based observations are a measure of the SO_2 **mixing ratio** with altitude and its variation at the top of the cloud deck. This provides information on its variation in spatial distribution and permits models to be constructed of the planet's atmospheric dynamics. Observations of the Venus nightside with Pioneer Venus orbiter and the IUE detected the Venus nightglow, which is caused by the emission bands of nitric oxide (NO). Because of the short lifetime of NO on the nightside, this finding implies the rapid dayside−nightside transport of material in the Venus atmosphere. Observations of the Venus dayside have led to the discovery that the dayglow emission is carbon monoxide fluorescence, probably due to fluorescent scattering of solar Lyman-alpha radiation.

UV measurements of the Venus atmosphere using the Venus Express SPICAV have found the presence of a thin ozone layer at Venus, at a mean altitude of 100 km. SPICAV has also characterized the hydrogen exospheric corona and is monitoring SO_2 and the UV dayglow at Venus.

3.3. Mars

The atmosphere of Mars, like that of Venus, is dominated by carbon dioxide, and also consists of small amounts of N_2, H_2O, and their photochemical products. Mars' atmosphere is much less dense than Venus's atmosphere (approximately 14,500 times lower surface pressure) and is relatively transparent at most wavelengths. Therefore, UV to IR observations of Mars reveal information about both its atmosphere and its surface. The observations of Mars by the UVS instruments on Mariner 6 and 7 were the first to reveal the UV dayglow of this planet; later observations by Mariner 9 confirmed and extended these results. NUV

spectra (Figure 49.2(a)) revealed the presence of CO (a-X) Cameron bands, CO^+ (B-X), CO_2^+ (A-X), and CO_2^+ (B-X) features. FUV spectra displayed oxygen features at 130.4 and 135.6 nm, neutral carbon emission features at 156.1 and 165.7 nm, and the CO (A-X) at fourth-positive bands. All these UV features of the Martian airglow are products of processes involving Mars' CO_2 atmosphere. The CO_2^+ band systems are the result of a combination of photoionization excitation of CO_2 and fluorescent scattering of CO_2^+, and the CO (a-X) and (A-X) bands are due to photon or electron dissociative excitation of CO_2. The presence of escaping hydrogen (Ly-α at 121.6 nm), suggested atomic hydrogen within the atmosphere and also suggested the accumulation of oxygen and loss of water.

More recent (1995) HUT observations (82−184 nm) confirmed these early Mariner results (Figure 49.2(b)), and FUSE measurements detected molecular hydrogen (H_2) emission features at 107 and 116.7 nm for the first time. EUVE provided the first measurements of helium 58.4 nm within the Martian atmosphere. These helium observations have been used to set constraints on outgassing processes. Recent UV observations from the Mars Express spacecraft have made the first detection of the Martian nightglow, revealing nitric oxide emission features similar to those seen on Venus, auroral emissions associated with crustal magnetic field features, and high-altitude CO_2 ice clouds.

Mariner 6 and 7 UVS observations revealed the presence of the Hartley band of ozone (O_3), centered around 255 nm. The feature was detected at the south polar cap, through ratios of south polar spectra to low-latitude spectra (Figure 49.2(c)). Further observations with the UVS on the Mariner 9 orbiter revealed that the north and south polar ozone amount varied with season. Ozone densities were highest in winter and lowest in summer, anticorrelating with atmospheric water vapor content. The correlation between higher amounts of ozone with a cold, clean, dry atmosphere led to the conclusion that ozone is formed through the combination of atomic and molecular oxygen, both of which are more readily present when less water is available. Subsequent HST observations, and particularly the global coverage obtained by Mars Express SPICAM, have studied the seasonal variation of atmospheric ozone and have linked low-latitude ozone abundance variations across the Martian perihelion−aphelion cycle with the large annual water vapor variation due to the eccentricity of Mars' orbit. These observations have also been used to study atmospheric aerosol (dust and cloud) opacities, demonstrating the critical function that is performed by the small amounts of H_2O in the Martian atmosphere, which control the buildup of CO and O_2 and sustain the stability of CO_2. It has also been found that chemical reactions occurring on ice clouds are critical to understanding the observed Martian ozone levels. Ozone is readily destroyed by hydrogen radicals and is therefore a sensitive tracer of the chemistry that regulates the atmosphere of Mars.

3.4. Jupiter

Jupiter, the target of numerous Earth-based observations as well as spacecraft flybys, is composed of 90% hydrogen and 10% helium, with small amounts of ammonia and methane. The uppermost layers of the atmosphere are observable in the UV wavelength range and display products of photochemical processes.

The first FUV spectra of Jupiter were measured in sounding rocket experiments in the late 1960s and the early 1970s. These early measurements displayed H_2 Lyman and Werner band emissions and hinted at the presence of absorption features due to C_2H_2, C_2H_4, and NH_3. Stellar occultation observations by the Voyager UVS were significant in providing measurements of upper atmospheric temperatures. Early IUE observations confirmed that C_2H_2 absorption bands are the dominant features in the 165−185 nm wavelength region. Figure 49.3(a) shows the geometric albedo of Jupiter in the FUV wavelength range, displaying C_2H_2 and NH_3 features, derived using a composite spectrum of Jupiter from the 1978−1980 time frame.

The spectral geometric albedo of Jupiter as measured by the IUE at NUV wavelengths is shown in Figure 49.3(b). Most of this spectral behavior is attributable to hazes that are high above the cloud deck. The best-fit model (solid line in the figure) to the data occurs for a Jovian cloud deck with a geometric albedo of 0.25 and for a haze composed of particles with a single-scattering albedo of 0.42. Although such a result may not be able to provide an unambiguous identification of the materials that compose the haze, it can constrain the eligible candidate materials that are suggested by other observations.

IUE observations also permitted the ammonia−hydrogen mixing ratio to be calculated, and it was found to be 5×10^{-7}. The fact that the IUE was able to observe the absorption features of these species indicates that they are above the Jovian tropopause, where the clouds create an opaque barrier to light emitted from the material underneath and hence make spectral identification of the underlying material impossible. In July 1994, the comet Shoemaker-Levy 9 (SL-9) collided with Jupiter. It was not until the impact of the fragmented comet that studies of this underlying material became possible. The EUVE satellite observed Jupiter before, during, and after this event. EUVE found that 2−4 h after the impact of several of the larger fragments, the amount of neutral helium temporarily increased by a factor of ~ 10. This transient increase is attributed to the interaction of sunlight with the widespread high-altitude remnants of the plumes from the larger impacts. HST also observed this event with the GHRS and the Faint Object Camera (FOC). The UV spectra obtained

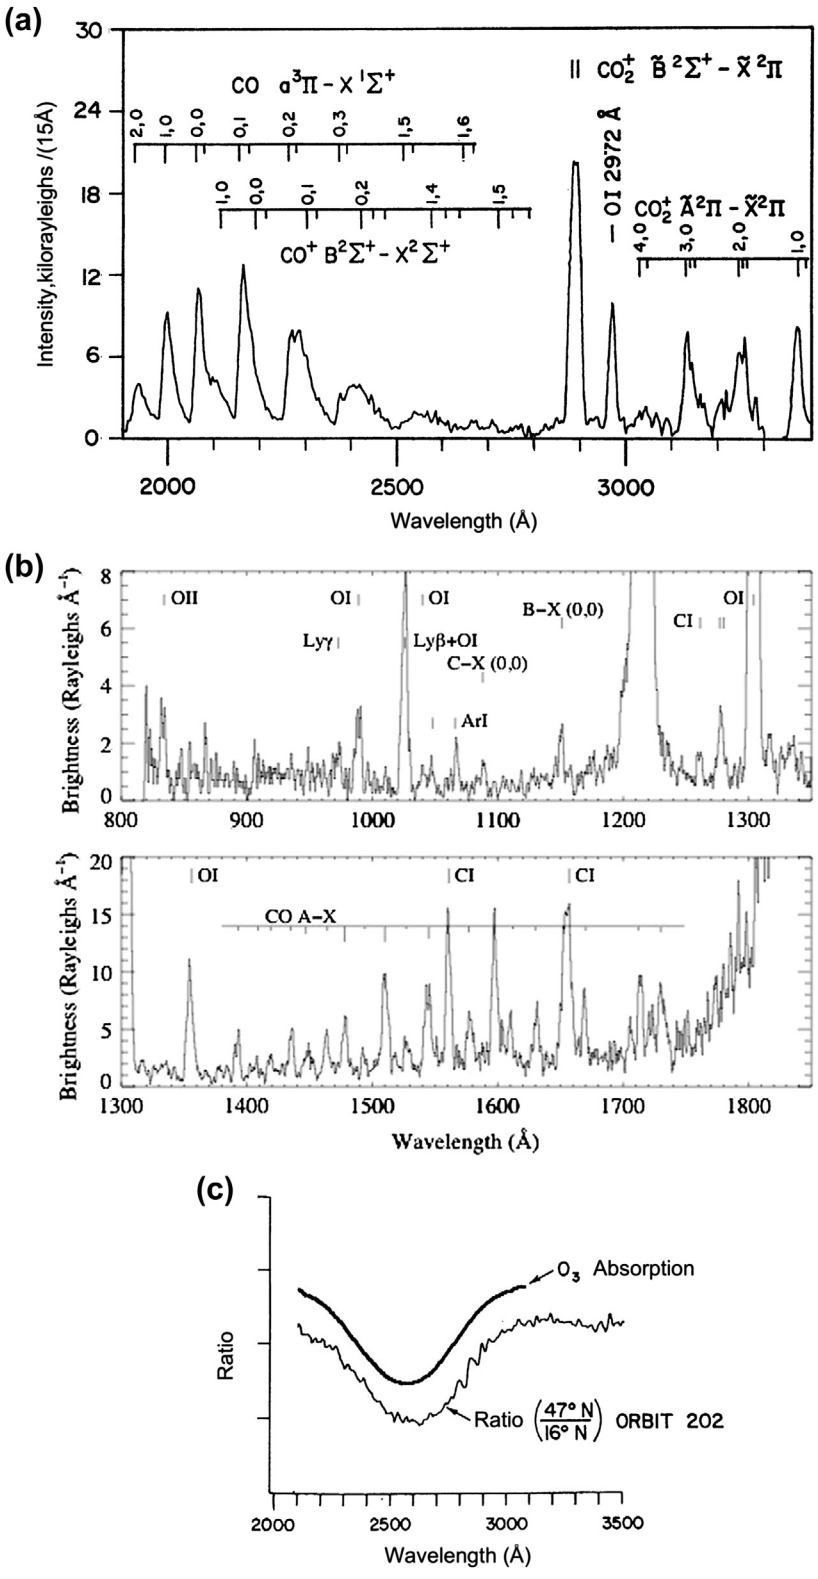

FIGURE 49.2 (a) Mars dayglow as measured by the Mariner 9 UVS. (b) Mars spectrum at EUV–FUV wavelengths as measured by HUT. (c) Ozone at high latitudes on Mars as measured by Mariner 9 UVS. A high-latitude spectrum is shown ratioed to a low-latitude spectrum, compared with a laboratory spectrum of the Hartley band of O_3. *Figures (a) and (c) reproduced with permission from Elsevier. Figure (b) reproduced with permission from AAS Publications.*

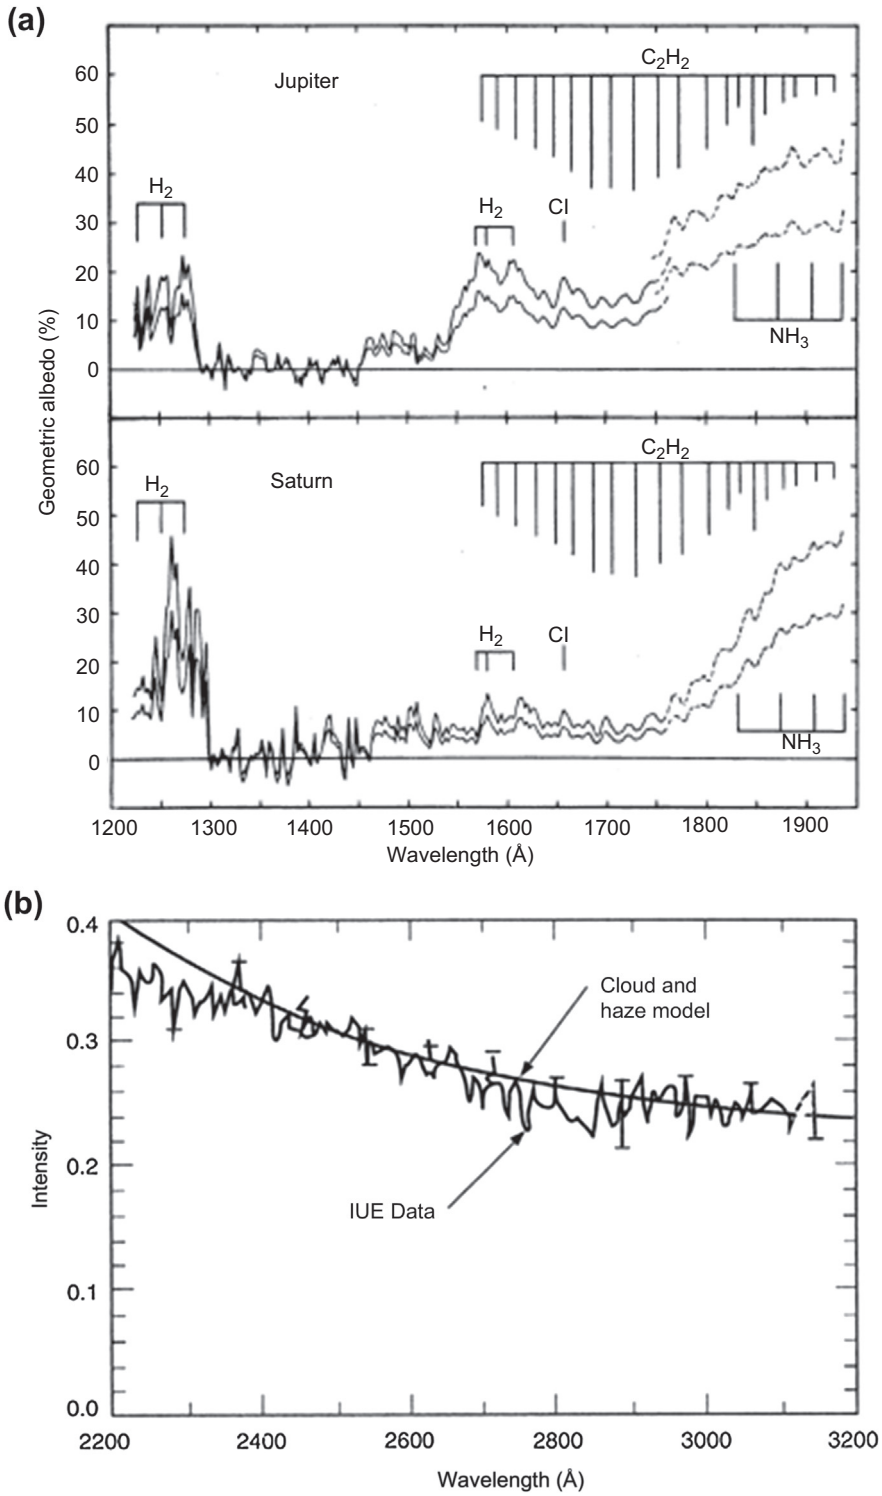

FIGURE 49.3 (a) FUV geometric albedos of Jupiter and Saturn as measured by the IUE. The albedos are derived from composite spectra of the planets between 1978 and 1980. The upper and lower curves for each planet correspond to assumptions of uniform and cosine-limb-darkened disks, respectively. The dashed lines represent data that are uncertain in magnitude owing to the subtraction of scattered light and are regarded as upper limits. (b) The spectral geometric albedo of Jupiter as measured by the IUE. The smooth solid line is the best fit from a model that assumes a layer of haze particles with single-scattering albedo of 0.42 that overlie a cloud deck with geometric albedo of 0.25. *Figure (a) reproduced with permission from AAS Publications. Figure (b) reproduced with permission from Elsevier.*

by HST of Jupiter after the collision of SL-9 identified approximately 10 species of molecules and atoms in the perturbed atmosphere, many of which had never been detected before in Jupiter's atmosphere. Among these were S_2, CS_2, CS, H_2S, and S^+, which are believed to be derived from a sulfur-bearing parent molecule native to Jupiter. The observations also detected stratospheric ammonia (NH_3). Neutral and ionized metals, including Mg II, Mg I, Si I, Fe I, and Fe II, were also observed in emission and are believed to be from the SL-9 comet fragments. The surprising observation was the absence of absorptions due to oxygen-containing molecules.

A major focus of study at UV wavelengths is the polar regions of Jupiter and their impressive exhibit of auroral activity. Jupiter's auroral displays are the most energetic in the solar system. FUV measurements were first made using the Voyager UVS, and subsequent observations were performed by the IUE. The FUV emissions are dominated by the hydrogen Lyman-alpha and the H_2 Lyman and Werner system bands. Synoptic observations of these UV emissions using the IUE have shown that they vary with Jupiter's magnetic (not planetary) longitude, and hence these emissions are magnetospheric phenomena. IUE observations have been used to construct a spatial map of the Lyman-alpha emission and the data indicate that the emitting material is upwelling at about 50 m/s relative to the surrounding material. More intensive UV observations with FUSE and HST instruments GHRS, FOC, STIS, and ACS have measured the temporal variability within the aurora and temperature variations within the auroral ovals seen at both poles. These variations are reflections of possible distortions in the magnetic field of Jupiter. HST measured the first detection of reversed Lyman-alpha emissions, which are linked to variable atomic hydrogen. Estimates of vertical column densities ($1-5 \times 10^{16}$ cm^{-2}) of atomic hydrogen above the auroral source have been made. HST has also detected UV emission from a superthermal hydrogen population. The Galileo spacecraft EUV spectrometer and UVS also observed Jupiter's aurora. These observations have placed constraints on the vertical distribution of methane (CH_4) in Jupiter's atmosphere. Slant methane column abundances are estimated to be 2×10^{16} cm^{-2} in the north and 5×10^{16} cm^{-2} in the south based on the Galileo observations. Cassini UVIS measurements showed that Jupiter's aurora responded strongly to the compression events produced when large solar coronal mass ejections reached Jupiter's magnetosphere. Figure 49.4 displays Jupiter's UV aurorae as imaged by *HST* in 1998. Evident in Figure 49.4 is the auroral "footprint" of Io, where the field line intersecting Io connects to the planet, revealing the magnetospheric relationship between the planet and its moon. Magnetic footprints of the other moons also exist but are less obvious in this image.

Bright H Ly-α emissions have been observed from Jupiter's equatorial region, and the source of this "equatorial bulge" has been debated. The source is likely a combination of charged particle excitation and solar resonance scattering and fluorescence. The emission has been shown to be consistent with resonant scattering of solar Ly-α with a large planetary line width, requiring a fractional ($\sim 1\%$) suprathermal population of fast H atoms in the uppermost atmosphere. The fast atoms are likely due to dissociative excitation of molecular hydrogen (H_2).

3.5. Saturn

Like Jupiter, Saturn's atmosphere is dominated by hydrogen and helium, with traces of water, ammonia, and methane. The FUV spectrum of Saturn was first measured in sounding rocket experiments in 1978. Absorption features in the UV spectrum of Saturn that have been associated with acetylene (C_2H_2) in the upper atmosphere were discovered using early IUE measurements. Figure 49.3(a) displays the FUV geometric albedo of Saturn derived using a composite of IUE Saturn spectra from the 1978–1980 time period. The mixing ratio of the acetylene is about 1×10^{-7}. Although acetylene is a well-known strong absorber of UV radiation, it alone cannot explain the low UV spectral geometric albedo of Saturn that has been reported by the IUE. Other UV-absorbing materials must be present. Comparisons of laboratory spectra of C_2H_2, PH_3, AsH_3, and GeH_4 with the IUE observations show that the best fit model for Saturn's atmospheric UV spectrum includes absorptions by C_2H_2, H_2O, CH_4, C_2H_6, PH_3, and GeH_4. The distribution of PH_3 and GeH_4 decreases with increasing altitude in these models, suggesting that UV photolysis is an important process occurring at higher altitudes.

Pole-to-pole mapping studies of the hydrogen Lyman-alpha emission across Saturn's disk led to the discovery of pronounced spatial asymmetries in the emission. Other observations of hydrogen do not find a variation in intensity with rotational period as with Jupiter. There is no rotational bulge in the Lyman-alpha emission as seen on Jupiter. This is probably due to the fact that Saturn's magnetic pole is coincident with the rotational pole, whereas in Jupiter's case, the poles are offset.

Like Jupiter, Saturn displays auroral activity. On both planets, this auroral activity also creates aerosols that are detectable in the UV as dark-absorbing regions. HST FOC UV observations discovered a dark oval encircling the north magnetic pole that is spatially coincident with the aurora detected by the Voyager UVS. Voyager 2 UV Photopolarimeter Subsystem (PPS) measurements also demonstrate a geographical correlation between the auroral zones of Jupiter and Saturn with UV-dark polar regions.

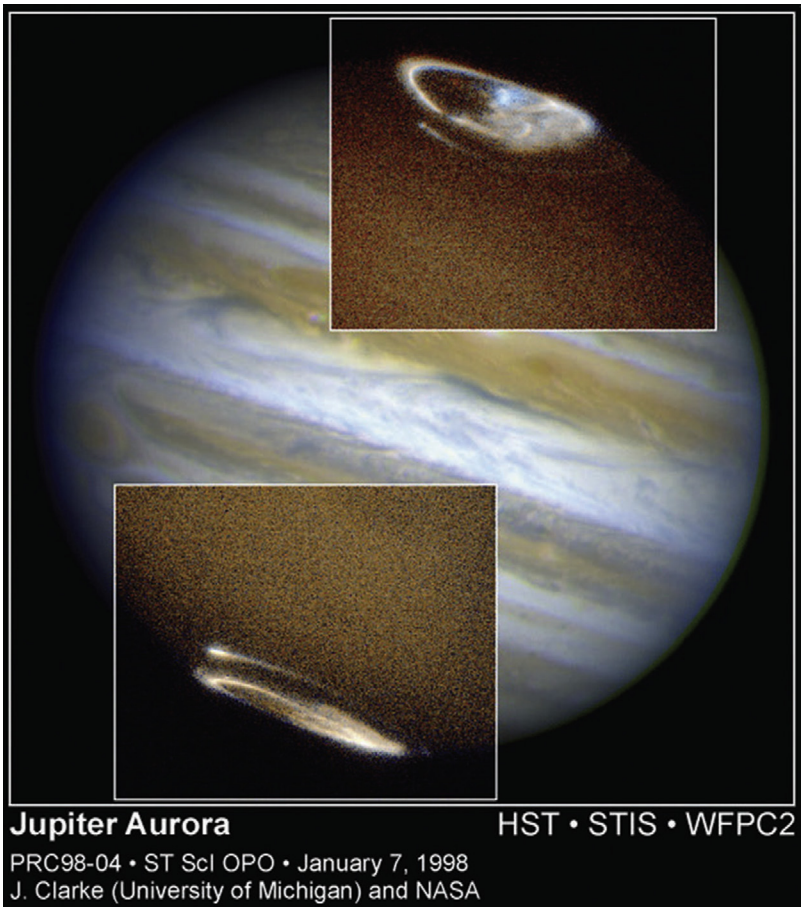

FIGURE 49.4 HST image of Jupiter aurora. The magnetic "footprint" of Io, marking the location where magnetic field lines joining the moon and Jupiter connect with the planet, is also seen as a bright spot with a tail outside the main auroral oval. WFPC2 is the Wide Field Planetary Camera 2 on HST. *Image credit: J. Clarke, NASA.*

Additional UV observations with the HST FOC of Saturn's northern UV aurora and polar haze support the hypothesis that the polar haze particles are composed of hydrocarbon aerosols produced during H_2^+ auroral activity. More recent HST UV imaging of Saturn's aurorae (Figure 49.5) shows that they behave differently from Jupiter's aurorae, varying in brightness and shifting in latitude. Cassini UVIS has also studied Saturn's UV auroral emissions and has discovered an auroral footprint connected to the moon Enceladus, similar to that of Io in Jupiter's auroral region.

3.6. Uranus

Uranus presents a unique observational circumstance to the inner solar system observer because of the fact that its pole is inclined 89° to the ecliptic and that at the present position in its 84-year orbit about the Sun it presents its pole to the Earth. This unusual inclination, combined with its great distance from the Earth, makes it impossible to use an Earth-based instrument to undertake pole-to-pole comparisons as was done with Jupiter and Saturn. Uranus has a geometric albedo at NUV wavelengths of about 0.5, more than twice that of Jupiter and Saturn. This suggests that additional absorbers are present in the Jovian and Saturanian atmospheres that are not present in the atmosphere of Uranus. Both Uranus and Neptune possess hot thermospheres and stratospheres that are substantially clear of hydrocarbons and other heavy constituents, making the UV albedos higher than those of Jupiter and Saturn. A sharp increase in measured reflectance intensity at wavelengths longward of 150 nm is indicative of acetylene (C_2H_2) present in the atmosphere of Uranus.

Voyager 2 spacecraft observations of Uranus found a very small internal heat source compared to the large internal heat sources found in Jupiter and Saturn. This suggests that there is very little atmospheric mixing driven by heating and buoyancy in the Uranian atmosphere. Thus, UV observations are able to sense a deeper region of the atmosphere.

The UV emissions from Uranus' atmosphere have been measured by the IUE and the Voyager UVS. To increase the signal-to-noise ratio, the IUE observers used principally low-resolution observations and binned broad-wavelength

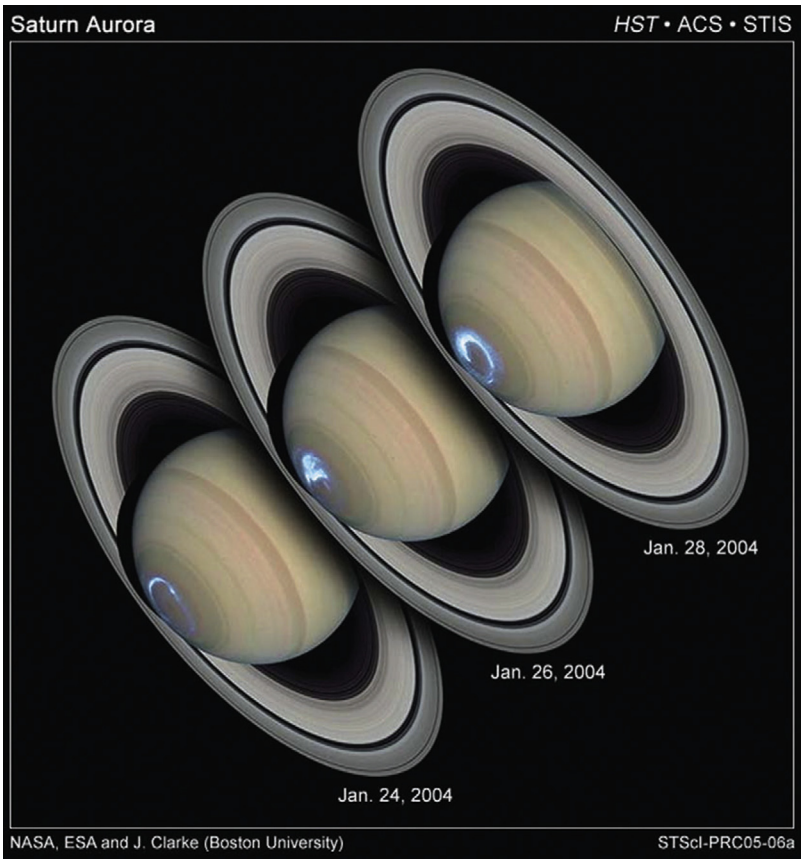

FIGURE 49.5 HST images of Saturn's varying aurorae. *Image credit: J. Clarke, NASA.*

regions together to search for broadband absorbers at UV wavelengths. Analysis of the IUE observations detected acetylene absorptions, which were also detected on Jupiter and Saturn. Based on these observations, the mixing ratio of acetylene is estimated to be 3×10^{-8}. Analysis of the Voyager UVS observations of H_2 band UV airglow emissions shows aurora at both magnetic poles, which are offset from the rotational poles by $\sim 60°$. The auroral emissions on Uranus are very localized in magnetic longitude and do not form complete auroral ovals as are seen on Jupiter and Saturn.

3.7. Neptune

Neptune is so distant that only broadband UV measurements are possible from the Earth's orbit. The geometric albedo of Neptune measured by the IUE is 0.5, which, like that of Uranus, is twice that of Jupiter and Saturn. Below 150 nm, Neptune's albedo is reduced by the higher hydrocarbon abundance carried into its stratosphere by its more vigorous vertical transport. Most of the important data for Neptune at UV wavelengths have come from the UVS onboard the Voyager 2 spacecraft and from HST. CH_4 and C_2H_6 abundances inferred from the Voyager UVS solar occultation experiment are between 0.0006 and 0.005 mole fraction for CH_4 in the lower stratosphere (with a mixing ratio of $5-100 \times 10^{-5}$) and the density of C_2H_6 is estimated to reach 3×10^9 cm^{-3}.

In 1994, HST imaged Neptune in six broadband filters, one of which was in the UV. The goal of these observations was to study the cloud structure on Neptune and compare the measurements with the observations made by Voyager 2. The HST images showed that the Great Dark Spot seen by Voyager no longer existed, but a new large dark feature of comparable size had appeared in the northern latitudes. HST measurements also detected weak carbon monoxide lines at 199.2 and 206.3 nm, suggesting a mixing ratio of $\sim 3 \pm 2 \times 10^{-6}$ in the upper troposphere.

Voyager 2 UVS measurements tentatively identified weak auroral emissions at Neptune's South Pole, interpreted as H_2 emissions. The North Pole was not observed by Voyager, so it is unknown whether this hemisphere displays aurora.

3.8. Pluto

For the dwarf planet Pluto and its large satellite Charon, UV spectroscopy is a potentially rich source of information

due to the atmospheric chemistry that is likely occurring in this distant part of the solar system. Pluto's atmosphere is known to contain N_2 predominantly. The additional presence of methane in the atmosphere suggests that photochemical products should include hydrocarbons and nitriles, detectable at UV wavelengths. The IUE obtained a few spectra of Pluto and Charon and observed that the UV albedos vary with rotation. The amplitude of the rotational variation as measured at UV wavelengths by the IUE is greater than the rotational variation measured at longer wavelengths by Earth-based observers, consistent with the presence of an absorbing material that is spectrally active in the 320–480 nm wavelength range; the geometric albedo of Pluto in the NUV is spectrally flat. The composition of the absorbing material is unknown. (*See* Pluto.)

Observations made with the FOS on HST were used to determine upper limits on Pluto's predicted atmospheric species C_4H_2, C_6H_2, HC_3N, and C_4N_2 of 1.6×10^{16}, 1.8×10^{16}, 2.7×10^{16}, and $4 \times 10^{16}\,cm^{-2}$, respectively. The UV spectrum of Pluto's satellite, Charon, was also measured by the HST FOS and was found to have a spectrally flat geometric albedo in the NUV; Charon's spectrum does not exhibit any absorption or emission features that provide compositional clues.

The Pluto–Charon system is the target of the *New Horizons* flyby mission, which includes the Alice FUV imaging spectrograph (which operates from 52 to 187 nm) to probe the atmospheres and surfaces of these distant worlds.

3.9. Galilean Satellites

Jupiter's moon Io has one of the most unique atmospheres in the solar system: The primary sources of the atmosphere are volcanic emissions and sublimation of SO_2 frost on the surface. The result is a tenuous, patchy atmosphere made up of SO_2, SO, S_2, S, and O; trace species include Na, K, Cl, NaCl, and H. Gaseous SO_2 can be deposited onto the surface at night or during eclipse by Jupiter. Material is also lost to the torus as the ionized material sweeps by Io. Gaseous SO_2 was discovered at Io by the IRIS instrument on Voyager; since this discovery, numerous studies of Io's atmospheric processes have been made at UV wavelengths. IUE, HST, and the Galileo UVS have made measurements of Io at NUV wavelengths (200–350 nm). FUV observations from HST and Cassini UVIS identified emissions from neutral oxygen and sulfur and have been used in mapping the distribution of the SO_2 atmosphere.

Associated with Io is a plasma torus, or a donut-shaped ion cloud, centered at Io's orbital radius. This torus has been studied by Pioneer, Voyager, IUE, HST, EUVE, HUT, FUSE, Galileo, and Cassini. Oxygen, sulfur, and sodium ions are the major constituents of the torus, and protons are present at ~10% abundance; chlorine ions have also been detected. The torus is not uniform, and the density of ions shows various asymmetries depending on Io's position and dawn–dusk timings, in addition to temporal variations.

Intriguing auroral features are a consequence of Io's SO_2 atmosphere, resulting from electron impact excitation of atomic oxygen and sulfur as well as electron dissociation and excitation of SO_2, and have been observed at visible and FUV wavelengths. The Io flux tubes (IFT) and the Io plasma torus are the two primary sources of electrons in the Io environment. Due to the 10° tilt of Jupiter's magnetic field, Io is alternately above and below the magnetic equator (depending on Io's System III Jovian magnetic longitude, λ_{III}), the primary region of the torus electrons. Furthermore, the tangent points between field-aligned electrons and Io's atmosphere change as Jupiter rotates. The interaction of the torus electrons and the IFT electrons with Io's atmosphere has been detected at FUV wavelengths. Equatorial spots (Figure 49.6) have been observed to wobble up and down, reflecting the changing location of the IFT tangent points in time. The equatorial spot on the anti-Jovian hemisphere has been measured to be brighter than the spot on the sub-Jovian hemisphere, likely due to the motion of electrons through Io's atmosphere by the Hall effect, with hotter electrons on the anti-Jovian side. (*See* Io: The Volcanic Moon.)

Observations with the HST GHRS detected atomic oxygen emissions at 130.4 and 135.6 nm from Jupiter's satellite Europa, which have been interpreted as evidence for a tenuous O_2 atmosphere about this satellite. The source of this oxygen atmosphere is likely sputtering of the icy surface by corotating magnetospheric particles. These

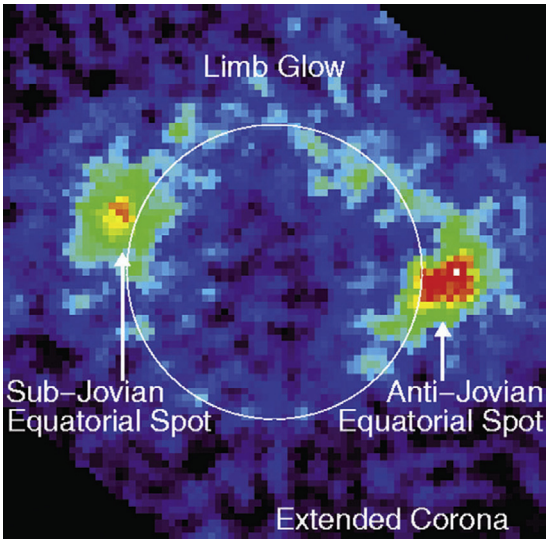

FIGURE 49.6 Io imaged at 135.6 nm by HST STIS. Equatorial "spots" are the result of interaction between electrons flowing along the IFT with Io's SO_2 atmosphere. *Figure courtesy of K. Retherford.*

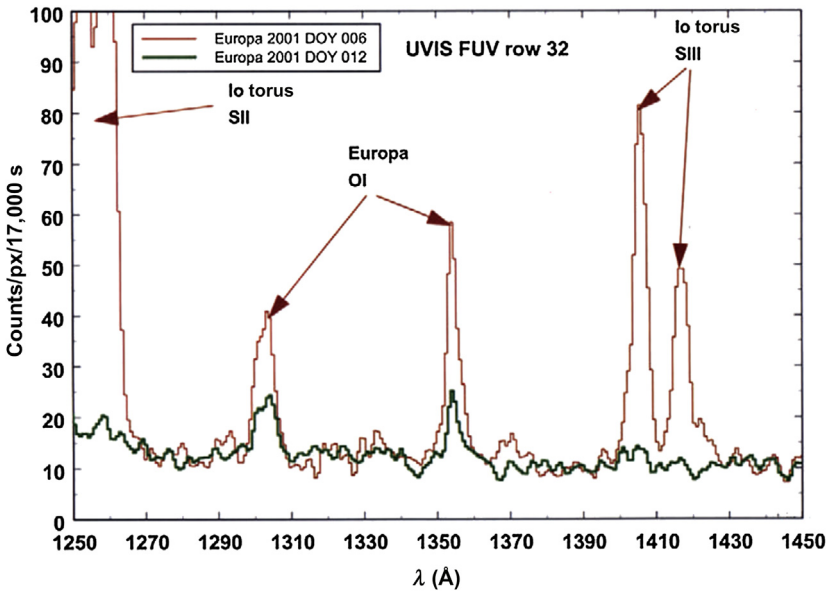

FIGURE 49.7 The FUV spectrum of Europa as measured by Cassini UVIS on January 6, 2001, and January 12, 2001. Neutral oxygen emission features appear at 130.4 and 135.6 nm in both observations. Io torus emission features from ionized sulfur also appear. The presence of the O I features is due to electron dissociation and excitation of a tenuous O_2 atmosphere at Europa. *Figure reproduced with permission from Elsevier.*

emission features were also measured by the Cassini UVIS instrument during the Jupiter system flyby in 1999–2000 (Figure 49.7). Similar oxygen emission features were detected by HST at Ganymede, although it was found that Ganymede's emissions are restricted primarily to the polar regions. The emissions are auroral features produced by dissociative excitation of O_2 by electrons traveling along the field lines of Ganymede's own magnetosphere. The HST imaged Ganymede's auroral emissions at 135.6 nm and found them to be temporally and longitudinally variable (Figure 49.8). *Galileo's* UVS detected hydrogen escaping from Ganymede, possibly due to sputtering of Ganymede's surface by charged particles. Callisto, in contrast to Ganymede and Europa, exhibits only weak oxygen emission features. An analysis of HST measurements found that the oxygen and CO emission features, expected after the discovery of CO_2 gas, are so faint that Callisto's interaction with the magnetosphere is like that of a unipolar inductor and that another species such as O_2 is likely abundant, enhancing the ionosphere and its conductivity. Callisto's ionosphere is apparently of sufficient conductivity to reduce the flow of plasma into its atmosphere and inhibits oxygen emission features in contrast to Ganymede and Europa.

3.10. Titan and Triton

Saturn's satellite Titan and Neptune's satellite Triton are among the largest satellites in the solar system. In addition, they are far from the Sun; therefore, the reduced solar energy allows the atmospheric gases to remain cold enough that they cannot easily escape by thermal processes (*See* Titan; Triton). Both Titan and Triton have nitrogen atmospheres that have been studied using UV techniques.

Titan is a solar system curiosity due to its very thick (~1.5 bar) nitrogen atmosphere, which prevents UV observations of the surface. The nitrogen atmosphere was discovered using a UV solar occultation by the Voyager spacecraft. Ground-based and Voyager spacecraft observations have identified methane (CH_4) as a significant constituent of Titan's atmosphere. Analyses of IUE and HST observations of Titan at NUV wavelengths have placed constraints on the properties of Titan's high-altitude haze and the abundances of simple organic compounds such as acetylene (C_2H_2). At FUV wavelengths, observations by Cassini UVIS demonstrate the presence of molecular and atomic nitrogen based on emission features due to electron dissociation and excitation (Figure 49.9). UVIS measurements are also being used to study the nature of the aerosols in Titan's atmosphere.

Triton's surface contains N_2, CO, and CH_4 frosts, which are highly volatile and in a continual state of exchange between the atmosphere and surface. IUE observations of distant Triton likely tested the limits of IUE's sensitivity. The photopolarimeter on Voyager 2 measured an albedo of 0.59 on all sides of Triton. HST FOS observations in 1993 detected broad apparent absorption features centered around 275 nm and between 200 and 210 nm. The FOS analysis also led to mixing ratio upper limits for atmospheric constituents of OH, NO, and CO of 3×10^{-6}, 8×10^{-5}, and 1.5×10^{-2}, respectively. HST STIS observations from August to September 1999 showed that Triton's albedo in the 250–320 nm range was 15–30% brighter and also spectrally redder than measured by the

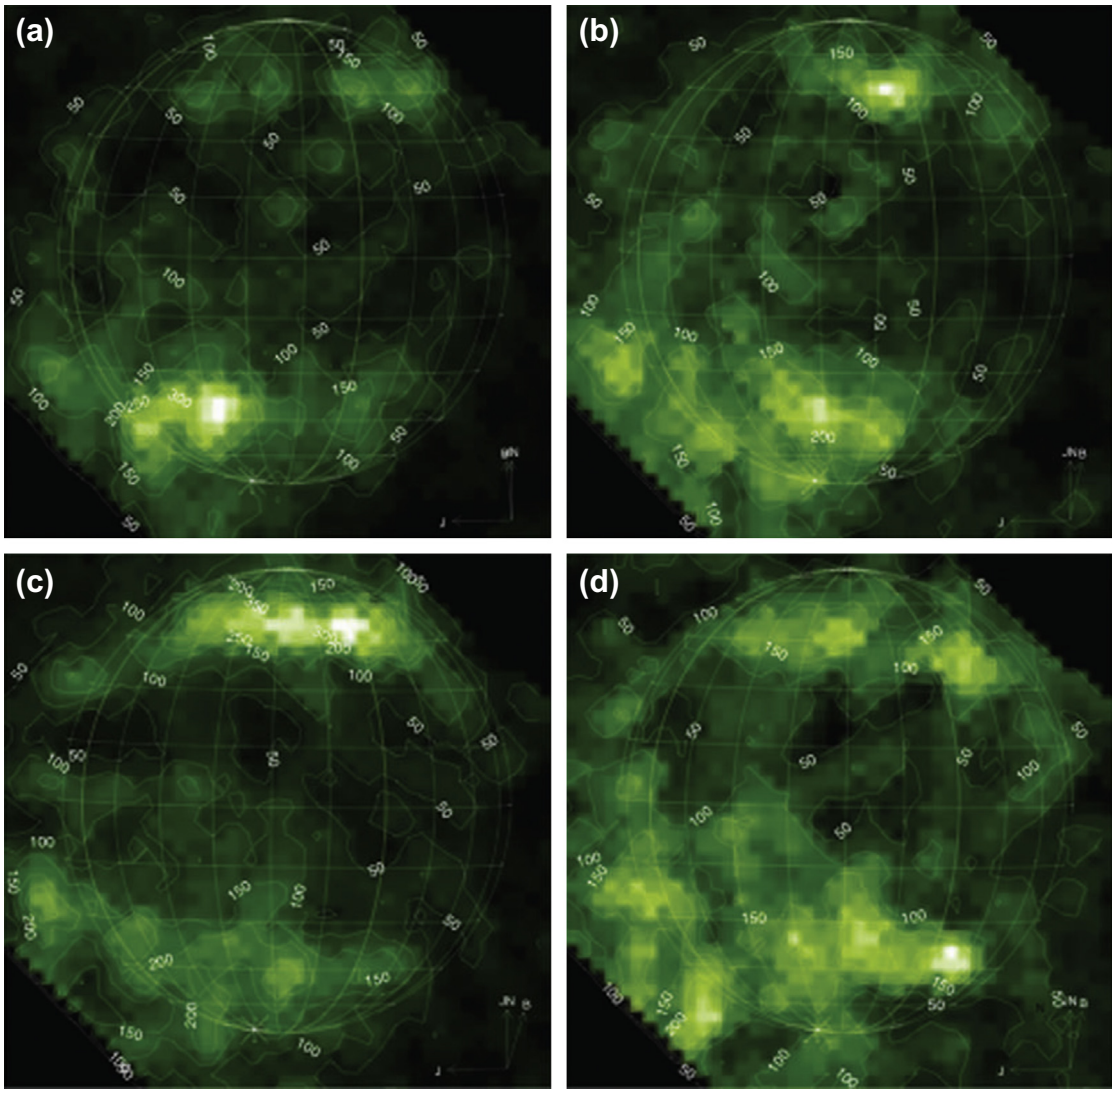

FIGURE 49.8 (A–D) HST STIS images of Ganymede's UV aurora. The images represent neutral oxygen at 1356 Å and reveal brightening in the polar regions that is variable over the four HST orbits during which the imaging took place. *Figure reproduced with permission from AAS Publications.*

HST FOS in 1993, suggesting that Triton's NUV albedo undergoes changes on timescales shorter than the seasonal cycle. Such changes may be due to bright frost deposition or to the emplacement of a relatively dark UV material. At this point, the source of the dramatic, short-timescale changes in UV brightness on Triton remains unknown.

4. OBSERVATIONS OF SOLID SURFACES

Many solid-state materials that make up the surfaces of solar system objects exhibit spectral absorption features, and thus it is possible to identify or constrain the abundance of solid components on the surfaces of these objects. This is accomplished by comparing the spectral geometric albedo of the object with the reflection spectrum of the solid-state materials as measured in the laboratory. The following discussion focuses on UV observations of solid surfaces throughout the solar system. Light is reflected from particulate surfaces by volume scattering and surface scattering. At longer visible and near-IR wavelengths, volume scattering dominates in most materials. At shorter NUV and FUV wavelengths, surface scattering dominates. Absorptions in the NUV are generally due to charge transfer and result in rather broad absorption features, compared with absorption features in the near-IR wavelengths, usually due to weaker electronic transitions. Many nonice materials absorb in the NUV wavelength, including organics, sulfur compounds, and many refractory materials. There is usually an absorption edge between 300 and 370 nm. In contrast, ices such as H_2O and CO_2 are not very absorbing at visible and NUV wavelengths (water and CO_2 ice exhibit strong absorption features near 165 nm). Atmosphereless bodies in

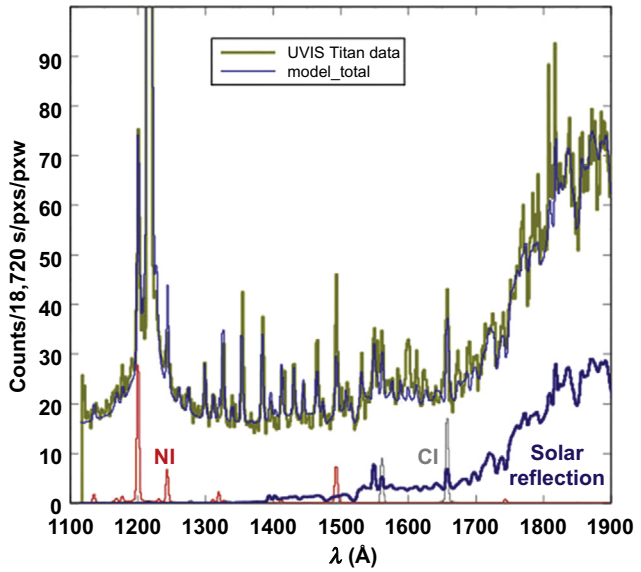

FIGURE 49.9 Titan's FUV spectrum as measured by the Cassini UVIS. The spectrum includes an overall continuum due to reflected solar light, in addition to emission features due to electron dissociation and excitation of molecular and atomic nitrogen. *Figure courtesy of D. Shemansky.*

the solar system experience weathering, whereby their surfaces are affected by bombardment of micrometeorites as well as charged particles, either from the solar wind in the case of the Moon and asteroids or from the magnetosphere of the parent planet in the case of the icy satellites of the outer solar system. Particularly in the case of icy surfaces, radiation-aged surfaces tend to be darker at UV wavelengths. Thus, UV observations of icy surfaces can be used to indicate ice "freshness," or the amount of contamination.

Of importance in studying the UV characteristics of the surfaces of many icy satellites of the outer solar system is the fact that most of these moons orbit synchronously. Their phase-locked nature means that one hemisphere (centered on 0° W) faces the planet at all times. The leading hemisphere is the side that faces the direction of motion of the satellite in its orbit and is centered on 90° W longitude, while the trailing hemisphere has a central longitude of 270° W. Ratios of spectra from the leading and trailing hemispheres are useful tools for studying hemispheric compositional variations, because processes such as plasma and micrometeoroid bombardment tend to affect primarily either the leading or the trailing hemispheres. In the Saturn system, many of the moons are affected primarily on one hemisphere by E-ring grain bombardment. These processes can induce absorptions as a result of ice regolith alteration, chemical and/or structural.

4.1. Galilean Satellites

The first in-depth UV studies of the Galilean satellites (Io, Europa, Ganymede, and Callisto) were accomplished with the use of the IUE satellite. Subsequent disk-integrated observations with the HST supported the initial findings of the IUE, in addition to adding to our knowledge of the composition of the surfaces of these satellites. Galileo studies contributed to disk-resolved studies of these bodies.

The high spatial resolution provided by Voyager and Galileo visible images shows that the Galilean satellites, particularly Io, are variegated in color on continental scales. Compositional information may be derived from high-spectral-resolution studies from Earth or near-Earth orbit because the satellite's synchronous rotation permits any given full-disk observation of a satellite to be associated with a uniquely defined hemisphere of that particular object. The extension of the available spectral range to shorter wavelengths with UV telescopes enhances this data set by permitting the identification of more absorption features, thereby providing further constraints on the compositional models that have been developed. (*See* Planetary Satellites.)

The corotating charged particles of Jupiter's magnetosphere have orbital speeds greater than those of the moons, so that the plasma sweeps by the moons impacting primarily the trailing sides. An in-depth study of several hundred IUE spectra of the Galilean satellites revealed significant hemispheric UV spectral asymmetries that are indicative of compositional variations.

Table 49.1 lists the geometric albedos of the Galilean satellites in three NUV wavelength bands, for the leading and trailing hemispheres. This table displays the significant hemispheric differences in brightness exhibited by these

TABLE 49.1 Ultraviolet Geometric Albedos of the Galilean Satellites

	260–270 nm	280–300 nm	300–320 nm
Io (leading)	0.015 ± 0.001	0.017 ± 0.001	0.042 ± 0.001
Io (trailing)	0.028 ± 0.002	0.030 ± 0.005	0.038 ± 0.003
Europa (leading)	0.213 ± 0.004	0.347 ± 0.010	0.407 ± 0.020
Europa (trailing)	0.118 ± 0.002	0.164 ± 0.004	0.222 ± 0.006
Ganymede (leading)	0.15 ± 0.007	0.190 ± 0.009	0.200 ± 0.001
Ganymede (trailing)	0.050 ± 0.003	0.060 ± 0.004	0.080 ± 0.008
Callisto (leading)	0.040 ± 0.008	0.049 ± 0.001	0.066 ± 0.002
Callisto (trailing)	0.056 ± 0.002	0.064 ± 0.002	0.105 ± 0.008

moons. Io's leading hemisphere is brighter than the trailing hemisphere only in the longest NUV wavelength band. Shortward of 300 nm, Io's trailing side has a higher albedo than its leading side, just the opposite of what is seen when Io is observed at visible wavelengths. (IUE's precursor, OAO-2, measured Io's albedo at 259 nm to be just 3%, in marked contrast to its 70% albedo at visible wavelength. This result was so unusual that it remained in doubt until IUE confirmed it by measuring Io's spectrum in this spectral range.) Io's reversal in brightness associated with orbital phase is more pronounced than for any other object in the solar system and proved to be important in efforts to determine the surface composition variation in longitude across Io's surface. It can be directly inferred from the Io data that there is a longitudinally asymmetric distribution of a spectrally active surface component on Io's surface. The material was determined to be sulfur dioxide (SO_2) frost, which strongly absorbs shortward of ~320 nm and is very reflective longward of that wavelength, as a result of IUE observations. Sulfur dioxide frost is in greatest abundance on the leading hemisphere of Io and is in least abundance on the trailing hemisphere. Figure 49.10 shows a Galileo UVS spectrum that displays Io's dramatic increase in albedo at wavelengths longer than 300 nm.

Europa and Ganymede exhibit a variation in brightness at NUV wavelengths with orbital phase that is in the same sense as the variation reported at the visible wavelengths; at all NUV wavelengths, these objects are brighter on their leading sides than on their trailing sides. A gradual decrease in albedo toward shorter wavelengths occurs on both hemispheres of both objects. The ratio of IUE spectra of Europa's trailing hemisphere to its leading hemisphere led to the discovery of an absorption feature present primarily on the trailing hemisphere centered around 280 nm.

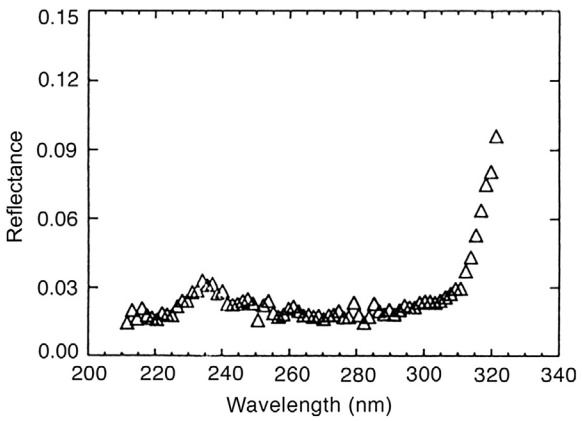

FIGURE 49.10 The NUV reflectance spectrum of Io, displaying the dramatic increase in brightness with wavelength starting at ~320 nm, due to the presence of SO_2 frost on the surface. This spectrum was measured by the Galileo UVS. The original discovery of SO_2 frost on the surface of Io in NUV spectra was made using IUE spectra. *Figure reproduced with permission from AAS Publications.*

The absorption feature, displayed in Figure 49.11(a), was attributed to an S−O bond and was suggested to be due to implantation of sulfur ions into the ice lattice on the trailing hemisphere. HST measurements confirmed the absorption feature, and it was suggested that the feature was similar to laboratory spectra of SO_2 frost layered on water ice. Subsequent disk-resolved Galileo UVS measurements showed that the 280-nm absorption feature is strongest in regions associated with visibly dark terrain. These locations have also been found to have relatively high concentrations of nonice material, interpreted to be hydrated sulfuric acid or hydrated salt minerals. An additional Galileo discovery was the presence of hydrogen peroxide (H_2O_2) on Europa, primarily in regions of lower nonice concentrations, such as on the leading hemisphere (Figure 49.11(b)). A study of Europa spectra from the early IUE era (1978−1984) compared to the late IUE era (1995−1996) suggested a temporal variation in Europa's leading and anti-Jovian hemisphere spectra that may be linked with variations in H_2O_2 abundances as a result of temporal variability in the space environment.

The IUE spectra of Ganymede's trailing hemisphere ratioed to the leading hemisphere revealed the presence of a possible absorption feature centered close to 260 nm, although the signal was approaching the IUE detection limits. It was suggested that ozone (O_3) in the ice could explain the apparent absorption feature. Subsequent HST measurements confirmed the presence of the O_3 absorption feature in the ice lattice on the trailing hemisphere. Disk-resolved observations of Ganymede from Galileo showed that the O_3 feature was strongest in the polar regions, and at large solar zenith angles, suggesting a connection with the magnetic field lines, or with photolysis or ice temperatures. Figure 49.11(c) displays the O_3 absorption feature as measured by the Galileo UVS.

Ground-based observations of Callisto have found that its albedo varies with **orbital phase angle** in the opposite sense to that of Europa and Ganymede (i.e. its trailing side has a higher albedo than its leading side). This is also true at NUV wavelengths. The albedo of Callisto decreases shortward of 550 nm and continues to decrease throughout the NUV. Its albedo at all wavelengths is lower than the albedos of Europa and Ganymede. Analysis of many of the IUE spectra, in addition to HST spectra, shows a broad, weak absorption at 280 nm similar to that seen on Europa (Figure 49.11(a)). These observations suggest the presence of SO_2 in a few leading hemisphere regions. The source of this SO_2 is not well understood and may be linked with implantation of neutral sulfur flowing outward from Io; disk-resolved measurements of Callisto from Galileo UVS do not exhibit the 280-nm absorption strongly. Rather, the Galileo observations indicate a different type of absorption at high latitudes, interpreted to be due to some type of organic species that is weathered away (carbonized) at

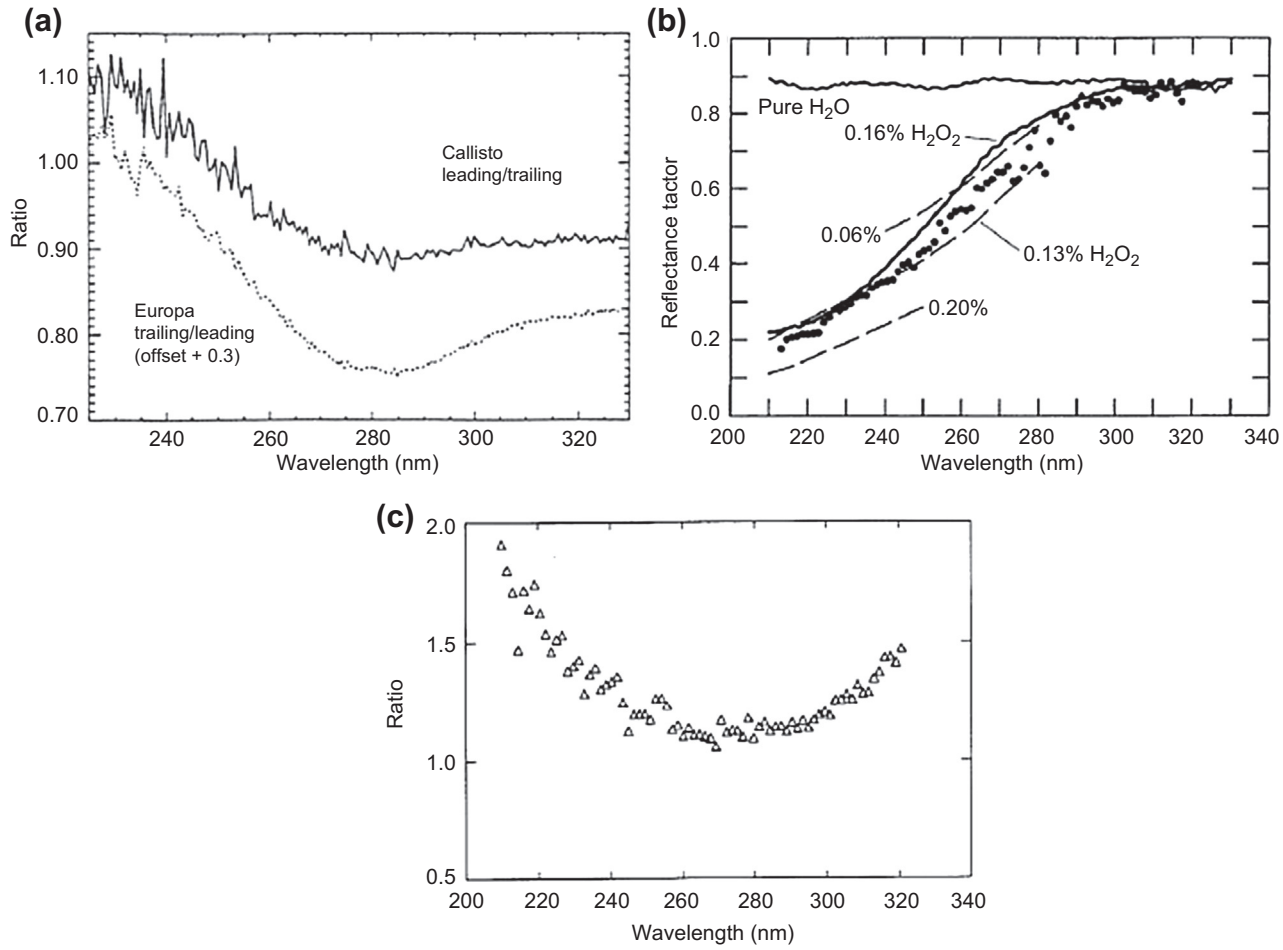

FIGURE 49.11 Spectra of significant absorption features on the icy Galilean satellites. (a) SO_2 absorption features on Europa and Callisto obtained by taking the ratio of the spectra of the trailing to leading hemisphere (Europa) and the spectra of the leading to trailing hemisphere (Callisto). (b) Hydrogen peroxide (H_2O_2) absorption feature as measured on Europa by the Galileo UVS. Also shown are mixture models for varying amounts of H_2O_2 in a water ice mixture, and the spectrum of pure H_2O ice. (c) Ozone (O_3) absorption feature as measured on Ganymede by Galileo UVS. Shown is the ratio of a spectrum from the north polar region to a region on the leading hemisphere. The broad absorption feature mimics O_3 in water ice. *Figures (a) and (c) reproduced with permission from AAS Publications. Figure (b) reproduced with permission from AAAS/Science.*

lower latitudes. The presence of CO_2 in the surface and in the atmosphere of Callisto and the dark nature of the surface suggest that carbon-based species are present across the surface associated with either endogenic or delivered organics. These organics experience chemical modification by UV radiation and are mixed into the regolith by meteoritic bombardment.

4.2. Saturnian Satellites

All of Saturn's large and medium-sized satellites, like the Galilean satellites and Earth's Moon, are in synchronous rotation (with the exception of Phoebe and Hyperion), and exogenic processes lead to hemispheric albedo dichotomies and absorptions in many wavelength ranges. At visual wavelengths, Tethys, Dione, and Rhea all have leading-side albedos that are 10–20% higher than their trailing-side albedos. The albedos of the satellites and their longitudinal asymmetries have been linked to the tenuous E-ring in which they all orbit, made up of fine-grained H_2O ice particles which tend to brighten the surfaces. IR observations of the large satellites of Saturn identified water ice as the principal absorbing species of the optically active surface of Mimas, Enceladus, Tethys, Dione, and Rhea and the trailing hemisphere of Iapetus.

Initial UV observations of the Saturnian satellites were made with IUE for Tethys, Dione, Rhea, and Iapetus. Mimas and Enceladus are too close to Saturn to obtain useful spectra from the Earth: the amount of scattered light from Saturn is too great to be overcome by IUE. Later UV observations of the satellites, including Enceladus, were made by the HST.

More recently, the Cassini UVIS has made numerous observations of the Saturnian satellites, providing clues to

their surfaces and processes. In particular, UVIS has performed critical stellar and solar occultations of the Enceladus plume, contributing to the discovery of the amazing activity, and monitoring its vapor output.

The UV geometric albedos for the Saturnian satellites were calculated for three near-UV bandpasses using a combination of IUE and HST data and for a far-UV bandpass using Cassini UVIS data. These are shown in Table 49.2. The NUV albedos were determined using photometric corrections considering Voyager geometric albedos at 350 nm.

The near-UV albedos of the leading hemisphere of Enceladus and Tethys are the highest of the Saturnian satellites and are comparable to the high visual albedo reported by Voyager and ground-based visual observations. Tethys' trailing hemisphere is more absorbing with decreasing wavelength than the leading hemisphere throughout the UV region, whereas little difference was seen at visible wavelengths in the Voyager data set. The leading side of Dione is nearly two times brighter than its trailing side, a greater difference than the brightness variation reported from ground-based and Voyager visual wavelength observations. These hemispheric differences in UV albedo signal the presence of a UV absorber focused on the trailing hemisphere of Tethys and Dione. The leading side of Rhea is ∼30% brighter than its trailing side at NUV wavelengths, similar to what is measured at visual wavelengths. All these satellites exhibit a strong absorption in the NUV wavelength, particularly in the region between ∼190 and ∼250 nm, a spectral region that has not been well studied. Ammonia, which absorbs strongly near 210 nm, could contribute to this absorption, particularly on Enceladus; H_2O_2 (Figure 49.11(b)) is another good candidate. Cassini measurements have not yet zeroed in on the precise nature of this nonice species; other candidates include some type of tholin or carbonaceous material, or perhaps a small amount of iron and/or hematite. Because Dione and Rhea have lower visual albedos than the other satellites, their NUV absorption is not as strong and could signal the presence of one of these latter species, which are also relatively dark in the visible.

The hemispheric albedo asymmetry of Iapetus at visual wavelengths is extremely large (the trailing side is brighter by a factor of five). The leading (dark) hemisphere of Iapetus does not show spectral features consistent with water ice and has an IR spectrum that is nearly featureless. In the case of the dark hemisphere of Iapetus, the source of the darkening material is primarily the moon Phoebe, dust from which forms a giant, tenuous ring surrounding the Saturn system. In the UV wavelength, as in the visual, the leading side of Iapetus is extremely absorbing, and the trailing side albedo is comparable to that of other Saturnian satellites. The leading-side albedo is almost six times lower than the trailing side albedo at the IUE wavelengths, somewhat more than the five times darker than reported at visual wavelengths. The spectral absorber that darkens the leading hemisphere of Iapetus is more absorbing toward shorter wavelengths. Thermal segregation in addition to the Phoebe dust is a critical component in the production of Iapetus' dramatic hemispheric albedo dichotomy.

HST observations of Dione and Rhea (Figures 49.12(a) and 49.12(b)) detected a broad absorption centered around 260 nm. Like Ganymede, the feature has been attributed to the presence of ozone on both satellites. Ozone on these satellites is likely a product of radiolysis, from magnetospheric plasma bombardment.

With the arrival of the Cassini spacecraft at the Saturn system, FUV measurements of the icy satellites have been made with the UVIS. The FUV spectra of the icy satellites are dominated by the strong water absorption feature

TABLE 49.2 Ultraviolet Geometric Albedos of the Saturnian Satellites

	175–185 nm	240–270 nm	280–300 nm	300–320 nm
Enceladus	0.35 ± 0.05	0.95 ± 0.05	1.0 ± 0.05	1.05 ± 0.05
Tethys (leading)	0.29 ± 0.02	0.58 ± 0.02	0.6 ± 0.05	0.67 ± 0.05
Tethys (trailing)	0.18 ± 0.02	0.42 ± 0.02	0.48 ± 0.03	0.55 ± 0.05
Dione (leading)	0.21 ± 0.01	0.46 ± 0.05	0.49 ± 0.03	0.52 ± 0.03
Dione (trailing)	0.13 ± 0.01	0.22 ± 0.05	0.25 ± 0.05	0.29 ± 0.04
Rhea (leading)	0.21 ± 0.01	0.41 ± 0.05	0.44 ± 0.03	0.48 ± 0.03

Figure (b) reproduced with permission from Nature Publishing Group.*

at ~165 nm. At wavelengths shortward of ~165 nm, the icy satellites are extremely dark due to the presence of water ice, and in fact are darker than the surrounding interplanetary hydrogen (IPH). Cassini UVIS images of the icy satellites therefore reveal both the dayside and nightside of the icy satellites. Figure 49.13(a) displays the FUV reflectance spectrum of Phoebe, one of the outermost satellites of Saturn and Figure 49.13(b) shows the FUV image of Phoebe; the visible wavelength image is shown in Figure 49.13(c) for comparison.

Cassini observations of Mimas have revealed a "lens"-shaped region at the low latitudes of the leading hemisphere which is bright at NUV wavelengths (338 nm, as measured by the imaging system). This region also exhibits different thermal inertia than the surrounding regions, likely due to bombardment by energetic electrons in this region. The energetic electrons do not appear to affect the FUV spectrum as much as the NUV spectrum, perhaps because of their penetration depth; UVIS measures only a hint of their effects. Instead, UVIS detects the seasonal effects of photolysis—at Mimas and Tethys—which likely produces H_2O_2 at the uppermost layers of the icy regoliths. Hydrogen peroxide is readily produced via photolysis, which is consistent with the UVIS-measured FUV darkening of the summer hemispheres of these moons.

4.3. Enceladus

Enceladus, not easily observed from the Earth's orbit due to its proximity to Saturn and the rings, has recently been the target of key UV measurements from the Cassini spacecraft in orbit around Saturn. Enceladus has long intrigued scientists because it is the brightest object in the solar system; Voyager images revealed vast regions that were evidently crater free, suggesting recent resurfacing by geologic activity. Furthermore, its orbit at the densest part of the broad, tenuous E-ring has suggested that Enceladus could somehow be the source of the E-ring ice particles.

UV measurements from the HST detected the hydroxyl radical, OH, in emission (308.5 nm) in the Saturn system, primarily near the orbit of Tethys. Similarly, Cassini UVIS measured neutral oxygen (at 130.4 nm), in varying amounts, with the greatest abundances near the orbit of Enceladus.

The presence of OH and O suggested that H_2O is produced by erosion of the inner icy satellites of Saturn by micrometeoroid bombardment and is then broken down by photodissociation to produce the neutral species. However, the amounts of H_2O necessary to produce the observed OH and O abundances were not consistent with sputtering rates; an additional source of H_2O was needed—and this remained a mystery until Cassini observations of Enceladus in 2005.

The Cassini spacecraft, through synergistic multi-instrument observations, discovered active water plumes on Enceladus. A stellar occultation by Cassini UVIS measured the presence of water vapor above the limb of the South Pole. Similar UV occultations of other regions of the moon had found no evidence of any gases, indicating that the vapor was locally confined to the South Pole. Surface temperatures, measured by the far-IR

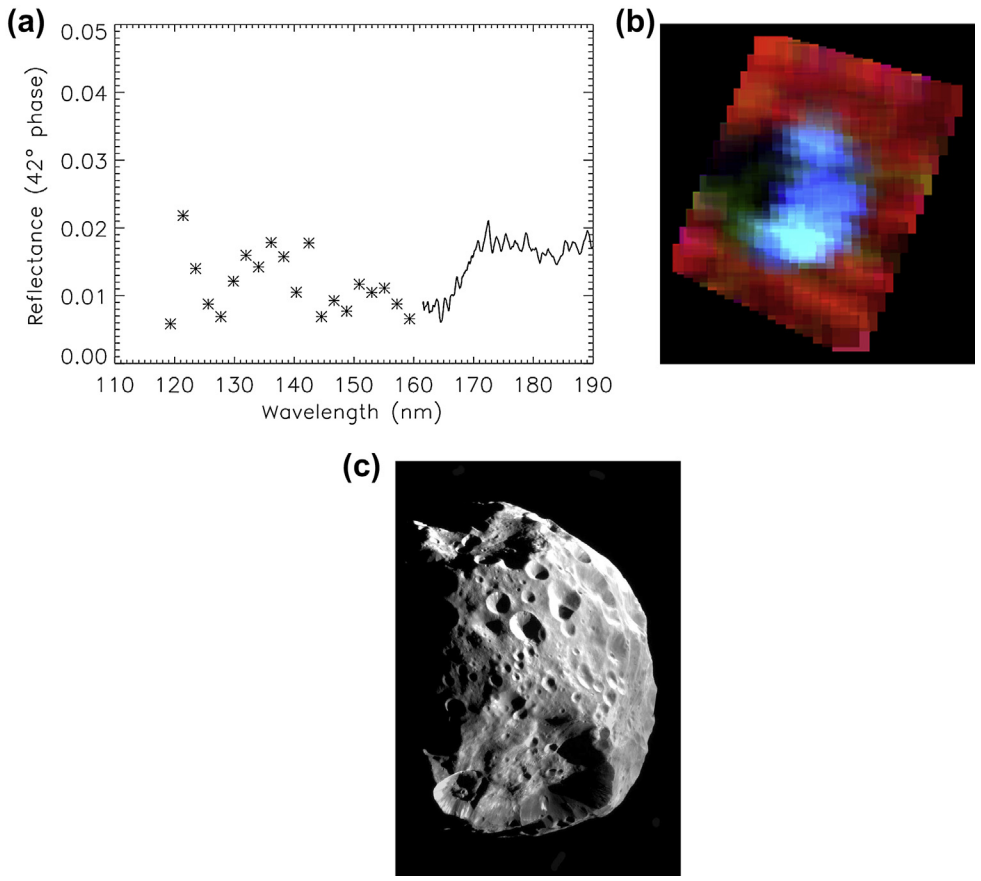

FIGURE 49.13 Saturn's moon Phoebe as measured by the Cassini UVIS. (a) Phoebe's FUV spectral reflectance measured at 42° *solar phase angle*. (b) FUV wavelength image of Phoebe. Red represents 1216 Å where IPH is bright throughout the solar system. Phoebe's water ice makes it darker than the background IPH on both the illuminated and the dark hemispheres so that the entire disk is visible. Blue colors represent longer FUV wavelengths and show that the brightness varies across Phoebe's surface due to solar incidence, topography, and compositional variations. (c) Visible wavelength image of Phoebe from Cassini. *Figures (a), (b), and (c) reproduced with permission from AAAS/Science; ISS image courtesy of NASA.*

spectrometer, were found to be anomalously high; measurements by the magnetometer, mass spectrometer, dust detector, and near-IR spectrometer on Cassini confirmed the presence of gaseous species and expulsion of ice grains from Enceladus' south polar hot spot. It is surprising that such a small, icy body is currently geologically active! The cause of the south polar hot spot and associated plumes is under investigation, and Enceladus remains a primary observational target of the Cassini mission.

4.4. Uranian Satellites

The five major satellites of Uranus—Miranda, Ariel, Umbriel, Titania, and Oberon—are a suite of icy satellites that are situated at about the limit at which the IUE was able to confidently return spectral information. They are so faint that it is not even possible to divide the IUE wavelength range into several bands, as was done with the Jovian and Saturnian satellites. All the spectral information is integrated into one wavelength range, and a geometric albedo can be determined.

The Uranian satellites are in an orbital plane that is parallel to the Uranian equator, and the pole of Uranus' orbit is tilted such that, at the present time, it is pointed toward the Earth. Therefore, only the poles of one hemisphere of the satellites of Uranus are observable with the IUE, and hence it is not possible to construct orbital phase curves and leading/trailing side ratio spectra.

IUE was able to observe Oberon, Uranus's brightest satellite. The IUE result proved to be an important and independent confirmation of results from the Voyager 2 photopolarimeter experiment. The UV geometric albedo of Oberon was found to be 0.19−0.025, an excellent confirmation of the earlier Voyager 2 PPS result of 0.17.

Spectra from 220 to 480 nm were obtained with the HST FOC for the Uranian satellites Ariel, Titania, and Oberon. The inner Uranian satellites Miranda and Puck were also observed from 250 to 800 nm with the HST FOC. The geometric albedos for Ariel, Titania, and Oberon

display a broad, weak absorption at 280 nm, similar to the feature seen on Europa. Although this absorption feature on the Galilean satellites has been attributed to SO_2, it has been attributed to OH on the Uranian satellites. Both SO_2 and OH produce an absorption feature near 280 nm; however, the molecule OH (a by-product of the photolysis and radiolysis of water) is unstable at the surface temperatures of the Galilean satellites but is stable at the colder surface temperatures of the Uranian satellites. The 260-nm ozone feature seen on Ganymede, Dione, and Rhea has not been detected in any of the Uranian satellite spectra.

4.5. A Comparison of Icy Satellite Systems

The UV observations of planetary satellites can be integrated with the results of observations at longer wavelengths to provide a comparative assessment of the families of large planetary satellites in the solar system. The IUE- and HST-determined photometric properties of the larger planetary satellites of Jupiter, Saturn, and Uranus are shown in Figure 49.14 as a plot of UV-to-IR color ratio versus UV geometric albedo. The geometric albedos of the Saturnian satellites indicate that in this system there is a wide variation in UV geometric albedo. The Galilean and Uranian satellites have photometric properties that are common within each group. This is consistent with the hypothesis that the surface modification processes that have occurred are similar within the Galilean and Uranian satellite systems, but the two systems have surface modification processes that are distinct from each other. The diverse nature of the photometric properties of the Saturnian satellites suggests that multiple surface modification processes are altering the surfaces of the satellites. Certainly coating/bombardment by E-ring grains, an ongoing process, effectively keeps the optical surface of the Saturnian satellites young and unweathered; this is particularly important for Mimas, Enceladus, and Tethys.

In general, the NUV spectra of icy satellites are dominated by weathering products. Radiolysis and photolysis are extremely important processes at the surfaces of these satellites, and products of these processes are apparent at NUV wavelengths. This is evidenced by the presence of SO_2, O_3, and H_2O_2 in the surfaces of the icy Galilean satellites (and O_3 in the surfaces of some of the icy Saturnian satellites). The icy Galilean satellites are all relatively dark at UV wavelengths. However, water ice, the primary constituent of these surfaces, is bright in the NUV wavelengths. Therefore, another material must be responsible for the UV absorption of the icy Galilean satellites. The most likely darkening agents are elemental sulfur and sulfur-bearing compounds originating from the very young and active surface of Io, which are transported as ions outward from Io's orbit by Jovian magnetospheric processes. These energetic ions and neutrals interact with the icy surfaces of Europa, Ganymede, and Callisto and cause the ices to become darkened at UV wavelengths. This process competes with other processes of surface modification such as infall of interplanetary debris.

In contrast to Jupiter's UV-dark icy satellites, Saturn's icy satellites, particularly those orbiting closer to Saturn, are relatively bright. This is likely related to the presence of the large and tenuous E-ring. Mimas, Enceladus, Tethys, Dione, and Rhea all orbit Saturn within this broad ring of tiny icy grains. The relative velocities between the E-ring particles and the icy satellites explains the overall visual

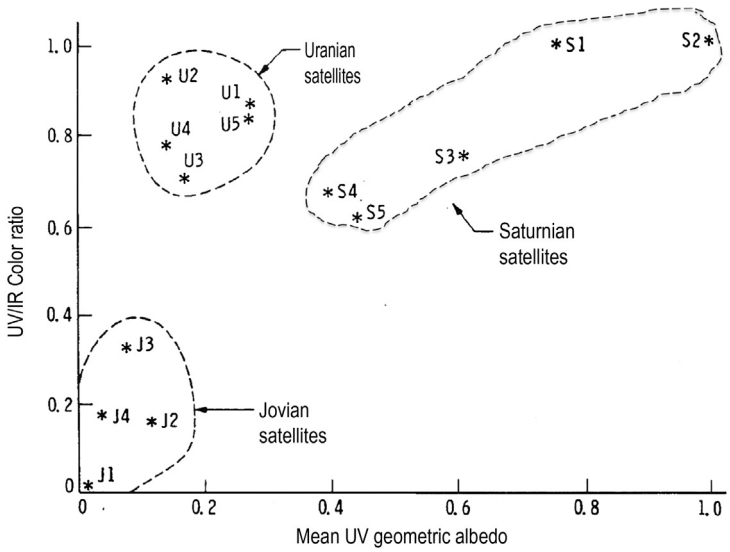

FIGURE 49.14 Comparisons of geometric albedos of the Galilean, Saturnian, and Uranian satellites. (Satellites are numbered such that the closest to the planet is #1; e.g. Io = J_1.) For the Galilean satellites and for Enceladus, Dione, Rhea, and Tethys, the UV albedos are from the IUE and HST. For Mimas, the UV albedo is from Voyager images (350 nm). The IR albedos of the Galilean and Saturnian satellites are from ground-based spectrophotometry. All the Uranian satellite data are from the Voyager photopolarimeter. With the exception of the slight difference in wavelength for Mimas noted previously, all the wavelength ranges are similar. Jovian and Uranian satellites each have distinct color ratios that distinguish the two groups of satellites from each other. The Saturnian satellites have little albedo similarity among themselves. This is consistent with the hypothesis that the surfaces of all the icy Galilean satellites are being modified by a common process. Likewise, the Uranian satellite surfaces may also have a common process of surface modification that is different from the Jovian system. The Saturnian satellite system may have multiple surface modification processes occurring.

brightness, as well as the large-scale longitudinal albedo patterns of the icy satellites. Mimas and Enceladus are both slightly darker on the leading hemispheres than on the trailing hemispheres, likely because the E-ring particles sweep by the trailing hemispheres, brightening them. The leading hemispheres of Tethys and Dione are brighter than the trailing hemispheres because their leading hemispheres sweep by the E-ring particles. Furthermore, Saturn's magnetosphere is different from Jupiter's and appears to be dominated by neutrals rather than by electrons and other charged particles. This difference may have an effect on the ice chemistry that occurs within the surfaces of the icy satellites because much of the ice chemistry occurring on the icy Galilean satellites is the result of charged particle bombardment.

4.6. Pluto and Charon

The first spatially resolvable images of Pluto and its satellite Charon were obtained by the HST FOC at visible (410 nm) and UV (278 nm) bandpasses. The image resolution is sufficient to show the presence of large, longitudinally asymmetric polar cap regions in addition to a variety of albedo markings. The combination of UV and visible images were used to look for regions of clean ice and nonclean (contaminated) ice—either radiation-darkened sites or sites where atmospheric chemistry products were deposited. No positive identification of solids on the surfaces of Pluto and Charon has been made at UV wavelengths. The cleanest ice (bright in UV and VIS bandpasses) was found in a location at the equator, although overall the equator was found to be heavier in contaminated ice than midlatitudes. The north polar region was found to have the cleanest ice.

4.7. Asteroids and Comets

At UV wavelengths, asteroids have been studied by the IUE and HST from Earth-based orbit. The Galileo spacecraft obtained NUV spectra of Ida and Gaspra during its travels through the asteroid belt, and the *Rosetta* Alice instrument studied Lutetia and Steins in the FUV wavelengths. Finally, the Mariner 9 UVS obtained spectra of Phobos and Deimos, the Martian moons that are likely captured asteroids.

The IUE satellite obtained UV observations of ~45 main belt asteroids in the wavelength range between 230 and 325 nm. The geometric albedos for these objects are consistently low, and three major asteroid taxonomic classes seen in the visible persist into the UV. Analysis of the IUE asteroid data shows that the asteroids observed have UV albedos that range from 0.02 for C-class asteroids to 0.08 for M-class asteroids; albedos of S-class asteroids are intermediate. Analysis of a set of IUE Vesta observations covering more than one rotation of Vesta indicates that this unusual asteroid displays UV albedo variations across the surface such that the UV light curve of Vesta is opposite that of the visible light curve. Such a spectral reversal is consistent with a hemispheric dichotomy in composition and/or a variation in geologic age (due to space weathering) across the surface. A study of IUE measurements of S-class asteroids has found that the UV spectral slope may be an important indicator of space weathering and ultimately exposure age; the strong decrease in albedo that is typical in silicates at NUV wavelengths decreases in strength with exposure, consistent with production of nanophase iron via weathering. Measurements at visible–IR wavelengths suggested the presence of hydrated minerals on Ceres; a search for OH (emissions at ~ 308.5 nm) in IUE spectra, however, found none. HST FOC, and more recently ACS, images of Ceres at UV wavelengths were the first well-resolved images of this largest asteroid. Albedo variations are detectable across the surface. The brightness of the surface in the FUV may rule out the presence of a large amount of water ice; a deep absorption band with a central wavelength of 280 nm appears be present but its cause is unidentified. Analysis of Mariner 9 UVS spectra of Phobos and Deimos show these bodies to be spectrally similar to carbonaceous chondrites. However, analysis of HST FOS data of these moons at UV–visible wavelengths, compared with FOS spectra of a C-type and a D-type asteroid, showed the Martian moons to be more similar to the D-type asteroid than to the C-type asteroid.

Both HST and IUE observed the Centaur asteroid 2060 Chiron, a possible former resident of the Kuiper Belt. Neither instrument detected emission from gaseous species at UV wavelengths, in contrast to CN emissions that have been reported at visible wavelengths. The UV albedo of Chiron is similar to that of some of the Saturnian and Uranian satellites. In particular, Chiron's UV/IR color and UV albedo are very similar to those of Dione. (*See* Kuiper Belt Objects: Physical Studies.)

Observations of comets at UV wavelengths are extremely useful for measuring fluorescence of solar photons by important atomic and molecular species, and thereby studying relative abundances of the vaporizing species and probing the photochemical and physical processes acting in the densest regions of the coma. UV observations of comets were first accomplished by sounding rockets and the *OAO* satellite prior to the launch of the IUE. These observations established the emission of hydroxyl ion at near the limit of ground-based observations, 308.5 nm. This is consistent with a cometary composition dominated by water ice; the hydroxyl ion is a product of exposure to solar radiation.

The IUE observed more than 50 comets (~400 individual spectra). IUE's photometric constancy provided the ability to compare observations of comets that appeared

several years apart. Those observed range from short-period comets with aphelion near Jupiter to long-period comets that may be first-time visitors to our solar system.

All the comets observed by the IUE have displayed the 308.5-nm hydroxyl line, which is consistent with water ice being a major part of comet composition. Although all comets appear to have similar principal compositional components (water), each has different amounts of trace components, including carbon dioxide, ammonia, and methane, detected by the IUE and HST. Gas production rates have been derived for species such as H_2O, CS_2, and NH_3. Several comets that were observed over a long time exhibited differences in their dust-to-gas ratios from one observation to the next, consistent with a variation as a function of heliocentric distance.

The first detection of diatomic elemental sulfur in a comet was seen in comet IRAS-Araki-Alcock. The lifetime of the diatomic sulfur in the cometary atmosphere is quite short ($\sim$500 s). This makes sulfur a useful tracer of the dynamics of the tenuous cometary atmosphere, which appears during the short time that the comet is near the Sun. Analysis of the S I triplet emission band near 181.4 nm in cometary comae spectra taken with the IUE and the HST FOS shows that cometary sulfur, which is present and stored in a variety of volatile species, is depleted in abundance compared to solar abundances. The detection of CS at UV wavelengths in comae is attributed to the presence of CS_2 in the comet. Sulfur detected in the comae in excess of the sulfur attributable to CS_2 is assumed to originate from H_2S and nuclear atomic sulfur in the comet. Using this assumption, models have been used to measure total sulfur versus water abundances, which range between $\sim$0.001 and $\sim$0.01. (*See* Physics And Chemistry Of Comets.)

UV observations using the IUE, HST, and FUSE have also detected UV CO Cameron band emissions from comets, which is useful for measuring the CO_2 production rate. This rate derived from IUE observations of comet 1P/Halley agrees with the rate measured in situ by the spacecraft *Giotto*. These HST and IUE observations suggest that the level of activity of a comet may be linked to its CO abundance; however, this is based on a small sample of the comet population. FUSE measurements of C/2001 A2 (LINEAR) displayed H_2 emission lines of the Lyman system at 107.2, 111.9, and 116.7 nm, in addition to CO features that suggested both a hot and a cold component of CO, the hot component likely being due to excitation of CO_2 and the cold component being attributed to fluorescent scattering of CO or to electron impact excitation of CO.

4.8. The Moon and Mercury

The first UV observations of the Moon were made at FUV wavelengths using the instrument aboard the Apollo 17 orbiter. It was noted in these measurements that the lunar maria regions, darker than the highlands at visible wavelengths, are brighter than the highlands in the FUV. This was the first indication of the so-called spectral reversal, which was also detected at EUV wavelengths using measurements by the EUVE. This phenomenon is attributed to the concept that FUV measurements probe just the outer layers of the grains (surface scattering, as opposed to volume scattering measured at longer wavelengths), and that space weathering processes may cause the lunar grains to be covered with a fine coating. Lunar samples measured in the laboratory support this idea: lunar soils (presumably more weathered) show spectral reversal, while ground-up lunar rocks (presumably less weathered) do not. Galileo UVS measurements in the NUV showed that the maria are darker than the highlands and that the spectral reversal must occur at a wavelength shorter than $\sim$220 nm. The HUT measurement of the lunar surface (a region near Flammarion-C, a border area between mare and highlands) at FUV wavelengths indicated an albedo of $\sim$4% with a slight increase in brightness toward shorter wavelengths. Because of the different spectral behavior at UV versus visible wavelengths, ratio images of UV to visible color images and visible reflectance spectra are used to map spectral trends related to opaque mineral abundance and the combined effects of FeO content and soil maturity. From the *Apollo* samples, it is known that the dominant opaque mineral is ilmenite, which is high in Ti content. Thus, UV/visible ratio images have been used to map Ti content variation in the lunar mare basalts.

More recently, the LRO LAMP has been mapping the Moon at FUV wavelengths. Hints of water frost in the polar PSRs have been found, as has dayside hydration, which varies in abundance with latitude and throughout the day. The hydration appears to be consistent with solar wind-produced H_2O which diffuses through the lunar regolith at warmer temperatures.

The Mariner 10 spacecraft carried a color imager that included a NUV filter (355 nm). Mercury image ratios (UV/visible) have been used to map spectral trends associated with geologic features, using similar methods as used on lunar images. A lower UV/visible ratio suggests more FeO, or more mature soil. Spectrally neutral opaque minerals (such as ilmenite) tend to lead to a higher UV/visible ratio. Mercurian regions believed to be volcanic in origin have been found to have FeO amounts slightly less than average, consistent with ancient lava flows.

4.9. Planetary Rings

The rings of Saturn were successfully observed by the IUE in a series of observations between 1982 and 1985. The spectrum of the rings in the 160–310 nm range is dominated by the water ice absorption edge at $\sim$165 nm. More recently, Cassini UVIS has made higher resolution

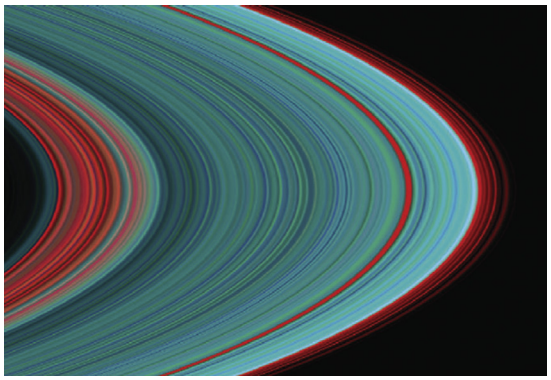

FIGURE 49.15 Saturn's rings as imaged by Cassini UVIS. This false color two-dimensional representation of Saturn's Cassini Division and A ring was generated from UVIS data obtained during a radial scan of the rings immediately after Saturn Orbit Insertion as Cassini flew over the rings. To generate the image, azimuthal symmetry was assumed. Although there are azimuthal variations in the structure of the rings, they are smaller than the 100-km resolution of this image. Red represents Lyman-alpha emission from IPH (121.6 nm) and shines through gaps and optically thin parts of the ring. Green and blue represent reflection of solar UV light longward of the water ice absorption edge near 165 nm. *Figure courtesy J. Colwell.*

observations of Saturn's rings; an image is shown in Figure 49.15. This image shows a combination of the UV reflectance and transmission of the ring system. The red-colored region at the left is the Cassini Division with a mean opacity of about 0.1, and the thin bright band near the outer edge of the rings is the 300-km-wide Encke gap. Brighter blue–green regions indicate cleaner water ice (less absorption by nonice species). The A-ring material is cleaner than the Cassini Division and the abundance of water ice is seen to increase near the outer edge of the A ring.

Cassini UVIS also utilizes UV stellar occultations to provide high-resolution profiles of the structure of Saturn's rings in three dimensions. (*See* Planetary rings.)

5. CONCLUSIONS

The importance of UV solar system science has been exhibited through discoveries and continuing studies spanning the topics of atmospheric and auroral science, surface composition and space weathering. UV observations of solar system surfaces and atmospheres have been made possible by the IUE and HST orbiting telescopes, along with FUSE, HUT, and EUVE, and have been substantially complemented by interplanetary missions such as Voyager, Mariner, Galileo, Cassini, LRO and New Horizons. The IUE spacecraft provided the astronomical community with the first stable long-term (spanning nearly two decades) observing platform in space, from which astronomers have been able to study regions of the spectrum that are inaccessible from telescopes on the Earth's surface. This foundation, with the support of UV spectrometers incorporated into the payloads of deep space missions, filled an observational void that had existed since the dawn of astronomy. These observations have led to important new discoveries and have provided tests of physical models that have been developed based on ground-based observations. IUE's observing capability was surpassed by HST, which has provided the astronomical community with the opportunity to look at fainter and more distant solar system objects and has led to new discoveries in the UV spectrum. The future of Earth-based orbiting UV telescopes is unclear, but such UV instruments, with ever-improving spectroscopic and imaging capabilities, are vital to understanding solar system objects and complementing longer wavelength observations.

Since 1983, a series of telescopes operating in the thermal infrared have been launched into Earth orbit and now heliocentric orbit. The images and other data returned have resulted in the discovery of new phenomena in the solar system and a new perspective on the processes within it. These observations have focused on comets, asteroids, and interplanetary dust, because until the launch of European Space Agency's (ESA's) Herschel Space Observatory, the major planets and Earth's Moon were too bright to be observed, overwhelming the detectors.

1. INTRODUCTION

At night we see objects in the solar system by the sunlight they reflect. The Moon, planets, comets and (with the help of telescopes) asteroids, and distant Kuiper Belt Objects are visible to the extent that they efficiently reflect that light, coupled with their apparent size. Small particles and dust are basically invisible with the exception of the zodiacal light, seen before sunrise and after sunset at certain times of the year, and the interplanetary particles that give off light as they burn up as meteors in the Earth's upper atmosphere. At thermal wavelengths, the sky is dramatically different (Figure 50.1). The otherwise invisible dust now dominates the view and "familiar" phenomena like comets have a very different appearance that has changed our understanding of their nature.

At thermal wavelengths, we are looking at the objects themselves as sources of light, instead of reflected light from another source like the Sun. All objects in the universe radiate heat. The energy distribution of this radiation with wavelength is a function of the temperature of the source. The Sun, at a temperature of more than 5000 K, radiates primarily at visual wavelengths and appears yellow. Colder sources radiate at longer wavelengths. Thus, the heating element of an electric stove appears orange-red.

Objects in space (e.g. asteroids, comets, and planets) also radiate, but at wavelengths much longer than can be detected by the human eye. This region of the spectrum (generally beyond 5 μm to the submillimeter) is referred to as the thermal infrared. Analysis of the thermal radiation from an object can tell us much about its composition and other physical properties including thermal inertia and grain size distribution and characteristics.

Observing this radiation from ground-based telescopes is complicated by thermal emission from the telescope itself and the atmosphere, both of which are much brighter than the astrophysical sources being observed. This has been compared to observing a star in the daytime with the telescope on fire.

Techniques that allowed objects within tiny patches of sky to be observed by ground-based and aircraft-borne telescopes were developed. Somewhat larger strips of the sky were observed by small-aperture, rocket-borne

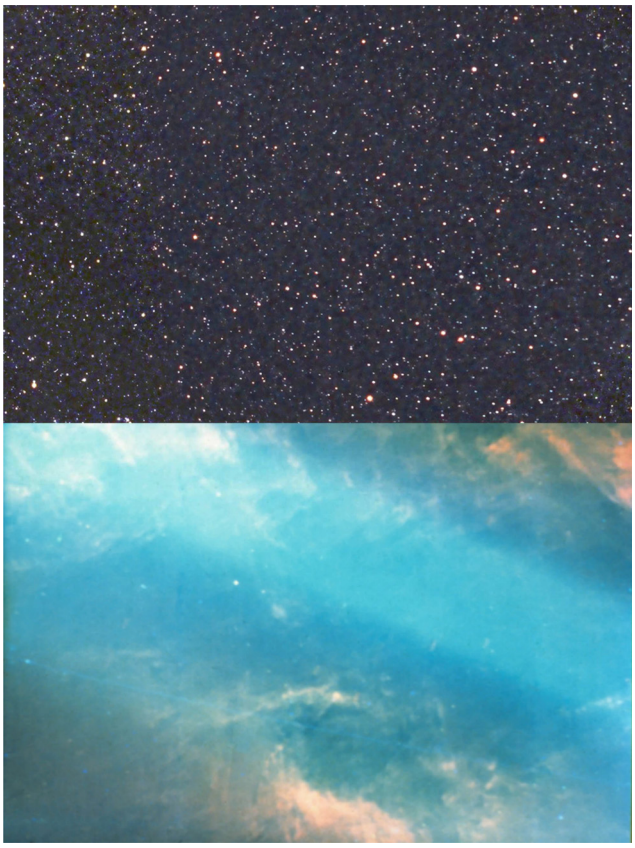

FIGURE 50.1 At wavelengths visible to the human eye, the night sky (above) is dominated by black space and pointlike stars. From space, in the thermal infrared the same area of sky (below) is dominated by clouds of interstellar dust and extended solar system structures. Both images span $30^\circ \times 20^\circ$ near the First Point of Ares. The false-color thermal image was constructed from scans made by the Infrared Astronomical Satellite. Interstellar dust, known as "cirrus" is cold (indicated by red). Warm (blue) interplanetary dust reveals rings of dust around the solar system arising from asteroid collisions (one of which is seen as the broad band extending diagonally across the top of the image), and long contrail-like structures consisting of cometary debris (one is seen below the band). *Source (above): A. Mellinger.*

telescopes with tantalizing results. Only by getting above the atmosphere with a cooled telescope would it be possible to study the sky on a large scale at these wavelengths. This was achieved on January 26, 1983, with the launch of the Infrared Astronomical Satellite (IRAS), a joint project of the United States, the United Kingdom, and the Netherlands. It was the first in a series of space-based infrared telescopes, the latest of which include the National Aeronautics and Space Administration (NASA) Spitzer Space Telescope and NASA Wide-field Infrared Survey Explorer (WISE) (Figure 50.2).

These telescopes and their detectors were cryogenically cooled to minimize the noise introduced by the telescope and detectors themselves. In general, their operating temperatures need to be well below that of the sources they wish to observe. For solar system objects, this means well below 20 K to study the Kuiper Belt and beyond (Figure 50.3). This is accomplished by carrying a reservoir of liquid helium (having a temperature between a fraction of a degree and several degrees Kelvin) or solid hydrogen, both of which have a finite lifetime before it is expended. At that point, the telescope and detectors warm up and loose their sensitivity, although more recent facilities, Spitzer and WISE, have continued to provide useful data in their postcryogenic states.

Since the launch of IRAS, infrared detectors have become increasingly sensitive, thus able to study fainter and fainter sources. At the same time, the different spacecraft have operated in different modes in order to focus on different science questions. IRAS was primarily a survey instrument, mapping out the complete celestial sphere almost three times. Since the sky had not been mapped at thermal wavelengths, this was a mission of discovery. The NASA Cosmic Background Explorer (COBE) was also a survey instrument, with the primary goal of understanding the distribution of the cosmic background radiation from the Big Bang. One of its instruments, the Diffuse Infrared Background Experiment operated at thermal and near-infrared wavelengths at lower spatial resolution than IRAS. The ESA Infrared Space Observatory (ISO) and US Ballistic Missile Defense Organization Midcourse Space Experiment (MSX) were primarily pointing instruments, designed to measure specific targets or map out small regions of the sky in detail. Spitzer is also primarily a pointing and small-area mapping instrument. The Japan Aerospace Exploration Agency's (JAXA) Akari spent a portion of its mission generating the first thermal map of the sky since IRAS and COBE, and spent the remainder of its time conducting pointed observations. ESA's Herschel was primarily a pointing instrument, functioning at longer, submillimeter wavelengths. Finally, the WISE telescope was the first telescope to fundamentally reproduce the original IRAS survey for point sources. Even though all these missions were designed to address primarily astrophysical questions, they have been a great boon to our understanding of solar system phenomena.

2. THE ZODIACAL DUST CLOUD AND ITS SOURCES

When we think of the solar system, the image that often comes to mind is the textbook picture of planets orbiting the Sun on concentric orbits, asteroids between Mars and Jupiter, and the occasional comet flying by. However, in the inner solar system we are immersed in a cloud of dust that we see sometimes on the horizon as the zodiacal light (Figure 50.4) and sometimes in the direction opposite the Sun as the gegenschein. (*See* Solar System Dust.)

The zodiacal light is caused by the scattering of sunlight off of small particles near the Earth's orbit viewed when the

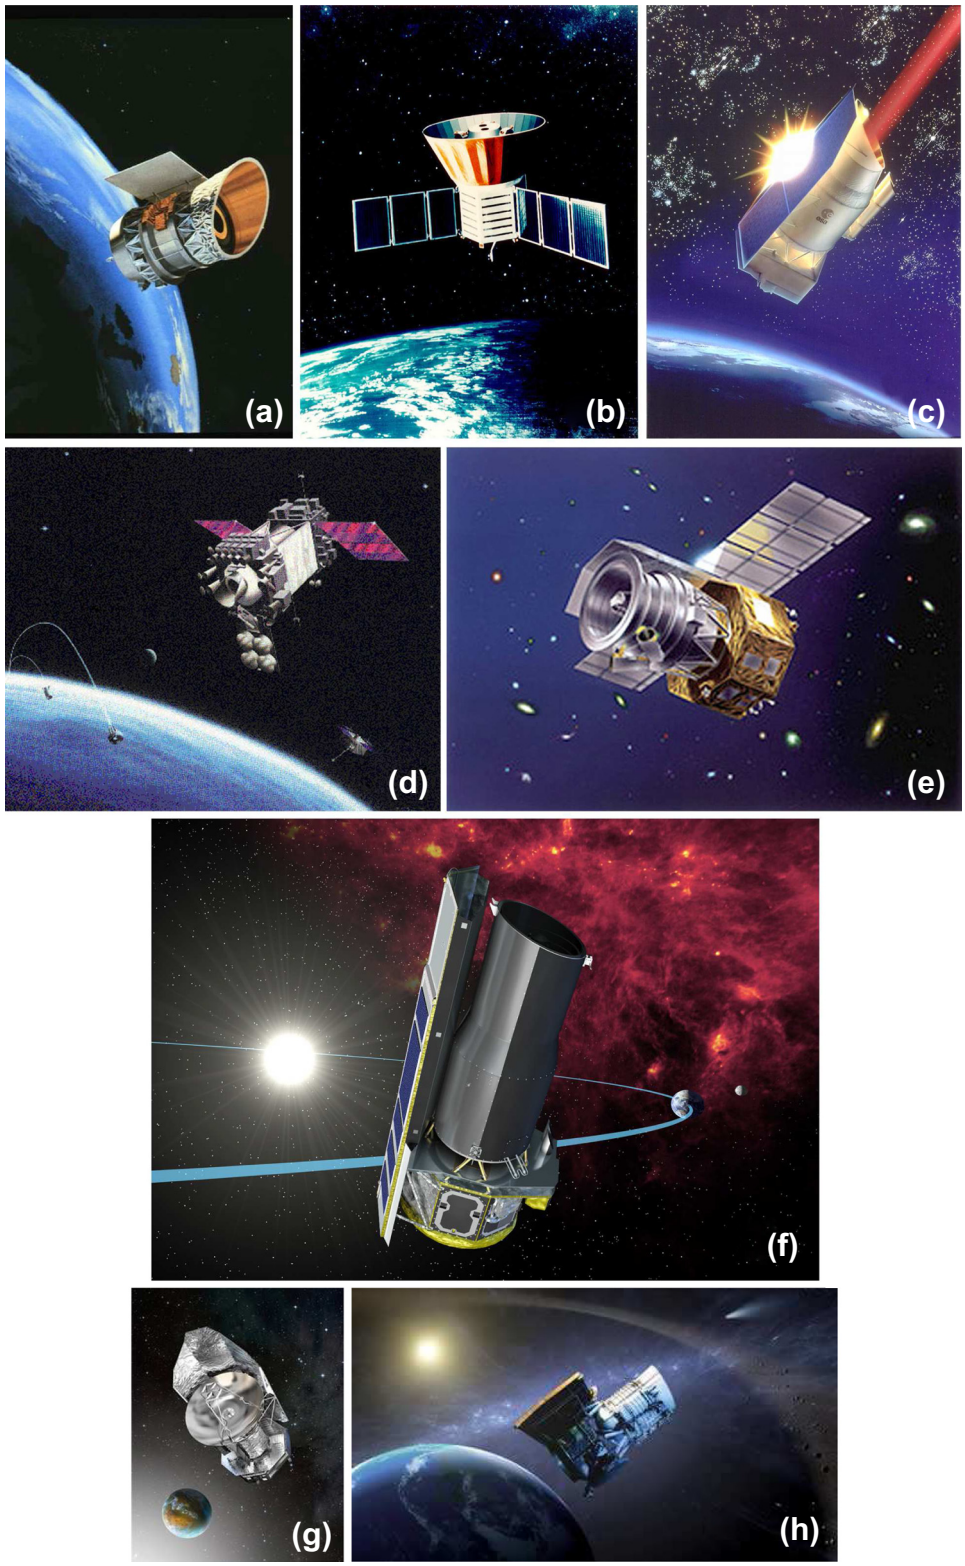

FIGURE 50.2 Space-based infrared telescopes in Earth orbit include (a) the Infrared Astronomical Satellite (IRAS) in 1983, (b) the Cosmic Background Explorer, 1989–1990, (c) the European Infrared Space Observatory (ISO), 1995–1998, (d) the US Air Force Midcourse Space Experiment (MSX), 1996–1997, (e) the Japanese Akari spacecraft, 2006–2011, (f) the Spitzer Space Telescope, which was launched into a heliocentric orbit in 2003, expected to operate 5 years, but has continued to operate in a postcryogenic phase since 2009, (g) the Herschel Space Telescope, 2009–2013, and (h) the Wide-field Infrared Survey Explorer (WISE), which launched in 2009, operated in postcryogen 2010–2011, at which time the spacecraft was put in hibernation. In 2013, WISE was reactivated for a 3 year s postcryo phase.

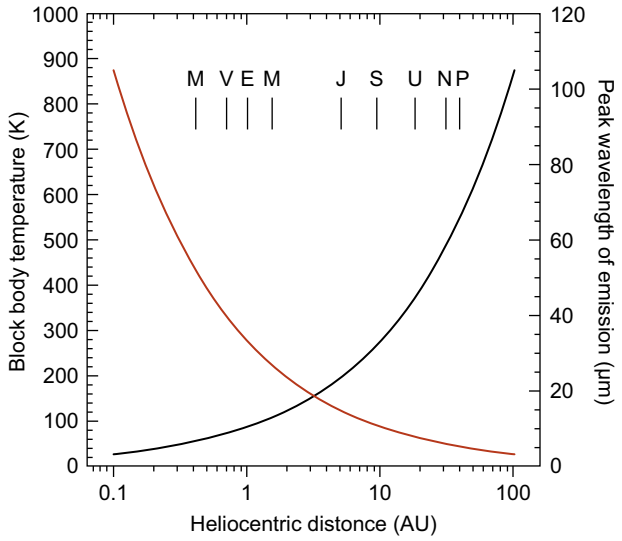

FIGURE 50.3 Bodies decrease in temperature with increasing distance from the Sun as shown by the red curve (which assumes that a body absorbs all incident sunlight). The corresponding wavelength at which the thermal emission spectrum peaks is shown by the black curve. At a given heliocentric distance, bodies that reflect increasing amounts of sunlight have lower equilibrium temperatures and will emit an increasing fraction of their thermal energy at longer wavelengths. For reference, distances of the planets are denoted by their first letters.

FIGURE 50.4 The zodiacal light from Mauna Kea, Hawaii. It is seen most prominently after sunset in the spring and before dawn in autumn at northern latitudes. *Source: Courtesy M. Ishiguro, ISAS.*

geometry is optimal. Comets were long thought to be the origin of the **zodiacal cloud**. However, early estimates of dust production by short-period comets fell far short of that needed to maintain the cloud in steady state against losses from particles spiraling into the Sun. This mechanism, where the absorption and reemission of solar radiation continually decreases particle velocity, is called Poynting–Robertson drag.

A cloud populated by comet emissions would have to be replenished by the occasional capture of "new", highly active comets into short-period orbits. Comet Encke was suggested as one such possible source in the past. Asteroid collisions have also been considered to be a source of interplanetary dust, but there were few observational constraints on estimates of their relative contribution to the cloud as a whole, until the advent of space-based telescopes operating in the thermal infrared (Table 50.1).

At thermal wavelengths, interplanetary dust is seen around the sky, peaking about the **ecliptic** plane (Figure 50.5). It appears brighter as we look closer to the Sun (where it is warmer and denser, hence giving off more thermal radiation). Within this broad band of dust there are structures related to dust-producing processes not seen before the advent of space-based infrared telescopes. The most prominent of these structures are the **dust bands**—parallel rings of dust straddling the plane of the ecliptic (Figure 50.5). These bands arise from collisions in the asteroid belt. When asteroids collide, the resultant fragments are ejected with velocities that are small compared to the orbital velocity of the original asteroid. Consequently, the orbits of the fragments are close to each other, forming a "family" of smaller asteroids (Figure 50.6). All asteroid orbits precess like tops because of the gravitational influence of Jupiter. Small differences in the semimajor axes of the debris orbits cause them to precess at slightly different rates, so that over time, while their semimajor axes, orbital inclinations, and eccentricities remain roughly the same, their nodes (orbit orientations) become randomized. They are still identifiable as families, but the volume of space they fill is a torus.

These fragments continue to experience collisions and generate smaller and smaller pieces that fill the torus, whose cross-section is shown in Figure 50.7, with peaks in number density in its corners. A torus of asteroid dust, observed from Earth's orbit, would have the appearance of parallel bands of dust, straddling the **ecliptic** (the bands closer to the Sun overlapping those further from the Sun along our line of sight).

TABLE 50.1 Space-Based Telescopes Operating in the Thermal Infrared

Spacecraft	Launch Date	End of Cryogenic Mission	Aperture (cm)	Wavelength Coverage (μm)
IRAS	January 1983	November 1983	57	12–100
COBE (DIRBE)	November 1989	September 1990	19	1.25–240
ISO	November 1995	May 1998	60	2.5–240
MSX	April 1996	September 1997	33	8.3–21.3
Spitzer[1]	August 2003	May 2009	85	3.6–106
Akari	April 2006	November 2011	68.5	1.7–180
Herschel	May 2009	April 2013	350	55–672
WISE[2]	June 2010	September 2010	40	3.4–22

[2]*WISE continued to operate in postcryogenic mode until February 2011. A second postcryogenic phase commenced in September 2013.*

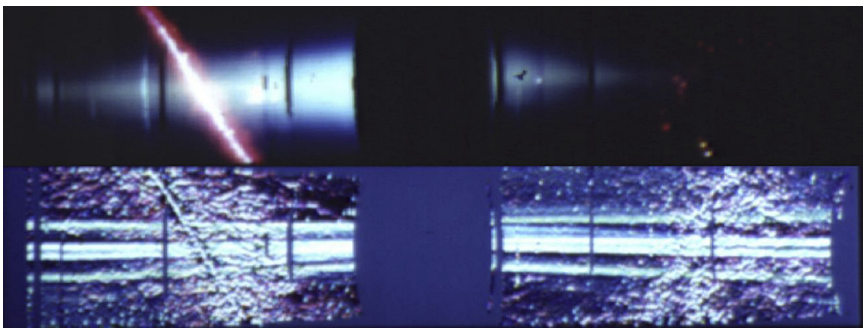

FIGURE 50.5 The zodiacal cloud (top) is seen extending from 0° to 360° in ecliptic latitude from right to left, constructed from scans of the ecliptic plane by IRAS. Ecliptic latitudes between 30° and −30° are shown. The diagonal structure crossing the ecliptic plane near 90° and 270° longitude is the galactic plane. Where the cloud is bright and wide (in latitude), the sky is being scanned at lower solar elongations, picking up the brighter thermal emissions of the warmer dust that lies closer to the Sun. As the satellite scans further away from the Sun at higher solar elongations, it is looking through less dust near the Earth and seeing a greater fraction of colder fainter dust. When filtered to remove its broad component (bottom), the zodiacal cloud reveals dust bands, located out in the asteroid belt and surrounding the inner solar system. Parallax results in their separation being smaller at lower solar elongations, where they are seen at a greater distance. Other solar system structures include dust trails.

Dust production from collisions is continuous down to sizes at which they are finally removed from the production region by radiation forces. When the fragments are around 1 μm in size they are immediately ejected from the solar system along hyperbolic orbits. These are known as **β-meteoroids**. For larger particles the solar radiation field and solar wind act as a friction to their orbital motion (**Poynting–Robertson drag**) and they will slowly spiral past the orbit of the Earth into the Sun. It is thought that the dust ultimately vaporizes and is incorporated into the Sun or recondenses into small particles that are then lost to the solar system as β-meteoroids.

Poynting–Robertson drag stretches out the small particle component of the torus (Figure 50.8), which retains its number density peak near its greatest distance from the ecliptic plane at a given heliocentric distance. When viewed in the thermal infrared from Earth's orbit, it still results in the appearance of distinct parallel bands straddling the ecliptic over all longitudes.

Initially, the **dust bands** were thought to be associated with the principal **Hirayama asteroid families** because of the proximity of their apparent latitudes with the orbital inclinations of those groups. These families are thought to have arisen from the catastrophic disruption of asteroids 100–250 km in diameter more than a billion years ago. If the asteroid belt as a whole was grinding down and generating dust, then it would follow that the most dust would be generated in the regions of greatest asteroid concentration—the largest asteroid families. Assuming this dust to be the main source of the **zodiacal cloud**, the cloud itself would be something expected to change slowly over much of the age of the solar system. An alternative hypothesis proposed that the dust bands arose from more recent collisions of smaller asteroids and that the zodiacal

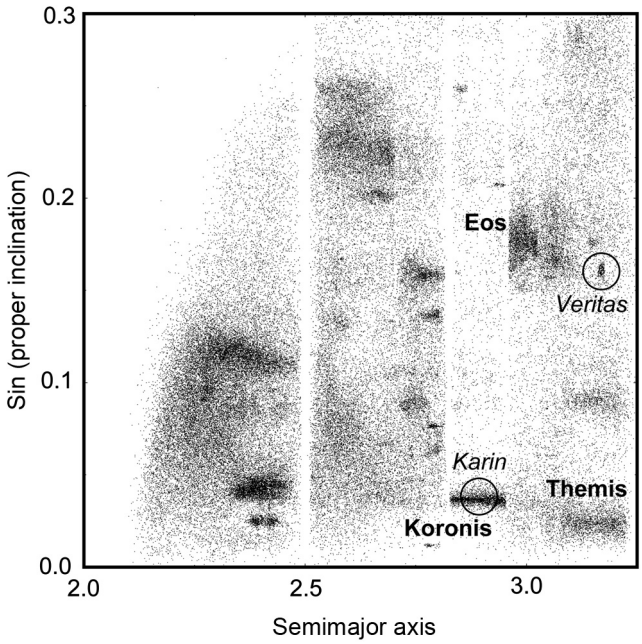

FIGURE 50.6 When a large enough asteroid is disrupted, its fragments are identified as other asteroids having similar orbital elements. The distribution of proper elements of asteroids in the main asteroid belt reveals many of these groupings referred to as families. The principal asteroid families, first identified by Kiyotsugu Hirayama in 1914, are Themis, Koronis, and Eos. The Karin (within Koronis) and Veritas families arose from the disruption of smaller asteroids within the past 10 million years and were identified as the sources of the two most prominent pairs of dust bands by D. Nesvorny.

cloud was highly variable over time. David Nesvorny and colleagues identified the sources of the two most prominent pairs of dust bands as the Karin and Veritas families and determined that the collisions forming these families occurred within the past 10 million years. This demonstrates that the zodiacal cloud, once assumed to be in relative steady state, may vary substantially over time as dust production in a given family slowly declines as more and more of its mass is ground up and removed by radiation forces and a new random collision creates family of debris that generates more dust. A faint inner pair of bands was originally associated with the very ancient Themis family, the largest asteroid family, which was formed by the catastrophic disruption of a 240 km diameter asteroid billions of years ago. Nesvorny and colleagues subsequently identified the origin of these bands as the Beagle cluster within the Themis family, arising from the disruption of a ~20-km-diameter asteroid less than 10 million years ago. Thus, the asteroidal contribution to the zodiacal dust complex appears to be dominated by recent catastrophic disruptions of small asteroids.

The mystery of whether asteroid collisions or short-period comets (or some combination) gives rise to the zodiacal dust cloud has been resolved in favor of Jupiter-family comets. Detailed simulations of the collisional and dynamical evolution of dust from the disintegration of these comets by Nesvorny and colleagues are shown to reproduce to good precision the broad thermal emission observed by IRAS (Figure 50.9).

3. A RING OF DUST AROUND THE EARTH'S ORBIT

As the sky was being mapped for the first time in the thermal infrared by IRAS, something odd was noticed; the sky always seemed to be slightly brighter in the direction opposite the Earth's motion about the Sun than in the direction of the Earth's motion. Since the satellite orbited above the terminator of the Earth and was looking out at different parts of the sky as the Earth orbited the Sun, if it was a difference in the actual sky brightness, would eventually result in a reversal of the direction of enhanced brightness. That did not happen. The "trailing" sky was always brighter. It made no sense that the Earth could be tracked by a large orbiting cloud—such a cloud would not be stable and disperse. Unable to come up with a satisfactory explanation, it was thought to be a strange calibration problem.

In 1993, a graduate student, Sumita Jayaraman, calculated that particles evolving from the asteroid belt past the Earth under **Poynting–Robertson drag** would have that orbital decay interrupted as a consequence of **resonance** interactions with the Earth (where the ratio of particle and

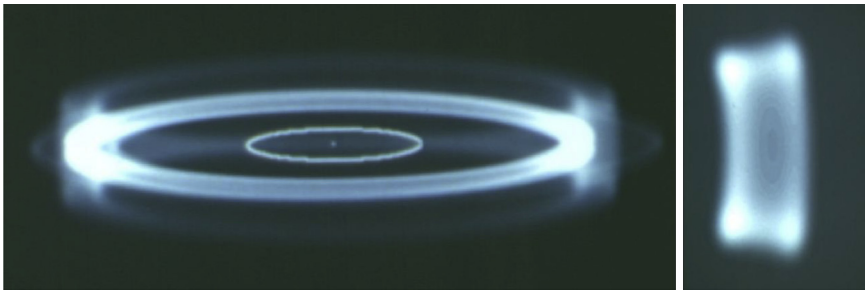

FIGURE 50.7 When nodes of particle orbits that are initially tightly clustered in semimajor axis, inclination, and eccentricity are randomized, they fill a torus. (Left) Tori associated with the principal Hirayama asteroid families would appear as parallel rings when viewed from Earth's orbit. (Right) Viewed in cross-section, particle number densities are maximum near the outer surface and are highest near the corners.

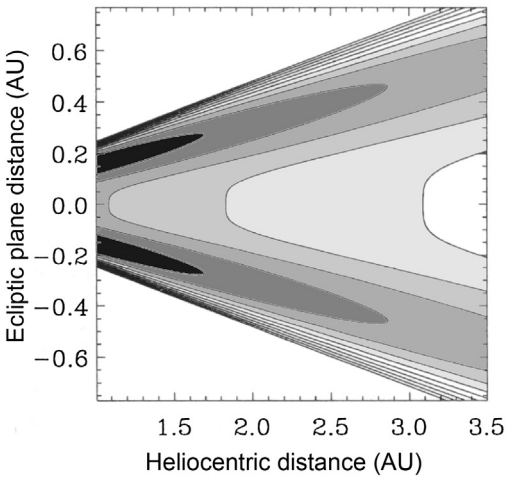

FIGURE 50.8 As hypothetical interplanetary dust particles originating in the Eos family torus migrate in toward the Sun, they contribute to the overall zodiacal cloud. The density contours of their contribution are shown, with darker regions corresponding to increasing particle number densities. The *x*-axis is heliocentric distance in astronomical units, and the *y*-axis is roughly the distance above the ecliptic plane. As the particles evolve to smaller heliocentric distances, the number density increases, and the extrema near the upper and lower edges of the cloud component is maintained. Viewed from the Earth, as we scan from the pole to the ecliptic, the column density of particles increases as we approach an angle near their average orbital inclination resulting in the appearance of a pair of parallel dust bands. *Source: Courtesy of W. Reach.*

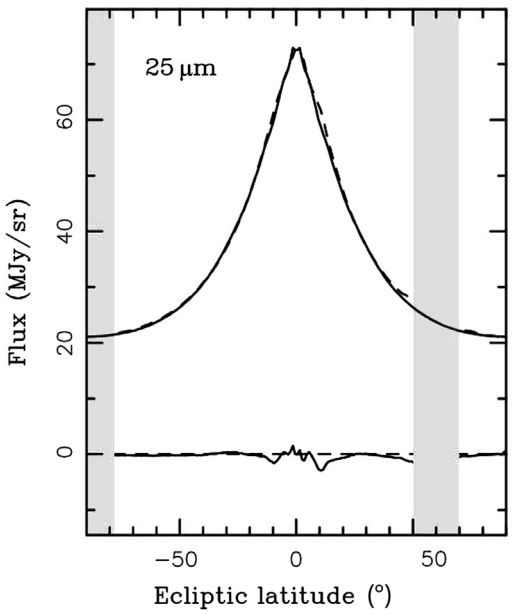

FIGURE 50.9 A scan through the broad zodiacal thermal emission by IRAS (above) is compared to a model of thermal emission from evolved debris of Jupiter-family comets (above). The residual is due to dust from recent asteroid collisions and not collisional activity within the main asteroid belt as a whole (below). *Source: Courtesy of D. Nesvorny.*

Earth orbital periods is a ratio of integers). This dust would pile up for a while before continuing its sunward spiral, forming a ring around the Earth's orbit. The resonant ring has a clump (about 10% enhancement in density over the background **zodiacal cloud**) always trailing the Earth by about 0.2 AU in its orbit (Figure 50.10). This resonant structure represents a volume through which particles are circulating around the Sun, to be distinguished from a cloud of self-attracting particles. This explained the IRAS mystery. The existence of the resonance ring structure was confirmed by COBE observations.

The Spitzer Space Telescope is in a heliocentric orbit slowly trailing further and further behind the Earth. Spitzer traveled completely through the trailing cloud, allowing its three-dimensional structure to be probed in detail. It confirmed the predicted gap in dust within 0.1 AU behind the Earth and found the cloud to be azimuthally symmetric, centered about 0.2 AU behind the Earth with a width of 0.08 AU along Earth's orbit. Evidence for substructures was also detected. These observations constrain the production and evolution of particles from the asteroid belt in the size range sensitive to **resonance** with Earth's motion, and provide insights into how such structures in dust disks about other stars may provide details about planets imbedded in those disks. (*See* Extra-Solar Planets.)

4. COMETS AND THEIR NATURE

Comets are members of the solar system that have been known since ancient times. At visible wavelengths they are characterized by distinctive tails of micron-sized dust particles ejected from the nucleus and pushed away under radiation pressure, a coma of gas, ice, and dust surrounding the nucleus, and sometimes an ion tail of gas molecules carried away by the solar wind (its typically blue color arising from electron recombination events) (Figure 50.11). In the 1950s, Fred Whipple developed the standard model of comet nuclei as bodies largely of ice with a mixture of some dust—a "dirty snowball", which actively sublimates on the sunlit side as it moves close to the Sun, explaining the nongravitational components of their motion. He also linked their activity to the maintenance of the **zodiacal cloud**, which required constant replenishment as its constituent particles spiraled into the Sun under **Poynting–Robertson drag.** (*See* Physics and Chemistry of Comets.)

Comets are known to eject large particles from their association with many meteor streams. These particles spread over a comet's orbit and are scattered within its plane. If the comet orbit happens to extend inside the Earth's, these particles will be seen as meteors as the Earth passes through their orbital plane. Because they are striking the Earth's atmosphere from the same direction, meteor streams seem to come from a particular location in the sky.

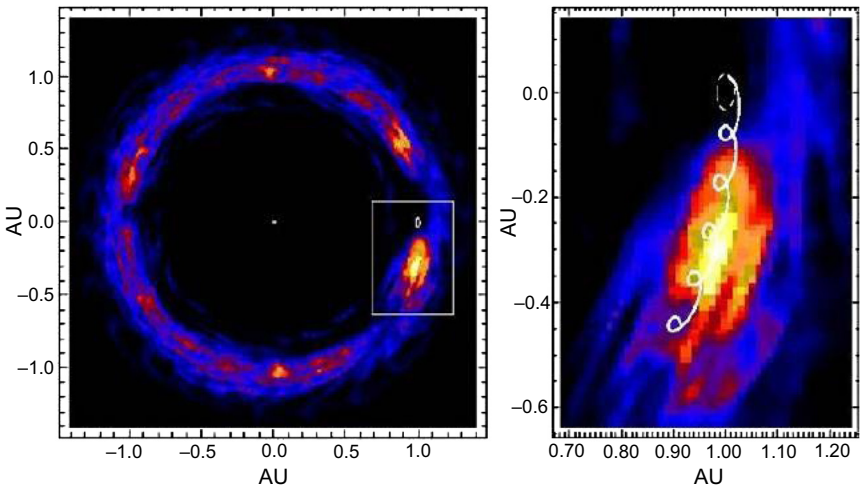

FIGURE 50.10 A simulated image of the Earth's resonant ring (left) showing a close-up of the cloud of dust that trails the Earth in its orbit through the year. The ellipse, in the inset box left and dashed at the top right, shows the orbit of the Earth in a rotating reference frame. The resolution of the image is 0.01 AU in the x and y directions. The cloud is modeled using 12 μm spherical particles of astrophysical silicate. The proximity of the clump of dust behind the Earth near its orbit explains why thermal scans of the sky behind the Earth along its orbit are always brighter than scans in front of the Earth. Over the course of its mission, Spitzer will travel through the dust cloud trailing Earth (right). The "loops" of Spitzer's orbital path and the oval of Earth's motion arises from the small eccentricity of the orbits. *Source: Figure courtesy of S. Jayaraman.*

FIGURE 50.11 Comet West on March 9, 1976, less than half an AU from the Sun after perihelion, exhibiting classic dust (white) and ion (blue) tails. *Source: Image by J. Laborde.*

This is called the radiant. Analysis of meteors as they burn up in the Earth's atmosphere indicates that particles associated with known comets have low (<1 g/cm^3) to modest (<2.5 g/cm^3) mass densities.

Viewed from space in the thermal infrared, many short-period comets were found to have very extensive, narrow trails consisting of millimeter- to centimeter-sized particles extending degrees to tens of degrees across the sky (Figure 50.12). The narrowness of the trails is due to the low velocities with which their constituent particles are ejected. They retain a record of comet emission history over a period of years to centuries. For comets having perihelia interior to the Earth's orbit, trails represent the birth of a meteor stream. The number density of particles within them are such that were the Earth to pass through one, there would be a "meteor storm" equal to or exceeding the famous Leonid storms of 1833 and 1966. First discovered by IRAS, it was inferred that **dust trails** were common to short-period comets. Surveys by Spitzer and WISE suggest this is the case (Figure 50.13).

Space-based infrared observations revealed that comets possessed far more dust than had been thought. Classical "gassy" comets such as P/Encke were found to possess both a significant large particle dust coma and trail (Figure 50.14). Encke's trail was found to extend over 80° of its orbit. It was determined that the ejection of large particles into trails was the principal mechanism by which comets lose mass. These particles quickly devolatilize after leaving the comet nucleus; this means that most of the comet's mass loss is in refractory particles.

The discovery of cometary dust trails has changed the picture of comet nuclei from being primarily icy bodies to objects more akin to "frozen mud balls", because of their much higher than expected fraction of refractory dust. The

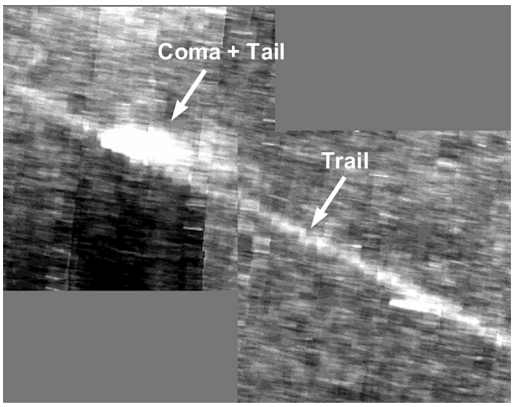

FIGURE 50.12 The most prominent dust trail in 1983 was associated with the short-period comet Tempel 2. The dust coma and tail appear as the fish to the dust trail's stream. Trails are characteristically narrow (as a consequence of the small relative velocities of the constituent dust relative to the nucleus of the parent comet) and trace out a portion of the comet's orbit. The particles ahead of the comet (to the left) are preferentially larger than those following the comet.

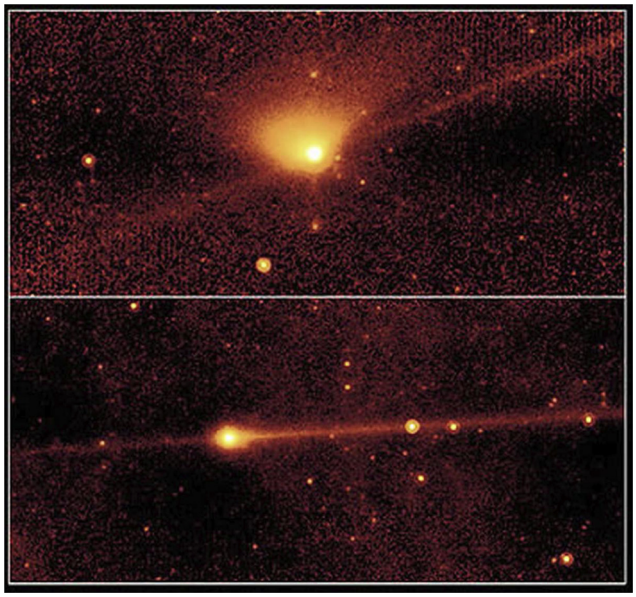

FIGURE 50.13 Spitzer has detected the first new dust trails in the infrared since IRAS. Shown are P/Johnson (top) and P/Shoemaker-Levy 3 (bottom). Spitzer is confirming the commonality of such large particle emissions across the short-period comet population. *Source: Figure courtesy of W. Reach.*

fraction of dust-to-gas in comet nuclei provides important information about where they formed and how they evolve, once captured into short-period orbits.

Dust-to-gas mass ratios corresponding to the canonical dirty snowball model range between 0.1 and 1. If we were to compress comet nucleus material so that refractories have a density of 3 g/cm^3 and volatiles had a density of 1 g/cm^3, this would give us a canonical nucleus in which 3−33% of the volume consisted of refractory material.

This picture is based largely on ground-based observations of dust at visual wavelengths, sensitive to particles within a decade or so of 1 μm in size. These observations underestimate the mass fluence of dust from comets.

Most of cometary mass loss appears to be in much larger (and dark) particles, which are difficult to detect at visual wavelengths. This conclusion was also reached after the European Giotto spacecraft was struck by a small number of large particles as it flew by comets Halley and Grigg-Skellerup.

Analysis of the IRAS observations of eight trails indicates that short-period comets lose their mass primarily in refractory particles in the millimeter to centimeter diameter size range. An average dust-to-gas mass ratio of 3 was calculated (Figure 50.15). This was the upper limit inferred for Halley by Giotto (with a nominal value of 2). Assuming the same densities for refractories and volatiles as previously, this corresponds to a comet nucleus that is 75% refractive by mass and 50% by volume (Figure 50.16). Mixing equal volumes of dirt and water in a backyard experiment demonstrates the apt description of such a mixture as a mud ball.

These dust-to-gas ratios also provide insight into the formation location of short-period comets. Dynamical considerations have lead investigators to focus on the proto-Uranus and proto-Neptune regions as that location. Significant amounts of ice have long suggested the outer solar system as the source of short-period comets. Consideration has also been given to their formation beyond the solar system, for instance, in molecular clouds. Models of comets forming in such interstellar locations yield comets dominated by their volatile components, contradicting inferences drawn from space-based thermal infrared observations. On the other hand, it is very interesting that both Pluto and Triton have effective dust-to-gas mass ratios that are identical to the average comet values determined from IRAS and Giotto (Figure 50.15). This is not unexpected if Pluto and Triton accumulated from protocomets in the vicinity of Neptune's orbit.

The existence of **dust trails** indicates that short-period comets are losing mass more rapidly than previously thought. Hence, their lifetime against sublimation may be shorter. A greater fraction of refractory material, however, would allow for the rapid formation of a nonvolatile mantle that is difficult to blow off, progressively choking off cometary activity. Such a mantle was apparent in the Giotto images of the Halley nucleus, which was near **perihelion** at the time. When activity is choked off, the comet would look like an asteroid until such time as sufficient pressure built up from subsurface ices to break through the crust in a burst of resumed activity. The discovery in August 1992 that asteroid 4015 was actually comet P/Wilson-Harrington (last seen in outburst in 1949) provided the first hard evidence of such "dormant" comets in the inner solar system.

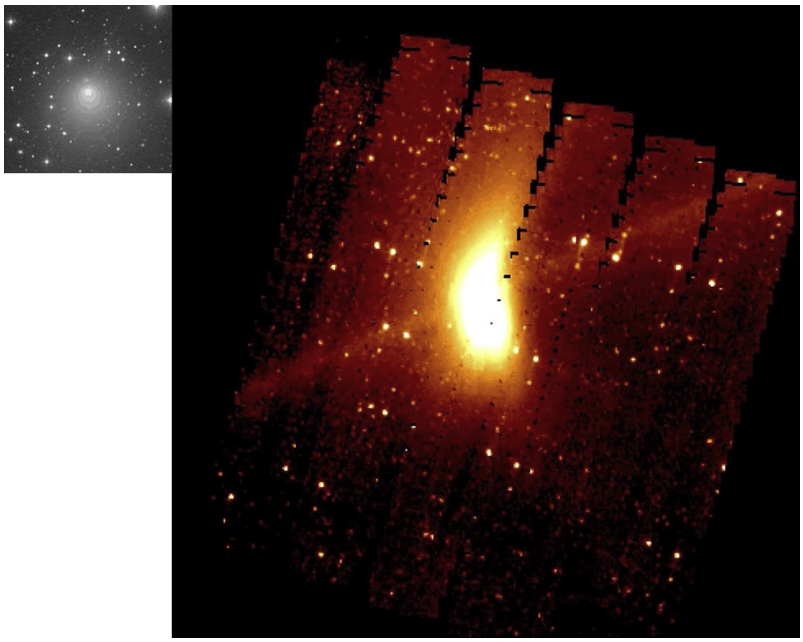

FIGURE 50.14 Comet Encke (left) is considered a classic "gassy" comet based on visible wavelength observations showing only a gas coma and no dust tail. *(Image courtesy of J. Scotti.)* An ISO map (right, to scale) of P/Encke and its trail at 11.5 μm, evidencing anisotropic emission and requiring the spin axis of the nucleus to lie nearly in the orbital plane. The inferred dust-to-gas mass ratio of 10–30 is even higher than that inferred from IRAS observations. *Source: Figure courtesy of W. Reach.*

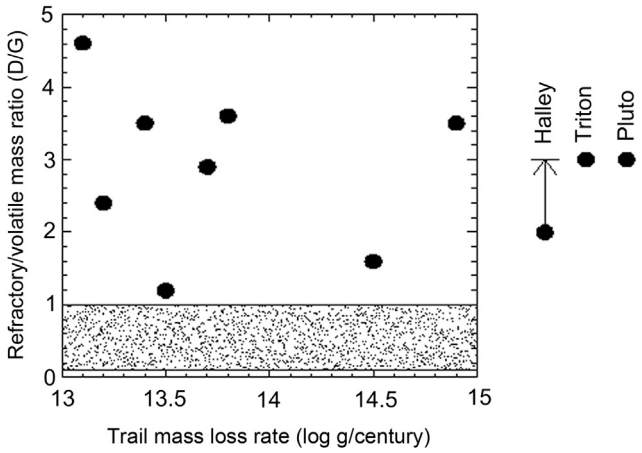

FIGURE 50.15 Dust-to-gas mass ratios are shown for comets having detected dust trails by IRAS. For comparison, values are shown for Halley, Triton, and Pluto. The shaded area spans the "canonical" ratios between 0.1 and 1.

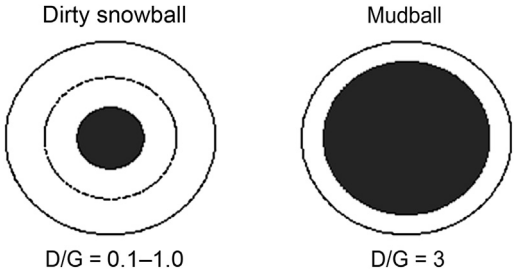

FIGURE 50.16 The canonical "dirty-snowball" model of comets, inferred from ground-based observations at visible wavelengths, is compared to the "frozen mud ball" or "frozen mud-ball" model inferred from space-based observations in the thermal infrared. All refractories are collected at the center in both cases.

In addition to trails associated with known short-period comets, IRAS also detected trails having no known source (Figure 50.17). Unfortunately, since these were discovered in the data long after the mission had ended, it was not possible to follow up the IRAS observations with observations from the ground in order to determine their orbits. So these objects are now lost. However, assuming a cometary origin, the numbers of these "**orphan trails**" suggest that there may be twice as many short-period comets as previously recorded, with the majority of them being less active and hence more difficult to detect by traditional means. The serendipitous detection of orphans requires a space-based thermal infrared survey of the sky having sufficient spatial resolution. More orphans may be waiting in the surveys obtained by the Japanese Akari mission and the WISE mission.

Space-based thermal infrared telescopes have also provided direct compositional information about comets through spectroscopic observations raising questions about the conditions in the early solar system when they formed. ISO made the first detections of crystalline silicates and CO_2 in its observations of the long-period comet Hale-Bopp and Jupiter-family comet P/Hartley 2. Crystalline silicates are formed at high temperatures not associated with the outer solar system. Spitzer measured the spectra of pristine material excavated by the Deep Impact event on P/Tempel 1, finding materials never before seen in comets such as carbonates and clay (which form in the presence of liquid water) as well metal sulfides, polycyclic aromatic

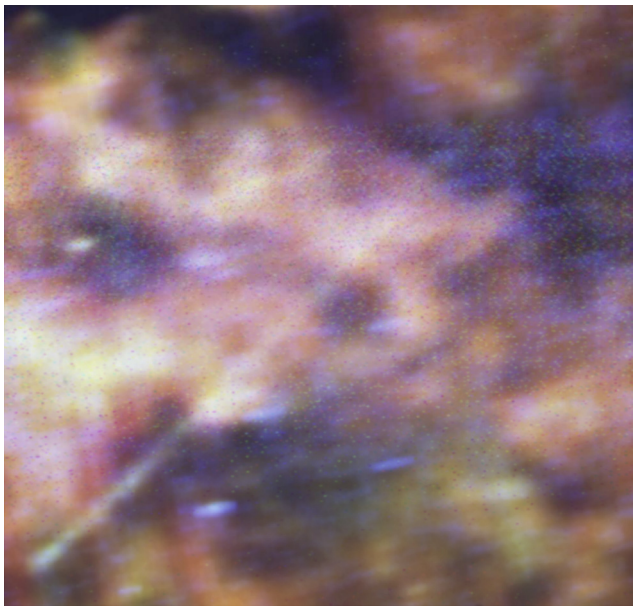

FIGURE 50.17 The brightest of the "orphan trails" detected by IRAS, seen against a background of interstellar clouds. Blue elongated sources are stars distorted by the rectangular shape of the detectors. Orphan trails are probably associated with comets never before detected.

hydrocarbons, and crystalline silicates. Liquid water is also not expected to be present in the outer solar system. These observations suggest perhaps substantial radial mixing of materials forming in hot and cold environments before the comets begin to accrete.

Yan Fernández and colleagues conducted Spitzer observations of 89 Jupiter-family comet nuclei and determined that their **albedos** are uniformly dark, with a cumulative size distribution with slope of $b = -1.9$ that may be enhanced in the 3- to 6-km-diameter range. This same survey showed 24% to be active at large distances from the Sun where water is inactive. In sum, Spitzer indicates that Jupiter-family comets, thought to derive from the Kuiper Belt, have a common origin, but a complex evolutionary history in their journey to the inner solar system. Ultimately, these comets may have been the source of Earth's oceans, as Herschel measurement of the D/H ratio in the Jupiter-family comet P/Hartley 2 found a value closely matching the ocean value.

5. ASTEROID PHYSICAL PROPERTIES

Over a million asteroids with diameters greater than 1 km reside primarily in a belt between Mars and Jupiter. (*See* Main-Belt Asteroids.) The asteroid population extends interior to the orbit of the Earth and beyond Jupiter. These objects are the scattered and disrupted remains of an early population of protoplanets whose continued growth was interrupted early on by mutual gravitational stirring, or the growth and migration of a massive Jupiter, or possibly both. The size distribution of asteroids provides insight into their origins and evolution through collisions and dynamical processes. Asteroid sizes are also important to determine the hazard of near-Earth objects. Asteroids are almost all unresolved to telescopes, and their brightnesses are insufficient for determining their sizes unless their **albedos** are known. By combining visible and thermal infrared observations of an asteroid, its diameter and albedo can be simultaneously determined. The difficulty of making radiometric (thermal) observations of asteroids from ground-based telescopes made for slow growth in the number for which physical properties could be determined. Space-based surveys in the thermal infrared greatly increased the numbers of asteroids for which albedos and diameters were available, providing new information about the composition of the asteroid belt.

Because most space-based infrared telescopes have operated in a pointed mode, targeting specific objects or locations for observations, few have engaged in asteroid surveys. The first significant catalog of asteroid albedos and diameters were derived from the IRAS survey in 1983. This survey resulted in 8210 observations of 2004 asteroids. A more limited survey by MSX in 1996 resulted in observations of 168 asteroids. By and large, such surveys rely upon the detection of asteroids in known orbits, since they are unable to provide sufficient astrometry to determine the orbits of newly discovered asteroids.

During the IRAS mission, there were tens of thousands of asteroids having known orbits. Three decades later that number has increased by an order of magnitude. Greatly increased detector sensitivity, has allowed even nonsurvey satellites to produce an even larger catalog of asteroid diameters and albedos. Over the nearly 6 year nominal mission of Spitzer, about 25,000 serendipitous asteroid measurements were made. It was the WISE mission, however, launched more than 27 years after IRAS, that has produced survey observations of more than 140,000 asteroids, providing the most comprehensive database of their thermal properties.

Known asteroid diameters inferred from WISE are shown in Figure 50.18 as a function of heliocentric distance. The absence of small asteroids with increasing heliocentric distance is a consequence of the limits of detector sensitivity.

Albedo provides insight into composition. Meteorite studies show that very dark surfaces arise from largely carbonaceous materials, while high-albedo surfaces are associated with silicic compositions lacking such carbonaceous material. IRAS confirmed that most C-type asteroids (thought to be carbonaceous) are indeed dark compared to the "stony" S-type asteroids, and that there is a trend toward darker asteroid surfaces with increasing heliocentric distance. This trend is seen in the WISE

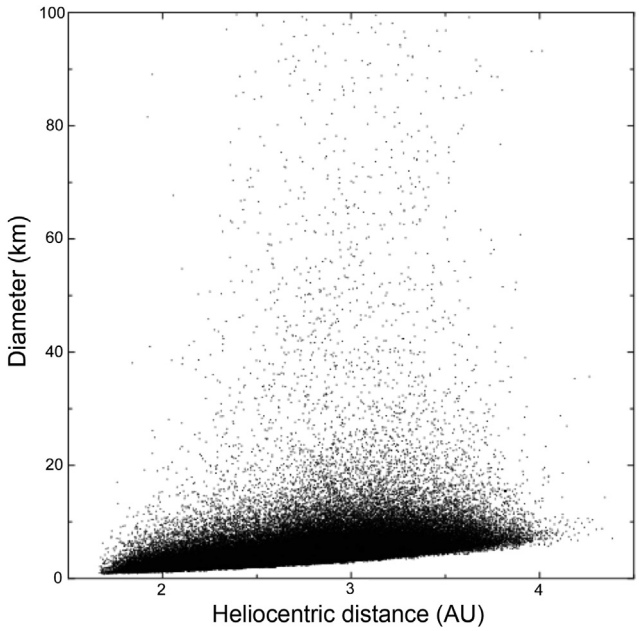

FIGURE 50.18 Main-belt asteroid diameters versus heliocentric distance of detection. The lower limit of detected asteroid sizes reflects the sensitivity limits of WISE detections. Asteroids with diameters less than 18 km dominate.

observations (Figure 50.19). This is consistent with the view that there is not only a primordial composition gradient through the asteroid belt, but that inner belt asteroids (predominantly S-type) were significantly processed by heating in the early solar system, while the outermost asteroids have experienced little heating and have retained a more "primitive" mineralogy.

New observations often result in as many new questions as new answers, and the WISE asteroid observations are no exception. Prior to IRAS, ground-based thermal observations had been preferentially made of the largest asteroids. It was noticed that there was a bimodal distribution in the inferred albedos, which was consistent with the main-belt asteroid population being dominated by dark C-type and bright S-type asteroids. IRAS added large numbers of observations of smaller asteroids and it was found that they had an albedo distribution quite different from the larger asteroids. WISE observations confirm this. Small asteroids have a fairly unimodal distribution spanning a far broader range of albedos than those of larger asteroids (Figure 50.20). Since the small asteroids are fragments of larger asteroids this might imply that surface mineralogies are not representative of interior mineralogies or that significant "space weathering" may affect the surface spectra of the larger bodies.

There has been some question as to whether all asteroid families mark the site of a past catastrophic disruption or whether in some cases asteroids might be clumped together due to dynamical forces such as gravitational perturbations

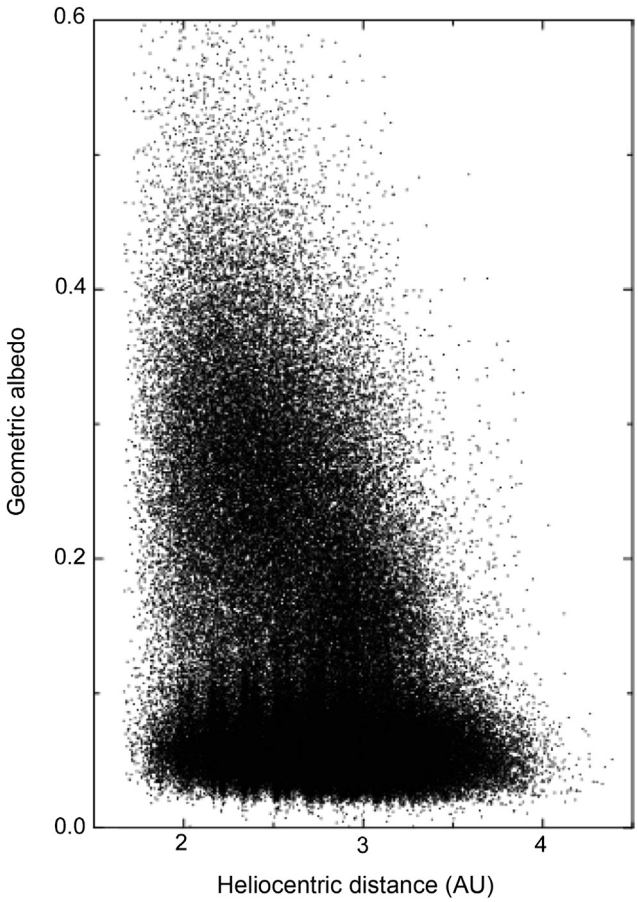

FIGURE 50.19 Geometric albedo versus heliocentric distance of known main-belt asteroids detected by WISE. The high-albedo asteroids are located predominantly in the inner portion of the main asteroid belt. Vertical structures are an artifact of asteroids whose orbits are not well determined.

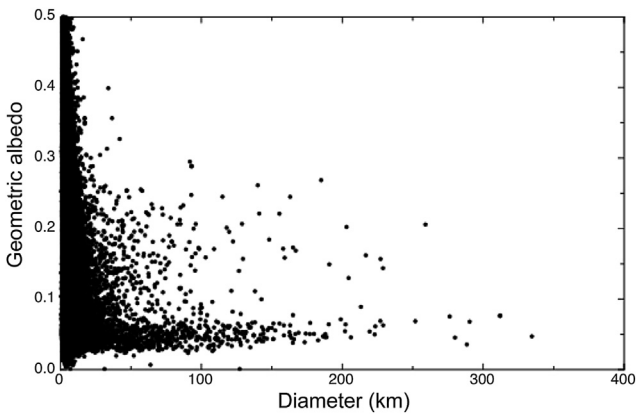

FIGURE 50.20 The geometric albedo of main-belt asteroid detected by WISE displays a bimodal distribution for asteroids larger than ~50 km, while smaller asteroids display a much greater, roughly unimodal, distribution of albedos.

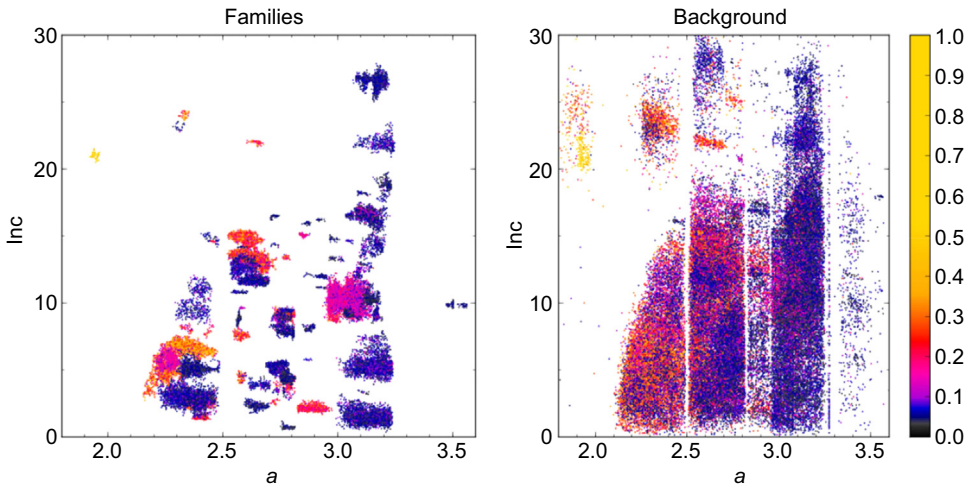

FIGURE 50.21 Proper inclination (inc, in degrees) versus proper semimajor axis (a, in AU) for 76 asteroid family members (left) and all nonfamily background objects (right). Color indicates albedo. Family members tend to have uniform albedos compared to corresponding background objects. *Source: Courtesy of J. Masiero.*

on their orbits by Jupiter. Albedo distributions can also provide clues to the origin of some asteroid families. Assuming the parent to have been compositionally homogeneous, the fragments should exhibit similar spectral properties. On the other hand, members of purely dynamical clusters would not be expected to have similar compositions. WISE scanned numerous members of 76 asteroid families and demonstrated that family members had albedos more similar to each other than to the background asteroids nearby, giving support, in those cases, to the asteroid breakup hypothesis (Figure 50.21).

Thermal spectra can provide information including thermal inertia and composition. Spitzer observations of Jupiter Trojan asteroids have yielded results suggesting fine-grained silicates in a relatively low-density, perhaps "fairy-castle" matrix. Does this indicate a possible cometary origin? Evidence for complex carbon compounds on primitive asteroids has also been detected. A Spitzer survey of M-class asteroids, spectrally similar at visible wavelengths, indicates major differences in thermal inertia among them, which could indicate significant differences in surface densities (due to relative age and collisional processing) or conductivity (some M-types are metallic, some may be stony). Thermal infrared observations of asteroids from space-based facilities are revealing an increasingly diverse population of objects.

6. PLUTO AND BEYOND

Thermal radiation from Pluto and its moon Charon was first detected by IRAS (Figure 50.22). The thermal flux of the system was consistent with that of a rapidly rotating **gray body** having an equatorial temperature of ~60 K. This information in combination with ground-based spectroscopic measurements and **albedo** maps derived from the mutual eclipses between Pluto and its moon between 1984 and 1990 has provided important insights into the nature and dynamics of the surface of Pluto. (*See* Pluto.)

When methane was first detected in visible wavelengths on the surface of these objects, it was thought that Pluto must be completely covered by the frozen ice, and would be isothermal because of the transport of heat as highly insolated locations would be cooled by sublimation and less insolated locations would be warmed by the condensation of atmospheric methane. Charon was thought to be a less likely location of such a coating of methane frost because of its lower gravity, from which methane would be expected to escape over time.

The detection of an extended atmosphere from a stellar occultation in 1988 and the subsequent detection of nitrogen ice on Pluto's surface required that the volatile surface ices be dominated by nitrogen with a small fraction of the more spectroscopically active methane, and that these surface ices must be very cold, ~35 K.

The spectroscopic- and IRAS-derived temperatures appear to contradict each other. Nitrogen ice at the warmer radiometric value would produce an enormous atmosphere that would have been evident in the occultation observations. The surface albedo maps, however, show that Pluto's surface is segregated into bright and dark regions with bright ices generally at higher latitudes. A high-albedo surface is bright at visible wavelengths (reflected light) and faint at thermal wavelengths, while a dark surface is faint at visible wavelengths and bright in the thermal. On Pluto, visible wavelength spectroscopy samples primarily the bright icy polar regions of the planet while space-based thermal observations are dominated by the dark equatorial region.

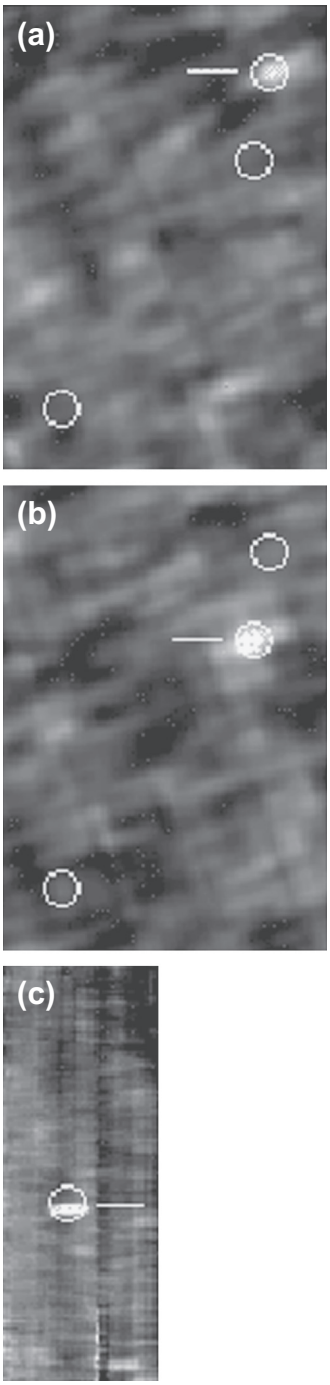

FIGURE 50.22 Pluto–Charon were detected moving across the infrared sky by IRAS. These images were constructed from 60 μm scans for (a) July 13, (b) July 23–24, and (c) August 16 in 1983. The predicted positions of Pluto–Charon at each of these times are indicated by circles. The August 16 position is the lower left circle in (a) and (b).

IRAS tells us that the volatile nitrogen ice—from which the atmosphere derives—is segregated on the surface of Pluto, away from the warmer regions giving rise to the thermal emission detected by the satellite. These warmer regions are probably a mixture of water ice and carbonaceous residue resulting from the radiation processing of methane ice over the age of the solar system. The dark regions are not contributing significantly to the atmospheric gases, which is consistent with a water/organic composition that would have negligible vapor pressure at the temperature inferred.

More sensitive Spitzer observations of Pluto–Charon have provided further insights into the properties of their surfaces, indicating high surface porosity and (on Pluto) the effect of what appears to be significant seasonal migration of surface ices. These observations will complement the spatially resolved studies, in reflected light, of the New Horizons mission as it passes by Pluto and Charon in 2015.

Spitzer and Herschel have been trained on trans-Neptunian objects (TNOs) beyond Pluto, finding that their **albedos** vary considerably. Short-period comets, which tend to have low albedos $\sim$0.04, are thought to derive from this region. The largest objects (in the dwarf planet category) have been determined to have very high albedos (>0.70). Nominally, an undifferentiated primitive surface exposed to galactic cosmic radiation over the age of the solar system would be expected to be covered with dark complex organics. For large bodies, bright surfaces suggest substantial evolution that allows volatile ices such as nitrogen to migrate to the surface—perhaps evidence of collisional activity or heating from early decay of radioisotopes resulting in differentiation.

Jupiter-family comets are thought to derive from the TNO region, yet Spitzer and Herschel have determined that many TNOs have significantly higher albedos than their cometary descendants. Comet nuclei are covered with dark refractory material. Their corresponding dust trails are likewise dark and refractory. Some smaller TNOs may be bright because their interiors are exposed by collisional activity. In that case, the bright ice and dark dust might not be in an intimate mixture, which would be necessarily dark. In fact, the 0.1–1 cm **dust trail** particles may be the principal size of the refractory component of comets. Thus, infrared studies of these distant bodies may be providing an important clue to the interior physical composition of comets and how they formed.

Beyond the Kuiper Belt lies the question of what additional parts of the solar system wait to be discovered. The sky is filled with cirruslike structures (Figure 50.1) and begs the question of whether any of them are local to the solar system.

IRAS surveyed 96% of the sky twice and 75% of the sky a third time. Images from these surveys were used to conduct the first-ever parallactic survey of the sky. Images of the same location taken weeks to several months apart were compared to search for reflex motion of extended sources, but in the end, nothing was identified in a volume extending 100 AU in some directions and 1000 AU in others—within the sensitivity of IRAS. With the greater

sensitivity of current radiometric detectors and the larger apertures of space-based telescopes, the question asked with IRAS can be asked again and again, perhaps one day with a positive result or a definitive answer.

7. AN EXCITING FUTURE

At the time this article is being written, the age of infrared surveys of the sky from space may be drawing down for the foreseeable future. After more than two and a half years in hibernation, WISE is being restarted to continuing scanning the sky again to find more near-Earth asteroids. Its second postcryogen phase will last 3 years. Spitzer continues to operate in its postcryogen phase. In 2018, NASA will launch the massive James Webb Space Telescope (JWST). JWST has a 6.5-m-diameter mirror, and will operate from the near-infrared out to 28 μm, keeping the system cold through a combination of shielding and long-lived cryocoolers. While concentrating on the early universe and far astrophysical sources, JWST will have the capability to conduct detailed studies of near-Earth objects to the faint, small TNOs, bringing new understanding to the most distant regions of our solar system.

Institute for Astronomy, University of Hawaii, Honolulu, HI, USA

Chapter Outline

1. Introduction 1089
2. Advances in the Construction of Large Telescopes and in Image Quality 1090
3. Advances with Detector Arrays 1098
4. Advances in Adaptive Optics (AO) 1099
5. Sky Survey Telescopes 1100
6. Concluding Remarks 1104
Bibliography 1105

1. INTRODUCTION

The telescope has played a critical role in planetary science from the moment of its use by Galileo in 1608. His observations of the craters on our Moon and the moons of Jupiter were the first astronomical discoveries made with a telescope. The development of larger refracting and reflecting telescopes led to the seminal discoveries of the rings of Saturn, asteroids, the outer planets Uranus and Neptune, new satellites of Mars and the outer planets, and Pluto by 1930.

Although spacecraft missions have revolutionized our understanding of the solar system (there are many examples in this encyclopedia), ground-based telescopes continue to play a very important role in making new discoveries, and this is the focus of this chapter. Figures 51.1–51.4 show a small sample of observations that illustrate the advantages of ground-based observations.

Solar system astronomers typically use telescopes built for other fields of astronomy. However, during the 1970s, NASA constructed ground-based telescopes to support its planetary missions. NASA funded the construction of the 1.7-m Kuiper telescope, the 2.7-m McDonald telescope, the University of Hawaii 2.2-m telescope, and the 3.0-m NASA Infrared Telescope Facility (IRTF) to provide mission support, but currently only the IRTF continues to be funded by NASA for that purpose. NASA also provides funding for searches for near-Earth objects (NEOs) as part of a Congressional directive.

Telescopes are designed to collect and focus starlight onto a detector. Larger telescopes not only allow more light to be collected and put onto the detector but also allow sharper images to be obtained at the **diffraction** limit of the telescope. While building larger telescopes may seem conceptually simple, ground-based observers have to contend with limitations imposed by physics, the atmosphere, technology, and funding. First, the collecting area of a telescope is limited in size. The largest optical telescope in the world presently has an equivalent collecting area of an 11.8-m diameter mirror. Although larger telescopes could be built, there are serious technical and financial difficulties to overcome. Second, the atmosphere limits observations to specific observing "windows" where the atmosphere is transparent; the wavelength range 25–350 μm is largely inaccessible to ground-based observers because of water absorption bands. Third, for infrared observations, the thermal emission of the atmosphere at wavelengths longer than 2.5 μm greatly reduces the sensitivity of observations. To overcome the problems of atmospheric absorption and thermal emission, it is necessary to go to high-mountain sites such as Mauna Kea in Hawaii and Atacama in Chile, or to use balloons, aircraft, or spacecraft. Fourth, atmospheric **seeing** typically limits the sharpness of images to 0.25–0.5 arcsecond at the best high-altitude sites. To achieve diffraction-limited imaging, one must employ special techniques that actively reduce the effects of atmospheric turbulence many times per

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00051-7

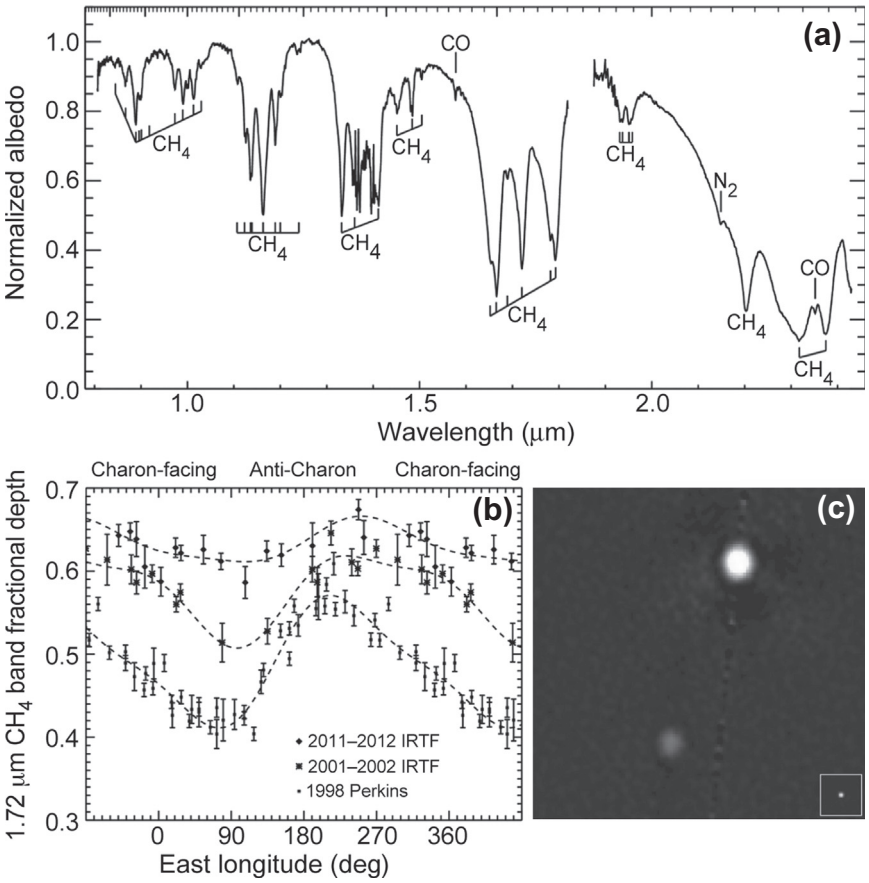

FIGURE 51.1 (a) Near-infrared spectrum of Pluto taken with the NASA Infrared Telescope Facility (IRTF). Absorption bands of methane (CH_4), carbon monoxide (CO), and nitrogen (N_2) ices on the surface of Pluto are shown. (b) Variation in the methane band depth with time and longitude on Pluto. These observations were taken over a period of 14 years and show surprisingly short timescale variations of composition on the surface of Pluto. (c) High angular resolution image of Pluto and its satellite Charon taken with the Gemini North telescope using a speckle camera. The angular resolution is 20 milli-arcseconds at a wavelength of 692 nm. The angular resolution of an unresolved star is shown in the insert in the lower right corner, and so Pluto and Charon are clearly resolved. The angular separation between Pluto and Charon is 0.81 arcsecond. These results show the long time base of observations and the extremely high angular resolution that can be obtained only with ground-based telescopes. *Courtesy of W. Grundy and S. Howell.*

second. One such technique, called **adaptive optics** (AO), is discussed later in Section 4.

Very large and low-noise visible and infrared detector arrays have been developed in the past decade, and this advance has been as significant as the improvement of telescope construction in providing greater observing capability. An important result of large-format detector arrays has been large sky surveys. Key objectives of these sky surveys are to detect asteroids that may present an impact hazard to Earth and to complete the reconnaissance of Kuiper Belt objects (KBOs). The major challenges of these survey projects are obtaining large enough detector arrays to provide the field of view required, and analyzing and storing the tremendous amounts of data that they generate.

In this chapter, we discuss very large telescopes that have been developed in the past 20 years to maximize collecting area, optimize image quality, and achieve diffraction-limited imaging with techniques to reduce the atmospheric turbulence. We also discuss sky survey telescopes that take advantage of the large-format detectors for the detection of solar system objects.

2. ADVANCES IN THE CONSTRUCTION OF LARGE TELESCOPES AND IN IMAGE QUALITY

The Hale 5.1-m telescope went into operation in 1949. It represented the culmination of continual telescope design improvements since the invention of the reflecting telescope by Newton in 1668. The basic approach was to scale up and improve design approaches that were used previously. Figure 51.5 shows the increase in telescope aperture with time. After the completion of the Hale telescope, astronomers recognized that building larger telescopes would require completely new approaches. Simple scaling of the classical techniques would lead to primary mirrors that would be too massive and an observatory (including the telescope enclosure) that would be too costly to build. Since the 1990s, a number of groundbreaking approaches have been tried, and the barrier imposed by classical telescope design has been broken. Table 51.1 shows a list of telescopes with apertures greater than 5 m. The increase in telescope area is a result of advances in telescope construction technology and the willingness of society to bear

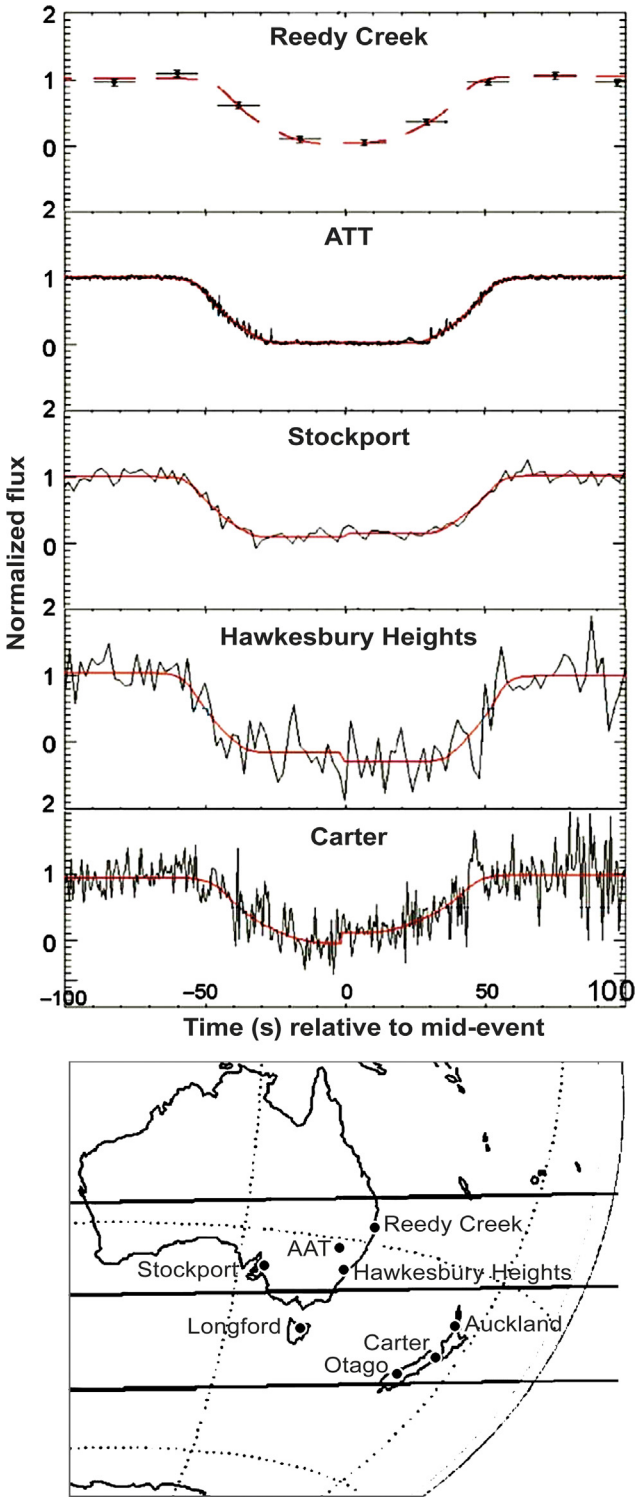

FIGURE 51.2 Occultation of a star by Pluto observed by a network of telescopes ranging in aperture from 0.2 to 4.0 m. The light curves are shown in the upper panel. The lower panel shows the locations of the telescopes. The three lines indicate the midpoint of the occultation track and the upper and lower limits of the track that are determined by the size of Pluto. This type of occultation observation provides a way to measure the size and shape of small solar system bodies that cannot be achieved in any other way. *Courtesy of L.A. Young.*

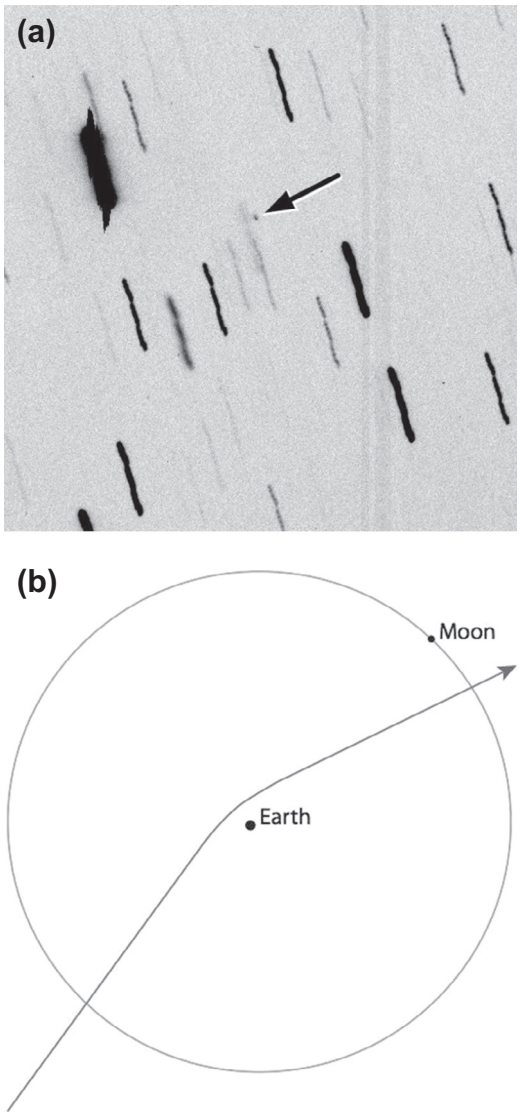

FIGURE 51.3 (a) Image of the asteroid 99942 Apophis. When it was discovered during its last close approach to Earth in 2004, it had a significant probability of striking Earth in the future. Subsequent observations show that it will pass within 5.6 Earth radii of the Earth in 2029 (see panel (b)). However, the future trajectory of the asteroid cannot be predicted well, and the asteroid will have to be carefully monitored with ground-based telescopes. The diameter of the asteroid is about 325 m. Close passages by an asteroid of this size are estimated to occur about once in 1300 years. The danger posed by such close-approaching asteroids has led to funding of asteroid surveys as discussed in Section 5. *Courtesy of R. Tucker, D. Tholen, and F. Bernardi.*

the costs. How much longer can this increase in telescope area continue on the ground?

Several groups in the United States are proposing the next leap in technology to a telescope in the 20–30 m class, and the engineering studies have started. One proposal is the 30-Meter Telescope (TMT), an international consortium consisting of the California Institute of Technology, University of California, Canada, Japan, China, and

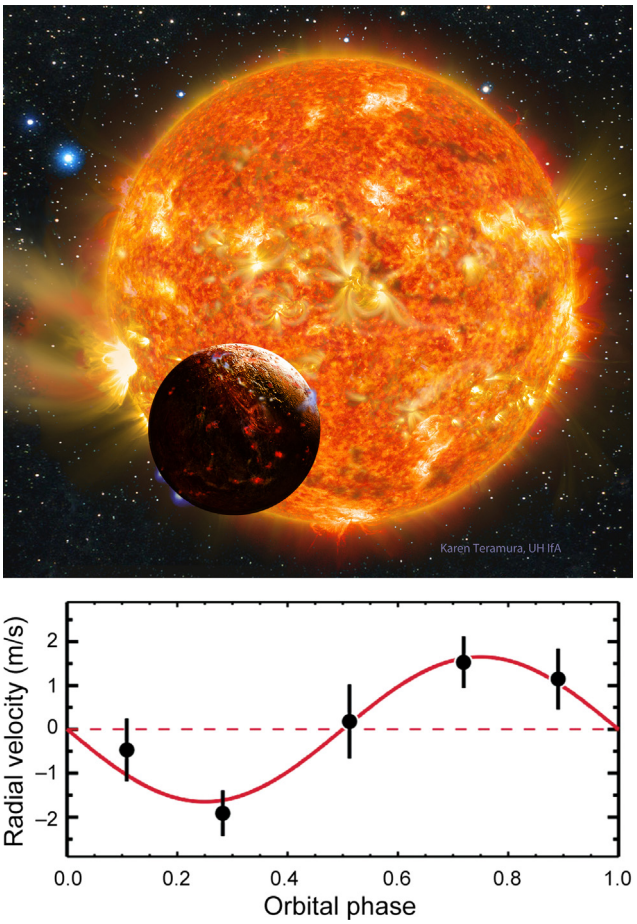

FIGURE 51.4 (Top) Artist conception of Kepler 78 and its planet, Kepler 78b. Kepler 78b was discovered as a transiting object with a radius of 1.2 times that of Earth by the Kepler telescope. With an orbital period of 8.5 h and a distance of only 0.01 AU from the star, the surface temperature of Kepler 78b is estimated to be 2000−2800 °C. (Botttom) The radial velocity variation of Kepler 78 caused by the planet measured with the Keck Telescope. From these measurements, the mass of the planet is estimated to be 1.69 times that of Earth. The mean density of the planet is similar to that of the Earth. It was recently estimated that there might be as many as 40 billion planets that are one to two times the size of Earth in our Galaxy. Ground-based observations such as shown here are essential for obtaining masses of transiting planets. *Courtesy of A. Howard.*

India (http://www.tmt.org/). This project proposes to build a telescope, similar in concept to the Keck telescopes, that will have a primary mirror composed of more than 492 hexagonal segments. As the name implies, the collecting area is equivalent to a circular mirror 30 m in diameter. The other project is the Giant Magellan Telescope, which is supported by a group of public and private institutions in the United States, Australia, and Korea (http://www.gmto.org/). This telescope concept consists of seven 8.4-m mirrors to create a single telescope with the collecting area equivalent to a 22-m circular mirror. In addition to these efforts the European Southern Observatory (ESO) is planning an even larger telescope, the European Extremely Large Telescope (E-ELT), with an equivalent mirror diameter of 39 m using 798 hexagonal mirrors (http://www.eso.org/public/teles-instr/e-elt/). Thus it seems inevitable that a ground-based telescope larger than 10 m will be built.

Five major technical advances have led to the development of large telescopes:

1. Advances in computer-controlled hardware allow correction for flexure of the primary mirror. This has permitted thinner mirrors to be used, reducing the mass of the mirror and the total mass of the telescope. For example, the mass of the ESO Very Large Telescope 8.2-m primary mirror is 23 tons with an aspect ratio (mirror diameter to mirror thickness ratio) of 46. This is a very thin mirror compared with the 5.1-m Hale telescope, which has a weight of 14.5 tons and an aspect ratio of 9.
2. Altitude-azimuth (alt-az) mounts reduce the size of the required telescope enclosure. An 8-m alt-az telescope can fit into the same size enclosure as a 4-m equatorial telescope. An alt-az telescope requires computer-controlled pointing and tracking on two axes, whereas the traditional equatorial mount requires tracking on only a single axis. The Hale telescope is the largest equatorial telescope ever built. All larger telescopes use alt-az mountings. Figure 51.6 illustrates the basic types of telescope mounts, and Figure 51.7 shows examples of telescopes with equatorial and alt-az mounts.
3. Advances in mirror casting and computer-controlled mirror polishing allow the production of larger primary mirrors with shorter focal lengths. A shorter focal length allows the telescope structure to be smaller, thus lowering the weight and cost of the telescope. It also greatly reduces the cost of the dome enclosure. The state of the art in short focal length primary mirrors is a focal length to diameter ratio of 1.14 used in the Large Binocular Telescope (LBT). For comparison, the Hale telescope primary mirror has a focal length to diameter ratio of 3.3. The smaller telescope structure with reduced mass requires less time to reach thermal equilibrium, and its lower mass makes it easier to move. This is extremely important in achieving the best image quality and to efficiently reposition in the telescope.
4. Advances in reducing dome **seeing** led to significant improvement in image quality. Dome seeing is caused by temperature differences within the dome, especially differences between the mirror and the surrounding air. To reduce dome seeing, it is necessary to flush the dome with outside air at night, refrigerate it during the daytime, and cool the primary mirror to about 0.5 °C below the ambient air temperature. Dome seeing is so important that large telescope projects use wind tunnel experiments to determine what type of dome design to employ. Careful attention to dome design is critical in

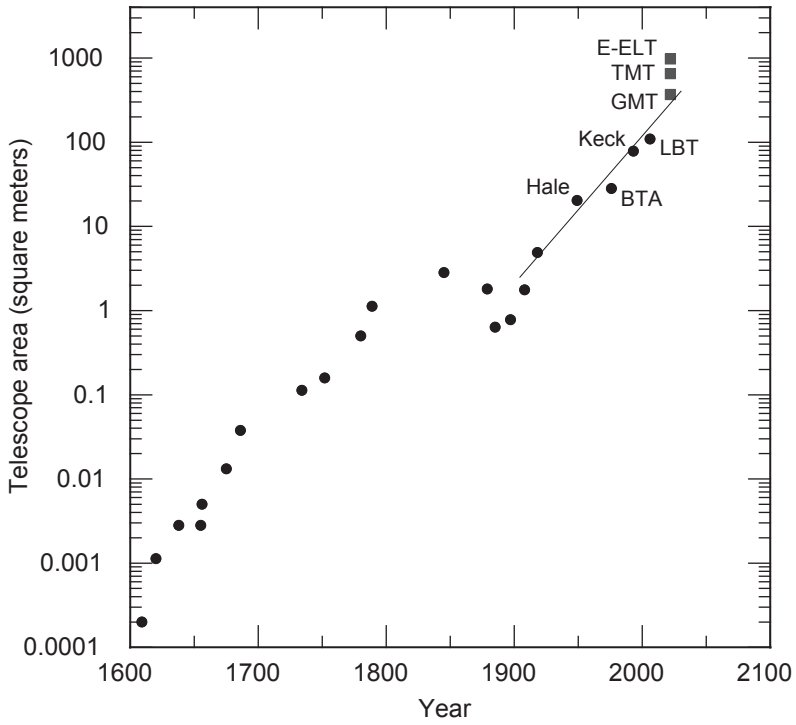

FIGURE 51.5 Increase in telescope area with time. Only the area of the largest telescopes at each time period is shown, so this indicates the envelope of maximum telescope area as a function of year. The time for the telescope area to double is about 26 years from the invention of the telescope in 1608 to the present. However, the doubling time has decreased from about 1900 to the present. The solid line shows a doubling of telescope aperture about every 19 years. The next jump in aperture size will be in the range of 22–40 m with an even shorter doubling time. See Table 51.1 and the text for a discussion of large telescopes.

eliminating dome seeing and achieving the very best seeing at the observatory site. Figure 51.7(b) shows an innovative approach to providing dome flushing by providing slits in the dome.

5. Advances in telescope construction have led to novel methods of reducing the cost of building extremely large telescopes. For example, the 10-m Keck telescopes have mirror segments that make up the primary mirror (Figure 51.7(c)). Although this technique had been used to build radio telescopes, the difficulty of making the segments and the high-precision alignment required at visible wavelengths presented formidable obstacles. Fortunately, the problems of fabricating segmented mirrors and aligning them were solved. The hexagonal mirror segments have a thickness of 75 mm, and so the aspect ratio of the 10-m primary is 133 and the total weight of the glass required is 14.4 tons, about the same weight as the 5-m Hale telescope. Another novel approach uses two 8.4-m primary mirrors on a single structure as in the LBT (Figure 51.7(d)). A third approach involves building a telescope with a fixed vertical elevation. Stars move past the prime focus and are tracked for a limited time. This approach has limitations, but it is much less expensive to build. Two projects (the Hobby–Eberly Telescope and the South African Large Telescope) have adopted this design to achieve 9-m class telescopes at about 15–20% of the cost of an equivalent alt-az telescope.

Large telescopes generally employ one of three different types of primary mirror fabrication: (1) Segmented mirrors. Each segment is figured appropriately, and all segments are aligned so as to act as a single mirror. (2) Thin meniscus mirror using low-expansion glass. Such mirrors are made as thin as possible to be lightweight and to have a short thermal time constant (thus coming into equilibrium with the atmospheric temperature quickly). (3) Thick honeycomb mirror using borosilicate glass. The advantage of using borosilicate glass instead of low-expansion glass is that the former is much cheaper. The disadvantage of borosilicate glass is that the mirror temperature needs to be controlled more carefully. All of these types of primary mirror fabrication approaches have been proven successful. Column (7) in Table 51.1 shows the type of mirror used for each telescope.

All large telescopes use **active optics** to control the shape of the primary mirror. Active optics is the slow adjustment of a mirror to correct aberrations in the image. These adjustments are not fast enough to correct for the atmospheric turbulence, but they can correct for flexure in the telescope structure and for temperature changes that will cause the telescope structure to expand and contract. The process for doing this is illustrated in Figure 51.8. A star is required for the active optics system to be able to compute the deformations on the primary mirror that are needed to correct the image. Although Figure 51.8 illustrates the case for a single mirror, a similar approach is

Column (1): The aperture is the diameter of the primary that can collect light. Unless specified, the number given is the diameter of a circular aperture. The LBT consists of two 8.4-m mirrors that are on a single mount, and the light from both mirrors is combined to form a single image. Two-mirror operations started in 2008. The Keck, HET, and SALT telescopes have primary mirrors that are made from hexagonal segments. The primary mirror has a hexagonal shape, and the largest and smallest widths of the hexagon are given.

Column (2): This is the diameter of the equivalent circular aperture equal to the total light collecting area of the telescope. For the HET and SALT telescopes, this is the maximum equivalent circular aperture that is accepted by the prime focus optics. The LBT, Keck, and VLT observatories can combine light from the mirrors for use as an interferometer. This mode of observations is not considered in this table for the purpose of determining the equivalent circular aperture.

Column (5): Year that science operations started.

Column (6): Primary mirror f/no, which is equal to the focal length of the telescope divided by the primary mirror diameter.

Column (7): Honeycomb: Primary mirror that is lightened with a honeycomb structure on the back. Segmented: Primary mirror is made out of hexagonal segments. Meniscus: Single thin concave mirror. Solid: Thick mirror with no light weighting.

Column (8): The aspect ratio is the primary mirror diameter divided by the mirror (or segment) thickness.

Column (9): The azimuth-only telescope mounts conduct observations by tracking objects in the focal plane of the telescope. For such telescopes, the telescope is fixed but the instrumentation tracks the object.

This table is adapted from J.M. Hill's web site: http://abell.as.arizona.edu/~hill/list/bigtel99.htm and http://en.wikipedia.org/wiki/List_of_largest_optical_reflecting_telescopes.

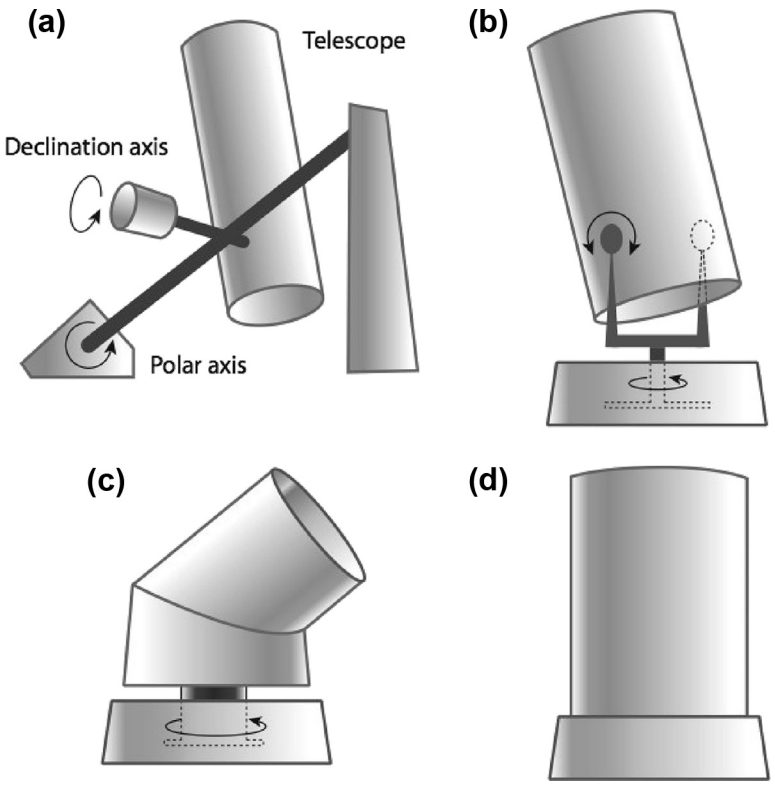

FIGURE 51.6 Schematic of different telescope mounts. (a) Equatorial, (b) altitude-azimuth (alt-az), (c) azimuth only, and (d) fixed. The Hale 5.1-m telescope was the last large telescope to be built with an equatorial mount. The equatorial mount has one axis aligned to the rotation axis of the Earth. (Note: there are many types of equatorial mounts. The Hale telescope uses a type known as the horseshoe equatorial mount.) All fully steerable large telescopes utilize the alt-az mount, such as the Keck, Gemini, Very Large Telescope, and Subaru telescopes (see Table 51.1). In the alt-az mount, the azimuth axis points to the zenith with a perpendicular altitude axis. Two large telescopes built specially for spectroscopy use the azimuth-only mount—the Hobby–Eberly and the South African Large Telescope. These telescopes move only in azimuth and is fixed in altitude. The fixed mount (the telescope points only to the zenith) is used for very specialized applications, such as a liquid mercury mirror telescope or in radio astronomy.

employed for correcting the surface figure of a segmented primary mirror, although the details are quite different.

Efforts to escape the harmful effects of Earth's atmosphere have led to telescopic observations using balloons, aircraft, and rockets. Although we do not discuss space observatories in this chapter, we note here that the Stratospheric Observatory for Infrared Astronomy (SOFIA), a major facility funded by NASA and the German Aerospace Center (DLR) to fly a 2.5-m telescope in the stratosphere, has been recently been completed (http://www.sofia.usra.edu/Sofia/sofia.html). At this high altitude, it is possible to observe throughout the 25–350 μm wavelength range that is inaccessible from the ground. This facility will provide long-term access to a critical wavelength range that otherwise could be exploited only infrequently with spacecraft.

We do not know what ultimately will be the largest ground-based telescope to be built (see Figure 51.5). The limitations arise from the need to be **diffraction** limited, the difficulty of building a suitable enclosure, and the cost. To be competitive with space observatories, all large telescopes must work at the diffraction limit using AO. But the need to be diffraction limited will ultimately cause AO systems to be too complex on an extremely large telescope. An enclosure is necessary to keep the disturbance by wind to acceptable levels, and the cost to build and operate the telescope will be enormous. At some point, it may be more cost-effective to go into space, where gravity and the weather are not factors driving the design.

The drive to build ever-larger telescopes is motivated by the need to collect as much light as possible and thereby increase the signal-to-noise (S/N) ratio of observations. One can derive that for a diffraction-limited telescope and a detector that is background limited, the S/N in a given integration time is proportional to

$$\mathrm{S/N} \approx (A * \eta/\varepsilon)^{0.5}/(\mathrm{FWHM}), \qquad (51.1)$$

where A is the area of the telescope, η is the total transmission of the optics and the detector quantum efficiency, ε is the background emission, and FWHM is the full width at half maximum of a stellar image. η takes into account all of the light losses that occur from the reflection of the mirrors and transmission losses of lenses as light propagates from the telescope to the detector. To minimize these losses, it is necessary to utilize high reflection coatings on mirrors and lenses as well as to minimize the number of lenses. The detector quantum efficiency is the fraction of light that is absorbed by the detector material. This is near the theoretical maximum of 1.0 at visual wavelengths and about 0.8–0.9 for the 1–15 μm wavelength range. The background emission, ε, arises from the sky emission lines at visual wavelengths and thermal background from the telescope and sky at

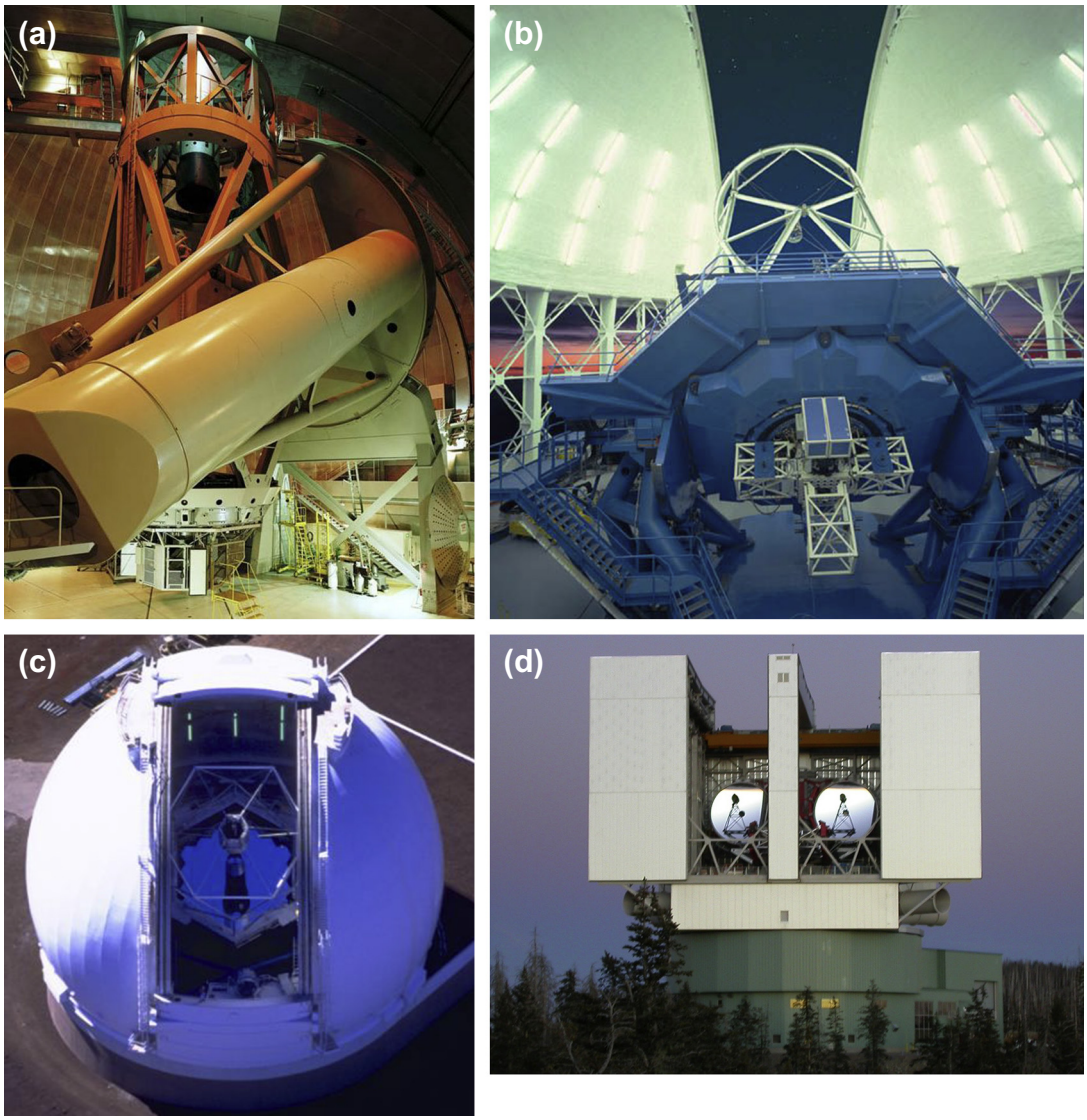

FIGURE 51.7 (a) Hale 5.1-m telescope. The largest telescope to be built in the "classical style" with an equatorial mount, a culmination of about 280 years of development of the reflecting telescope. *(© 2005 Gigapxl Project.)* (b) The 8-m Gemini South telescope. Instruments are mounted on the back of the telescope. These instruments are on the telescope all of the time so that instrument changes can be made very quickly. The dome has vents to allow flushing of the dome by the night air. This allows the telescope and dome to quickly reach equilibrium with the air temperature. *(Courtesy of Gemini Observatory/AURA.)* (c) The 10-m Keck telescope. This image shows one of the two Keck telescopes. The primary mirror consists of 36 hexagonal segments that are aligned to optical precision. The instruments are located on a platform on two sides of the telescope facing the declination bearings. The segmented mirror design approach was first used with the Keck telescopes. The Gran Telescopio Canarias was based on this design, and two of the next-generation large telescopes, the TMT and the E-ELT will use segmented mirrors. *(Courtesy of R. Wainscoat.)* (d) LBT consisting of two 8.4-m primary mirrors. Two mirror science operations started in 2008. The light-gathering power of the two primary mirrors combined is equivalent to an 11.8-m telescope. Both mirrors are on a single structure, and the light from both mirrors can be combined for imaging, spectroscopy, and interferometry. The combined light from the two mirrors will have the angular resolution of a 22.8-m telescope when the LBT is used as an interferometer. *Courtesy of the Large Binocular Telescope Observatory.*

wavelengths longer than 2 μm. To reduce the thermal emission from the telescope, it is necessary to have the highest reflectivity mirrors available and to reduce or eliminate the thermal emission from the secondary mirror. The latter is often accomplished by forming an image of the secondary within the instrument and then blocking it with a cooled metal plate. Then the infrared detector will sense only the thermal emission from the sky and the object being observed.

After maximizing η and reducing ε as much as possible, one can only increase the telescope area and reduce the FWHM to further increase the S/N. Reducing the image FWHM requires decreasing the dome **seeing** to the absolute minimum, building on sites that have good atmospheric

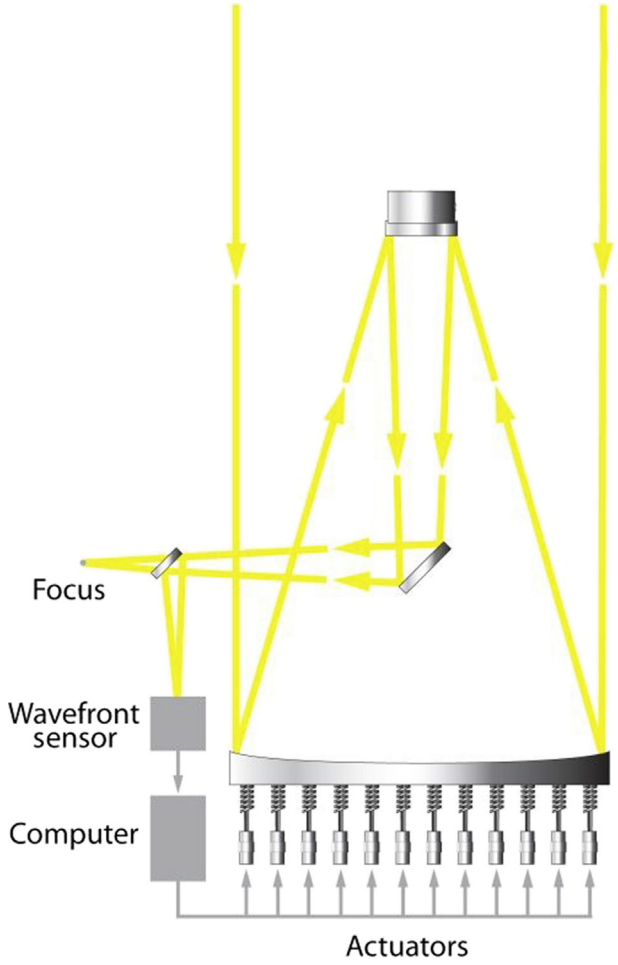

FIGURE 51.8 Schematic of an active optics system. Starlight from the telescope is sent to a beam splitter just in front of the focus that simultaneously sends light to the focus and to a wavefront sensor. The computer analyzes the output of the wavefront sensor and sends control signals to the primary mirror to correct any aberrations in the image. *Courtesy of C. Barbieri.*

seeing, and working at the diffraction limit of the telescope. Astronomical sites in Hawaii, Chile, and La Palma are prime locations for large telescopes because of the good seeing and the good weather they offer.

Figure 51.9 shows the advances in image quality that have been achieved. The development of AO has led to the ability to work at the diffraction limit in the near infrared and to achieve improvements in S/N given by Eqn (51.1). The principles underlying AO are discussed in Section 4.

3. ADVANCES WITH DETECTOR ARRAYS

Initial observations with telescopes were conducted solely with the human eye, but the advantages of using photographic plates to record and archive observations of the sky were quickly exploited beginning in the 1850s. Photographic plates were eventually supplemented with electronic devices like the photomultiplier tube, which amplified the signal from stars by about one million. At infrared wavelengths, there were specialized detectors that employed bolometers, photovoltaic devices, and photoconductive devices. However, photographic plates were a necessity for recording high-resolution images of large areas of sky and recording spectra with a wide wavelength range.

Images recorded by photographic plates depend on the chemical reaction that is induced by a photon of light. Although their efficiency in converting a photon to an image is only a few percent, photographic plates allowed quantitative measurements of the brightness of stars and the strength of spectral lines to be made, and enabled scientists to archive the information for future use.

The next technological revolution came with the invention of the **charge-coupled** device (CCD) in 1973. CCDs are composed of millions of picture elements or pixels. Each pixel is a single detector and is capable of converting photons to electrons. The accumulated electrons can then be sent to an amplifier to be "readout" and recorded by a computer. CCD technology is employed in digital cameras, and just as digital photography has replaced film photography, a similar transformation has taken place in astronomy.

The impact of the CCD on astronomy was immediately apparent. CCDs have two major advantages over the photographic plate: the capability to directly record photons with an efficiency of 80–90% and to store data electronically. The stored data can then be processed with a computer. Until recently, the main deficiency of the CCD relative to the photographic plate was the relatively small amount of sky that could be covered. However, the recent development of very large CCD mosaics now permits larger areas of sky to be covered by a CCD than by a photographic plate. The rapid development of computing power and disk storage has made it practical to use large CCD mosaics. While astronomers have worked hard to develop CCD technology that is optimized for astronomy, the consumer market has driven the development of the necessary computing power and storage. Figure 51.10 shows an example of a state-of-the-art large-format CCD.

There has been a similar revolution in the development of infrared arrays. The first infrared arrays for astronomy were used in the early 1980s. While initially very modest in size (32×32 pixels), infrared arrays now typically contain more than a million pixels. There are several significant differences between CCDs and infrared arrays. One is that a CCD has a single readout amplifier, while an infrared array has one readout amplifier per pixel. The electrons in a CCD are transferred to a single readout amplifier (hence the origin of the term "charge transfer"). Only a single readout amplifier is needed since the readout electronics and the detector material are made out of the same semiconductor

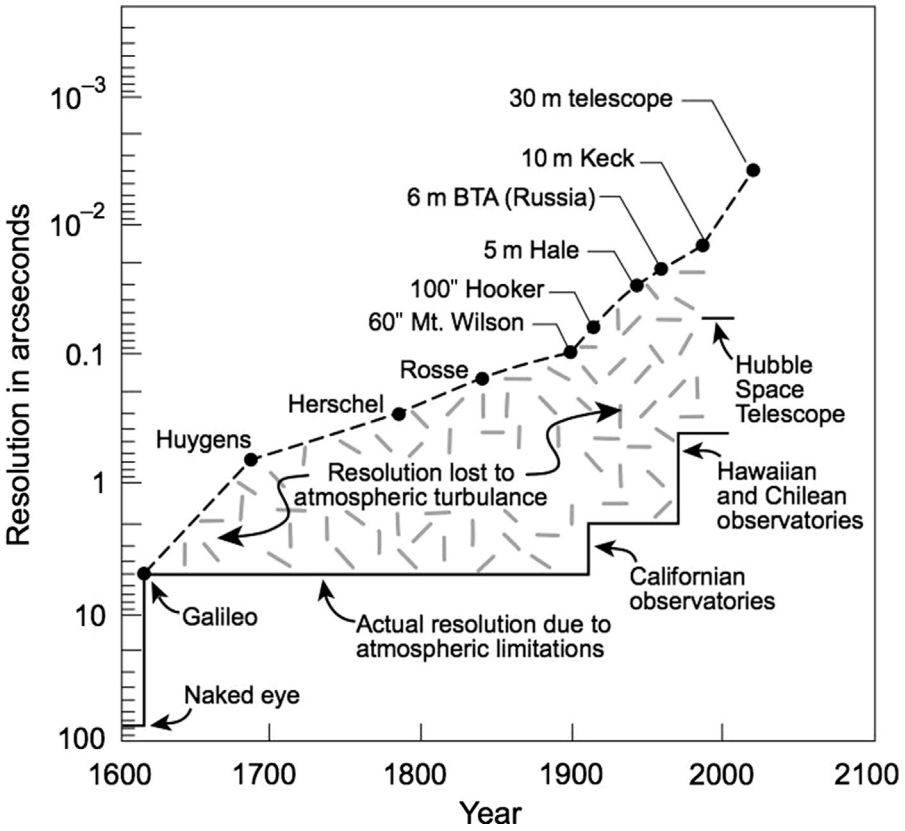

FIGURE 51.9 Improvement in angular resolution at optical wavelengths. The development of adaptive optics (AO) has permitted diffraction-limited observations from ground-based observatories since 1990, largely eliminating the effects of the atmosphere. The dashed line shows the theoretical diffraction-limited resolution for the telescope that can be achieved with AO. The solid line shows the seeing limit imposed by the atmosphere where improvements were obtained by going to sites with very good seeing. The resolution of the Hubble Space Telescope is shown, from which it is evident that the frontier for high angular resolution is being advanced with ground-based observatories. *From P. Bely, 2003.*

material. In an infrared array, the detector material and the readout amplifier have to be made out of different materials, so each pixel must have a separate amplifier. A second difference is that the infrared arrays must be cooled to much lower temperatures. CCDs can operate effectively at about −30 to −40 °C. Infrared arrays must be cooled to liquid nitrogen (−196 °C) or liquid helium (−269 °C) temperatures.

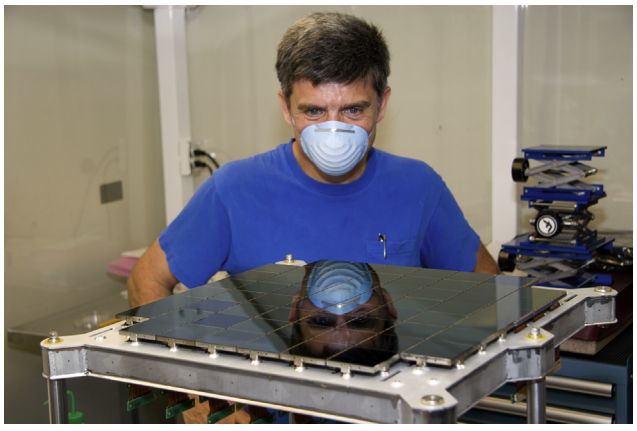

FIGURE 51.10 Large CCD mosaic with 1.4×10^9 pixels that is being used with the Pan-STARRS 1 telescope. This CCD mosaic consists of 60 individual CCDs and is the largest CCD mosaic in use for astronomy. A larger CCD mosaic with more than twice as many pixels is planned for use with the Large Synoptic Survey Telescope. Large CCD mosaics have led to many types of sky surveys and are a driving force for a virtual observatory where large collections of imaging and spectroscopic data are made available for research programs. *Courtesy of the Pan-STARRS project.*

The development of large-format CCDs and infrared arrays has enabled astronomers to undertake large-scale digital sky surveys at visible and infrared wavelengths (see Section 5), just as the use of large photographic plates enabled astronomers to make the first deep sky surveys over 60 years ago.

Figure 51.11 shows an image of Saturn at a wavelength of 18 μm taken with an infrared array. At these wavelengths, we are observing the thermal emission (heat) from the planet. Thus the temperatures in Saturn's atmosphere and the dust particles in the rings can be measured.

4. ADVANCES IN ADAPTIVE OPTICS (AO)

AO is a technique that removes the atmospheric disturbance and allows a telescope to achieve **diffraction**-limited imaging from the ground. This is critical in achieving the maximum S/N given in Eqn (51.1). The basic idea of AO is to first measure the amount of atmospheric disturbance, then correct for it before the light reaches the camera. A schematic of how this can be done is shown in Figure 51.12.

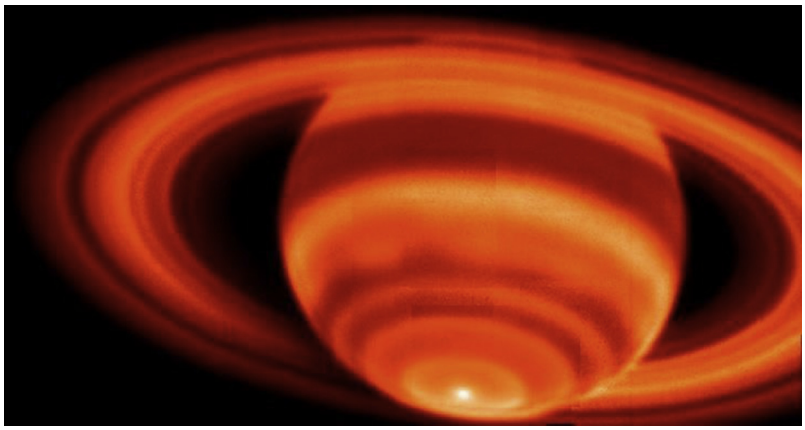

FIGURE 51.11 Image of Saturn and its rings obtained in 2004 with the 10-m Keck I telescope at a wavelength of 17.6 μm. This is a false color image, where higher signal levels are lighter. At these wavelengths, we are seeing the heat radiated by the atmosphere and the rings of Saturn. The South Pole has an elevated temperature (−182 °C) compared with its surrounding. This is likely because the South Pole was illuminated by the Sun for 15 years. *Courtesy of G. Orton, JPL.*

AO requires a star or another object that is bright enough for rapidly and accurately measuring the incoming wavefront. If the object of interest is not bright enough, then it is necessary to use a nearby bright star. This limits the sky coverage, since not every region of the sky will have a bright enough star nearby. If there is no nearby bright star, then it is necessary to use a laser guide star. A laser is pointed in the same direction as the telescope and is used to excite a thin layer of sodium atoms in Earth's ionosphere (at an altitude of 90 km). This provides a point source that acts as an artificial star for the AO system.

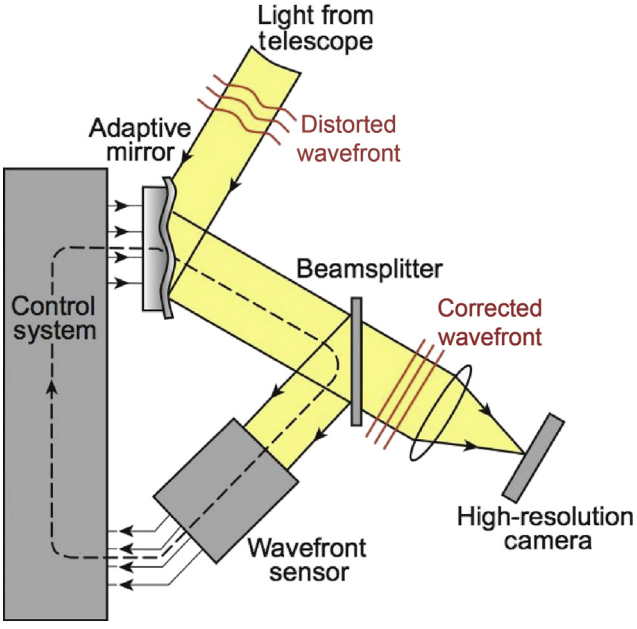

FIGURE 51.12 Simplified diagram of an AO system. Light from the telescope is collimated and sent to an adaptive or deformable mirror. If there were no atmospheric turbulence, the wavefront of the light would be perfectly straight and parallel. The light is then reflected to a beam splitter, where part of the light is reflected to the wavefront sensor. The wavefront sensor measures the distortion of the wavefront and sends a correction signal to the adaptive mirror. The adaptive mirror is capable of changing its shape to remove the deformations in the light wave caused by the atmospheric turbulence. In this way, the light with a corrected wavefront reaches the high-resolution camera, where a diffraction-limited image is formed. *Courtesy of C. Max.*

Figure 51.13 shows a dramatic photo of laser guide stars in use at the Keck and Subaru telescopes on Mauna Kea. All large telescopes now have AO and laser guide stars. The effect of using AO is striking. It is like placing the telescope into space. An impressive example of how AO can improve image quality is shown in Figure 51.14. A further example of the high angular resolution provided by AO is shown in Figure 51.15. Here the volcanoes on the satellite Io can be individually resolved. Such high angular resolution is impressive and rivals the images from the Voyager and Galileo spacecraft.

We can look forward to the exploration of other solar systems. Figure 51.16 shows an image of an exoplanetary system. The physical characteristics of other solar systems and exoplanets can be studied for the first time, and this is certainly a scientific area where large telescopes with AO are necessary.

5. SKY SURVEY TELESCOPES

Although large telescope projects tend to get a lot of attention, recently there has been a corresponding quantum jump in the construction of visible and infrared survey telescopes. This has been made possible by the availability of large-format CCDs and infrared arrays. In addition, the discovery of the Kuiper Belt has led to fundamental advances in our understanding of how our solar system formed. There is a great need to continue the survey of the Kuiper Belt because detailed knowledge of the size and orbit distributions of these objects will allow us to test theories of the orbital migration of the outer planets (Jupiter, Saturn, Uranus, Neptune), the origin of the

FIGURE 51.13 Sodium laser guide stars in simultaneous use at the Keck and Subaru telescopes. The laser operates at a wavelength of 5890 Å (0.589 μm), and the laser light is propagated through a smaller telescope attached to the telescopes. It excites sodium atoms at an altitude of 90 km in Earth's atmosphere. The sodium atoms emit light at the same wavelength as the laser, and this is viewed as an artificial star by the telescope. All large telescopes employ laser guide stars to achieve diffraction-limited imaging. This is a long exposure photograph. The laser guide star is barely visible with the naked eye from this angle. *Courtesy of Dan Birchall.*

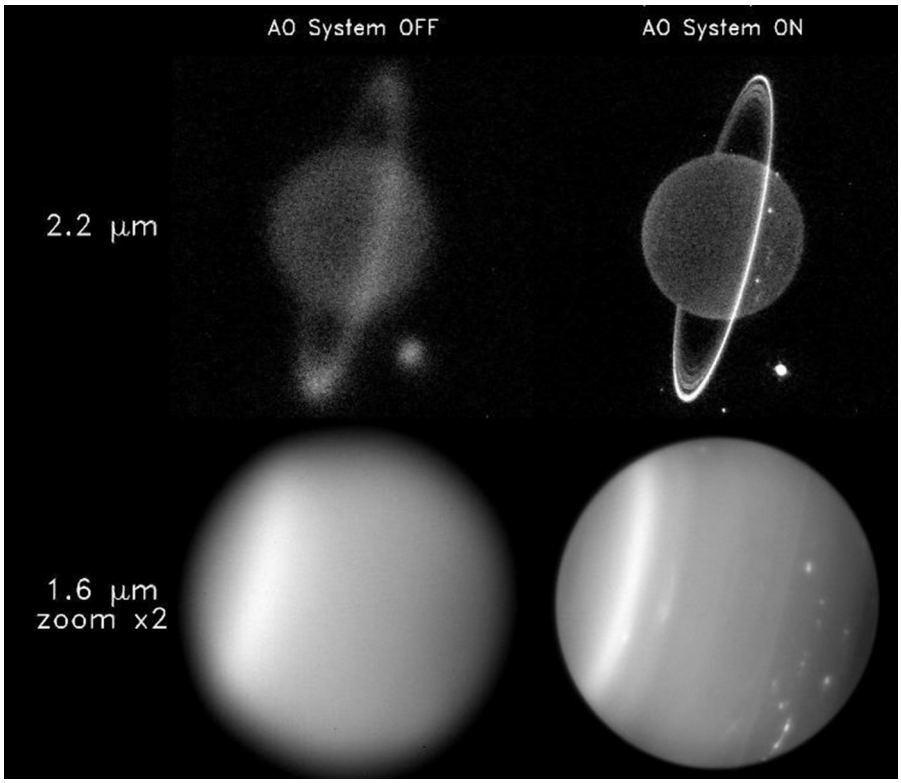

FIGURE 51.14 Images of Uranus with and without adaptive optics (AO). This is a striking demonstration of the effectiveness of AO in removing atmospheric turbulence. One can also see that the signal-to-noise ratio is greatly enhanced because light is concentrated into a diffraction-limited image with AO, thus greatly increasing the ability to detect faint spots and cloud structure. At a wavelength of 1.6 μm, we are seeing reflected light from low-altitude clouds, while at 2.2 μm the high-altitude clouds are revealed. The planet is much darker at 2.2 μm because of absorption of methane gas in the atmosphere. This allows a much longer exposure and for the rings to be seen clearly. The point-like cloud features at 2.2 μm show that in certain places turbulence is very strong, and it is pushing material from lower altitudes into the stratosphere. *Courtesy of H. B. Hammel, I. de Pater, and the W. M. Keck Observatory.*

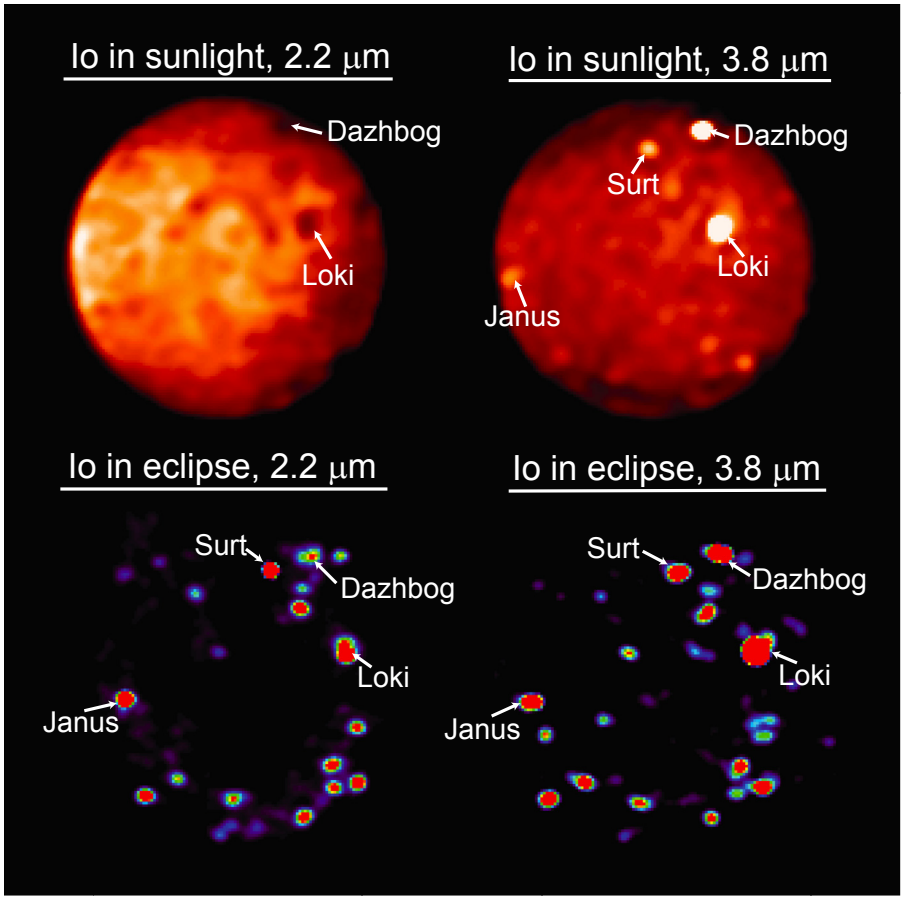

FIGURE 51.15 Adaptive optics images of Jupiter's satellite Io obtained with the Keck Observatory. The angular size of Io is 1.2 arcseconds. (Top): Io in sunlight. At 2.2 μm the reflected light from the Sun dominates, while at 3.8 μm thermal emission (heat) from the volcanoes can be observed. Some volcanoes (Loki, Dazhbog) show up as hot spots at 3.8 μm, but as low-albedo features at 2.2 μm. (Bottom): Io in eclipse. Images of Io taken 2 h later, after the satellite had entered Jupiter's shadow. Without sunlight reflecting off the satellite, even the faintest hot spots can be discerned. The difference in brightness between the two wavelengths gives an indication of the temperature of the spot. Dazhbog, very bright at 3.8 μm, is a low-temperature (500 K) hot spot. Janus, on the other hand, is very bright at both 3.8 and 2.2 μm, indicative of higher temperatures (800 K). *Courtesy of I. de Pater.*

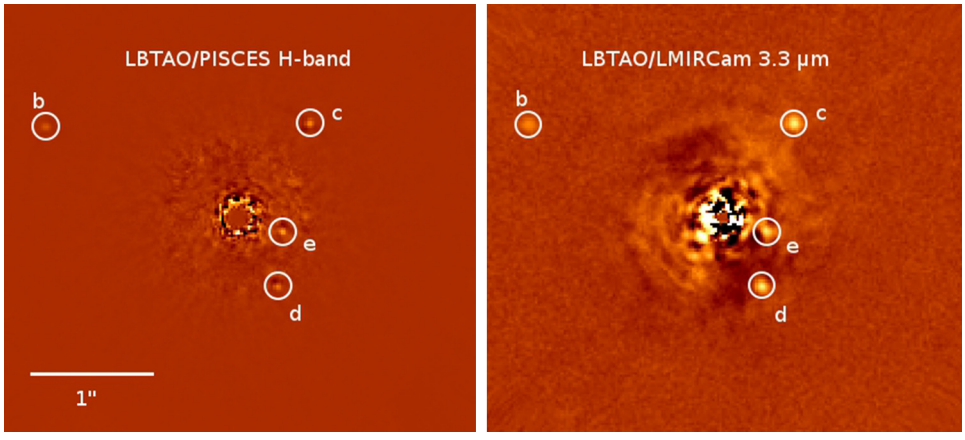

FIGURE 51.16 Large Binocular Telescope AO images of the HR 8799 planetary system in the H-band (1.65 μm) and 3.3 μm. The objects labeled b, c, d, and e are thought to be planets that are less than 13 Jupiter masses, although this depends on the assumed age of the host star, HR 8799. The data presented along with spectra obtained of the objects indicate the atmospheres of the objects are cloudy and have a mixture of temperatures of 400 and 1100 °C. *Courtesy of A.J. Skemer.*

short-period comets, and the cause of the late heavy bombardment of the inner solar system.

There is also an increased awareness that it is important to identify asteroids and comets that could collide with Earth (see Figure 51.3). In 1998 the Congress of the United States directed NASA to identify within 10 years at least 90% of NEOs larger than 1 km that may collide with Earth, and this has been achieved. There are a number of scientific benefits that arise from the NEO surveys, including determining the origin of NEOs, identifying interesting NEOs that could be visited by spacecraft, improving our knowledge of the numbers and sizes of the asteroids in the main asteroid belt, and the discovery of new comets.

The discovery of all NEOs larger than 1 km is important because if such an object collides with Earth, the consequences will be catastrophic. If it is possible to predict that there will be a collision, it may be possible to divert the asteroid so that it misses Earth. The earlier such a prediction can be made, the more likely it is that the diversion is possible. This is a case in which there is a practical use for astronomy.

Table 51.2 shows a list of asteroid search programs that are currently in progress or planned to find asteroids that present a hazard to the Earth. Current productivity of various programs is shown in Figure 51.17, which shows all NEOs discovered irrespective of size. While the NASA directive is aimed at identifying NEOs larger than 1 km in diameter, many NEOs smaller than 1 km are also discovered because of the sensitivity of the search programs and because small objects that come very close to Earth may be bright enough to be detected. For example in 2012, an NEO named 2012 KT42 with an estimated diameter of only 7 m was discovered and it came to within 16,000 km of Earth's surface.

The number of known NEOs has been increasing because of the larger number of funded survey programs and advances in detector arrays that have allowed much larger areas of sky to be covered in a single exposure. The number of NEOs discovered as a function of time is shown in Figure 51.17. Note that while the total number of asteroids that approach Earth are still being discovered at a rapid rate, the number of new asteroids larger than 1 km discovered each year is decreasing, since there are fewer large asteroids left to find. As can be seen in Figure 51.17 most NEOs are discovered by two dedicated asteroid survey programs: the Catalina Sky Survey in Arizona and Pan-STARRS in Hawaii.

There are three major ground-based sky surveys currently under development or study (see Table 51.2). Pan-STARRS 2 is a 1.8-m telescope similar to the Pan-STARRS 1 telescope. The construction work is funded and the telescope and camera should be ready in 2014. The Asteroid Terrestrial-impact Last Alert System (ATLAS) is a pair of small telescopes designed to find asteroids that about to impact with Earth. This project is funded, and

[1]*Collecting area is the area of the telescope corrected for any obscuration by the secondary mirror.*

[2]*Field of view is the area of sky covered in a single exposure.*

[3]*Magnitude limit is the faintest star recorded at visible wavelengths.*

[4]*Etendu is a figure of merit that is the collecting area of the telescope multiplied by the field of view. This is a measure of how fast a sky survey can be achieved assuming the cameras operate at the same wavelength and efficiency.*

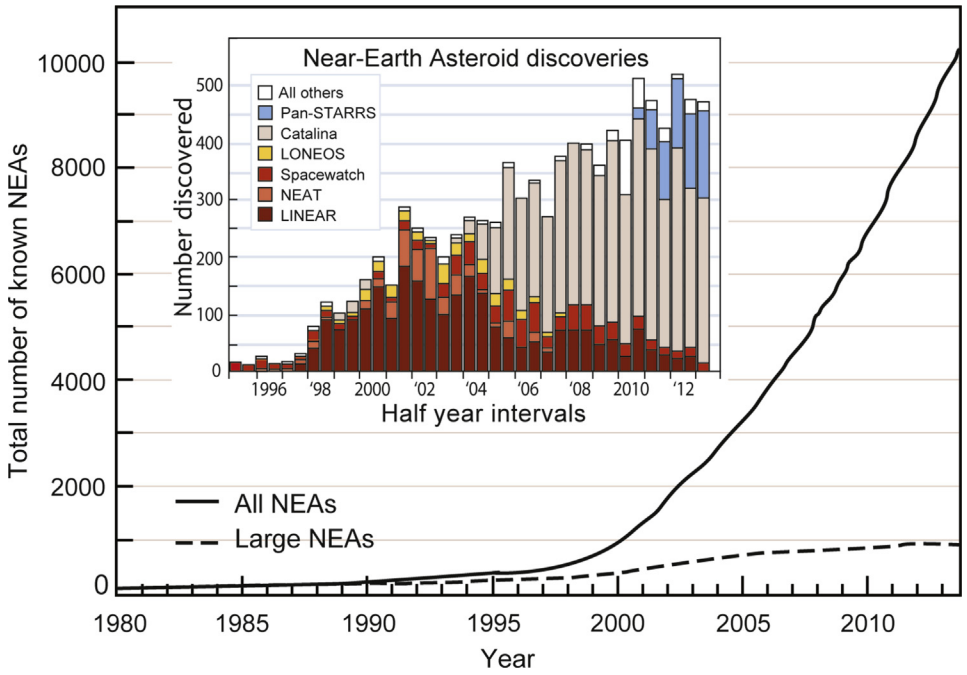

FIGURE 51.17 Cumulative discoveries of near-Earth asteroids. The total number of large near-Earth asteroids (larger than 1 km) is increasing at a slower rate since most of the easy-to-detect near-Earth asteroids have already been discovered. Most near-Earth asteroid discoveries are now made with the Catalina Sky Survey and the Pan-STARRS telescopes. *Courtesy of Alan Chamberlin.*

observations should start in 2015–2016. The proposed Large Synoptic Survey Telescope is currently under development and is envisioned to be a monolithic 8.4-m wide-field telescope (with a collecting area equal to a 6.7-m telescope). It is planned to be completed by 2025 in the Southern Hemisphere.

6. CONCLUDING REMARKS

Space does not allow coverage of all of the relevant subjects related to the vibrant topics of novel telescope construction, optical fabrication techniques, advances in mirror figure control, AO, and detector improvements at visible and infrared wavelengths. The topics covered in this chapter can only hint at the tremendous advances that have taken place in recent years and that carry on unabated. Since the invention of the refractive and reflective telescopes by Galileo and Newton, the construction of ground-based telescopes has continued to challenge the very best minds in physics and engineering. There are now strong scientific drivers to build larger telescopes in the 20–40 m range, and three such projects are underway.

Solar system astronomy is driven by the need to have large telescopes to study very faint objects in the Kuiper Belt and very faint NEOs that may present a hazard to Earth. It is also necessary to have the highest spatial resolution possible by working at the **diffraction** limit of large telescopes. This will enable researchers to study the surface and atmospheric features of the outer planets, dwarf planets, and their satellites. Large telescopes also allow the study of exoplanets, and thus bring about a merging of studies of our solar system with those around distant stars.

Another driver of solar system astronomy is the need to detect and characterize NEOs that may present an impact hazard to Earth. Asteroid search programs are underway to detect these NEOs. These survey programs will play a significant role in greatly expanding our knowledge of the building blocks of our solar system—the asteroids and comets from the inner to the outer reaches of the solar system. These studies are profoundly affecting our understanding of the formation of our solar system and of life itself.

Although we have not emphasized it in this chapter, there is also strong interest in the use of small telescopes for solar system astronomy. Networks of small telescopes are now routinely employed for the study of stellar occultations by small bodies such as asteroids and KBOs (see Figure 51.2). A new type of observatory, the Las Cumbres Observatory Global Telescope Network, provides observing time on small telescopes distributed around the world. The Taiwan American Occultation Survey is a cluster of small telescopes searching for stellar occultations by KBOs. These efforts are likely to increase in importance in the future.

We anticipate continuing growth in telescope and instrument development for many generations to come. This is indeed a period of great innovation—a renaissance in

telescope building and instrumentation—that we are fortunate to be able to witness and to participate in.

Bibliography **1131**

1. INTRODUCTION

Ground- and space-based radio astronomical observations of planetary objects provide information that is complementary to that obtained at other (visual, infrared (IR), ultraviolet (UV)) wavelengths. We distinguish between thermal and nonthermal emissions. *Thermal radio emission* originates from a body's surface (or more appropriately subsurface) and/or atmosphere, and *nonthermal radio emissions* are produced by charged particles in a planet's magnetosphere. The thermal emission can be used to deduce the structure and composition of a planet's atmosphere and surface layers; the nonthermal radiation provides information about its magnetic field and charged particle distributions therein. Ground-based radio astronomy is essentially limited to frequencies above about 10 MHz because of the shielding effects of the Earth's ionosphere at lower frequencies. Space-based measurements extend the frequency range of solar system radio astronomy as low as a few kilohertz. In this chapter, we discuss radio emissions from a few kilohertz up to $\gtrsim$500 GHz. Since we cover over nine orders of magnitude in frequency, we can include only brief summaries of a select number of topics.

1.1. Instrumentation

A radio telescope consists of an antenna and a receiver. The antenna can be a simple monopole, dipole, or parabolic dish (Figure 52.1). The sensitivity of the antenna depends on many factors, but the most important are the effective aperture and system temperature. The effective aperture depends on the size of the dish and the aperture efficiency. The sensitivity of the telescope increases when the effective aperture increases and/or the system temperature decreases.

The response of an antenna as a function of direction is given by its antenna pattern, which consists of a "main" lobe and a number of smaller "side" lobes, as depicted in Figure 52.2(a). The resolution of the telescope depends on the angular size of the main lobe. It is common to express the main lobe width as the angle between the directions for which the power is half that at lobe maximum; this is referred to as the half power beam width. This angle depends on the size of the dish and the observing wavelength: For a uniform illumination, the beam width is approximately λ/D radians, with D the dish diameter in the same

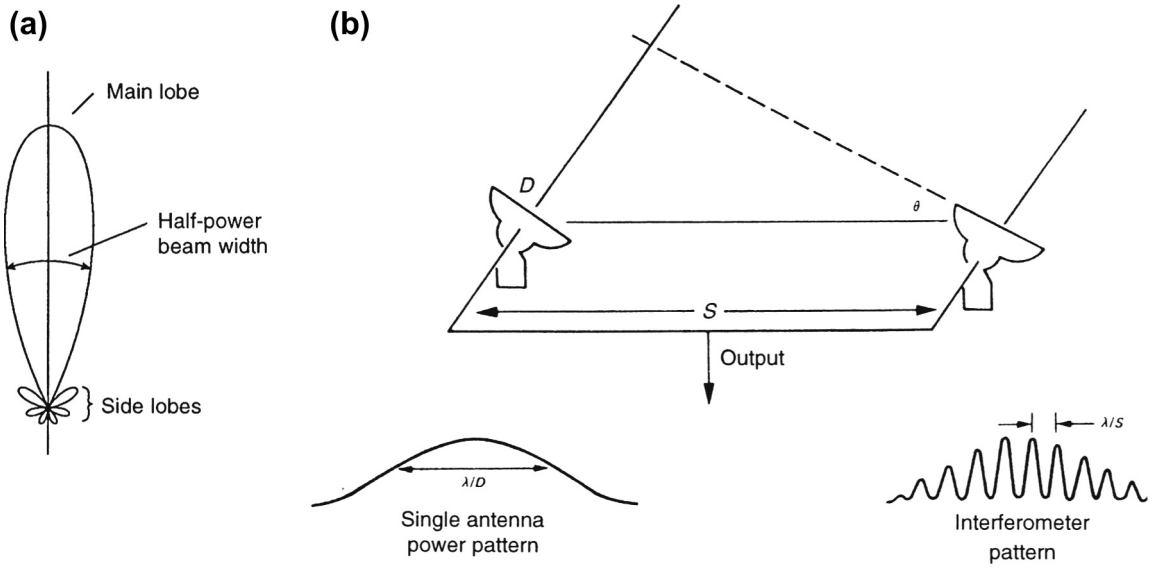

FIGURE 52.2 (a) A generic antenna pattern consists of a "main" lobe and a number of smaller "side" lobes, as depicted in the figure. The half power beam width is the full width at half power. *(After Kraus (1986).)* (b) Top: Geometry of a two-element interferometer. Bottom: Antenna response for a single element of the interferometer (left) and response of the interferometer (right) to an unresolved radio source. *Gulkis, S. & de Pater, I. (2002).*

units as the wavelength λ. Space-borne radio telescopes at low frequencies usually are composed of one or more long cylindrical elements since dish antennas are prohibitive in terms of mass.

The resolution of a radio telescope can be improved by connecting the outputs of two antennas that are separated by a distance S at the input of a radio receiver. The Very Large Array (VLA) in Socorro, New Mexico, consists of a Y-shaped track, with nine antennas along each of the arms (Figure 52.1(a)). This telescope thus provides 351 individual interferometer pairs, each of which has its own instantaneous resolution along its projected (on the sky) baseline S'. Such an array of antennas is needed to construct an image that shows both the large- and small-scale structures of a radio source. At short spacings, the entire object can be "seen", but details on the planet are washed out due to the low resolution of such baselines. At longer baselines, details on the planet can be distinguished, but the large-scale structure of the object gets resolved out, and hence would be invisible on the image unless short spacing data are included as well. Hence, arrays of antennas are crucial to image an object.

2. THERMAL EMISSION FROM PLANETARY BODIES

2.1. Thermal or Blackbody Radiation

Any object with a temperature above absolute zero emits a continuous spectrum of electromagnetic radiation at all frequencies, which is its thermal emission, usually modeled as "*blackbody*" radiation.

Blackbody radiation can be described by Planck's radiation law, which, at radio wavelengths, can usually be approximated by the Rayleigh–Jeans law:

$$B_\nu(T) = \frac{2\nu^2}{c^2}kT \tag{52.1}$$

where $B_\nu(T)$ is the brightness (W/m^2/Hz/sr), ν is the frequency (Hz), T is the temperature (K), k is the Boltzmann's constant (1.38×10^{-23} J/K), and c is the velocity of light (3×10^8 m/s). With a radio telescope, one measures the *flux density* emitted by the object. A common unit is the flux unit or Jansky, where 1 Jy $= 10^{-26}$ W/m^2/Hz. This flux density can be related to the temperature of the object:

$$S = \frac{abT}{4.9 \times 10^6 \lambda^2}\ \text{Jy} \tag{52.2}$$

where λ is the observing wavelength (in meters), $2a$ and $2b$ are the equatorial and polar diameters (in arc seconds), and T is the temperature (in Kelvin). Usually, planets do not behave like a blackbody, and the temperature T in Eqn (52.2) is called the brightness temperature, defined as the temperature of an equivalent blackbody of the same brightness.

2.2. Radio Emission from a Planet's (Sub) surface

Radio observations can be used to extract information about the (sub)surface layers of planetary bodies. The temperature structure of the (sub)surface layers of airless bodies depends on a balance between solar insolation, heat transport within the crust, and reradiation outward. The fraction of the solar flux absorbed by the surface depends on the object's albedo, A, while the energy radiated by the surface (at a given temperature) depends on its emissivity, e (which is 1 for a blackbody). The parameters e and A are related through Kirchoff's law:

$$e = 1 - A \tag{52.3}$$

During the day, a planet's surface heats up and reaches its peak temperature at noon or early afternoon (the exact time depends on the body's thermal inertia, a body's ability to store energy); at night the object cools off. Its lowest temperature is reached just before sunrise. Because it takes time for the heat to be carried downward, there will be a phase lag in the diurnal heating pattern of the subsurface layers with respect to that at the surface, and the amplitude of the variation will be suppressed. At night, heat is carried upward and radiated away from the surface. Hence, while during the day the surface is hotter than the subsurface layers, at night the opposite is true.

Radio waves typically probe $\sim$10 wavelengths into the crust, as determined by the electrical skin depth, L_r, which is equivalent to the depth at which unit optical depth is reached:

$$L_r = \lambda/(2\pi\sqrt{\varepsilon_r}\tan\Delta) \tag{52.4}$$

with λ the wavelength, ε_r the real part of the dielectric constant, and $\tan\Delta$ is the "loss tangent" (or absorptivity) of the material—the ratio of the imaginary to the real part of the dielectric constant. Hence, by observing at different wavelengths, one can determine the diurnal heating pattern of the Sun in the subsurface layers. Such observations can be used to constrain thermal and electrical properties of the crustal layers. The thermal properties relate to the physical state of the crust (e.g. rock versus dust), while the electrical properties are related to the mineralogy of the surface layers (e.g. metallicity).

2.3. Radio Emission from a Planet's Atmosphere

Radio spectra of a planet's atmosphere can be interpreted by comparing observed spectra with synthetic spectra,

which are obtained by integrating the equation of radiative transfer through a model atmosphere:

$$B_\nu(T_\mathrm{D}) = 2\int_0^1\int_0^\infty B_\nu(T)e^{(-\tau/\mu)}\mathrm{d}(\tau/\mu)\mathrm{d}\mu \qquad (52.5)$$

where $B_\nu(T_\mathrm{D})$ can be compared to the observed disk-averaged *brightness temperature*. The brightness $B_\nu(T)$ is given by the Planck function and the optical depth $\tau_\nu(z)$ is the integral of the total absorption coefficient over the altitude range z at frequency ν. The parameter μ is the cosine of the angle between the line of sight and the local vertical. By integrating over μ, one obtains the disk-averaged brightness temperature, to be compared to the observed brightness temperature.

Before the integration in Eqn (52.5) can be carried out, the atmospheric structure, as composition and temperature–pressure profile, needs to be defined. Usually, above and just below the tropopause the temperature–pressure profile as derived from spacecraft data (e.g. occultation data) or from ground-based mid-IR observations is adopted. At deeper layers, the temperature structure is commonly approximated by an *adiabatic lapse rate*, appropriately changed if species condense. The temperature, pressure, and density of an atmosphere are related to one another through the ideal gas law. The shape of absorption/emission lines depends on the temperature and pressure of the environment, and may vary from relatively narrow lines (e.g. Mars, Venus, Titan, Io) to broad quasi-continuum spectra (e.g. giant planets).

2.4. Terrestrial Planets and the Moon

2.4.1. The Moon

Lunar radio astronomy dates back to the mid-1940s, well before the first *Apollo* landing on the Moon. Since the mid-1970s, after a decade of "neglect", there was renewed interest in lunar radio astronomy since radio receivers had improved substantially and laboratory measurements of *Apollo* samples provided a ground truth for several sites on the Moon. By using lunar core samples, one could determine a density profile of the soil with depth near the landing sites, as well as the complex dielectric constant of a variety of rocks and powders, both useful in modeling radio observations.

A microwave image of the full Moon reveals that the maria are ∼5 K warmer than the highlands. This may result from a difference in albedo (the maria are darker than the highlands), radio emissivity, and/or the microwave opacity. Lunar samples suggest that the microwave opacity in the highlands is somewhat (factor of ∼2) lower than that in the maria, so that deeper cooler layers are probed in the lunar highlands compared to the maria during full moon (as observed); at new moon the temperature contrast should be reversed, since the temperature increases with depth at night. No observations have yet been reported, however.

2.4.2. Mercury

Radio images of Mercury show a brightness variation across the disk, which displays the history of solar insolation. Figure 52.3(a) shows a radio image at 3.6 cm, probing

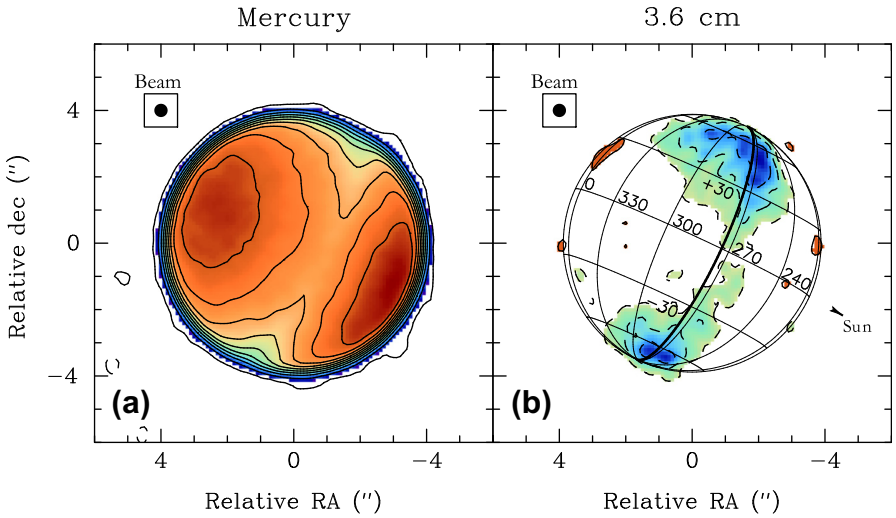

FIGURE 52.3 (a) The 3.6-cm thermal emission from Mercury observed with the VLA. Contours are at 42-K intervals (10% of maximum), except for the lowest contour, which is at 8 K (dashed contours are negative). The beam size is 0.4″ or 1/10 of Mercurian radius. Note the two "hot" regions, discussed in the text. (b) A residual map after subtracting a model image from the map in panel a. Mercury's geometry is indicated, including the direction to the Sun and the morning terminator (heavy line). The hot regions have been modeled well, since they do not show up in this residual map. Instead, large negative (blue) temperatures near the poles and along the morning side of the terminator are visible, likely caused by shadows on the surface resulting from local topography. Contour intervals are in steps of 10 K, which is roughly three times the root mean square noise in the image. *Mitchell, D. L. & de Pater, I. (1994).*

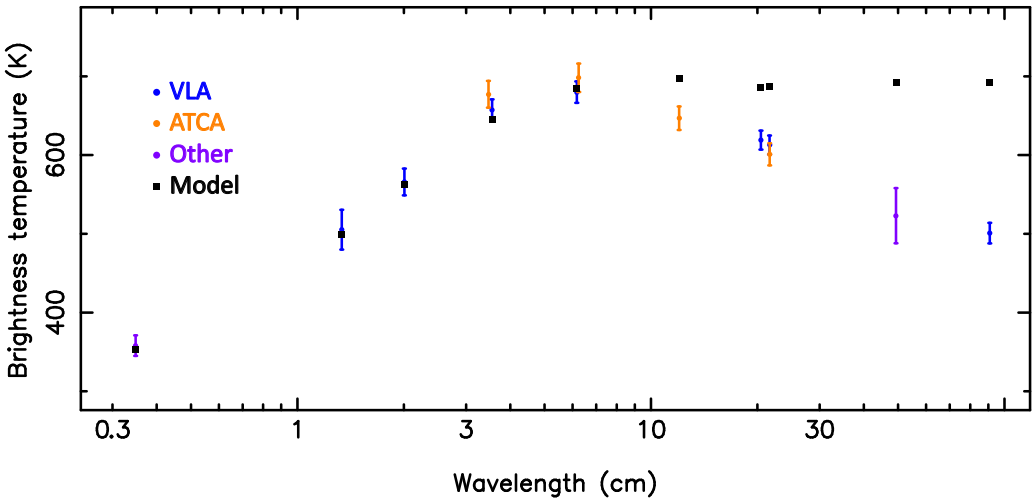

FIGURE 52.4 A radio spectrum of Venus. At short wavelengths, the radio emissions arise approximately from altitudes near Venus' cloud layers. The brightness temperature increases when deeper warmer layers are probed and decreases again at wavelengths long enough to probe down into Venus' surface. VLA = Very Large Array; ATCA = Australia Telescope Compact Array. *Butler, B. J. & Sault, R. J. (2003).*

a depth of ∼70 cm. Two "hot" regions are visible, one of them almost opposite to the direction of the Sun. This hot–cold pattern results from Mercury's 3/2 spin–orbit resonance: Mercury rotates three times around its axis for every two revolutions around the Sun. This, combined with the planet's large orbital eccentricity, causes Mercury's peak (noon) surface temperature to vary between 700 K for longitudes facing the Sun at perihelion to 570 K 90° away. While the surface temperature responds almost instantaneously to changes in illumination, the subsurface layers do not, and this variation in solar insolation remains imprinted at depths well below the surface, giving rise to the "hot" regions displayed in Figure 52.3(a).

These hot regions are modeled well, as exemplified by the map in Figure 52.3(b), which shows the difference between the observed map and a thermal model. The viewing geometry is superimposed on the latter image. The negative temperatures near the poles and along the terminator are indicative of areas colder than predicted in the model. This is likely caused by surface topography, which causes permanent shadowing in craters at high latitudes and transient effects in the equatorial regions, where crater floors and hillsides are alternately in shadow and sunlight as the day progresses.

Radio spectra and images, together with *Mariner 10* IR data show that Mercury's surface properties are quite similar to those of the Moon, except for the microwave opacity, which is ∼2–3 smaller than that of most lunar samples. This suggests a low ilmenite ($FeTiO_3$) content, the mineral that is largely responsible for the dark appearance of the lunar maria. The absence of minerals bearing iron (Fe) and titanium (Ti) from Mercury's surface has been confirmed via X-ray spectroscopy from the MESSENGER spacecraft, and suggests the absence of extensive basaltic volcanism from Mercury's deep interior.

2.4.3. Venus and Mars

Venus and Mars have atmospheres which consist of over 95% carbon dioxide gas (CO_2). Other than having a similar composition, the atmospheres are very different. The surface pressure on Venus is approximately 90 times that on the Earth, while on Mars it is ∼140 times smaller. The shear amount of CO_2 gas on Venus provides so much opacity that Venus' surface can only be probed at wavelengths longward of ∼6 cm (Figure 52.4), whereas Mars' atmosphere is essentially transparent at most radio wavelengths. On both planets, CO_2 gas is *photodissociated* (molecules are broken up) by sunlight at high altitudes into carbon monoxide (CO) and oxygen (O). CO gas has strong rotational transitions at millimeter wavelengths, which can be utilized to determine the atmospheric temperature profile and the CO abundance on Venus and Mars in the altitude regions probed.

Since CO is formed in the upper part of the atmosphere, the line is seen in absorption against the warm continuum background on both Venus and Mars (Figure 52.5). On Venus, one probes the so-called *mesosphere* in these transitions, a region between the massive lower atmosphere (altitudes $\lesssim$70 km), in which the radiative time constant is much greater than a solar day, and the upper atmosphere (altitudes $\gtrsim$120 km), which has a low heat capacity. In contrast to the lower atmosphere, a strong day-to-night gradient in temperature exists above the mesosphere, which leads to strong winds from the day- to the nightside. This is very different from the retrograde zonal winds observed in the visible cloud

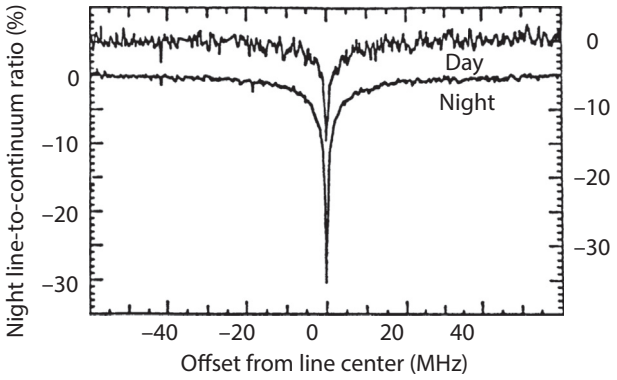

FIGURE 52.5 Spectra of Venus in the $J = 1{-}0$ line. The upper curve is for the dayside hemisphere (when Venus is near superior conjunction), and the lower curve is for the nightside hemisphere (when Venus is near inferior conjunction). *Schloerb, F. P. (1985).*

layers. These mesospheric winds carry CO, formed on the dayside through photodissociation of CO_2, to the nightside of the planet. The spectra in Figure 52.5, therefore, show the nightside line to be much deeper and narrower than the dayside line.

2.5. Giant Planets

2.5.1. Radio Spectra

At millimeter to centimeter wavelengths, one typically probes altitudes in the giant planet atmospheres from within to well below (pressure of tens of bars) the cloud layers. Representative microwave spectra are shown in Figure 52.6(a) (Jupiter) and (b) (Uranus). They generally show an increase in brightness temperature with increasing wavelength beyond 1.3 cm, due to the combined effect of a decrease in opacity at longer wavelengths, and an increase in temperature at increasing depth in the planet. The main source of opacity is ammonia (NH_3) gas, which has a broad absorption band at 1.3 cm. At longer wavelengths (typically >10 cm) absorption by water vapor and droplets may affect the spectra, while at short millimeter wavelengths the contribution of collision-induced absorption by molecular hydrogen becomes noticeable. On Uranus and Neptune, there is additional absorption by hydrogen sulfide (H_2S) and (perhaps) phosphine (PH_3) gas.

The composition of all four giant planets is dominated by H_2 and He gases, while the condensable gases CH_4, NH_3, H_2S, and H_2O constitute only a small fraction of the total. These gases, however, determine much of the "weather" on these planets. Although only cloud tops are seen "visually", thermochemical equilibrium calculations reveal the presence of a number of cloud layers deeper in the atmosphere, as depicted in Figure 52.6(c) and (d): an aqueous ammonia solution cloud, water ice, a cloud of ammonium hydrosulfide particles ($NH_3 + H_2S \rightarrow NH_4SH$ around 250 K), ammonia and/or hydrogen sulfide ice, and methane ice. The "visible" cloud layers on Jupiter and Saturn are composed of ammonia ice, while Uranus and Neptune are cold enough to allow condensation of methane gas.

To first approximation, the spectra of both Jupiter and Saturn resemble those expected for a solar composition atmosphere, while the spectra of Uranus and Neptune indicate a depletion of ammonia gas compared to the solar value by $\sim$2 orders of magnitude. As shown in Figure 52.6(d), this depletion has been explained via formation of an extensive NH_4SH cloud, which essentially removes all NH_3 from the upper atmosphere.

The thermal emission from all four giant planets has been imaged with the VLA. To construct high sign-to-noise images, the observations are integrated over several hours, so that the maps are smeared in longitude and only reveal brightness variations in latitude. The observed variations have typically been attributed to spatial variations in opacity (NH_3, H_2S gases), as caused by a combination of atmospheric dynamics and condensation at higher altitudes. Below we briefly discuss findings for each planet individually.

2.5.2. Jupiter

In situ observations by the *Galileo* probe revealed that the NH_3 and H_2S abundances in Jupiter's deep atmosphere ($P \gtrsim 8$ bar) are three to four times solar, while radio spectra (Figure 52.6) show a subsolar abundance of NH_3 gas at pressures $P < 2$ bar. The apparent decrease in the NH_3 abundance at higher altitudes may be caused by dynamical processes, but the jury is still out on this.

Radio images of Jupiter clearly show bright zonal bands across the disk, co-located with the bright 5-μm bands; these all coincide with the brown belts seen at visible wavelengths (Figure 52.7). The radio and 5-μm bright bands have a higher brightness temperature due to a lower opacity in the belts relative to the zones, so deeper warmer layers are probed in the belts. This phenomenon is suggestive of gas rising in the zones; when the temperature drops below $\sim$140 K, ammonia gas condenses out. In the belts the air, now depleted in ammonia gas (i.e. dry air), descends. The low NH_3 abundance enables deep layers to be probed at radio wavelengths, while the absence of clouds allows one to see deep at 5 μm.

Earlier this century, an algorithm has been developed to construct longitude-resolved images of Jupiter, and these maps reveal, for the first time, that the 5-μm hot spots are also hot at radio wavelengths (Figure 52.7(d)). At radio wavelengths, the hot spots indicate a relative absence of NH_3 gas, whereas they suggest a lack of cloud particles in the IR. Models show that ammonia must be depleted down

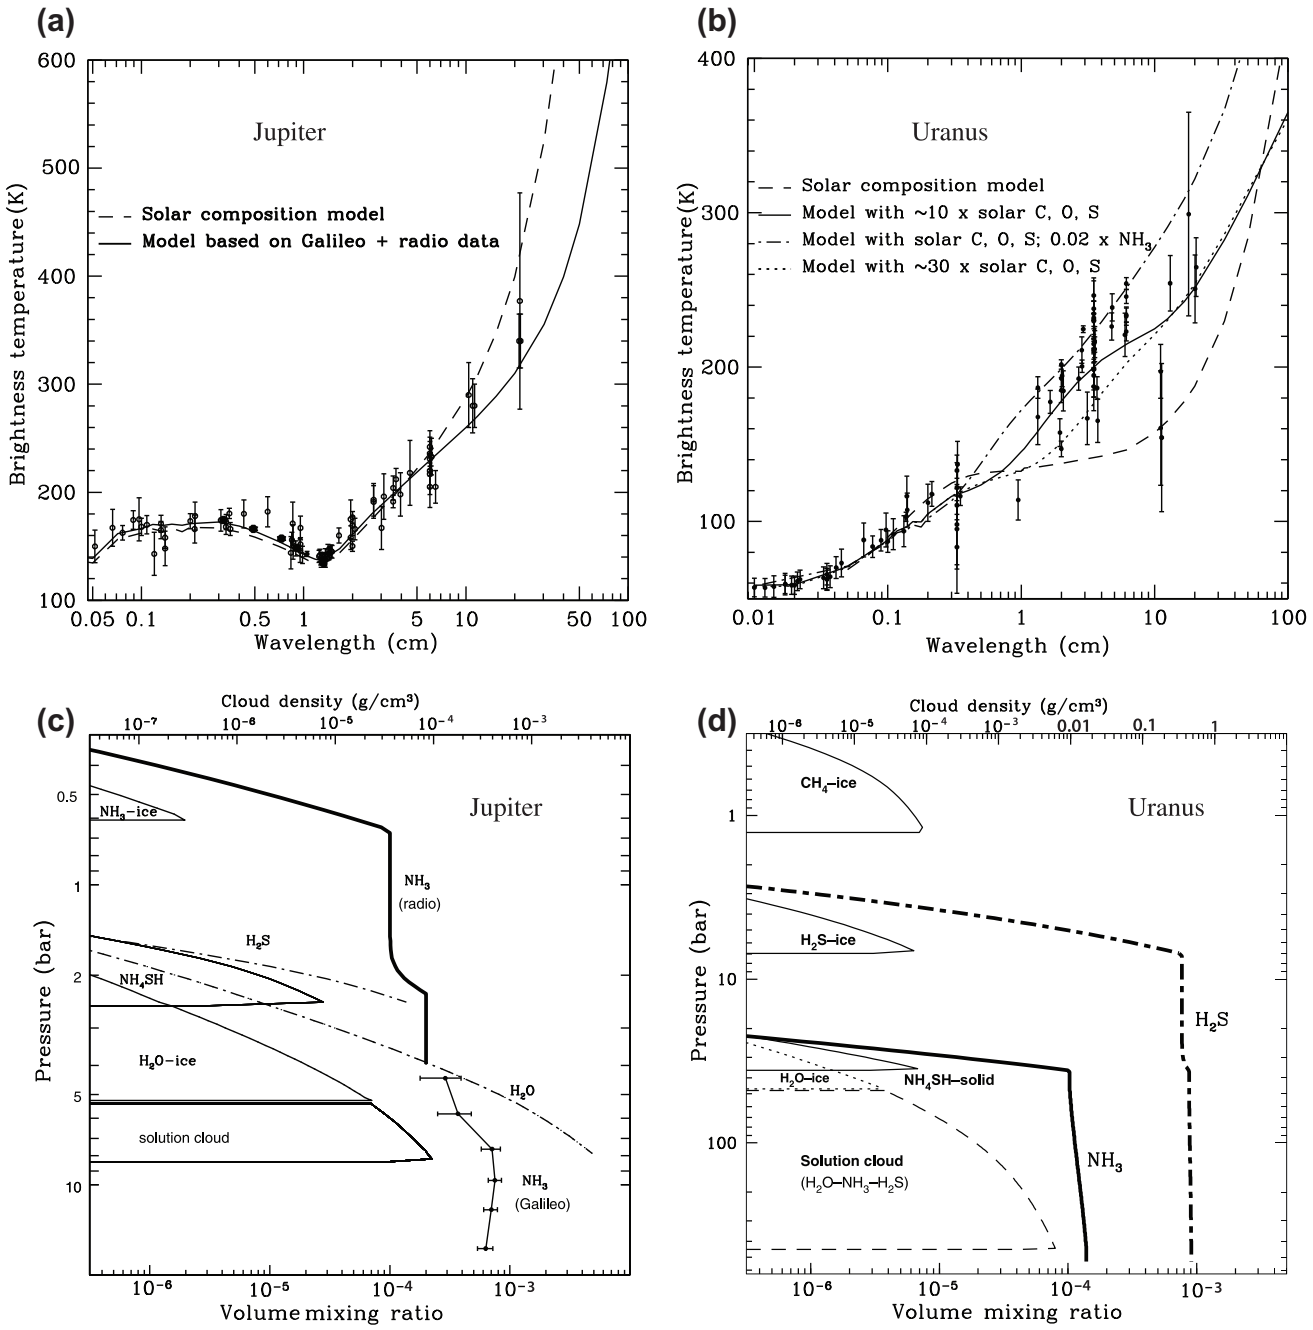

FIGURE 52.6 (a) Microwave spectrum of Jupiter, with superposed models for a solar composition atmosphere (dashed line), and one in which the altitude profiles for the condensable gases were based on the *Galileo* probe data at $P > 8$ bar, decreasing to $\sim 1/2$ the solar value at $P < 2$ bar (solid line). (b) Microwave spectrum of Uranus, with superposed models for a solar composition atmosphere (dashed line), and one in which H_2S and H_2O gases are enhanced by a factor ~ 10 above solar values. In these models, ammonia gas is significantly depleted at higher altitudes in Uranus atmosphere through formation of NH_4SH, so that deeper warmer levels are probed. (c) Cloud structure in Jupiter's atmosphere as calculated assuming thermochemical equilibrium. The altitude profile of ammonia gas, based on *Galileo* and ground-based radio data (used in panel a), is superposed. (d) Cloud structure in Uranus' atmosphere as calculated assuming thermochemical equilibrium and CH_4, H_2O, and H_2S abundances 30 times solar. The altitude profiles for H_2S and NH_3 gas are indicated. *de Pater, I. & Lissauer, J. J. (2010).*

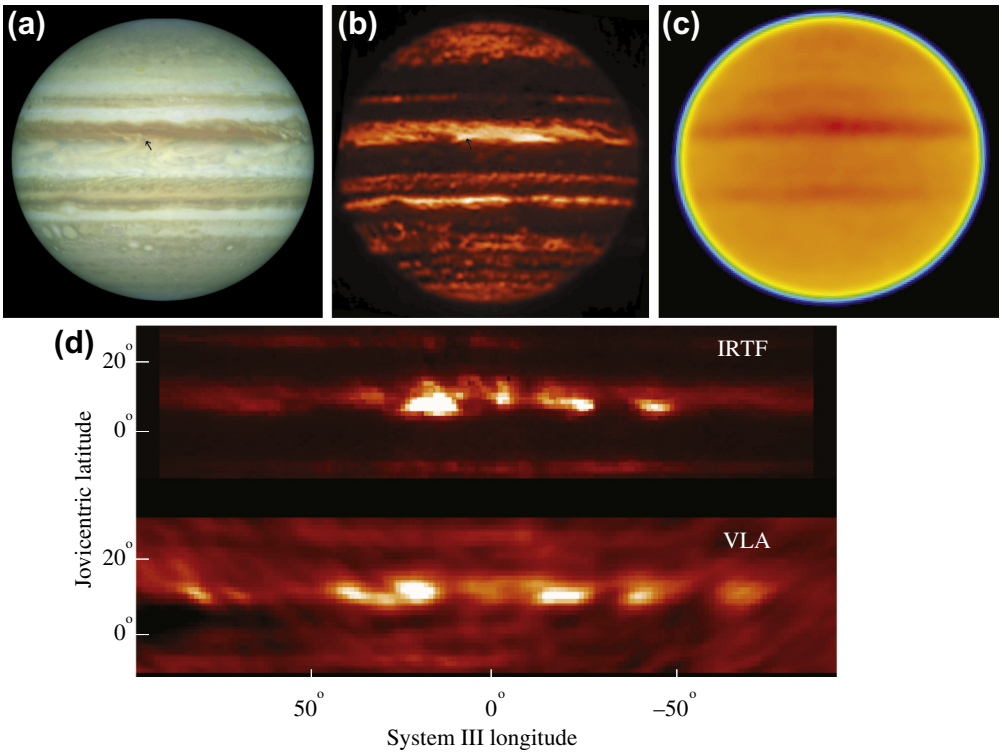

FIGURE 52.7 Images of Jupiter at (a) visible (Hubble Space Telescope (HST)), (b) thermal infrared (IR) (5 μm, NASA's Infrared telescope Facility, IRTF) and (c) radio wavelengths (2 cm, VLA). At visible wavelengths, the planet is seen in reflected sunlight, and its zones and belts show up as white and brown stripes, respectively. At 5 μm and radio wavelengths we receive thermal radiation from the planet. The belts, as well as other brown regions, are warmer than the zones, attributed to a lower opacity in the belts, so deeper warmer layers are probed in belts than zones. The IR and visible light images were taken in October 1995, just 2 months before the Galileo probe entry. The radio image was obtained in January 1996, about 1.5 months after probe entry. The position of the probe entry is indicated by an arrow on the visible light and IR images; the radio image is integrated over ∼6−7 h, so that any longitudinal structure is smeared out. *(HST: Courtesy R. Beebe and HST/NASA; IRTF: Courtesy G. Orton; VLA: de Pater, I., et al. (2001)).* (d) A comparison of the North Equatorial Belt of Jupiter at 5 μm (like in panel b) and the radio image in panel c. This longitude-resolved image was constructed by using a novel data reduction technique. *Sault, R. J., et al. (2004).*

to pressure levels of over ∼5 bar in the hot spots, the approximate altitude of the water cloud.

2.5.3. Saturn

Images of Saturn's microwave emission at different viewing geometries are shown in Figure 52.8. The planet itself is visible through its thermal emission, while the emission from the planet's rings is dominated by Saturn's thermal radiation reflected off the ring particles. Only a small fraction of the radiation at centimeter wavelengths is thermal emission from the rings themselves.

Like on Jupiter, radio spectra of the atmospheric emission can be interpreted in terms of its ammonia abundance and local variations therein with altitude and latitude. The ammonia and hydrogen sulfide abundances on Saturn are likely ∼3−5 times the solar values. The latitudinal structure on Saturn's disk, presumably caused by latitudinal variations in microwave opacity, changes considerably over time.

Figure 52.9 shows a radio map of the planet at 2 cm constructed from Cassini radiometer observations. The deviation in brightness temperature is plotted relative to that expected for a model in which the atmosphere is fully saturated. In many areas the atmosphere appears to be subsaturated (in NH_3 gas, the main source of Saturn's microwave opacity), indicative of subsiding dry air. Note the large extended bright region near 40° N latitude. This is Saturn's large Northern Storm that was visible at that time. The radio-bright areas are suggestive of dry subsiding air, down to ∼2−3 bar pressure level. Cassini observations at 2 cm and 5 μm show similar anticorrelations as observed for Jupiter (Figure 52.7), although not all radio-bright areas correspond exactly to 5-μm bright regions.

The classical A, B, and C rings, with the Cassini Division, are clearly visible on Figure 52.8. The inner B ring is brightest, with a brightness temperature of ∼10 K. At 1−3 mm the temperature rises to ∼20−25 K. In front of the planet, the rings block out part of Saturn's radio

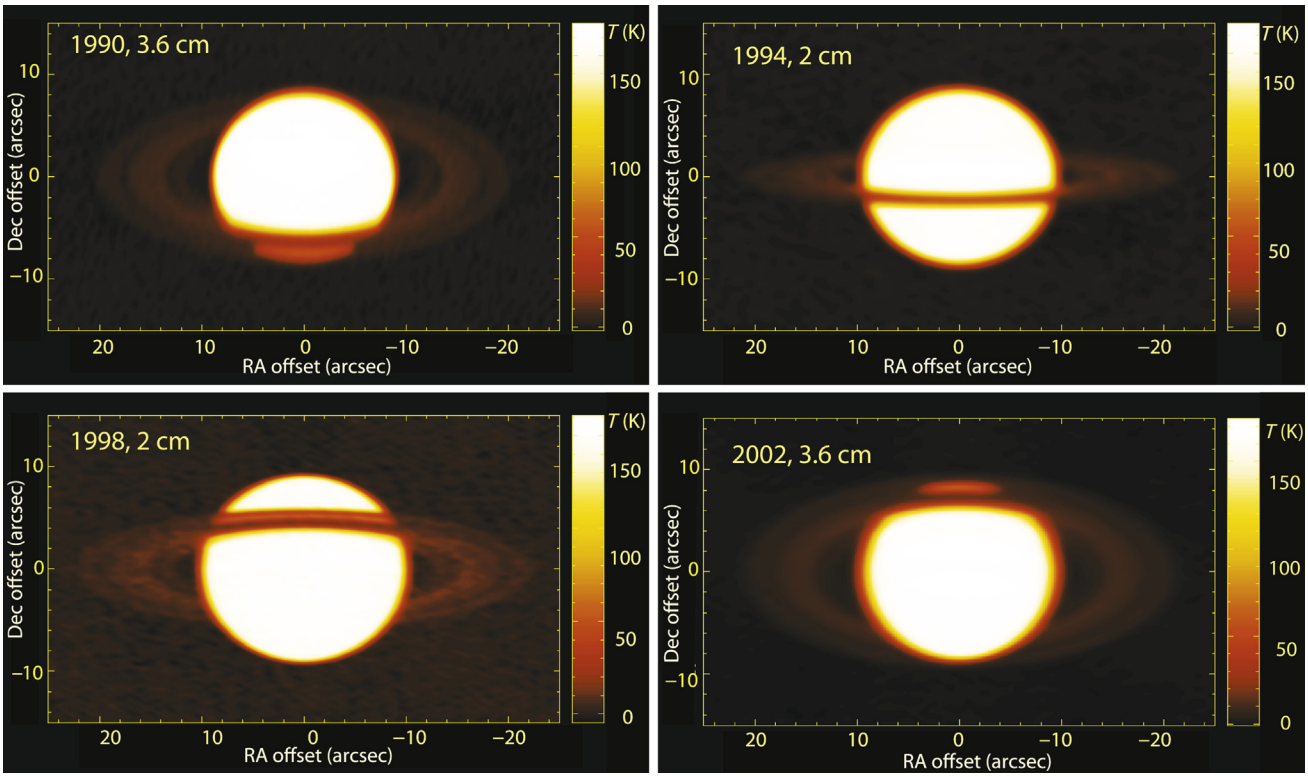

FIGURE 52.8 Radio photographs of Saturn at 2 and 3.6 cm, at different viewing aspects of the planet. (a) 3.6 cm, 1990; (b) 2 cm, 1994; (c) 2 cm, 1998; (d) 3.6 cm, 2002. *Dunn, D. E., de Pater, I., & Molnar, L. A. (2006).*

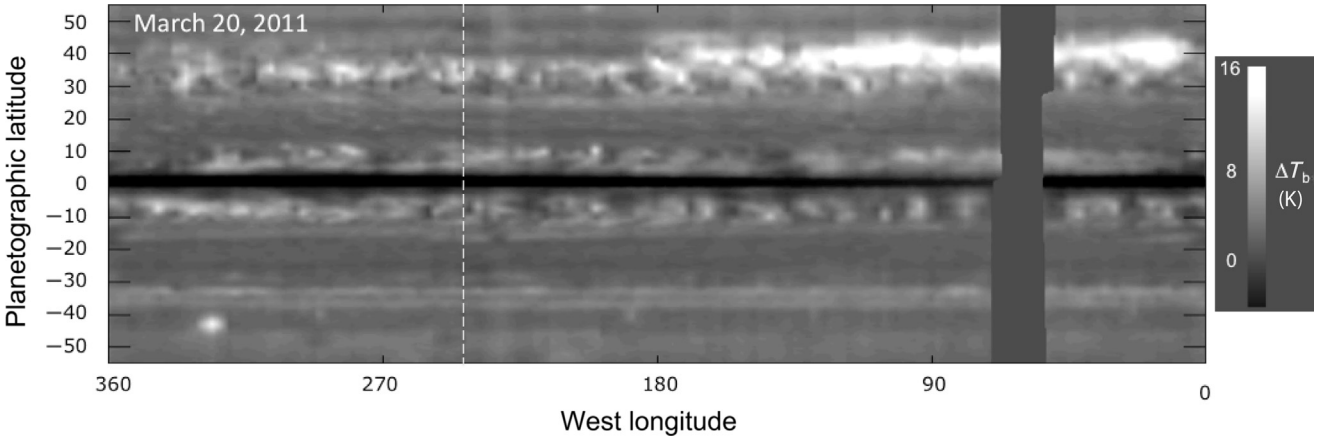

FIGURE 52.9 Cylindrical map of Saturn's 2-cm brightness temperature constructed from Cassini radiometer observations taken in March 2011. The value plotted is the residual brightness relative to a model for a fully saturated atmosphere. The black stripe across the equator is Saturn's ring, blocking the planet's thermal radiation from behind. The planet was mapped by continuous pole-to-pole scans during 14 h when the spacecraft was near periapse. Periapse (indicated by the dashed line) was at 3.72 Saturn radii, where the resolution was best (1.6° in latitude). The resolution degrades linearly with spacecraft distance, out to 5.64 Saturn radii. The spacecraft motion along its trajectory combined with the planet's rotation-combined sweep through the longitude range depicted. *Janssen, M. A., Ingersoll, A., Allison, M. D., Gulkis, S., Laraia, A., Baines, K., et al. (2013).*

emission, resulting in an absorption feature. The west (right) side of the ring is usually somewhat brighter than the east side, which has been attributed to the presence of gravitational "wakes", which are 10- to 100-m-sized density enhancements behind large ring particles which, because of Keplerian shear, travel at an angle to the big particle's orbit. Similar asymmetries have been seen in the A ring in front of the planet.

A combination of radio and radar data show that the ring particles have sizes from ∼1 cm up to ∼5−10 m, where the number of particles, N, at a given size, R, varies approximately as $N \sim R^{-3}$. Such a particle size distribution would be expected from a collisionally evolved population of particles.

2.5.4. Uranus and Neptune

Uranus is unique among the planets in having its rotation axis closely aligned with the plane in which the planet orbits the Sun. With its orbital period of 84 years, the seasons on Uranus last 21 years. During the Voyager encounter, in 1986, Uranus south pole was facing the Sun (and us). Since that time, this pole has slowly moved out of sight, while the north pole has come into view. Figure 52.10(a) shows a radio (2 cm) image taken with the VLA in the summer of 2003, along with an image at near-IR wavelengths (1.6 μm, panel b) taken with the adaptive optics system on the Keck telescope. The VLA image shows a bright (i.e. hot) south pole, as well as some enhanced brightness in the far north (to the right on the image). At near-IR wavelengths Uranus is visible in reflected sunlight. The bright regions are clouds (presumably CH_4 ice) at high (upper troposphere) altitudes. The bright band around the south pole is at the lower edge of the radio-bright south polar region. Air in this infrared-bright band likely rises, with condensibles forming clouds and the dry air descending over the pole. At radio wavelengths, this dry air allows one to probe deeper warmer layers in Uranus' atmosphere.

Also Neptune's south pole is hot, as shown in Figure 52.10(c). This particular image was obtained with the VLA after its sensitivity was increased by an order of magnitude. For comparison, an image at near-IR wavelengths is shown in Figure 52.10(a). A comparison of the Uranus and Neptune images suggests very similar dynamics in these planets' atmospheres, with air rising at midlatitudes and descending over the poles and the equator.

Prominent emission lines of CO and HCN were detected on Neptune in the early 1990s, with abundances ∼1000 times higher than predicted from thermochemical

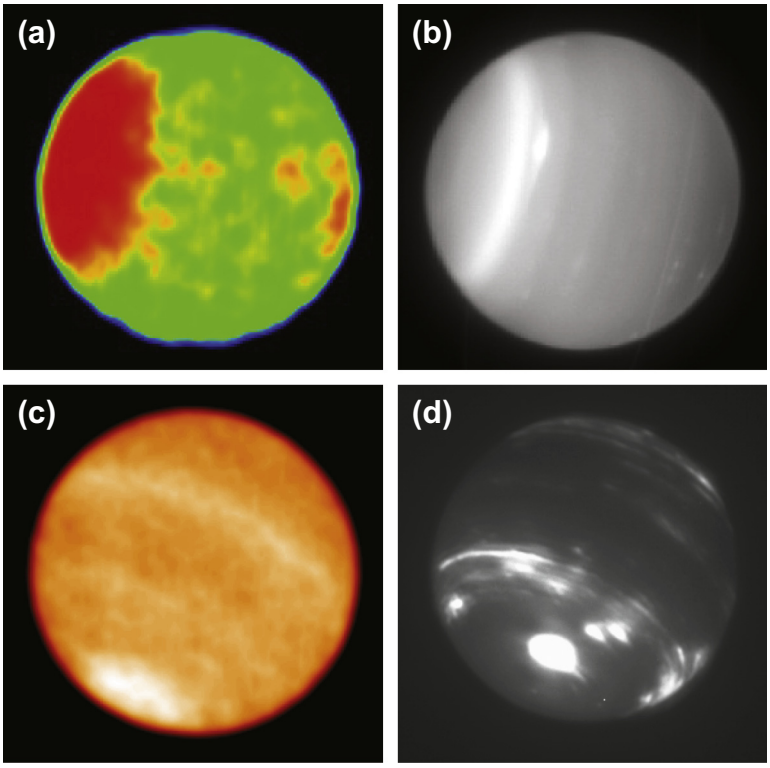

FIGURE 52.10 (a) VLA image of Uranus at 2 cm wavelength taken in the summer of 2003. Note the hot (red) poles. *(Hofstadter, M. D. & Butler, B. J. (2003).* (b) IR (1.6 μm) image of Uranus taken with the Keck adaptive optics system in October 2003. The polar collar around the south pole (left in figure) lines up with the edge of the hot pole seen at radio wavelengths. Several cloud features are visible in the IR image, and the thin line near the right is Uranus' ring system. *(Hammel, H. B., de Pater, I., Gibbard, S., Lockwood, G. W., & Rages, K. (2005).* (c) False-color image of Neptune at a wavelength of 0.9 cm. White is brightest, red dimmer, and black is dimmest. The brightest feature (about 20 K above its surroundings) is centered on the South Pole of the planet, and extends down to ∼60° S latitude. The equatorial region is marked by a band about 10 K brighter than its surroundings. There is also a hint of a band at ∼40° S latitude. Observations were made with the upgraded VLA, on August 6 and 9, 2011 *(Butler, B.J., Hofstadter, M., Gurwell, M., Orton, G., & Norwood, J. (2012).* (d) Near-IR (1.6 μm) image of Neptune taken with the Keck adaptive optics system on July 14, 2009 (by Imke de Pater and Heidi B. Hammel). The bright regions are clouds in Neptune's atmosphere.

equilibrium models. Recent work with the Combined Array for Research in Millimeter-wave Astronomy (CARMA) shows that the CO 2−1 and 1−0 lines are consistent with about 1 ppm CO in Neptune's stratosphere and no CO in the troposphere. CO appears to be uniformly distributed over Neptune's disk. Both findings suggest an external source, such as cometary impacts.

2.6. Major Satellites and Small Bodies

2.6.1. Galilean Satellites

Radio spectra of the Galilean satellites are diverse. The brightness temperature at thermal IR wavelengths can be related directly to the satellite's albedo, and hence Callisto, with its relatively low albedo ($A = 0.13$) is warmer than Io and Europa. The brightness temperature at radio wavelengths is determined by the physical temperature and radio emissivity, e, of the subsurface through Kirchoff's laws (Eqn (52.3)), with A being the radar geometric albedo. As expected from the high radar albedos (0.33 for Ganymede and 0.65 for Europa), the observed radio brightness temperatures for Ganymede and Europa are well below the expected physical temperature of the subsurface layers. These high albedos and consequently low emissivities and radio brightness temperatures are likely caused by coherent backscattering in fractured ice.

Since the detection of an ionosphere around Io by the *Pioneer 10* spacecraft in 1973, this satellite is known to posses a tenuous atmosphere. The first detection of a global atmosphere was obtained in 1990, where a rotational line of sulfur dioxide (SO_2) gas was measured at 222 GHz. Io is the only object with an atmosphere dominated by SO_2 gas. Part of the gas is of direct volcanic origin, and part is driven by subliming SO_2 frost, which itself is a product of volcanic eruptions. Several SO_2, as well as SO, lines have been observed. Analysis of the spectra suggests a surface pressure of a few, perhaps up to 40 nbar, covering 5−20% of the surface. The atmosphere may be relatively hot (500−600 K) on the trailing and cooler (250−300 K) on the leading hemisphere.

SO_2 maps have been obtained with the Smithsonian Submillimeter Array (SMA) at ∼346 GHz, with a synthesized beam size slightly smaller than the disk of Io itself. These maps confirm differences in the SO_2 abundance between the leading and trailing hemispheres and have been interpreted to favor an atmosphere supported primarily via sublimation of SO_2 ice.

2.6.2. Titan

Of all solar system bodies, Titan's atmosphere is most similar to that of the Earth, in being dominated by nitrogen gas and with a surface pressure 1.5 times that on the Earth. Methane gas, with an abundance of a few percent, has a profound effect on the atmosphere (*see* Titan). Photolysis and subsequent chemical reactions lead to the formation of hydrocarbons and nitriles. Because CO and the nitriles HCN, HC_3N (cyanoacetylene), and CH_3CN (acetonitrile) have several transitions at (sub)millimeter wavelengths (Figure 52.11), radio observations can be used to constrain the vertical distributions of these species. As expected from

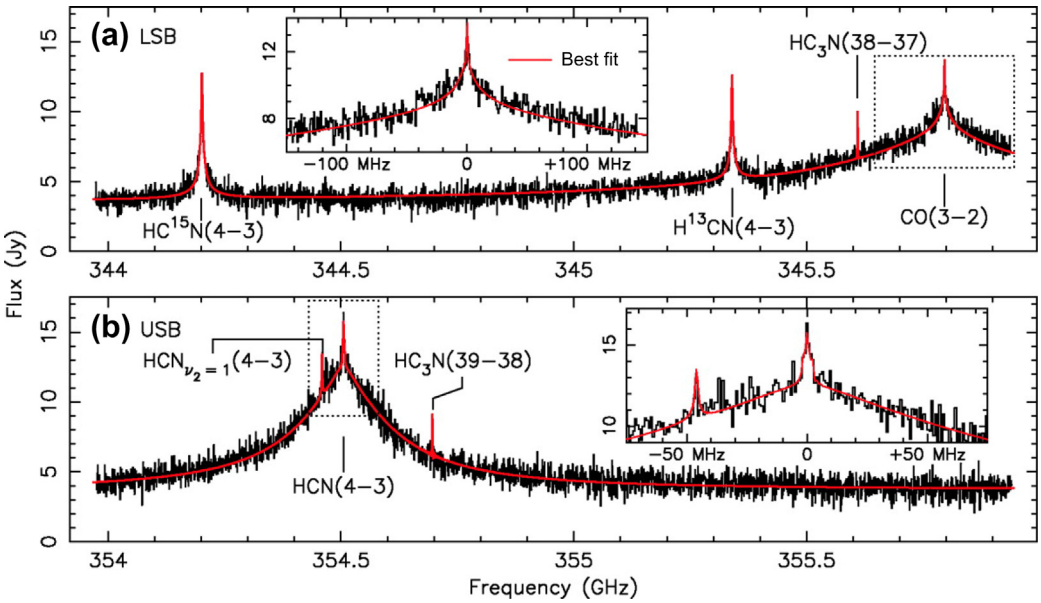

FIGURE 52.11 Submillimeter whole-disk spectrum of Titan obtained with the SMA, with an overlaid best-fit model spectrum. (a) Lower sideband (LSB) containing CO (3−2), $H^{13}CN$ (4−3), $HC^{15}N$ (4−3), and HC_3N (38−37) rotational transitions. (b) Upper side band (USB) with both the ground and vibrationally excited HCN (4−3) $\nu_2 = 0,1$ transitions and the HC_3N (39−38) transition. *Gurwell, M. A. (2004).*

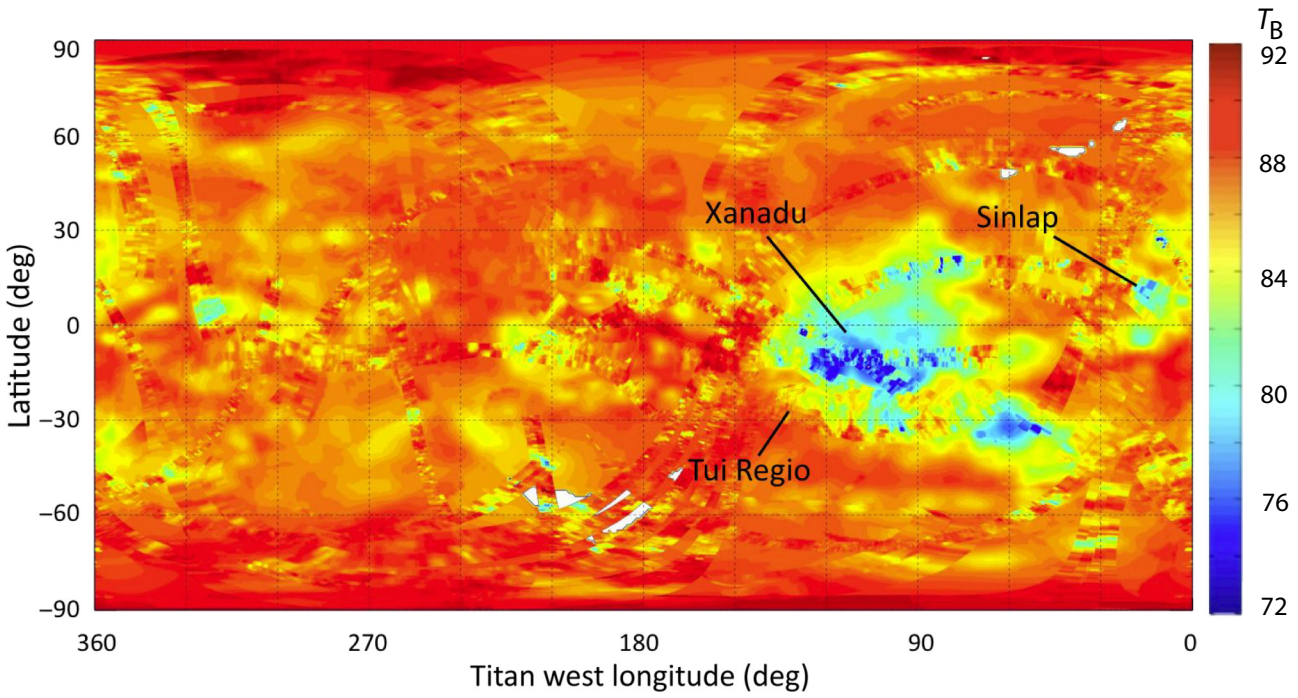

FIGURE 52.12 Map of Titan's absolute brightness temperature derived from Cassini radiometer data at a wavelength of 2 cm. A few regions discussed in the text are indicated. *Janssen, M. & Le Gall, A. (2011).*

photochemical models, their abundances increase with altitude and are highest in the stratosphere.

Disk-resolved spectra, such as obtained with the Submillimeter Array (SMA) and Institute for Radio Astronomy in the Millimeter Range (IRAM) Plateau de Bure Interferometer, also contain information on the zonal wind profile. Although 12-μm spectroscopic measurements had already suggested the winds to be prograde at ∼100−300 km altitude, the radio data confirmed the direction of the winds and reported more precise values for the wind speeds in the upper stratosphere and lower mesosphere. At lower altitudes, the winds were determined by measuring the Doppler shift in the radio (communication) signal transmitted from the *Huygens* probe to the *Cassini* orbiter. This signal was recorded by the *very long baseline interferometry network* (VLBI). These measurements revealed weak prograde winds near the surface, rising to ∼100 m/s at 100−150 km altitude, with a substantial drop (down to a few m/s) near 60−80 km altitude.

The isotopic carbon and nitrogen ratios were first determined from ground-based radio data (such as in Figure 52.11), and subsequently confirmed/improved by instruments on board the *Cassini* spacecraft and *Huygens* probe. The $^{12}C/^{13}C$ isotope ratio on Titan is very similar to that on the Earth (89), while $^{14}N/^{15}N$ was measured to be several times less than the terrestrial value of 272. This has been explained by a large loss of Titan's primitive atmosphere over time, which would lead to an isotopic fractionation in nitrogen. In contrast, the similar-to-Earth value of $^{12}C/^{13}C$ hints at a continuous or periodic replenishment of methane gas into Titan's atmosphere, such as could happen, for example, through *cryovolcanism* or a methane cycle akin to the hydrology cycle on the Earth.

Radiometry maps of Titan obtained with the *Cassini* spacecraft at 2 cm wavelength can be used with radar and IR measurements to better constrain the surface composition and compactness. Observations show variations in brightness temperature up to ∼10 K (Figure 52.12), which are more or less anticorrelated with IR brightness, i.e. the IR/optically bright areas have a low radio brightness temperature.

The effective dielectric constant of Titan's surface is low, averaging about 1.6. There are only a few places where the dielectric constant is close to the value of 3.1 for pure water ice—near the Sinlap crater and the region separating Tui Regio from Xanadu. The overall low value is consistent with a fluffy surface of organic material. In most cases the radar reflectivity and radio emissivity are anticorrelated, as expected from Kirchoff's laws (Eqn (52.3)). In Xanadu, however, the reflectivities are anomalously high, indicative of coherent scattering on scales of a few wavelengths.

2.6.3. Asteroids and Trans-Neptunian Objects

In analogy with the terrestrial planets, a comparison of multiwavelength radio data of small airless bodies with thermophysical models provides information on the (sub) surface properties of the material, as composition and compactness. Radio spectra of several main belt asteroids

suggest that these bodies are typically overlain by a layer of fluffy (highly porous) dust a few centimeters thick.

The Microwave Instrument for the Rosetta Orbiter (MIRO) on the European Space Agency's (ESA) Rosetta spacecraft observed thermal emissions from the main belt asteroids 2867 Steins and 21 Lutetia at submillimeter (0.6 mm) to millimeter (1.6 mm) wavelengths during the Rosetta spacecraft encounters with these asteroids in 2008 and 2010, respectively. The MIRO instrument consists of a 30-cm-diameter telescope coupled to a dual-frequency heterodyne radiometer/spectrometer. Steins is a small-diameter ($\sim$5 km) E-type asteroid; Lutetia is 100-km-diameter C- or M-class asteroid. The observed continuum thermal emission from both asteroids allowed their regoliths to be probed to depths of 2 mm$-$2 cm below their surfaces and their thermal inertias to be measured. Lutetia is covered by a very low thermal inertia ($<$20 J/K/m^2/s$^{0.5}$) and high-emissivity ($>$0.9) fine powder or dust, similar to the lunar regolith. The thermal inertia of Steins is between 450 and 850 J/K/m^2/s$^{0.5}$ and its emissivity is $\sim$0.8. These properties are indicative of a more rocklike surface material, as expected for smaller asteroids. Asteroids covered by powder or dust will have large dayside temperature gradients, $\sim$50 K/cm, and hence observers at radio wavelengths will sense lower temperatures than found on the surface.

It has been challenging to observe trans-Neptunian or Kuiper Belt objects (KBO) at radio wavelengths, including Pluto, due to their small angular extent and low surface temperature. For an object in radiative equilibrium with an albedo of $\sim$0.6, the surface temperature should be $\sim$50 K, consistent with the 53$-$59 K temperatures for Pluto as measured by the IRAS satellite at 60 and 100 μm. Observations of Pluto with the 30-m IRAM telescope at millimeter wavelengths revealed a brightness temperature of $\sim$30 K, 10 K less than expected $\sim$10 wavelengths below its surface, indicative of a low radio emissivity ($e \approx 0.6$–0.7), similar to that seen on Ganymede. Such a low emissivity can be reconciled with a surface composed of icy grains, and hence a relatively high porosity.

Radio measurements of KBOs have been used to determine the size and albedo of several of the largest objects (Eris, Quaoar, Ixion, Varuna, 2002 AW197), in concert with optical measurements and the so-called Standard Thermal Model (STM) to interpret the data. Although one has to be aware of the assumptions made in the STM, which can lead to over- or underestimates of the size and albedo, such measurements are usually our only means to get a reasonable size estimate for these objects.

2.7. Comets

Continuum measurements at radio wavelengths measure the thermal emission from a cometary nucleus and from large dust grains in its coma, while spectroscopic observations provide information on the "parent" molecules in a comet's coma. Upper limits to the radio continuum emission of a few comet nuclei suggest that the temperature gradient in the nucleus may be very steep, or, alternatively, that the emission is substantially suppressed by subsurface scattering.

The most significant advances in cometary radio research have been obtained from spectroscopic studies. The cometary nucleus consists primarily of water ice, which sublimates off the surface when the comet approaches the Sun. H_2O dissociates into OH and H (lifetime $\sim$1 day). Since the early 1970s, the 18-cm OH line has been observed and monitored in many comets, providing indirect information on the production rate and time variability therein of water, a molecule that remains difficult to observe on a routine basis.

The OH line is sometimes seen in emission, and at other times in absorption against the galactic background. The OH emission is maser emission, i.e. stimulated emission from molecules in which the population of the various energy levels is inverted, so that the higher energy level is overpopulated compared to the lower energy level. This population inversion is caused by absorption of solar photons at UV wavelengths. However, this excitation process depends on the comet's velocity with respect to the Sun (heliocentric velocity), referred to as the Swings effect, attributed to the astrophysicist P. Swings. If the heliocentric velocity is such that solar Fraunhofer (absorption) lines are Doppler shifted into the OH excitation frequency, the molecule is not excited. In that case, OH will absorb 18-cm photons from the galactic background and be seen in absorption against the galactic background. If the line is excited, background radiation at the same wavelength (18 cm) will trigger its de-excitation, and the line is seen in emission (maser or stimulated emission). With radio interferometers, the OH emission can be imaged. Such images have, for example, revealed the so-called quenching region directly, a region around the nucleus where collisions between particles thermalize the energy levels of OH molecules, so they no longer produce maser emission (Figure 52.13).

One of the strengths of radio astronomy is the detection of "parent" molecules in a cometary coma, molecules that evolve directly from its icy surface. Such observations are crucial for our understanding of a comet's composition, and, indirectly, of the conditions in the early solar nebula from which our planetary system formed (cometary nuclei have not been altered by excessive heating or high pressures). A growing number of molecular species have been detected at radio wavelengths. Figure 52.14 shows the time evolution of observed production rates for a large number of gases, subliming from comet Hale$-$Bopp (C/1995 O2). Only the most volatile materials sublime at heliocentric

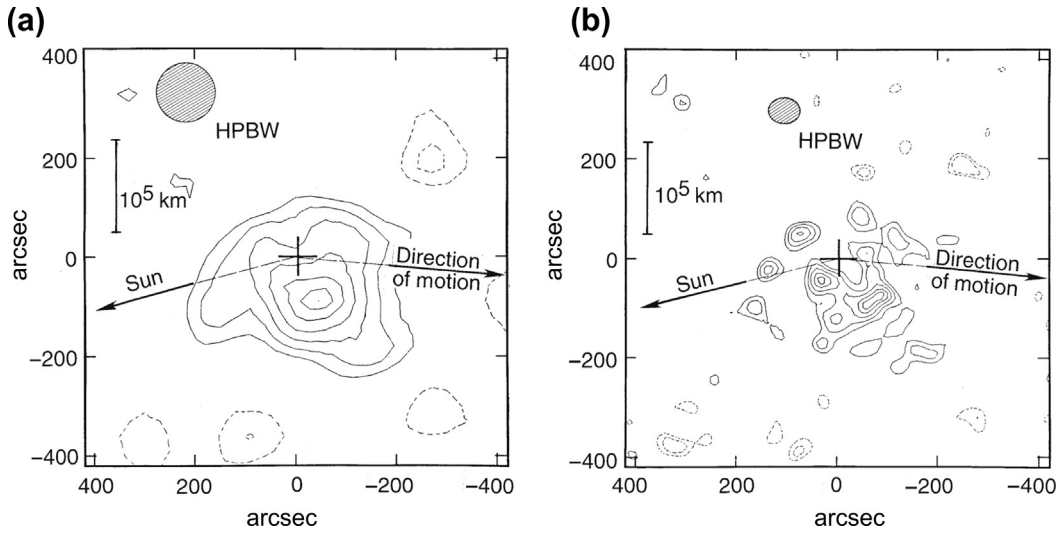

FIGURE 52.13 Contour plots of comet Halley, November 13−16, 1985. The image is taken at the peak flux density of the line (0.0 km/s in the reference frame of the comet). Panel a) shows a low-resolution image (HPBW=3′), and panel b) shows a high-resolution image (HPBW=1′), after the data for both dates were combined. Contour levels for the low-resolution image are 4.9, 7.8, 10.8, 13.7, 16.7, and 18.6 mJy/beam. For the high-resolution image, they are 4.4, 4.4, 6.0, 7.7, 9.3, and 10.4 mJy/beam. Dashed contours indicate negative values. The half power beam width (HPBW), a linear scale, the direction of motion, and the direction to the Sun are indicated in the figures. The cross indicates the position of the nucleus at the time of the observations. *de Pater, I., Palmer, P., & Snyder, L.E. (1986).*

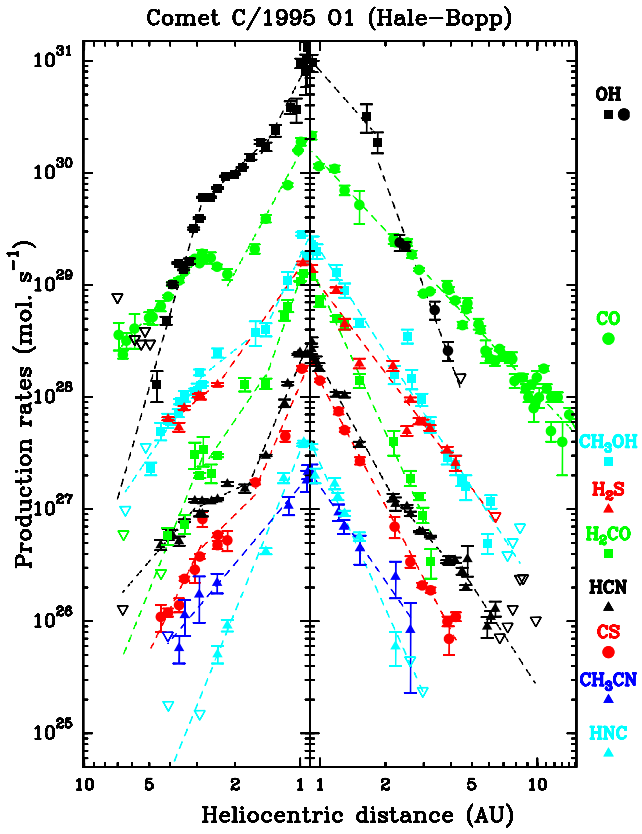

FIGURE 52.14 Time evolution of the production rates of 9 different molecules in C/Hale-Bopp as observed at (sub)mm-wavelengths. Power law fits (dashed lines) are superposed on the data. Biver, N., et al., 2002.

distances $r \gtrsim 5$ AU, while OH (from H_2O) becomes dominant at $r < 3$ AU.

Whereas most molecules sublime directly off the cometary nucleus, some gases, such as CO and formaldehyde (H_2CO), are also released from dust grains in a comet's coma (Figure 52.15).

3. NONTHERMAL RADIATION

Nonthermal planetary radio emissions are usually produced by electrons spiraling around magnetic field lines. Until the era of spacecraft missions, we had only received *nonthermal radio emissions* from the planet Jupiter, and these were limited to frequencies $\gtrsim$10 MHz, since radiation at lower frequencies is blocked by Earth's ionosphere. Strong radio bursts at frequencies below 40 MHz were attributed to emissions via the cyclotron maser instability in which *auroral* electrons with energies of a few to several kiloelectronvolt power the emission, while radiation at frequencies $\gtrsim$ 100 MHz was interpreted as synchrotron radiation, emitted by high-energy (megaelectronvolt range) electrons trapped in Jupiter's radiation belts, a region in Jupiter's magnetic field analogous to the Earth's *Van Allen belts*. Like Earth, the magnetic fields of the four giant planets resemble to first approximation a dipole magnetic field and are strong radio sources at low frequencies (kilometric wavelengths). Jupiter's moon Ganymede is also a source of nonthermal radio emissions. The strongest planetary radio emissions usually originate near the auroral regions and are intimately related to auroral processes.

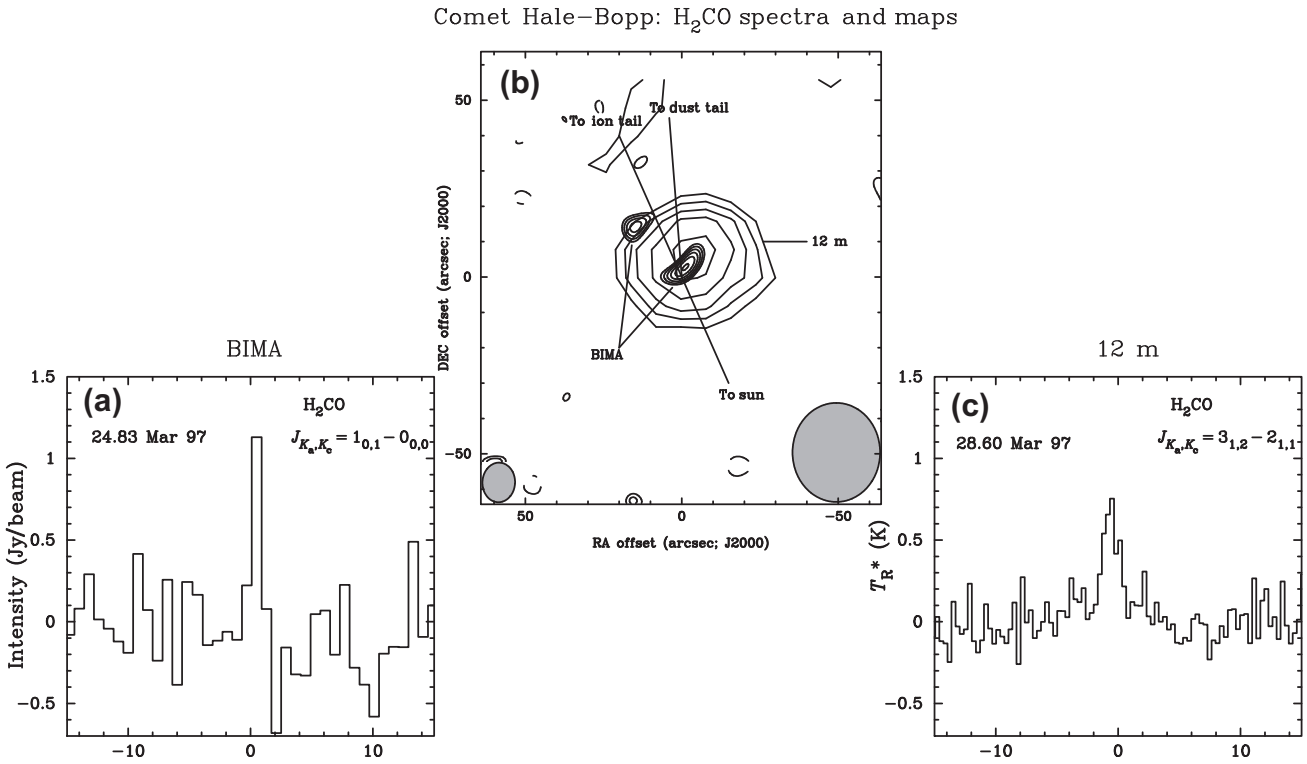

FIGURE 52.15 Images and spectra of H_2CO in comet C/1995 O1 (Hale–Bopp) taken with Arizona Radio Observatory (ARO) 12-m telescope and the Berkeley–Illinois–Maryland Association (BIMA) array. Panels (a and c) show spectra at different frequencies. Panel (b) shows a contour map from BIMA at 72.8 GHz (in bold; from spectrum in panel (a)), superposed on the ARO 225.7-GHz image (from spectrum in panel (c)). The synthesized beam for BIMA is shown in the lower left, and that of ARO appears in the lower right. These observations show that formaldehyde originates both from the nucleus and in the coma, where the coma source appears dominated by a single fragment. *Milam, S. N., et al. (2006).*

A graph of the average normalized spectra of the auroral radio emissions from the four giant planets and the Earth is displayed in Figure 52.16(a). Jupiter is the strongest low-frequency radio source, followed by Saturn, Earth, Uranus, and Neptune. In Sections 3.3–3.7, we discuss the emissions from each planet.

3.1. Low-Frequency Emissions

3.1.1. Cyclotron Maser Emissions

Electron cyclotron maser radiation is emitted at the frequency at which electrons spiral around the local magnetic field lines (the cyclotron or Larmor frequency):

$$\nu_L = \frac{qB}{2\pi m_e c} \tag{52.6}$$

where q is the elemental charge, B is the magnetic field strength, m_e is the electron mass, and c is the speed of light. Propagation of the radiation depends on the interaction of the radiation with the local plasma, or charged particle population. The oscillation of these particles, as caused by the electromagnetic properties of the plasma, leads to a complex interaction between the propagating radiation (the electromagnetic waves) and the local plasma. For example, the radiation can escape its region of origin only if the local cyclotron frequency is larger than the electron plasma frequency:

$$\nu_e = \left(\frac{4\pi N_e q^2}{m_e}\right)^{1/2} \tag{52.7}$$

with N_e being the electron density. Hence, the plasma frequency is the frequency at which electrons oscillate about their equilibrium positions in the absence of a magnetic field. This similarly sets the limit for propagation through Earth's ionosphere at $\sim$10 MHz. If the local cyclotron frequency is less than the electron plasma frequency, the waves are locally trapped and amplified, until they reach a region from where they can escape. The cyclotron maser instability also requires a large ratio of ν_L/ν_e. The auroral regions in planetary *magnetospheres* are characterized by such conditions. The mode of propagation (or polarization) of auroral radio emissions is predominantly in the so-called extraordinary (X) sense, and the polarization (direction of the electric vector of the radiation) depends upon the direction of the magnetic field. The emission is right-handed (RH) circularly polarized if the field at the source is

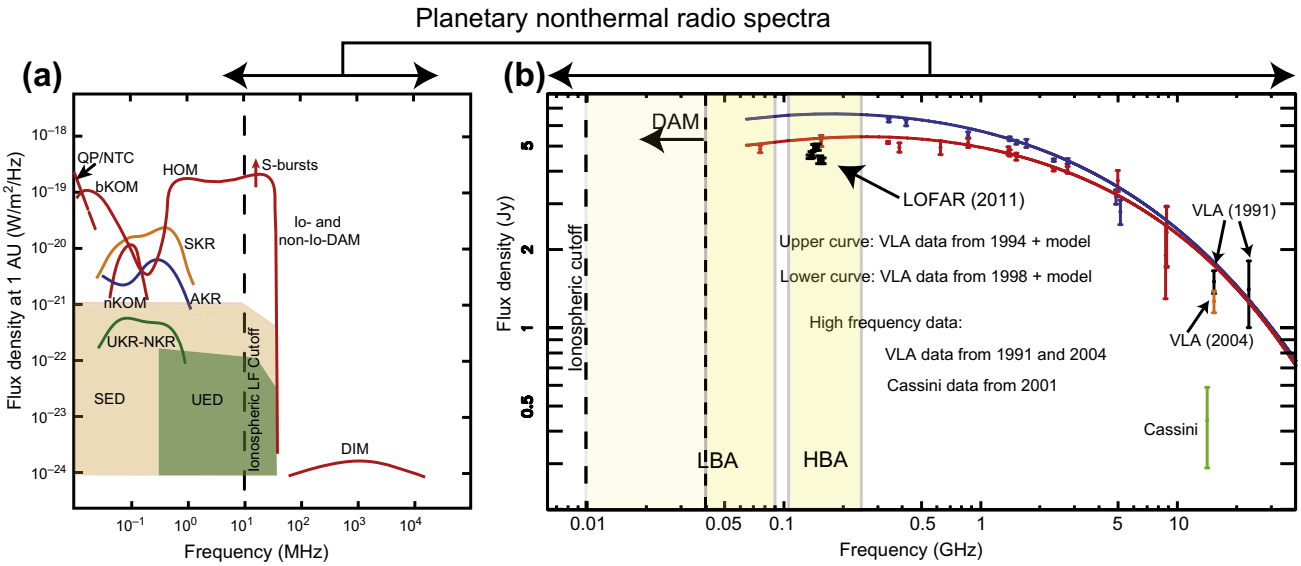

FIGURE 52.16 (a) A comparison of the peak flux density spectrum of the kilometric continuum radio emissions of the four giant planets and the Earth. All emissions were scaled such that the planets appear to be at a distance of 1 AU. Jovian emissions shown include quasi-periodic (QP) bursts, nonthermal continuum (NTC), broadband and narrowband kilometric radiation (bKOM, nKOM), hectometric radiation (HOM), decametric radiation (DAM), and decimetric radiation (DIM). Saturn's kilometric radiation is designated SKR, and its electrostatic discharge emissions are labeled SED. Terrestrial auroral kilometric radiation is designated AKR. UKR and NKR refer to kilometric radiation from Uranus and Neptune, respectively. Uranus' electrostatic discharges are labeled UED. *(Adapted from Zarka, P. & Kurth, W. S. (2005).* (b) Jupiter's synchrotron radio spectrum covers a fraction of the frequency range in the panel (a), as indicated by the arrows above the panels. The spectra were taken in September 1998 (lower curve) and June 1994 (upper curve), augmented with higher frequency VLA data from 1991 to 2004, and an anomalously low measurement taken by the Cassini spacecraft en route to Saturn. Superposed are model calculations that match the data. Preliminary results from Low-Frequency Array (LOFAR) commissioning data taken in November 2011 are indicated in black. The ionospheric cutoff frequency, DAM frequency range, and LOFAR low band (LBA) and high band (HBA) frequency coverage are indicated. *Figure adapted from Kloosterman, J. L., Butler, B., & de Pater, I. (2008). LOFAR data from: Girard, J. N., Zarka, P., Tasse, C., Hess, S., & the LOFAR Collaboration (2012).*

directed toward the observer and left-handed (LH) circularly polarized if the field points away from the observer.[1]

Cyclotron radiation is emitted in a dipole pattern, where the lobes are bent in the forward direction. The resulting emission is like the hollow cone pattern shown in Figure 52.17. The radiation intensity is zero along the axis of the cone, in the direction of the particle's parallel motion, and reaches a maximum at an angle Ψ. Theoretical calculations show that Ψ is very close to 90°. Observed opening angles, however, can be much smaller, down to ~50°, which has been attributed to refraction of the electromagnetic waves as they depart from the source region.

The cyclotron maser instability derives energy from a few kiloelectronvolt electrons, which have distribution

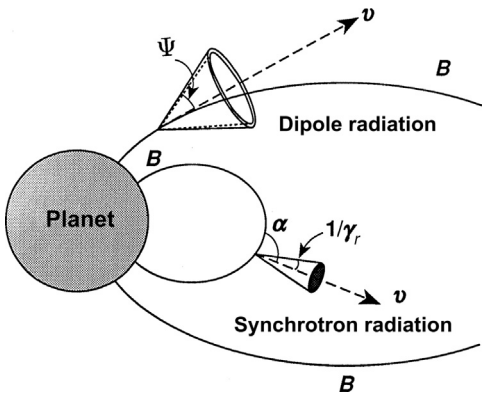

FIGURE 52.17 Radiation patterns in a magnetic field. Indicated is the hollow cone pattern caused by cyclotron (dipole) radiation from nonrelativistic electrons in the auroral zone. The electrons move outward along the planet's magnetic field lines. The hollow cone opening half-angle is given by Ψ. At low magnetic latitudes, in the Van Allen belts, the instantaneous cone of emission of a single relativistic electron is indicated. The angle between the particle's direction of motion and the magnetic field, commonly referred to as the particle's pitch angle, α, is indicated on the sketch. The emission is radiated into a narrow cone with a half width of $1/\gamma$. *de Pater, I. & Lissauer, J. J. (2001).*

1 Circular polarization is in the right-hand (RH) sense when the electric vector of the radiation in a plane perpendicular to the magnetic field direction rotates in the same sense as an RH screw advancing in the direction of propagation. Thus, rotation is counterclockwise when propagation is toward and viewed by the observer. RH polarization is defined as positive; left-hand polarization (LH), as negative. In some cases, the radio emissions propagate in the ordinary (O) magneto-ionic mode. In this mode the polarization is reversed. The theory of the cyclotron maser instability does admit the possibility of emission in the ordinary mode. However, it is less common.

functions with a positive slope in the direction perpendicular to the magnetic field. Recent observations in the source of Earth's auroral kilometric radiation (AKR) reveal "horseshoe"-shaped electron distributions that provide a highly efficient (of order 1%) source of free energy for the generation of the radio waves. This distribution is thought to result from parallel electric fields in the auroral acceleration region, the loss of small pitch-angle electrons to the planetary atmosphere, and trapping of reflected electrons. Radio emissions generated in planetary magnetospheres by this mechanism often display a bewildering array of structure on a frequency–time spectrogram including narrowband tones that rise or fall in frequency, sharp cutoffs, and more continuum-like emissions. While it is generally accepted that emissions that rise or fall in frequency are related to tiny sources moving down or up the magnetic field line (hence, to regions with higher or lower cyclotron frequencies), there is no generally accepted theoretical explanation for the fine structure.

3.1.2. Other Types of Low-Frequency Radio Emissions

While the radio emissions generated by the cyclotron maser instability are, by far, the most intense in any planetary magnetosphere, other types of radio emissions do occur that are of interest. Perhaps the most ubiquitous of these is the so-called nonthermal continuum radiation that arises from the conversion of wave energy in electrostatic waves near the source plasma frequency to radio waves, usually propagating in the ordinary mode. There are arguments for both linear and nonlinear conversion mechanisms. The term "continuum" was originally assigned to this class of emissions because they can be generated at very low frequencies (VLFs) and can be trapped in low-density cavities in the outer portions of the magnetosphere when the surrounding solar wind density is higher. The mixture of multiple sources at different frequencies and multiple reflections off the moving walls of the magnetosphere tend to homogenize the spectrum. However, at higher frequencies, these emissions are often created as narrowband emissions from electrostatic bands at the upper hybrid resonance frequency on density gradients in the inner magnetosphere and can propagate directly away from the source, yielding a complex narrowband spectrum. These emissions were first discovered at Earth and have been found at all the magnetized planets. Furthermore, emissions of this nature are also produced by Ganymede's magnetosphere.

Another type of planetary radio emission is closely related to a common solar emission mechanism, the conversion of Langmuir waves to radio emissions at either the fundamental plasma frequency (fp) or its harmonic (2fp). The Langmuir waves are common features of the solar wind upstream of a planetary bow shock, which arises from the interaction of the supersonic flow of solar wind plasma past the planets. This mechanism is a nonlinear mechanism involving three waves: the Langmuir wave, the radio wave, and a low-frequency wave in the case of emission near the plasma frequency or a second Langmuir wave in the case of harmonic emission. The resulting emissions are weak, narrowband emissions.

3.1.3. Atmospheric Lightning

Radio emissions from planets are sometimes associated with atmospheric lightning. The lightning discharge, in addition to producing the visible flash, also produces broad, impulsive radio emissions. If the spectrum of this impulse extends above the ionospheric plasma frequency and if absorption in the atmosphere is not too great, a remote observer can detect the high-frequency end of the spectrum. The "interference" detected with an AM radio on Earth during a thunderstorm is the same phenomenon.

3.2. Synchrotron Radiation

Synchrotron radiation is emitted by relativistic electrons gyrating around magnetic field lines. In essence, this emission consists of photons emitted by the acceleration of electrons as they execute their helical trajectories about magnetic field lines. The emission is strongly beamed in the forward direction (see Figure 52.17) within a cone $1/\gamma$:

$$\frac{1}{\gamma} = \sqrt{1 - \frac{v^2}{c^2}} \tag{52.8}$$

where v is the particle's velocity and c is the speed of light. The relativistic beaming factor $\gamma = 2E$, where E is the energy in mega-electronvolt. The radiation is emitted over a wide range of frequencies, but shows a maximum at $0.29\,\nu_c$, with the critical frequency, ν_c, in megahertz:

$$\nu_c = 16.08E^2B \tag{52.9}$$

where the energy E is in mega-electronvolts and the field strength B is in Gauss. The emission is polarized, where the direction of the electric vector depends on the direction of the local magnetic field. Jupiter is the only planet for which this type of emission has been observed. It has been mapped by ground-based radio telescopes and by *Cassini* to provide some of the most comprehensive, although indirect, information about Jupiter's intense radiation belts.

3.3. Earth

The terrestrial version of the cyclotron maser emission, commonly referred to as Auroral Kilometric Radiation

(AKR), has been studied both at close range and larger distances by many Earth-orbiting satellites. The radiation is very intense; the total power is 10^7 W, sometimes up to 10^9 W. The intensity is highly correlated with geomagnetic substorms, thus it is indirectly modulated by the solar wind. It originates in the nightside auroral regions and in the dayside polar cusps at low altitudes and high frequencies and spreads to higher altitudes and lower frequencies. Typical frequencies are between 100 and 600 kHz. Since AKR is generated by auroral electrons, it can be used as a proxy for auroral activity. And, since numerous in situ studies of the terrestrial auroral electron populations and the resulting radio emissions have been carried out, we can apply our understanding of this emission process to similar emissions at other planets where in situ studies have not yet been carried out.

Earth is also a source of nonthermal continuum radiation. Below the solar wind plasma frequency this radiation is trapped within the magnetosphere. The spectrum is relatively smooth down to the local plasma frequency, typically in the range of a few kilohertz, where the emission cuts off at the ordinary mode cutoff. A few observations of this emission also show an extraordinary mode cutoff. Hence, the emission is either generated in both polarizations or some of the initially dominant ordinary mode is converted into the extraordinary mode via reflections or other interactions with the magnetospheric medium. Above the solar wind plasma frequency, typically at a few tens of kilohertz, the "continuum" radiation spectrum exhibits a plethora of narrowband emissions; some of these extend well into the range of a few hundred kilohertz.

While not as important as the auroral radio emissions from an energetics point of view, the low-frequency limit of the continuum radiation at the plasma frequency provides an accurate measure of the plasma density, an often-difficult measurement for a plasma instrument because of spacecraft charging effects.

3.4. Jupiter's Synchrotron Radiation

Jupiter is the only planet from which we receive synchrotron radiation. The variation in total intensity and polarization characteristics during one Jovian rotation (the so-called beaming curves) indicate that Jupiter's magnetic field is approximately dipolar in shape, offset from the planet by roughly one-tenth of a planetary radius toward a longitude of 140°, and inclined by ~10° with respect to the rotation axis. Most electrons are confined to the magnetic equatorial plane. The magnetic north pole is in the northern hemisphere, tipped toward a longitude of 200°. The total flux density of the planet varies significantly over time (Figure 52.18). The smoothly varying component seems to be correlated with solar wind parameters, in particular the solar wind ram pressure, suggesting that the solar wind may influence the

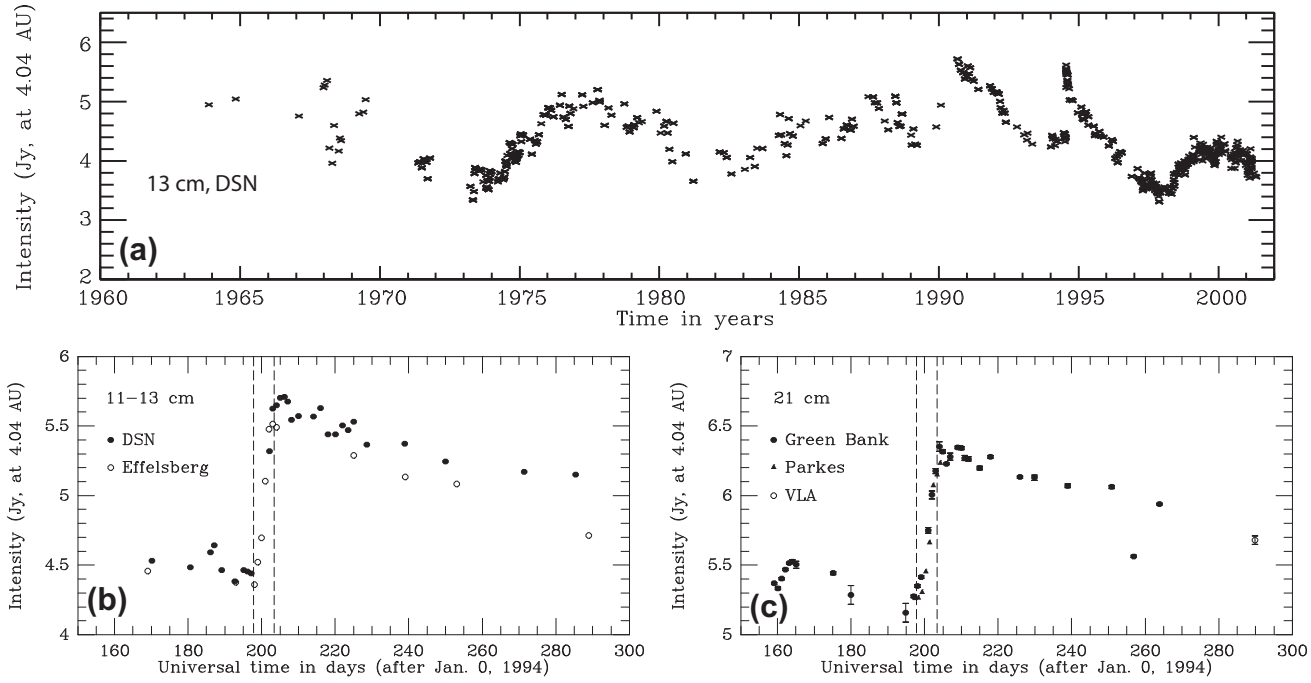

FIGURE 52.18 Time variability in Jupiter's radio emission. Panel (a) shows the radio intensity at a wavelength of 13 cm between the years 1963 through early 2001, as compiled by M.J. Klein. Panels (b) and (c) show Jupiter's radio intensity at 11−13 and 21 cm, respectively, during 1994 up to the summer of 1995. The impact of comet D/Shoemaker−Levy 9 with Jupiter occurred in July of 1994 (indicated by the vertical dashed lines). *Figure from de Pater and Lissauer (2010).*

supply and/or loss of electrons into Jupiter's inner magnetosphere. In addition to variations in the total flux density, the radio spectrum changes as well (Figure 52.16).

An image of Jupiter's synchrotron radiation at a wavelength of 20 cm, obtained with the VLA in 1994, is shown in Figure 52.19(a). Since Jupiter's synchrotron radiation is optically thin, one can use tomography to extract the three-dimensional distribution of the radio emissivity from data obtained over a full Jovian rotation. The example in Figure 52.19(b) shows that most of the synchrotron radiation is concentrated near the magnetic equator, which, due to the higher order moments in Jupiter's field, is warped like a potato chip. The secondary emission regions, apparent at high latitudes in Figure 52.19(a), show up as rings of emission north and south of the main ring. These emissions are produced by electrons at their mirror points and reveal the presence of a rather large number of electrons bouncing up and down field lines that thread the magnetic equator at $\sim$2.5 Jovian radii. This emission may be "directed" by the moon Amalthea. A fraction of the electrons near Amalthea's orbit undergoes a change in their direction of motion, caused perhaps by interactions with low-frequency plasma waves near Amalthea (such plasma noise was detected by the *Galileo* spacecraft when it crossed Amalthea's orbit), and through interactions with dust in Jupiter's rings, while regular synchrotron radiation losses also lead to small changes in an electron's direction of motion.

Figure 52.16(b) shows radio spectra of Jupiter's synchrotron radiation from 74 MHz up to $\gtrsim$20 GHz. These spectra show that the electrons in Jupiter's radiation belts do not follow a simple $N(E) \propto E^{-a}$ power law. Well outside the synchrotron radiation region, beyond Io's orbit at 6 Jovian radii, the electron energy spectrum appears to follow a double power law, $N(E) \propto E^{-0.5}(1 + E/100)^{-3}$, consistent with in situ measurements by the *Pioneer* spacecraft. Processes such as radial diffusion, pitch angle scattering, synchrotron radiation losses, and absorption by moons and rings change the electron spectrum. The radio spectra superposed on the data were derived from such models.

Sometime between 1930 and 1970, Jupiter captured a comet, now known as comet D/Shoemaker–Levy 9 (SL9). During a close encounter with the planet, this comet was ripped apart by Jupiter's strong tidal force into over 20 pieces. These comet fragments, all in orbit about Jupiter, were discovered by the Shoemaker–Levy comet hunting team in May 1993. About a year later, from July 16 to 22 (1994), all comet fragments hit Jupiter. These events were widely observed, at wavelengths across the entire electromagnetic spectrum. At IR wavelength these impacts were incredibly bright, while at optical wavelengths the impact sites were visible as dark spots with even the smallest telescopes. This collision also triggered large temporary changes in Jupiter's synchrotron radiation. The total flux density increased by $\sim$20% (Figure 52.18), the radio spectrum flattened toward shorter wavelengths, and the spatial brightness distribution changed considerably (Figure 52.20(a) and (b)). These changes were brought about by a complex interaction of the radiating particles with shocks and electromagnetic waves induced in the magnetosphere by the series of cometary impacts. Results from models simulating the effects are shown in Figure 52.20(c–f).

Although impacts like those by SL9 were expected to be once in a lifetime events, only 15 years later, in July 2009, amateur astronomer Anthony Wesley in Australia

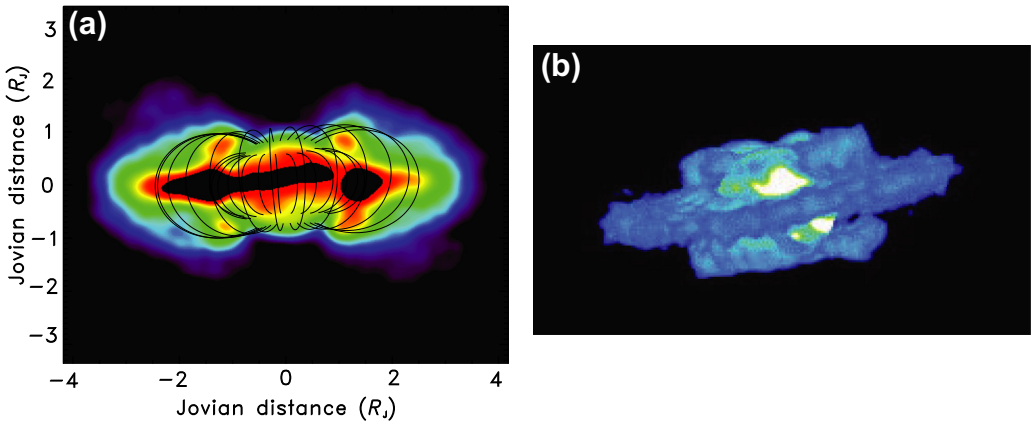

FIGURE 52.19 (a) Radio photograph of Jupiter's decimetric emission at a wavelength of 20 cm, and a central meridian longitude of $\lambda_{cml} \sim 312°$. Magnetic field lines at equatorial distances of 1.5 and 2.5 Jupiter radii are superposed. Field lines are shown every 15°, between $\lambda_{cml} - 90°$ and $\lambda_{cml} + 90°$. The image was taken with the VLA in June 1994. The resolution is 0.3 Jupiter radii, roughly the size of the high-latitude emission regions. *(de Pater, I., et al. (1997).* (b) Three-dimensional reconstruction of Jupiter's nonthermal radio emissivity, from VLA data taken in June 1994, as seen from the Earth at $\lambda_{cml} = 140°$ ($D_E = -3°$). The planet is added as a white sphere in this visualization. *Adapted from de Pater, I. & Sault, R. J. (1998).*

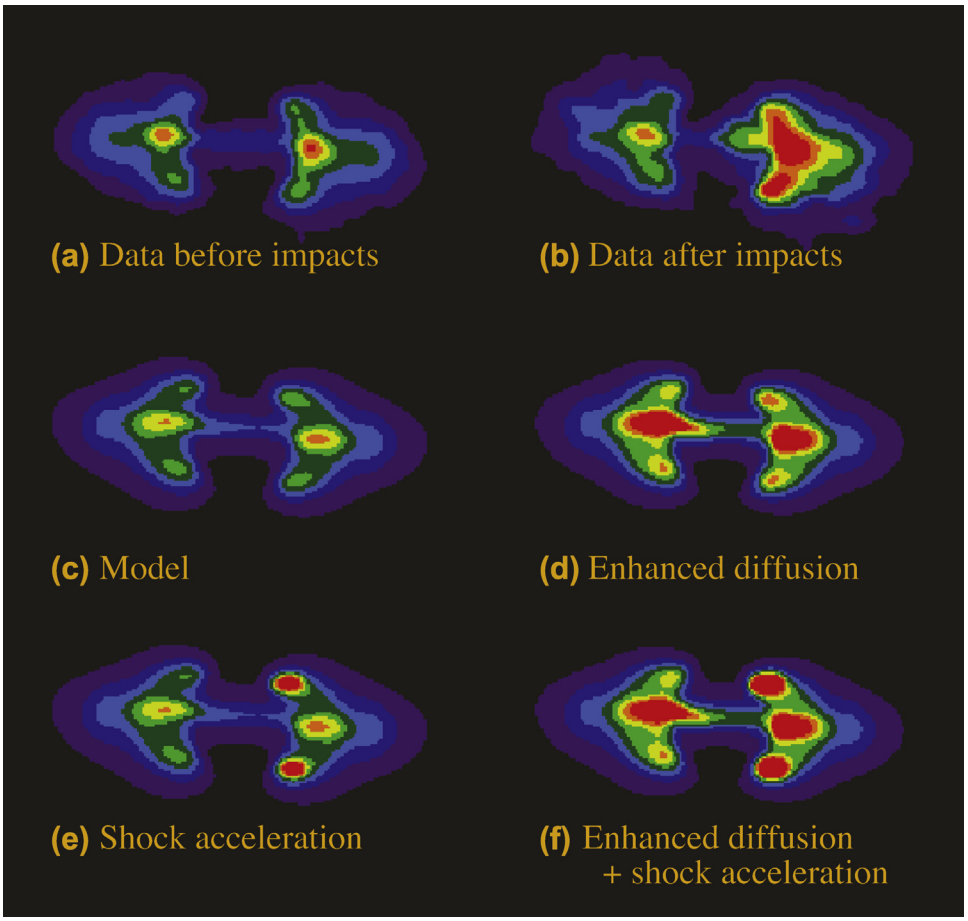

FIGURE 52.20 Real and synthetic false-color images at a wavelength of 20 cm (1.5 GHz) of Jupiter following the impacts of comet D/Shoemaker–Levy 9 with the planet. announced the discovery of a brown "spot" on Jupiter, which he attributed to an impact. Indeed, follow-up observations confirmed that Jupiter was hit yet again by an object several hundreds of meters across, this time of asteroidal rather than cometary nature. By chance, Jupiter had been observed with the VLA both before and after the impacts took place, and as in 1994 the radiation belts were again affected. As only one object hit the planet, enhancements in emission were only seen in the main radiation belts, in agreement with expectations (like the model in Figure 52.20(d)).

3.5. Jupiter at Low Frequencies

Jupiter has the most complex low-frequency radio spectrum of all the planets. Examples of most of these are shown in Figure 52.21 and are discussed in this section.

3.5.1. Decametric and Hectometric Radio Emissions

From the ground, Jupiter's decametric (DAM) emission, confined to frequencies below 40 MHz, has routinely been observed since its discovery in the early 1950s, occasionally down to frequencies of 4 MHz. The upper frequency cutoff is determined by the local magnetic field strength in the auroral regions: 40 MHz for RH circularly polarized emissions translates into $\sim$14 Gs in the north polar region, and 20 MHz for LH into $\sim$7 Gs in the south.

The dynamic spectra in the frequency–time domain are extremely complex, but well ordered.

On timescales of minutes, the emission displays a series of arcs, like open or closed parentheses (Figure 52.21). Within one storm, the arcs are all oriented the same way. The emissions have been interpreted as coherent cyclotron emissions. The satellite Io appears to modulate some of the

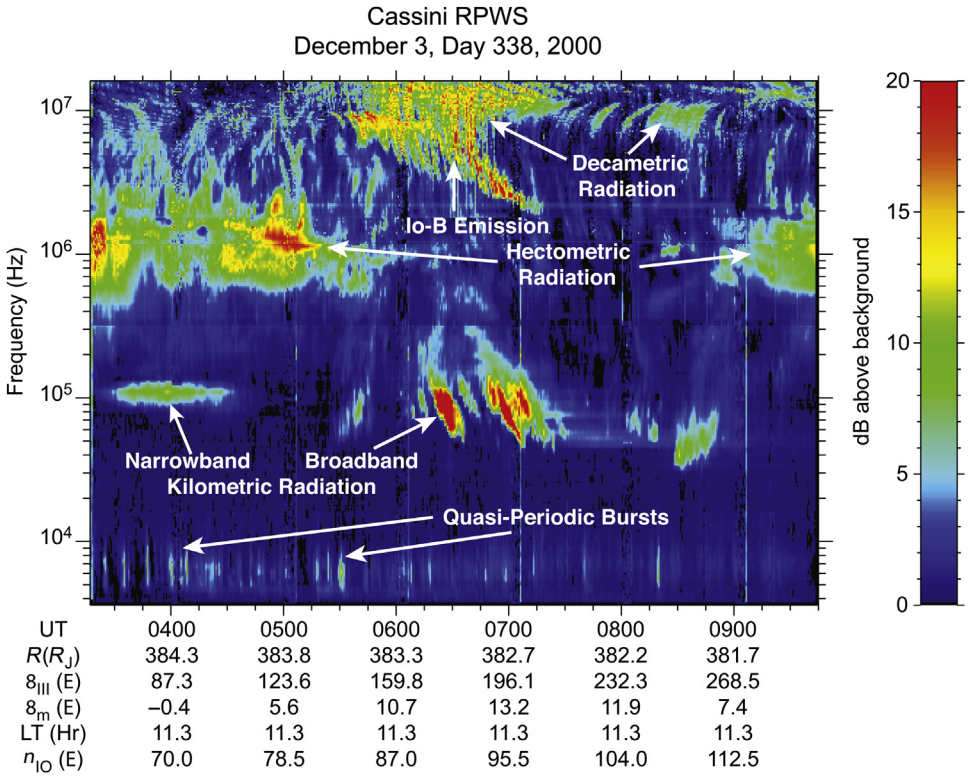

FIGURE 52.21 A representative dynamic spectrum of several of Jupiter's low-frequency radio emissions. The color bar is used to relate the color to the intensity of the emission. The emission is plotted as a function of frequency (along the *y*-axis) and time (along the *x*-axis). *Lecacheux, A. (2001).*

emissions: Both the intensity and the probability of the occurrence of bursts increase when Io is at certain locations in its orbit with respect to Jupiter and the observer. The non-Io emission originates near Jupiter's aurora, and is produced by electrons that travel along magnetic field lines from the middle to outer magnetosphere toward Jupiter's ionosphere. Particles that enter the atmosphere are "lost". These may locally excite atoms and molecules through collisions, which upon de-excitation are visible as aurora at UV and IR wavelengths. Other electrons are reflected back along the field lines, and produce DAM, where their motion along the field line is reflected in the form of arcs in the radio emission (i.e. a drift with frequency). The Io-dependent emissions are produced at or near the footprints of the magnetic flux tube passing through Io (similar, but much weaker, emissions originate along the flux tubes passing through Ganymede, and perhaps Callisto).

Hectometric (HOM) emissions are, in many ways, indistinguishable from DAM except that they are found at lower frequencies, from a few hundred kilohertz to a few megahertz, with a local maximum near 1 MHz. The source region of HOM must be further from Jupiter than the DAM source. Otherwise, like DAM, HOM is predominantly emitted in the extraordinary mode and is likely generated by the cyclotron maser instability.

Because the dipole moment of Jupiter is tilted by $\sim 10^\circ$ from the rotational axis, most Jovian radio emissions exhibit a strong rotational modulation. Given that Jupiter is a gas giant, this modulation is thought to be the best indicator of the rotation of the deep interior of the planet. The rotation period of the interior is important, for example, because this provides a rotating coordinate system against which the atmospheric winds can be measured. Because these radio observations have been recorded over many decades of time, analysis of these data lead to an extremely accurate determination of Jupiter's rotation period, $9^h\ 55^m\ 29^s.6854$.

3.5.2. Kilometric Radio Emissions

Between a few kilohertz up to 1 MHz various spacecraft detected both broadband kilometric (bKOM) and narrowband kilometric (nKOM) radiation from Jupiter (Figure 52.21). The lower frequency cutoff for bKOM, $\sim$20 kHz (sometimes down to $\sim$5 kHz) is likely set by propagation of the radiation through the Io plasma torus. The source of these emissions is at high magnetic latitudes and appears fixed in local time. The forward lobe near the north magnetic pole is of opposite polarization than a "back lobe" of the same source. The nKOM emissions last longer

(up to a few hours) than bKOM; are confined to a smaller frequency range, 50−180 kHz; and show a smooth rise and fall in intensity. The recurrence period for nKOM events suggests that the source lags behind Jupiter's rotation by 3−5%, which was the first indication that this emission, in contrast to any other low-frequency emissions, is produced by distinct sources near the outer edge of the plasma torus. *Galileo* and *Ulysses* studies have shown that these emissions occur as a part of an apparently global magnetospheric dynamic event. There is a sudden onset of these emissions, they are visible for a few to several planetary rotations, and finally, they fade away.

3.5.3. Very Low-Frequency Emissions

The *Voyager* spacecraft detected continuum radiation in Jupiter's magnetosphere at frequencies below 20 kHz, both in its escaping and trapped form. As discussed in Section 3.1, radiation can be trapped inside the magnetic cavity if it cannot propagate through the high-plasma-density *magnetosheath*. This trapped emission has been observed from a few hundred hertz up to ∼5 kHz. Occasionally, it has been detected up to 25 kHz, suggesting a compression of the magnetosphere caused by an increased solar wind ram pressure. Outside the magnetosphere the lower frequency cutoff of the freely propagating radiation corresponds to the plasma frequency in the magnetosheath and appears to be well correlated with the solar wind ram pressure. This escaping component is characterized by a complex narrowband spectrum, attributed to a linear or nonlinear conversion of electrostatic waves near the plasma frequency into freely propagating electromagnetic emissions. The linear mechanism favors ordinary mode radiation, but the trapped emission appears to be a mix of both ordinary and extraordinary radiation, perhaps from the multiple reflections off high-density regions in the magnetosphere and at the magnetopause.

The quasi-periodic (QP), or Jovian type III emissions (in analogy to solar type III bursts, because of their similar dispersive spectral shape) often occur at intervals of 15 and 40 min as observed by *Ulysses,* but neither *Galileo* nor *Cassini* found particularly dominant periodicities at these or other intervals (see Figure 52.21). The emission likely originates near the poles. Simultaneous measurements by the Galileo *and* Cassini spacecraft, both in the solar wind but at different locations, observed similar QP characteristics, suggestive of a strobe light pattern rather than a searchlight rotating with the planet. Within the magnetosphere, the QP bursts can then appear as enhancements of the continuum emission. At the magnetosheath, the lower frequency components of the bursts are dispersed by the higher density plasma, which produces the characteristic type III spectral shape. The 40-min QP bursts were correlated with energetic (∼1 MeV) electrons observed by *Ulysses*. *Chandra* detected similar periods in X-rays from the auroral region, although not directly correlated with QP bursts themselves. Such observations suggest that the QP bursts are related to an important particle acceleration process, but the details of the relationship and the details of the process remain elusive.

3.5.4. Ganymede

Jupiter's satellite Ganymede has its own magnetosphere embedded within Jupiter's magnetic field. It presents a rich plasma wave spectrum, similar to that expected from a planetary magnetosphere. It is also the source of nonthermal narrowband radio emissions at 15−50 kHz, very similar to the escaping continuum emissions from Jupiter. The more intense cyclotron maser emission, seen from the auroral regions of all giant planets and the Earth, is absent, however. This is almost certainly because the electron plasma frequency is greater than the cyclotron frequency; hence, the cyclotron maser instability does not operate.

3.6. Saturn

Saturn's nonthermal radio spectrum consists of several components, as displayed in Figure 52.21 and discussed in the following section.

3.6.1. Saturn Kilometric Radio Emissions

Saturn's kilometric radiation (SKR) is characterized by a broadband of emission, 100% circularly polarized, covering the frequency range from 20 kHz up to several hundred kilohertz. When displayed in the frequency−time domain, it is sometimes organized in arclike structures, reminiscent of Jupiter's DAM arcs (see Figure 52.22(a)). *Cassini* has revealed some fine structure characteristic of cyclotron maser emissions (Figure 52.22(b)). As on the Earth, the SKR source appears to be fixed at high latitudes primarily in the local morning to noon sector, but it also appears at other local times. The SKR intensity is strongly correlated with the solar wind ram pressure, perhaps suggesting a continuous transfer of the solar wind into Saturn's low-altitude polar cusps. In fact, a detailed comparison between high-resolution *Hubble Space Telescope* images of Saturn's aurora with SKR suggests a strong correlation between the intensity of UV auroral spots and SKR.

Cassini has flown through the top of an SKR source on at least one occasion. The observed SKR was at and just below the electron cyclotron frequency, consistent with generation by the cyclotron maser instability. The source was in an upward current region, consistent with a region of precipitating electrons. Low-energy plasma observations are suggestive of an unstable shell-like distribution. Hence, the SKR source region appears to be similar to the source of AKR at the Earth.

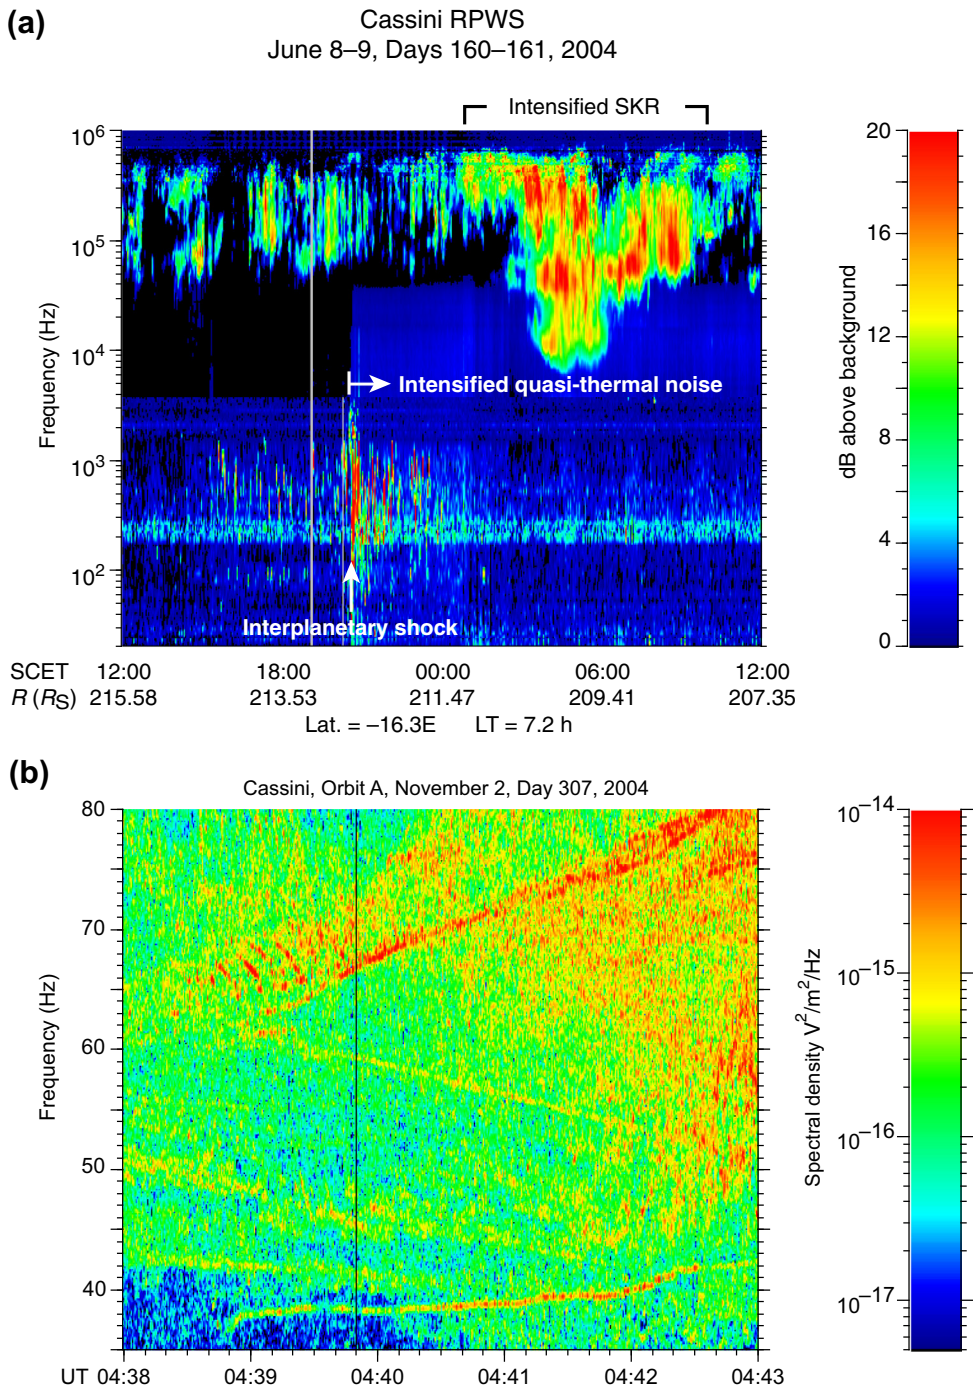

FIGURE 52.22 (a) Dynamic spectra of Saturn's SKR emission as observed with the Radio and Plasma Wave Science Instrument (RPWS) on the Cassini spacecraft. Frequency is plotted against the spacecraft event time (SCET) and distance, R, from the planet in planetary radii (R_S). The local time, LT, is listed below the figure. This illustrates a dramatic intensification of the SKR in response to an interplanetary shock that passed *Cassini* at about 20:30 on June 8, 2004. (b) A high temporal and spectral resolution record of SKR obtained by *Cassini*. Frequency is plotted against universal time (UT). This spectrogram illustrates the complex structure and variations in the SKR spectrum, which is also typical of cyclotron maser emissions at Jupiter and Earth. *After Kurth, et al. (2005).*

Even though the emission is highly variable over time, a clear periodicity at $10^h\ 39^m\ 24^s \pm 7^s$ was derived from the *Voyager* data, which was adopted as the planet's rotation period. Because the emission is tied to Saturn's magnetic field, which is axisymmetric, the cause of the modulation remains a mystery, although it may be indirect evidence of higher order moments in Saturn's magnetic field. Even more mysterious, however, is that the SKR modulation

period measured by *Ulysses* and *Cassini* varies by 1% or more (several minutes) on timescales of a few years or less. Clearly, this change in period cannot represent a change in the planet's rotation itself, but there is no commonly accepted explanation.

Cassini has not only confirmed this variation in SKR period but also discovered that, in fact, two variable periods exist with one in the northern hemisphere and one in the south, as displayed in Figure 52.23. A number of other magnetospheric measurements have also suggested this dichotomy of rotational modulation periods. Further, near the Saturnian equinox the two periods appeared to merge or exchange several months afterward. A number of models have been proposed to explain these curious rotational periods, but it seems most likely that they are due to variations in the upper level winds in the atmosphere.

The existence of rotational modulation in Saturn's magnetosphere remains an enigma; however, it is likely that the axisymmetric nature of the magnetic field has uncovered a range of periodic phenomena not unlike the so-called system IV period at Jupiter exhibited by nKOM radiation.

3.6.2. Very Low Frequency Emissions

While the spacecraft was within Saturn's magnetosphere, it detected low-level continuum radiation (trapped radiation) at frequencies below 2−3 kHz (VLF). At higher frequencies, the emission can escape and appears to be concentrated in narrow frequency bands. One of the most predominant narrowband emissions is typically observed around 5 kHz. It is generated by mode conversion from Z-mode emissions near 3 Saturn radii at auroral latitudes. Higher frequency narrowband emissions may be generated by mode conversion from electrostatic upper hybrid bands, again at high latitudes.

3.6.3. Saturn Electrostatic Discharges

Saturn electrostatic discharges (SEDs) are strong, impulsive events, which last for a few tens of milliseconds from a few hundred kilohertz to the upper frequency limit of the *Voyager* planetary radio astronomy experiment (40.2 MHz), and are also detected by the *Cassini* spacecraft. Structure in individual bursts can be seen down to the *Voyager* time resolution limit of 140 μs, which suggests a source size less than 40 km. During the *Voyager* era, episodes of SED emissions occurred approximately every 10^h 10^m, distinctly different from the periodicity in SKR. Cassini has been able to link SED episodes directly to cloud systems near 35° south planetocentric latitude observed in Saturn's atmosphere by the *Cassini* spacecraft. *Cassini,* however, has found SEDs to be much less common, generally speaking, than *Voyager.* Cassini can go months without seeing the discharges. Perhaps it may be a seasonal effect or related to

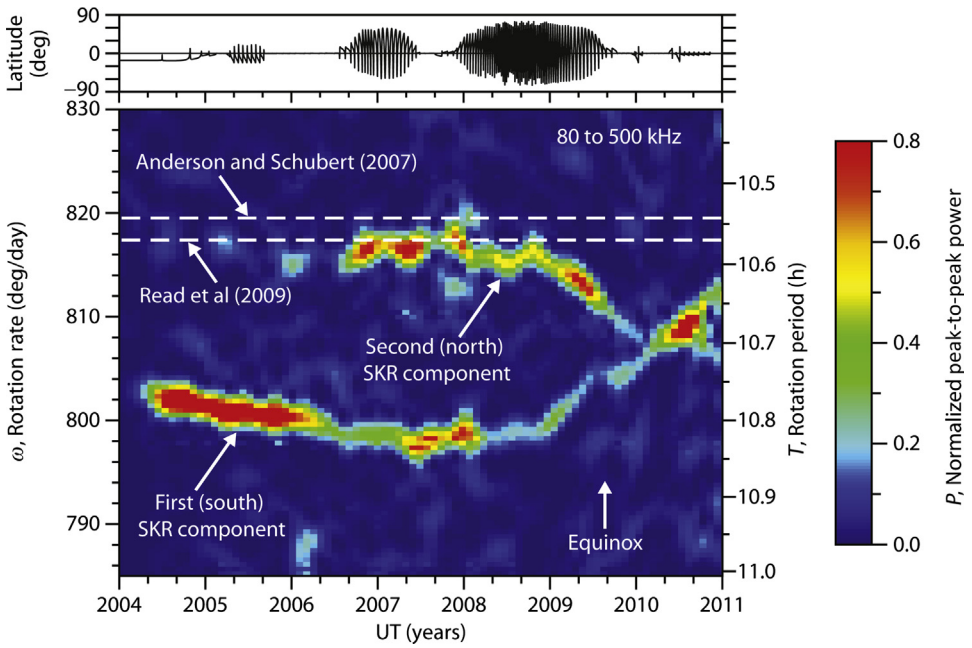

FIGURE 52.23 Top: Latitude of the Cassini spacecraft. Bottom: Frequency−time spectrogram of the normalized peak-to-peak power of the SKR modulation as a function of time and the rotational modulation rate, ω. The white dashed horizontal lines are the internal rotation rates of Saturn inferred by different authors. All rotational modulation rates are less than the inferred internal rotation rate which implies that the magnetosphere is slipping with respect to the rotation of Saturn's interior. *Gurnett, D. A., Groene, J. B., Averkamp, T. F., Kurth, W. S., Ye, S.-Y., & Fischer, G. (2011).*

the extent of ring shadowing on the atmosphere (or ionosphere, if propagation is an issue).

In December 2010 Cassini observed the onset of a very intense lightning storm commensurate with the onset of a planetwide convective storm in the northern hemisphere, likely similar to "Great White Spot" storms which occur approximately once per Saturn year (see also Figure 52.9). This storm quickly encircled the planet at planetocentric latitudes near and around 35°. All previous lightning observed by Cassini had originated near 35° S, hence, this great storm apparently reflects the early spring season in the northern hemisphere.

3.7. Uranus and Neptune

Like Saturn's radio emissions, both smooth and bursty components are apparent in the radio emissions from Uranus and Neptune, and these emissions probably originate in the southern auroral regions of the planets. Note, though, that the magnetic fields of these planets are inclined by large angles (47° for Uranus, 59° for Neptune) with respect to their rotational axes, and hence the auroral regions are not near the rotation poles. The periodicity of the emissions leads to the determination of the rotation periods of both planets, 17.24 ± 0.01 h for Uranus and 16.11 ± 0.02 h for Neptune. The upper bound to the frequency of the emissions is determined by (and indicative of) the planets' surface magnetic field strength.

From Uranus, we have also received impulsive bursts, similar to the SED events of Saturn, which are referred to as Uranus electrostatic discharge events. They were fewer in number and less intensive than the SEDs. If these emissions are caused by lightning, the lower frequency cutoff suggests peak ionospheric electron densities on the dayside of $\sim 6 \times 10^5$ cm^{-3}. In addition to the broadband emissions, both planets also emit trapped continuum and narrowband radiation.

4. FUTURE OF RADIO ASTRONOMY FOR SOLAR SYSTEM RESEARCH

This chapter highlighted the value of radio observations for planetary atmospheres (composition, dynamics), surface composition and structure, comets (parent molecules, source of material, outgassing), and magnetospheres (magnetic field configurations, particle distributions). While writing this review chapter, three new large arrays of telescopes are being commissioned. At centimeter wavelengths, the VLA has been upgraded, and sensitivities have improved by an order of magnitude. The image of Neptune in Figure 52.10(c) was an early result from this upgraded array. The next leap in mapping sources at centimeter wavelengths will be with the Square Kilometer Array, an array of telescopes spread out over 3000 km with a collecting area of 1 km^2. The array will be built in South Africa and Australia, and is expected to be finished by 2024.

At millimeter wavelengths the ALMA is being built in Chile, jointly by the United States, Canada, Europe, and Chile. ALMA will enable detection of, e.g. hundreds of asteroids, "bare" cometary nuclei, emissions from molecular "jets" from comets at high spatial and time resolution, Io's volcanic plumes, Titan's hydrocarbon chemistry, and "proto-Jupiters" in nearby stellar systems.

At long wavelengths, operations of the Low Frequency Array in the Netherlands has just commenced. This array will, for the first time, enable mapping of Jupiter's DAM emissions, and pinpoint its sources with high accuracy.

ESA's *Rosetta* spacecraft, currently on its way to comet 67P/Churyumov–Gerasimenko, carries a microwave instrument, MIRO, with receivers centered at 190 and 562 GHz. Starting in mid-2014, Rosetta will move with the comet from a *heliocentric distance* of ~3.5 AU down to perihelion near 1.3 AU. MIRO will measure near-surface temperatures and temperature gradients in the comet's nucleus using broadband channels on both receivers. Particularly exciting is its spectrometer, sensitive to several major volatile species (H_2O, CO, CH_3OH, and NH_3) at extreme high spatial and spectral resolution. These measurements will provide unprecedented information on the outgassing of the comet as a function of heliocentric distance.

Juno, a New Frontiers Jupiter mission, expected to arrive at Jupiter in 2016, will measure the planet's composition down to ~100 bar using six microwave radiometers sensitive to wavelengths between 1.3 and 50 cm. It also carries a radio and plasma wave sensor to make in situ measurements of the radio emissions and plasma in the auroral regions.

ESA expects to launch the Jupiter Icy Moon Explorer (JUICE) which is also expected to carry radio and plasma wave instruments. Orbit insertion is currently planned for 2030.

1. INTRODUCTION

1.1. Scientific Value of Radar

Radar describes the act of transmitting a radio signal towards a target and receiving its echo. Planetary radar refers specifically to the study of the solar system's planets, moons, and small bodies. The principles of planetary radar are similar to those used in other radar systems, such as aircraft navigation and weather forecasting, except that the distances involved are generally orders of magnitude larger, requiring the world's most powerful radar systems.

Unlike most forms of remote sensing, which rely on light sources for which the user has no control (passive astronomy), radar astronomy uses its own transmitting system to illuminate a surface (active astronomy). This gives the user complete control over the transmitted signal, making radar one of the few forms of "experimental astronomy". The transmitters and receivers used in a radar system can be housed in Earth-based telescopes or on orbital spacecraft, and can be colocated (monostatic) or separated in space (**bistatic**).

There are several advantages to observing planetary objects at radio wavelengths, in addition to visual and infrared (VIR) wavelengths. Firstly, radar represents the best way to observe the surface of planets with optically opaque atmospheres, such as Venus and Titan, leading to a better understanding of their surface morphology. Secondly, radar provides a wealth of information on the physical properties of the surface being imaged, on scales not accessible with VIR images. Unlike VIR images, which typically probe the chemical composition of the uppermost surface layer, radar images are sensitive to physical and electrical properties, highlighting differences in the slope, roughness, and dielectric constant of the surface and near subsurface (to depths of centimeters to meters). These properties make radar data very complementary to optical

data, since features that are difficult to perceive in optical data are often easily seen in radar data, and vice versa.

Radar also has the advantage of utilizing a range of wavelengths easily accessible from the surface of the Earth. Although the Earth's atmosphere is generally quite transparent at radio wavelengths, there are some frequency limitations when transmitting with Earth-based telescopes. Molecular absorptions in the Earth's atmosphere lead to losses for frequencies >50 GHz (<1 cm) and the ionosphere reflects frequencies <10 MHz (>30 m). Other worlds have different limitations: on Venus, the dense atmosphere leads to absorption at all frequencies above a few gigahertz (<10 cm), and on Titan, the atmosphere limits operation to frequencies <30 GHz (>1 cm). Of course, there are no such limitations when observing airless worlds from orbital platforms. See Table 53.1 for typical frequencies used in planetary radar.

1.2. History

Radio-based detection and tracking was first developed during World War II for air defense and other military purposes (see History of Solar System Exploration). During this time, the US Navy coined the acronym RADAR (RAdio Detection And Ranging). These early radars generated relatively long wavelength (∼1 m) radiation, but the development of the cavity magnetron in 1940 allowed for the creation of narrow-beam, higher frequency radar systems.

The birth of planetary radar did not come until 1946, when the US Army Signal Corps station at Fort Monmouth, NJ, USA, obtained the first radar echoes from the surface of the Moon. A Hungarian group led by Zoltan Bay made an independent measurement only a few weeks later. Equipped with a less powerful transmitter than the Americans, Bay had devised a technique in which he sent repeated signals to the Moon and summed the received signals.

Radar imaging progressed rapidly after the war, and synthetic aperture radar (SAR) was developed in the 1950s. As we discuss in Section 2, SAR has the benefit of increasing the along-track resolution of radar images and making the resolution independent of the distance to the target. During this time, radars were also used to map the Moon at a variety of wavelengths in support of the Apollo program, and the first echoes were received from the terrestrial planets. Radar observations allowed for the first accurate determination of the rotation period of Venus and Mercury. These were difficult to determine from optical data alone, due to Venus's obscuring atmosphere and Mercury's proximity to the Sun.

Radar experiments were carried aboard the Apollo spacecraft, the first radars to orbit another planetary object. **Bistatic** radar measurements were made during the Apollo 14, 15, and 16 missions by transmitting a radio signal from the spacecraft and receiving the echoes on the Earth. At short wavelengths, these experiments found that the lunar regolith could be approximated by a surface made of a material with a dielectric constant of ∼3, while at long wavelengths, evidence of volume scattering was present. The first SAR to orbit another planet was carried on board the Apollo 17 mission. The Apollo 17 Lunar Sounder Experiment operated at 5 MHz (60 m), 15 MHz (20 m), and 150 MHz (2 m). At short wavelengths, it was used to determine the topography of the lunar surface, while at 60 m, it was capable of penetrating as much as 2 km in dry lunar rocks, providing evidence of subsurface layering.

TABLE 53.1 Frequency Bands Typically Used in Planetary Radar

Band Name	Frequency	Wavelength	Planetary Usage	Notes
Ka-band	27–40 GHz	0.75–1.1 cm		Above K-band
K-band	18–27 GHz	1.1–1.7 cm		From German "*kurz*", for short
Ku-band	12–18 GHz	1.7–2.5 cm	Cassini RADAR	Under K-band
X-band	8–12 GHz	2.5–3.75 cm	Haystack, Goldstone	Used in missile guidance – "X" marks the spot
C-band	4–8 GHz	3.75–7.5 cm	Mini-RF	A compromise between X- and S-band
S-band	2–4 GHz	7.5–15 cm	Arecibo, Goldstone, Apollo 14/15/16, Venera 15/16, Magellan, Mini-RF	Short wave
L-band	1–2 GHz	15–30 cm	Millstone-Hill, Pioneer-Venus	Long wave

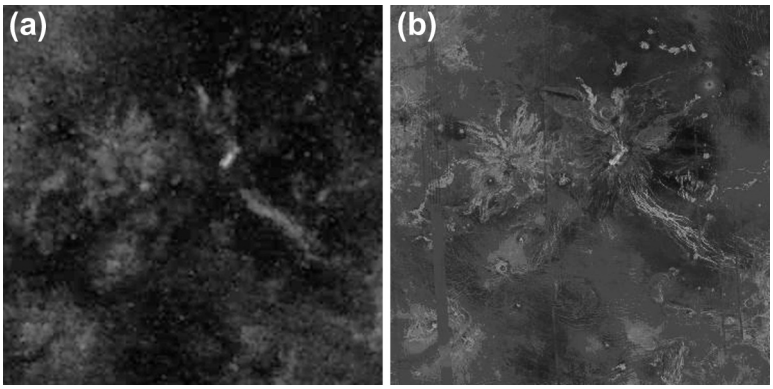

FIGURE 53.1 Our understanding of surface processes on Venus improved greatly between 1978 and 1990, as the resolution of orbital radars improved from ~25 km (Pioneer-Venus) to ~100 m (Magellan). Note the differences in this image of Venus, centered between Sif Mons (22° N, 352° E) and Gula Mons (22° N, 359° E), when viewed at (a) a lower resolution at 17 cm (Pioneer-Venus) and (b) a higher resolution at 12.6 cm (Magellan).

The first spaceborne imaging radar used for scientific studies was Seasat, which was launched in 1978 and collected data on the properties of the Earth's ocean and land surfaces. That same year, Pioneer Venus used a radar altimeter to measure the global surface topography of Venus and to create a 25-km resolution map of its equatorial region. Since then, radar images of the surface of Venus have improved from 1 km resolution of the northern hemisphere by Venera 15 and 16 in 1982 to ~100 m resolution of 98% of the planet by Magellan in the early 1990s (Figure 53.1). Ground-based radar systems have detected echoes from objects as far away as Saturn. The first echoes from Jupiter's moons and Saturn's rings were received in the mid-1970s. These observations showed that Saturn's rings are made of relatively large particles and that icy satellites backscatter radar waves in an unusual way, unlike that seen on rocky objects.

Radar has also revolutionized our knowledge of small bodies in the solar system. The first echo from an asteroid was detected in 1968, and the first echo from a comet was detected in 1980. An upgrade in the Arecibo radio telescope in 1997 provided an order of magnitude improvement in sensitivity, causing the number of asteroids detected and characterized by radar to rise exponentially (Figure 53.2). As of September 2013, radar has detected 16 comets, 397 near-Earth asteroids (NEAs), and 134 main belt asteroids (MBAs). A knowledge of the orbits of these objects has proved to be extremely important for hazard mitigation on the Earth from impacting bodies.

A recent explosion of orbiting radars has increased our knowledge of many of the objects in the solar system. Cassini RADAR (2004 to present) has provided the first high-resolution views of Titan. Mars Advanced Radar for Subsurface and Ionosphere Sounding (MARSIS) (2005 to

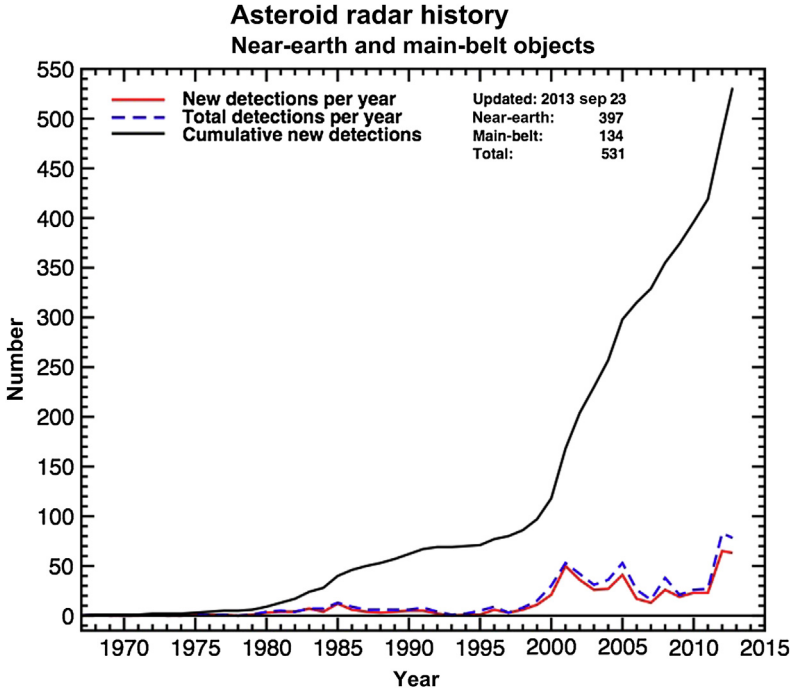

FIGURE 53.2 Improvements in ground-based radar systems have increased our understanding of the surface properties and orbits of many of the small bodies in the solar system. *Image from http://echo.jpl.nasa.gov.*

present) and Mars SHAllow RADar sounder (SHARAD) (2006 to present) have helped to quantify the volatile inventory on Mars. The Miniature Radio-Frequency instrument (Mini-RF) (2009 to present) has provided the first radar images of large portions of the far side of the Moon, and the first **bistatic** radar images of another planetary body at large beta angles. In addition, the MESSENGER mission has provided the first optical views of the non-imaged hemisphere of Mercury, adding contextual information to the ground-based radar images of that world.

2. TECHNIQUES

Radar systems are classified in one of several categories depending on the type of measurement needed. Radar imagers acquire two-dimensional images of planetary surfaces (Section 2.1), radar sounders probe an object's subsurface structure along a satellite track (Section 2.2), and altimeters and interferometric radars acquire accurate height measurements of a planetary surface (Section 2.3). Scatterometry is another type of radar technique, which measures the reflectivity of a surface by sending pulses and measuring the backscattered power in the radar beam. Although not discussed in detail here, scatterometry measurements are crucial for determining the average scattering properties of large areas of a surface and are used extensively for the interpretation of high-resolution radar images.

2.1. Radar Imagers

Radar imagers, whether ground based or orbital (Figure 53.3), produce two-dimensional images of a planetary surface by observing changes in the **Doppler shift** (motion relative to observer) and time delay (distance) of an object. Thus, to obtain high-resolution images, it is necessary to have high-resolution measurements of time, t, and frequency, ν.

For example, if there are two point targets separated by a distance dr, the echoes received from these points will be separated by a time $\mathrm{d}t = 2\mathrm{d}r/c \sin\theta$, where c is the speed of light and θ is the look angle of the radar. To achieve this range resolution, it is necessary to pulse the transmitted radio wave into discrete time intervals. However, smaller pulses (resulting in images with higher range resolution) contain less energy than longer pulses. Therefore, to achieve both a small dt and a large pulse energy, radar signals are *modulated* over a longer time interval τ. This is often done by phase modulation, wherein a monochromatic signal has its phase shifted by 0° or 180° at time intervals $\mathrm{d}t \ll \tau$, in essence producing a binary code (Figure 53.4). The received signal is cross-correlated with the known transmitted signal, and the returning echo is identified when the correlation between transmitted and received signals is high. At all other times, the correlation is near zero. Note that in many radars, the transmitted pulses are separated by a time T, yielding a pulse repetition frequency $\mathrm{PRF} = 1/T$. Between pulses, the radar can switch from transmit to receive mode, to collect the signals from previously transmitted pulses.

Once identified, the pulses can be stacked to produce a time series of echoes at each individual range. The Fourier transform of that time series yields information about the Doppler shift of each point, providing the second dimension of the radar image (Figure 53.4). The resolution can be adjusted after the data is collected by adjusting the length of the Fourier transform, again emphasizing the experimental nature of planetary radar. In essence, a delay-Doppler image maps a three-dimensional (3D) object into a two-dimensional representation (Figures 53.5 and 53.6). This introduces ambiguities into the resultant image, since there exist two points north and south of the subradar point with identical time delay and Doppler shift. However, if the radar beam is smaller than the target or is offset from the rotational equator, these ambiguities can be minimized, and the

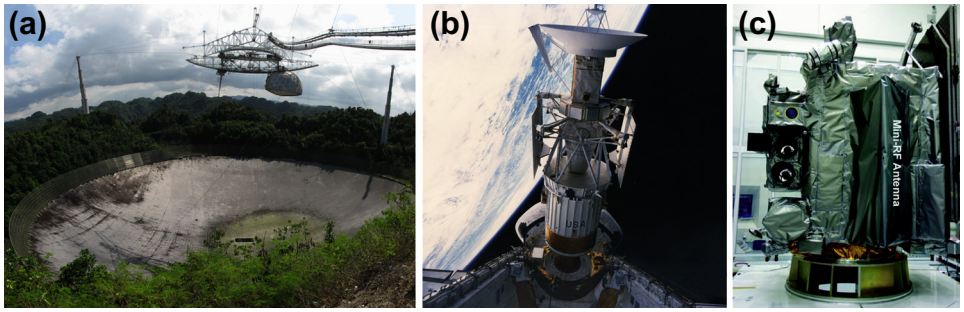

FIGURE 53.3 Typical ground-based and orbital radar systems. (a) The Arecibo radio telescope in Puerto Rico has a 305-m-diameter primary reflector. The S-band transmitter and receiver are housed in the Gregorian dome suspended above the reflector. (b) The Magellan spacecraft weighed 1035 kg, and supported one instrument, the Radar System (RDRS). This instrument used a 3.7-m antenna, which functioned as a radar imager, altimeter, and radiometer. (c) One recent orbital radar—Mini-RF—is orders of magnitude less massive (14 kg) than Magellan, acting as just one of the seven instruments on the Lunar Reconnaissance Orbiter. *Image credit: NASA/GSFC.*

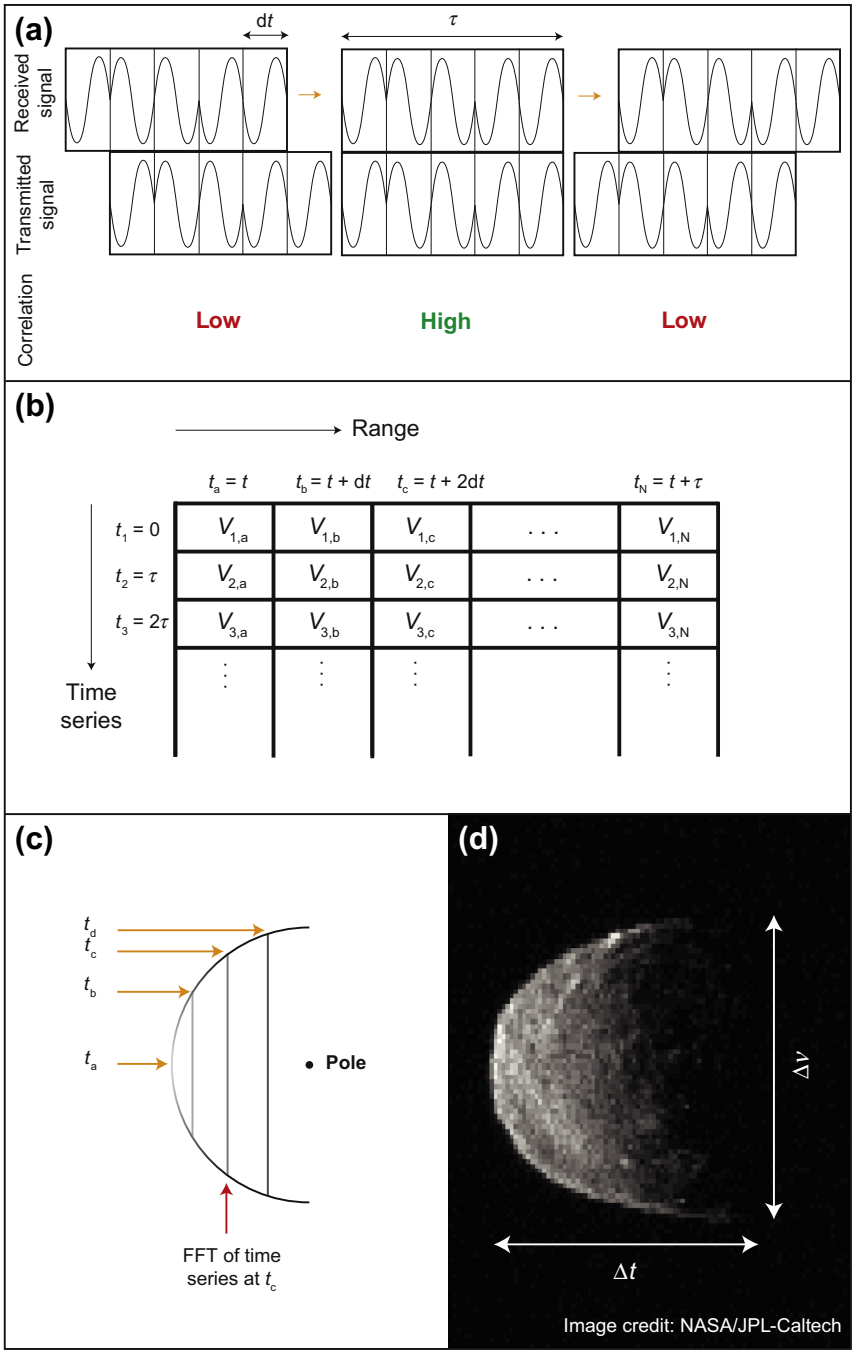

FIGURE 53.4 (a) In radar imaging, the incoming radar pulse is compared with the transmitted signal. The start of the received signal is identified where the correlation is high. (b) The received pulses are then stacked to produce a time series of echoes at each range (delay). The Fourier transform of the time series yields information about the Doppler shift at each point. (c) The radar target viewed from its spin vector. Regions near the limb will have larger time delay and correspondingly smaller radar backscatter. (d) Delay-Doppler image of asteroid 2005 YU55. For reasonably spherical objects, the spread in time delay (Δt) can be used to determine the size of the asteroid, and the spread in Doppler shift ($\Delta \nu$) can be used to determine its rotation rate. *Image credit for part (d): NASA/JPL-Caltech.*

delay-Doppler images can later be transformed into map coordinates.

Orbital radars acquire data in the Doppler direction in a slightly different way than what is described above for ground-based radars. Here, the Doppler (or "along-track") resolution corresponds to the two nearest separable points along a constant delay line. For real aperture radars, this is equal to the width of the antenna footprint, which is generally quite large. For this reason, SARs were developed. SAR exploits the fact that a particular target P is illuminated by the radar from numerous locations along the orbital path. These echoes can be combined in a processor to synthesize a much larger antenna of length D, with a correspondingly smaller beam width, λ/D (Figure 53.7). In SAR systems, the along track resolution is also independent of the distance between the sensor and the target being imaged, h, and depends only on the size of the physical antenna, L. This surprising result can be understood in the

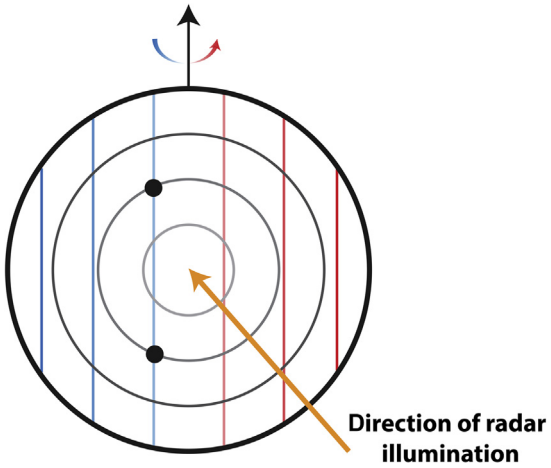

FIGURE 53.5 Delay-Doppler radar images map a 3D object into a two-dimensional image. Circles represent constant delay (t) and lines represent constant Doppler shift (ν). Unless the radar beam is smaller than the target or offset from the center of the object, ambiguities are introduced since there exist two points north and south of the subradar point with identical time delay and Doppler shift (black dots).

following way: the farther the sensor is from the target, the larger the footprint is on the ground, leading to a longer synthetic array with a correspondingly finer resolution. The only disadvantage of using larger orbital altitudes is that more power will be required to acquire a detectable echo. Note that unlike ground-based radars, in which the target is generally comparable in size to the radar beamwidth, SAR illuminates a discrete swath on only one side of the subspacecraft track. This eliminates any right–left ambiguity in the image. If the surface topography is known, geometric distortions can be corrected, allowing for registration with optical imagery and other data sets.

2.2. Radar Sounding

Radar sounding instruments are similar to the imaging SAR systems described above, but they utilize long wavelengths (meters to hundreds of meters) and have been optimized for detecting subsurface structure. At shorter wavelengths (meters), sounding radars can be used to probe the upper tens of meters of ice sheets, while at longer wavelengths they are capable of probing hundreds of meters to kilometers through rock and ice. Prior planetary sounding radars spanned a wide range of frequencies: from longest to shortest wavelength, these instruments are the MARSIS radar (0.1–5.5 MHz, or 50–3000 m) on Mars Express, the Lunar Radar Sounder (5 MHz, or 60 m) on the Kaguya spacecraft, the Apollo Lunar Sounder Experiment (5–150 MHz, or 2–60 m) on Apollo 17, and the SHARAD radar (20 MHz, or 15 m) on the Mars Reconnaissance Orbiter.

Sounding radar data are usually displayed as radargrams, with time delay on the y-axis and along-track distance along

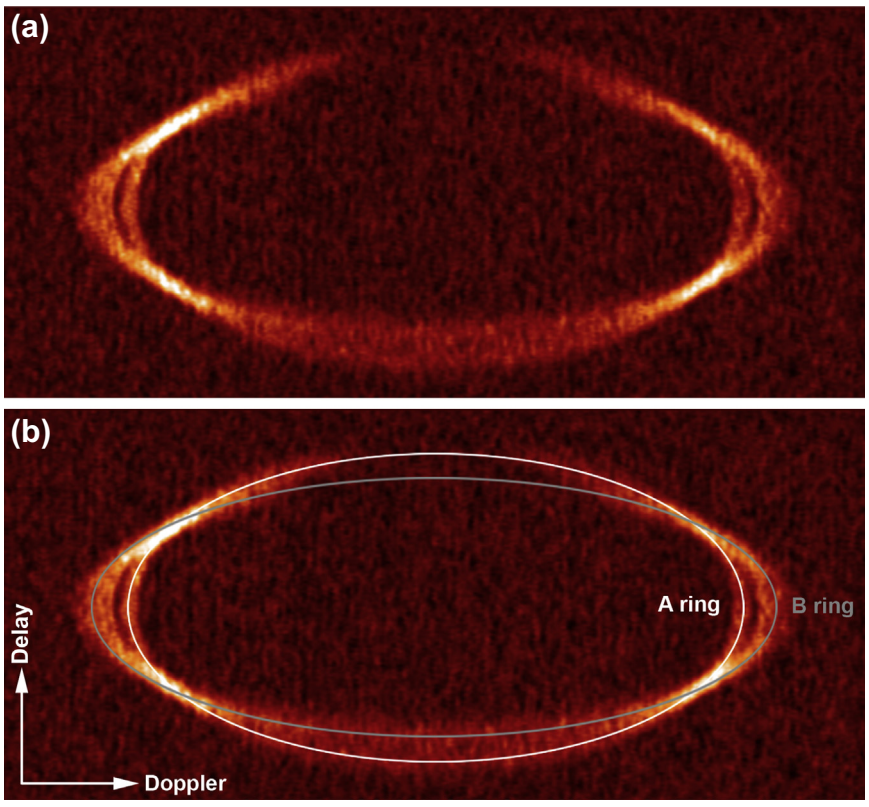

FIGURE 53.6 (a) The difference between angle–angle space as perceived by the human eye and delay-Doppler space as perceived by radar is well illustrated by this S-band image of Saturn's rings. (b) The outermost "A" ring returns the earliest echo in the delay direction, but orbits more slowly than the "B" ring, making it narrower in the Doppler direction. This leads to four "cross-over" regions, where signal from the two rings add together. *Image modified from Nicholson, P. D., et al. (2005).*

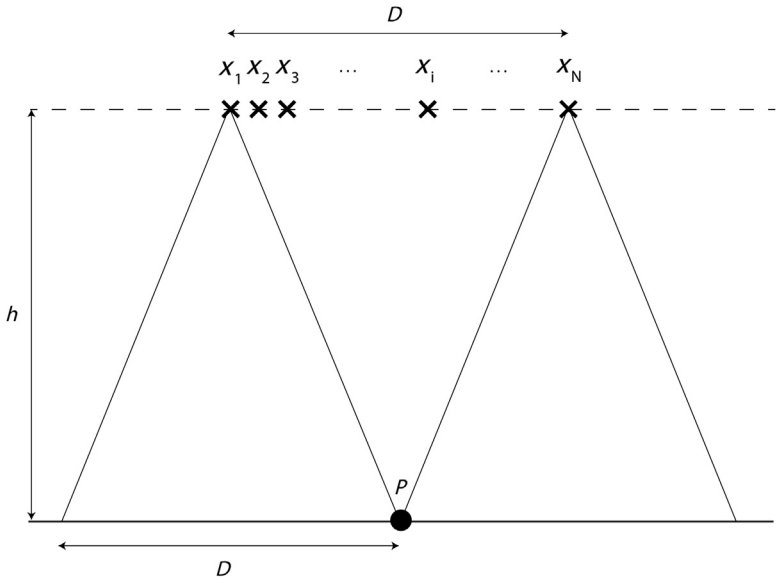

FIGURE 53.7 A SAR is capable of observing the same point P from many different positions, x_i. This improves the along-track or Doppler resolution of the image by increasing the size of the antenna from its physical size L to its synthetic size D. The resolution of the radar is independent of the orbital altitude, h.

the x-axis. Sounding radars have large spatial footprints (hundreds of kilometers), and so are not typically used to make images. However, low-resolution maps of radar reflectivity can be obtained if multiple orbital tracks are mosaicked. During the radargram formation, synthetic aperture processing is applied along track to improve the spatial resolution and signal to noise. SAR "focusing" also combines power from a feature observed at multiple distances and Doppler shifts into a single radargram element, eliminating parabola-shaped time-delay "tails" that are caused by the radar moving toward and away from a topographic feature.

Sounding radars are nadir-pointing instruments, but radargrams can contain "clutter", or power from off-nadir surface elements. These occur at later time delay values than the surface echo and therefore appear to be subsurface features. To verify that apparent subsurface features in the radargrams are not clutter, simulated radargrams are generated using topographic data (Figure 53.8). Clutter is more problematic in rough terrains, at shorter radar wavelengths where there are increased reflections from wavelength-scale surface roughness, and in regions that lack topographic data with sufficient resolution to accurately model the expected radar echo power.

Long-wavelength radars are also sensitive to the ionosphere, which distorts the phases of radar waves passing through. The SHARAD and MARSIS radars must both account for these phase distortions in processing, especially for daytime orbital tracks where electron densities are high due to sunlight interacting with atoms in the atmosphere. The phase distortion is greater at longer wavelengths, and the MARSIS radar has ionospheric modes that are used to probe the structure of the ionosphere and its temporal variability.

Sounding radar is particularly well suited to measurements of dielectric properties. If a subsurface interface is detected, then the round-trip light travel time (Δt) can be measured from the radargram. If an estimate of the thickness or depth of the deposit can be made using separate topographic information (h), the permittivity (ε') can be computed from:

$$\varepsilon' = \left(\frac{c\,\Delta t}{2\,h}\right)^2$$

The loss tangent can also be calculated by measuring how the reflected power from a subsurface interface decreases with greater depth. These dielectric values can then be compared to laboratory-derived values for terrestrial rocks in order to constrain the density and composition of the rocks.

2.3. Radar Topography

Radar systems can be used to acquire topography of a planetary surface using one of a number of different techniques. One of the most straightforward methods is the use of radar altimeters. These instruments provide a measure of the distance between the sensor and the surface at the nadir point by measuring the time delay between the transmission of the signal and the receipt of the echo. The accuracy of the time difference depends mainly on the "sharpness" of the pulse ($dt = 1/B$, where B is the bandwidth of the pulse) and any pulse dispersion resulting from surface roughness. Rough surfaces will return energy from various heights on the surface, leading to a gradual rise in the echo leading edge and a decrease in the echo strength. To reduce these uncertainties, a narrow beam covering a

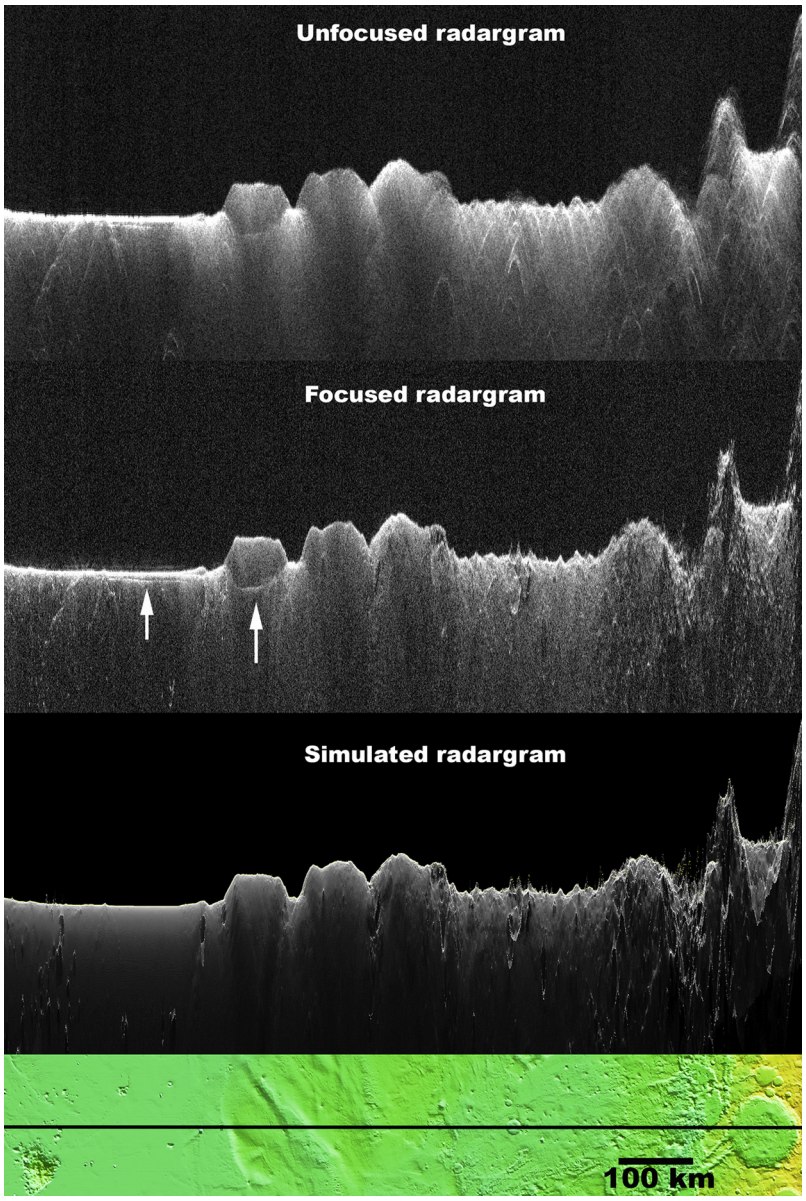

FIGURE 53.8 SHARAD sounding radar data over a portion of the Medusae Fossae Formation (MFF) on Mars. The top two images illustrate the effect of synthetic aperture focusing on the data. The third panel is a simulation of the focused data product that uses Mars Orbital Laser Altimeter data to predict the echoes produced by surface reflections. Subsurface features (arrows) are apparent in the data beneath hills of MFF material that are ~600 m above the surrounding plains. The lowest panel shows the orbit track and topography. *Source: Carter, L. M., et al. (2009).*

smaller surface area is generally desirable. Conventional altimeters will acquire a single topographic profile along the flight line, but two-dimensional topography can be acquired with a multibeam altimeter. Radar altimeters were flown on the Pioneer Venus, Venera 15/16, Magellan, and Cassini missions.

Solid surface topography can also be measured by stereo imaging (see Stereophotogrammetry). It requires acquiring two images of the same surface area with two different viewing geometries. The principles behind radar stereo imaging are similar to those for the more familiar method of optical stereo imaging, but take into account the geometric principles by which SAR images are formed (i.e. delay-Doppler format rather than angle–angle format). Two-dimensional digital terrain models are produced using highly adjustable image matching algorithms. These match points can be edited interactively to account for noise in the images and any differences in illumination direction. The image matching algorithms require a sensor model, a type of software that converts image pixel location into a ground location in latitude, longitude, and elevation. This sensor model will differ for images acquired with different spacecraft. Stereo topography has been derived with radar images from the Magellan, Cassini, and Lunar Reconnaissance Orbiter (LRO) missions.

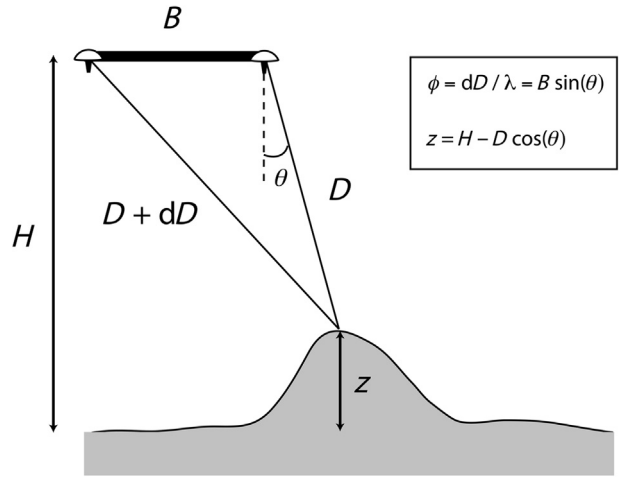

FIGURE 53.9 Diagram showing the relevant geometry for radar interferometric measurements of topography.

Radar interferometry, or "InSAR", is another technique by which high-resolution topography can be obtained over large areas using a spacecraft. InSAR works in one of two ways. The first involves a spacecraft flying at an altitude of H that carries a boom with two radar antennas at either end. Radar waves are transmitted to the ground and later received by the antennas on the spacecraft. The phase difference between the waves received at either end of the boom, ϕ, can be measured. Knowing the boom length, B, and the wavelength of the radar waves, λ, one can calculate the incidence angle, θ, using simple geometry:

$$\phi = \mathrm{d}D/\lambda = B\sin(\theta)$$

Knowing the incidence angle, θ, the altitude, H, and the direct distance from the antenna to the ground, D (the speed of light times the measured return time divided by 2), you can then solve for the topography:

$$z = H - D\cos(\theta)$$

A schematic of the relevant geometry for radar interferometric measurements is given in Figure 53.9. Alternatively, a spacecraft can make two nearly identical passes over a region, and the phase difference from the two passes can be used to determine the topography. InSAR has been used to determine the topography of the Earth (e.g. the Shuttle Radar Topography Mission and TerraSAR-X), but has yet to be successfully implemented on any planetary mission. However, ground-based telescope interferometry has been used to derive the topography of the Moon, using two telescopes separated by a baseline B to receive the signal.

Finally, a technique known as "SARTopo" has recently been developed that estimates surface heights by comparing the calibration of overlapping radar beams. This technique has been particularly useful for determining the topography of Saturn's moon Titan with the Cassini RADAR instrument, a world with only a limited amount of

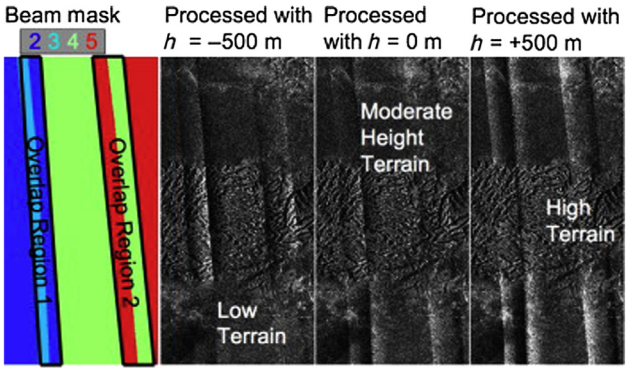

FIGURE 53.10 In regions where radar beams overlap, it is possible to correlate the received power to the antenna gain pattern to estimate surface heights. Three examples from Cassini RADAR are shown here, processed at three different heights. Dark to light banding indicates that the height was underestimated, while light to dark banding indicates that the height was overestimated. *Figure from Stiles, B. W., et al. (2009).*

altimetry and stereo topography. The Cassini RADAR instrument has five different antenna feeds (or beams), and data from overlapping beams are acquired nearly simultaneously. Surface heights are computed by maximizing the correlation between the received power and the antenna gain pattern at each point along track in the overlap region (Figure 53.10). This technique is capable of estimating surface heights for most of the radar-imaged surface of Titan with ~10 km horizontal resolution and a vertical resolution of tens of meters. It has extended the area over which colocated topography and radar imagery is available on Titan by at least an order of magnitude.

3. TARGET PROPERTIES

Radar images can appear superficially quite similar to images acquired at optical wavelengths. However, the information contained in the images—namely, its albedo and polarimetric properties—is very different. While optical images are primarily sensitive to the absorption of light due to varying chemical compositions, radar images are primarily sensitive to the physical and electrical properties of the surface. Electromagnetic waves impinging on **dielectric materials** will excite atoms in the target, such that they become small electromagnetic oscillators and radiate energy. How the energy is radiated will depend on the slope, roughness, dielectric constant, conductivity, etc. of the surface, which in turn affect the albedo (Section 3.1) and polarimetry (Section 3.2) of the radar image.

3.1. Radar Albedo

The intrinsic radar albedo of a surface is characterized by its backscatter cross-section, $\sigma(i)$. This parameter is a function of the incidence angle, i, of a radar, its polarization

and wavelength, and the properties of the surface, especially its roughness (Figure 53.11). For example, if a surface is perfectly flat, it will scatter energy away from the radar receiver, at an angle equal to the incidence angle (specular reflection). If a surface is rough at the scale of the radar wavelength, it will scatter energy in every direction, including back toward the radar receiver (diffuse scattering). Most surfaces are some combination of both: small-scale roughness superimposed on large, flat facets. As natural surfaces do not typically vary by more than ~30°, at small angles the return is dominated by the quasispecular return from the large facets. At larger angles, the return is dominated by the effect of the diffuse scattering from the small-scale roughness.

Radar backscatter functions like those shown in Figure 53.11(b) can be determined by scatterometers measuring the average scattering properties of large areas of a planetary surface as a function of frequency and illumination direction. It is then possible to fit these data to a variety of models that have been developed to approximate the scattering behavior of natural surfaces. These are generally a superposition of the facet model, and the diffuse scattering, or Bragg, model. For example, a facet model commonly used in planetary radar applications is the Hagfors model:

$$\sigma(i) = \frac{C\rho}{2}\left(\cos^4 i + C\sin^2 i\right)^{-3/2}$$

where $C^{-1/2}$ is the root mean square slope of the surface in radians and ρ is the Fresnel reflectivity, related to the dielectric constant by $\rho = (|1-\sqrt{\varepsilon}|/|1+\sqrt{\varepsilon}|)^2$. For planetary surfaces, the dielectric constant, $\varepsilon = \varepsilon' + i\,\varepsilon''$, will be most sensitive to the density of the rock, and the presence of metals. Higher densities and high concentrations of metals will increase ε from a typical value of 3 for dry rocks. The presence of liquid water will also produce significant effects in radar images, given its extremely high dielectric constant of $\varepsilon \sim 80$. Generally, though, dielectric constant is a secondary effect in radar images compared to surface roughness variations.

A Bragg-type model commonly used in planetary radar applications is the Muhleman model:

$$\sigma(i) = \frac{\beta\cos i}{(\sin i + \alpha\cos i)^3}$$

where α and β are empirical constants. This model was used for Magellan SAR data processing.

Note that scattering occurs not only at the surface but also from the near subsurface. Radars have relatively long penetration depths, and will scatter wherever there is an interface separating two regions of different electromagnetic properties, such as bedrock buried under regolith. The imaginary part of the dielectric constant, ε'', is known as the loss factor, and it determines the ability of the target material to absorb the radar energy and convert it into another form of energy,

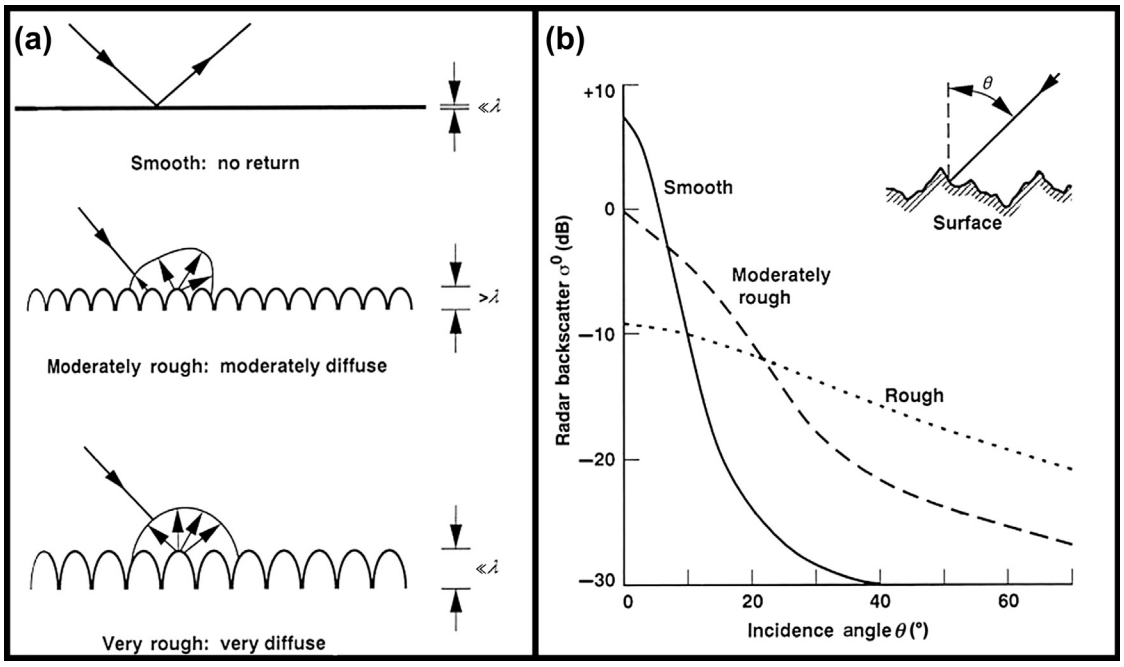

FIGURE 53.11 (a) Planetary bodies scatter radar energy in particular directions depending on the wavelength-scale roughness of its surface. Smooth surfaces scatter energy in the specular direction, away from the radar receiver, and rough surfaces scatter energy in every direction, including back toward the radar receiver. (b) Radar backscatter will also vary depending on the incidence angle of the radar beam. Smooth surfaces have brighter returns when the incidence angle is close to specular, but quickly drop to zero at angles greater than ~30°. *Figure adapted from Farr, T. G. (1993).*

such as heat. For most materials, this factor decreases with wavelength, such that longer wavelengths penetrate further than shorter wavelengths into a particular material. The penetration depth, or the distance in the subsurface at which the radar power has decreased by $1/e$, can be approximated by $L \sim \lambda/(2\pi\varepsilon'^{1/2} \tan\delta)$, where the loss tangent, $\tan\delta = \varepsilon''/\varepsilon'$. For dry low-loss soils, this typically gives $L \sim 10\lambda$.

3.2. Radar Polarimetry

Additional information about target properties can be found in the orientation of the returned radar signal, known as its polarization. In particular, radars that are capable of receiving an echo in two or more known polarizations contain more information about the surface properties than backscatter measurements acquired in a single polarization. Radar signals can be horizontally polarized (perpendicular to the plane of incidence, *H*) or vertically polarized (in the plane of incidence, *V*). Alternatively, they can be circularly polarized, a case in which the electric field magnitude remains constant but its direction is constantly rotating. These polarizations can be right handed (clockwise rotation, R) or left-handed (counterclockwise rotation, L). Often, they are simply referred to in terms of the same sense that was transmitted (SC) and the opposite sense that was transmitted (OC). Examples of radars capable of polarimetric measurements include ground-based radars such as Arecibo, which transmits in one circular polarization and receives in two orthogonal circular polarizations, and the recent Mini-RF radars on the Chandrayaan-1 and LRO spacecraft. These radars transmit in one circular polarization, and receive in both horizontal and vertical polarizations, a technique known as "hybrid polarity".

The polarization properties of a surface may be expressed by the Stokes vector. The first Stokes parameter (S_1) is a measure of the total average power in the echo, S_2 and S_3 describe the linearly polarized state of the wave, and S_4 gives the direction and magnitude of the circularly polarized power. For any radar that receives in two orthogonal polarizations, the Stokes vector can be given by:

$$\begin{aligned} S_1 &= \left\langle |E_H|^2 + |E_V|^2 \right\rangle = \left\langle |E_L|^2 + |E_R|^2 \right\rangle \\ S_2 &= \left\langle |E_H|^2 - |E_V|^2 \right\rangle = 2Re\langle E_L E_R^* \rangle \\ S_3 &= 2Re\langle E_H E_V^* \rangle = 2Im\langle E_L E_R^* \rangle \\ S_4 &= 2Im\langle E_H E_V^* \rangle = \left\langle |E_L|^2 - |E_R|^2 \right\rangle \end{aligned}$$

Here, E represents the complex received voltage in the subscripted polarization (H, V, L, or R), * denotes the complex conjugate, $<\ldots>$ denotes averaging, and Re and Im refer to the real or imaginary part of the complex amplitude. Two particularly useful products can be derived from the Stokes vector: the circular polarization ratio (CPR) and the degree of linear polarization (DLP). These are defined as:

$$CPR = \frac{S_1 - S_4}{S_1 + S_4} = \frac{SC}{OC} \text{ and } DLP = \frac{\sqrt{S_2^2 + S_3^2}}{S_1}$$

The CPR is a useful indicator of surface roughness (Figure 53.12). This is because when a circularly polarized radar wave is backscattered off an interface, the polarization state of the wave changes. Thus flat, mirrorlike surfaces, dominated by single-bounce reflections, tend to have high OC returns and low CPR values. Rough surfaces, dominated by multiple-bounce reflections, tend to have approximately equal OC and SC returns, with CPR values approaching unity. Incidence angle also affects the CPR. As we discussed in Section 2.1, low incidence angles are dominated by quasispecular scattering off smooth facets, leading to a larger OC return, while high incidence angles are dominated by diffuse scattering, increasing the SC/OC ratio and hence the CPR.

Rarely, CPR values can exceed unity. CPRs greater than 1 have been observed in rocky areas such as Maxwell Montes on Venus, blocky lava flows on the Earth, lava flows on Mars, and fresh ejecta blankets on the Moon. CPRs up to

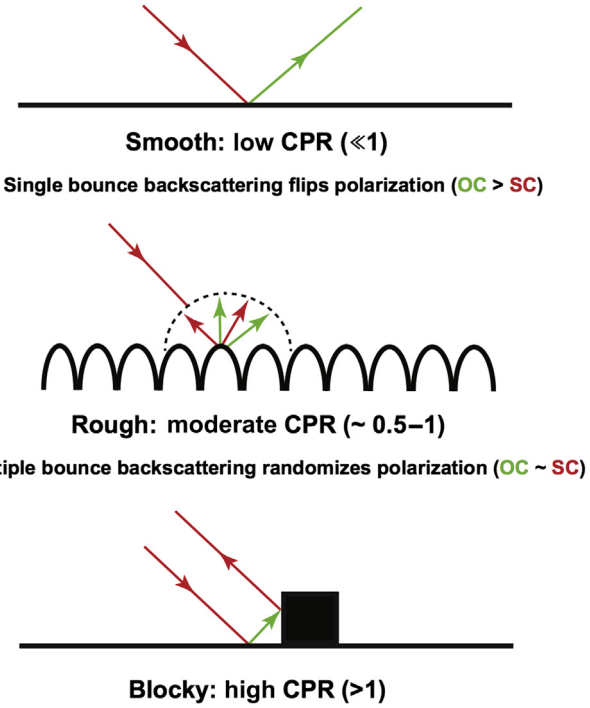

FIGURE 53.12 The roughness of a planetary surface affects the CPR. Smooth surfaces are dominated by single-bounce backscattering, which tends to flip the polarization (OC > SC). Rough surfaces are dominated by multiple-bounce backscattering, which randomizes the polarization (OC ~ SC). Blocky surfaces act as corner reflectors, causing double-bounce or **dihedral scattering** (OC < SC).

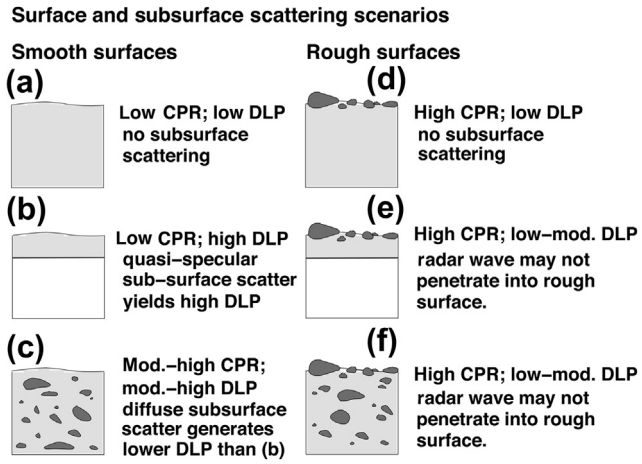

FIGURE 53.13 The CPR and DLP can be used to infer differences in the surface and subsurface structure. Note that smooth surfaces (depicted in a, b, and c) and low-loss tangents will increase the relative amount of subsurface scattering compared to rough surfaces (depicted in d, e, and f). *Figure from Carter, L. M., et al. (2011).*

2 can be produced via multiple reflections from rock edges and cracks, while scattering from natural corner reflectors (**dihedral scattering**) can produce an average CPR up to 3–4. High CPRs can also be caused by the presence of water ice, a phenomena we discuss in Section 4.1. Note, however, that ice cannot account for CPRs greater than 2.

The DLP can be used to infer the presence of subsurface scattering. A circularly polarized wave can be thought of as a combination of vertically and horizontally polarized waves. These two components have different power transmission coefficients, so if the wave penetrates the surface, the reflected wave will change from circular to elliptical. This introduces a linear component to the signal that was not present before, increasing the DLP. Thus, echoes from subsurface interfaces will have a larger DLP than those from most types of surface interfaces. Combined with the CPR, these products can be used to infer differences in the surface and subsurface structure of the planetary body (Figure 53.13). For example, a surface made of a fine-grained material overlying bedrock will have low CPR (from scattering off a smooth surface), but a high DLP (from subsurface scattering off of the bedrock) (Figure 53.14).

4. RADAR MEASUREMENTS OF PLANETARY BODIES

There have been countless studies of planetary bodies using radar, covering a variety of geologic topics. In this chapter, we touch on a selected set of highlights from that body of work and invite the reader to explore the references below for a more complete picture of planetary radar.

4.1. Mercury

Mercury has been studied by ground-based radars for many decades (see Mercury). Indeed, one of the earliest discoveries made by planetary radar was that Mercury was in a 3:2 spin–orbit resonance and not synchronously rotating about the Sun. Radar imaging of the planet began in earnest in the 1990s, producing the best images of the non-Mariner-imaged hemisphere of Mercury prior to the arrival of the MESSENGER spacecraft. In these images, two types of features were most prominent: radar-bright deposits near the north and south poles and rayed craters near the equator and midlatitudes. New optical images from the MESSENGER spacecraft have recently allowed for more detailed study of these features.

4.1.1. Polar Deposits

Radar-bright features were first discovered near Mercury's north pole using Goldstone and the Very Large Array (VLA) in a **bistatic** configuration. These results were soon confirmed by observations at Arecibo, and similar deposits near the south pole were also discovered. These deposits have large same-sense radar reflectivities and CPRs that

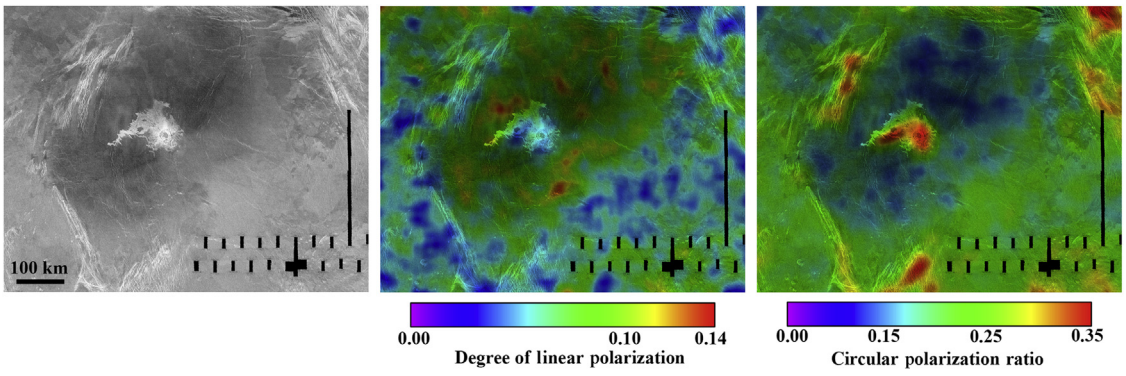

FIGURE 53.14 Galina crater on Venus (47.6° N, 307.1° E) has a radar dark halo with a high DLP and a low CPR. This suggests the presence of a smooth, fine-grained deposit over a buried interface. *Figure from Carter, L. M., et al. (2011).*

exceed unity. Similar radar properties have been observed on the Galilean satellites and Mars' polar ice caps.

These properties are relatively unusual compared to most targets in the solar system, and are thought to be indicative of the coherent backscatter effect in cold water ice (Table 53.2, Figure 53.15). When an incident circularly polarized radar wave is backscattered off an interface, the polarization state of the wave changes. For most surfaces, this leads to a return with more of an "opposite sense" (OC) polarization than a "same sense" (SC) polarization, so the CPR (CPR = SC/OC) remains less than 1. However, in weakly absorbing media (such as water ice), the radar signal can undergo a series of forward scattering events off small imperfections in the material, each of which preserves the polarization properties of the signal. Those portions of the wave front that are scattered along the same path but in opposite directions combine coherently to produce an increase in the SC radar backscatter. This coherent backscatter effect leads to large returns in the same sense (SC) polarization and values for CPR that can exceed unity.

The resolution of the radar images of Mercury improved over time, and many of these radar-bright features were observed to lie within impact craters imaged by Mariner 10. However, many more features could not be mapped in this way, since Mariner 10 only imaged roughly half of the planet during its two encounters in 1974 and 1975. In March 2011, MESSENGER became the first spacecraft to orbit Mercury. Subsequent analysis of the images collected during its 1-year prime mission was able to identify regions of persistent shadow near the north and south poles. For both poles, there is a remarkable correlation between regions of persistent shadow and radar-bright deposits (Figure 53.16(a)). Indeed, within 10° of the north pole, almost all craters larger than 10 km in diameter host radar-bright deposits. This work is an excellent example of the complementary nature of optical and radar imagery in understanding planetary surfaces.

Some craters located at lower latitudes (as far south as 66° N) or smaller than 10 km are also correlated with radar-bright deposits. This is odd because thermal models of Mercury's polar craters suggest that temperatures within such regions are likely to be too high to maintain water ice over geologic timescales, even if it is insulated by a thin (a few decimeters) layer of regolith. Understanding the thermal environment in these craters will be

TABLE 53.2 Radar Properties of the Icy Galilean and Saturnian Satellites Compared to Mars' Polar Caps and the Putative Ice Deposits Near the Poles of Mercury

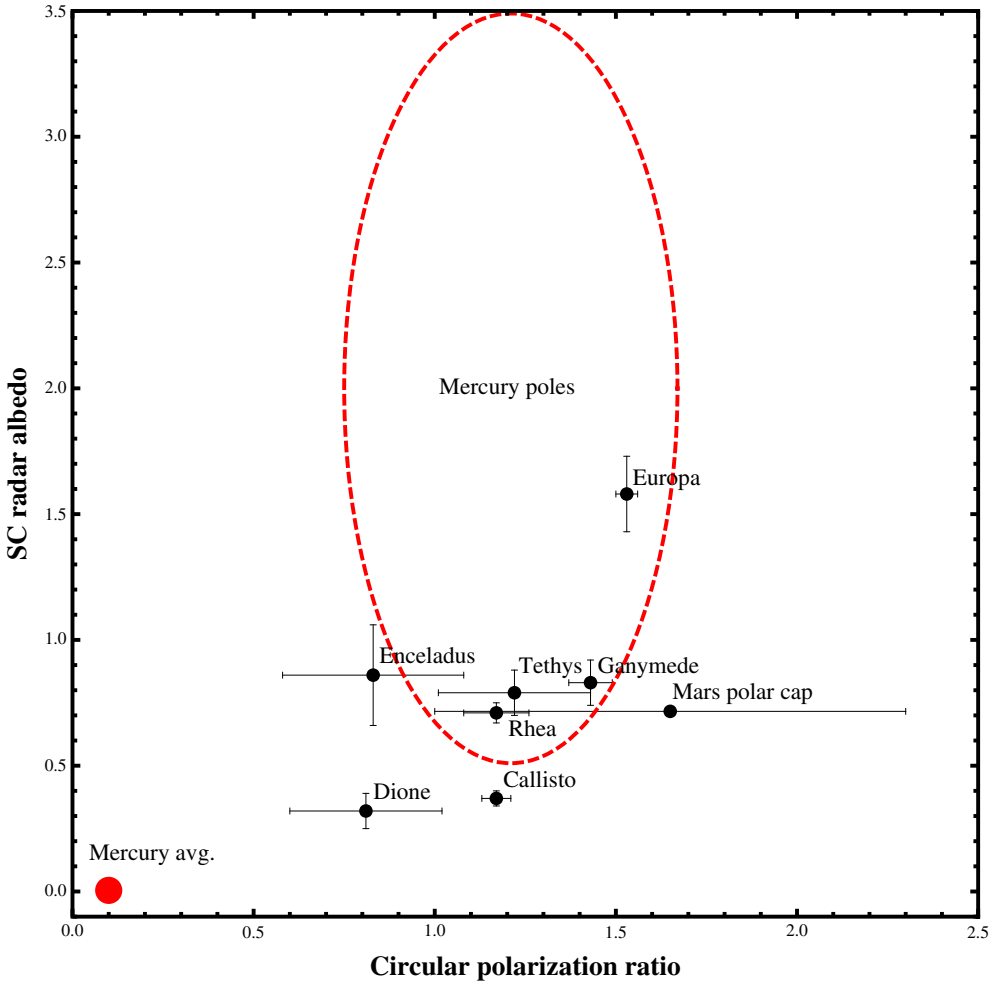

FIGURE 53.15 Radar properties of the polar deposits on Mercury (red ellipse). The polar deposits have radar properties more similar to the icy satellites of Jupiter and Saturn (black dots) than the average rocky surface of Mercury (red dot).

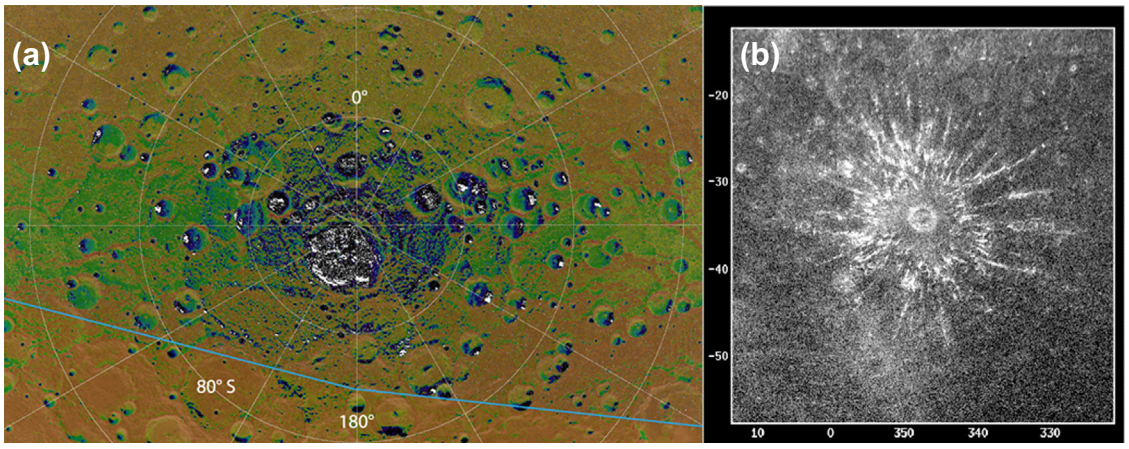

FIGURE 53.16 (a) The radar-bright deposits near Mercury's south pole (white regions) correlate well with regions of permanent shadow as observed by the MESSENGER spacecraft (black regions). *(Image from Chabot, N. L., et al. (2012), Journal of Geophysical Research 118,* http://dx.doi.org/10.1029/2012JE004172*.)* (b) Debussy crater (85 km diameter, 348° W, 34° S), formerly "Radar A", is one of the most spectacular rayed craters in the solar system. Rough ejecta appears radar bright in this SC radar image. *From Harmon, J. K., et al. (2007).*

key for constraining the timing of the emplacement of the radar-bright deposits. The presence of ice within such craters may suggest that it was emplaced relatively recently. Models of the burial of ice on Mercury through regolith emplacement estimate emplacement times of $<$50 million years for relatively pure ice covered by 20 cm of regolith.

There had been suggestions that the radar-bright deposits were a material other than water ice, such as sulfur, which would be more stable at the temperatures expected within Mercury's craters. However, recent measurements by the neutron spectrometer on the MESSENGER spacecraft show decreases in the flux of epithermal and fast neutrons that are consistent with the presence of water ice. The radar-bright deposits also have an infrared reflectance consistent with water ice and persist in areas where water ice is predicted to be stable at the surface. In regions where water ice is predicted to be stable only in the near subsurface, the infrared reflectance is lower, possibly indicative of a sublimation lag deposit.

4.1.2. Rayed Craters

In general, the radar reflectivities of the equatorial and midlatitude regions of Mercury are similar to those measured for the Moon. These low reflectivities suggest that the surface of Mercury, like that of the Moon, is covered in a loose regolith. However, unique to Mercury is the presence of several large features with enhanced "same-sense" (SC) backscatter. Large returns in SC radar are indicative of rough surfaces with wavelength-scale scatterers, and high-resolution radar imaging identified these features as fresh impact craters, some with extensive ray systems (Figure 53.16(b)).

These images provided our first look at the craters on the non-Mariner-imaged hemisphere of Mercury. Four craters identified there—originally dubbed "Radar A", "Radar B", "Radar C", and the "ghost feature"—have recently been observed by the MESSENGER spacecraft, and renamed Debussy, Hokusai, Xiao Zhao, and Amaral, respectively. Many of these craters have prominent ray systems, made up of a dense collection of narrow rays not typical of the Moon. On the Moon, radar rays tend to be more sparsely distributed, and extend to longer distances, if they are observed at all. The difference in radar ray appearance on the Moon and Mercury is not well understood, but could be related to differences in gravity, impact velocities, and/or crater maturation rates.

Optical rays are also prominent features on Mercury, but only a small fraction of these have corresponding radar rays. This suggests that crater maturation advances more quickly for radar brightness than for optical brightness. Given that craters on Mercury are observed to weather more quickly at optical wavelengths compared to the Moon, it seems likely that the radar-rayed craters on Mercury are very young.

4.2. Venus

Thick cloud cover has made radar the primary means of studying the surface of Venus (see Venus: Surface and Interior; Venus: Atmosphere; Solar System Dynamics: Rotation of the Planets). In the early 1960s, observations by the Goldstone Tracking Station were used to identify regions of anomalous reflectivity, and the rotation rate was computed for the first time. In the 1970s, delay-Doppler imaging from the Earth and the Pioneer Venus orbiter provided radar maps of portions of the surface at kilometer-scale resolution. Unfortunately, the same side of Venus always faces the Earth during inferior conjunction due to a resonance, so ground-based imaging is limited to one side of the planet. The highest resolution and most comprehensive imaging of Venus was completed in the early 1990s with the Magellan spacecraft. Magellan was not capable of polarimetry and used a horizontal linear polarization for transmitting and receiving, although the spacecraft was rotated for a few orbit tracks to produce vertical polarization image strips. Ground-based radar observations continue to provide new data (at $\sim$3–15 km resolution), including polarimetric mapping and long time baseline imaging to search for possible surface changes.

4.2.1. Magellan Reveals the Surface

The Magellan mission produced a new, high-resolution map of surface features that had been identified in prior data sets but were still enigmatic. It also produced complementary topography and emissivity data. One notable mystery is the provenance of the high-reflectivity, low-radiothermal emissivity material on Venus mountaintops (Figure 53.17(a)). At altitudes above 3 km near the equator (e.g. Beta Regio) and above 5 km at the poles (e.g. Maxwell Montes), the Fresnel reflectivity increases and the emissivity drops from a plains average 0.85 to values as low as 0.3. At the highest altitudes on Maxwell Montes, the emissivity shifts back to normal values. The sharp onset of this reflectivity change with altitude suggests that a temperature- or pressure-dependent process is responsible for the changes. **Bistatic** observations of Maxwell using Magellan and the Deep Space Network yielded dielectric constant values with a large imaginary component suggestive of an electrically conducting or semiconducting surface coating. It is still not certain what material condenses at the surface, but possibilities include minerals with lead or bismuth, or ferroelectrics, magnetite, or metal halides.

Magellan also provided an improved view of the 900 or so Venusian impact craters. The Venus atmosphere does not allow small impactors to reach the surface, so there are few

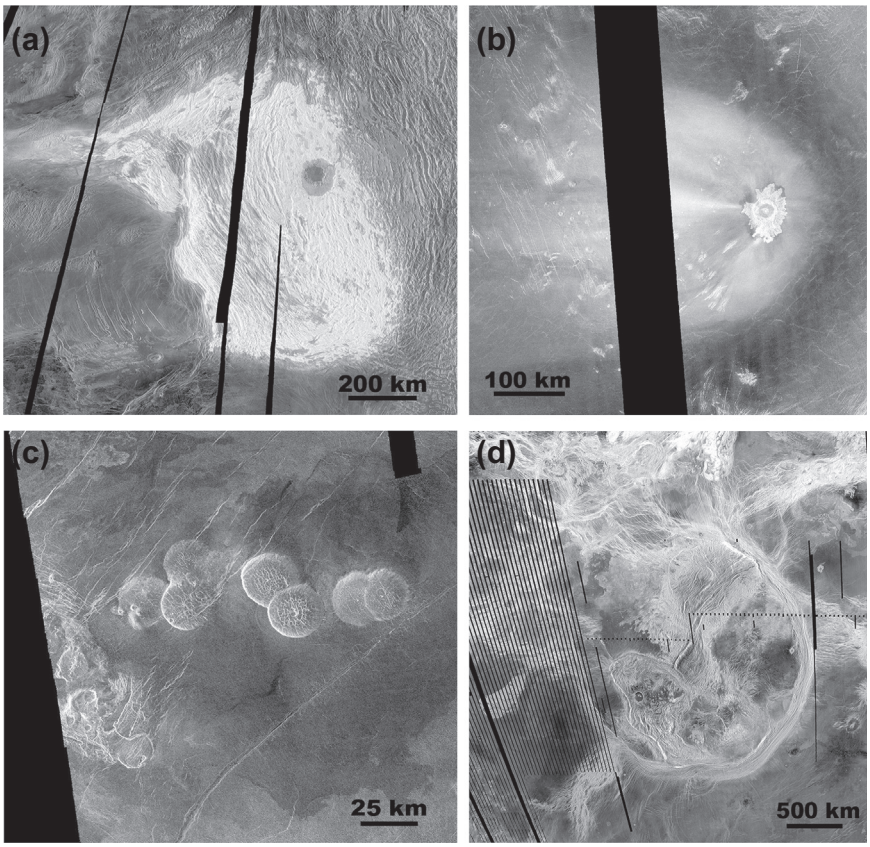

FIGURE 53.17 (a) Maxwell Montes is the highest mountain on Venus (11 km) and displays the unusual high-reflectivity, low-emissivity behavior common at high altitudes on Venus. (b) Adivar crater has a radar bright-parabola created when winds transported impact debris lofted during the impact explosion. (c) Pancake domes east of Alpha Regio are ~25 km in diameter and ~750 m high. (d) Artemis Corona is the largest of the coronae, with a diameter of 2100 km. The circular ring fractures encompass a trough with up to 2.5 km of relief, and the interior has numerous fractures, lava flows, and volcanoes.

small-diameter (<5 km) craters. Many craters have long impact melt flows, and some craters have dark haloes or parabola-shaped features that are likely generated as impact ejecta is deposited near the crater or blown by the wind (Figure 53.17(b)). The small number of craters relative to the Moon and Mars, and their statistically even distribution across the planet, suggests that the surface is young (~500 My).

Dune fields, wind streaks, and **yardang** features are all present in Magellan images, indicating that there is fine-grained material on the surface that is transported by the wind. The radar images also revealed a wide range of volcanic features, from groups of small shield volcanoes on the plains to large lava flow complexes associated with major volcanoes such as Beta Regio, Sif and Gula Mons, and Atla Regio (see Planetary Volcanism). Some volcanic features are unique to Venus, such as the flat-topped pancake volcanoes (Figure 53.17(c)) and the ring-shaped 60 to 2100 km-wide coronae (Figure 53.17(d)). The former are thought to have formed from viscous lavas (having either a high silica content or cooler temperatures), while the latter have a complex relationship between tectonic annuli, lava flows, and interior topography that suggest they are formed by mantle plumes.

4.2.2. Post-Magellan Radar Imaging and the Search for Surface Changes

Magellan provided nearly full-coverage imaging of Venus, but it lacked polarimetry information that could provide more details about the nature of the surface. Comparisons of 1988 Arecibo data with Magellan and terrestrial analog terrains showed that most volcanic flows on Venus have CPR values less than 0.3, similar to terrestrial pahoehoe flows or smoother a'a flows. Imaging of Venus between 1999 and 2012 provided improved signal-to-noise polarimetry due to enhancements to the Arecibo radar system. Fine-grained **pyroclastic deposits** are typically radar dark with low CPR values due to their smooth surface and lack of embedded rocks, and polarimetry can be used to search for possible mantling deposits. A few volcanic deposits have DLP and CPR values that are consistent with fine-grained mantling, including flows near Sif Mons (Figure 53.18). Polarimetry has also shown that some craters have mantling deposits that likely represent deposition of material during impacts (Figure 53.13).

Decades of ground-based radar imaging using the radar system at Arecibo have also enabled a search for surface changes. This is particularly important in the light of recent

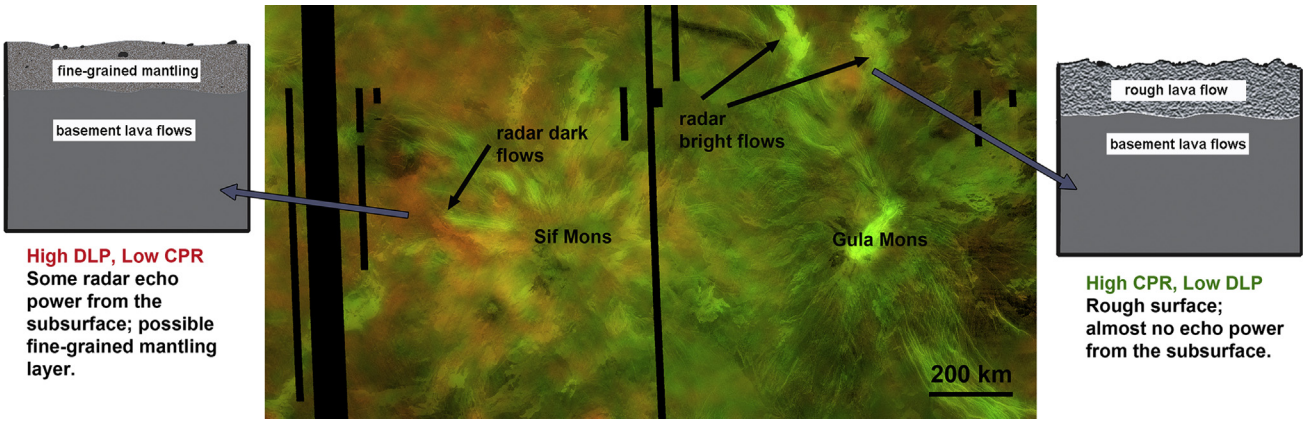

FIGURE 53.18 Polarimetry of Sif and Gula Mons (see also Figure 53.1) illustrate how radar polarimetry can reveal the complexity and variety of different surfaces present in volcanic areas. This image shows the DLP (red) and CPR (green) overlaid on a Magellan radar image. Radar-bright flows have a high CPR values consistent with rough lava flows. Radar-dark flows have higher than average DLP values and low CPRs, which indicates that the radar wave is penetrating into fine-grained material such as **pyroclastics**. *Source: Carter, L. M., Campbell, D. B., & Campbell, B. A. (2011).*

results from the Venus Express infrared instrument that revealed regions near some volcanoes that have a different infrared emissivity compared to surrounding areas. These areas have been interpreted as being less weathered, and hence young (<2.5 Million years), volcanic deposits. If active volcanism occurred in geologically recent times, it could still be ongoing, and if flows of sufficient size were produced, they might be visible in Arecibo images. When comparing radar imaging, it is best to use very similar geometries, and the 1988 and 2012 observing geometries are nearly identical. To date, no temporal changes in radar properties have been found, but studies will continue since the topic of active volcanism is one of the key unanswered questions about Venus.

4.3. Moon

The Moon was the first planetary object to be detected by radar, with the ground-breaking experiment conducted by the US Army Signal Corps in 1946 (see The Moon; Lunar Interior; Exploration of the Moon). It could be argued that it is the most extensively studied object in the solar system (other than the Earth), having been imaged by ground-based radars at a variety of wavelengths and polarizations. Still, given the synchronous rotation of the Moon about the Earth, the far side of the Moon remained unseen at radar wavelengths until SARs were launched in 2008 and 2009 on the Chandrayaan-1 and LRO spacecraft. These spacecraft have allowed for the whole Moon to be imaged at a consistent look angle.

4.3.1. Polar Environment

Like Mercury, the Moon has a reasonably small obliquity (1.5° from the ecliptic), leading to large regions of permanently shadowed areas in depressions near the poles. Given radar's sensitivity to the presence of thick deposits of water ice, and its ability to "see in the dark", it is uniquely qualified to assess the presence of ice in these permanently shadowed regions. Unfortunately, the region of permanent shadow that can be imaged from the Earth is much smaller than the total area of shadow, making the question of polar ice deposits difficult to assess from the Earth. The first attempt to use an orbital spacecraft to search for ice on the Moon was conducted during the Clementine mission. The spacecraft transmitted a 13.2-cm signal from its high-gain antenna toward the lunar south pole, and received the signal on the Earth at **bistatic** angles ranging between 0° and 5°. Targets that exhibit the coherent backscatter opposition effect, such as water ice, will have an opposition surge at $\beta = 0°$, with the signal decreasing sharply at angles greater than $\sim 1°$. A return of this nature was reported over Shackleton crater, but the inference of ice was not supported by other workers in their interpretation of subsequent, higher resolution polarimetric imaging of shadowed crater floors.

The launch of the Mini-SAR instrument on Chandrayaan-1 in 2008 and Mini-RF on LRO in 2009 allowed for high-resolution, monostatic imaging of the lunar poles. Of the permanently shadowed regions identified there, some do appear to have enhanced CPRs (Figure 53.19), but many others do not. Complicating matters, the presence of high CPRs can be explained through other mechanisms, such as **dihedral scattering**, that do not require the presence of water ice. New **bistatic** observations by the Mini-RF instrument on LRO should help to discriminate between high CPRs caused by ice and those caused by rough surfaces. Note that these tests will only be effective if the ice is present as a thick deposit (tens of wavelengths) of nearly pure water ice. If water is present

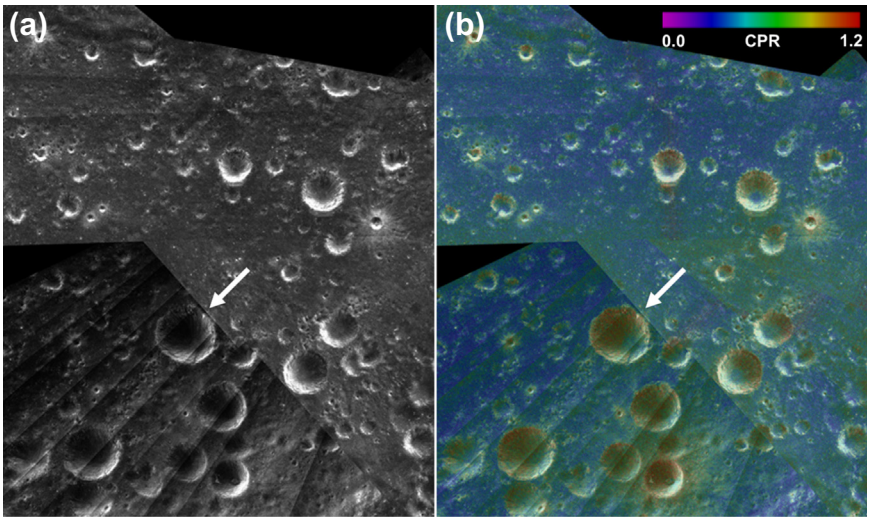

FIGURE 53.19 Several small craters within Peary crater, near the lunar north pole, have high CPRs within their crater rims, but lack the bright ejecta blankets associated with young, fresh craters. This is consistent either with the presence of ice, or rough, blocky crater walls. Shown here is (a) total radar backscatter as observed by Mini-RF on LRO and (b) CPR overlaid on total radar backscatter, scaled from 0 (purple) to 1.2 (red).

in the form of small grains of ice mixed into the regolith, it will be difficult to distinguish from a rocky surface, since the change in dielectric constant caused by the presence of a small concentration of water ice would not produce large scattering differences.

4.3.2. Lunar Geology

Radar has also been an extremely useful tool for studying the geology of the lunar surface. Nearly complete radar maps of the lunar nearside exist for 3.8 cm, 12.6 cm, 70 cm, and 7.5 m wavelengths (in addition, the Mini-RF instrument on LRO has imaged 70% of the lunar far side at 12.6 cm). The radar scattering behavior for the Moon mimics the **dichotomy** between the maria and highlands. The highlands have higher radar backscatter, likely due to a lower loss tangent in the regolith, which allows for more scattering from subsurface rocks. This difference is most pronounced at longer wavelengths, which have larger penetration depths. The dominant control on the microwave loss tangent of the regolith appears to be related to the mineral ilmenite, which contains most of the titanium in **mare** basalts.

Radar is also a particularly powerful tool for studying impact craters on the Moon. Radar exposes rough ejecta blankets, impact melts, and secondary craters not easily seen by optical instruments alone. In particular, radar can be used to date lunar craters. The blocky ejecta around young, fresh craters will break down over time, reducing their roughness and hence their radar backscatter. This decline in radar backscatter is most pronounced for smaller wavelengths, since smaller ejecta blocks will be removed from the population most quickly. The oldest craters will show little to no radar enhancement, as the crater approaches the same stable regolith as the surroundings. Radar is also proving to be extremely useful for identifying and characterizing impact melt deposits around lunar craters. These features appear to be some of the roughest materials on the Moon and can be identified even if partially buried by regolith (Figure 53.20).

4.4. Mars

The ubiquitous dust cover on Mars makes it a prime target for radar instruments that can see below these mantling layers and reveal buried terrain (see Mars: Surface and Interior; Mars Interior). However, Mars is a difficult target for ground-based radar systems because the planet rotates rapidly, which causes echoes that are overspread in frequency and leads to **aliasing** when images are formed. Early radar experiments used continuous-wave observations to generate **power spectra** at different longitudes, or used **radio interferometric synthesis** imaging with a radar transmitter to avoid the radar imaging issues. In 1990, a long code technique was developed at Arecibo Observatory that avoids the overspreading problem, and the first radar images were generated at 12.6 cm wavelength. More recently, two sounding radars, MARSIS (operational in 2005) and SHARAD (operational in 2006) have provided unprecedented information about the subsurface of Mars.

4.4.1. Radar Heterogeneity

Radar imaging from ground-based telescopes has shown that the upper surface of Mars has variable textures and dielectric properties. The most obvious radar feature, first detected in the 3.5-cm-wavelength synthesis imaging data, is an extremely low-reflectivity region near the equator that was dubbed “Stealth”. Its anomalously low reflectivity is indicative of a low-density, low-permittivity surface with few embedded wavelength-sized rocks. Much of the Stealth region corresponds to mapped exposures of the Medusae

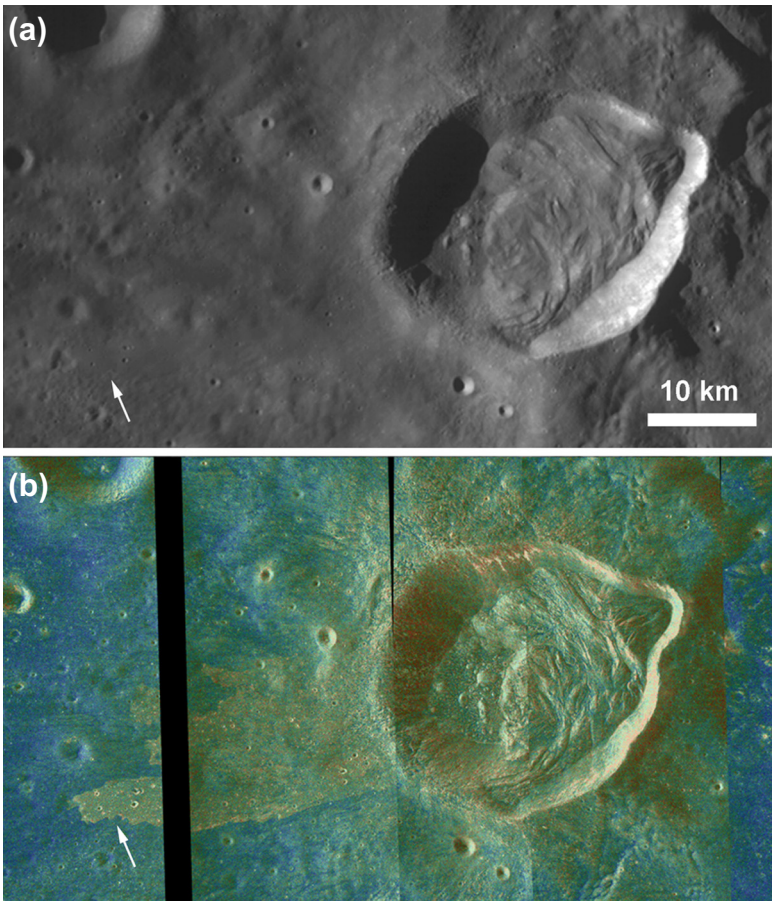

FIGURE 53.20 Image of the crater Gerasimovich D, located on the far side of the Moon, as seen (a) at optical wavelengths by the LRO wide-angle camera, and (b) at radar wavelengths by Mini-RF on LRO. Due to its sensitivity to rough surfaces, radar is able to highlight a previously unrecognized impact melt flow (indicated by an arrow).

Fossae Formation, an extensive equatorial deposit stretching from 140 to 240° E longitude. Optical images show that this deposit has numerous **yardangs**, slope streaks, and dunes and has been heavily wind eroded, consistent with a very fine-grained low-density material. The most likely origin for this formation is **pyroclastic volcanic deposits**, but other hypotheses include **aeolian deposits** or relic polar deposits that may contain ice.

Radar observations of Mars using Arecibo Observatory at S-band (12.6 cm) during the 2005–2012 oppositions produced 3-km-resolution dual-polarization images (Figure 53.21). Radar-bright lava flows surround the Tharsis volcanoes, Olympus Mons, and Elysium Mons. The flows have CPR values approaching and exceeding 1.0, indicating that rough, blocky (at the centimeter to meter scale) lava flows must be common on Mars. Changes in radar backscatter along the flows reveal channels and changes in flow texture. Radar-dark fan-shaped deposits are visible west of the Tharsis volcanoes and correspond to deposits thought to have a glacial origin. The low reflectivity suggests that these deposits have a uniform covering of fine-grained material such as dust or ash with few embedded centimeter-sized or larger rocks. The Marte Vallis channel, which is thought to be a water-carved channel subsequently filled with lava, is very radar bright and links the Cerberus plains with Amazonis Planitia. Both these plains regions, which are dust covered in optical imagery, have detailed lava flow features in the radar imagery.

4.4.2. Subsurface Structure

Sounding radar observations from the MARSIS and SHARAD radars have dramatically improved our understanding of the Martian subsurface, particularly for the polar ice deposits. MARSIS has a longer wavelength (~60 m vs. 15 m) and can therefore detect deeper interfaces, but SHARAD has higher time resolution and can detect surface layering in the upper hundreds of meters. Both MARSIS and SHARAD penetrate through the north polar layered deposits of Mars and reveal remarkable internal stratigraphy (Figure 53.22). The north pole has four packets of finely layered reflectors that are continuous throughout the polar layered deposits separated by featureless intervals that likely indicate changes in Martian climate. The maximum deflection of the subsurface due to ice loading at the north pole is no more than 100 m, which means that either Mars has a lithosphere greater than 300 km thick or the response to the ice loading is currently in a transient state.

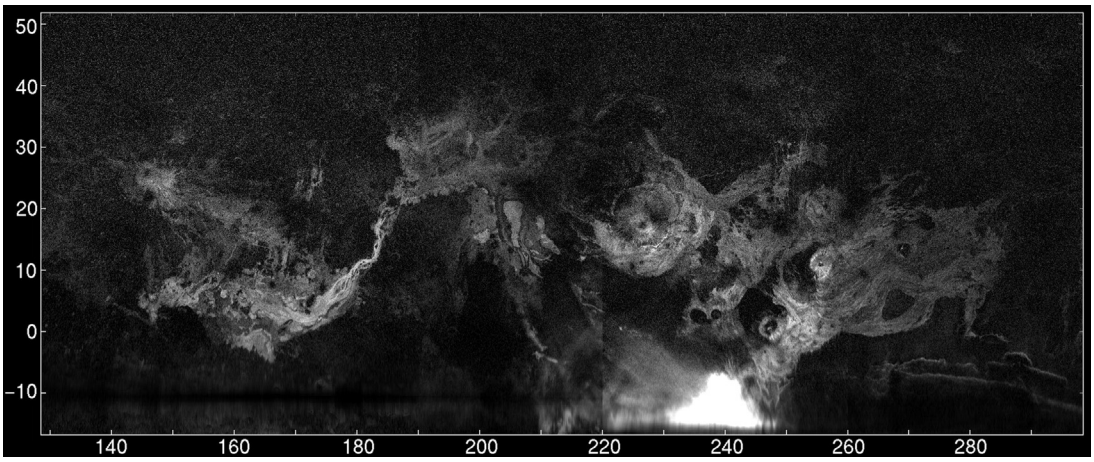

FIGURE 53.21 Radar image of Mars at S-band (12.6 cm wavelength) acquired using Arecibo Observatory during the 2005–2012 oppositions. The radar-bright lava flows associated with (left to right) Elysium, Olympus, and the Tharsis Montes are clearly visible, as are radar-dark fan-shaped deposits west of the Tharsis volcanoes and the equatorial "Stealth" areas south and west of Olympus Mons. Marte Vallis is a very bright sinuous feature near 180° E. *Figure from Harmon, J. K., et al., (2012).*

At the south pole, MARSIS penetrates to the base of the polar layered deposits but SHARAD usually does not. However, SHARAD data show reflection-free zones with no internal layering in the upper part of some radargrams that have dielectric properties and a surface morphology consistent with CO_2 ice. These unusual areas cover a large portion of the south polar layered deposits and have been interpreted as an extensive reservoir of CO_2 capable of increasing the atmospheric mass by 80% if released. As more data is collected, a complete view of layering in both poles is steadily building up and full 3D modeling of the internal structure will be possible in at least some locations. In addition to polar ice deposits, SHARAD has detected subsurface interfaces beneath many of the midlatitude lobate debris aprons, thought to be relic debris-covered glaciers, and confirmed that these deposits have dielectric properties consistent with ice.

SHARAD and MARSIS have also produced interesting results in volcanic and plains regions. Both radars see through exposures of the Medusae Fossae Formation. The permittivity measured from both radars is ~3, and the MARSIS-derived loss tangent is 0.005, which are values consistent with either low-density volcanic ash or ice. Neither radar instrument detects interfaces within the outcrops, despite evidence of layering in optical imagery. SHARAD penetrates through tens-of-meters-thick lava

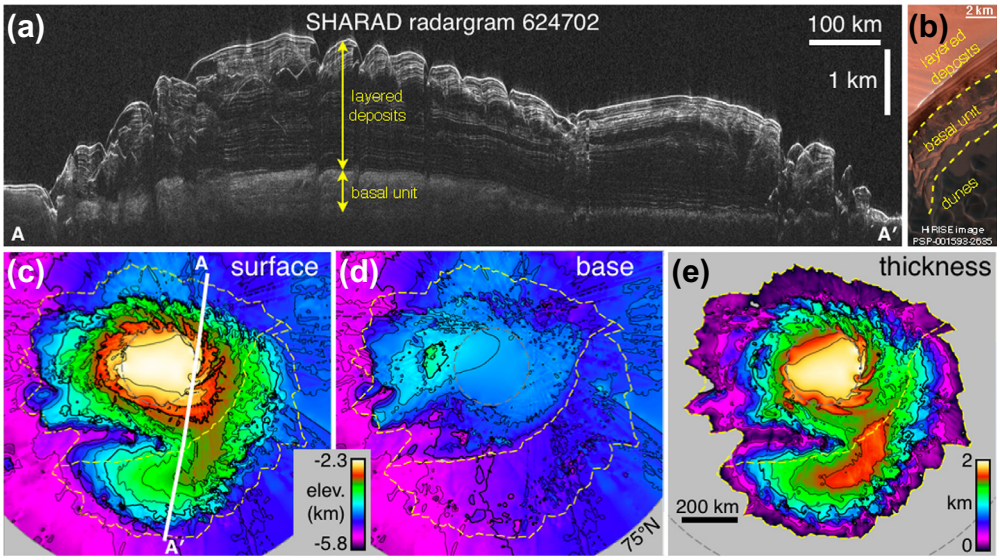

FIGURE 53.22 SHARAD radar view of the Mars North Polar Layered Deposits. (a) SHARAD radargram, showing detailed internal layering. (b) Optical image showing the layered deposits on the basal unit layer. (c) Surface topography with the SHARAD orbital track indicated. (d) The base of the polar layered deposits as measured from SHARAD data. (e) The thickness of the deposits measured from topography and radar data. *NASA/JPL-Caltech/University of Rome/Southwest Research Institute/University of Arizona.*

flows, and flows northwest of Ascraeus Mons have permittivities and loss tangents that are consistent with low-iron and low-titanium lunar and terrestrial basalts. In Amazonis Planitia, a set of dipping kilometers-long subsurface interfaces have loss tangent values consistent with sedimentary packages and were interpreted as the base of the Vastitas Borealis Formation. In Elysium Planitia, SHARAD detects the buried surface of the original water-carved channels of Marte Valles and mapping of the channels suggests that Cerberus Fossae was the source of the Marte Vallis flows.

4.5. Asteroids

Radar is a powerful tool for post-discovery physical and dynamical characterization of NEAs (see Near-Earth Objects; Main Belt Asteroids). Radar provides high-resolution imagery of these asteroids, which can be inverted to yield shape models, allows for long-term orbit refinement, and is well suited to detect the presence of satellites.

4.5.1. Imaging and Shape Reconstruction

Delay-Doppler imaging of asteroids has provided views of these small worlds at resolutions as fine as 4 m. These images provide direct size estimates and apparent rotation rates, as well as information about the asteroid's surface properties, such as the topographic relief, metal concentration, and surface roughness. Surface roughness can be characterized by the CPR of an object, and CPRs for NEAs span the range from near zero (very smooth) to more than unity (very rough). A recent survey of 214 NEAs revealed a correlation between CPR and the visual-infrared spectral class, which is determined by mineralogy (Figure 53.23). This correlation could be a reflection of the intrinsic mechanical properties of the asteroids and the response of different mineral assemblages to impact bombardment, or it may reflect differing formation ages and collisional histories. The highest ratios, and hence the roughest objects, are associated with groups connected to igneous rocky meteorites, such as the V-class, derived from MBA 4 Vesta.

Radar images of asteroids also allow for accurate shape determination. Given the north–south ambiguity present in delay-Doppler images, it is not possible to determine shape from one image along. However, if the radar is not in the target's equatorial plane, then as the object rotates, it will provide unique views of the asteroid in delay-Doppler space. A set of images like this can be inverted to reconstruct the target's 3D shape and spin state. For example, radar observations of (4179) Toutatis in 1992 and 1996 provided high-resolution delay-Doppler images that were used to produce the shape model shown in Figure 53.24. The resulting shape suggests that Toutatis might consist of two separate objects joined in a gentle collision.

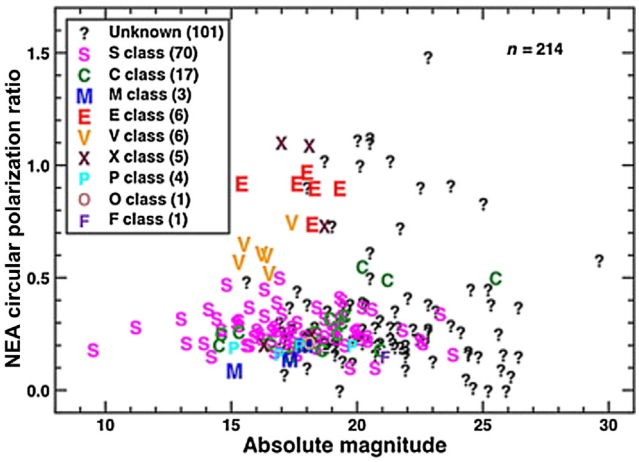

FIGURE 53.23 The CPR of NEAs is correlated with their spectral class. E-, V-, and X-class asteroids have larger CPRs than the more common S-class asteroids, suggesting differences in their mechanical properties or collisional histories. *Figure from Benner, L., et al. (2008).*

These images also allowed for a determination of the asteroid's spin state. It was found to be rotating in a long-axis non–principal axis spin state, with periods of 5.4 days (long-axis rotation) and 7.4 days (long-axis precession).

Radar imaging also provided the first undeniable evidence for NEA binary systems, and has since discovered 26 binary and two trinary systems, representing two-thirds of all known NEAs with companions (see, for example, Figure 53.25). These observations are particularly important, because they provide a constraint on the density of the asteroids, one of the few methods for determining this value. Given the orbital period, T, and semimajor axis, a, of the secondary, it is possible to determine the total mass of the system from Kepler's third law:

$$T^2 = a^3\left(\frac{4\pi^2}{G(M_1 + M_2)}\right)$$

Then, if one assumes that both asteroids have the same density and are roughly spherical, one can determine the density, ρ, given the radii of the primary and secondary, r_1 and r_2:

$$(M_1 + M_2) = \rho(V_1 + V_2) = \frac{4\pi}{3}\rho\left(r_1^3 + r_2^3\right)$$

The density was determined this way for the binary asteroid (5381) Sekhmet, giving $\rho = 1.98 \pm 0.65$ g/cm^2, consistent with its spectral classification as an S-type asteroid.

4.5.2. Orbit Determination and the Yarkovsky Effect

Radar observations of NEAs can be used to reduce the uncertainty in an asteroid's orbital parameters by many

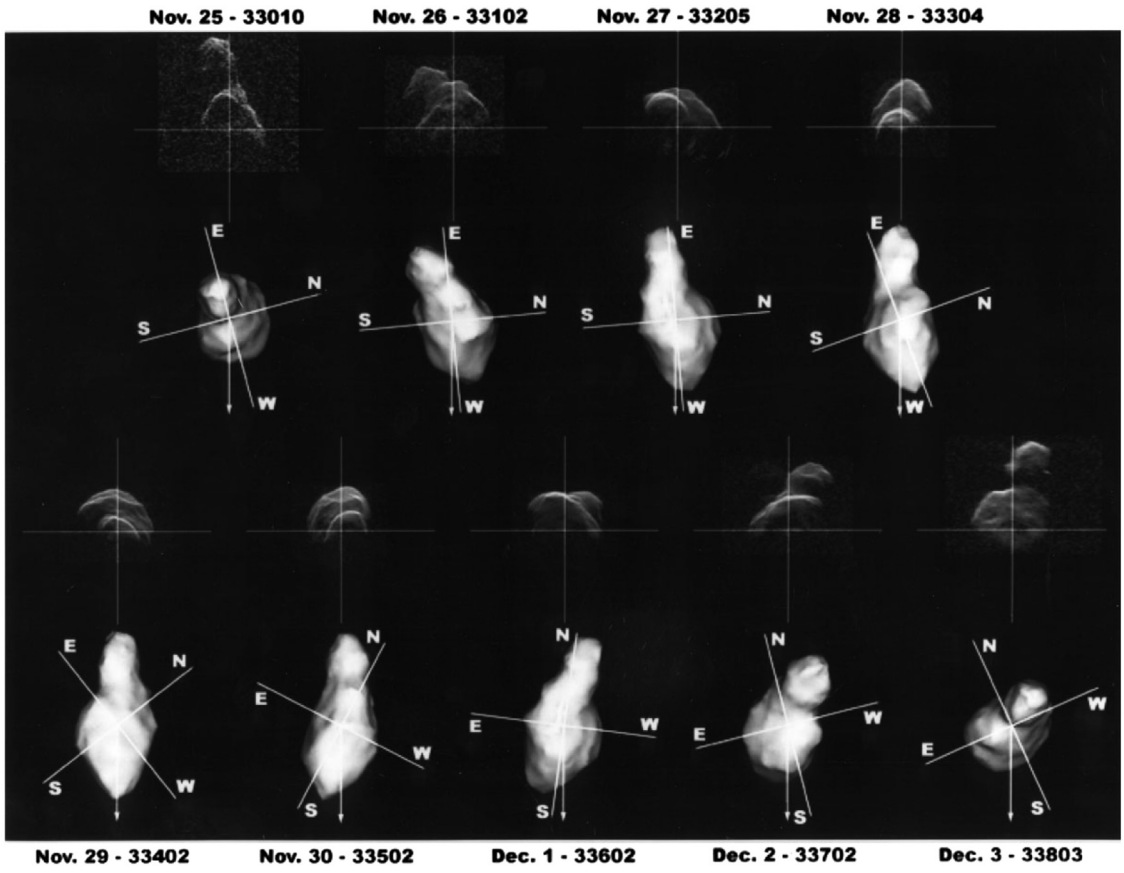

FIGURE 53.24 Delay-Doppler images (3.5 cm) of Toutatis acquired over 9 days in 1996 were used to construct a shape model of that asteroid. The corresponding plane-of-sky appearance is shown beneath the radar image. The illumination direction is from the top for the radar images, and colocated with the viewer for the model images. The arrow indicates the instantaneous spin vector. *Figure from Ostro, S. J., et al. (1999).*

orders of magnitude. The line-of-sight astrometry provided by radar is orthogonal to the plane-of-sight optical astrometry, making the combination a powerful tool for refining orbits. A single radar measurement can often extend the useful lifetime of an orbital solution by ~200 years. This prevents objects from being lost, and allows careful tracking of potentially hazardous close-Earth approaches.

The dominant source of uncertainty in the long-term tracking of asteroids involves the Yarkovsky effect (see Solar System Dynamics; Regular and Chaotic Motion). This is a nongravitational acceleration caused by the anisotropic thermal emission of absorbed sunlight, leading to changes in an object's semimajor axis over time. The magnitude of the Yarkovsky effect is related to an object's mass, size, spin properties, and surface thermal characteristics. This effect can be detected for NEAs up to a few kilometers in size, given precise radar astrometry spanning a decade or more. The first detection came in 2003 for

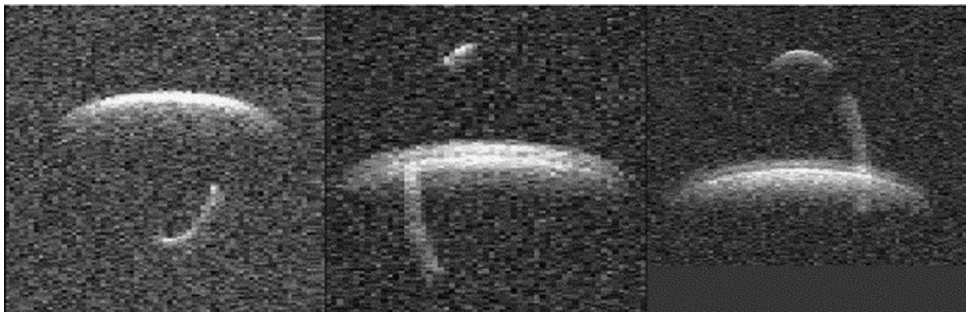

FIGURE 53.25 Hours-long delay-Doppler time exposures of binary asteroid 1999 KW4. Gaps in the secondary orbit are due to breaks in data collection. The primary looks much wider than the secondary because it is a few times larger and rotating much faster. Information about the size of the asteroids and the secondary's orbital parameters can be used to deduce the asteroid's density. *Figure from Chapman, C. R. (2004).*

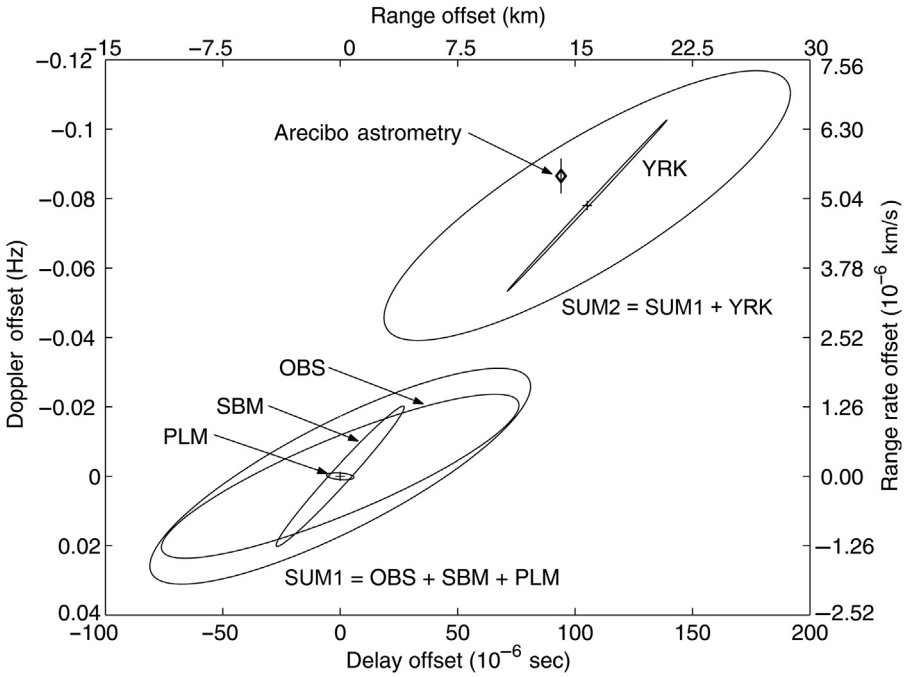

FIGURE 53.26 The observed offset of the asteroid (6489) Golevka's orbit in May 2003 is most consistent with the Yarkovsky effect (YRK), as opposed to uncertainties associated with astrometric measurements (OBS), small body masses (SBM), and planetary masses (PLM). The SUM1 ellipse depicts the 90% confidence region for a non-Yarkovsky prediction, and the SUM2 ellipse depicts the 90% confidence region for the prediction with Yarkovsky accelerations. *Figure from Chesley, S. R., et al. (2003).*

the asteroid (6489) Golevka, using radar observations from 1991 to 2003 (Figure 53.26). This asteroid has a Yarkovsky drift of $(-6.39 \pm 0.44) \times 10^{-4}$ AU/per million years. More recently, semimajor axis drifts were found in 54 NEAs, 42 of which agree with numerical estimates of Yarkovsky drifts. Typical rates are 0.001 AU/per million years for kilometer-sized asteroids. Due to its dependence of asteroid mass and size, the Yarkovsky effect provides one of the few constraints on asteroid density for non-binary objects. For example, the asteroid Golevka has a density of 2.7 (+0.4/−0.6) g/cm^3 for reasonable values of thermal conductivity.

4.6. Jupiter and Saturn Systems

4.6.1. Icy Satellites

The first echoes from Jupiter's moons were received in the mid-1970s. These observations showed that icy satellites backscatter radar waves in an unusual way, unlike that seen on rocky objects (see Planetary Satellites; Europa; Ganymede and Callisto; Titan; Enceladus). Since then, additional ground-based and space-based observations have refined our understanding of the scattering mechanisms that control the radar properties of these icy worlds, as well as their close cousins at Saturn.

As we discussed in Section 4(a), icy satellites generally have high radar reflectivities and CPRs (see Figure 53.15). This indicates that the radar scattering is dominated by subsurface volume scattering, not single scattering from the vacuum−surface interface, as is typical for rocky bodies. This scattering behavior has been modeled as a coherent backscatter effect resulting from scatterers embedded in the weakly absorbing water ice surfaces of these moons. The observation that the radar cross-sections of the Galilean satellites at 3.5 and 12.6 cm are much higher than those observed 70 cm can be reproduced by a model with scatterers that follow a fairly steep power-law distribution and are no larger than 0.5−1 m in size. Efficient scatterers, like voids, are required to reproduce the observations. Partially absorbing scatterers, such as silicate rocks, cannot reproduce the high radar cross-sections observed.

Saturn's icy satellites also appear to be dominated by subsurface volume scattering, although their radar reflectivities are somewhat lower than those of the Galilean satellites at 13 cm. This suggests that the subsurface scattering is operating less efficiently than on the Galilean satellites, most likely due to a difference in composition. A likely candidate is ammonia, since water ice's absorption length is extremely sensitive to ammonia concentration. At 2.2 cm, the radar albedo of the Saturnian satellites is much higher, although average radar albedos decrease as you move outward from Enceladus and Tethys to Iapetus and Phoebe. This is likely a function of increasing contamination of near-surface water ice.

Two interesting case studies are Enceladus and Iapetus. At 13 cm, Enceladus has higher radar albedo on the leading side than the trailing side, yet is uniformly bright at 2.2 cm. This suggests that the regolith on the trailing side is too fresh for meteoroid bombardment to have developed the

large-scale heterogeneities needed to elevate the 13-cm radar albedo, but all of Enceladus is mature enough at small scales to enhance the 2-cm albedo. Iapetus also has a hemispheric asymmetry, but only in the 2-cm data, mimicking the albedo asymmetry that is so obvious at optical wavelengths. The fact that the 13-cm data shows no asymmetry suggests that the leading side's optical contaminant is present to a depth of at least a decimeter, but no further.

4.6.2. Titan

Prior to the Cassini mission, the surface geology of Titan was unknown (see Titan). The Voyager imagers, operating only in the visible, were barely able to penetrate the haze layer than shrouds this world, while near-infrared observations from the Earth had too low a spatial resolution (>50 km) to permit geological interpretation. It was not until 2004 that Cassini began collecting the first high-resolution images of Titan's surface, using SAR at 2.2 cm. The images obtained from these encounters (along with images from the Huygens probe in 2005) provided the first look at the surface of this hazy moon. Through these observations, Titan has been revealed to be an active world, surprisingly Earth-like in appearance. Large dune fields extend around the equatorial region, stream channels carve the landscape, and the poles are covered in lakes of liquid hydrocarbons.

Observations by Cassini RADAR, along with complementary observations by the Visual and Infrared Mapping Spectrometer (VIMS) and Imaging Science Subsystem (ISS), have revealed that the main processes occurring on Titan are aeolian and fluvial modification, tectonics, cryovolcanism, and impact cratering (Figure 53.27). Dunes are one of the most ubiquitous features on Titan, and indeed, the fraction of Titan's surface covered by dunes is larger than on any terrestrial planet. Given its high resolution (∼350 m), data from Cassini RADAR has been used to map thousands of dunes on Titan (Figure 53.27(b)). The dunes mostly lie in the equatorial regions, between 30°S and 30°N, where there is apparently the requisite dry, transportable sediment and winds to move the material. The dunes are principally linear, and their direction indicates that sand transport operates from west to east, suggesting a modestly changing wind regime, with winds that are predominantly westerly. Unlike silicate sand on the Earth, these dunes appear to be composed of sand-sized organic particles, likely sintered from Titan's abundant haze material.

Fluvial features are also common on Titan, and appear remarkably similar to the lakes and streams seen on the Earth. The lakes are concentrated exclusively near the

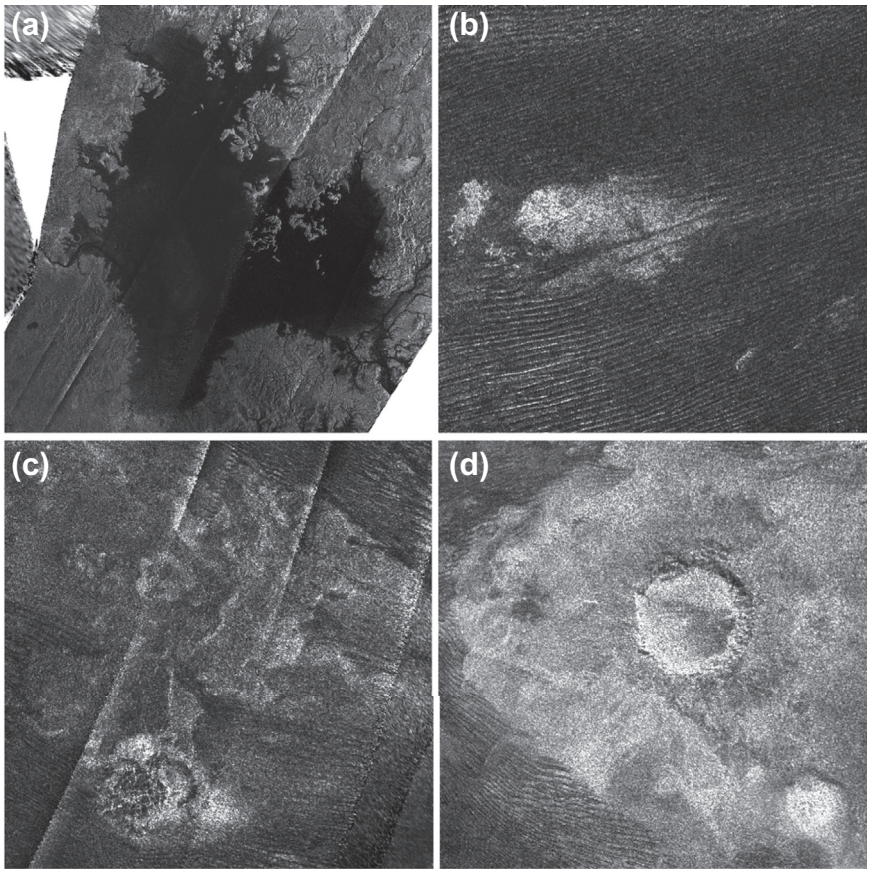

FIGURE 53.27 Cassini RADAR has revealed Titan to be an intriguingly Earth-like world. (a) Lakes of liquid hydrocarbons are common near Titan's north and south poles, including Ligeia Mare, which is larger than Lake Superior on the Earth. Titan's lakes appear dark to radar because they are smooth at radar wavelengths; as of yet, no waves have been detected on Titan. (b) Long, linear dunes of sand-sized organic material extend around Titan's equator and dominate the region between 30° S and 30° N. Specular reflections of dune slip faces are seen at lower left. (c) Sotra Facula is the best candidate for a cryovolcano on Titan. Here, flowlike features extend to the northeast of two peaks more than 1000 m tall and multiple pits as deep as 1500 m. (d) Like the Earth, Titan has a dearth of recognizable impact craters. Sinlap (∼80 km in diameter) is one of only ∼60 craters discovered thus far. The lack of impact craters indicates that Titan's surface is relatively young.

poles, and appear to be composed of a mixture of ethane and methane. Although first observed at near-infrared wavelengths at the south pole, RADAR was able to provide strong supporting evidence for the lake interpretation. The radar return for these features is at the noise floor of the data, consistent with an extremely smooth surface at 2.2 cm (Figure 53.27(a)). RADAR also made the first discovery of lakes at the north pole of Titan, which were in darkness during the first part of the Cassini mission, when Titan was in northern winter. Ground-based radar has also found intriguing evidence for specular reflections near the equator, indicating large surfaces smooth at a wavelength of 12.6 cm. No obvious lakes have been observed here, so these observations may be suggestive of smooth surfaces saturated in liquid hydrocarbons. Streams and valley networks have been observed at all latitudes, from the equator to the poles. Remarkably, the conditions required for sediment transport by liquid methane on Titan are within a factor of a few of those required for transport by liquid water flow on Mars and the Earth, resulting in remarkably similar features given the different surface conditions. Some channels are radar bright, suggesting that they are filled with rough boulders, while others are radar dark and thought to contain either liquid or deposits of smooth sediments.

In addition to the exogenic processes discussed above, there is some evidence for internal geologic activity occurring on Titan. Tectonic terrain has been observed by RADAR in the form of linear chains of radar-bright mountains. The heights of these mountains (as determined from radarclinometry) range from $<$300 to 2000 m, with slopes approaching 45° in some cases. Radar evidence of cryovolcanism is controversial, but if it is present, discrete cryovolcanoes are not ubiquitous. The best candidate cryovolcano yet observed is Sotra Facula (Figure 53.27(c)). Stereo topography from overlapping RADAR swaths revealed this feature to be a mountain more than 1000 m tall with multiple pits as deep as 1500 m, with flows perhaps 100 m thick extending away from the complex. Note that effusive volcanism, if present on Titan, is likely to consist of liquid ammonia−water lavas.

Unlike most worlds in the solar system, Titan has a relatively small number of confirmed impact craters, indicating that most parts of its surface are relatively young. Many craters on Titan show evidence of erosion, suggesting that (as on Earth) there are processes at work that can modify and erase craters (Figure 53.27(d)). A recent survey of the depths of Titan's craters show that they are on an average several hundred meters shallower than comparably sized craters on Ganymede, supporting this idea. Of the regions on Titan viewed by RADAR, the polar regions appear to have the lowest concentration of impact craters, and the bright equatorial region Xanadu appears to have the high concentration of impact craters, suggesting that it is a remnant of an older surface.

5. THE FUTURE OF PLANETARY RADAR

Many worlds have already been surveyed with radar, but many more remain unexplored. Even those worlds that have been observed at radar wavelengths would benefit from higher resolution data at new wavelengths with dual- or quad-polarization. Orbital radars could be imagined for any solid surface in the solar system, but the two worlds that would benefit especially from new radar observations are Mars and Europa.

Two sounding radars, SHARAD and MARSIS, are currently investigating the Martian subsurface. However, an imaging radar is one of the few instruments not yet flown on any Mars mission. Currently, our best radar images of Mars come from ground-based observatories and offer relatively poor spatial resolutions (see Section 4.4). Imaging radars are a particularly important instrument for characterizing the Martian surface. Mars has been extensively modified by aeolian processes, so that a widespread layer of dust covers large portions of the planet. Orbital SARs allow for the investigation of landscapes buried beneath this dust layer, revealing features unseen in optical images, which probe only the top surficial layer, or by long wavelength radar sounders, which are dedicated to deep (several hundred meters) sounding with low spatial resolution. Without an imaging radar, geological structures such as fluvial channels, ancient shorelines, lava flows, and icy polygonal terrain still await discovery under Mars' dusty surface. Note that imaging radars have been used on the Earth for similar purposes, demonstrating the ease with which one can study ancient fluvial networks in sand-covered regions (Figure 53.28). In addition, an orbital radar would be sensitive to the presence of ice and water, and could therefore help to constrain Mars' volatile inventory. Liquid water's extremely high dielectric constant would make it particularly easy to spot in radar images. Finally, there is the possibility that the radar could be used interferometrically to track changes in Martian surface, such as that caused by the subsidence or swelling of volcanoes.

Orbital radars for Mars have been proposed by several groups. The key system design parameters include the sensitivity of the radar, its wavelength, and its polarization. A radar with a VV polarization is recommended to minimize transmission losses and maximize penetration depth. A wavelength between 30 and 60 cm (L-band) is also recommended, as it allows for a large penetration depth while also being sensitive to differences in wavelength-scale roughness. For most natural surfaces, the wavelength-scale roughness declines with wavelength.

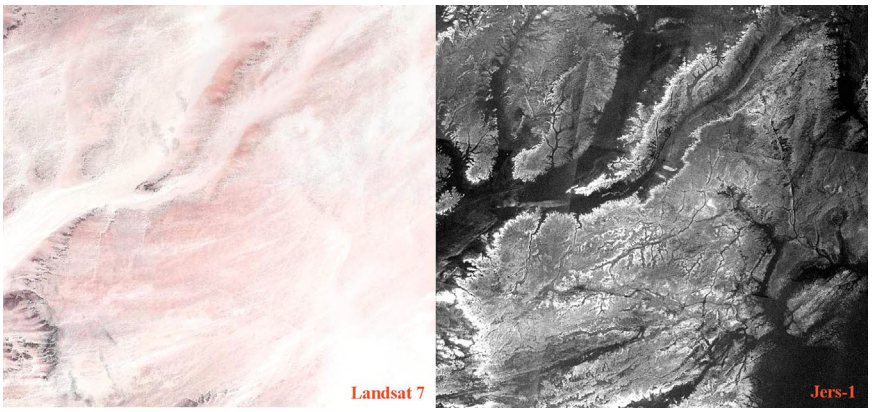

FIGURE 53.28 (left) Optical image and (right) L-band SAR image of northern Sudan, showing an ancient river valley obscured beneath several meters of sand. *Image from Paillou, P., et al. (2006).*

Other workers recommend a slightly longer wavelength—70 cm or P-band—to compensate for the higher iron content on Mars, which may limit penetration depth at shorter wavelengths. Such a radar would be less sensitive to roughness differences in the upper few meters of the subsurface.

Europa is another high-priority target for radar, in this case, an ice-penetrating radar. Europa likely has a saltwater ocean under an ice shell that is several kilometers to several tens of kilometers thick. Since life as we know it depends on a long-lived liquid water environment, this makes Europa a prime candidate in the search for habitable environments in the solar system. Therefore, it is critical to understand the existence and extent of its subsurface ocean, and to determine the presence of any water within the ice shell. Over the past decade, the National Aeronautics and Space Administration has been considering several mission options for exploring Europa. Due to the constrained budget environment, recent studies have focused on reduced-scope options in order to find cost reductions for this mission. One of these proposed missions is a multiple flyby concept, which includes exploring Europa's ice shell for evidence of liquid water within or beneath it. Included in the proposed payload is an ice-penetrating radar. This radar would have two modes: a higher frequency band to study the ice shell above 3 km depth at 10-m vertical resolution (nominally 60 MHz with a 10 MHz bandwidth), and a low-frequency band to search for the ice−ocean interface at a depth of up to 30 km at 100-m vertical resolution (nominally 9 MHz with a 1 MHz bandwidth). Since this radar is heavy, requires significant operating power, and generates large volumes of data, a multiple flyby mission is ideal for this instrument. A multiple flyby mission design allows for high-data-rate science collection followed by days of playback time, and reduces the amount of shielding needed to lower the radiation dose.

In addition to advances in space-based radars, it is expected that ground-based radars will continue to characterize an increasing number of NEAs. Such discoveries will bring with them new scientific information for our understanding of small bodies in the solar system, and may someday protect us from a devastating impact.

ACKNOWLEDGMENTS

The authors would like to dedicate this chapter to Steve Ostro, whose work in radar astronomy provided much of the inspiration and background for this chapter. This work was supported by an appointment to the NASA Postdoctoral Program at the Goddard Space Flight Center, administered by Oak Ridge Associated Universities through a contract with NASA to C.N.

1. INTRODUCTION

Nuclear spectroscopy is used to determine the elemental composition of planetary surfaces and atmospheres. Radiation, including **gamma rays** and **neutrons**, is produced steadily by cosmic ray bombardment of the surfaces and atmospheres of planetary bodies. Gamma rays are also produced by the decay of naturally occurring radioelements. The leakage **flux** of gamma rays and neutrons contains information about the abundance of major elements, selected trace elements, and light elements such as H and C. Gamma rays and neutrons can be measured from high altitudes (less than a planetary radius), enabling global mapping of elemental composition by an orbiting spacecraft. Radiation that escapes into space originates from shallow depths (<1 m within the solid surface of airless bodies and those with thin atmospheres through which galactic cosmic rays can penetrate). Consequently, nuclear spectroscopy is complementary to other surface mapping techniques, such as reflectance spectroscopy, which is used to determine the mineralogy of planetary surfaces.

The main benefit of gamma ray and neutron spectroscopy is the ability to reliably identify elements important to planetary geochemistry and to accurately determine their abundance. This information can be combined with other remote sensing data, including surface thermal inertia and mineralogy, to investigate many aspects of planetary science. This article provides an overview of this burgeoning area of remote sensing. The origin of gamma rays and neutrons, their information content, measurement techniques, and scientific results from the Lunar Prospector and Mars Odyssey missions are highlighted.

Cosmogenic nuclear reactions and radioactive decay result in the emission of gamma rays with discrete energies, which provide a fingerprint that can uniquely identify specific elements present within the surface. Depending on the composition of the surface, the abundance of major rock-forming elements, such as O, Mg, Al, Si, Cl, Ca, Ti, Fe, and radioactive elements, such as K, Th, and U can be determined from measurements of the gamma ray spectrum. The geochemical data provided by nuclear spectroscopy can be used to investigate a wide range of topics including the following:

- Determining bulk composition for comparative studies of planetary geochemistry and the investigation of theories of planetary origins and evolution;
- Constraining planetary structure and differentiation processes by measuring large-scale stratigraphic variations within impact basins that probe the crust and mantle;
- Characterization of regional-scale geological units, such as lunar mare and highlands;

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00054-2
Copyright © 2014 Elsevier Inc. All rights reserved.

- Estimating the global heat balance by measuring the abundance of radioelements such as K, Th, and U;
- Measuring the ratio of the volatile element K to the refractory element Th to determine the depletion of volatile elements in the source material from which planets were accreted and to estimate the volatile inventory of the terrestrial planets.

Neutrons are produced by cosmic ray interactions and are sensitive to the presence of light elements within planetary surfaces and atmospheres, including H, C, and N, which are the major constituents of ices, as well as elements such as Fe, Ti, Gd and Sm, which are strong neutron absorbers. In addition, alpha particles are produced by radioactive decay of heavy elements such as U and Th and have been used to identify radon emissions from the lunar surface, possibly associated with tectonic activity.

Close proximity to the planetary body is needed to measure neutrons and gamma rays because their production rate is relatively low. Unlike optical techniques, distances closer than a few hundred kilometers are needed in order to obtain a strong signal. In addition, sensors that detect neutrons and gamma rays are generally insensitive to their incident direction. Consequently, spatial resolution depends on orbital altitude, and higher resolution can only be achieved by moving closer to the planet. Regional-scale measurements are generally made using nuclear spectroscopy, in contrast to the meter to kilometer scales sensed by optical methods.

Measurements of the solid surface are not possible for planets with thick atmospheres, including the Earth and Venus. Variations in atmospheric composition can be measured and, for example, have important implications to understanding seasonal weather patterns on Mars. Gamma ray and neutron spectroscopy can be applied to investigate the surfaces of planets with little or no atmosphere, such as Mercury, Mars, the Moon, comets, asteroids, and dwarf planets. In principle, the satellites of Jupiter and Saturn could be investigated using nuclear spectroscopy; however, the intense radiation environment within the magnetospheres of these planets may be a limiting factor.

X-ray spectroscopy can also be used to determine elemental composition and is complementary to nuclear spectroscopy. Solar X-rays cause planetary surfaces to fluoresce. The spectrum of fluorescence X-rays can be analyzed to determine the abundance of rock-forming elements such as Fe and Mg. In contrast to nuclear spectroscopy, surface coverage may be limited, especially when solar activity is low; however, high statistical precision for elemental abundances can be achieved during flares. Since the intensity of solar X-rays diminishes with increasing heliocentric distance, the technique is limited to inner solar system bodies. The depth sensitivity of X-ray and nuclear spectroscopy is very different. X-rays are produced close to the surface (typically to depths less than a 100 μm), whereas gamma rays and neutrons sample bulk surface materials to depths of few tens of decimeters. Missions that have used X-ray spectroscopy include Apollo, Near Earth Asteroid Rendezvous (NEAR) (*see* Near-Earth Objects), and Small Missions for Advanced Research in Technology 1 (SMART-1). The MErcury Surface, Space ENvironment, GEochemistry, and Ranging (MESSENGER) mission used both X-ray and nuclear spectrometers to determine the elemental composition of Mercury, and an X-ray spectrometer was on the payload of Chandrayaan-1, the Indian Space Research Organization's first mission to the Moon.

2. ORIGIN OF GAMMA RAYS AND NEUTRONS

Neutrons and gamma rays are produced by the interaction of energetic particles and cosmic rays with planetary surfaces and atmospheres. While solar energetic particle events can produce copious gamma rays and neutrons, we will focus our attention on **galactic cosmic rays**, which are higher in energy, penetrate more deeply into the surface, and have a constant flux over relatively long periods of time. Gamma rays are also produced steadily by the decay of radioactive elements such as K, Th, and U. A diagram of production and transport processes for neutrons and gamma rays is shown in Figure 54.1.

2.1. Galactic Cosmic Rays

Galactic cosmic rays consist primarily of protons with an average flux of about 4 protons/cm^2/s and a wide distribution of energies extending to many gigaelectronvolts (Figure 54.2; inset). The flux and energy distribution of galactic protons reaching a planetary surface is modulated by the solar cycle (*see* The Sun). Sunspot counts are a measure of solar activity (Figure 54.2). Higher fluxes of galactic protons are observed during periods of low solar activity. A larger portion of protons penetrate the heliosphere during solar minimum, resulting in a shift in the population toward lower energies. The flux and energy distribution of the cosmic rays are controlling factors in the production rate, energy distribution, and depth of production of neutrons and gamma rays. For example, the neutron counting rates at McMurdo Station in Antarctica are modulated by the solar cycle as shown in Figure 54.2.

The gigaelectronvolt-scale kinetic energy of galactic protons can be compared to the relatively small binding energy of protons and neutrons in the nucleus (for example, 11.2 MeV is required to separate a neutron from a tightly bound ^{56}Fe nucleus). High-energy interactions with nuclei can be modeled as an intranuclear cascade, in which the energy of the incident particle is transferred to the nucleons, resulting in the emission of secondary particles by spallation, followed by evaporation, and subsequent

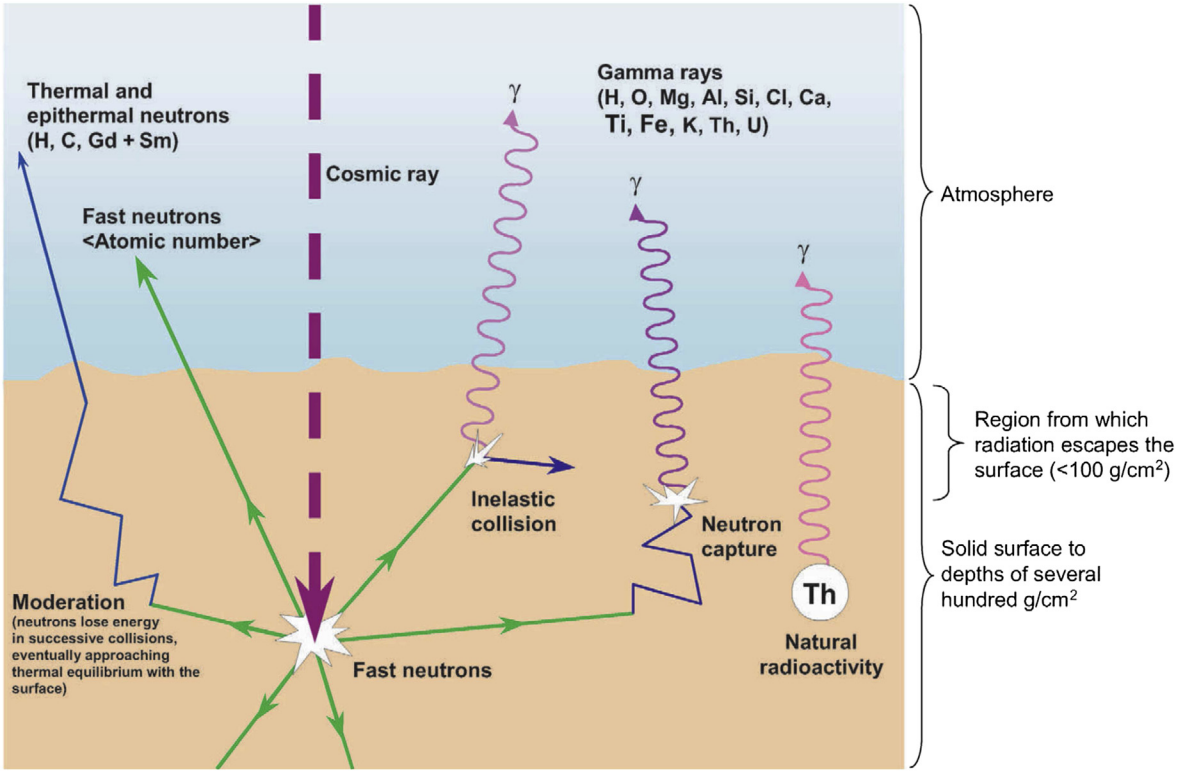

FIGURE 54.1 Overview of the production of gamma rays and neutrons by cosmic ray interactions and radioactive decay. Fast neutrons produced by high-energy cosmic ray interactions undergo inelastic collisions, resulting in the production of characteristic gamma rays that can be measured from orbit. Neutrons lose energy through successive collisions with nuclei and approach thermal equilibrium with the surface. Thermal and epithermal neutrons provide information about the abundance of light elements, such as H and C, and strong thermal neutron absorbers, such as Fe, Ti, Gd and Sm. Fast neutrons are sensitive to the average atomic mass of the surface. Gamma rays produced by neutron capture and inelastic scattering can be used to measure the abundance of rock-forming elements, such as O and Fe. Gamma rays are also produced by the decay of long-lived radioisotopes, including K, Th, and U. While cosmic rays can penetrate deep into the surface, the radiation escaping the surface originates from shallow depths, generally less than 100 g/cm^2.

deexcitation of the residual nuclei. The secondary particles, which include neutrons and protons, undergo additional reactions with nuclei until the initial energy of the cosmic ray is absorbed. Since most of the gamma ray production is caused by reactions with neutrons, we will focus our attention on how neutrons slow down in matter.

2.2. Fundamentals of Neutron Moderation

Neutrons transfer their energy through successive interactions with nuclei and are eventually absorbed within the surface or atmosphere or escape into space. The process of slowing down via repeated collisions is known as "moderation". There are three general interaction categories that are important in the context of planetary science: (1) nonelastic reactions, in which the incident neutron is absorbed, forming a compound nucleus, which decays by emitting one or more neutrons followed by the emission of gamma rays; (2) elastic scattering, a process that can be compared to billiard ball collisions for which kinetic energy is conserved; (3) neutron radiative capture, in which the neutron is absorbed and gamma rays are emitted.

The probability that a neutron will interact can be expressed in terms of the **microscopic cross-section** of the target nucleus, denoted σ, which is an effective, cross-sectional area with units of barns (1 barn $= 10^{-24}$ cm^2). The magnitude of the microscopic cross-section depends on the reaction type, target nucleus, and the energy (E) of the incident neutron. Microscopic cross-sections for natural Fe are shown, for example, in Figure 54.3, for radiative capture, elastic scattering, and inelastic scattering. Inelastic scattering occurs above a threshold determined by the energy required to produce the first excited state of the compound nucleus. The elastic scattering cross-section is constant over a wide range of energies. The cross-section for radiative capture usually varies as $E^{-1/2}$. Consequently, radiative capture is important at low energies. The sharp peaks that appear at high energy (greater than 100 eV) are resonances associated with the nuclear structure of the Fe isotopes. Neutron inelastic scattering is an important energy loss mechanism at high energies (greater than about 0.5 MeV for most isotopes of interest to planetary science).

Under the steady bombardment of cosmic rays, the population of neutrons slowing down in the regolith is, on

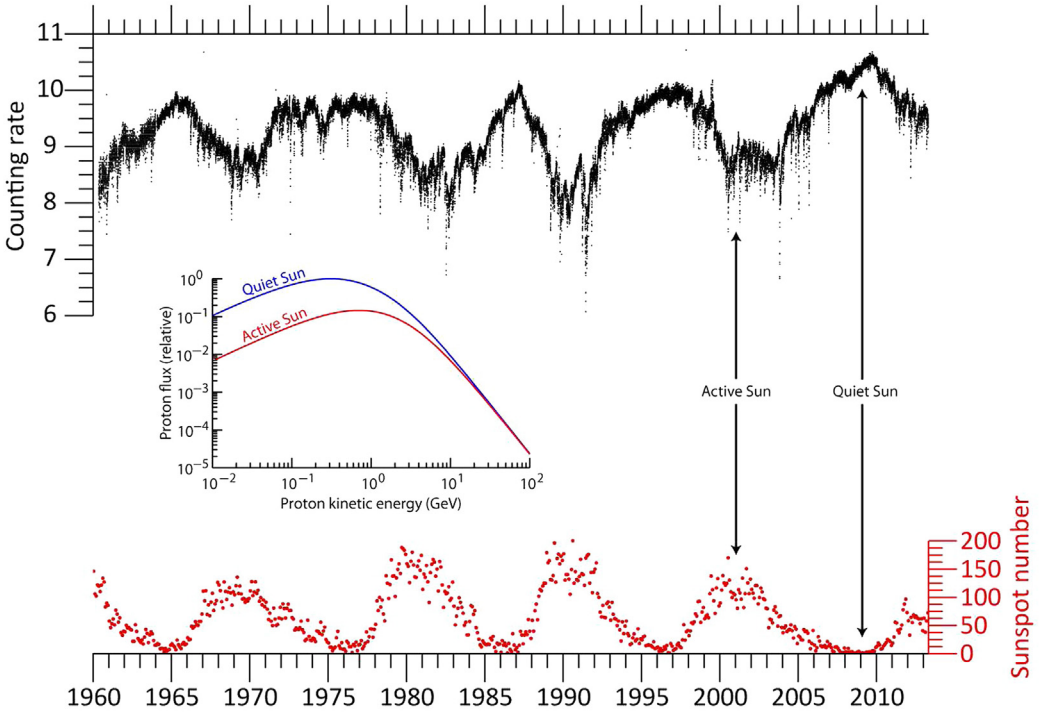

FIGURE 54.2 The variation of neutron counting rates (with units of 10^5 counts per hour) measured at McMurdo Station in Antarctica as a function of time (neutron monitors of the Bartol Research Institute are supported by NSF grant ATM-0000315). Monthly sunspot counts are shown for comparison *(courtesy of SIDC, RWC Belgium, World Data Center for the Sunspot Index, Royal Observatory of Belgium, 1960–2013)*. During periods of low solar activity (low sunspot counts), low-energy galactic cosmic rays penetrate the heliosphere, which results in relatively high neutron production rates. During periods of high solar activity (high sunspot counts), the low-energy galactic cosmic rays are cut off, resulting in lower neutron counting rates. The variation in neutron counting rates is about 20% over the solar cycle. Theoretical galactic proton energy spectra within the heliosphere, representative of quiet and active solar years, are shown (inset).

average, constant with time. The steady state neutron energy, angle, and spatial distributions depend on the composition and structure of the surface and atmosphere. An important property of the neutron population is the scalar flux (φ), which varies with depth beneath the surface and is given by the product of the speed of the neutrons, v (centimeters per second), and the number density of neutrons slowing down in the planetary surface (n neutrons per cubic centimeter); $\varphi = nv$, with units of neutrons per square centimeter per second. The rate at which neutrons interact with nuclei is given by the product of the flux of neutrons, the density of the target nuclei (N nuclei per cubic centimeter), and the microscopic cross-section for the nuclear reaction of interest: $R = \varphi N\sigma$ (interactions per cubic centimeter per second).

Cosmic ray showers can be modeled using Monte Carlo methods, in which the random processes of particle production and transport are simulated. The number of times something interesting happens, such as a particle crossing a surface, is tallied. Statistical averages of these interesting events are used to determine different aspects of the particle population such as fluxes and **currents**. Monte Carlo transport simulations generally provide for the following: a description of the cosmic ray source and the target medium (including geometry, composition, and density of the planetary body); detailed physical models of interaction mechanisms and transport processes (including tabulated data for interaction cross-sections); and a system of tallies.

The general purpose code Monte Carlo N-Particle eXtended (MCNPX) developed by Los Alamos National Laboratory provides a detailed model of cosmic ray showers, including the intranuclear cascade and subsequent interactions of particles within the surface and atmosphere.

For example, a model of the Martian surface used to calculate neutron leakage spectra is shown in Figure 54.4(a). The model includes several layers, representative of the high latitude surface, which is seasonally covered by CO_2 ice due to condensation of atmospheric CO_2 in the polar night, and whose frost-free surface consists of a dry lag deposit covering ice-rich soil. The curvature of Mars was included in the MCNPX calculations along with details of the incident galactic proton energy distribution. The goal was to determine the effect of surface parameters on neutron output, including the **column abundance** (grams per square centimeter) of the layers, their water abundance, and major element composition. The variation of the density of the atmosphere with altitude (the scale height is roughly 11 km) was also modeled.

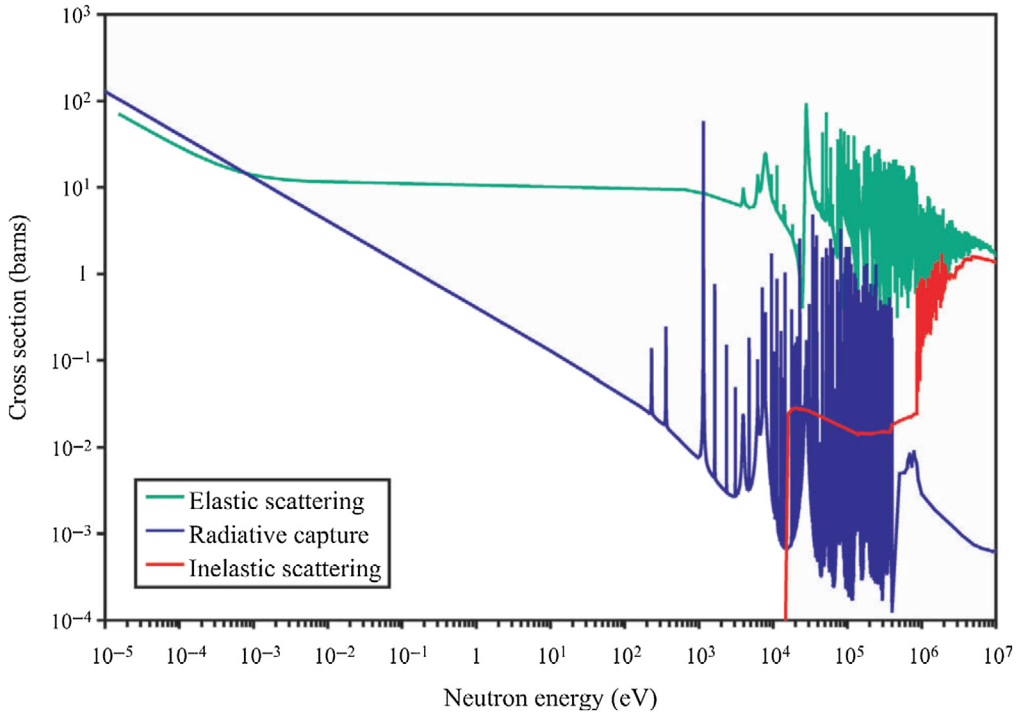

FIGURE 54.3 Neutron **microscopic cross-sections** for natural Fe (see text).

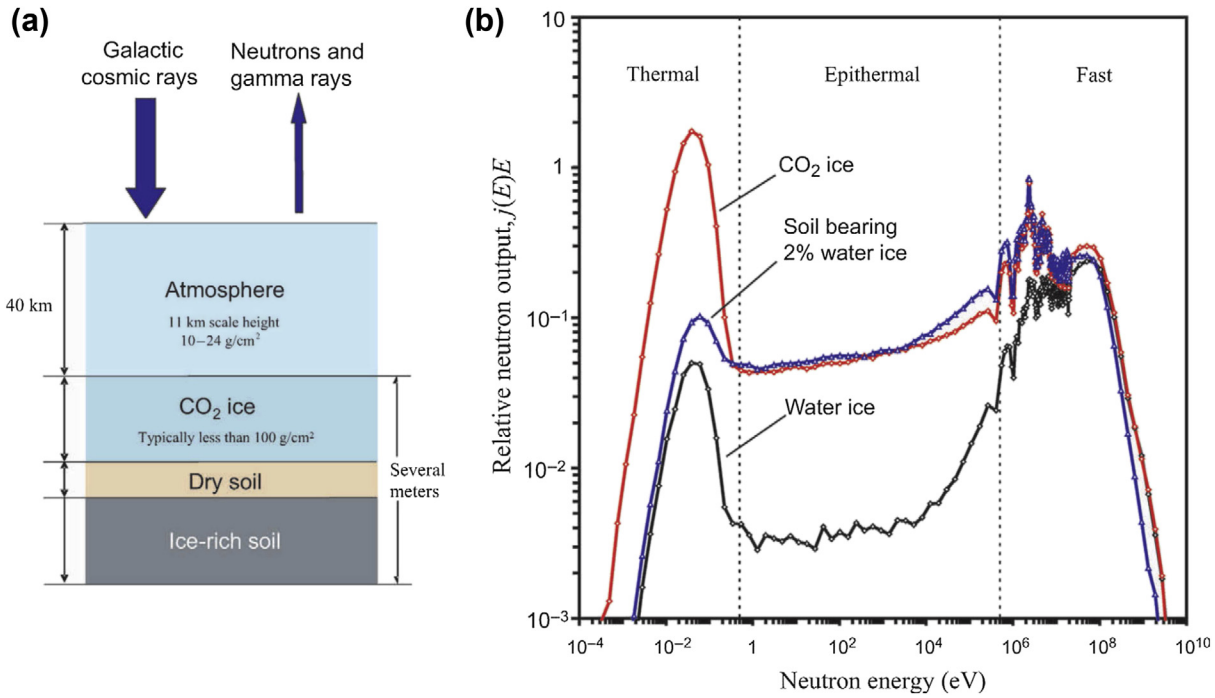

FIGURE 54.4 (a) Model of the Martian surface at high latitudes; (b) the current of neutrons leaking away from Mars for three different solid surface compositions. Neutron energy ranges are indicated. (See text for details.)

The population of neutrons escaping the solid surface or atmosphere can be represented as a current, J, which is the ratio of the number of neutrons escaping into space per galactic cosmic ray incident on the planet. The energy distribution of leakage neutrons is given by the current density $j(E)$, which is the number of escaping particles per unit energy per incident cosmic ray, such that $J = \int_0^\infty j(E)\mathrm{d}E$. The current density of neutrons leaking away from Mars was calculated by MCNPX for homogeneous solid surfaces consisting of water ice, which is representative of the north polar residual cap; relatively dry soil bearing 2% water ice, which is representative of dry equatorial regions; and CO_2 ice, which is representative of the seasonal polar caps. The relative neutron output, given by the product of the current density and neutron energy is shown in Figure 54.4(b) for each of these materials. Integrating the current density over all energies gives 5, 3, and 1 for the total number of neutrons escaping the surface per incident cosmic ray proton for the CO_2 ice, dry soil, and water ice surfaces, respectively.

The neutron current density spans 14 decades of energy and can be divided into three broad ranges (Figure 54.4(b)), representing different physical processes: (1) thermal neutrons, which have undergone many collisions, have energies less than about 0.5 eV, and are approaching thermal equilibrium with the surface; (2) epithermal neutrons, which have energies greater than about 0.5 eV and are in the process of slowing down from higher energies; and (3) fast neutrons, with energies greater than the threshold for inelastic scattering (about 0.5 MeV). Absorption and leakage result in a hardened energy distribution for the thermal portion of the spectrum. The most probable neutron energy in the thermal range is slightly higher than would be predicted if the neutrons were in thermal equilibrium with the regolith.

Elastic scattering is the most important loss mechanism for planetary neutron spectroscopy because it provides strong differentiation between H and other more massive nuclei. For elastic scattering, the energy loss per collision varies systematically with atomic mass. The maximum energy that a neutron can lose in a collision is given by fE where $f = 1 - [(A-1)/(A+1)]^2$, E is the energy of the neutron before the collision, and A is the atomic mass of the target nucleus. Thus, a neutron could lose all its energy in a single collision with hydrogen ($A = 1$), which has roughly the same mass as a neutron. This fact is readily verified by observing head-on collisions in a game of billiards. In contrast, the maximum energy loss in a collision with C, which is the next most massive nucleus of interest in planetary science, is 28%. For Fe, the maximum energy loss per collision is 7%. The mean energy loss per collision follows a similar trend. Consequently, for materials that are rich in H, such as water ice, energy loss by elastic collisions is high and neutrons slow down more quickly than for materials that do not contain H.

For H-rich materials, the population of neutrons that are slowing down is strongly suppressed relative to materials without H. For example, the epithermal current density for the simulated water ice surface in Figure 54.4(b) is considerably lower than either the soil or CO_2 surfaces. The current density of fast neutrons, which have undergone relatively few collisions following their production, are influenced not only by elastic scattering, but also by variations in neutron production, which depend on the average atomic mass of the medium.

Absorption of neutrons by radiative capture significantly influences the population of thermal neutrons. Elements such as H, Cl, Fe, and Ti have relatively high absorption cross-sections and can suppress the thermal neutron flux. C and O have very low absorption cross-sections compared to H. Consequently, the thermal neutron output for the water ice in Figure 54.4(b) is suppressed relative to the surfaces containing CO_2 ice and soil.

2.3. Gamma Ray Production and Transport

For galactic cosmic ray interactions, gamma rays are produced by neutron inelastic scattering and radiative capture. Deexcitation of residual nuclei produced by these reactions results in the emission of gamma rays with discrete energies. The energies and intensities of the gamma rays provide a characteristic fingerprint that can be used to identify the residual nucleus. Since, in most cases, a residual nucleus can only be made by a reaction with a specific target isotope, gamma rays provide direct information about the elemental composition of the surface.

For example, neutron inelastic scattering with ^{56}Fe frequently leaves the residual ^{56}Fe nucleus in its first excited state, which transitions promptly to ground state by the emission of an 847 keV gamma ray. The presence of a peak at 847 keV in a planetary gamma ray spectrum indicates that the surface contains Fe. The intensity of the peak is related directly to the abundance of elemental Fe in the surface.

Gamma rays produced by the decay of short-lived neutron activation products and long-lived (primordial) radioisotopes also provide useful information about elemental abundance. Radioactive elements such as K, Th, and U can be detected when present in trace quantities. Most notably, the Th decay chain produces a prominent gamma ray at 2.6 MeV, which can be measured when Th is present in the surface at low levels (>1 ppm).

To illustrate a typical gamma ray leakage spectrum, a Monte Carlo simulation of the lunar gamma ray leakage current induced by galactic cosmic ray protons is shown in Figure 54.5. The composition of the surface was assumed to be the mean soil composition from the Apollo 11 landing

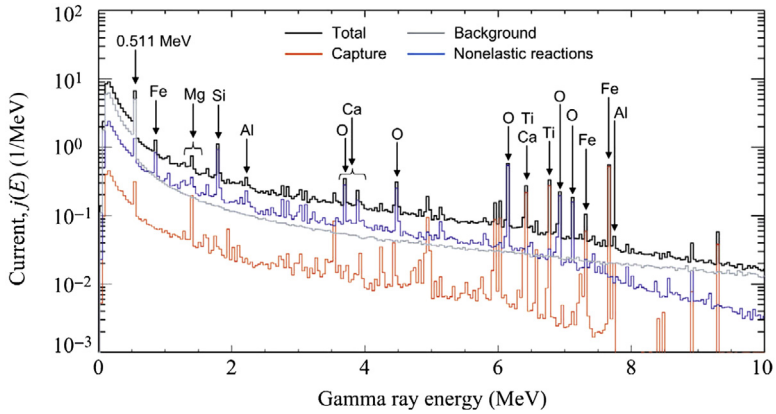

FIGURE 54.5 Simulated current of gamma rays leaking away from the Moon for a composition representative of the Apollo 11 landing site. Gamma rays from radioactive decay are not included in the simulation.

site. Contributions from nonelastic reactions and capture are plotted separately. A background continuum produced by various processes including pion decay is also shown. The peaks correspond to gamma rays that escape into space without interacting with the surface material. The peaks are superimposed on a continuum, which results from the scattering of gamma rays in the surface. The total number of gamma rays escaping the surface per incident cosmic ray proton was 2.7, which is within the range of values for the number of neutrons escaping the Martian surface, presented in Section 2.1.

Gamma ray peaks associated with neutron interactions with major elements are labeled with the target element in Figure 54.5. The intensity (or area) of each peak is proportional to the product of the abundance of the target element and the number density of neutrons slowing down within the solid surface or atmosphere. Specifically, the measured intensity (I) of a gamma ray peak with energy E for a selected reaction can be modeled as the product of three terms: $I \propto gyR$, where g accounts for attenuation of gamma rays by intervening surface materials and the variation of detection efficiency with gamma ray energy; y is the number of gamma rays of energy E produced per reaction; and $R = \varphi N\sigma$ is the **reaction rate**, the product of the neutron flux, cross-section, and atom density of the target element.

Because gamma rays are produced by neutron interactions, the absolute atom density or, equivalently, the weight fraction of the target element cannot be determined unless the neutron flux is known. Thus, neutron spectroscopy plays an important role in the analysis of gamma ray data. Relative abundances can be determined without knowledge of the magnitude of the neutron flux. For example, the ratio of Fe to Si abundances can be determined from the ratio of the intensities of the prominent Fe doublet (at 7.65 and 7.63 MeV) and the Si gamma ray at 4.93 MeV. Because attenuation of gamma rays by surface materials depends on gamma ray energy and the distribution of gamma ray production with depth, models of the depth profile of the neutron flux are needed in order to analyze gamma ray data.

For homogeneous surfaces, accurate results can be obtained for absolute and relative abundances; however, layered surfaces present a difficult challenge for analyzing nuclear spectroscopy data. Compositional layering of major elements on a submeter scale is widespread on Mars as shown, for example, by the Spirit and Opportunity rovers and the Mars Science Laboratory (MSL) (*see* Mars: Landing Site Geology, Minerology, and Geochemistry). In some cases, geophysical assumptions can be made that simplify the analysis and allow quantitative results to be obtained; however, it is often the case that insufficient information is available. In these cases, it is sometimes possible to establish bounds on composition that are useful for geochemical analysis. Development of accurate algorithms for determining elemental abundances, absolute or relative, requires careful synthesis of nuclear physics with constraints from geology, geophysics, and geochemistry.

3. DETECTION OF GAMMA RAYS AND NEUTRONS

In this section, a simple model of the counting rate observed by orbiting neutron and gamma ray spectrometers (GRSs) is presented along with an overview of radiation detection concepts for planetary science applications.

3.1. Counting Rate Models

The flux of radiation reaching an orbiting spectrometer varies in proportion to the solid angle subtended by the planet at the detector, which depends on orbital altitude. The fractional solid angle of a spherical body is given by

$$\Omega(h) = 1 - \sqrt{1 - R^2/(R+h)^2}, \qquad (54.1)$$

where h is the orbital altitude and R is the radius. The fractional solid angle varies from 1 at the surface (for $h = 0$) to 0 far away from the planet. For galactic cosmic ray interactions, the flux of gamma rays or neutrons at the orbiting spectrometer is approximately

$$\phi(h) = 1/2\Phi J\Omega(h), \tag{54.2}$$

where Φ is the flux of galactic cosmic ray protons far from the planet (about 4 protons/cm^2/s, depending on the solar cycle and location within the heliosphere), and J is the leakage current. Because alpha particles and heavier nuclei of galactic origin contribute to neutron and gamma ray production, Eqn (54.2) must be multiplied by a factor, approximately 1.4, in order to estimate the total leakage flux.

Equation (54.2) can be used, for example, to calculate the flux of neutrons incident on the *Mars Odyssey* neutron spectrometer (NS). The orbital altitude for *Mars Odyssey* is 400 km, and the volumetric mean radius of Mars is 3390 km. The fractional solid angle, given by Eqn (54.1), is 0.55. The total leakage current for a surface consisting of thick CO_2 ice, representative of the polar seasonal caps during winter, was $J = 5$ (from Section 2.2). Consequently, from Eqn (54.2), the total flux of neutrons at Odyssey's orbit from thick CO_2 deposits is approximately 8 neutrons/cm^2/s. For a surface that is 100% water, which is representative of the north polar residual cap, J was 1, and the total flux at orbital altitude is expected to be about 2 neutrons/cm^2/s.

Radiation detectors, such as the gamma ray and neutron spectrometers on *Mars Odyssey*, count particle interactions and bin them into energy or pulse height spectra, for example, with units of counts per second per unit energy. For both gamma rays and neutrons, the net counting rate (with units of counts per second) for selected peaks in the spectrum is needed in order to determine elemental abundances.

The flux of particles (gamma rays or neutrons) incident on a spectrometer can be converted to counting rate (C), given the intrinsic efficiency (ε) and projected (cross-sectional) area (A) of the spectrometer in the direction of the incident particles:

$$C = \varphi(h)\varepsilon A. \tag{54.3}$$

The intrinsic efficiency is the probability that an incident particle will interact with the spectrometer to produce an event that is counted. Because particles can pass through the spectrometer without interacting, the intrinsic efficiency is always less than or equal to 1. For example, $\varepsilon \cdot A$ is on the order of 10 cm^2 for the *Mars Odyssey* epithermal neutron detector, which has a maximum projected area (A) of about 100 cm^2. The efficiency-area product ($\varepsilon \cdot A$) varies with the energy and angle of incidence of the particles. So, the value for $\varepsilon \cdot A$ used in Eqn (54.3) must be appropriately averaged over neutron energy and direction.

One of the main sources of uncertainty in measured counting rates is statistical fluctuations due to the random nature of the production, transport, and detection of radiation. While a detailed discussion of error propagation is beyond the scope of this article, the most important result is given here. The statistical uncertainty (precision) in the counting rate is given by $\sigma = \sqrt{C/t}$ where t is the measurement time and C is the mean counting rate. For example, to achieve a precision of 1% ($\sigma/C = 0.01$) when $C = 10$ counts/s, which is typical of the epithermal and thermal counting rates measured by the *Mars Odyssey* NS, a counting time of 1000 s is required. Longer counting times are needed when background contributions are subtracted, for example, to determine counting rates for peaks in gamma ray and neutron spectra. Uncertainties in the counting rate due to random fluctuations propagate to the uncertainties in elemental abundance and other parameters determined in the analysis of spectroscopy data. Long counting times are desired to minimize statistical contributions. Improved precision can be achieved by increasing the counting rate, which can be accomplished through instrument design, by maximizing the efficiency-area product and/or by making measurements at low altitude.

3.2. Gamma Ray and Neutron Detection

Radiation spectrometers measure ionization produced by the interaction of particles within the sensitive volume of a detector. Gamma ray interactions produce swift primary electrons that cause ionization as they slow down in the sensitive volume. Neutrons undergo reactions that produce energetic ions and gamma rays. The recoil proton from neutron elastic scattering with hydrogen can produce measurable ionization. The charge liberated by these interactions can be measured using a wide variety of techniques, two of which are illustrated here.

Semiconductor radiation detectors typically consist of a semiconductor dielectric material sandwiched between two electrodes. An electric field is established in the dielectric by applying high voltage across the electrodes. Gamma ray interactions produce free electron–hole pairs, which drift in opposite directions in the electric field. As they drift, they induce charge on the electrodes, which is measured using a charge-sensitive preamplifier. The amplitude of the charge pulse, or pulse height, is proportional to the energy deposited by the gamma ray. Consequently, a histogram of pulse heights, known as a pulse height spectrum, provides information about the energy distribution of the incident gamma rays.

For example, a diagram of a high-purity germanium (HPGe) detector is shown in Figure 54.6(a) along with a photograph of an HPGe crystal in Figure 54.6(b). The closed-end coaxial geometry is designed to minimize

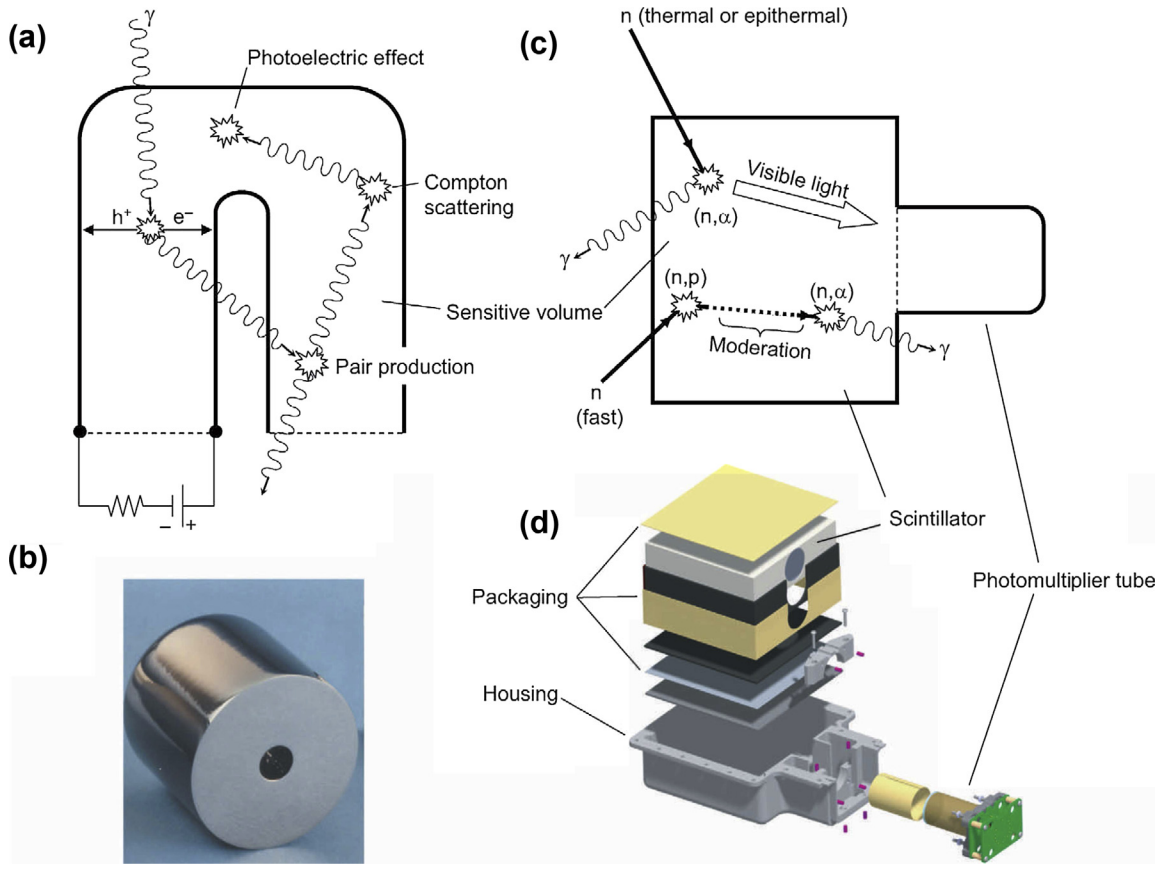

FIGURE 54.6 (a) Schematic diagram of a coaxial HPGe spectrometer and gamma ray interactions; (b) photograph of a HPGe crystal; (c) diagram of a scintillation-based spectrometer with neutron interactions; and (d) assembly diagram for a boron-loaded plastic scintillator for Dawn's Gamma Ray and Neutron Detector, including the housing and packaging designed to withstand the vibrational environment during launch. *Part (b) courtesy of AMETEK, Advanced Measurement Technology, Inc., ORTEC Product Line, 801 South Illinois Avenue, Oak Ridge, TN 37830.*

trapping of carriers as they drift to the electrodes. To minimize noise due to leakage current, the HPGe must be operated at cryogenic temperatures. The requirement for cooling adds to the mass and complexity of the design for space applications.

A hypothetical gamma ray interaction is superimposed on the diagram in Figure 54.6(a). Gamma rays undergo three types of interactions: pair production, Compton scattering, and photoelectric effect. High-energy gamma rays (greater than 1.022 MeV) can undergo pair production, in which the gamma ray disappears and an electron−positron pair is produced. The kinetic energy of the electron and positron is absorbed by the medium. When the positron is annihilated by an electron, two back-to-back (511 keV) gamma rays are produced, which can undergo additional interactions. In Compton scattering, a portion of the energy of the gamma ray is transferred to an electron. The energy lost by the gamma ray depends on the scattering angle. At low energies, the gamma ray can be absorbed by an electron via the photoelectric effect. All these interactions vary strongly with the atomic number (Z) and density of the detector material. High Z, high density, and a large sensitive volume are desired to maximize the probability that all the energy of the incident gamma ray is absorbed in the detector.

A pulse height spectrum for a large volume (slightly larger than the crystal flown on *Mars Odyssey*), coaxial HPGe detector is shown in Figure 54.7. The gamma rays were produced by moderated neutrons, with an energy distribution similar to the lunar leakage spectrum, incident on an Fe slab. Well-defined peaks corresponding to neutron capture and inelastic scattering with Fe appear in the spectrum. For example, the doublet labeled Fe(1) corresponds to gamma rays (7646 and 7631 keV) produced by neutron capture with Fe. The peaks labeled Fe(2) are shifted 511 keV lower in energy and correspond to the escape of one of the 511 keV gamma rays produced by pair production in the spectrometer. The continuum that underlies the peaks is caused by external Compton scattering and the escape of gamma rays that scattered in the spectrometer. Gamma rays from neutron capture with H and the radioactive decay of K and Th are also visible.

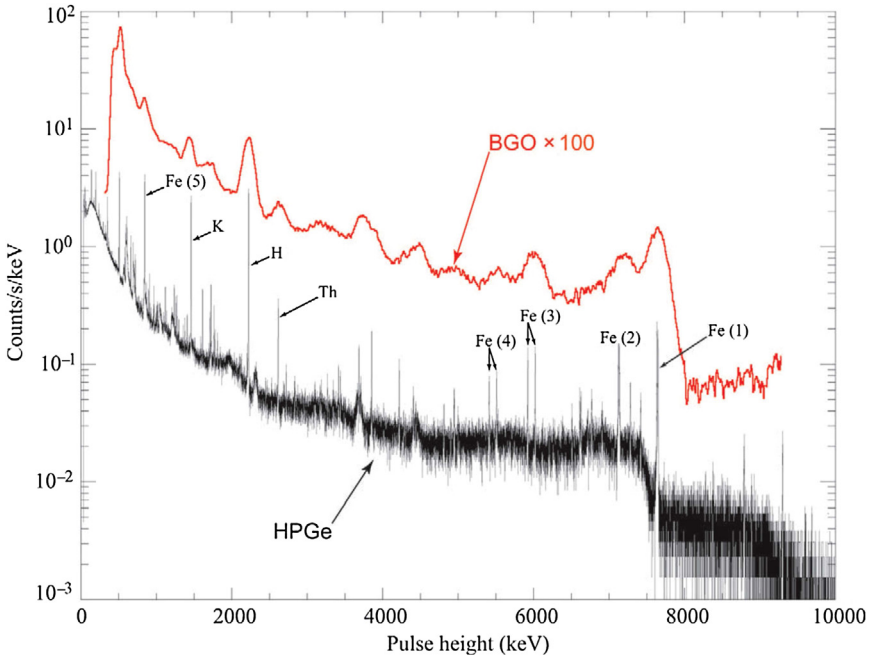

FIGURE 54.7 Gamma ray spectra acquired in the laboratory by liquid nitrogen-cooled HPGe (black) and BGO (red) spectrometers. The BGO spectrometer is part of Dawn's Gamma Ray and Neutron Detector (GRaND). To improve visualization, the spectrum for BGO has been multiplied by 100. The source was moderated neutrons, with energy distribution similar to a planetary leakage spectrum, incident on an iron slab. Gamma rays from natural radioactivity in the environment are also visible (from K at 1461 keV and Th at 2615 keV). A gamma ray at 2223 keV from neutron capture with H (from polyethylene in the moderator) is a prominent feature in the HPGe and BGO spectra. Major gamma rays from neutron interactions with Fe that are resolved by the HPGe spectrometer are labeled: (1) 7646 and 7631 keV doublet from neutron capture; (2) their single escape peaks; (3) 6019 and 5921 keV gamma rays from neutron capture; (4) their single escape peaks; and (5) 846.7 keV gamma ray from neutron inelastic scattering. *HPGe spectrum courtesy of S. Garner, J. Shergur, and D. Mercer of Los Alamos National Laboratory.*

Scintillators provide an alternative method of detecting ionizing radiation, which can be used for gamma ray and neutron spectroscopy. Scintillators consist of a transparent material that emits detectable light when ionized. The light is measured by a photomultiplier tube or photodiode, which is optically coupled to the scintillator. The amount of light produced and the amplitude of the corresponding charge pulse from the photomultiplier tube and pulse processing circuit is proportional to the energy deposited by the radiation interaction.

A diagram of a boron-loaded, plastic scintillation detector is shown in Figure 54.6(c) along with an assembly diagram of flight sensor (Figure 54.6(d)). Thermal and epithermal neutrons are detected by the ^{10}B(n, $\alpha\gamma$) ^{7}Li reaction (see glossary for an explanation of **reaction notation**). The recoiling reaction products (alpha particle and ^{7}Li ion) produce ionization equivalent to a 93 keV electron, which makes a well-defined peak in the pulse height spectrum. The area of the peak depends on the flux of incident thermal and epithermal neutrons. Thermal neutrons can be filtered out by wrapping the scintillator in a Cd foil, which strongly absorbs neutrons with energies below about 0.5 eV. Thus, the combination of a bare and Cd-covered scintillator can be used to separately measure contributions from thermal and epithermal neutrons. Above about 500 keV, light is produced by recoiling protons from neutron elastic scattering with hydrogen in the scintillator. Fast neutrons (greater than about 500 keV) can be detected by a prompt pulse from proton recoils followed a short time later by a second pulse, corresponding to neutron capture of the moderated neutron by ^{10}B. This characteristic, double-pulse time signature can be used to identify, and separately measure, fast neutron events.

Scintillators are also used routinely for gamma ray spectroscopy. For example, a pulse height spectrum acquired by a bismuth germanate (BGO) scintillator is shown in Figure 54.7. The source was exactly the same as measured by the HPGe spectrometer, and the two spectra share similar peak features. Note, however, that the peaks measured by BGO are considerably broader than those measured by HPGe. For BGO, the width of the peaks is controlled by statistical variations in the number of scintillation photons produced by full-energy gamma ray interactions. Similar dispersion occurs for charge carriers (electrons and holes) produced in the HPGe crystal; however, the effect is far less pronounced. Pulse height resolution is determined by the full width at half maximum (FWHM) of the gamma ray peaks, which is often quoted for a standard gamma ray (e.g. the 1332 keV gamma ray from ^{60}Co). Spectrometers that produce narrower peaks

have higher resolution and, in principle, contain more detailed information about the incident gamma ray spectrum and backgrounds.

The ability of the HPGe technology to resolve individual peaks is coveted by the planetary spectroscopist; however, the added cost and complexity of HPGe relative to scintillation technology has made scintillators competitive for some missions. HPGe has been successfully flown on three planetary missions (Table 54.1). A comparison between whole Moon spectra acquired by Lunar Prospector (BGO), Chang'E-2 ($LaBr_3$), and Kaguya (HPGe) is shown in Figure 54.8.

Other technologies that have been flown for gamma ray and neutron detection include ^{3}He ionization chambers (for thermal and epithermal neutron detection on Lunar Prospector) and various scintillators, including Tl-doped NaI on NEAR and Apollo, Tl-doped CsI on Phobos and Chang'E-1 and -2, and Ce-doped $LaBr_3$ on Chang'E-2. Lanthanum halides such as $LaBr_3$ are very bright scintillators and thus have excellent pulse height resolution; however, the presence of radioactive contaminants within these scintillators (e.g. ^{138}La and Th decay products) produce backgrounds that interfere with measurement of radioelements in planetary regoliths. The Dawn mission deployed a large-volume BGO scintillator as the primary GRS and demonstrated a new compound semiconductor technology (CdZnTe). CdZnTe-based spectrometers have significantly better pulse height resolution compared to BGO and, in contrast to HPGe, can be operated at ambient temperatures.

3.3. Spatial Resolution

The spatial resolution that can be achieved by a spectrometer depends on the angular distribution of radiation emitted from the surface, the angular response of the spectrometer, and the altitude of the orbit. The angular response of most spectrometers is roughly isotropic or weakly dependent on incident direction. Consequently, the spectrometer is sensitive to radiation emitted from locations from underneath the spectrometer all the way out to the limb. Due to their increased area, off-nadir regions contribute more to the counting rate than regions directly beneath the spacecraft.

When the spectrometer passes over a point source of radiation on the surface, the counting rate as a function of distance along the orbital path has an approximately Gaussian shape, with the peak occurring when the spacecraft passes over the source. Consequently, the ability of the spectrometer to resolve spatial regions with different compositions depends on the FWHM of the Gaussian, which as a general rule is approximately 1.5 times the orbital altitude. For example, the lowest orbital altitude of *Lunar Prospector* was 30 km for which the FWHM was 45 km or 1.5° of arc length. For *Mars Odyssey*, the orbital altitude was 400 km, and the FWHM was approximately 600 km or 10° of arc length.

The broad spatial response of gamma ray and neutron spectrometers must be considered in the analysis and interpretation of data, especially where comparisons to high resolution data (for example, from optical spectroscopy) are concerned. It may be possible to increase the resolution of a spectrometer by the addition of a collimator, which would add mass to the instrument and also reduce the precision of the measurements. Alternatively, spatial deconvolution and instrument modeling techniques can sometimes be employed to study regions that are smaller in scale than the spatial resolution of the spectrometer.

4. MISSIONS

Since the dawn of space flight, nuclear spectroscopy has been used for a wide variety of applications, from astrophysics to solar astronomy. Planetary science missions with gamma ray and/or neutron spectrometers on the payload are listed in Table 54.1. While nuclear spectroscopy was used on earlier missions to the Moon, Mars, and the surface of Venus, the first major success was the Apollo Gamma Ray Experiment, which flew on the Apollo 15 and 16 missions, providing global context for lunar samples. Phobos II traveled to Mars and provided a glimpse of the regional composition of the western hemisphere, which includes Tharsis and Valles Marineris. Due to the small size of Eros and high orbital altitudes, the GRS on NEAR provided little useful information about Eros until the NEAR landed on the asteroid. Once on the surface, the NEAR GRS acquired data with sufficient precision to determine the abundance of O, Mg, Si, Fe, and K. NEAR also had an X-ray spectrometer that provided complementary information about surface elemental composition. The first intended use of neutron spectroscopy for global mapping was on Mars Observer, which was lost before reaching Mars.

Lunar Prospector was the first mission to combine gamma ray and neutron spectroscopy to provide accurate, high-precision global composition maps of a planetary body. Missions that followed, including 2001 Mars Odyssey, MESSENGER, and Dawn also included neutron and GRSs on their payloads. The results of Lunar Prospector and Mars Odyssey are detailed in Section 5.

Recent missions to the Moon, including the Japanese Kaguya (also known as the SELenological and ENgineering Explorer (SELENE)) mission and the Chinese Chang'E missions used gamma ray spectroscopy to confirm many of the initial findings of Lunar Prospector regarding the geochemistry of the Moon. The SELENE mission, with its high-resolution HPGe spectrometer, directly measured the concentration of U and the U/Th ratio, supplementing measurements of K and Th by Lunar Prospector. A NS

TABLE 54.1 Summary of Planetary Science and Exploration Missions with Gamma Ray and/or Neutron Spectrometers. Missions prior to Apollo, including Luna and Ranger, are not listed (for information about these missions, see Bibliography).

Mission	Country/ Program	Launch Date(s)	Status	Planet or Minor Body	Orbit	Mapping Duration[1]	Gamma Ray Spectrometer	Neutron Spectrometer	Results and/or Objectives[2]
Apollo 15 and 16	US	July 26, 1971 April 16, 1972	Completed	Moon	Equatorial orbit covering 20% of the lunar surface	10.5 days (Apollo 15 and 16 combined)	NaI(Tl) with plastic anticoincidence shield	None	Maps of major and radioactive elements, including Fe, Ti, and Th
Venera 8	USSR	March 27, 1972	Completed	Venus	Not applicable (N/A): descent module/lander	42 min of data acquisition on the surface	NaI(Tl)	None	Abundances of K, Th, and U; found K/Th ratio similar to that of Earth rocks
Phobos II[3]	USSR	July 12, 1988	Lost during Phobos encounter	Mars and Phobos	Elliptical, equatorial orbit, 900 km periapsis, 80,000 km apoapsis	2 orbits analyzed	CsI(Tl)	None	Abundances of O, Si, Fe, K and Th in two equatorial regions in the western hemisphere
Mars Observer	US, NASA Mars Exploration Program	September 25, 1992	Lost prior to orbital insertion	Mars	400 km altitude circular polar mapping orbit[2]	1 Mars year[2]	HPGe, passively cooled	Boron-loaded plastic scintillators	Global maps of major elements and water-equivalent hydrogen (objectives not achieved)
Near Earth Asteroid Rendezvous (NEAR)	US, NASA Discovery Program	February 17, 1996	Completed	Eros	Useful data acquired following successful landing on Eros	7 days on the surface	NaI(Tl) with BGO anticoincidence shield	None	Abundances of O, Mg, Si, Fe, and K
Lunar Prospector	US, NASA Discovery Program	January 6, 1998	Completed mission by planned impact in a south polar crater	Moon	High- and low-altitude circular polar mapping orbits (100 km and 30 km, respectively)	300 days at high altitude; 220 days at low altitude	BGO with boron-loaded plastic anticoincidence shield	^{3}He gas proportional counters and boron-loaded plastic scintillator	Discovery of enhanced water-equivalent hydrogen associated with polar cold traps; global maps of major and radioactive elements
2001 Mars Odyssey	US, NASA Mars Exploration Program	April 7, 2001	Completed primary mission; ongoing extended mission	Mars	400 km altitude circular polar mapping orbit	Over 6 Mars years completed; gamma ray spectra available through September of 2009	HPGe, passively cooled	Boron-loaded plastic scintillators (NS); Stilbene and ^{3}He tubes (HEND[4])	Distribution and layering of water-equivalent hydrogen; seasonal variations in CO_2 ice and noncondensable gasses; and global maps of major and radioactive elements
MESSENGER	US, NASA Discovery Program	August 3, 2004	Primary mission completed; extended mission underway	Mercury	Elliptical polar mapping orbit with periapsis at 400 km altitude at >60° N latitude, 15,000 km apoapsis	1 year primary mission began in March of 2011	HPGe, actively cooled with boron-loaded plastic anticoincidence shield	^{6}Li-loaded glass and boron-loaded plastic scintillator	Mapped elemental composition of the northern hemisphere; detected large amounts of hydrogen, consistent with deposits of ice in permanently shadowed polar craters

Dawn	US, NASA Discovery Program	September 27, 2007	Completed Vesta encounter; en route to Ceres	Main-belt bodies 4 Vesta and 1 Ceres	Survey, high-, and low-altitude circular polar mapping orbits	5 months data acquisition at low altitude (210 km) around Vesta; Ceres planning underway	CdZnTe and BGO	^{6}Li-loaded glass and boron-loaded plastic scintillators	Global elemental ratios confirm Vesta as the HED parent body; discovered extensive hydrogen deposits on Vesta, consistent with exogenic delivery of hydrated minerals by carbonaceous chondrites; search for water ice and evidence for aqueous alteration at Ceres
SELENE (Kaguya)	Japan	September 14, 2007	Completed mission by planned impact into lunar surface (June 11, 2009)	Moon	High- and low-altitude polar mapping orbits (100 km and 30 km × 50 km, respectively).	1.5 years duration (70 days accumulation of data at low altitude)	Actively cooled HPGe with BGO anticoincidence shield	None	Global maps of U, Th, K, and Ca. Maps of Fe, Ti, Si, Mg, Al, and H in preparation
Lunar Reconnaissance Orbiter (LRO)	US, NASA Lunar Exploration Program	June 18, 2009	Primary mission completed; extended mission underway	Moon	~50 km circular polar mapping orbit	1 year primary mission	None	Eight ^{3}He tubes, four with passive shielding intended for collimation of epithermal neutrons (LEND[4])	Confirmed the presence of enhanced hydrogen at the lunar poles; efficacy of collimation debated
Chang'E-1 and -2	China National Space Administration	October 24, 2007 and October 1, 2010	Completed	Moon	200 and 100 km circular polar mapping orbits for Chang'E-1 and -2, respectively	1 year, ~85 days accumulation time (Chang'E-1); 178 days accumulation (Chang'E-2)	CsI(Tl) (Chang'E-1) and $LaBr_3$ (Chang'E-2), both with CsI(Tl) anticoincidence shields	None	Distribution of radioelements, confirming results of Lunar Prospector and SELENE
Mars Science Laboratory (MSL)	US, NASA Mars Exploration Program	November 26, 2011	Deployed within Gale crater; first drive August 22, 2012; Data acquired within the 400 m traverse completed in the first 90 sols	Mars	N/A	1 Mars year (5 to 20 km traverse)	None	^{3}He tubes with active neutron interrogation with a pulsed, 14 MeV, D-T neutron generator (DAN[4])	Preliminary results presented for WEH abundance, H-layering, and the abundance of neutron-absorbing elements
BepiColombo	European Space Agency	2015	Planning for launch	Mercury	Elliptical, polar mapping orbit (400 × 1500 km)	1 year	$LaBr_3$ scintillator[4]	Design based on HEND[4]	Global maps of elemental abundances

[1]Refers to the time periods during which gamma ray and/or neutron data were acquired.
[2]Objectives are listed for Mars Observer, Dawn at Ceres, and BepiColumbo.
[3]Neutron and gamma ray spectrometers were flown on Phobos I, which was launched on 7 July, 1988; however, Phobos I was lost during the cruise phase of the mission. The Mars 4 and 5 missions (USSR, 1973) flew identical sodium iodide gamma ray spectrometers. A few gamma ray spectra were acquired by Mars 5 while in an elliptical orbit around Mars (apoapsis 32,560 km, periapsis 1760 km, and inclination 35° to the equator).
[4]The High Energy Neutron Detector (HEND) on Odyssey, the Lunar Exploration Neutron Detector (HEND) on LRO, the Dynamic Albedo of Neutron (DAN) instrument on MSL, and the gamma and neutron spectrometers on BepiColumbo were provided by the Russian Federation.

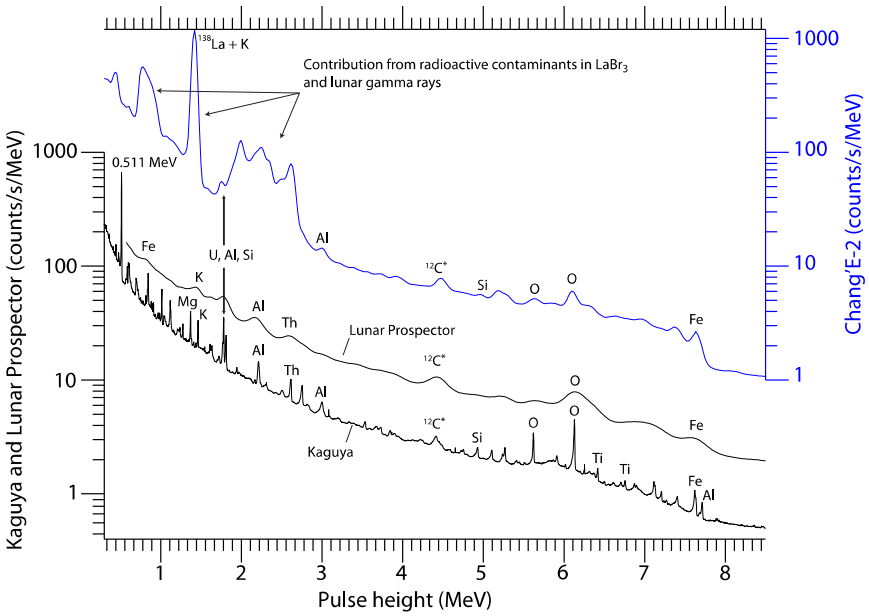

FIGURE 54.8 Gamma ray spectra acquired by Lunar Prospector (BGO), Kaguya (HPGe) and Chang'E-2 ($LaBr_3$) missions averaged over the whole Moon. The data were acquired in their respective low-altitude orbits (see Table 54.1). Prominent peaks, mostly of lunar origin, are labeled. For Chang'E-2, strong contributions from lunar K were determined by subtracting the background produced by radioactive contaminants within $LaBr_3$. The Kaguya spectrum contains some peaks (e.g. reactions with Al) that have strong background contributions from nearby structural materials. The relatively low mass of housing materials and boom deployment minimized background contributions for the Lunar Prospector Gamma Ray Spectrometer. The spectrum acquired by Kaguya has broader peaks than that of the spectrum shown in Figure 54.7, which was acquired in the laboratory. The mechanical (Stirling) cryocooler used in flight operations does not cool the HPGe crystal as effectively as liquid nitrogen and is also a source of microphonic noise. In addition, low-energy tailing due to radiation damage accrued during flight is evident. *Lunar Prospector data are from the NASA Planetary Data System; Kaguya data are courtesy of N. Hasabe, Research Institute for Science and Engineering, Waseda University, Japan; Chang'E-2 data are courtesy of M. Zhu, Space Science Institute, Macau University of Science and Technology, China.*

provided by the Russian Federation was flown on NASA's Lunar Reconnaisance Orbiter (LRO). LRO's Lunar Exploration Neutron Detector (LEND) included a massive collimator intended to provide high spatial-resolution measurements of hydrogen deposits within permanently shadowed craters. The efficacy of the collimator is the subject of controversy among scientists. Nevertheless, LEND's uncollimated neutron detectors confirmed the presence of enhanced hydrogen deposits at the lunar poles discovered by Lunar Prospector.

Data acquired by MESSENGER's GRS were analyzed to map the abundance of K, Th, U, Na, S, Ca, Al, and Fe on Mercury at high northern latitudes. Measurements of the K/Th ratio indicate that the material from which Mercury formed had similar volatile-to-refractory content as other terrestrial planets, in contrast to the Moon, which is volatile depleted. High S and Na contents show that the Mercury's surface was not depleted in volatiles, which implies that present models of Mercury's formation are inadequate. Despite Mercury's high bulk Fe content, its surface is Fe-poor, which remains a puzzle. Neutron spectroscopy revealed high concentrations of H near the north pole, consistent with thick deposits of water ice trapped within permanently shadowed polar craters.

The NASA Dawn mission successfully completed operations at the giant, main-belt asteroid 4 Vesta and is now in interplanetary cruise for an encounter with the dwarf planet Ceres in 2015. Dawn's Gamma Ray and Neutron Detector (GRaND) found global Fe/O and Fe/Si ratios consistent with that of the howardite, eucrite, and diogenite meteorites, providing chemical evidence that Vesta is the parent body of these achondrites. Neutron spectroscopy revealed relatively high abundances of H (at least 400 μg/g) in low-albedo regions near Vesta's equator where water-ice is not stable. The hydrogen observed by GRaND is thought to be exogenous, in the form of hydrated minerals emplaced within Vesta's otherwise basaltic regolith by the gradual infall of carbonaceous chondrites. High-velocity impacts into this volatile-rich material may have formed pitted terrain seen in relatively young craters on Vesta.

The Dynamic Albedo of Neutrons (DAN) experiment on the NASA MSL is the first rover-based NS. DAN features active neutron interrogation with a 14 MeV pulsed deuterium−tritium (D−T) neutron generator as well as the ability to acquire passive neutron counting data. With MSL operations underway, DAN is expected to provide data on the abundance and layering of **water-equivalent hydrogen (WEH)** as well as information about neutron-absorbing

elements such as Cl and Fe as the rover traverses Gale crater.

Finally, the launch of BepiColumbo, a European-led mission to Mercury, is anticipated in 2015. BepiColumbo's proposed orbit should enable the acquisition of global compositional maps using nuclear spectroscopy.

5. SCIENCE

Lunar Prospector and *Mars Odyssey* acquired high-precision gamma ray and neutron data sets for the Moon and Mars, respectively. Highlights of the science carried out on these missions are presented along with a description of their instrumentation. The Moon and Mars are very different, both in their origin and composition. With the possible exception of polar water ice, the Moon is depleted in volatile elements and has no atmosphere. The lunar surface has been extensively modified by cratering and basaltic volcanism. Mars has a tenuous atmosphere, extensive water ice deposits, and seasonal CO_2 caps. Volcanic, aqueous, and eolian processes have continued to shape the surface of Mars long past the primordial formation of the crust. The differences between these two bodies will provide the reader with insights into the wealth of information provided by nuclear spectroscopy and the challenges faced in the analysis of the data. For *Lunar Prospector*, emphasis is placed on the combined analysis of neutron and gamma ray data to determine the abundance of major and trace radioactive elements. For *Mars Odyssey*, results from the NS for global water abundance and the seasonal caps are presented.

5.1. Lunar Prospector

Lunar Prospector was a spin-stabilized spacecraft, with the spin axis perpendicular to the plane of the ecliptic. The instruments were deployed on booms to minimize backgrounds from the spacecraft (Figure 54.9(a)). The payload included a large-volume BGO GRS, which was surrounded by a boron-loaded plastic anticoincidence shield (Figure 54.9(b)). The shield served two purposes: (1) to suppress the Compton continuum caused by gamma rays escaping the BGO crystal and to reject energetic particle events; and (2) to measure the spectrum of fast neutrons from the lunar surface using the double-pulse technique described in Section 3.2. Sn- and Cd-covered ^{3}He gas proportional counters were used to detect and separately measure thermal and epithermal neutrons. Gamma ray and neutron spectroscopy data were acquired for long periods of time (Table 54.1), providing full coverage of the Moon at 100 and 30 km altitude.

The data were analyzed to determine global maps of surface elemental composition. The resulting abundance data were mapped on different spatial scales, depending on the precision of the data and the altitude of the spectrometer. Results of the analysis were submitted to the NASA Planetary Data System and include the following data sets: the abundance of hydrogen from neutron spectroscopy

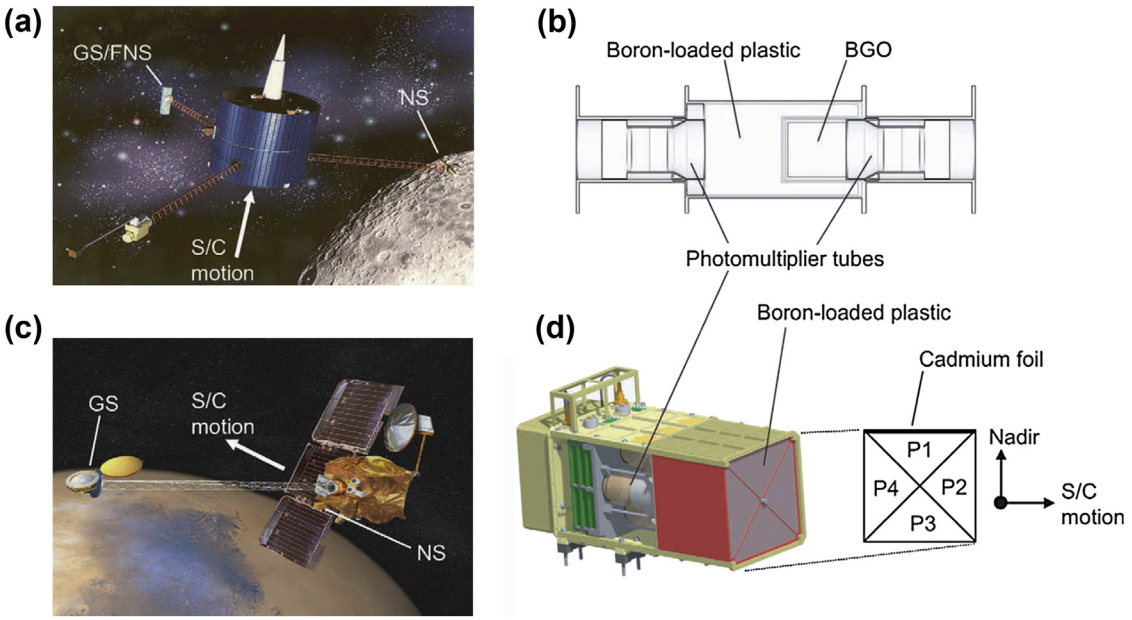

FIGURE 54.9 (a) Annotated artist's conception of Lunar Prospector; (b) Cross-sectional view of the gamma ray and fast neutron spectrometer (GS/FNS); (c) annotated artist's conception of 2001 Mars Odyssey; (d) engineering drawing of the neutron spectrometer on Odyssey cut away to show the boron-loaded plastic scintillators. A schematic diagram of the arrangement of scintillators and their orientation relative to spacecraft motion and nadir is also shown. *Parts (a) and (c) courtesy of NASA.*

(0.5° **equal angle map**); the average atomic mass from fast neutron spectroscopy (2° **equal-area maps**); the abundance of major oxides, including MgO, Al_2O_3, SiO_2, CaO, TiO_2, and FeO, and trace incompatible elements K, Th, and U (2°, 5°, and 20°equal-area maps) using a combination of gamma ray and neutron spectroscopy; and the abundance of the rare-earth elements (Gd + Sm) from neutron spectroscopy (0.5° equal angle map).

Perhaps the most significant result of *Lunar Prospector* was the discovery of enhanced hydrogen at the poles in association with craters in permanent shadow, which are thought to be cold traps for water ice. If present in ample quantities, water ice could be an important resource for manned exploration. Consequently, the polar cold traps are a prime target for future missions. The presence of cold-trapped volatiles within Cabeus crater near the lunar south pole was recently confirmed by the NASA Lunar CRater Observation and Sensing Satellite (LCROSS) mission, in which the ejecta plume generated by the deliberate impact of the launch vehicle's upper stage with the crater floor was analyzed. Data acquired by *Lunar Prospector* and the *Lunar Reconnaissance Orbiter* were used in the selection of the target crater. Geochemical results from the analysis of neutron and gamma ray spectra fully reveal the dichotomy in the composition of the Moon, with a near side that is enriched in incompatible elements and mafic minerals and a thick far-side crust primarily consisting of plagioclase feldspar.

Global geochemical trends observed by *Lunar Prospector* are not significantly different from trends observed in the sample and meteoritic data; however, there are some notable discrepancies that point to the existence of unique lithologies that are not well represented by the lunar sample data. Interpretation and analysis of the data is ongoing with emphasis on regional studies. For example, the impact that formed the South Pole Aitken (SPA) basin could have excavated into the mantle. Analysis of the composition of the basin floor may reveal information about the bulk composition of the mantle and lower crust.

The analysis of major and radioactive elements was carried out using a combination of gamma ray and neutron spectroscopy data. A typical gamma ray spectrum is shown in Figure 54.10 for a 20° equal-area pixel in the western mare. Two intense, well-resolved peaks, labeled in Figure 54.10, were analyzed to determine the abundance of Fe and Th. In addition, a spectral unmixing algorithm similar to those used to analyze spectral reflectance data was developed to simultaneously determine the abundance of all major and radioactive elements from the gamma ray spectrum.

Lunar gamma ray spectra can be modeled as a linear mixture of elemental spectral shapes. The magnitude of the spectral components must be adjusted to account for the nonlinear coupling of gamma ray production to the neutron number density (for neutron capture reactions) and the flux of fast neutrons (for nonelastic reactions). Once the adjustment is made, a linear least squares problem can be

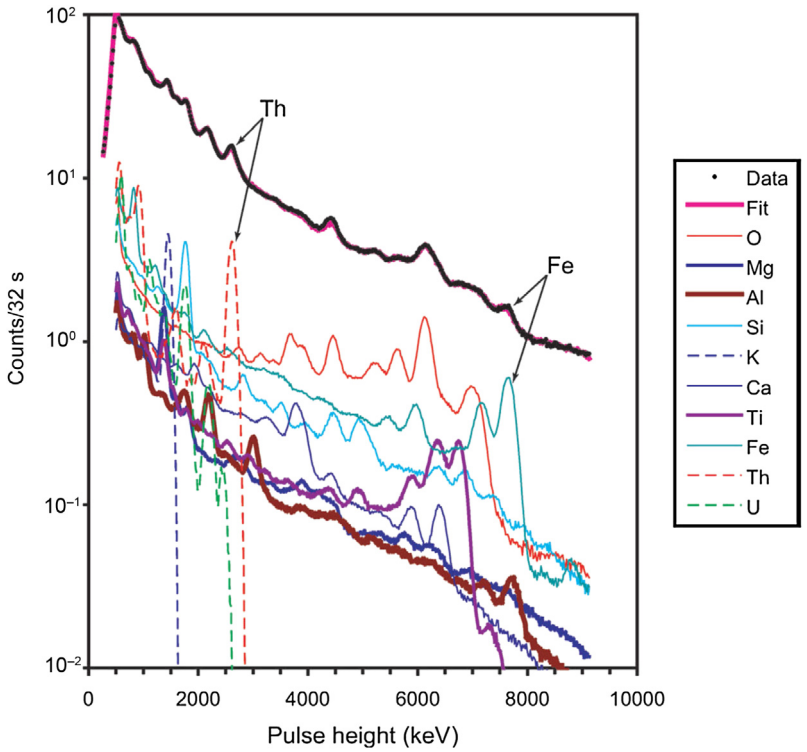

FIGURE 54.10 Lunar Prospector gamma ray spectrum for a 20° equal-area pixel in the western mare is compared to the fitted spectrum and elemental spectral components.

solved to determine elemental weight fractions. Fitted elemental spectral shapes are shown, for example, in Figure 54.10.

Abundance maps for selected elements determined by *Lunar Prospector* are shown in Figure 54.11. To provide context for the elemental abundance maps, a map of topography determined by *Clementine*, superimposed on a shaded relief image, is shown in Figure 54.11(a). The far side includes the feldspathic highlands and the SPA basin. The near side consists of major basins, including Procellarum and Imbrium, which contain mare basalts. The mare basalts are rich in Fe, with the highest concentrations occurring in western Procellarum (Figure 54.11(b)). The low abundance of FeO in the highlands, which are rich in plagioclase feldspar, reflects a significant lunar geochemical trend in which mafic silicate minerals are displaced by plagioclase, which is Fe-poor.

A large portion of the western near side is enriched in radioactive elements such as Th (Figure 54.11(c)). K, Th, and U are incompatible with major lunar minerals and were likely concentrated in the residual melt during lunar differentiation. Consequently, their distribution on the surface and with depth has important implications to lunar evolution. The association of high Th concentrations with the mare suggests that heating by radioactive elements may have significantly influenced lunar thermal evolution and mare volcanism.

The distribution of TiO_2 is shown in Figure 54.11(d) as a 5° equal-area map. The low spatial resolution of the TiO_2 map compared to FeO and Th is a consequence of the relatively low intensity of the Ti gamma rays and their position in the gamma ray spectrum near strong peaks from O and Fe (Figure 54.10). The abundance of TiO_2 can be used to classify mare basalts. Strong spatial variations in the abundance of TiO_2, for example, indicate that different source regions and processes were involved in creating the basalts that comprise the mare. The highest concentrations of TiO_2 are found in Tranquillitatis as shown in Figure 54.10(d); however, high concentrations are also found in western Procellarum. The abundances of Fe and Ti observed in western Procellarum suggest that this region has a unique composition that is not well represented by the lunar samples.

5.2. Mars Odyssey

As of this writing, 2001 *Mars Odyssey* is in an extended mission having successfully completed over six Mars years of mapping (each Mars year is 687 days). *Odyssey* is in a circular polar mapping orbit around Mars at an altitude of approximately 400 km (Table 54.1). The nuclear spectroscopy payload consists of a GRS, a NS, and a Russian-supplied high-energy neutron detector. Gamma ray and neutron spectroscopy data acquired by *Mars Odyssey* provide constraints on geochemistry, the water cycle, climate history, and atmospheric processes, including atmospheric dynamics and atmosphere–surface interactions (*see* Mars Atmosphere: History and Surface Interactions).

Since the discovery of abundant subsurface WEH at high latitudes, *Odyssey's* gamma ray and neutron spectrometers have continued to provide a wealth of new information about Mars, including the global distribution of near-surface WEH, the elemental composition of the surface, seasonal variations in the composition of the atmosphere at high latitudes, and the column abundance of CO_2 ice in the seasonal caps. This information has contributed to our understanding of the recent history of Mars. The climate is driven strongly by short-term variations in orbital parameters, principally the obliquity, and the surface distribution of surface water ice is controlled by atmosphere–surface interactions. The discovery of anomalously large amounts of WEH at low latitudes, where water ice is not stable, has stirred considerable debate about the mineral composition of the surface and climate change.

The GRS on *Odyssey* is boom-mounted, passively cooled, HPGe spectrometer, similar in design to the instrument flown on *Mars Observer* (Figure 54.9(c)). The NS is a deck-mounted instrument that consists of a boron-loaded plastic block (roughly 10 cm on a side), which has been diagonally segmented into four prisms and read out by separate photomultiplier tubes (Figure 54.9(d)). The orientation of the spacecraft is constant such that one of the prisms faces nadir (P1), one faces zenith (P3), one faces in the direction of spacecraft motion (P2), and one faces opposite the spacecraft motion (P4). P1 is covered with a Cd foil that prevents thermal neutrons from entering the prism. Consequently, P1 is sensitive to epithermal and fast neutrons originating from the surface and atmosphere.

Neutrons with energy less than the gravitational binding energy of Mars, approximately 0.13 eV, corresponding to an escape speed of about 5000 m/s, travel on parabolic trajectories and return to Mars unless they decay by beta emission. The mean lifetime of a neutron is approximately 900 s. The most probable energy for neutrons in thermal equilibrium with the surface of Mars (for the mean Martian temperature of 210 K) is 0.018 eV, which corresponds to a neutron speed of 1860 m/s. Consequently, a significant portion of the thermal neutron population travels on ballistic trajectories and arrive at the spectrometer from above and below. Neutrons that leave the atmosphere with energies less than about 0.014 eV, just below the most probable energy, cannot reach the 400 km orbital altitude of *Odyssey*. Consequently, gravitational binding has a significant effect on the flux and energy distribution of neutrons at *Odyssey's* orbital altitude, and, in contrast to the simplified discussion in Section 3.1, gravitational effects must be accounted for in models of the flux and instrument response.

To separate thermal and epithermal neutrons, the NS makes use of the orbital speed of the spacecraft, which is

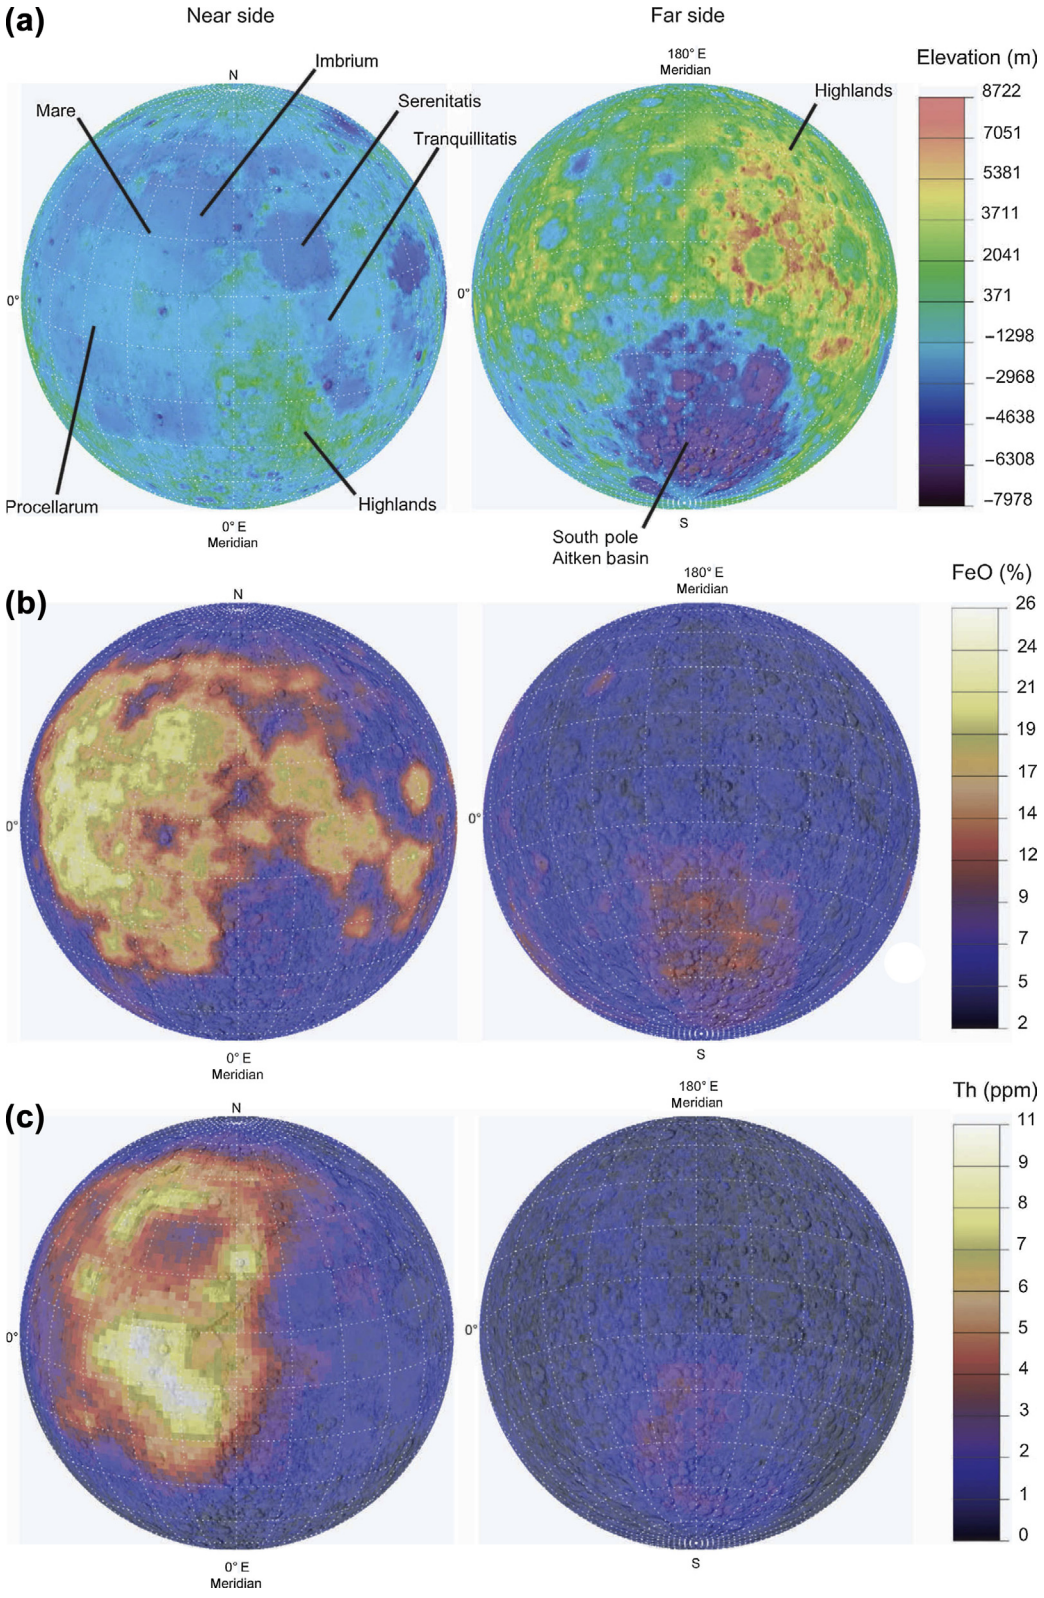

FIGURE 54.11 Orthographic projections of the lunar near and far sides: (a) elevation; (b–d) abundance (as percent or parts per million (ppm) g/g) of selected elements. The map data are superimposed on a shaded relief image. *FeO data courtesy of NASA Planetary Data System; image courtesy of United States Geological Survey.*

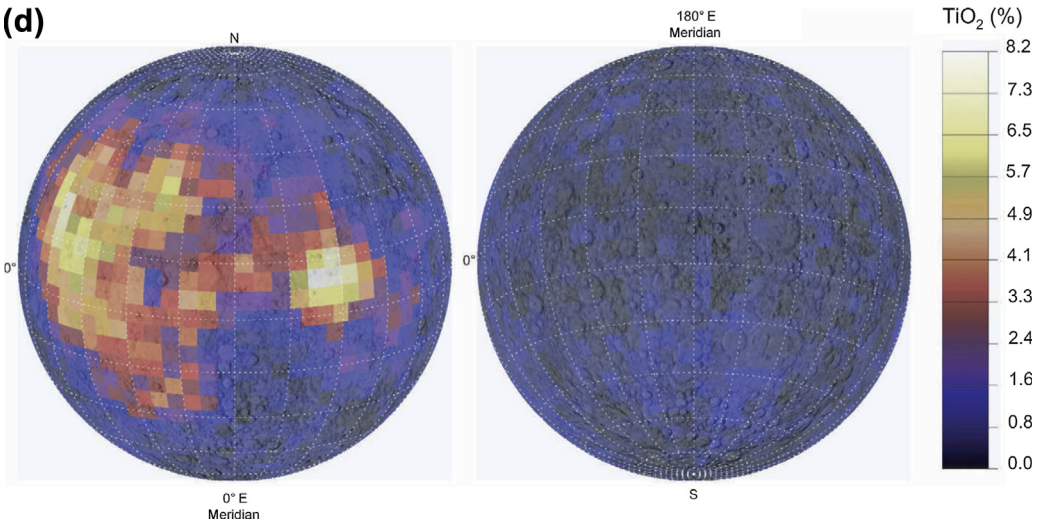

FIGURE 54.11 (*continued*).

approximately 3400 m/s, the same speed as a 0.06 eV neutron. Neutrons arriving at orbital altitudes with velocities less than that of the spacecraft (most of the thermal neutron population) cannot enter P4. So, P4 is primarily sensitive to epithermal neutrons. In contrast, P2 "rams" into thermal neutrons that arrive at the orbital altitude ahead of the spacecraft. P2 has roughly the same sensitivity as P4 for epithermal neutrons. Consequently, the thermal flux is given by the difference between the counting rates for P2 and P4.

Thermal, epithermal, and fast neutrons are sensitive to surface and atmospheric parameters, including the abundance and layering of hydrogen in the surface, the presence of strong neutron absorbers such as Cl and Fe in the Martian rocks and soil, the presence of CO_2 ice on the surface, the column abundance of the atmosphere, and the enrichment and depletion of noncondensable gasses, N_2 and Ar, as CO_2 is cycled through the seasonal caps (Table 54.2). The effect of these parameters on the neutron counting rate can be explored using a simple physical model of the surface and atmosphere as described in Section 2.2 (Figure 54.4(a)). Models of the counting rate are then used to develop algorithms to determine parameters from observations.

For example, the variation of thermal, epithermal, and fast neutron counting rates as a function of water abundance in a homogeneous surface is shown in Figure 54.12(a). Epithermal and fast neutrons are sensitive to hydrogen (as described in Section 2.2) and their counting rates decrease monotonically with water abundance. Both are insensitive to the abundance of elements in the surface other than hydrogen, as illustrated in Figure 54.12(a) by changing the abundance of Cl, which is a strong thermal neutron absorber. In contrast, thermal neutrons are sensitive to variations in major-element composition and relatively insensitive to hydrogen when the abundance of WEH is less than about 10%. Epithermal neutrons are a good choice for determining the WEH abundance because of their high counting rate and relative insensitivity to other parameters.

TABLE 54.2 Sensitivity of Neutron Energy Ranges to Mars Surface and Atmospheric Parameters

Type	Energy Range	Major Interactions	CO_2-Free Surface Parameters[1]	Atmospheric/Seasonal Parameters
Fast	>0.5 MeV	Inelastic scattering, elastic scattering	WEH abundance and layering, Average atomic mass	Atmospheric mass, CO_2 ice column abundance <100 g/cm^2
Epithermal	0.5 eV (**Cd cutoff**) to 0.5 MeV	Elastic scattering	WEH abundance and layering	Atmospheric mass, CO_2 ice column abundance up to about 150 g/cm^2
Thermal	<0.5 eV (hardened Maxwellian energy distribution)	Elastic scattering, capture (absorption)	WEH abundance, absorption by Fe, Cl, Ti. Layering of WEH and absorbers	CO_2 ice column abundance up to about 1000 g/cm^2, absorption by N_2 and Ar

[1] *The surface in the northern or southern hemisphere during summer following the recession of the seasonal cap.*

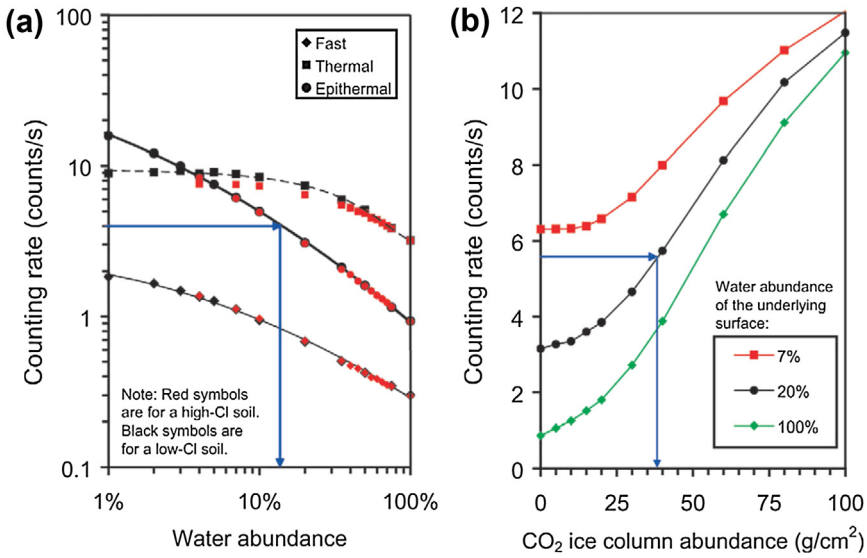

FIGURE 54.12 (a) Variation of thermal, epithermal, and fast neutron counting rates as a function of water abundance for a soil composition with low Cl abundance (black symbols). The red symbols correspond to a soil with higher Cl abundance, similar to the average composition of soils at the Pathfinder landing site. Note that the epithermal and fast neutron counting rates are unaffected by the change in Cl abundance. Because Cl is a strong absorber of thermal neutrons, the thermal neutron counting rate is sensitive to Cl abundance. (b) Variation of epithermal counting rate as a function of CO_2 ice column abundance covering homogeneous surfaces containing 7%, 20%, and 100% water ice (mixed with dry soil). Observed counting rates can be converted directly to water-equivalent hydrogen abundance or CO_2 ice column abundance using the model results in parts (a) and (b) as indicated by the arrows. The counting rate during the summer, which is a measure of the water abundance of the underlying surface, must be known in order to select the correct trend for CO_2 ice column abundance.

Measured epithermal counting rates can be converted directly to WEH as indicated by the arrows in Figure 54.12(a).

A map of WEH determined from measured epithermal counting rates is shown in Figure 54.13. In order to avoid contributions from the seasonal CO_2 ice, the northern and southern high latitudes only included counting rates measured during their respective summers. The algorithm for determining WEH included corrections for minor variations in the counting rate due to changes in the atmospheric column abundance with topography. The map gives a lower bound on WEH. Higher WEH abundances could be present if the surface is stratified, for example, with a dry top layer covering a water-rich medium.

The minimum WEH abundance on Mars ranges from 2% in equatorial and midlatitude regions to nearly 100% for the north polar water ice cap. Low abundances of WEH are found in regions such as northern Argyre Planitia, the midlatitude, southern highlands, Solis Planum, and the eastern flanks of the Tharsis Montes. Correlations between WEH and topography suggest that some aspects of the surface distribution of WEH can be explained by regional and global weather patterns. Moderate WEH abundances (8–10%) can be found in large equatorial regions, for example, in Arabia Terra. Ice stability models predict that water ice is not stable at equatorial latitudes on Mars under present climate conditions. Consequently, the moderate abundances of WEH may be in the form of hydrated minerals, possibly as magnesium sulfate hydrate. High abundances of WEH are found at high northern and southern latitudes (poleward of 60°). A detailed analysis of neutron and gamma ray counting rates suggests that the high-latitude surface outside of the residual caps consists of soil rich in water ice covered by a thin layer of dessicated material (soil and rocks). This result is consistent with models that predict that water ice is stable at shallow depths at high latitudes. Similar terrestrial conditions are observed in the Dry Valleys of Antarctica, where ice is stable beneath a dry soil layer that provides thermal and diffusive isolation of the ice from the atmosphere.

Seasonal variations on Mars are driven by its obliquity relative to the orbital plane, which is similar to that of Earth. In the polar night in the northern and southern hemispheres, atmospheric CO_2 condenses to form ice on the surface. Approximately 25% of the Martian atmosphere is cycled into and out of the northern and southern seasonal caps. Consequently, the seasonal caps play a major role in atmospheric circulation. The main questions about the seasonal caps that remain unanswered concern the local energy balance, polar atmospheric dynamics, and CO_2 condensation mechanisms. Seasonal parameters constrained by neutron spectroscopy include the column abundance of CO_2 ice on the surface and the column abundance of noncondensable gasses (N_2 and Ar) in the atmosphere. For example, analyses of gamma ray and neutron spectroscopy data reveal that the southern

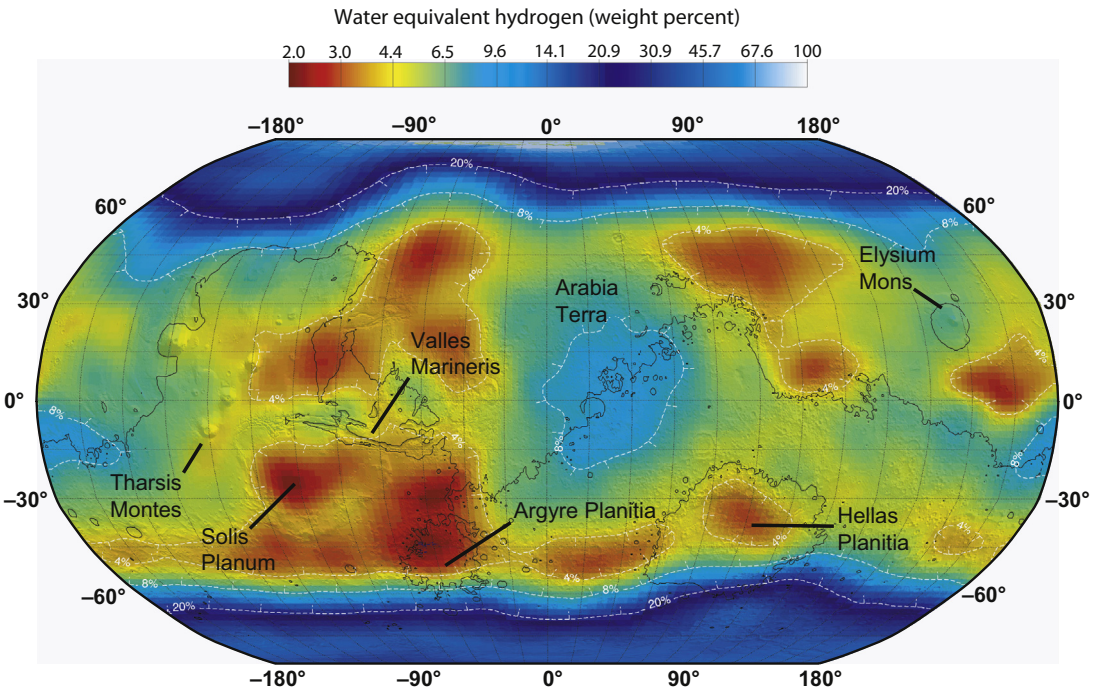

FIGURE 54.13 Global map of the abundance of WEH within the surface of Mars. The map gives a lower bound on the abundance of WEH. Contours for 4%, 8%, and 20% WEH are shown as dashed white lines. The black contour line corresponds to 0 km elevation. The map data are superimposed on a shaded relief image. *Elevation data and shaded relief image courtesy of the NASA Mars Orbiter Laser Altimeter Science Team.*

atmosphere is strongly enriched in N_2 and Ar during cap growth. The observed enrichment may be caused by the formation of a strong polar vortex accompanying the condensation flow, which inhibits **meridional mixing** of the polar atmosphere with lower latitudes.

Based on simulations, the epithermal neutron counting rate generally increases with the column abundance of CO_2 ice on the surface; however, the trend depends on the abundance of water ice in the underlying surface as is shown in Figure 54.12(b). The sensitivity of epithermal neutrons to CO_2 ice is higher for surfaces that contain more water ice. At high latitudes, the column abundance of CO_2 can be determined from seasonal epithermal counting rates, given the counting rate during summer, when no CO_2 ice is present.

Maps of epithermal counting rates are shown in Figure 54.14(a). The extent of the seasonal caps can be seen by comparing maps of the northern and southern hemispheres during the two time periods shown in Figure 54.14(a). For example, during late southern winter, low counting rates are observed in the northern high latitudes, corresponding to the summertime CO_2 frost-free surface, which contains abundant water ice. In early northern spring, elevated epithermal counting rates are observed in the northern hemisphere, corresponding to CO_2 ice on the surface.

During their respective winters, the counting rate at high latitudes increases toward the poles, which indicates that the CO_2 ice column abundance increases with latitude. The observed spatial variation is expected since the polar night lasts longer at higher latitudes and frost has more time to accumulate. The time variation in epithermal counting rates for the north and south poles (poleward of 85°), shown in Figure 54.14(b), reveals the cyclic behavior of the seasonal caps during two Mars years. The total inventory of CO_2 in the seasonal caps determined from epithermal counting data is similar to that predicted by general circulation models (GCMs) (for example, see Figure 54.14(c)). The ability to measure the thickness of the CO_2 caps in the polar night is unique to gamma ray and neutron spectroscopy. Local ice column abundances determined by nuclear spectroscopy can be compared to GCM predictions, providing information needed to improve physical models of the seasonal caps and the polar energy balance.

6. FUTURE PROSPECTS

The first two decades of the twenty-first century will likely be remembered as a golden age of planetary exploration, when new discoveries were made throughout the solar system from data acquired by an international armada of robotic spacecraft. Ongoing missions continue to provide scientists and the general public a close-up view of alien worlds, which hitherto were fuzzy points of light in the viewfinder of a telescope. Nuclear spectroscopy has played an important role in this process, providing unique chemical information inaccessible by telescopic observations.

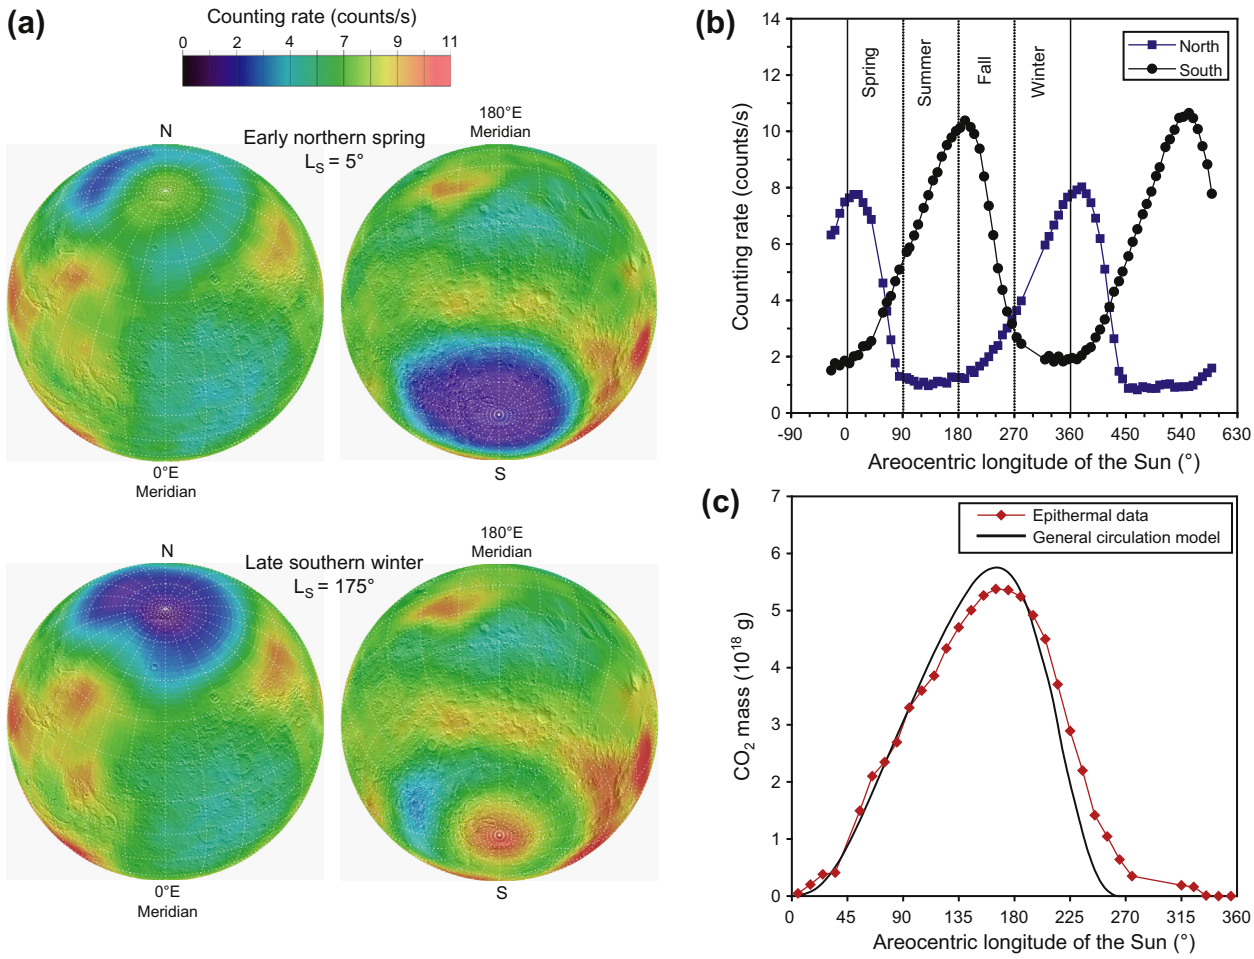

FIGURE 54.14 (a) Orthographic projections of epithermal counting rates in northern and southern hemispheres of Mars during early northern spring and late southern winter; (b) Epithermal counting rate as a function of time (**Areocentric longitude**) at the north and south poles (poleward of 85° latitude); (c) total mass of CO_2 in the southern seasonal cap poleward of 60° S from a general circulation model is compared to that determined from the epithermal counting data. *General circulation model results courtesy of NASA Ames Research Center and the New Mexico State University Department of Astronomy.*

Space exploration, whether by robots or humans, is not merely a source of wonder—it has the potential to provide us with a better understanding of the world in which we live and is a source of inspiration for future engineers and scientists. The development and application of nuclear instrumentation in support of these endeavors is expected to continue in the foreseeable future.

In the short term the planetary science community is focused on completing missions currently underway, such as MSL, MESSENGER, LRO, and Dawn. For example, the 2015 rendezvous of the Dawn spacecraft with the dwarf planet Ceres promises to provide the first spectacular view of an enigmatic, icy body, which does not appear to be represented in the meteorite collection. Surface expressions of a briny, liquid-water ocean possibly hidden beneath the crust of Ceres could be revealed by nuclear spectroscopy. Dawn's GRaND is sensitive to Cl, which is a tracer for aqueous processes, as well as volatiles such as ammonia ice, which, if present, may indicate recent cryovolcanism. A high-latitude, subsurface ice table, if detected by GRaND, could provide further clues needed to determine how water has shaped Ceres.

In the decades to come, nuclear spectroscopy will continue to be used in the exploration of the Moon, Mars, and asteroids, including preliminary investigations by robots in advance of human exploration and possible commercial endeavors. Missions to Jupiter's icy moons and the Martian satellite Phobos are also envisioned. On the Moon, nuclear spectrometers may be used on rovers or incorporated into borehole logging tools to search for and characterize water ice deposits in polar craters. On Mars, they may be included on future rovers (e.g. the 2020 follow-on to MSL), landers, weather stations, and drilling systems, for example, to search for water deep within the Martian cryosphere. In addition, there may be opportunities for low-altitude, high-spatial resolution measurements of portions of the Martian surface from an airplane or balloon.

Finally, continued effort is needed to analyze and interpret nuclear spectroscopy data that has already been acquired by missions to Mercury, Mars, the Moon, and asteroids. Mission science and instrument teams lack the resources to harvest all the information from these data sets. Thus, careful archiving of data in a stable repository accessible to the scientific community, such as NASA's Planetary Data System, is an invaluable legacy of many planetary science missions. Students of nuclear spectroscopy are sure to make new discoveries and will find the data useful for planning future missions far beyond the Moon and Mars.

Chapter Outline

1. Introduction **1185**
2. Investigating Planetary Interiors Using Seismology **1186**
2.1. Terrestrial Seismology 1186
2.2. Lunar Seismology 1187
2.3. Mars Seismology 1190
2.4. Jovian Seismology 1190
3. Investigating Planetary Interiors Using Gravity and Dynamics **1190**
4. Investigating Planetary Interiors Using Heat Flow Measurements **1192**
4.1. Measurement Techniques 1192
4.2. The Heat Flow of the Earth 1193
4.3. Lunar Heat Flow 1194
4.4. Future Investigations 1196
5. Investigating Planetary Interiors Using EM Sounding **1198**
5.1. Natural Sources 1198
5.2. Measurement Techniques 1199
5.3. Terrestrial Exploration 1199
5.4. Magnetic Sounding of the Moon 1200
5.5. Magnetic Sounding of the Galilean Satellites 1201
5.6. Future Exploration 1202
6. Summary **1203**
Bibliography **1203**

1. INTRODUCTION

Understanding the structure and processes of the deep interior of the planets is crucial for understanding their origin and evolution, as well as the surface history and processes. Planetary interiors record evidence of conditions of planetary **accretion** and **differentiation**. The crust of a planet is generally thought to form initially through **fractionation** of an early magma ocean, with later addition through partial melting of the mantle and resulting volcanism. Thus the volume (thickness) and structure of the crust can place strong constraints on the depth and evolution of a putative magma ocean. Interior processes also exert significant control on surface environments. The structure of a planetary interior and its dynamics control heat transfer within a planet through **advected** mantle material, heat conducted through the lithosphere, and volcanism.

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00055-4

2014 Published by Elsevier Inc.

Volcanism in particular controls the timing of volatile release, and influences the availability of water and carbon. The existence and strength of any planetary magnetic field depends in part on the size and state of the core.

Even the comprehension of how life developed and evolved on the Earth requires knowledge of the Earth's thermal and volatile evolution and how mantle and crustal heat transfer, coupled with volatile release, affected habitability at and near the planet's surface. Although geophysics can provide information about past processes and states required to reach this understanding, it primarily provides a "snapshot" at the present time of how the Earth behaves. This "boundary condition" is a powerful constraint on all models that describe the history of the Earth and attempt to place the evolution of life in this framework, as such models must evolve to this present state.

However, this realm of the deep planetary interior is inaccessible to direct observation, with tens to thousands of kilometers of rock blocking our "view"; note that the deepest hole ever drilled is the Kola SG-3 in Russia, which reached 12.262 km in 1989. Whereas some deep material is inevitably transported to the surface (for example, through volcanism, impact excavation, and outgassing), these materials typically undergo complex changes on their journey that are difficult to unravel and are subject to sampling biases, and thus provide limited insight.

The most effective way to explore the interior of a planet is through geophysics, as it provides tools that allow for "remote sensing" of the interior. Seismology, together with surface heat flow, magnetic and gravity field measurements, and electromagnetic (EM) techniques, have revealed the basic internal workings of the Earth: its thermal structure, its compositional **stratification**, as well as significant lateral variations in these quantities. For example, seismological, magnetic, and **paleomagnetic** measurements revealed the basic components of seafloor spreading and subduction, and seismology and EM measurements have mapped the structure of the core, compositional and phase changes in the mantle, three-dimensional velocity anomalies in the mantle related to **subsolidus convection**, and lateral variations in lithospheric structure. Additionally, seismic information placed strong constraints on Earth's interior temperature distribution and the mechanisms of **geodynamo** operation (see Magnetic Field Generation).

This chapter describes the four major classes of geophysical techniques that are used to probe deep planetary interiors: seismology, geodesy (which includes both gravimetry and planetary dynamics), heat flow, and electromagnetism. We choose to exclude techniques that have limited penetration depths (such as gamma-ray scattering, which samples to about a meter; microwave/radar techniques, which penetrate a few meters to a few kilometers; and active/exploration seismology, which typically concerns itself with depths less than 10 km), as well as a few exotic techniques (such as neutrino and muon tomography) whose use in planetary exploration is likely beyond any practical horizon.

2. INVESTIGATING PLANETARY INTERIORS USING SEISMOLOGY

2.1. Terrestrial Seismology

Seismology is the most powerful tool available for probing the interior of planets. Seismic waves (for terrestrial planets) or acoustic waves (for giant gas planets or the Sun) propagate at **seismic velocities**, or the speed of sound. These velocities, as well as the amplitude, polarization, and propagation direction of seismic waves, are directly related to quantities such as the temperature, pressure, and/or composition of the material through which the waves travel.

Modern seismology started in 1889, with the detection in Germany by Ernst von Rebeur-Paschwitz of ground displacements associated with waves generated by an earthquake in Japan. In quick succession, compositional (as manifested in seismic velocity) discontinuities between the mantle and core (the core–mantle boundary, or CMB, discovered by Richard Dixon Oldham in 1906) and the crust and mantle (the Moho discontinuity, discovered by Andrija Mohorovičić in 1909) were detected through the analysis of seismograms, as was the solid inner core, somewhat later, by Inge Lehmann in 1936 (Figure 55.1).

Waves are either reflected or **refracted** by these discontinuities, and they propagate in ways very similar to optical rays. Two types of **body waves** can propagate inside a planet: compressional waves (or P-waves), which generate pressure changes and displacements along the propagation direction, and shear waves (or S-waves), which do not generate a pressure change but rather displacements perpendicular to the propagation direction. The latter cannot exist in fluids and have velocities about 1.7 times smaller than the P velocities, and thus arrive after the P-waves. S-waves are fully reflected by solid–fluid boundaries, and these reflections are key to detecting underground fluids, such as the liquid iron of the outer core or underground oil and natural gas reservoirs. Because of its power and flexibility, seismology has been used extensively for both basic research and resource exploration, and now enables three-dimensional imaging of deep crustal structure or of the convection patterns in the Earth's mantle, through the small changes in seismic velocities generated by both temperature differences and the preferred orientation of the component crystals in mantle rocks in the direction of convective motion.

In addition to the crust–mantle and core–mantle boundaries, several additional global discontinuities have been found in the mantle and in the core by seismology. In the mantle, these discontinuities mark the transition between an olivine upper mantle (at 600 km depth for one

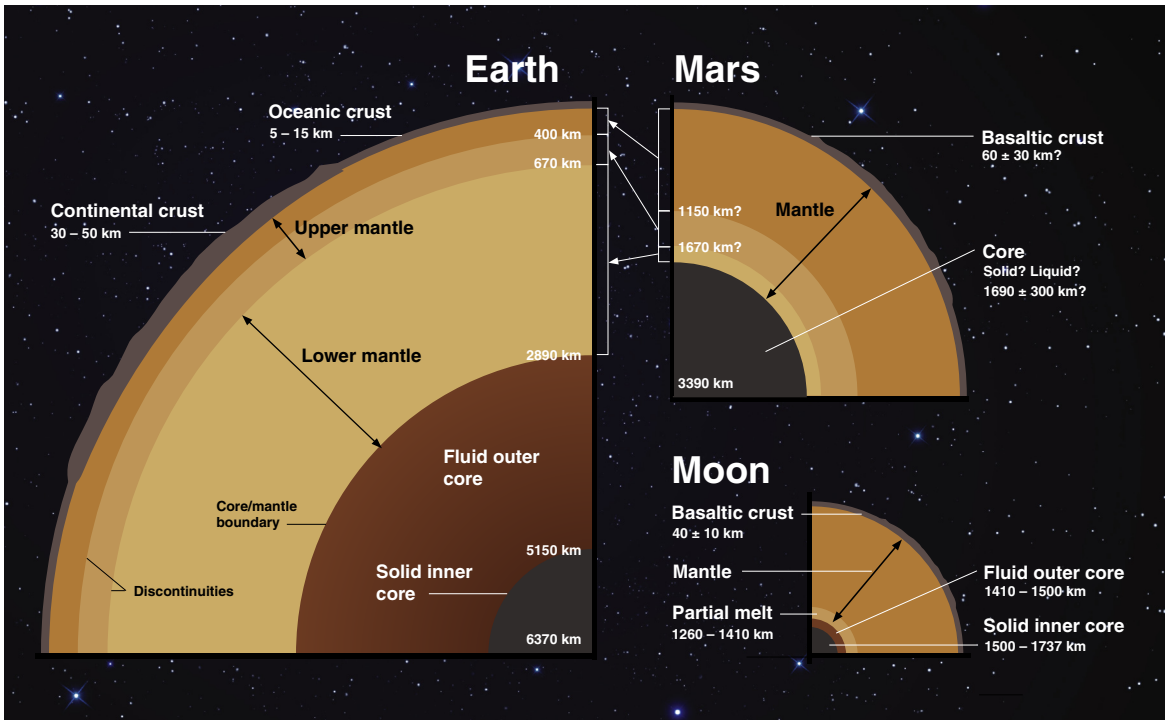

FIGURE 55.1 Interior structure of the Earth and Moon, as seen by seismology. The expected structure of Mars is shown in comparison. Shown are the depths to the major interior boundaries of the planets, between the crust, mantle, outer core, and inner core, as well as discontinuities at the two major phase boundaries. On the Moon there also appears to be a partially-molten zone at the base of the mantle. For the Earth the range of observed crust thicknesses are given, whereas for the Moon and Mars the uncertainty in the average crust thickness is shown. A smaller planet with weaker gravity has a slower pressure increase with depth; consequently, most of the Martian mantle is in a pressure state similar to the Earth's upper mantle, while most of the Moon's mantle corresponds to the conditions in only the first 300 km of the Earth.

of the most widely accepted average Earth models, called PREM, or Preliminary Reference Earth Model) and a perovskite lower mantle (at 770 km depth). In the region between these two discontinuities, called the transition zone, the dominant mineral, olivine, is in a spinel crystal structure. These two discontinuities may play a major role in controlling the convection of the mantle and therefore its geodynamic evolution. Much of modern seismology focuses on the details of these discontinuities, such as their topography or the thin transition zones just above the CMB (perhaps associated with a post-perovskite phase in the mantle) and outer-inner core boundary (due to the accumulation of lighter elements in a slushy layer just above the solid inner core).

Two other major discoveries have marked terrestrial seismology. The first was the measurement of global oscillations of the Earth, which are bell-like global vibrations with discrete periods directly related to the Earth's structure and composition. This was first done following the 1960 9.5 magnitude earthquake in Chile, which remains the largest earthquake ever observed with seismometers. These data, along with those subsequently recorded for quakes with magnitudes larger than 7−7.5, have revealed not only the natural resonant frequencies of the Earth (called eigenfrequencies, with periods ranging between 52 min and about 1 min) but also a fine structure of these tones, mathematically comparable to the fine structure of atoms in quantum mechanics.

The second major discovery was made in the early twenty-first century. Much of the ground noise measured during the quiet periods (when no coherent seismic waves from quakes are noticeable) is in fact the superposition of seismic waves excited by ocean waves and atmospheric winds and turbulence. It was shown that analysis of these vibrations can be used to measure not only the seismic speeds between two locations but also very small time variations of these seismic speeds, associated, for example, with changes in the structure of volcanoes prior, during and after an eruption or in the crustal structure after an earthquake. These findings opened the area of time-dependent seismology, which aims to detect temporal changes in the Earth's structure.

2.2. Lunar Seismology

In a sense, the long-term goal of planetary seismology is to repeat this geophysical success story on other planets. Planetary seismology began almost at the same time as space exploration itself; one of the instruments carried by the Ranger 3 mission, launched toward the Moon on January

26, 1962, was a seismometer. This first attempt, as well as those of Rangers 4 and 5 (also launched in 1962), all failed, but the first Apollo mission, Apollo 11, successfully deployed the first planetary seismometer. This instrument was powered by solar panels and did not survive the end of the second lunar day. The next five Apollo missions, however, each had a long-lived nuclear-powered seismometer called a Passive Seismic Experiment (PSE; Figure 55.2), able to record both long-period and high-frequency ground displacements. With the exception of Apollo 13, they were all successfully installed and worked until 1977, forming a network of four stations. This regional network (stations 12 and 14 were only about 180 km apart and formed one corner of an approximately equilateral triangle, with stations 15 and 16 at the other corners, each about 1100 km away), was complemented by local seismic arrays at the Apollo 15, 16, and 17 sites for active seismic studies of the shallow lunar subsurface. A gravimeter, deployed at the Apollo 17 site, was also able to detect seismic waves with a much lower sensitivity than the Apollo PSE seismometers. These instruments remain the only seismometers operated on the Moon, and this is likely to remain the case until at least 2020, as none of the confirmed missions of this decade plan to deploy new seismometers on the Moon.

Due to their extraordinary sensitivity, the Apollo PSE instruments revolutionized our understanding of the lunar interior. Even more surprising is that their data are still being used today to perform original research, more than 35 years after they were turned off.

The principle of a seismometer is to detect the small vibrations of the ground associated with passing seismic waves. Although technology development since the 1960s has allowed higher and higher sensitivities, the fundamental design on which virtually all seismometers are based has remained the same for more than 120 years: a mass, called the proof mass, supported by a spring. When the ground (and the instrument which is fixed to it) moves, the inertia of the mass causes it to remain stationary, which is physically equivalent to a motion with respect to the frame of the instrument. The displacement or velocity of the mass is detected by a transducer. The Apollo seismometers were able to detect ground displacement with amplitudes of about 0.5 Å, which is of the order of the radius of a hydrogen atom. These measurements were performed simultaneously by a three-axis (vertical and two mutually perpendicular horizontal directions) long-period instrument, focused on periods around 2 s, and by a single-axis (vertical) short-period instrument, focused on vibrations with periods of around 0.125 s.

These instruments discovered a seismically active Moon and detected about 12,500 moonquakes during more than 7 years of operation. The Moon is still only weakly active compared to the Earth; all these events have very small magnitudes with respect to terrestrial standards, and the largest moonquake has a **moment magnitude** (M) of only about 4, as compared to $M \sim 9.5$ of the largest quake detected on the Earth (the 1960 Chile earthquake). This is a factor of 10^8 smaller in terms of long-period amplitudes.

Three types of seismic signals were detected (Figure 55.3): about 30 were tectonic quakes, including the largest ones. Like most earthquakes, they occurred in the upper part of the planet, at depths no greater than about 200 km. Much more numerous (almost 9000 events) were the deep moonquakes, occurring at depths between 800 and 1200 km. These events were found to occur with the periodicity of the lunar orbit around the Earth, and occurred at a limited number of epicenters (less than 300), where quakes repeated regularly during the 7 years of network operations. These quakes appear to be associated with the solid-body tidal stresses caused by the Earth on the Moon, which are modulated by small variations of distance between the two bodies. Most of these quakes are very small, most with M smaller than 2 and only a few reaching magnitude 3. The last class of events is meteoroid impacts, with almost 2000 impacts detected. In contrast to the Earth, no atmosphere

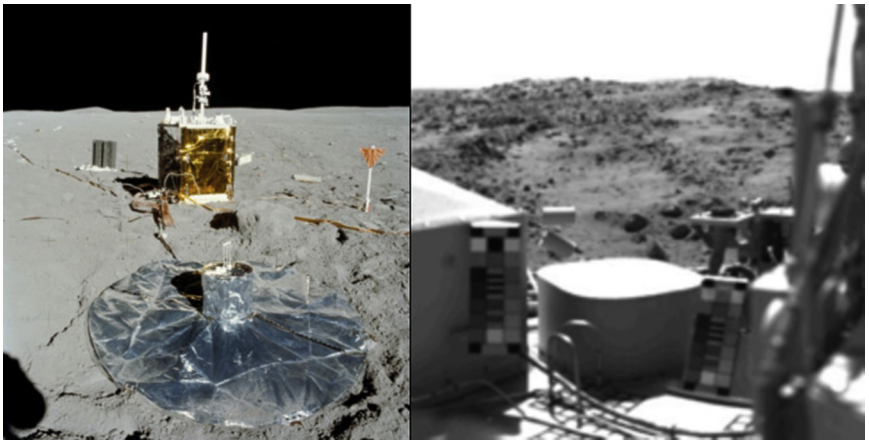

FIGURE 55.2 On the left is an Apollo PSE seismometer on the lunar surface. The image on the right shows the Viking seismometer, on the deck of the Viking Lander (the shorter box near the center of the picture).

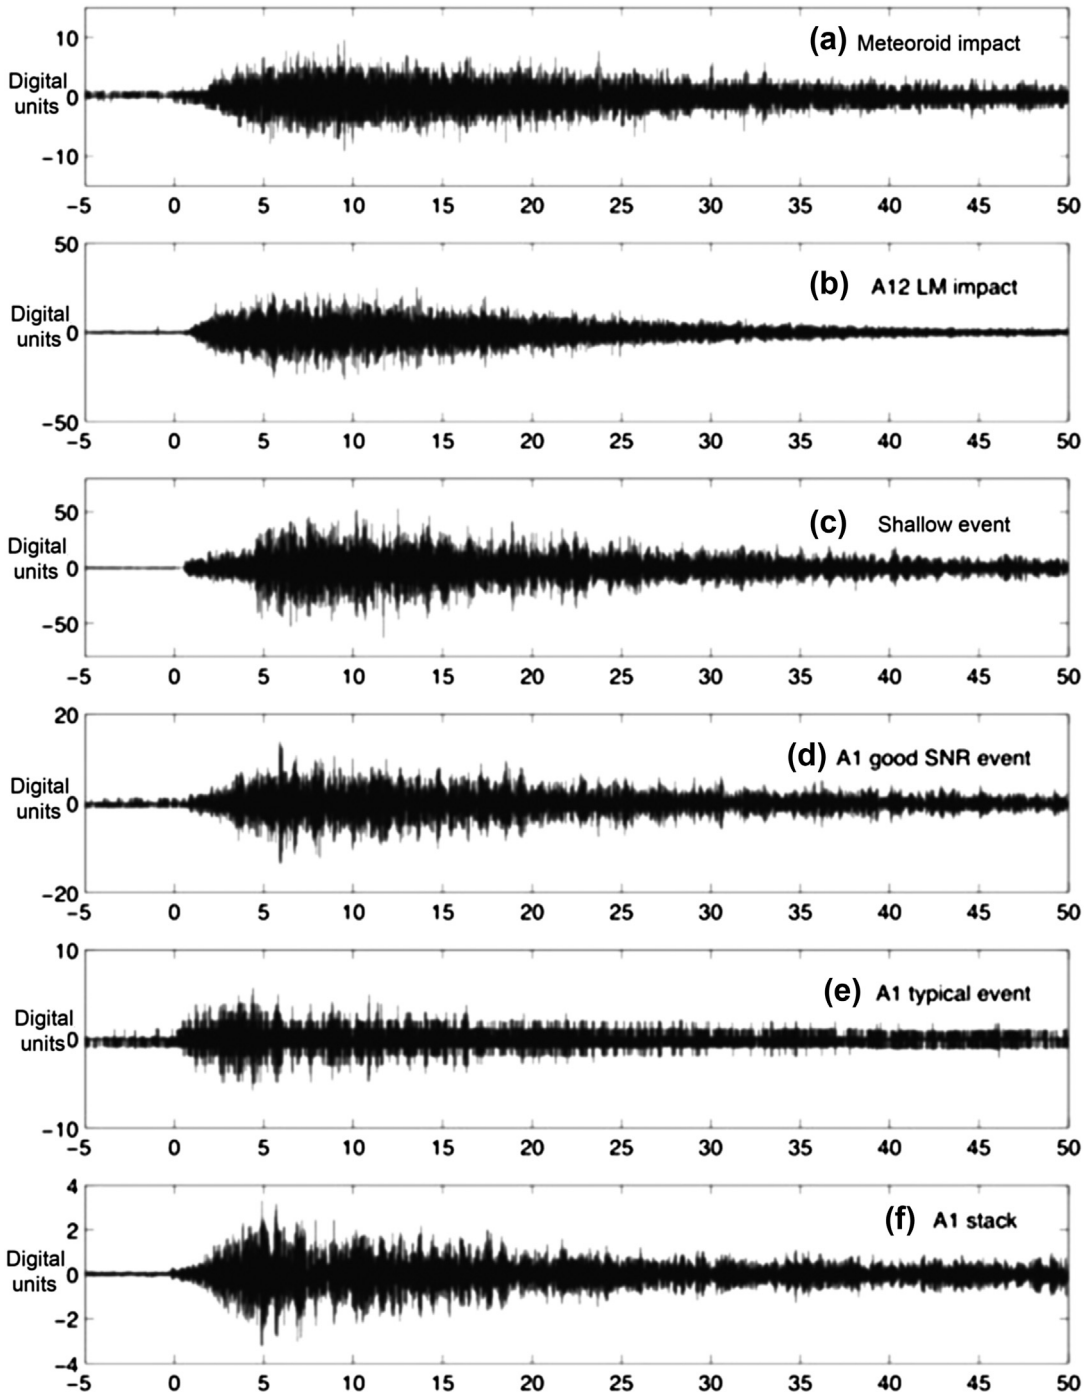

FIGURE 55.3 Examples of lunar seismograms for (a) natural impacts, (b) artificial impacts, (c) tectonic quakes, and (d–f) deep moonquakes. All seismograms are recorded on long period channels by the Apollo Passive Seismic Experiment; one digital unit corresponds to 0.5 Å of ground displacement at 0.5 Hz; *x*-axis is time in minutes. The tectonic quake in this example is one of the largest magnitude shallow events and has a comparable amplitude to the chosen artificial impact. Note the low amplitude and poor data quality of typical deep moonquakes in (e). However, the repeated similar waveforms of deep moonquakes from distinct source regions allows stacking of many events to improve the signal-to-noise ratio (f). Note: LM is Lunar Module, SNR is Signal-to-Noise Ratio. *From Lognonne and Johnson (2007).*

protects the Moon from **meteoroids**, and they can therefore generate seismic waves when they hit the lunar surface with mean impact velocities of about 20 km/s. All these seismic events were characterized with seismograms very different from those typically seen on the Earth. Due to the lack of atmosphere, the surface and subsurface lunar materials are extremely dry. Moreover, the billions of years of impacts have generated a highly fractured, low-seismic-velocity zone near

the lunar surface, which is very effective in trapping and scattering waves. These conditions result in extremely long duration (sometimes hours in length) seismic signals, even for very small quakes. Such long reverberations are never observed on the Earth.

Thanks to these seismic sources, both the location of many of these events and the associated travel time of the seismic waves between the **epicenter** and the seismic stations have been determined, enabling scientists to model the interior of the Moon and to identify a crust, a mantle, and a core, like on the Earth. The crustal thickness has a mean value of 40 ± 5 km. From there down to about 1400 km, a relatively homogeneous mantle was seen, possibly relatively hot and **attenuating** at depths larger than 1100−1200 km. And finally, a 350-km-radius liquid core was discovered in early 2012, more than 40 years after the transmission of the Apollo data, thanks to new seismic processing techniques and to the capability of the modern computers to perform calculations beyond the reach of the 1970s' Apollo seismologists. Seismology has also been able, through the measurement of seismic velocities in the mantle, to constrain the temperature at the bottom of the mantle. Because of the different melting temperatures for iron and iron alloys, this suggests that the lunar core is composed of iron mixed with some light element rather than pure iron. Evidence for seismic discontinuities in the lunar mantle remains weak. A possible discontinuity at a depth of 500 km, proposed by the Apollo seismic experiment team, is still controversial, as it might in fact be related to the poor resolution of the Apollo network at this depth. Thus much more remains to be done on the Moon in terms of seismology, and several prospective projects plan to redeploy seismometers on our natural satellite.

2.3. Mars Seismology

The seismic exploration of Mars was the logical next step after the Moon, and this motivated the inclusion of seismometers in the payload of the two Viking landers, launched by National Aeronautical and Space Administration (NASA) to Mars in 1976 (Figure 55.2). Unfortunately, due to cost and technical limitations, the seismometers were about 10,000 times less sensitive than the Apollo seismometers and were mounted on the lander deck, not placed in direct contact with the ground. In addition, the seismometer on Viking 1 failed to uncage (the seismometers were locked, or "caged", during flight to avoid damage) due to a technical failure. The seismometer onboard Viking 2 lasted for 19 months on Mars, but due to operational limitations it accumulated only a little more than 3 months of usable data and did not detect any marsquakes. During the day, the data were dominated by wind-generated lander vibrations, while during the night, its quality was limited by the seismometer's poor sensitivity and coupling to the ground. Given the various limitations, this lack of marsquake detection remains compatible with a Mars activity comparable to that of the Earth away from tectonic plate boundaries (where most of the activity is located). Thus it is generally accepted that Mars likely has a level of seismic activity between this upper limit and that of the Moon. Constraining this level of activity will be the first goal of the Interior exploration using Seismic Investigations, Geodesy and Heat Transport (InSight) project, which is currently under development by NASA. This mission aims to deploy a seismometer on Mars in September 2016, together with other geophysical sensors (heat flow, geodetic, and magnetic measurements, in addition to some atmospheric sensors).

2.4. Jovian Seismology

Mars' seismic activity will therefore remain hidden for a few more years. But the next planet, Jupiter, has finally revealed its continuous vibration after almost 30 years of attempted observations. In this case, data are obviously not coming from seismometers, but from remote observation through telescopes on the Earth. The technique consists of measuring the vertical velocity of the Jovian optical surface with spectroscopic techniques originally developed for solar and stellar seismology. Thanks to a steady increase in sensitivity, the observations have finally detected continuous oscillations with an amplitude of about 0.5 m/s, putting Jupiter third on the list of the bodies of the solar system for which global oscillations have been detected (after the Earth and the Sun). It is likely that a significant improvement in these observations will be made in the next 5 years, and we can therefore reasonably expect that by the end of this decade, comparative seismology will be possible among three terrestrial bodies (Earth, Moon, and Mars) and between two fluid ones (the Sun and Jupiter).

3. INVESTIGATING PLANETARY INTERIORS USING GRAVITY AND DYNAMICS

Historically, the most common method for exploring planetary interiors has been through observed variations in their gravitational fields, orientation, and rotation, which can be collectively described as geodesy. The data can be obtained as a by-product of the communication and navigation systems of planetary probes flying by, in orbit around, or landed on the planets. Gravity and rotation provide information primarily on the distribution of mass within a planet, including density differences due to overall structure (crust, mantle, and core) and from processes such as volcanism and tectonic deformation.

The major disadvantage of these techniques is their inherent ambiguity. It can be shown mathematically (**Gauss' theorem**) that for any gravity field measured

outside a body, there are an infinite number of distinct mass distributions inside the body that could generate that field (a similar result holds for rotational dynamics). While this seems daunting, in practice, there is usually other information that can be used to constrain the possible (or likely) distributions. Thus, geodetic methods are most powerful when used in combination with other techniques.

Spatial variations in the gravity field of planetary bodies are obtained by monitoring the trajectory of passing or orbiting spacecraft. For example, if an orbiter passes over a buried body with higher density than its surroundings, it will experience a higher gravitational attraction than otherwise and will be pulled slightly downward in its orbit. This deviation is determined via Doppler (which gives velocity) and ranging (which gives distance) measurements on radio links between the Earth and the spacecraft. These measurements use the precision transmitters and receivers at large deep space antennas such as the ESTRACK stations (European Space Agency (ESA) TRACKing stations) at Perth and Madrid and the NASA DSN (Deep Space Network) antennas at Goldstone, Madrid, and Canberra (see Figure 55.4). The precision possible with these systems is impressive, with resolution of velocity changes of fractions of a millimeter per second and absolute locations in inertial space of a few centimeters now possible.

For the analysis of these radio science data and for theoretical simulations of planetary interiors with which to compare them, sophisticated numerical codes are used to compute accurate orbits of spacecraft from radio tracking data. Spatial and temporal variations in the gravity field can be used to determine physical properties of the interior and atmosphere of the planet. Since the beginning of the space age, the large-scale structure of the gravity field of planets and moons has been successfully used to determine the moment of inertia, which is a measure of the global density distribution and an important constraint on the interior structure.

FIGURE 55.4 Deep Space Network 70-m station at Goldstone, California.

In addition to global mass distribution, regional or local properties above target surface features can also be measured from the deviation of spacecraft trajectories. As an example, the Mars radio science experiment (MaRS) aboard Mars Express acquired gravity data during a number orbits above the Tharsis volcanoes, which form the largest volcanic region in the solar system.

The data analysis shows that the overall density of the volcanoes is higher than the average density of the Martian crust, in agreement with the basaltic composition of many Martian meteorites probably originating in the Tharsis area. One volcano, Ascraeus Mons, differs from the others in being of lower density in its upper part, although its overall density remains high. If the Tharsis Montes were built in succession by a single moving mantle plume, this suggests that Ascraeus Mons formed as the last of the Tharsis Montes. These data also show that Olympus Mons, the highest mountain in the solar system, lacks a low-density root, which indicates that it was built on a lithosphere of high rigidity, whereas the other volcanoes partly sank within a less rigid lithosphere.

Solid-body tides, which can be observed through their time-variable effect on the gravity field, can also provide information on the deep interior. These are particularly sensitive to global fluid layers such as a liquid iron core in terrestrial planets or an internal subsurface ocean in icy satellites. From the latest available data on the **moment of inertia** and the tidal amplitude of Mars, the best estimates yet obtained have been determined for the core size and composition of Mars. These show that the core size is expected to be between 1715 and 1850 km and that the weight fraction of sulfur in the core is between 13% and 18%. The addition of sulfur decreases the melting temperature of iron, and for the current estimates of the internal temperature of Mars, this high sulfur estimate implies that the core of Mars is entirely liquid and contains no solid inner part, in contrast to the Earth.

Constraints on planetary interiors can also be obtained from rotation variations. Three broad classes of rotation variations are usually considered: rotation rate (also called length-of-day) variations, orientation changes of the rotational axis with respect to inertial space (**precession** and **nutation**), and orientation changes of the planet's surface with respect to the rotation axis (polar motion and polar wander). These are due to both internal (angular momentum exchanges between solid and liquid layers) and external (gravitational torques) causes. As the rotational response depends on the planet's structure and composition, insight into the planetary interior can also be obtained. This is particularly so for the rotational variations due to well-determined external gravitational causes, such as for the nutations of Mars and the **librations** of Mercury and natural satellites.

Observation of the rotation may be performed using orbital measurements or, more precisely, by direct tracking

of landers on the surface of a planet. The latter will be the case with Rotation and Interior Structure Experiment (RISE) onboard the InSight Lander. Precise Doppler tracking from the Earth of a location on the Martian surface over extended periods (months to years) can be used to obtain Mars' rotation behavior. More specifically, measuring the relative position of the lander on the surface of Mars with respect to the terrestrial ground stations allows the reconstruction of Mars' time-varying orientation and rotation in space. Precession (long-term changes in the rotational orientation occurring over many tens of thousands of years) and nutations (periodic changes in the rotational orientation occurring on subannual timescales) as well as polar motion (motion of the planet's surface with respect to its rotation axis) are determined from this experiment and are used to obtain information about Mars' interior. Precession measurements improve the determination of the moment of inertia of the whole planet, which is particularly sensitive to the radius of the core. Using geochemical constraints to specify a plausible range of possible compositions, the core radius is expected to be determined with a precision of a few tens of kilometers (compared to $\sim$150 km currently). A precise measurement of variations in the orientation of Mars' spin axis also enables an independent (and more precise) determination of the size of the core via the core resonance in the nutation amplitudes. The amplification of this resonance depends on the size, moment of inertia, and flattening of the core. For a large core, the amplification can be very large, ensuring the detection of the free core nutation and determination of the core moment of inertia.

At the same time, measurement of variations in Mars' rotation rate reveals variations of the angular momentum due to seasonal mass transfer between the atmosphere and polar caps and zonal winds.

Investigation of the dependence of rotation variations, gravity field, and tidal variations on interior and atmosphere properties and orbital motion characteristics is essential to understand the interior and evolution of terrestrial planets. These studies include the development of advanced models of rotation, the construction of detailed models for the structure and dynamics of solid and fluid layers of the planets, the investigation of the dynamical response of these models to both internal and external forcing, the modeling of the orbital motion of large bodies of our solar system, and the inclusion of general relativistic effects into the data analysis.

4. INVESTIGATING PLANETARY INTERIORS USING HEAT FLOW MEASUREMENTS

The amount of heat escaping from a planet's interior is diagnostic of the subsurface temperature structure, which in turn is connected to the activity we observe on the surface. Essentially all geologic activity, except for meteorite impacts and wind and water erosion (which are powered by the sun), are driven by the internal heat engine of a planet. In addition, many material parameters of crustal and mantle rocks are temperature dependent, and subsurface temperatures influence the velocity of seismic waves, the **rheology** of crustal and mantle rocks, as well as the capability of crustal rocks to record **remanent magnetic fields** through the magnetic minerals' **Curie temperatures**. In addition, subsurface temperatures drive hydrothermal circulation in the crust, and, apart from pressure, temperature is the main factor controlling melting in the crust and upper mantle. Temperature differences also drive solid-state convection in the mantle and determine tectonic surface deformation to a considerable degree.

Heat emanating from a planetary interior derives in unknown proportions from primordial heat accumulated during accretion and core formation, and heat released by the decay of radioactive elements. Apart from the short-lived isotopes ^{26}Al and ^{60}Fe that have considerable influence on the earliest evolution of a planetary body, decay of ^{40}K, ^{232}Th, ^{235}U, and ^{238}U is the main source of heat in planetary interiors. Heat is transported to the surface through mantle convection and thermal diffusion, before it is finally radiated to space. Therefore, planets act like heat engines, and planetary cooling from initial temperatures after accretion and core formation is governed by the efficiency of the different heat transport mechanisms.

In order to quantify the heat flow from the Earth's interior, the first terrestrial heat flow measurements were conducted in the late 1930s by Bullard and Benfield, and tens of thousands of measurements have been performed since. It was found that heat flow varies substantially with tectonic setting, composition, and the age of rocks, and the average amount of heat lost from the Earth's interior was estimated to be of the order of 40 TW. It is estimated that only about 35% of the Earth's heat loss is balanced by present-day heat generation in the deep interior, while the bulk of the radiated energy is drawn from primordial heat accumulated during accretion and differentiation and previous radioactive decay. This implies that the Earth's interior is cooling more efficiently than a purely conductive sphere, a process likely driven by the plate tectonics cycle and the associated transport of hot mantle material to the surface at midocean ridges. However, the fraction of the heat released in the interior to that which is radiated to space, known as the Urey ratio, could have been significantly larger in the past due to greater radiogenic heat production and possibly less efficient cooling in previous epochs of the Earth's evolution.

4.1. Measurement Techniques

A measurement of the planetary heat flow requires knowledge of the subsurface temperature gradient as well

as the thermal conductivity of the material in which the measurement is made. The amount of heat passing perpendicularly through a surface of unit area is then given by Fourier's Law, $F = k\,\mathrm{d}T/\mathrm{d}z$, where k is the thermal conductivity (in units of W/m/K), $\mathrm{d}T/\mathrm{d}z$ is the thermal gradient (in units of K/m), and F is heat flow, or, more precisely, the heat flux density, in units of W/m^2.

Apart from the heat originating in the planetary interior, temperatures at shallow crustal depths can be significantly affected by **diurnal**, annual, or even climatic changes of the surface temperature. While daily temperature fluctuations penetrate crustal rocks to depths of only a few meters, annual temperature variations have noticeable effects down to a few tens of meters, while glaciation cycles, which act on 100,000-year timescales, can affect subsurface temperatures to depths of a few kilometers. In order to measure the planetary heat flow, measurements must be conducted below the influence of these perturbations, or, alternatively, their influence must be taken into account by modeling.

Therefore, heat flow measurements on the Earth's continents are generally performed in boreholes whose depths extend from a few tens to a few hundreds of meters. The thermal gradient in the boreholes is determined by logging temperatures for extended periods of time, and the thermal conductivity of the host rock is generally determined from drill cores which are investigated in the laboratory. In contrast, because of its extremely stable surface temperature, measurements in the oceanic crust can be performed at much shallower depth, and probes derived from the original design by Bullard (see Figure 55.5) and having lengths of several meters are usually employed. This reduction in measurement depth is made possible by the almost isothermal conditions at the bottom of the oceans. In ocean bottom measurements, thermal conductivity of the sediments is usually determined from drill cores using needle probes in the laboratory, but can also be estimated from the cooling curves of the probes in situ. Integrated gradient and thermal conductivity probes using active heating techniques to determine thermal conductivity in situ were proposed by Christoffel and Calhaem in the late 1960s, and have been widely applied since then.

First attempts to measure extraterrestrial heat flows were made using ground-based radio observations in the early 1960s, but reliable results were only later obtained during the Apollo missions, where Bullard-like probes were emplaced in the lunar subsurface by the Apollo astronauts. Remote sensing techniques have also been proposed for extraterrestrial heat flow measurements, and microwave emissions, which are sensitive to temperatures at different depths for different wavelengths, could in principle be used to determine the thermal gradient in the lunar subsurface. Lacking insolation, surface temperatures in permanently shadowed polar craters are strongly influenced by interior heat flow, and infrared emissions from such regions could be used to estimate heat flow near the lunar poles from orbital measurements. However, there are large uncertainties associated with the interpretation of such data, so in situ measurements using borehole logging techniques remain the most reliable for surface heat flow determination to date.

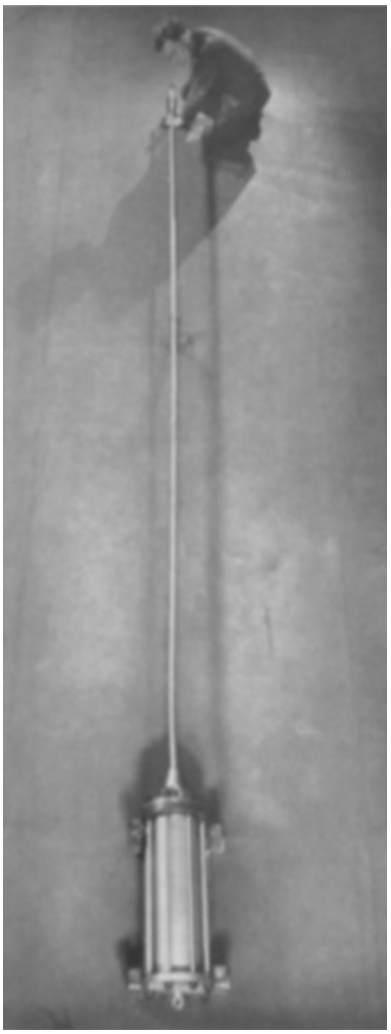

FIGURE 55.5 Original design of a heat flow probe for marine measurements by *Bullard (1954)*. The approximately 5-m-long and 3-cm-thick probe is equipped with temperature sensors to record the thermal gradient as well as the cooling of the probe after insertion into the sediments. Data logging equipment is located in the pressure-proof cylinder at the top of the probe (bottom of the image). *From Bullard (1954).*

4.2. The Heat Flow of the Earth

The heat flow from the Earth's interior has been determined at more than 20,000 field sites in both continental and oceanic terrains, and a representation of the data is shown in Figure 55.6. Surface heat flow is largest near divergent plate boundaries where hot mantle material is advected

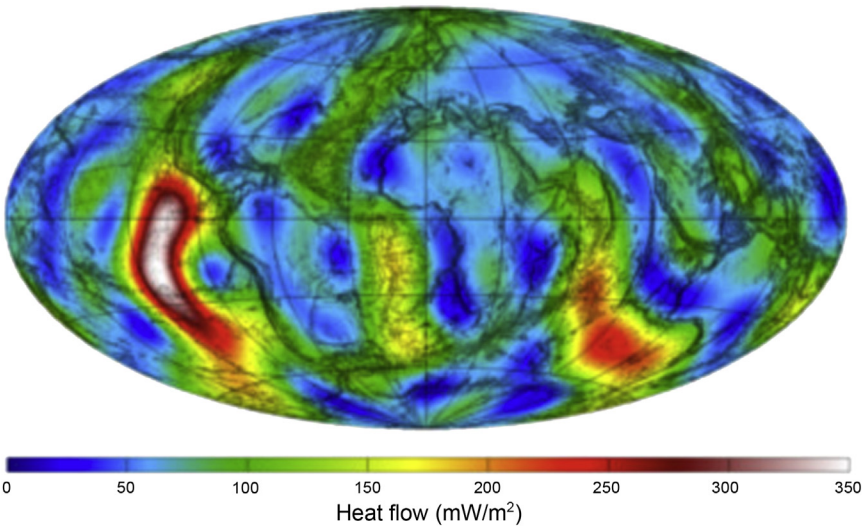

FIGURE 55.6 Color-coded map of the terrestrial heat flow derived from 24,774 measurements at 20,201 sites (*Pollack et al. (1993)*), plotted over a shaded relief topographic map (Hammer projection). Heat flow is at a maximum at midocean ridges where hot mantle material is advected toward the surface by mantle convection. Minimum heat flow is observed on the continental shields.

toward the surface, and heat flow in the oceanic lithosphere averages 101 mW/m^2. In contrast, continental heat flow is significantly less and measures only 65 mW/m^2 on an average. This difference is a direct consequence of the difference in heat transport efficiency, which is partly advective in the oceanic crust, but purely conductive in the continents. Heat flow on the continents is dominated by the heat released through radioactive decay in the crustal rocks, and is at a minimum in old continental regions. Taken together, the average heat loss from the surface of the Earth is 87 mW/m^2, corresponding to a total heat loss of 44.2 TW. Using numerical simulations, it has been shown that this heat loss corresponds to a present-day cooling rate of the Earth's mantle of 50 ± 25 K/Gyr.

The heat flow pattern observed on the Earth's surface reflects the action of the plate tectonics cycle, and surface heat flow is thus indicative of interior processes. Plate tectonics (see Evolution of Planetary Interiors and Earth: Surface and Interior) appear to be absent on planets other than the Earth, which is usually attributed to the lack of surface water on these bodies. Water acts to weaken the crustal rocks and facilitates breakup and finally subduction of the lithospheric plates.

The identification of large-scale heat flow variations on planets other than the Earth would further our understanding of heat transport mechanisms in these bodies, ultimately shedding light on the question why plate tectonics as observed on the Earth is unique in the solar system. Through analysis of the global heat flow data set it was found that the surface heat flow field correlates well with the seismic shear wave velocity in the upper mantle, thus establishing a link between seismic and heat flow investigations. For the Earth, heat flow data is collected and archived by the International Heat Flow Commission, and the global data set can be accessed through their website.

4.3. Lunar Heat Flow

In contrast to the Earth, structures like subduction zones, back-arc volcanoes, or midocean ridges are absent on the Moon, indicating the absence of plate tectonics. Instead, the Moon's interior can be viewed as an immobile outer shell underlain by a convecting mantle, a style of convection termed "stagnant lid convection". In fact, there is debate as to whether the Moon continues to convect. In any case, since no hot material is being transported directly to the surface, the heat flow pattern on the Moon only weakly reflects any mantle convection pattern, thus making the lunar surface similar to Earth's continental shields from a heat flow perspective.

Therefore, lunar heat flow mainly reflects the distribution and abundance of heat-producing elements in the lunar crust. Surface abundances of radioactive elements can be determined from orbit using gamma-ray spectroscopy, as gamma-ray data are sensitive to elements in the upper few decimeters of the crustal material. In this way, the Lunar Prospector mission between 1998 and 1999 determined elemental abundances on the lunar surface. It was found that K and Th vary widely across the surface, being significantly enriched in a region in the Oceanus Procellarum. This unique geochemical province was subsequently termed the Procellarum KREEP (for potassium (K), rare earth elements (REE), and phosphorus (P)) Terrane (PKT). A map of thorium on the Moon is shown in Figure 55.7. Thorium in the PKT is enriched by a factor of up to 10 with respect to the surrounding highlands, and although slightly elevated Th concentrations are observed

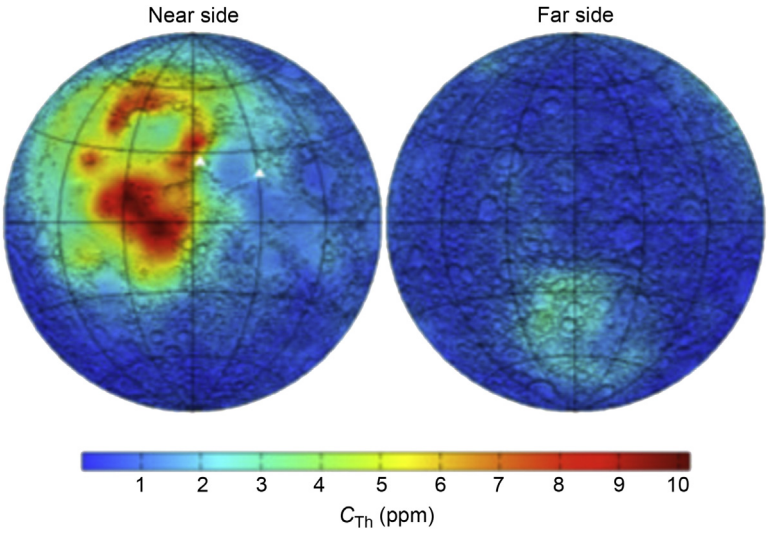

FIGURE 55.7 Surface abundance of Th as determined from Lunar Prospector gamma-ray data. The Procellarum KREEP terrane exhibits Th abundances which are elevated by up to a factor of 10 with respect to the lunar highlands. The Apollo 15 and 17 landing sites are indicated by triangles.

in the South Pole—Aitken Basin on the lunar farside, such large concentrations are absent anywhere else on the surface. However, from remote sensing data alone, the depth extent of the deposits cannot be determined, and in situ heat flow experiments are necessary to address this question.

While deep boreholes are needed to reliably determine the heat flow from the interior of the Earth, drilling deep holes on extraterrestrial bodies is inhibited by the mass of the necessary equipment. For the foreseeable future, the subsurface of the Moon will only be directly accessible to a depth of a few meters, and the deepest holes drilled by the Apollo astronauts extended to 2.4 m depth (Figure 55.8). Given that surface temperature fluctuations on the Moon are large, deeper boreholes might seem to be required for heat flow measurements. But the shallow depth of the boreholes is compensated by the low thermal conductivity of the lunar regolith, which rapidly attenuates surface temperature fluctuations. Thus nearly isothermal conditions are attained at a depth of only about 1 m, and temperature gradients can be reliably determined from data collected at shallow depth. Similar approaches would be feasible on Mercury or Mars. The latter environment is more challenging due to the presence of the Martian atmosphere, which acts to increase thermal conductivity and thus the penetration depth of temperature perturbations.

The history of extraterrestrial heat flow measurements starts with the ill-fated Apollo 13 mission, and the first successful measurement was not performed until Apollo 15. Technical problems during the emplacement of the probes on Apollo 16 frustrated a successful measurement during that mission, and only one further successful measurement was performed during Apollo 17 before the Apollo program ended. Material including images, videos, and radio communication transcriptions connected to the Apollo missions is accessible through the Apollo Lunar Surface Journal Web sites maintained by NASA.

FIGURE 55.8 The heat flow experiment during emplacement on Apollo 15. The drill rack is in the foreground and the Apollo lunar surface drill is on the surface behind the borestem, which is emplaced in the ground. The dark, two-segment rod in the left hand of the crewman is the heat probe. The white probe emplacement tool is in his right hand (*Apollo image AS-15-92-12407*).

For Apollo 15, thermal gradients were determined to depths of up to 1.4 m, while the Apollo 17 probes were emplaced to a final depth of 2.4 m (Figure 55.9). Thermal

FIGURE 55.9 The Apollo 17 heat flow probe after emplacement in the borehole. The probe is connected to the Apollo Lunar Surface Experiment Package central station in the background. *Apollo image AS17-134–20496.*

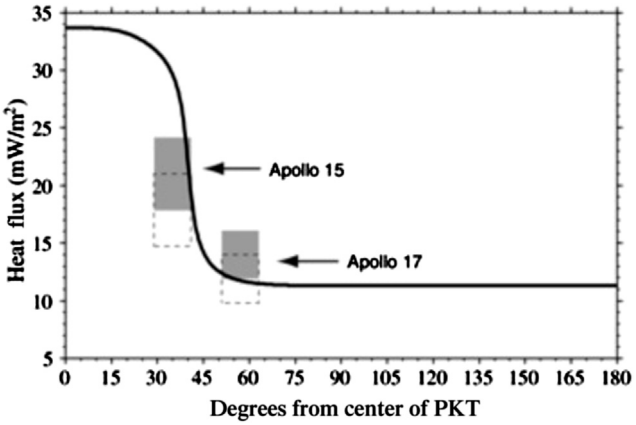

FIGURE 55.10 Modeled present-day lunar heat flow as a function of distance from the center of the Procellarum KREEP terrane (PKT). Initial heat flow estimates derived for the Apollo 15 and 17 measurements are indicated in gray, and subsequent corrections accounting for lateral heat transport in the lunar crust are shown as dashed rectangles. The sizes of the rectangles indicate the measurement uncertainty. *Figure from Wieczorek & Phillips (2000).*

conductivity was determined in situ from a line heat source method, and thermal diffusivity κ was independently estimated from the attenuation of the annual temperature wave. Together with measurements of density ρ and heat capacity c_p on drill core samples returned to the Earth, thermal conductivity $k = \kappa/\rho c_p$ could be independently estimated from the thermal diffusivity measurement. Results of the latter method were finally given preference over the line heat source data, as it was concluded that the direct heating method likely overestimated thermal conductivity due to regolith compaction during probe emplacement.

From these measurements, Langseth and colleagues estimated heat flows of 21 and 16 mW/m^2 at the Apollo 15 and 17 sites, respectively, and the average lunar heat flow was estimated to be 18 mW/m^2. Accounting for effects of lateral heat transport, these values were later revised downward and an average heat flow of 12 mW/m^2 was determined. This heat flow corresponds to a bulk lunar Uranium concentration of 20 ppb, a value close to that derived for the silicate fraction of the Earth, lending support to the hypothesis that the Moon reaccreted from the debris after a giant impact of a Mars-sized planetary body with the proto-Earth. However, it should be kept in mind that the wealth of new data returned by recent lunar missions (SELENE, Gravity Recovery and Interior Laboratory (GRAIL)) suggests that the average crustal thickness is less than previously thought and that it maintains significant porosity to depths of tens of kilometers. Therefore, a fresh look at the implications of the Apollo measurements is warranted.

Models of the heat production in the lunar interior indicate that the observed concentration of heat-producing elements in the Procellarum region must be the surface expression of a larger reservoir at depth. The Apollo heat flow data are compatible with the local presence of a KREEP layer up to 10 km thick at the base of the lunar crust (see Figure 55.10), which would be in line with the persistent volcanic activity observed in the region. Youngest mare basalts are only slightly over 1 Gyr old, and it has been speculated that the concentration of heat-producing elements in the PKT could have been caused by large-scale mantle flow following the gravitational overturn of a freezing magma ocean that likely covered the Moon following accretion. However, further heat flow measurements would be needed to corroborate this view and, ideally, future measurements should be conducted in the center of the PKT and/or far away in the lunar highlands. The latter would be unaffected by the surface concentrations of heat-producing elements and be more representative of the global average.

4.4. Future Investigations

Future lunar heat flow measurements are currently being studied in the frame of an international collaboration termed the International Lunar Network, but definite plans for mission implementation do not exist at present. However, the recently selected Discovery-class mission InSight, which is due to launch in 2016, will place a geophysical lander carrying a heat flow probe in the southern Elysium region of Mars in September 2016. The heat flow probe,

termed the Heat flow and Physical Properties Package, or HP^3 for short, is built to access the Martian regolith to a depth of up to 5 m by means of a hammering mechanism, emplacing a suite of temperature sensors into the subsurface. The overall measurement approach is similar to that taken by Bullard or Langseth, and a depth-resolved measurement of the subsurface temperatures will be used to determine the thermal gradient. Active heating elements inside HP^3 will be used to determine the thermal conductivity in situ, and the attenuation of the annual temperature wave will be used to independently estimate thermal diffusivity and to provide a consistency check for the thermal conductivity value determined from active heating.

While a single heat flow measurement is hardly enough to confidently constrain the average heat flow from a planet, the InSight measurement will provide an important baseline. In addition, the seismic experiment on InSight will provide an estimate of crustal thickness, which can be used to validate thickness models derived from gravity data. The thickness of the crust is a key constraint needed to interpret local heat flow measurements in terms of the global average. Furthermore, the heat flow pattern on the Martian surface is expected to be much simpler than that of either the Earth or the Moon for two reasons: First, Mars currently lacks a plate tectonics cycle (although it may have possessed one during its earliest evolution), and second, Mars does not show any geochemically anomalous regions like the PKT of the Moon (compare Figure 55.11). Therefore, a first global estimate of the average heat flow can be derived from the InSight data, but further measurements in different locations are clearly desirable.

Another device built to measure the energy balance at the surface of an extraterrestrial body is the Rosetta MUPUS instrument (MUlti PUrpose sensor for Subsurface observation), currently on its way to comet 67p/Churyumov–Gerasimenko. Its goal is to measure the heat flow into the comet, the largest unknown contribution to the surface energy balance of the comet. The instrument will be delivered to the cometary surface onboard the Rosetta Philae Lander and is shown in Figure 55.12. MUPUS consists of a 35-cm-long rod equipped with temperature sensors and heaters, and a hammering mechanism is mounted on top of the rod to emplace it into the ground. The instrument will then determine the surface temperature, subsurface thermal gradient, as well as the thermophysical properties of the cometary regolith, thus quantifying the heat flow into the comet and help to detail the solar energy input responsible for driving activity and liberating gas and dust to the cometary coma and tail.

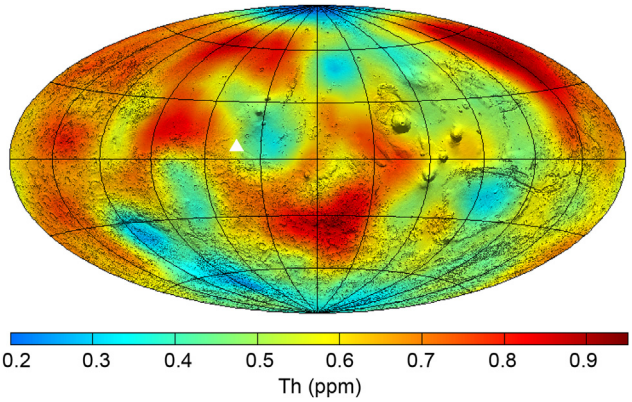

FIGURE 55.11 Abundance of Th on the Martian surface as determined from gamma-ray spectroscopic measurements of the Mars Odyssey spacecraft.

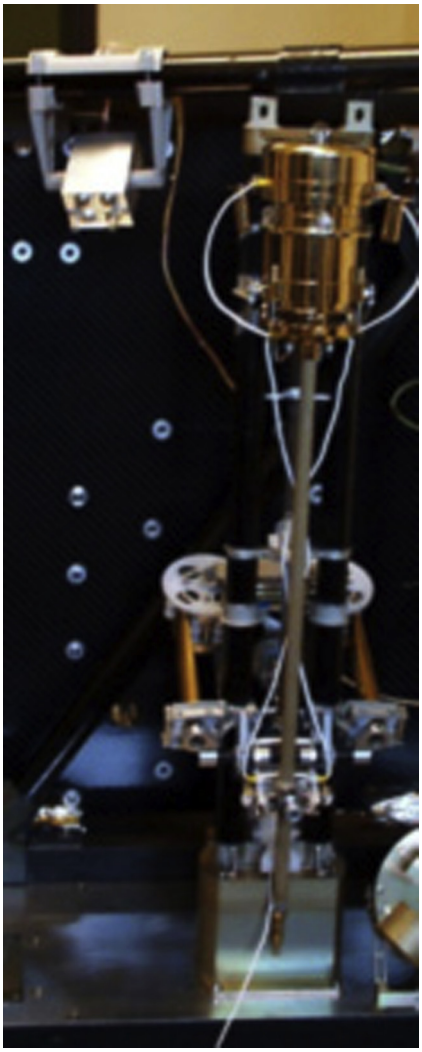

FIGURE 55.12 The Multi Purpose Sensor (MUPUS) onboard the Rosetta Lander Philae, currently on its way to rendezvous the comet 67p/Churyumov–Gerasimenko in 2014. The MUPUS probe on the right-hand side of the picture houses 16 temperature sensors, which can simultaneously be operated as heaters for thermal conductivity determination. MUPUS will be deployed away from the lander using an extendable boom. The golden cap houses a hammering mechanism which will drive the probe into the cometary surface. *From Spohn et al. (2007).*

Other measurement approaches which have been proposed to determine heat flow on extraterrestrial bodies include the so-called flux plates, which can measure surface heat flow in environments with constant surface temperatures. Flux plates are placed on the planetary surface from which the heat flow is to be measured, and the temperature difference across a layer of known thermal conductivity is recorded. Such a device would be suited to determine the heat flow on Venus, whose rocky surface precludes drilling to any significant depth. The constant cloud cover and very dense atmosphere of Venus result in very stable surface temperatures, such that a flux plate measurement could be successfully executed there. Such a measurement would provide a very important constraint on how Earth-sized planets without plate tectonics lose their heat. Many models of the interior evolution of Venus speculate that it should currently be heating up, resulting in a present-day Urey ratio >1.

5. INVESTIGATING PLANETARY INTERIORS USING EM SOUNDING

EM sounding encompasses a wide variety of methods used to sense subsurface structure from depths of less than a few meters to a thousand kilometers or more. EM sounding is distinct from surface-penetrating radar (or its seismological cousins) in being inductive rather than wavelike: the diffusive transfer of energy is akin to that in heat flow, groundwater, and electrical circuits. This transition to induction occurs at low frequency, in the kilohertz to megahertz range depending on ground electrical conductivity. Thus a vast part of the EM spectrum, from below 1 μHz to perhaps 1 MHz, is within the realm of EM sounding. In this section we will be focusing on the so-called passive techniques—those that use natural EM energy in planetary magnetospheres, ionospheres, and atmospheres as the source.

Electrical conduction in the familiar sphere of Earth's upper crust is largely electrolytic, i.e. by movement of ions in water—conductivity increases with porosity and fluid content. In frozen H_2O systems, conduction through ice and hydrates is protonic, through charge defects resulting from lattice substitutions of salts, acids, and bases. Analogous substitutions by iron, aluminum, oxygen, and hydrogen in silicates result in electronic semiconduction, both from electrons and holes. Conductivity is also strongly temperature dependent. In contrast, the outer portions of all other silicate or icy bodies in the solar system are likely to be much more resistive than the Earth, for the simple reason that free water is lacking. This opens up these regions to EM sounding at higher frequencies (see below), which in turn provides better measurements and more convenient signal integration.

The effective penetration depth for EM waves is a strong function of frequency and resistivity. The EM skin depth (in meters) is given by $\delta = 500/\sigma^{1/2} f^{1/2}$, where σ is the conductivity (S/m) and f is the frequency (Hz). This relation indicates what frequencies are necessary to probe to a specified depth at a particular average conductivity. For example, terrestrial exploration geophysics seeking targets at several tens of meters to several kilometers depth utilizes frequencies from $\sim$10 mHz to 10 kHz, but mantle studies require 10 μHz or lower. Conversely, the lunar lower mantle has been adequately sounded in the millihertz range, but better characterization of the more resistive upper mantle and crust will require frequencies up to 1 Hz or higher.

In practice, the true conductivity vs depth is determined from the apparent conductivity (or other measurement parameters; see below) vs frequency using classical inverse methods. Note that unlike the potential field methods discussed above, EM inversions are not formally nonunique. The inversion can be thought of as assigning the conductivity at the highest measured frequency to the uppermost layer, and progressively solving for the conductivity at greater depths by comparing the apparent conductivity at the next depth to the true conductivity of the overlying material.

5.1. Natural Sources

Within the low-frequency branch of diffusive EM, the primary division of techniques is between those that use an artificial source (a transmitter) and those that rely on natural sources. The former enjoy considerable flexibility and high signal to noise but require significant additional resources and are generally limited to investigation depths of several kilometers. On Earth, abundant energy exists at less than 1 Hz from magnetospheric pulsations and the interaction of the magnetosphere with diurnal heating of the ionosphere. Above 1 Hz, the ground−ionosphere waveguide allows lightning energy to be recorded globally as the low-frequency Schumann resonances and regionally at higher frequencies. These signals are collectively known as spherics. These sources of energy for EM sounding will likely be present on other bodies with magnetospheres, ionospheres, and chargeable atmospheres. In interplanetary space, temporal variations in the plasma density of the solar wind provide signals that have already been exploited for lunar sounding. Finally, special circumstances around specific planets can provide unique sources; in particular, the inclination of satellite orbits with respect to the static magnetic field of Jupiter yields an apparent time variation at the orbital period. Overall, some kind of ambient energy is likely present at most bodies that would enable EM sounding.

TABLE 55.1 Approaches to Natural Source EM Sounding

Method	Measurements	Number of Stations	Comments
Transfer function (TF)	Magnetic field B	2	Determine source field by distant second station unaffected by target
Transfer function-1 (TF-1)	B	1	Special cases using prior knowledge of source field *or* target is "perfect" conductor
Geomagnetic depth sounding (GDS)	B	3 or more	Compute impedance from vertical field and horizontal gradients
Geomagnetic depth sounding (GDS-1)	B	1	Special case where horizontal gradient can be computed using known periods and length scales
Magnetotellurics (MT)	B + Electric field	1	General single-station method
Wave tilt (WT)	Electric field	1	General single-station method

5.2. Measurement Techniques

The fundamental quantity that must be derived in any sounding is the frequency-dependent EM impedance Z, and it is the variety of approaches to Z that lead to more individual techniques in EM than in any other geophysical method. A commonly used parameter, the apparent conductivity, is simply related to the impedance as $\sigma_a = \mu\omega/Z^2$, where μ is the permeability and ω is the angular frequency. Apparent conductivity is useful because it is dimensionally identical to true conductivity but instead represents an aggregate response of the target.

Two known quantities are necessary to determine the impedance (see Table 55.1). One of these quantities is nearly always the magnetic field B near the target, i.e. the sum of source and induced magnetic fields. Note that measurement need not be made at the surface, as long as it is at an altitude substantially less than one skin depth at the highest frequency of interest. This can include spacecraft if the desired exploration depth is sufficiently large. Active methods can measure either electric or magnetic fields; the second known quantity is the transmitted signal.

The magnetic transfer function (TF) method is straightforward, measuring three components of the magnetic field at a location on or near a planetary body and comparing that to a measurement distant from the body. This relates the sum of source and induced fields to the source field alone, from which the induced field and internal conductivity structure can be derived. The TF method was used for Apollo-era lunar soundings. In a few special cases (TF-1) of accurately characterized natural signals—the Earth's ring current or the time variation introduced by the motion of the Galilean satellites in Jupiter's main field—the source can be specified a priori, so a single platform is sufficient. Single-magnetometer characterization can also be performed where the target can be approximated as a perfect conductor, like the Moon's core.

Geomagnetic depth sounding (GDS) uses surface arrays of magnetometers to determine impedance from the ratio of vertical B to the magnitude of the horizontal gradient of B. Because the wavelength in the ground $\lambda = 2\pi\delta$, GDS requires array spacing comparable to the skin depth in order to resolve the relevant horizontal wave structure. This calls for dense arrays to resolve the outer tens to hundreds of kilometers of planetary bodies.

In the magnetotelluric (MT) method, measurement of the electric field E supplies the required second piece of information and enables complete EM soundings from a single station. Finally, the wave-tilt (WT) method is preferable for aerial surveys because the quadrature horizontal E (containing most of the inductive signal) can be readily determined by comparison to the vertical E.

Only magnetic methods have been used heretofore in planetary exploration because of their simplicity: electric field measurements are more challenging at low frequencies and noninductive contributions to E must be identified. Nonetheless, those methods using E have the significant advantage of complete soundings from a single vehicle that do not require a priori knowledge or special conditions.

5.3. Terrestrial Exploration

Regional EM soundings of the crust and upper mantle of the Earth began in the 1960s using magnetometer arrays (GDS) and have since been supplemented by MT. The deepest soundings in the mantle use very long period signals from reasonably well-known sources. Two examples here illustrate how EM sounding can elucidate regional

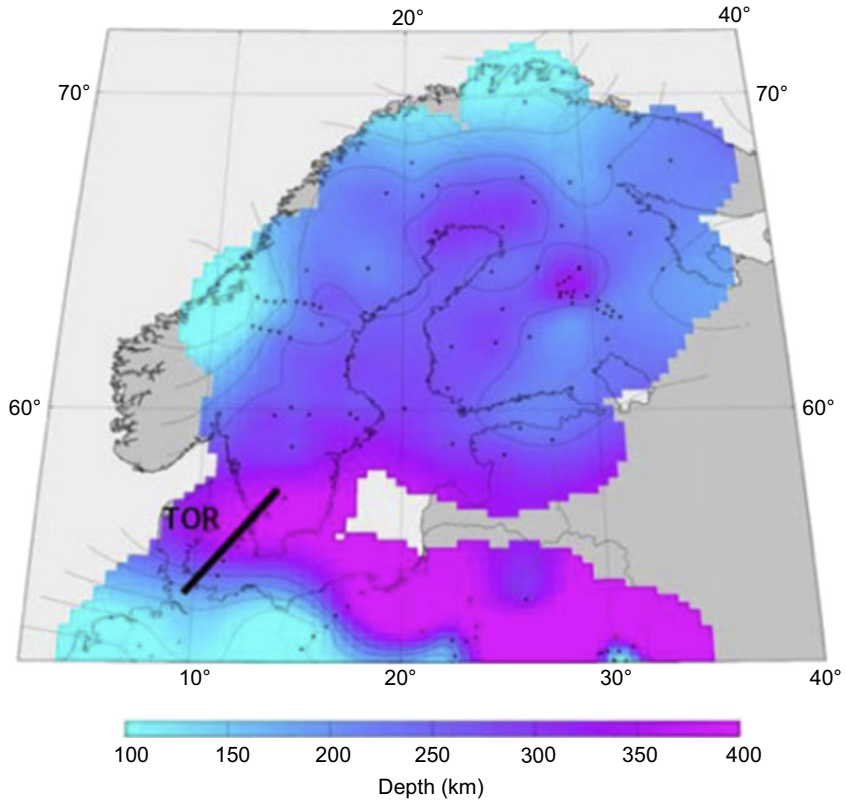

FIGURE 55.13 Thickness of the thermal lithosphere in northern Europe compiled from magnetotelluric soundings. Profile "TOR" crosses the Trans-European Suture Zone, a region of thickening caused by multiple plate tectonic collisions. *Korja (2007)*.

variations in upper mantle structure (Figure 55.13) or deep mantle structure (Figure 55.14). At present, fully three-dimensional images of the Earth are emerging, using decades of observations from hundreds of geomagnetic observatories.

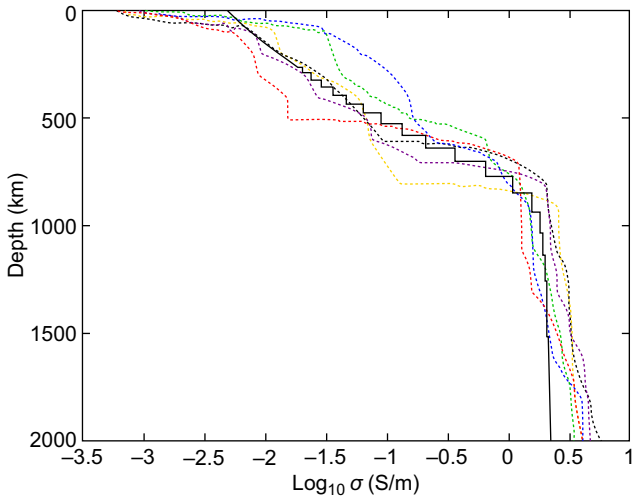

FIGURE 55.14 Electrical conductivities at six European stations (in various colors) and global average (black) from MT and GDS methods (*Semenov & Kuvshinov (2012)*). Much current work in interpreting these kinds of profiles using laboratory data focuses on the tradeoff of temperature (including partial melting) vs dopants such as trace amounts of water.

Variations in electrical conductivity revealed by EM sounding are interpreted in terms of temperature and composition. The former dominate Figure 55.13 where the thickness of cold lithosphere is doubled in the Trans-European Suture Zone. Both may affect the deep profiles of Figure 55.14. The effect of trace quantities of water (hundreds of ppm) in the Earth's mantle is hotly debated.

5.4. Magnetic Sounding of the Moon

During the Apollo Program, a variety of lunar surface experiments were performed in geophysics, space physics, and astrophysics. Simultaneously, the robotic Explorer program was reaching full stride. The Apollo 12 surface magnetometer performed continuous dayside measurements for several months; throughout this time the Explorer 35 spacecraft, also including a magnetometer, orbited the Moon at distances up to several thousand kilometers. The two instruments jointly recorded fluctuations in the Earth's magnetotail and the solar-wind-embedded interplanetary magnetic field from 10^{-5} to 3×10^{-2} Hz. EM sounding was performed using the frequency-dependent magnetic TFs. Due to the fact that the outer portions of the Moon are so electrically resistive (because it is both cold and dry), measured EM waves at even the highest observed frequency penetrate a few hundred kilometers before being able to induce measurable eddy

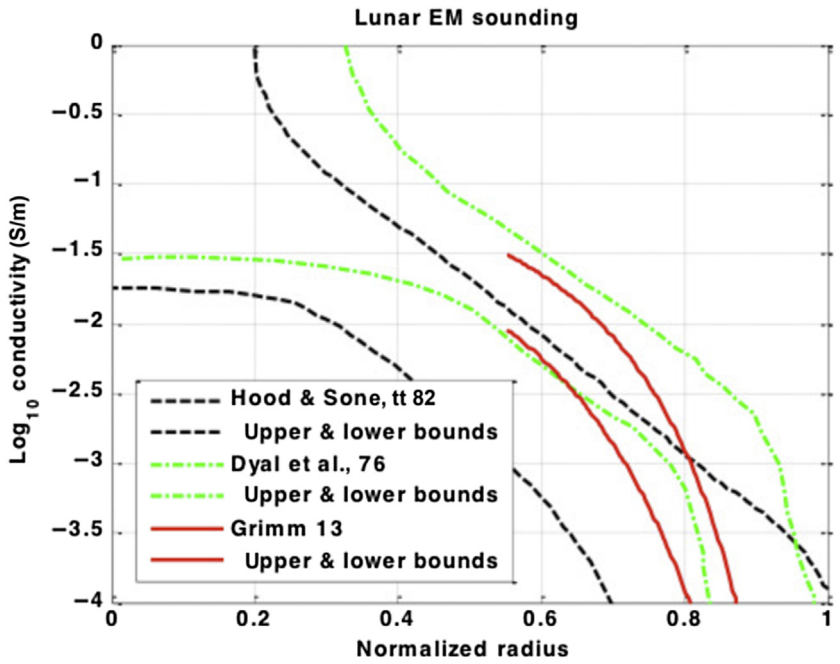

FIGURE 55.15 Electrical conductivity of the Moon, derived by comparing the time-varying magnetic field at the lunar surface with that of a distant satellite (transfer function method). Conductivity increases with depth due to increasing temperature. The large uncertainty at depth is because the volume fraction is so small. Results are also poorly constrained at depths less than a few hundred kilometers (normalized radius >0.8) because this region is so resistive it is transparent to the millihertz signals used for the soundings. Conductivities in the midmantle (normalized radius = 0.7, 500 km depth) indicate higher than expected temperatures (1600 K), perhaps due to higher radionuclide abundance or a thermally insulating megaregolith. Alternatively, impurities such as Fe^{3+}, Al^{3+}, or H^{+} can raise the mantle conductivity.

currents. Hence there are large uncertainties in the electrical properties of the lunar crust and upper mantle. Conversely, the lowest frequencies ($\ll 10^{-4}$ Hz) fully penetrate the Moon but are relatively insensitive to the innermost 20−30% of the radius (Figure 55.15).

Although the Apollo Explorer TFs established an upper limit to the size of a lunar core, better bounds were determined many years later during the Lunar Prospector mission. External magnetic field lines are nearly parallel when the Moon is passing through Earth's magnetotail. If the permeability−conductivity product of the core is very large—effectively equivalent to infinite conductivity—the induced fields will completely exclude the source field, so the induced dipole produces a perturbation to the parallel external field lines that depends only on the core size (Figure 55.16). The resulting bounds 340 ± 90 km are consistent with seismology and laser ranging. It is also worth noting that magnetic **hysteresis** measured with Apollo Explorer indicates 4−14 wt% free iron, depending on assumptions of bulk mineralogy.

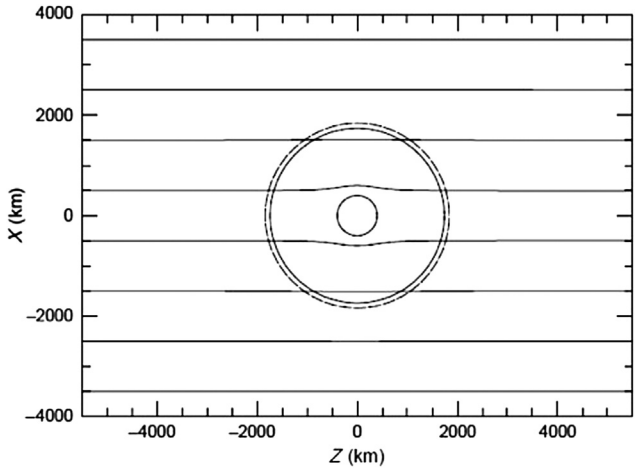

FIGURE 55.16 Modeled deflection of field lines in the Earth's magnetotail by a perfectly conducting lunar core of radius 400 km (inner circle). This is a feature of time-varying signals: eddy currents in the conducting core exclude the primary magnetic field, whereas a static field would be focused into a magnetically permeable core. A range of core radii 250−430 km was found to match small perturbations observed by the Lunar Prospector spacecraft at the outermost circle. *Hood et al. (1999).*

5.5. Magnetic Sounding of the Galilean Satellites

Among the most significant results of the Galileo mission was the discovery of EM induction signatures in the magnetometer records for flybys of Io, Europa, and Callisto, and perhaps for Ganymede as well. Because the conductivity of solid ice or rock is small, salty subsurface oceans on the icy satellites and a global partial melt layer on Io are the most likely causes of these signatures. Jupiter's massive magnetic moment produces field amplitudes of 4−1700 nT at the Galilean satellites and because this field is not orthogonal to the plane of the satellites, it varies periodically with **synodic periods** of 10−13 h as viewed from the satellites. The result is a source field variation of $\sim 10^{-6}$ Hz with known amplitude and direction, so the TF can be evaluated using the Galileo spacecraft alone (TF-1). The depth to and conductivity of the

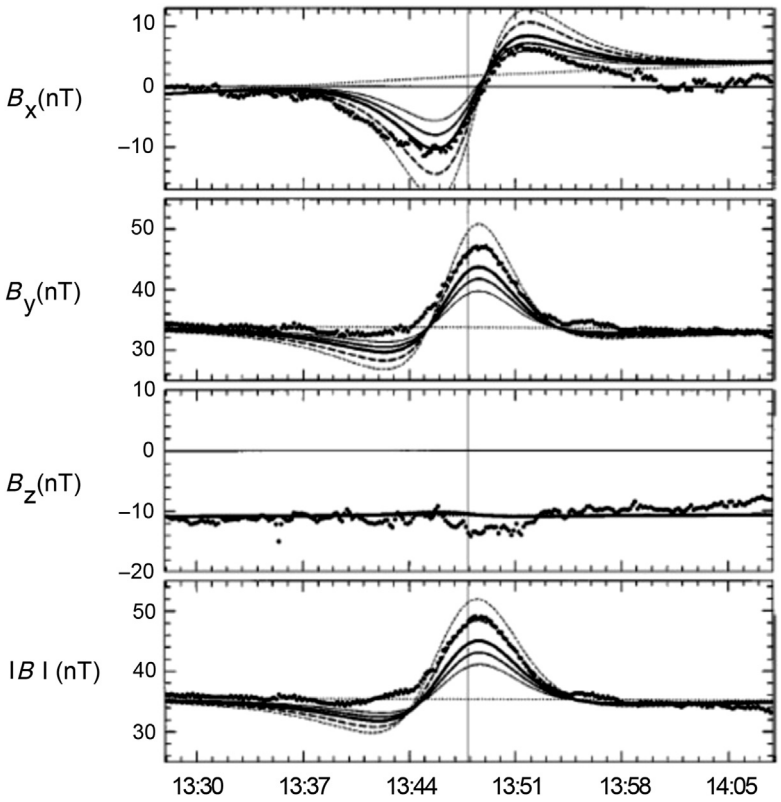

FIGURE 55.17 Galileo magnetometer data (dots) at Callisto flyby on June 25, 1997, compared to various induction models for internal oceans (lines). The temporal variation in Jupiter's static field due to its inclination with respect to Callisto's orbit causes inductive eddy currents to flow in the satellite's interior, forming an induced dipole. This dipole is evident in the raw data above and because its orientation always opposes the main field, it cannot have a static origin. *Zimmer et al. (2000)*.

internal water or magma oceans can be inferred to be tens of kilometers and ∼1 S/m, respectively. Skin effects allow these fields to penetrate through much of the satellite, but ocean thicknesses are harder to estimate because EM sounding is sensitive only to the conductance (the product of conductivity and thickness) when trying to assess a highly conductive layer. Nonetheless, magma and water ocean thicknesses of 100−200 km have been derived (Figures 55.17 and 55.18).

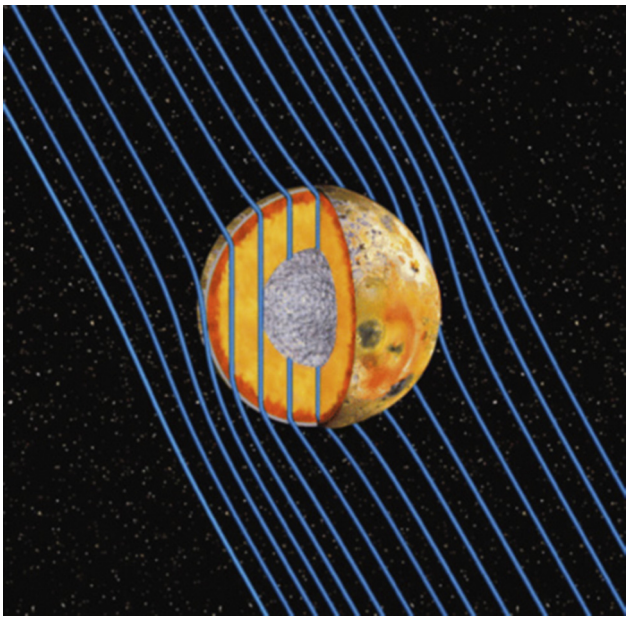

FIGURE 55.18 Internal structure of Io revealed by EM sounding (TF-1 method). Red layer ∼40 to >90 km deep is the global partial melt. *Khurana et al. (2011)*.

5.6. Future Exploration

Many missions can exploit EM sounding of planetary interiors using natural sources and simple sensor configurations. A significant magnetosphere makes Mercury the most Earth-like in terms of classical natural EM sources, yet frequent **reconnection** events define an even more dynamic environment. Its core will also be a prime EM target and the conductivity profile in the mantle may show whether it is convecting or whether the lithosphere comprises the entire mantle. The iron content of the mantle may also be recovered.

With a shielding ionosphere and no defined external sources, EM soundings of Venus must be performed from the surface or atmosphere, but both ionospheric disturbances and lightning are known to exist. A balloon in the benign middle atmosphere can perform long-duration remote sensing of the subsurface using MT or WT. The dearth of water on Venus implies that these signals will penetrate tens of kilometers into the ground enabling the mean thickness and lateral variations of the **thermal lithosphere** to be determined.

FIGURE 55.19 Concept for a lunar geophysical station including a magnetotelluric sounder. Three spring-launched orthogonal wires have electric field sensors at their tips, whereas boom at left supports fluxgate and search-coil magnetometers. Other instruments include seismometer, heat flow probes (2), and retroreflector. *Courtesy Jet Propulsion Laboratory.*

EM soundings of the Moon can be improved by expanding the frequency range: shallower skin depths at higher frequencies can resolve the outer resistive portions, and stable long-term measurements may detect the core and distinguish molten silicate from iron. Low-altitude orbital coverage or a surface network (Figure 55.19) would allow geographic variations to be resolved, for example, if the Moon's most volcanically active regions are also distinct in the upper mantle.

The cold surface and lower heat flow of Mars result in a cryosphere many kilometers thick, putting liquid groundwater and potential stable microbial habitats out of reach of conventional planetary remote or in situ sensing. This conductivity contrast would be comparable to that observed for the Galilean satellites, and its depth would provide a ready estimate of geothermal gradient.

The extremely low frequency time variations developed at the satellites of Jupiter by their inclined orbits with respect to the main field will also be present at Uranus and Neptune. This will enable single-magnetometer global TF soundings for close flybys of satellites of the ice giants. Saturn's satellites have negligible inclination with respect to the main field, but for all the giant planets, the diversity of magnetospheric phenomena may provide a rich spectrum of EM signals. Titan is of course different because of its atmosphere; like Venus, MT or WT measurements from landed or aerial assets could exploit ionospheric disturbances or lightning.

6. SUMMARY

For the past 40 years, the geophysical exploration of the deep interiors of the terrestrial planets had lagged far behind the exploration of their surfaces. This is partly due to the difficultly in making the necessary precise measurements, which often requires multiple long-lived surface platforms for the best results, and partly due to the difficultly in generating the same level of public excitement as a surface mission, with its easily communicated imagery and sense of exploration. However, the scientific value of these measurements is unquestioned, and we now stand at the beginning of a new era of geophysical missions. The GRAIL mission has recently completed its mapping of the gravity field of the Moon at unprecedented resolution, and MESSENGER (MErcury, Surface, Space ENvironment, GEochemistry and Ranging) is currently exploring the interior of Mercury with gravity and magnetic measurements from orbit. Also, the InSight mission to Mars will, starting in late 2016, obtain surface seismic, heat flow, and magnetic measurements which will allow us to address many of the fundamental questions regarding the structure, origin, and evolution of Mars. Looking farther ahead, ESA is studying INSPIRE (Integrated Network of Seismic Probes to Invigorate Robotic Exploration), a Mars geophysical network mission to use multiple landers to sharpen the seismic resolution of that planet's interior, and there are plans within NASA to explore the possibility of a habitat/environment on Europa using geophysical techniques to probe the extent of its putative subcrustal ocean. Thus the next decade promises to be an exciting one for planetary interior exploration.

1. INTRODUCTION

Immediately upon the launching of *Sputnik* in 1957, it was clear that technical and political conditions would soon permit humans to realize a dream of centuries—exploring the Moon and planets. With large military rockets plus advanced radio techniques and the dawning skills of robotics, it would be possible eventually to send spacecraft throughout the solar system.

At first, however, the effort mostly failed. Driven by Cold War desires to show superiority in both military and civil endeavor, the Soviet and US governments sponsored hectic attempts to penetrate deep space, using strategic-weapon boosters, cobbled-together upper rocket stages, and hastily prepared robotic messengers. In time, as the equipment became more reliable and the management more capable, successes came—but in-flight failures have continued for decades to afflict all deep space programs. Lunar and planetary exploration is barely achievable even with the finest skills.

Here, where our purpose is to trace the development of flight missions, we do not dwell on the failures. We thus list only those missions that yielded some data in accord with their objectives (See Table 4 of the Appendix for a more complete listing).

In the early years, the Soviet Union garnered all the main firsts: the first escape from Earth's gravity, the first man and first woman in orbit, the first lunar impact, the first lunar landing, and the first lunar orbit. But the US program came from behind and scored the first data from a planet, Venus, and ultimately the grand prize, the first human exploration of the Moon.

Although Cold War rivalry provided emotional stimulus and government support, both programs were scientific right from the start. The earliest satellites were launched in support of the International Geophysical Year (IGY). Every mission carried some instruments to elucidate the character of its target body or region, and this largely continued as more nations and agencies joined the program. As a result, there is now a huge body of data, some of it still unexamined, from flight missions complementing an important archive of ground-based and Earth-orbiting telescopic observations of the Moon, planets, and small bodies in the solar system.

In what follows, recent and established near-future missions will be emphasized and only the most important earlier missions will be described. More complete lists are given in cited references.

Exploration of the Sun's domain by robots and of the Moon by humans has now placed us in a position to build strong hypotheses about the origin and evolution of the solar system and life and also to begin the study of other such systems as they are discovered. The missions that made this possible are an unprecedented expression, on a grand international scale, of peaceful human values and achievement.

2. PROGRAM EVOLUTION

2.1. Launch Services

Sputnik, which orbited on October 4, 1957, galvanized a huge response from the United States. Less than 12 years later, two astronauts walked on the Moon. In both USSR and the United States, an existing military rocket legacy enabled launch of the first satellites in 1957 and 1958. In time, space mission developers in other nations, driven primarily by a desire to have assured, independent access to space and also by a desire for their own organic technology advancement, began to provide their own launch services, at first for low Earth orbit (LEO) missions and later for missions beyond LEO, including geosynchronous Earth orbit (GEO), lunar, interplanetary, and planetary ventures. The required upper rocket stages were, and remain, an exasperating cause of failures.

The search for lower cost launch services, regarded as a key to future space development, has led over decades to the spending of resources equaling billions of dollars in studies and aborted vehicle developments, with as yet no promising result. However, work continues on a variety of approaches including air launch, hybrid air-breathing and rocket propulsion, and alternatively just extreme simplification in booster design.

Commercial launch services, now being encouraged by partial government subsidy, may offer another route toward lower costs.

Even without a radical launch cost reduction, a human breakout into the solar system is conceivable through the use of extraterrestrial resources. With energy and especially materials collected off the Earth, in a manner that has come to be called in situ resource utilization, great savings are possible in the mass that must be lifted from the Earth. This technique has yet to be demonstrated at a large enough scale for its true potential and its real comparative costs to be known.

2.2. Tracking and Data Acquisition

Without some way of delivering robotic mission results to the Earth, it does not matter what else works or does not work. In the time before the invention of radio, space science fiction authors assumed that signaling with light beams would be used. In a way they were right: Optical communications using lasers may yet become the method of choice in certain applications. Meanwhile, however, telemetry, tracking and orbit determination, command, and science in deep space entirely depend on radio technique.

For the first satellites, tracking stations were improvised based on previous military communications systems. For missions to the Moon and beyond, however, it was necessary to adapt methods used by strategic defense radar developers and radio astronomers. Huge antennas, supersensitive receivers, transmitters with enormous power output, and advanced data recording and processing all were needed.

From the outset, a difference in philosophy guided Soviet and American deep space engineers. In the then secretive USSR, the initial plan was to have spacecraft turn on their transmitters only when over Soviet territory, thus requiring ground stations in only the eastern hemisphere (In response to that, an American deep space signals intercept site was built in Eritrea). In the United States, on the other hand, the policy called for continuous contact, meaning that stations would have to be located worldwide, with of course a worldwide ground and space communications system for command, control, and data acquisition. That led to the

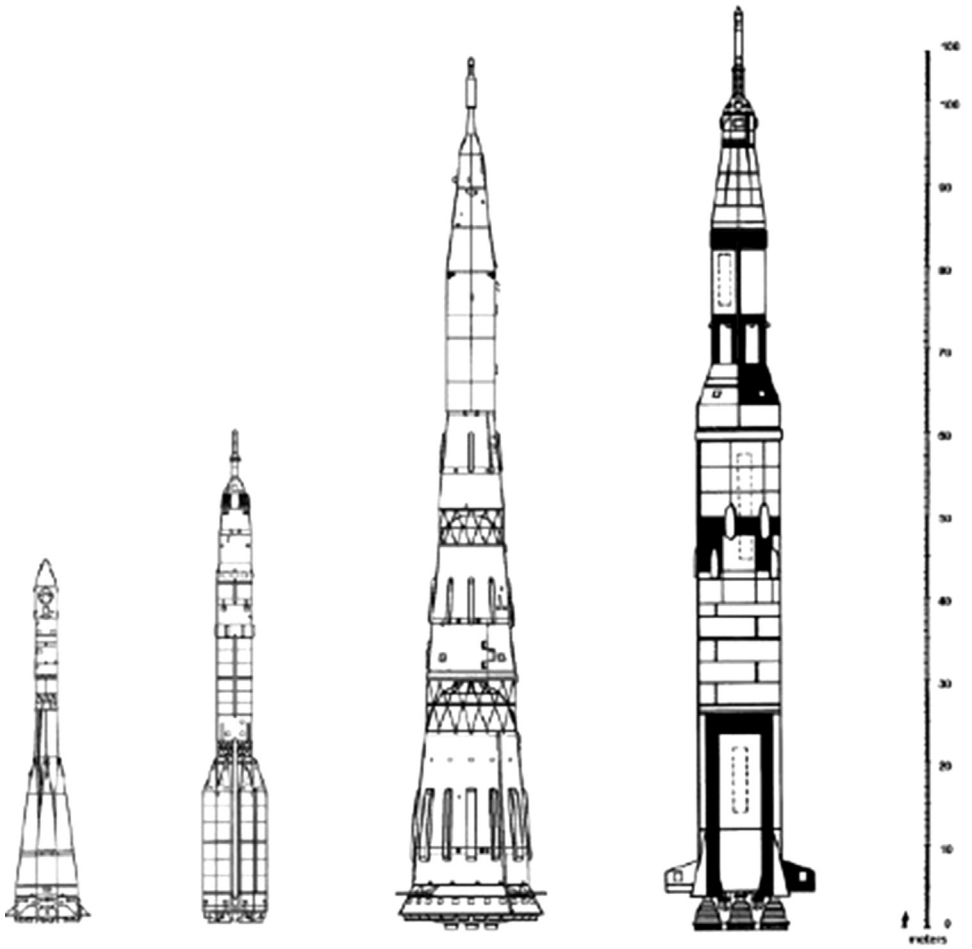

FIGURE 56.1 Soviet Soyuz/Molniya and Proton, American Saturn V, and Soviet N-1. *NASA History Division.*

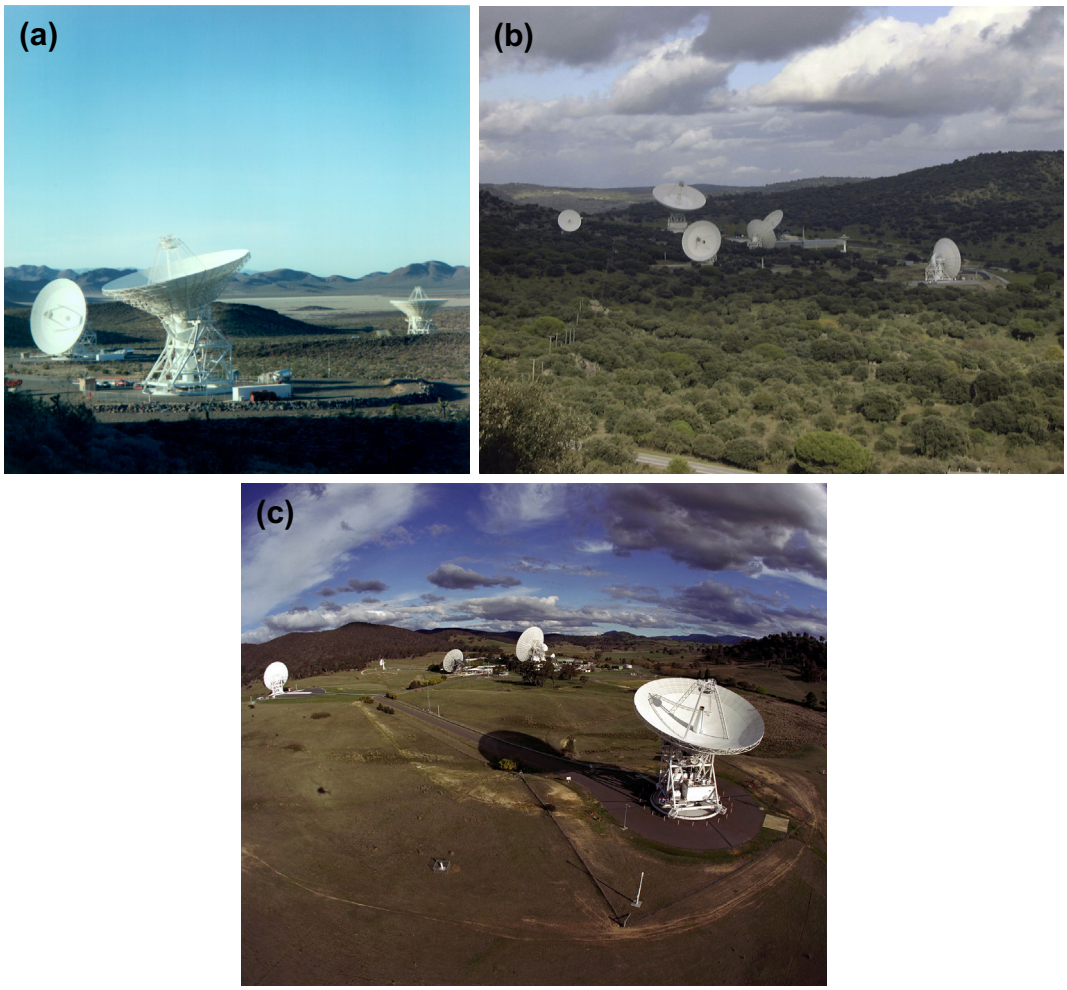

FIGURE 56.2 Deep Space Network stations today are in (a) California, (b) Spain, and (c) Australia. *Courtesy of NASA.*

creation of the Deep Space Network (DSN) whose stations today are in California, Spain, and Australia. For *Apollo,* a dedicated network was built, and it was backed up by the DSN plus a few specially equipped radio astronomy sites (Figure 56.1).

Meanwhile, the Soviet system evolved. At first located only in the Crimea, the Soviet network expanded to include sites in the Far East and in the central USSR, plus a fleet of tracking ships offshore. As additional nations joined in exploring the solar system and the cosmos beyond, many more stations were built for both tracking and radio science. Figure 56.2 shows three typical examples of the modern deep space stations that now exist in several countries.

2.3. Spacecraft

From a modest beginning, robotic spacecraft in LEO and GEO have evolved into the thousands of diverse science and applications machines that have been sent into orbit. Among these are large, multifunction craft devoted to observing the Earth as a planet, such as the European *Envisat* and the American *Terra* and *Aqua.*

Meanwhile, spacecraft designed to explore the solar system beyond the Earth underwent a similar evolution. The most important early mission was that of *Luna 3* in 1959, ending centuries of speculation by returning the first images of the Moon's far side. Soon after that, spacecraft design began to elaborate on the features that are essential in interplanetary space: attitude stabilization for pointing cameras and high-gain antennas, capable onboard data handling systems, long-duration power supplies, and long-surviving electronic equipment.

Three interplanetary technologies, whose mathematical foundations have been known for a century or more, are now starting to be applied. They are solar electric propulsion, weak stability boundary flight paths, and solar sailing. All may supplement or supplant chemical spacecraft propulsion with much increased efficiency in exchange for much longer transit times.

For human spaceflight, the earliest craft were mainly just capsules capable of sustaining life and returning safely to the Earth. But as space stations in LEO and flight beyond LEO became program objectives, more functions became the responsibility of human pilots and other crew members. The *Apollo* and space shuttle designs took full advantage of human capacities, while Soviet missions continued to make more use of teleoperation and onboard automation, as shown by the routine automated dockings of *Soyuz* and *Progress* servicing craft with the ISS.

2.4. Operations

In even the earliest lunar and planetary missions, it was necessary to keep track of the spacecraft's trajectory and issue commands for onboard functions both engineering and scientific. Gradually a humans-and-machines art developed, represented today by large rooms full of people and displays backed by buildings full of computers and data systems. Initially centered in main theaters, as missions have become more complex, these facilities have become dispersed, providing work spaces for the many specialized flight management and scientific teams working during a mission. With the Internet and other modern communications available, scientists can now reside at their home institutions and participate in missions in real time.

The latest trend is toward increasing onboard autonomy, holding the promise of reducing the large staffing needed round the clock to control missions. Some degree of autonomy, for example, stabilization with Sun and star references, is needed anyway in deep space, simply because of the round-trip signal times to distant spacecraft, tens of minutes for Mars and Venus and many hours in the outer solar system.

Operations have become more and more dependent on software whose design and verification now constitute one of the main cost items in each new mission's budget. With the maturing of the operations art have come numerous stories of remarkable rescues when a distant robot (or, as in *Apollo 13,* a human crew) got into trouble, but there are also instances where a mistake on the Earth sent a mission to oblivion.

2.5. Reliability and Quality Assurance

A vital part of the deep space exploration art is the creation of systems having but a small chance of disabling failures, plus an ability to work around failures when they do occur. One reason for the high cost of lunar and planetary missions is the need for multiple levels of checking, testing, reviewing, and documentation at every stage from the manufacturing of thousands of tiny components through assembly into subsystems and systems for both ground and flight, organization of human teams capable of imagining and analyzing failure scenarios and designing around them, and finally launching and controlling a mission during its years or decades of activity.

These costs are aggravated by the nature of deep space exploration as a work of building very complicated systems (hardware, software, and human−machine complexes) in ones and twos, as distinct from the repetitive manufacture of highly reliable items such as cars or computers whose teething troubles can be eliminated in early prototype testing. In a sense, every lunar or planetary mission is a first effort.

2.6. Management

In the twentieth century, as cold and hot warfare became more and more technological, a suite of skills, traditions, and managerial methods grew and created the capability of planning and executing large complicated projects. Many disciplines were involved, ranging from what became known as systems engineering all the way to new ways of organizing academic institutions, industries, and government agencies. The sometimes maligned worldwide military−industrial complex is a product of those developments, and it was the seedbed of the world's deep space programs.

The great lunar contest of the midtwentieth century highlighted some stark differences between American and Soviet management methods and organizations. At the outset, both used existing military hardware and existing military ways of working, but over time, the programs evolved along different paths. With their head start, the Soviets garnered all the early prizes in robotic lunar exploration, but when planning began for human lunar exploration the Soviet system fell into both technical and managerial disarray.

3. SUN AND HELIOSPHERE

The emphasis in this chapter is on missions to the Moon and planets. Now that star−planet aggregates are at last being observed as a class of known objects in the cosmos, it is essential for us to include at least a part of the story of missions devoted to our own star as host of a planetary system.

Our tale begins with the IGY. Centuries of ground-based investigations of sunspots and solar and terrestrial magnetism, plus decades of ionospheric and auroral research, had led by the midtwentieth century to a drive by scientists for a worldwide campaign of coordinated measurements resembling previous efforts such as international polar years. The new element now was the knowledge that rockets could take instruments beyond Earth's atmosphere and even into orbit. In both the USSR and the United States, satellite experiments were planned and announced in support of this goal, and in 1957 and 1958, it was achieved.

Explorer I found an excess of radiation saturating its detector. *Explorer IV* showed that this radiation is due to energetic particles trapped in the Earth's magnetic field, the Van Allen belts. Then, in 1962, an instrument aboard *Mariner II,* en route to Venus, confirmed predictions of a fast outward flow of plasma from the Sun—the solar wind, now known to bathe the entire solar system out to the boundary of the heliosphere, where it meets the oncoming, tenuous interstellar medium. *Voyager 1* and *2* are now entering that interaction region, more than 100 AU from the Sun. Over the next 5–10 years, they are expected to continue to yield information on phenomena at the outer limits of the Sun's domain.

Meanwhile, over the past five decades, many spacecraft have journeyed into interplanetary space, investigating the particles and fields environment of the solar system or the Sun itself. The first international solar mission, *Helios,* a US–German cooperative mission, with interplanetary spacecraft observing the solar wind and radiation, was launched in the mid-1970s.

Now the Sun is continuously observed from space. In the aggregate, as described in the chapter on the heliosphere, these investigations have shown a common portrait, with variations, of what happens as the Sun's streaming plasma, coronal mass ejections, and electromagnetic radiations interact with the magnetic fields, ionospheres, and atmospheres and surfaces of solar system bodies. These effects are most dramatic when they result in spectacular comet plasma tails, but they are also important in causing magnetic storms and driving the evolution of atmospheres due to dissociation of molecules and ionization and sweeping away of atoms.

Voyager 1 has reached the limit of the heliosphere and is entering interstellar space, 110 AU from the Sun.

Study of these interactions as they are imagined to have happened in the ancient past, for example, when our star is thought to have gone through a huge energetic T Tauri phase, enables not only the analyses of early planetary history here but also productive reasoning about what may be observed in other star–planet systems as they are found.

3.1. Helios

Two German spacecraft, launched by National Aeronautics and Space Administration (NASA) *Titan-Centaurs* in 1975 and 1976, explored solar phenomena between the Earth's orbit and as close as 0.29 AU from the Sun. An arrangement of mirrors and radiators enabled the spinning spacecraft to survive the consequent extreme heating.

3.2. Solar Maximum Mission

Launched in 1980, *Solar Maximum Mission (SMM)* carried a suite of instruments investigating the Sun at the height of the sunspot cycle. Ultraviolet, X-ray, gamma-ray, and visible light observations combined to give a picture of the Sun's total radiation and its variations due to flares. The spacecraft failed and was dramatically rescued by a shuttle crew in 1984, whence it continued until atmospheric reentry in 1989.

3.3. Ulysses

Launched in 1990, European Space Agency's (ESA's) *Ulysses* used Jupiter's gravity to kick its orbit out of the plane of the ecliptic and send the spacecraft back inward, passing over the Sun's poles to survey a region never before explored. Now the craft goes out to the distance of Jupiter's orbit and back to the Sun every 5 years; its functions were switched off in 2009.

3.4. SOHO

The ESA/NASA Solar and Heliospheric Observatory (SOHO), launched by the American *Atlas-Centaur* in 1995, orbits about the L1 Lagrangian libration point 1.5 million km sunward from the Earth, where its 14 instruments continuously observe phenomena relevant to understanding the solar interior, the solar atmosphere, and the solar wind (Figure 56.3). SOHO's observations are immediately fed to users via the Internet at umbra.nascom.nasa.gov. The mission has already made observations through most of an 11-year solar cycle, and it is expected to continue for several more years. It too survived a massive onboard failure with a dramatic rescue—this time by remote control from the Earth.

3.5. Advanced Composition Explorer

The *Advanced Composition Explorer (ACE),* a NASA mission with nine instruments and an international team of

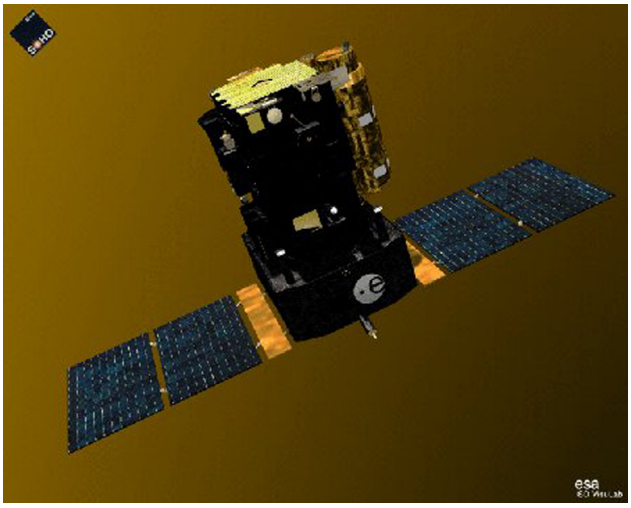

FIGURE 56.3 The ESA/NASA Solar and Heliospheric Observatory.

20 investigators, was launched in 1997. Like SOHO, it orbits in the L1 region where it continuously surveys the isotopic and elemental composition of particles from the solar corona, the interplanetary medium, and the interstellar space. In 1998, the ACE data system began providing public, real-time observations that can give warning of solar events that cause geomagnetic storms.

3.6. TRACE

A small *Explorer* satellite launched in 1998, TRACE provides nearly continuous solar coronal observations with high spatial and temporal resolution, complementing the data from SOHO.

3.7. Genesis

In an audacious venture using gravity assist at Earth and libration orbiting for 2 years near L1, the *Genesis* mission, launched in 2001, in 2004 returned a capsule to the Earth bearing actual samples of the solar wind and interplanetary medium embedded in ultraclean collector plates. Due to a failure to signal its parachute to open, the capsule crashed in the Utah desert, but not all was lost: A number of the collector units survived in condition good enough for the recovery of isotopic information and other science data.

3.8. Solar Dynamics Observatory

The 3-ton Solar Dynamics Observatory spacecraft, launched in 2010, is in an inclined geosynchronous orbit near the 100° West meridian. Its three instruments continuously observe the solar atmosphere driven by changing magnetic fields and ultimately causing the solar variations that drive space weather.

4. MERCURY

4.1. Mariner 10

Flight to the innermost planet began with *Mariner 10,* launched on November 3, 1973, (Figure 56.4). It was the first mission to use gravity assist, flying by Venus on February 5, 1974, en route to Mercury, where it arrived on 29 March. Then using Mercury gravity assist, it flew by again on September 21, 1974, and March 16, 1975.

4.2. MESSENGER

The *MESSENGER* spacecraft, launched on August 2, 2004, entered obit about Mercury in 2011 after an Earth gravity assist in 2005, Venus gravity assists in 2006 and 2007, then three Mercury assists in 2008 and 2009. The spacecraft carries a suite of instruments to investigate Mercury's surface and interior composition, its gravity and magnetic fields, its particles and radiation environment, and the polar regions where it confirmed Earth-based radar observations showing the presence of ices in permanently shadowed craters.

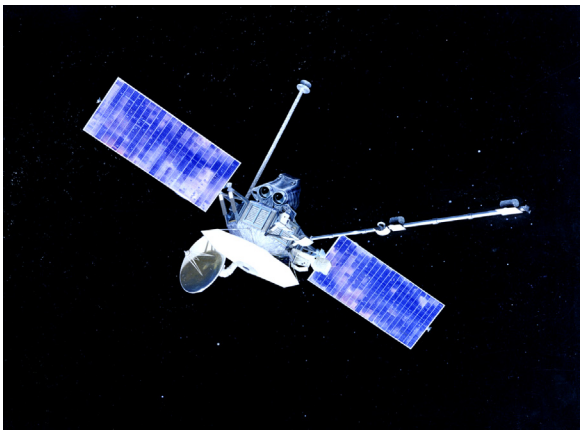

FIGURE 56.4 Flight to the innermost planet, Mercury, began with *Mariner 10,* launched on November 3, 1973. *NASA.*

5. VENUS

5.1. Mariner 2

The first mission to return data from another planet, *Mariner 2* in 1962, had amazing escapes from disaster. During ascent, its *Atlas* went into uncontrolled rolling and miraculously stopped in an orientation such that the *Agena* upper stage could deliver the spacecraft onto a trajectory toward Venus. En route, the spacecraft survived a series of mortal threats, and shortly after flying by Venus, it succumbed to overheating. But during the flyby, as described in the chapters on Venus of this book, it produced proof of the planet's hellish greenhouse.

5.2. Veneras 4 Through 16 and Vega

First to enter another atmosphere, *Venera 4* in 1967 carried the emblem of USSR to Venus. It began the Soviets' most successful interplanetary program. *Venera* missions of increasing complexity and scientific yield continued to be launched at nearly every celestial mechanics opportunity until 1983, and then in 1985, the two Vega spacecraft, en route to Halley's Comet, delivered balloons into the Venus atmosphere. Scientific results of this decades-long exploration are described in the chapter Venus.

5.3. Mariner 5

Launched 2 days after *Venera 4* in 1967, *Mariner 5* made flyby observations, including ultraviolet cloud imaging,

FIGURE 56.5 Vega 1, a large Soviet spacecraft, flew by Venus in 1985 en route to Halley's Comet.

which revealed the rapid rotation and spiraling equator-to-pole circulation of the Venusian atmosphere.

5.4. Mariner 10

During its gravity assist flyby of Venus in 1974 en route to Mercury, *Mariner 10* made observations of the Venusian atmosphere and ionosphere, confirming the equator-to-pole circulation and absence of a magnetosphere.

5.5. Pioneer Venus

The two *Pioneer Venus* spacecraft, launched in 1978, had complementary objectives. *Pioneer Venus 1* went into orbit with a radar altimeter to survey the surface through the planet's permanent cloud cover. *Pioneer Venus 2* delivered four probes into the atmosphere to measure its character and composition down to the surface.

5.6. Vega 1 and 2

Two large Soviet spacecraft *Vega 1* and *2* (Figure 56.5) flew by Venus in 1985 en route to close encounters with Halley's Comet. Their spherical entry capsules released balloons that were inflated and floated in the Venus atmosphere, returning data for several days.

5.7. Magellan

The ubiquitous clouds of Venus forever hide the planet's surface from outside visual examination. *Venera* landers in 1975–1981 gave close-up surface panoramas and in 1983 radars on the *Venera 15* and *16* orbiters mapped most of the northern hemisphere. Long delayed through years of attempts to gain government approval, *Magellan* (Figure 56.6) was finally launched in 1989 into a series of orbits enabling it

FIGURE 56.6 *Magellan* was launched in 1989 into a series of orbits enabling it to map the entire planet using synthetic-aperture radar.

to map the entire planet using synthetic-aperture radar. Once the radar mission was complete, the spacecraft was moved into a lower orbit to map the Venusian gravity field and to test aerobraking techniques.

5.8. Venus Flyby

En route to Jupiter, the *Galileo* spacecraft performed a gravity assist flyby at Venus in February 1990. Spacecraft observations included infrared imaging of the planet's cloud layers and even surface features, through infrared "windows" in the atmosphere and clouds. MESSENGER and Cassini–Huygens also flew by Venus for gravity assists en route to their destinations.

5.9. Venus Express

By modifying the design to cater to the hot environment near Venus, but otherwise using many proven components and operational techniques, ESA was able to mount a low-cost mission to place in a 24-hour Venus orbit a spacecraft based on the successful *Mars Express* described later below. Launched in 2005, the mission has delivered unique images of Venus' north polar cloud vortex.

6. EARTH

Among the thousands of spacecraft launched to date, at least hundreds have made some contributions to the study of our Earth as a planet. Here, we make no attempt at a catalog of all those ventures. Instead, we highlight a few recent and representative missions that illustrate the state of humans' ongoing endeavor to understand the Earth's interior, its oceans and lands, its atmosphere, its evolution, and its fate, including that of its biosphere.

Observations by ISS astronauts, and their descriptions for onlookers, constitute a rich legacy that goes beyond science to give us all an appreciation of our precious and beautiful planet.

Scientific and applications satellites not only look down upon the Earth but also observe our planet's electromagnetic and particle environments, including auroral kilometric radio emissions and X-ray and even gamma-ray outbursts from thunderstorms. These energetic upward-going phenomena are characteristic of other planets too: auroras are seen on Jupiter and Saturn and must exist on some extrasolar planets. Thus, the study of our own fascinating home has implications throughout the cosmos.

6.1. Resurs

Soviet and Russian film-return photoreconnaissance satellites have operated over many years for Earth observation. Civil uses have been publicized since 1979, with increasingly capable camera systems used for both applications and science.

Corresponding US imagery was mostly kept classified until 1995, when much previously secret overhead reconnaissance information was released for public use in historical and scientific studies.

6.2. Galileo Earth Flybys

En route to Jupiter (see Outer Planets section below) the *Galileo* spacecraft made gravity assist passes at the Earth in 1990 and 1992. Spectrometric observations were made to simulate a search for evidence of life on an unknown planet, and the data did show an out-of-equilibrium, oxygen-rich atmosphere.

6.3. Terra

Launched in 1999, NASA's *Terra* spacecraft carries five advanced international radiometric and spectrometric instruments observing global phenomena of land, oceans, and atmosphere. Measuring Earth's radiation budget, its carbon cycle, and evolution of its climate and biosphere are the main mission goals.

6.4. TOPEX/Poseidon and Jason-1 and Jason-2

Launched in 1992, 2001, and 2008, respectively, as parts of a collaboration between NASA and the French national space agency CNES, *TOPEX/Poseidon, Jason-1, and Jason-2* use radar altimetry and very precise orbit determination to determine ocean topography, aiding studies of currents, winds, and climate effects including El Niño.

6.5. GRACE

In a collaboration among NASA, the German space agency DLR, and other partners, two small satellites, *GRACE,* launched in 2002 use very precise measurements of the distance between them to gain knowledge of the bumps and hollows in Earth's gravity field, leading to information on the exchanges of mass, momentum, and energy between oceans and atmosphere. The measurements are so precise that they have revealed changes in groundwater masses over large regions.

6.6. Envisat

ESA's 8200-kg Earth observing satellite, *Envisat,* launched in 2002, carries 10 large instruments including a synthetic-aperture radar, a radar altimeter, and a suite of radiometers and spectrometers recording atmospheric, ocean, ice, land, and biosphere data, spanning the spectrum from ultraviolet to microwave frequencies. Its polar orbit gives global coverage.

6.7. Aqua

NASA's *Aqua* satellite, launched in 2002, carries six radiometric and spectrometric instruments surveying Earth's water cycle, sea and land ice, atmospheric temperature, aerosols and trace gases, and soil moisture, so as to increase the understanding of climate and Earth's radiation balance, with both physical and biological influences.

6.8. Aura

Launched in 2004, the *Aura* satellite's four instruments complement those of *Terra* and *Aqua* by measuring atmospheric chemistry, including the formation and dissipation of polar ozone holes and the distribution of greenhouse gases.

7. MOON

After centuries of careful naked-eye and telescopic observation from Earth, the Moon has at last become a body to be investigated by robots, visited by human explorers, and perhaps ultimately inhabited by the people of a first outward wave of civilization. At its beginning, scientific lunar exploration was caught up in the great twentieth-century struggle between the United States and the USSR. With the end of the USSR, the program fell victim to low priority and languished for decades, but now a lively international revival is in progress. Here, we list the most important robotic missions of the past, then briefly mention the grand *Apollo* venture and its failed Soviet competitor, and finally

remark on the new missions now established in a widening group of countries.

7.1. Luna 1, 2, and 3

The *Luna* Soviet missions in 1959 yielded the first escape from Earth's gravity, the first lunar impact, and the first farside images ending centuries of speculation.

7.2. Ranger 7, 8, and 9

After two nonlunar tests and three failed attempts to deliver seismometers to the lunar surface, the NASA *Ranger* missions, launched by *Atlas-Agenas* in 1964 and 1965, yielded thousands of high-resolution television (TV) images of the lunar surface showing that all features are mantled by the impact-generated regolith.

7.3. Zond 3

A Soviet planetary spacecraft, *Zond 3,* launched on a test flight including a lunar flyby, this mission in 1965 returned improved imagery of parts of the Moon's far side.

7.4. Luna 9 and 13

After many Soviet lunar failures in 1960–1965, *Luna 9 and 13* in 1966 (Figure 56.7) achieved history's first and third successful lunar touchdowns, delivering image panoramas showing fine surface details.

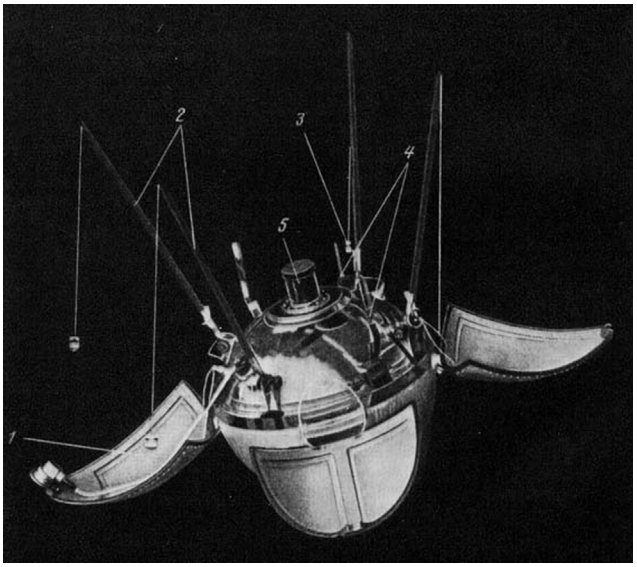

FIGURE 56.7 *Luna 9,* a Soviet spacecraft, achieved history's first successful lunar touchdown, delivering image panoramas showing fine surface details.

7.5. Luna 10, 11, 12, and 14

These Soviet missions, *Luna,* in 1966 and 1968 achieved the first entry into lunar orbit and made some measurements of lunar gravity and geochemistry.

7.6. Lunar Orbiter 1–5

Designed to image landing sites on the Moon in support of Apollo, the first three of the *Atlas-Agena*-launched *Lunar Orbiter* NASA photographic missions were so successful that the last two were given the expanded task of mapping the entire Moon.

7.7. Surveyor 1, 3, 5, 6, and 7

NASA's *Surveyor 1*, launched by Atlas-Centaur, achieved the first lunar soft landing and returned TV mosaics of its surroundings. In addition to imagery, the *Surveyors* in 1966 and 1967 yielded information on the mechanical and chemical properties of the regolith.

7.8. Zond 5, 6, 7, and 8

The *Zond* Soviet spacecraft, launched from 1968 to 1970 by large Proton vehicles, flew on circumlunar trajectories, returning to the Earth after passing over the Moon's farside. They were test flights for a never-completed human lunar flight program. Payloads consisted of environmental instrumentation and biological specimens including tortoises. The later flights demonstrated an ingenious skip reentry, dipping briefly into the atmosphere over the Indian Ocean and then traveling on to land in central Asia.

7.9. Apollo 8

When in 1961 US President John F. Kennedy called for starting *Apollo,* he had asked his advisors to describe a program in which "we can win" in competition with the USSR. Observation of Soviet lunar launch preparations and test flights led to a decision to send a human crew to the Moon as soon as possible. The risky *Apollo 8* mission in 1968 was the result. It went into lunar orbit with only the Command and Service Modules (CSMs) because the lunar landing module (LM) was not yet available. Thus there was no prospect of saving the mission in "LM Lifeboat" mode as had to be done in *Apollo 13* (see below). The *Apollo 8* crew broadcast TV images and a Christmas voice reading of the first chapter of Genesis in the King James Bible from lunar orbit, took photos, made visual observations, and returned safely to splashdown in the Pacific Ocean.

7.10. Apollo 10

In the final rehearsal for a lunar landing in 1969 (after *Apollo 9's* successful Earth-orbiting test of the LM), the *Apollo 10* crew exercised all LM functions in low lunar orbit, rendezvoused with the CSM, and returned safely to the Earth.

7.11. Apollo 11

Apollo 11, the mission that won the greatest peaceful international contest placed, on July 20, 1969, the first human footprints on the Moon. The LM crew gathered rock and soil samples and installed a set of long-lived instruments on the surface. Meanwhile, a photographic survey from the orbiting CSM covered landing sites for future missions.

7.12. Apollo 12

An outstanding achievement in 1969 by the *Apollo 12* ground and flight crews is shown in Figure 56.8. Navigating to a landing within 170 m of *Surveyor 3,* which had been sitting on the Moon for 31 months, the LM crew walked over to the *Surveyor,* cut off its camera and soil sampler claw, and returned them to the Earth. The mission also brought back a new harvest of rocks, soils, orbital and surface imagery, and other science data.

7.13. Apollo 13

When the *Apollo 13* spacecraft was en route to the Moon in 1970, an oxygen tank in the service module exploded. The dramatic rescue of the mission during the following week is an epic tale of devotion and ingenuity by the ground and flight crews. Moving out of the crippled CSM into the LM, the crew used the LM descent engine to adjust their trajectory to a circumlunar return to the Earth. In the midst of the emergency, they even managed to obtain some lunar farside photographs.

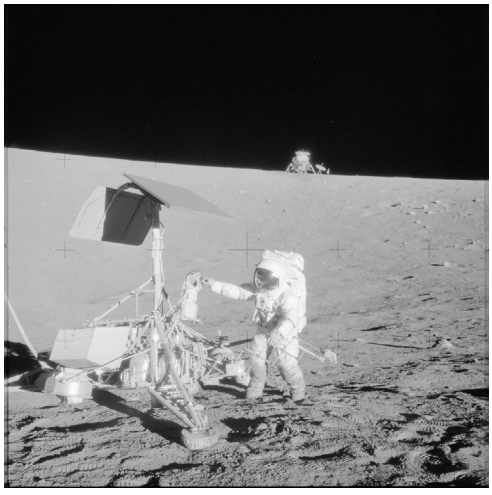

FIGURE 56.8 Astronaut Pete Conrad examines Surveyor 3's camera and soil sampler claw in 1969.

7.14. Apollo 14

Continuing to expand *Apollo*'s scientific capabilities, the 1971 Apollo 14 mission's surface exploration included a hand-drawn cart for carrying instruments.

7.15. Apollo 15, 16, and 17

During three *Apollo* missions in 1971 and 1972, human lunar scientific exploration showed its real potential. With augmented geological training of astronauts, plus one crew member a professional geologist, plus a rover to carry the LM crew on extended surface traverses, plus a suite of remote sensing instruments on the CSM, these missions yielded a cornucopia of information that is described in the chapter on Moon.

7.16. Luna 16, 17, 20, 21, and 24

During the *Apollo* years the USSR had three lunar programs. The first was the robotic science program that began in 1959 and continued with increasing capabilities until 1976. The second was the Proton-launched circumlunar *Zond* (a name meaning sounder) human precursor tests. The third was the human lunar landing effort based on the giant N-1 vehicle that failed in four launch attempts.

Lunas 16 through *24* were emissaries of the first program. The Proton-launched *Luna 16, 20,* and *24* (Figure 56.9) drilled into the regolith, encapsulated small soil samples, and returned them to the Earth. *Luna 17* and *21* delivered Lunokhod rovers to the Moon's surface.

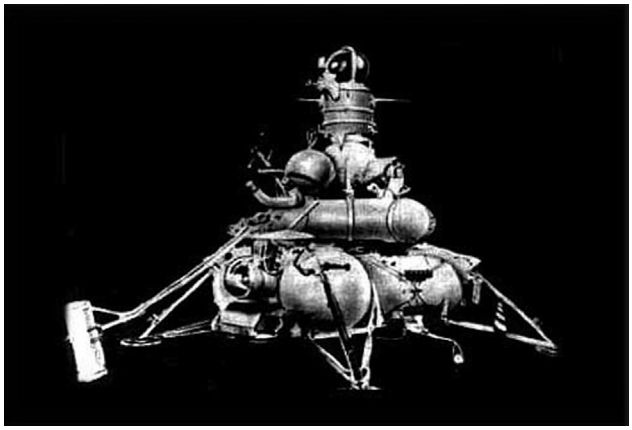

FIGURE 56.9 The *Luna 16* spacecraft.

7.17. Clementine

The mission that revived lunar exploration in 1994 after its decades of stasis, *Clementine,* had an innovative management and technical plan. Proposed as a test of instrument technologies for the American Strategic Defense Initiative, it was sponsored by the Ballistic Missile Defense Organization and NASA, managed by the Naval Research Laboratory, and launched from the Pacific Missile Range on a Titan II-G.

During 2 months in lunar orbit, it mapped the entire Moon at many wavelengths and hinted at the presence of theoretically predicted excess volatiles, possibly a signature of cold-trapped water ice near the lunar poles.

7.18. Lunar Prospector

Launched in 1998 by an Athena solid-fueled vehicle, the NASA *Lunar Prospector* continued the trend toward small, highly capable lunar spacecraft and relatively low mission costs. With neutron, gamma-ray, and alpha-particle spectrometers plus measurements of lunar magnetic and gravity fields, the mission yielded data on the Moon's surface composition and its geochemical and geophysical properties. By sending convincing evidence of excess hydrogen near both poles, it added confidence to the *Clementine* findings of possible polar ices.

7.19. SMART-1

ESA's first lunar mission, *SMART-1,* was launched in 2003 with a small, highly advanced spacecraft demonstrating solar electric propulsion, onboard autonomy, and several new instrument technologies. Spiraling slowly outward from the Earth and then inward toward the Moon, the craft was captured by the Moon's gravity late in 2004 and began science operations in lunar orbit in 2005, whence it delivered a fine harvest of imaging and other remote sensing data until its planned crash into the Moon on September 3, 2006.

7.20. Kaguya/SELENE

Japan and China both launched lunar polar remote sensing orbiters in 2007, returning a rich harvest of multispectral observations as well as gravity and selenodesy data obtained from precise tracking. Kaguya/SELENE carried 14 science instruments and two small subsatellites.

7.21. Chang'e 1

China's first lunar mission gave excellent data on lunar surface and interior properties, including a global thermal map from microwave radiometry.

7.22. Chandrayaan-1

Chandrayaan-1, India's first lunar venture, a remote sensing polar orbiter launched in 2008 and ended in 2009, among other instruments carried an American infrared spectrometer, the Moon Mineralogy Mapper, that confirmed the existence of varying amounts of water at the lunar surface (see Moon chapter).

7.23. Lunar Reconnaissance Orbiter

This US mission, launched in 2009, continues to provide huge amounts of data including imaging of such high quality as to show landed spacecraft from previous missions.

7.24. LCROSS

This mission, opportunistically taking advantage of a large available payload excess, was launched with Lunar Reconnaissance Orbiter. The launch vehicle's spent upper stage was targeted to crash in a shadowed polar crater while a following spacecraft observed the impact debris cloud, illuminated by sunlight, with an infrared spectrometer, yielding confirmation of water ice.

7.25. ARTEMIS

Another ingenious mission of opportunity, this venture uses two of the five THEMIS spacecraft, moved from their original orbits, observing auroras and other magnetospheric phenomena, into new libration orbits inward and outward from the Moon.

7.26. Chang'e 2

The second Chinese lunar orbiter, after completing its mapping mission in 2010, was sent off toward asteroid Toutatis.

7.27. GRAIL

Launched in 2011 and using the same measurement principle as the GRACE mission at the Earth, the twin lunar orbiters, with the varying distance between them recorded at extreme precision, have yielded a new high-resolution map of the Moon's gravity. In addition, one spacecraft carries a camera, dedicated to educational outreach, targeted by school children.

7.28. LADEE

Delivered into Lunar orbit in 2013, this mission is to investigate the Moon's tenuous atmosphere and the

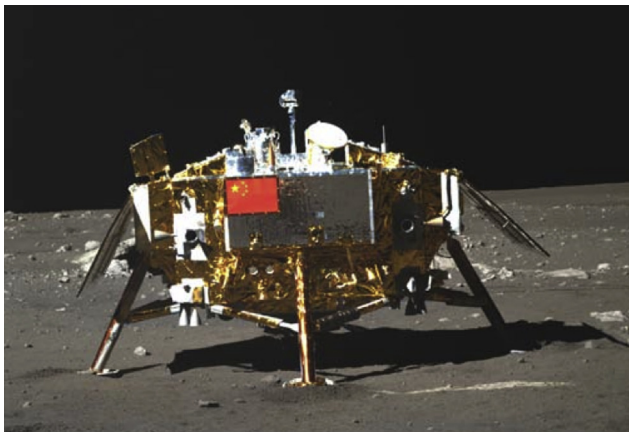

FIGURE 56.10 *Chang-E 3* lunar lander (CNSA)

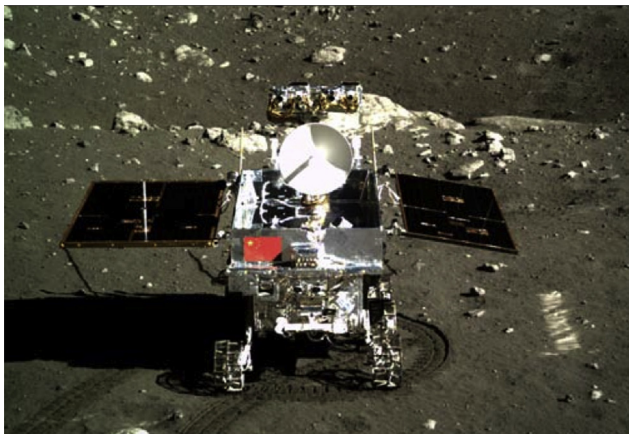

FIGURE 56.11 *Yutu* (Jade Rabbit) lunar rover (CNSA).

levitated dust phenomena observed by robotic landers and Apollo astronauts. It also carries an ultra-broadband laser communications technology demonstration experiment.

7.29. Chang-E 3 and Yutu

In December 2013 China's *Chang-E 3* landed in northern Mare Imbrium and deployed the rover Yutu (Jade Rabbit). See Figures 56.10 and 56.11. Both spacecraft began observing the lunar surface, subsurface and sky with suites of instruments including ground-penetrating radar and ultraviolet telescopes. After landing both spacecraft survived their first lunar night, but after the second night Yutu was found to be partly inoperative due to temperature extremes after a solar panel mechanism fault. Yutu continued to operate as a fixed observer.

8. MARS

With nineteenth-century telescopic observation showing polar caps and other indications of an atmosphere and changing surface features, Mars became the planet of choice for speculation about other life in the cosmos and about human travel to other worlds.

These pervasive ideas have since driven planetary program priorities with the result that huge resources have been devoted to Martian robotic exploration and to studies of the prospect of human ventures to Mars. But Mars has proved to be a difficult destination: Failure has been an ever present hazard—not only in flight missions but also in the councils where budget decisions are made.

In what follows, we concentrate on successes, but those must be seen as just the most visible parts of a remarkable, decades-long striving toward a possible breakout of humanity beyond the bounds of Earth.

8.1. Mariner 4

Mars launch opportunities occur about every 26 months. In both the United States and the USSR, the October 1960 window was the favored first chance. The Soviets did launch, with two upper stage vehicle failures. During the 1962 window, the Soviets tried three launches, one of which sent *Mars 1* toward the planet. That spacecraft failed en route. In 1964, NASA launched two *Atlas-Agenas* with one success. *Mariner 4* flew by Mars and returned 22 images of the cratered southern highlands, leading to the impression of a Moon-like Mars, proved false by later missions.

8.2. Mariner 6 and 7

Two Mars flyby missions, *Mariner 6* and *7,* launched by *Atlas-Centaurs* in 1969, demonstrated the rapid advance of deep space data acquisition technology. Their imaging was greatly improved over that of *Mariner 4* in both quality and quantity, and in addition, infrared spectrometry gave some first indications of Martian surface compositions. They still covered mainly southern, including polar, ancient landforms, omitting the vast volcanoes and canyons discovered by *Mariner 9.*

8.3. Mars 2 and 3

During the 1971 Mars window, the USSR and United States each launched two missions. The Soviet *Mars 2* and *3* orbiter/landers both arrived successfully into orbit at the planet; *Mars 2* returned some orbital science data but its lander crashed. *Mars 3,* in addition to its orbital operations, delivered its lander with a small tethered mobile platform. But the transmissions from the lander ceased only 20 s after touchdown.

8.4. Mariner 9

The *Atlas-Centaur* carrying *Mariner 8* failed but *Mariner 9* became the most rewarding Mars mission up to its time, waiting out a global dust storm in orbit and then sending imagery of most of the Martian surface until its mission ended in 1972, revealing enormous volcanoes, canyons, apparent river channel networks, sapping collapse features and clouds, as well as images of the two small moons, Phobos and Deimos.

8.5. Mars 4, 5, 6, and 7

At the 1973 opportunity, the Soviets made an all-out effort to upstage the American *Viking* missions planned for 1975. They launched four large spacecraft, all of which arrived in the vicinity of Mars but each of which ultimately failed for a different reason. *Mars 4* failed to brake into orbit but did return some flyby data; *Mars 5* entered orbit, sent some images, and failed after 22 days; *Mars 6* released a lander that failed during descent; and *Mars 7's* lander missed the planet.

8.6. Viking 1 and 2

In 1975, two large NASA orbiter/landers, *Viking 1* and *2*, were launched by powerful *Titan-Centaurs.* Arriving in June and July 1976, they entered orbit and began surveying for landing sites. The *Viking 1* lander set down in Chryse Planitia on 20 July and the *Viking 2* lander descended to Utopia Planitia on 3 September on the opposite side of Mars. While the orbiters began imaging the whole planet and making spectrometric remote sensing observations, during descent the landers measured atmospheric composition. Then the landers began to operate a suite of instruments for imaging their surroundings and determining meteorological, geological, and biological properties. At first, microbial activity was suspected, but eventually most scientists concluded that no life did or could exist in the soil samples. The Viking 1 landing site was renamed the Thomas A. Mutch Memorial Station.

8.7. Phobos 1 and 2

After a long pause in Martian exploration, in 1988, two large and complex Soviet spacecraft, *Phobos 1* and *2*, were launched by *Proton* vehicles toward the vicinity of Mars. *Phobos 1* was lost en route due to a human error in ground control. *Phobos 2* arrived and began phasing orbits for a rendezvous with the little moon, where it was to make close-up observations and deposit two small landing packages, one of them a hopping rover. Imagery and some other data of Phobos and Mars were obtained, but the spacecraft failed before the landings could occur.

8.8. Mars Pathfinder and Mars Global Surveyor

The 1996 launch window saw the revival of detailed American exploration of Mars. NASA's *Pathfinder* delivered a lander, named the Carl Sagan Memorial Station, and a small rover, named Sojourner, which explored nearby surroundings in the Ares Vallis outwash plain. The *Global Surveyor* spacecraft entered an eccentric orbit and was delicately aerobraked down into circular mapping orbit over a period of months, the long period being needed due to structural failure of the attachment of one solar panel. The mission has yielded a continuing stream of imaging and other data, revolutionizing scientists' knowledge and modeling of Martian geology and atmospheric processes.

8.9. Failures of the 1990s

The years 1992, 1998, and 1999 saw three US missions fail during arrival at the planet: *Mars Observer, Mars Climate Orbiter,* and *Mars Polar Lander.* An elaborate international Russian mission's launch, *Mars 96,* failed in 1996—a series of events that led in the United States to a management overhaul and in Russia to the end of Mars exploration for the time being.

8.10. Mars Odyssey

Mars Odyssey, a NASA orbiter launched in 2001, is instrumented for measurements complementing those of the *Global Surveyor.* With infrared/visible, gamma-ray, and particle spectrometers, it produces thermal imaging enabling evaluation of surface physical properties, subsurface elemental chemistry, and the planet's radiation environment. *Odyssey's* findings have greatly stimulated interpretations of many of Mars' landforms as resulting from the action of subsurface briny water, ice, and carbon dioxide.

8.11. Spirit and Opportunity

In an intense 3-year effort, two NASA Mars rover missions, *Spirit* and *Opportunity,* were prepared for the 2003 launch opportunity. Both succeeded, and the two rovers continue to make discoveries in Meridiani Planum and Gusev Crater, on opposite sides of the planet, reinforcing the orbiters' findings of a history dominated by the effects of water.

Spirit finally became mired and its mission has ended, but Opportunity made its way to the large crater Endeavour where it goes on adding to the history of the planet's watery past.

8.12. Mars Express

ESA's *Mars Express* orbiter, launched in 2003, delivered the small British *Beagle-2* lander, which failed, and has then gone

on to yield excellent three-dimensional imaging, plus spectrometric measurements indicating, among other findings, that there is a correlation between regions of enhanced water vapor and methane concentrations in the atmosphere. Mars Express also carries a ground-penetrating radar for detecting the signatures of subsurface brines and ices.

8.13. Mars Reconnaissance Orbiter

Launched in 2005 and delivered in 2006 into aerobraking orbit at Mars, *Mars Reconnaissance Orbiter* has increased by orders of magnitude the quantity and quality of remote sensing data from Mars, because of its powerful radio system and advanced on-board instruments and system software. An example of MRO's amazing imaging capacity is given in Figure 56.12.

8.14. Phoenix

A reflight of the failed *Mars Polar Lander*, in 2007, the *Phoenix* spacecraft, during its 5-month surface mission, confirmed the existence of high-latitude ice within centimeters of the Martian surface. Droplets of brine were observed on parts of the lander.

8.15. Curiosity

Delivered into the huge ancient crater Gale in 2012 by an elaborate entry, descent, and landing system including a rocket sky crane, at the time of this writing, the 1-ton rover is in fine working condition and has begun traveling toward its goal of exploring the layered deposits of Mount Sharp (officially Aeolis Mons). Some of its chemical analyses have revealed all elements necessary to support life (Figure 56.13).

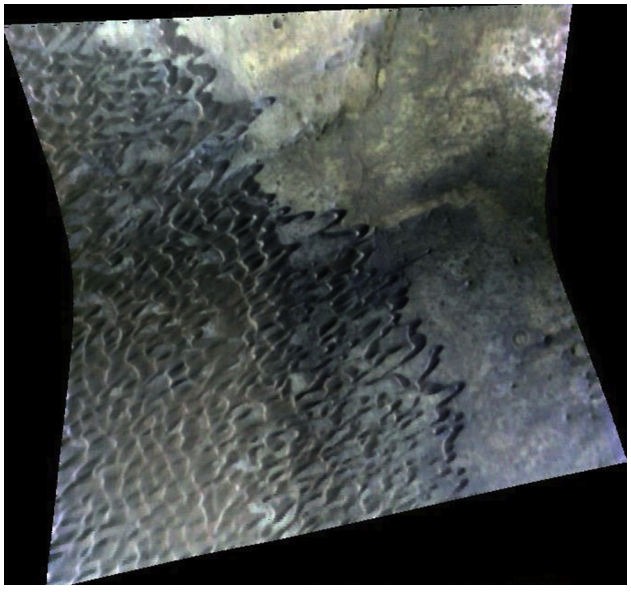

FIGURE 56.12 Dune field in Nili Patera taken by the Compact Reconnaissance Imaging Spectrometer for Mars (CRISM). The image was taken in 544 colors in the wavelength range between 0.36 and 3.92 μm and shows features as small as 20 m across. © *NASA/JPL/JHUAPL/USGS.*

8.16. Mangalyaan

Launched in 2013 to arrive at Mars in September 2014, this first Indian planetary mission is to investigate the Martian atmosphere, including the methane detected by previous orbiters; image the surface; and demonstrate technologies for exploring Mars.

9. SMALL BODIES

As scientists have come to realize that comets and asteroids contain clues to the ancient history of the solar system—clues largely obliterated by geologic processes in planets and moons—missions to small bodies have increased in importance. Also, studies of cratering and meteorite records show that near-Earth asteroids present both a threat and an opportunity. The threat is that of devastating impacts and the opportunity is that of useful resources not found in the Moon.

9.1. International Cometary Explorer

After completing its solar mission as *ISEE-3* (see Sun and Heliosphere sections), the spacecraft was retargeted and renamed *International Cometary Explorer.* It flew through the tail of Comet Giacobini–Zinner in 1985, and then continued on in heliocentric orbit where it sent low-rate data for the next several years. It is now returning toward the vicinity of Earth.

9.2. The Halley Armada

As Halley's comet arrived near the Sun in 1986 on its 76-year orbit, it was met by spacecraft from Japan, Europe, and the USSR. Comet enthusiasts lamented the absence of the United States from this once-in-a-lifetime opportunity. Japan's *Suisei* and *Sakigake* made distant observations of the ultraviolet coma. ESA's *Giotto* passed within 600 km of the nucleus collecting imaging, spectra, and detailed chemical data. The Soviet *Vega 1* and *2* flew by at intermediate distances after their productive en route encounters with Venus (see Venus section).

9.3. Galileo En Route Encounters

While en route to Jupiter on its long journey with gravity assists at Venus and Earth, the NASA *Galileo* spacecraft flew by two Asteroids, 951 Gaspra in 1991 and 243 Ida in 1993, and obtained close-up imagery, spectra, and other

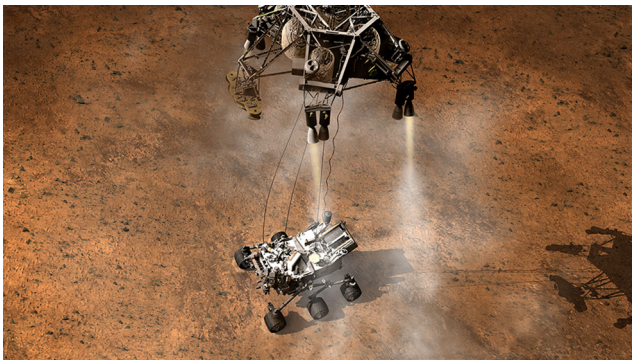

FIGURE 56.13 With an unprecedented landing technique NASA's Mars Science Laboratory was lowered with a sky crane to the surface on August 4, 2012. After crossing the Gale crater plane, rover *Curiosity* will climb 5500 m elevation Aeolis Mons. © *NASA/JPL/JHUAPL/USGS.*

measurements. A highlight of the Ida encounter was the discovery of the tiny moon Dactyl orbiting Ida.

9.4. NEAR-Shoemaker

Launched in 1996, the NASA spacecraft *NEAR-Shoemaker* entered orbit about Asteroid 433 Eros in 2000, delivered imagery, spectrometric data, and gravitometric data. After 1 year in orbit, it was commanded to a gentle touchdown, which it survived, even though not designed for landing.

9.5. Deep Space 1

The NASA craft *Deep Space 1* launched in 1998 to demonstrate solar electric propulsion, autonomous navigation, and other new technologies encountered Asteroid 9969 Braille in 1999, although it only returned a few distant, low-resolution images. Its mission was extended to a close flyby of Comet Borrelly on September 22, 2001, and successfully imaged the nucleus at visible and infrared wavelengths.

9.6. Stardust

With the goal of collecting samples of cometary dust and returning them to the Earth, NASA's *Stardust* mission, launched in 1999, flew by Asteroid 5535 Annefrank in 2002, and encountered Comet Wild 2 in 2004, returning imaging data. The sample return capsule successfully parachuted to Earth on January 4, 2006, with its precious cargo of thousands of cometary (and interstellar) dust particles.

9.7. Hayabusa (Muses-C)

JAXA mission with assistance from NASA, *Hayabusa* was launched in 2003 and used solar electric propulsion to rendezvous with Asteroid 25143 Itokawa in September 2005. It returned multispectral imaging and gravity data and collected surface samples for return to the Earth. Despite problems causing long delays and calling for heroic action by mission planners and controllers, the returning payload was recovered in Australia in June 2010.

9.8. Rosetta

Rosetta, an ESA mission launched in March 2004 with the *Ariane 5,* is scheduled to arrive at Comet Churyumov–Gerasimenko in 2014 after three Earth gravity assists and one at Mars. It was also targeted to flyby Asteroids 2867 Steins in 2008 and 21 Lutetia in 2010.

9.9. Deep Impact

With the goal of determining the physical and chemical makeup of a cometary nucleus, NASA's *Deep Impact* mission, launched in January 2005, successfully delivered a 370-kg projectile to a 10 km/s collision with Comet Tempel 1 on July 4, 2005. Imaging from the impactor and the flyby spacecraft returned the highest resolution pictures of a comet to date and documented the impact event, which provided new insights into the nature of cometary nuclei.

9.10. Dawn

The ongoing Dawn mission is beginning to deliver the full benefits of solar electric propulsion. Launched in 2007, it orbited and mapped Asteroid Vesta until 2012 and is now en route to Asteroid Ceres, potentially yielding comparative planetological information on the two largest, and notably different, asteroids (Figures 56.14 and 56.15).

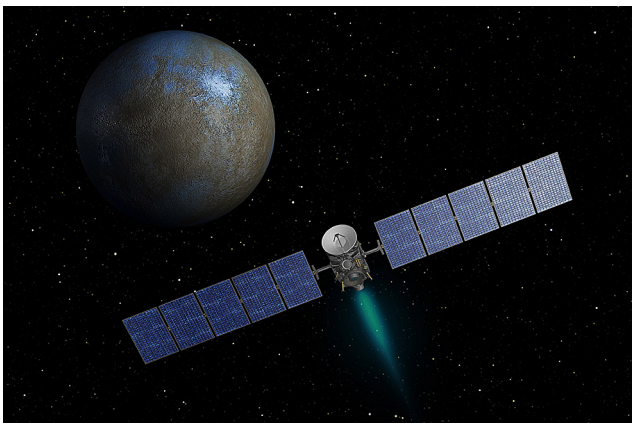

FIGURE 56.14 With its xenon-ion thrusters, Dawn will be the first space probe orbiting two different planetary bodies beyond Earth: Vesta (December 2001), and Ceres (2015, artist's rendition). *NASA.*

FIGURE 56.15 The Hayabusa sample container after landing in Australia. *JAXA*.

10. OUTER PLANETS AND MOONS

In 1610, when Galileo observed four bright specks moving near Jupiter, he set in motion a quest that culminated in the twentieth century with history's greatest robotic exploration program, giving never-to-be-repeated first close looks at the giant outer planets and their retinue of moons and rings.

10.1. Pioneers 10 and 11

Two NASA missions launched the first two of five human artifacts to escape forever from the Sun's domain. Leaving Earth in 1972, *Pioneer 10* flew by Jupiter in 1973 with imaging and magnetospheric measurements. Its signal continued to be detected at the Earth until 2003. After launch in 1973, *Pioneer 11's* flyby trajectory was adjusted so that, at its encounter in 1974, Jupiter's gravity would fling it onward toward Saturn, where it flew by in 1979. Each spacecraft carried a golden plaque illustrating humans and encoded information on where and when in the cosmos the flight had originated.

10.2. Voyagers 1 and 2

Launched in 1977 by Titan-Centaurs and still operating today, the NASA missions *Voyagers 1* and *2* are a mighty achievement. *Voyager 1* flew by Jupiter in 1979 and Saturn in 1980, whence it headed toward the heliopause, the boundary between the Sun's realm and that of interstellar space. En route it delivered a family portrait of the solar system showing Earth as a pale blue dot. *Voyager 2* was targeted to a Jupiter flyby and then to Saturn, where Saturn's gravity would send it on to Uranus and Neptune, taking advantage of a planetary alignment that happens at intervals of 173 years. *Voyager 2* passed Uranus in 1986 and Neptune in 1989. The two *Voyagers* returned a vast harvest of imagery, geochemical and geophysical data on the giant planets and their moons and rings, and magnetospheric information. Each one carried a golden phonograph and video record showing characteristics of our planet, its inhabitants, and human civilization. In 2005, *Voyager 1* detected the heliopause, and in 2006, it passed 100 astronomical units from the Sun. At the time of this writing, it has detected passage from the heliosphere into interstellar space.

10.3. Galileo

NASA's *Galileo* mission was launched by the space shuttle plus the *Inertial Upper Stage* in 1989 after a fraught history of replanning and delays including one due to the *Challenger* disaster. *Galileo* entered Jovian orbit in 1995, having made one Venus and two Earth gravity assist flybys en route. During the flybys, some science data were collected, including multispectral observations of the Earth and Moon. Galileo performed the first two asteroid flybys, targeted to Gaspra and Ida, and was in position to image the Comet Shoemaker–Levy 9 impacts on Jupiter. At arrival in the Jovian system, the spacecraft delivered a probe into the huge planet's atmosphere, reaching a level of 55 bars and 152 °C. Despite the failure of the orbiter's high-gain antenna to deploy, the mission returned a large volume of imaging, spectra, and other data on the planet and its moons. In 2003, the craft was commanded to a Jupiter impact, with destruction in Jupiter's atmosphere to keep it from becoming a contamination risk toward any possible biology in the putative subsurface oceans of Europa and Ganymede.

10.4. Cassini–Huygens

Launched in 1997 by a *Titan-Centaur,* NASA Saturn orbiter spacecraft *Cassini-Huygens* carried ESA's *Huygens* probe designed to enter the dense atmosphere of the huge moon Titan (Figure 56.13). With a 1998 Venus gravity assist and a 2000 Jupiter flyby with some scientific observations en route, the combination entered Saturn's orbit in 2004. The probe descended to Titan in 2005, delivered remarkable images, and survived landing on the surface for more than 2 h. Both spacecraft returned unique new observations that will cause active scientific analysis and argument for years to come (Figures 56.16 and 56.17).

10.5. New Horizons

Launched in 2006 at such a high speed that it passed Jupiter in less than 13 months from Earth departure, the *New Horizons* spacecraft's purpose is to investigate the surfaces and atmospheres of Pluto and its large moon Charon during a flyby in 2015. After that it is expected to continue

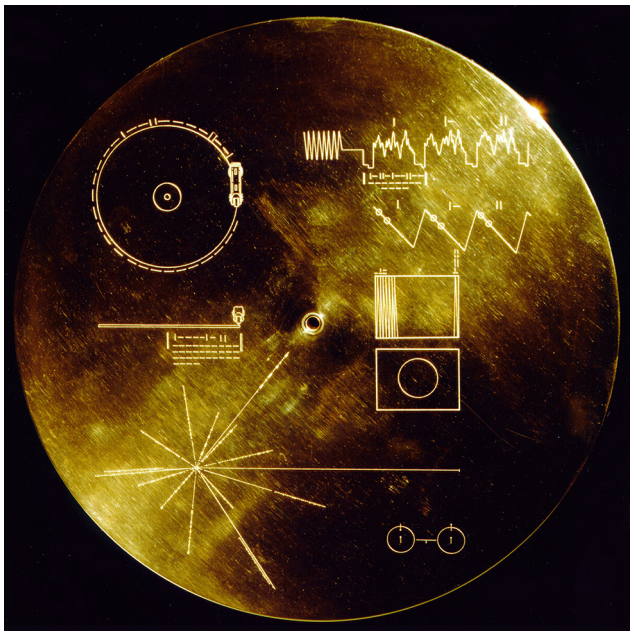

FIGURE 56.16 At the end of 2012, scientists concluded that *Voyager 1* had crossed the heliopause and, as the first man-made object, had been entering the interstellar space. On board is the famous Golden Record, inspired by the late Carl Sagan. *NASA.*

functioning for several more years, exploring the mysteries of the Kuiper Belt, that far-out region of the solar system where the first representatives of a likely multitude of small, icy objects have already been discovered by telescopic observation from the Earth and from the Hubble Space Telescope.

10.6. JUNO

Launched in 2011, another grand mission to Jupiter and its moons is in progress. After a gravity assist flyby of the Earth in 2013 the spacecraft is expected to enter Jovian orbit in 2016.

FIGURE 56.17 *Cassini* was launched in 1997. *NASA.*

11. CONCLUSION

Thus continues the first, magnificent phase of investigation throughout the Sun's domain. Meanwhile, spaceflight in the inner solar system is reinvigorated as robotic missions to the Moon and Mars take on the purpose, in addition to science, of searching for extraterrestrial energy and material resources and acting as precursors to renewed human exploration and perhaps ultimately settlement of communities off the Earth. And discoveries of planets (hundreds confirmed, thousands of candidates) orbiting other stars tell us that exploration of star and planet systems has a limitless future.

Chapter 57

Exploration and Analysis of Planetary Shape and Topography Using Stereophotogrammetry

Jürgen Oberst, Klaus Gwinner and Frank Preusker

Planetary Geodesy Department, German Aerospace Center, Institute of Planetary Research, Berlin, Germany

Chapter Outline

1. Introduction **1223**
2. Missions and Cameras **1224**
2.1. Framing Cameras 1224
2.2. Scanners 1224
2.3. Cameras on Surface Landers and Rovers 1224
2.4. Built-in Stereo Capability 1225
2.5. Acquisition of Ancillary Orbit and Pointing Data 1225
2.6. Camera Calibration 1225
3. Coordinate Systems **1225**
4. Photogrammetric Processing **1225**
4.1. Image Matching 1226

6. Examples **1228**
7. Summary and Conclusions **1231**
Acknowledgments **1232**
Bibliography **1233**

1. INTRODUCTION

Acquiring information on the surface morphology is among the foremost goals in the exploration of the solar system **planets, satellites**, and minor bodies. In addition to its key role in understanding geologic structures and geophysical processes, morphology is also a critical factor in the coregistration of images for studies of spectrometry, photometry, and temporal change. Geodetic reference systems, maps, and appropriate data visualizations are essential contributions to modern planetary remote sensing missions. With the availability of modern digital camera systems and improved processing techniques, the resolution and quality of digital terrain models (DTMs) covering planetary surfaces has improved considerably in the past 20 years.

DTMs are of great interest for studies of surface features over a variety of scales, from giant volcanoes to small sand dunes. Useful physical parameters can be obtained, such as excavation depths and ejecta volumes for craters of various sizes. Slope measurements in DTMs are used to assess mass wasting effects. Precise topographic data are also used to study illumination conditions and surface shading effects. From precise topography, we can predict areas to be in daylight or in shadow at any given time. Also, terrain models are used to rectify images (i.e. to correct images for local displacements that are caused by surface topography), which is essential for the production of geometrically accurate maps or the coregistration of data sets. In combination with gravity models, topography is essential to assess crustal thickness.

Stereophotogrammetry is a well-established technique in terrestrial mapping that exploits perspective effects in images acquired with different viewing angles to derive information on object positions in three dimensions. The discipline name "photogrammetry" was introduced more than a century ago to express that images were used for precise positional measurements. The term "stereogrammetry" is an abridgment often found in the American literature. An analogous term, "radargrammetry", has been coined to describe the similar geometric analysis and topographic mapping capability of side-looking radar images.

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00057-8
Copyright © 2014 Elsevier Inc. All rights reserved.

Stereophotogrammetry has a unique performance concerning the geometric resolution of three-dimensional (3-D) data products and does not require assumptions regarding the physical properties of the surface to be analyzed. In contrast, one of the alternative techniques, photoclinometry or "shape from shading", uses brightness information to constrain slopes and topography, and requires knowledge of the radiometric properties of the reflecting surface and any intervening atmosphere, which is typically limited. Other more direct observations of shadows or surface contours against the dark sky (limb observations) have been used to estimate topographic profiles or to determine heights of individual features ("shape from silhouette"), when adequate stereo image coverage was not available. The latter techniques fall within the definition of photogrammetry but in this paper, we focus on the stereophotogrammetric techniques alone.

Alternative topographic mapping techniques, such as laser altimetry or the above-mentioned radargrammetry are not discussed in this paper. However, at the end, we will discuss synergies of stereo mapping with laser altimetry, as the combination of these two techniques has shown valuable benefits in modern planetary missions.

2. MISSIONS AND CAMERAS

The coordinates of a 3-D point are determined by computing viewing vectors from two or more different observation positions and by computing the intersection point of the rays defined by these viewing vectors. The exterior orientation of the camera, i.e. the positions of the viewing posts at the time of exposure and the camera pointing (more specifically, the rotation matrix relating the target coordinate system to image coordinates) must be precisely known or inferred to determine the viewing vectors. For convenience, positions and viewing vectors are computed in the coordinate system fixed to the target body. In the case that the target-fixed coordinate system (e.g. a planet's rotational model) is not sufficiently well known, this must be modeled in the process.

Viewing vectors are computed from the exterior orientation parameters of the camera in combination with the measured image coordinates of features and of calibration data describing the imaging system itself. The latter include focal length, image distortion parameters, and mounting offsets of the sensor system typically determined from calibration campaigns carried out either before flight on ground or in-flight, e.g. by using observations of star fields.

As navigation and calibration data are typically not as well known as one might wish, sophisticated techniques for reconstructing orbit and/or pointing data in combination with parameters of the imaging system have been developed. Depending on the properties of the available data and the desired characteristics of the surface model, these steps play an important role in establishing a reliable geometric framework for the reconstruction of topography.

2.1. Framing Cameras

Framing cameras are equipped with frame **Charge-Coupled Device (CCD)** or **Active Pixel Sensor (APS)** array sensors or even (in the early mapping of the Earth and Moon) photographic film. Here, mathematically simple geometric conversions exist that relate positions of a feature on the sensor surface to viewing vectors for each sensor **pixel**. The image geometry is very stable, i.e. the relative positions of the pixels are precisely known. Stereo images are acquired by pointing the camera from different body-fixed positions to the surface feature of interest. Alternatively, for small objects as asteroids, the camera may remain at some inertially fixed position, while the asteroid rotates beneath the camera position.

2.2. Scanners

For spacecraft in low planetary orbits, it is advantageous to use line scanners rather than framing cameras for topographic mapping. Line scanners are equipped with linear CCD or APS sensors, which are operated at high rates. Images are obtained along the spacecraft ground track, while the spacecraft moves ("pushbroom mode"). The stereo processing of scanner images or the combination of several such scans requires that the spacecraft trajectory and attitude of the sensor are known or modeled on a quasi-continuous basis, according to the high sampling rate of the imager. By using multiple line sensors side by side, large image blocks can be obtained. For example, the High-Resolution Imaging Science Experiment (HiRISE) camera on Mars Reconnaissance Orbiter has 14 separate line sensors on its large focal plane. Sensors equipped with filters can provide multispectral images. One of the advantages of scanners over framing cameras is that they can produce quickly very large-format images, limited by available onboard data storage only.

2.3. Cameras on Surface Landers and Rovers

A special but increasingly important case of planetary photogrammetry is the recovery of topography from stereo images obtained by cameras on surface landers or rovers. Such spacecraft are typically equipped with pairs of framing cameras mounted on a mast, on the rover body, or both. Dual lenses, separated horizontally by a fixed and precisely calibrated base length are used to obtain the perspective effects. The stereo reconstruction process is challenged by the fact that ranges to features of interest and corresponding perspective effects vary greatly. Perspective effects are large near the camera, and approach zero at the

horizon, depending on the separation and angular field of view of the dual cameras. Also, due to the specific viewing conditions ("frog perspective") and a possibly rough surface, large parts of the image may be hidden from the camera, thus preventing the construction of a contiguous terrain model from only one pair of stereo images.

2.4. Built-in Stereo Capability

Using multiple sensors pointed at different along-track viewing directions, stereo images can be obtained simultaneously during a single orbital pass. For spacecraft in orbits dedicated to surface mapping, it may be worthwhile carrying cameras with such a built-in stereo capability. As the first camera of this kind, the high-resolution stereo camera (HRSC) line scanner on Mars Express is equipped with nine sensors, five of which are pointed at different viewing directions and are dedicated to stereo imaging. While the spacecraft moves, the stereo sensors will scan an area several times under different viewing angles. Similar camera systems featuring dual or triple line arrays for terrain mapping have flown on the Japanese Kaguya, the Indian Chandrayaan-1, and the two Chinese Chang'e missions. Alternatively, dual-frame cameras pointed forward and backward can be used. The built-in stereo capability does not require any dedicated pointing or spacecraft maneuvers. The stereo images are typically obtained within minutes under near-identical illumination conditions, which facilitates the data analysis.

2.5. Acquisition of Ancillary Orbit and Pointing Data

For the stereo processing excellent navigation data are required. Spacecraft orbits are usually obtained from radio range and Doppler measurements. Long tracking arcs of several hours are used to determine the trajectory of the spacecraft at any time. The attitude of the spacecraft and, hence, pointing of the cameras, is obtained by star sensors in combination with gyroscopes mounted on the craft.

2.6. Camera Calibration

For the processing, also good knowledge of the camera geometric parameters is required. This includes the focal length and principle point of the camera as well as alignment parameters with the spacecraft coordinate system. Parameters of image distortion can be relevant as well, usually expressed in polynomial functions relating the image coordinates at which a feature is observed to the "ideal" coordinates for a distortionless camera. Camera geometric properties are normally determined on the ground before flight. However, after launch, updates of camera calibration parameters may be required. Typically, dedicated imaging campaigns of star fields (in which positions of stars are accurately known) are used to verify the camera calibration parameters.

3. COORDINATE SYSTEMS

Established coordinate systems are essential for the geometrically correct reconstruction of planetary topography, where images taken from different positions and at different times are analyzed jointly. The definitions of coordinate systems for planets and their satellites, the asteroids, and the comets, enjoy common standards established by the International Astronomical Union working group on Cartographic Coordinates and Rotational Elements. The coordinate systems are defined by their rotational states with the z-axis pointing into the direction of the rotational axis, and the equator constraining the plane of the x- and y-axes. The origin is located at the bodies' center of mass. The choice of the prime meridian (i.e. where $y = 0$) is not unique for planets and satellites. If bodies are in locked rotation (i.e. it is always the same hemisphere that is facing the central body), the mean subplanet point typically defines the prime meridian. Alternatively, the principle axes of the **moment of inertia** are used to define this meridian. For example, two such body-fixed coordinate systems, the Mean Earth and the Principle Axis system are currently in use for the Moon. As a practical matter, once sufficiently detailed images are available, longitudes are usually defined relative to a surface feature, e.g. a prominent crater. The longitude assigned to the reference feature can be chosen to provide continuity with earlier coordinate definitions for the same body.

The orientation of the rotational axis is specified by the intersection of this axis with the celestial sphere. For some planetary bodies (Moon, Mars), sufficient observational data are available to describe a secular motion of the rotational axis on the celestial sphere. Objects in tidal locks, like Moon, Mercury, and small satellites are subject to tidal interaction and show physical librations (slight oscillations about their equilibrium rotation state). Photogrammetric measurements of librational amplitude and phase represent important constraints for planetary interior models.

4. PHOTOGRAMMETRIC PROCESSING

Significant advances in the application of photogrammetric techniques in planetary exploration (as well as earth observation) were made with the availability of digital image sensors, increased computing power, and development of improved techniques and algorithms for the full exploitation of the sensor data. Despite the apparent ease of capturing 3-D views with human eyes, the derivation of geometrically accurate gridded DTMs covering large

contiguous areas, and suitable for quantitative terrain analysis, is a complex and computationally intensive process.

4.1. Image Matching

Stereoscopic measurements are based on registering the different positions of a common feature in the image planes of stereo images. The process of identifying corresponding image points (called tiepoints or conjugate points) and of accurately measuring the image coordinates of these points is commonly denoted as "image matching".

Once the position and attitude of the sensor and the geometric properties of the camera are determined through the analysis described in Section 4.2, the image coordinates of a dense set of points (as required to generate a contiguous terrain model) can be converted to absolute coordinates including the distance of the object from the camera. Sophisticated matching techniques are required to produce a high density of corresponding points, as the goal is a contiguous model of surface topography with highest possible spatial resolution.

So-called area-based image matching methods have proven to perform well for this task. Coordinates of tiepoints are sought via comparisons of gray values in small image patches (e.g. 11×11 pixels, or larger). By means of least-squares techniques, positions of the tiepoints can be established with subpixel precision using minimization techniques. The currently available matching techniques applied to planetary surfaces differ in a number of aspects. For example, different strategies are used in how similarity of patches is measured (using minimum deviation in image brightness or maximum mutual information content), how the search process is initialized (with the help of an approximate 3-D model or random seed points) and how the search is organized (using grid search, hierarchical multiresolution, or region growing approaches). The available matching algorithms also differ in their capability to avoid false correlations, and by their different approaches to subpixel matching.

High-performance matching tools regularly apply a range of control procedures for avoiding miscorrelations. These can include quality thresholds of the correlation process or consistency checks obtained from 3-D analysis of the resulting corresponding points. The use of multiple (i.e. more than two) stereo images is valuable, because the redundancy introduced allows for verifying and improving overall precision.

Image matching techniques generally have to cope with various challenges associated with "real life". For example, differing solar illumination conditions in stereo pairs can limit the performance of image matching. For cameras with built-in stereo capabilities, this effect is minimized because stereo images are obtained near-simultaneously.

Occasionally, DTMs are constructed from large numbers of overlapping images, where appropriate matching partners must be identified beforehand. For large blocks of images, this may become a challenging sorting task. At the end, the image matching is carried out individually for each "stereo model", where we may take advantage of parallel computing, if available.

4.2. Triangulation and Bundle Block Adjustment Techniques

If camera position and pointing were accurately known, accurate absolute ground coordinates of points could be derived from the successfully matched points without much computational effort. However, the typical errors in the orientation data make complex block adjustments necessary.

The main goal of the photogrammetric bundle block adjustment is to obtain an improved model of the positions and orientations of the sensor during the image acquisition. The adjustment has to warrant that the 3-D surface point positions resulting from the joint analysis of many individual images form a geometrically consistent and rigid model of the surface. Also, every point of the model must be positioned at its correct position in the planet-fixed coordinate system.

The mathematical backbone of this adjustment are the so-called collinearity equations, which define the relationship between the coordinates of points in the images via the orientation data to the corresponding surface points for one image. From multiple observations of large numbers of surface features in large numbers of images, large systems of the collinearity equations are assembled, which are simultaneously solved in several iterative steps.

Sufficiently large numbers of conjugate points (or "tiepoints") must be determined in overlapping areas of the images, as input for the adjustment. This is usually accomplished by automated techniques, such as the image matching, described above. Block adjustments can become computationally challenging, when several thousands of images are involved (see examples below), in which case sophisticated matrix inversion schemes are required to reduce computing time and memory allocations.

The tiepoints are the input (observations) to the block adjustment, whereas the 3-D coordinates of the points on the surface (object points) and the orientation data of each image are the unknowns to be determined. The nominal position and pointing data are used as starting values to begin the iterative process. If appropriate observations are available, it is also possible to improve further unknown parameters, e.g. planet rotation models, spacecraft orbit parameters, or camera constants, by varying the relevant rotation parameters until the minimum of error totals is reached.

For small isolated image blocks, systematic errors in the orientation data may remain uncorrected after the adjustment. Even though coordinates of ground points are internally consistent, the resulting DTMs may have vertical and lateral offsets or small tilt with respect to the surface-fixed coordinate systems at the end. This is caused by the fact that these offsets or tilts are not well constrained by the limited surface coverage of the images. The issue may be resolved when ground control points with specified absolute coordinates (e.g. from laser altimetry) are included in the calculations. The absolute positioning of the DTMs is typically well constrained if large regional blocks of images or even closed global image coverage are available (see examples below).

The results of the block adjustment are improved values for the orientation data and the coordinates of the related surface points. Even without subsequent DTM processing, the improved navigation data are of great interest, as the data enables the construction of geometrically accurate image mosaics.

4.3. DTM Interpolation

The coordinates of matched points are used to compute 3-D object (i.e. surface) points by means of forward ray intersection. The adjusted position and pointing data are used to define the viewing rays for each image. As a result, a large number of object points represented in body-fixed coordinates as well as information on ray-intersection accuracy for each combination of corresponding rays are obtained. The accuracy estimates provide verification for image matching and the block adjustment.

In the case that DTMs are constructed from multiple sets of stereo partner images, point clouds from each single stereo model are merged. This resulting point cloud will generally show variations in point density. It is therefore desirable to convert the irregular point cloud into a contiguous surface model. This is achieved either by point triangulation, which will partly preserve the pattern of the point distribution. More commonly, particularly in cases of billions of 3-D points, the points are integrated into a regular grid of height values in a map coordinate system. The 3-D points therefore are first transformed to geographic latitude/longitude/height coordinates, and finally converted to line/sample coordinates in map space using some appropriate map projection, e.g. sinusoidal, stereographic, etc.

The chosen grid spacing of the raster DTM must properly relate to the spacing of the previously derived object points. If several object points are located within a DTM pixel, these are combined and represented as one average value. DTM pixels without any object point information should represent a subordinate fraction of the grid and, where present, are filled using neighborhood information. The grid values of a DTM represent height values above some chosen reference body (usually a sphere having the planet's mean radius, but in some cases an ellipsoid of revolution or a gravitational equipotential surface defined by gravity field measurements).

4.4. Orthorectification

Production of DTMs is seldom the final photogrammetric step of mapping. Images (including those of the stereopair used to create the DTM, but possibly others as well) are usually projected onto the detailed topographic surface in accordance with the 3-D coordinates of each pixel. The horizontal map coordinates are then used to locate the feature in map projection. Provided the DTM is sufficiently detailed and the orientation data of the images to be rectified are precisely known, this process of orthorectification removes the parallax distortions in the original images and provides an undistorted "overhead" view. It is therefore worth noting that even when a sufficiently detailed DTM is available from other sources such as altimetry, the photogrammetric adjustment processes are essential for registering different observations so they can be compared at full resolution to assess subtle differences such as temporal change, spectral features, and photometric effects.

5. QUALITY ASSESSMENT

While ground control points are widely available for the land surface of the Earth, the quality of surface models for planetary bodies must be assessed almost entirely by analysis of internal consistency and comparisons with complementary remote sensing data.

Parameters derived directly from the stereo image processing represent a most obvious quality criteria. Among these, the 3-D ray intersection error, i.e. the Root Mean Square (RMS) deviation of the minimum distance between rays defining a 3-D point from an ideal intersection point, is the most powerful measure. However, simple intersections obtained from only two rays can be biased by certain conditions of projective geometry as well as certain illumination conditions. In contrast, triple and higher fold intersections have been shown to provide very reliable estimates of point precision using terrestrial airborne images for example.

Topographic profiles obtained from orbital laser altimetry are reliable reference data for stereophotogrammetric DTMs (Figure 57.1), as the individual laser measurements typically have a height accuracy of few meters or better. Laser altimeter data also show a high degree of geometric consistency on regional and global scale, which is useful, because of the occasional height offsets and model tilts of DTMs, as discussed above (Section 4.2).

Comparisons are particular useful where the laser footprint on the surface and the sampling distance along the

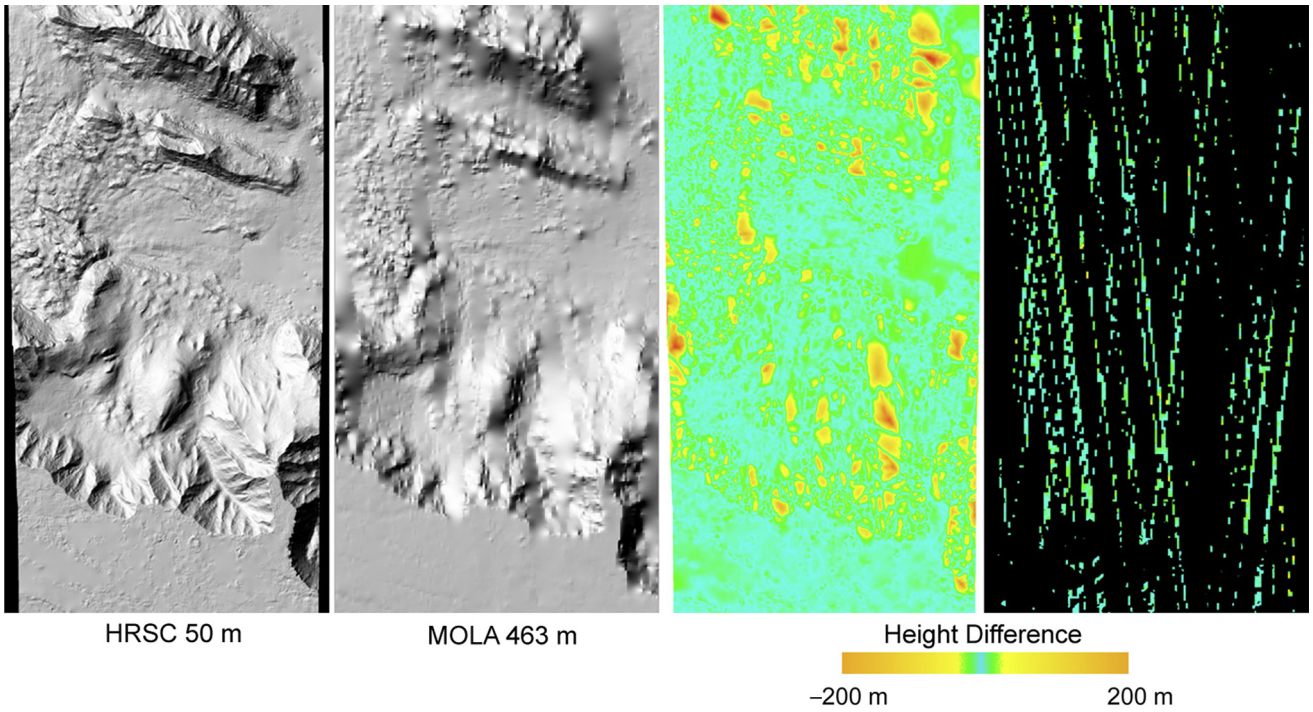

FIGURE 57.1 Difference maps between MOLA and HRSC DTMs, with and without excluding data gaps. Left side: shaded relief maps for comparison. Note that the persisting height deviation observed when measurement gaps on both sides are excluded can be often associated with prominent relief elements such as narrow valleys and ridges, etc. Ophir Labes, Valles Marineris, south is up. *Source: ESA/DLR/FU Berlin (G. Neukum).*

altimeter track are similar to the resolution of the stereo data. This is approximately the case for HRSC and Mars Orbiter Laser Altimeter data. Here, laser altimeter data may be used to assess effective resolutions of the stereo DTMs. The altimeter tracks are typically merged to gridded DTMs, where areas between the tracks are filled by interpolation. When comparisons are made, care must be taken to cope with possible interpolation errors.

Quality assessments can also be made if several DTMs are available for the same area. The comparison can also be performed in the spectral domain using Fourier analysis of the topography. Fourier spectra are also sometimes used to separate "natural" spectral components from a higher frequency noise. These limits are subject to interpretation, however, as the "true" frequency distribution related to the surface alone is basically unknown.

Another class of quality checks makes use of qualitative comparisons of reconstructed surface shapes and corresponding images to study visibility of well-known features, e.g. craters. A crater detection curve showing the fraction of craters of a given diameter range seen in the DTM, typically sheds light on the quality and resolution limits of the DTM.

6. EXAMPLES

With availability of digital image data, planetary photogrammetry has made enormous advances in the past 20 years (Table 57.1). The two Viking Orbiters delivered a large volume of stereo images, for which computer-aided production of topographic models of a planetary surface was carried out for the first time. Beginning in 1990, a sophisticated stereo camera HRSC and a related photogrammetric software system were developed for the Mars '94 mission. However, after the failed launch of this mission in 1996, it was the large volumes of digital image data provided by the Clementine mission as well as by an airborne version of HRSC, from which the first stereo terrain models could be produced using this software (Figure 57.2).

Ever since, stereo data are obtained on a regular basis during planetary missions using various stereo viewing schemes or using dedicated cameras with built-in stereo capability. The Galileo spacecraft arrived in Jupiter **orbit** in 1995. During its operation until 2003, the spacecraft engaged in multiple flybys of the Galilean satellites. Many stereo images were obtained, notably for Ganymede. These revealed the unusual character of Ganymede's surface, attesting to the satellite's early tectonic activity (Figure 57.3).

In 2003, the Mars Express mission was launched, carrying the HRSC camera, originally intended for flight on Mars '94. The spacecraft, moving in its elliptic Mars orbit, is still operating up to the present day. Images are typically obtained during pericenter passes, where spatial resolutions

of up to 10 m are achieved. Based on its built-in stereo capability (Table 57.1), stereo images have been acquired systematically for almost the entire surface of Mars and are used to reconstruct terrain models, which are released to the public as HRSC standard products with typical grid spacing of 50−75 m (Figure 57.4). Likewise, stereo images have been obtained during multiple flybys of the Martian satellite Phobos, from which full shape models are being obtained (Figure 57.5). Several other missions to Mars have obtained stereo images of selected targets, including Mars Reconnaissance Orbiter with its powerful HiRISE (0.3 m/pixel) (Figure 57.6) and the Context Camera (CTX) (6 m/pixel), both of which obtain stereo coverage by rolling the spacecraft to image the same target from different angles on multiple flybys.

The Japanese spacecraft Kaguya (former name, SELENE), launched in September 2007, carried a dedicated Terrain Camera (TC) which had two line sensors, looking forward and backward. Stereo images at spatial resolution of 10 m were obtained for most of the Lunar surface, from which large regional terrain models were produced. The Indian Chandrayaan-1, launched 1 year after, had an even higher resolution (5 m) stereo scanner TMC, used for delivery of regional DTMs. The Lunar Reconnaissance Orbiter, launched on June 18, 2009, and still in operation, returns large volumes of images on a regular basis. The **Narrow-Angle Camera** (NAC) is equipped with two linear CCD sensors mounted side by side, which create high-resolution swaths across the lunar surface, typically 5 km wide, at a resolution of 0.5 m/pixel. By combination with overlapping images from adjacent orbits (as for HiRISE and CTX), local high-resolution stereo models can be produced. In contrast, the **Wide-Angle Camera** (WAC) is equipped with an array sensor, operated in the push-frame mode. Using stereo effects in

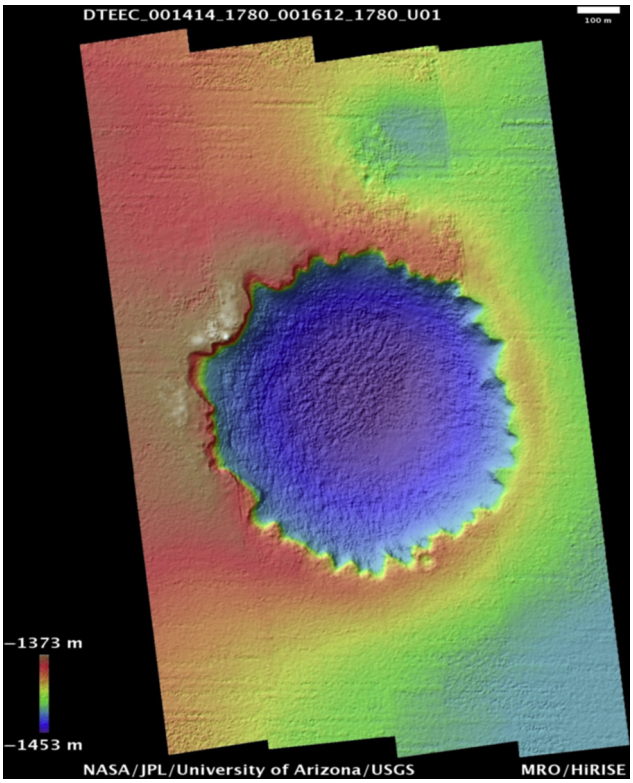

FIGURE 57.6 HiRISE DTM of Victoria crater, Mars. This terrain model with 1 m grid spacing was one of the first DTMs produced from the submeter resolution stereo images of the HiRISE instrument. It covers an area of Meridiani Planum explored by the Mars Exploration Rover "Opportunity". Planetary Data System (PDS) data set DTEEC_001414_1780_001612_1780_U01. *Image credit: NASA/JPL/University of Arizona/USGS.*

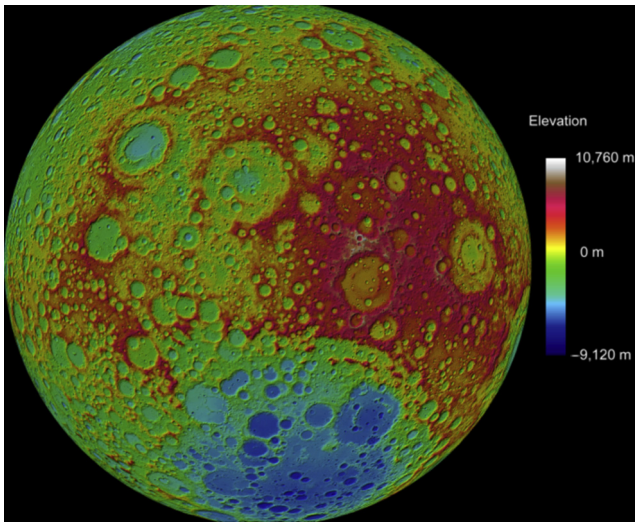

FIGURE 57.7 Far side of the Moon. Elevations are given above 1737.4 km lunar sphere. The model is a subset of the "GLD100" which was published in 2012. *Source: NASA/GSFC/Arizona State University/DLR.*

overlapping consecutive images a near-global topographic model at a resolution of 100 m/pixel ("GLD100") was generated (Figure 57.7), which complements the global topographic model by LRO's Laser Altimeter Lunar Orbiter Laser Altimeter (LOLA).

MESSENGER (Mercury Surface, Space Environment, Geochemistry and Ranging) was launched in 2004 and arrived in Mercury orbit in 2011. The spacecraft is equipped with the MESSENGER Dual Imaging System, which includes a wide- and a narrow-angle framing camera. While some stereo images were obtained for selected regions during early planet flybys in 2008 and 2009, the large volumes of stereo images, currently being obtained during the orbital mission aim at global coverage (Figure 57.8). Full coverage of the planet was initially obtained with the camera system looking nadir. On the second month, the imaging sequence was repeated under similar lighting conditions, with the cameras being tilted along the orbit track to obtain corresponding stereo viewing. The harsh thermal environment of Mercury requires sophisticated models for calibrations of focal length and distortion of the camera as well as associated software adaptations.

The Dawn spacecraft was launched in September 27, 2007, and reached **asteroid** Vesta in July, 2011. Dawn has completed three mapping orbit phases: the Survey Orbit, the High Altitude Mapping Orbit (HAMO), and the Low Altitude Mapping Orbit (LAMO). The Survey and HAMO orbits were designed to map the entire illuminated surface stereoscopically using the onboard framing camera. From the stereo images, a global shape model of Vesta could be obtained, which includes a rotational pole solution (Figure 57.9). In 2015, Dawn will arrive at asteroid Ceres, the largest asteroid (recently reclassified as a **dwarf planet**) in our solar system, to complete the mission. Several other spacecraft have engaged in flybys of smaller asteroids (e.g. Galileo and Rosetta) and **comet** nuclei (Deep Space 1, STARDUST, Deep Impact) or have carried out orbital missions (NEAR spacecraft, Hayabusa-1), during which stereo images were obtained and processed to derive hemispheric terrain or global shape models.

7. SUMMARY AND CONCLUSIONS

In the past years, production of DTMs from planetary images has become one of the most important tools for planetary exploration, and many missions carrying cameras have provided useful 3-D data products. While the production of large and geometrically accurate stereo models requires considerable know-how and powerful software tools, several teams worldwide have specialized in this processing and analysis of stereo images.

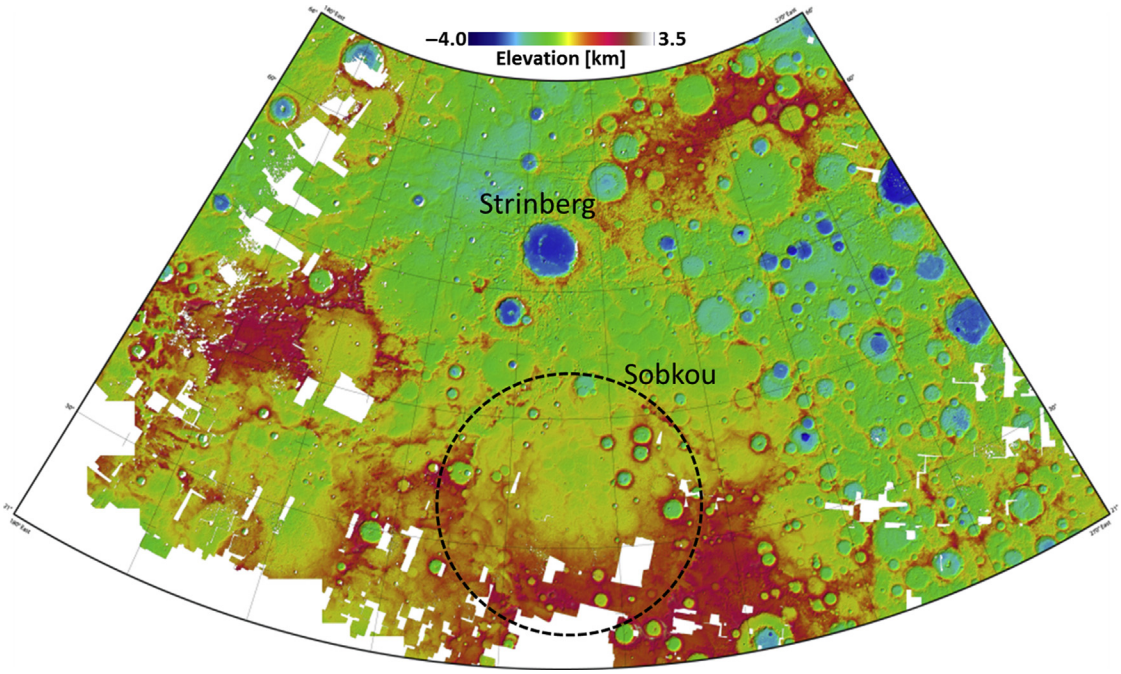

FIGURE 57.8 A DTM (hill-shaded color-coded heights) of Mercury H03 quadrangle (Shakespeare), computed from MESSENGER stereo images. The model was computed from 9500 stereo pairs by the Narrow- and Wide-Angle camera images and contains 2.3 billion object points. The raster grid is 250 m/pixel. The DTM is produced in a Lambert (conformal conic) projection centered at 225°E. Gaps are due to missing data to be filled within the remaining mission time. *Source: NASA/Johns Hopkins University Applied Physics Laboratory/Carnegie Institution of Washington/USGS/DLR.*

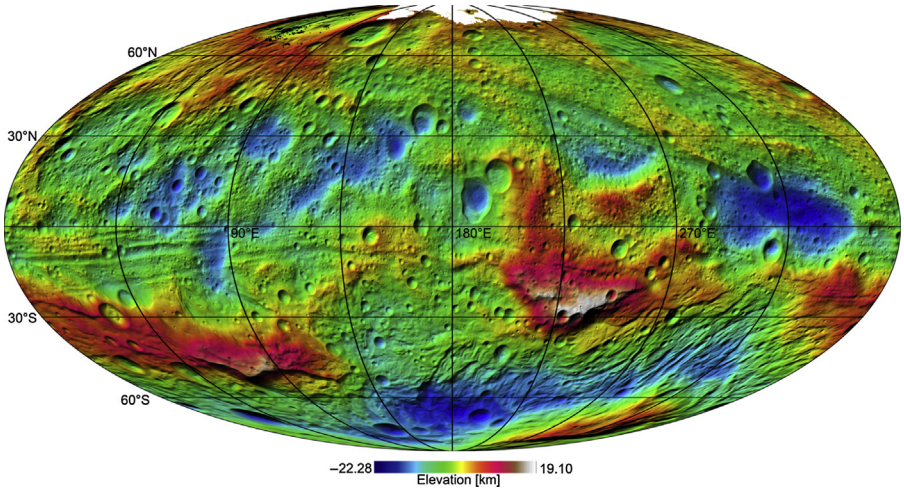

FIGURE 57.9 DTM of asteroid Vesta from the High Altitude Mapping Orbit (HAMO) of the Dawn spacecraft. The DTM (hill shaded and color coded) has a lateral spacing of 100 m and is produced in Mollweide projection (equal-area) centered at 180°. Heights are given with respect to ellipsoid (285/285/229 km). This DTM consists of about 25,000 stereo pairs from which 14.6 billion object points were generated with a mean object point error of 7.5 m. White areas are gaps in the stereo coverage. *Source: NASA/JPL-Caltech/UCLA/MPS/DLR/IDA.*

In the coming years, we will see further planetary exploration missions with cameras, which will have dedicated stereo capability. This includes the Bepi Colombo mission to Mercury, or the Jupiter Icy Moon Explorer (JUICE) mission which will orbit Jupiter's satellite Ganymede. Also, asteroid sample return missions are being planned, where stereo imaging will play a crucial role for landing site selection and assessment.

ACKNOWLEDGMENTS

We wish to thank our colleagues Thomas Roatsch, Klaus-Dieter Matz, Ralf Jaumann, Bernd Giese, Stephan Elgner, and Marita Wählisch (all at German Aerospace Center, DLR), who contributed data and support to this paper. In particular, we wish to thank Frank Scholten (DLR) and Randy Kirk (US Geological Survey) who provided thorough reviews to an earlier version of this manuscript.

TABLE 4: SOLAR SYSTEM EXPLORATION MISSIONS

Prepared by Susanne Pieth, DLR German Aerospace Center, Institute of Planetary Research, Berlin.

Introduction

This is a compilation of robotic and human exploration missions to the bodies of the solar system except for Earth observation missions. Missions that failed to launch in the early time of space flight are not listed as are missions under development.

Missions to the Sun

Mission	Launch Date	Description
Pioneer 5	11 Mar 1960	NASA mission, solar and interplanetary research, solar orbit between the orbits of Venus and Earth, successful first testing of digital data transmission, end of mission: 26 Jun 1960
Pioneer 6	16 Dec 1965	NASA mission, study of the solar wind, the interplanetary electron density, solar and galactic cosmic rays, and the interplanetary magnetic field from a solar orbit between the orbits of Venus and Earth, last tracking: 8 Dec 2000
Pioneer 7	17 Aug 1966	NASA mission, study of the solar wind, interplanetary electron density, solar and galactic cosmic rays, and interplanetary magnetic field from a solar orbit at 1.1 AU, last tracking: Mar 1995
Pioneer 8	13 Dec 1967	NASA mission, study of the solar wind, the interplanetary electron density, solar and galactic cosmic rays, and interplanetary magnetic field, cosmic dust, and electric fields from a solar orbit at 1.1 AU, last tracking: 22 Aug 1996
Pioneer 9	08 Nov 1968	NASA mission, study of the solar wind, the interplanetary electron density, solar and galactic cosmic rays, and interplanetary magnetic field, cosmic dust, and electric fields from a solar orbit at 1.1 AU, contact until May 1983, unsuccessful attempt to contact the spacecraft in 1987
Skylab	26 May 1973	NASA's first manned space station (171 days), 150,000 images of the Sun with the Apollo Telescope Mount
Explorer 49 (Radioastronomy Explorer B)	10 Jun 1973	NASA mission, second of a pair of Radioastronomy Explorer satellites, study low-frequency radio emissions from the planets, the Sun, and the galaxy from lunar orbit, last contact: Aug 1977
Helios 1 (Helios A)	10 Dec 1974	German–American mission, study of the solar wind, magnetic and electric fields, cosmic rays, and interplanetary dust from a elliptic solar orbit, closest approach to the Sun: 47 million km, loss of contact: 16 Mar 1986
Helios 2 (Helios B)	16 Jan 1976	German–American mission, study of the solar plasma, the solar wind, magnetic and electric fields, cosmic rays, and cosmic dust from an elliptic solar orbit, closest approach to the Sun: 43.5 million km, end of mission: Dec 1981
Solar Maximum Mission	14 Feb1980	NASA mission, coordinated monitoring of solar activity especially solar eruptions during a period of maximum solar activity, successful repair mission on STS-41C, data collection until 24 Nov 1989, Earth atmosphere reentry: 2 Dec 1989
Hinotori (Astro-A)	21 Feb 1981	Japanese mission, monitoring of solar eruptions during a period of maximum solar activity from Earth's orbit, Earth atmosphere reentry: 11 Jul 1991
Ulysses	06 Oct 1990	European–American mission, study of the Sun poles, corona, solar wind, solar magnetic field, plasma waves, and cosmic radiation from heliocentric orbit with high inclination after flyby at Jupiter on 8 Feb 1992, end of mission: 29 Jun 2009
Yohkoh	31 Aug 1991	Japanese–American–British mission, study of high-energy radiation during solar eruptions from Earth's orbit, successor to Hinotori, end of mission: 14 Dec 2001, Earth atmosphere reentry: 12 Sep 2005
SAMPEX	03 Jul 1992	"Solar Anomalous and Magnetospheric Particle Explorer", NASA mission, study of the anomalous components of cosmic rays, of solar energetic particles emission from the Sun, and of magnetospheric relativistic electrons from Earth's orbit, Earth atmosphere reentry: 13 Nov 2012
Koronas-I	02 Mar 1994	Russian–Ukrainian mission, study of the Sun in ultraviolet light and X-ray from Earth's orbit, end of mission: 4 Mar 2001
Wind	01 Nov 1994	NASA mission, study of the incoming solar wind, magnetic fields, and particles from a halo orbit around L1 Lagrangian point, still active
SOHO	12 Dec 1995	"Solar and Heliospheric Observatory", European–American mission, study of the inner structure and the physical processes that form the solar corona from a halo orbit around L1 Lagrangian point, still active

(*Continued*)

—cont'd

Mission	Launch Date	Description
ACE	25 Aug 1997	"Advanced Composition Explorer", NASA mission, measurements of the solar wind between Sun and Earth to allow "geomagnetic storm warnings" with a 1-h lead time from the orbit at L1 Lagrangian point, still active
TRACE	02 Apr 1998	"Transition Region and Coronal Explorer", NASA mission, study of solar eruptions, the photosphere, the geometry and dynamics of the upper solar atmosphere from a Sun-synchronous Earth orbit, end of mission: 22 Jun 2010
Koronas-F	31 Jul 2001	Russian—Ukrainian solar observatory, study of the Sun in ultraviolet light and X-ray from Earth's orbit
Genesis	08 Aug 2001	NASA mission, collection of samples of solar wind at the L1 Langrangian point and its return to Earth after two years, parachute of the sample return capsule failed to deploy on reentry on 8 Sep 2004
RHESSI	05 Feb 2002	"Reuven—Ramaty High-Energy Solar Spectroscopic Imager", NASA mission, study of the particle acceleration and energy release during solar eruptions from Earth's orbit, still active
SORCE	25 Jan 2003	"Solar Radiation Climate Experiment", NASA mission, precise measurements of solar radiation in different wavelengths from X-ray to near infrared from Earth's orbit, still active
STEREO	26 Sep 2006	"Solar Terrestrial Relations Observatory", NASA mission, consists of two probes, three-dimensional study of the structure and the evolution of solar storms on its way through space, heliocentric orbit ahead, and behind the Earth, still active
Hinode (SOLAR-B)	23 Sep 2006	Japanese mission, study of the interactions between the magnetic field and corona from a sun-synchronous orbit about Earth, still active
Koronas-Foton	30 Jan 2009	Russian mission, study of processes during solar flares, acceleration mechanisms, propagation, and interaction of fast particles in the solar atmosphere from Earth's orbit, end of mission due to a failed power system in Jan 2010
SDO	11 Feb 2010	"Solar Dynamics Observatory", NASA mission, study of the solar atmosphere in different wavelengths, solar activity and space weather, measurements of solar interior, plasma of solar corona, and radiation from Earth's orbit, still active
Picard	15 Jun 2010	French microsatellite, study of the solar irradiance, the diameter and solar shape and the Sun's interior through helioseismology from Earth's orbit, still active
IRIS	28 Jun 2013	"Interface Region Imaging Spectrograph", NASA mission, study of the outer solar atmosphere from Earth orbit, still active

Missions to Mercury

Mission	Launch Date	Description
Mariner 10	03 Nov 1973	NASA mission, first mission to two planets, Venus flyby and three Mercury flybys, study of the environment, atmosphere, surface, and figure parameters of Mercury and Venus, >10,000 images, 57% of Mercury covered, closest approach: 327 km, end of mission: 24 Mar 1975
MESSENGER	03 Aug 2004	"Mercury Surface, Space Environment, Geochemistry and Ranging", NASA mission, study of the chemical composition of the surface, geology, magnetic field, core, poles, exosphere and magnetosphere of the planet from orbit, orbit entry on 18 Mar 2011 after three flybys, still active

Missions to Venus

Mission	Launch Date	Description
Venera 1	12 Feb 1961	Soviet mission, first flyby of a satellite at Venus, closest approach: 99,800 km, radio contact lost at 7 million km distance on 4 Mar 1961
Mariner 1	22 Jul 1962	NASA mission, intended to perform a Venus flyby, lost 293 s after launch due to a failure in the guidance commands
Mariner 2	26 Aug 1962	NASA mission, backup for Mariner 1, flyby at Venus, study of the atmosphere, magnetic field, charged particle environment, and mass, closest approach: 34,773 km, last transmission: 3 Jan 1963
Zond 1	22 Apr 1964	Soviet mission, loss of radio contact soon after 14 May 1964, Venus flyby at a 100,000-km distance on 14 Jul 1964, solar orbit
Venera 2	12 Nov 1965	Soviet mission, television (TV) system, and scientific instruments, Venus flyby, closest approach: 23,950 km, because of radio interference no data transmission possible, solar orbit
Venera 3	16 Nov 1965	Soviet mission, landing on the surface, atmosphere entry, communication system failed at an altitude of 32 km, impact on the planet
Venera 4	12 Jun 1967	Soviet mission, atmosphere entry, release of instruments, descent on the night side, transmission of the atmosphere and surface data for 96 min until it reached an altitude of 24.96 km
Mariner 5	14 Jun 1967	NASA mission, refurbished backup of Mariner 4, study of the structure of the atmosphere, its radiation and magnetic field environment, closest approach: 4094 km, contact lost on 4 Dec 1974
Venera 5	05 Jan 1969	Soviet mission, study of the atmosphere, release of a capsule into the atmosphere, data transmission on 16 May 1969 for 53 min
Venera 6	10 Jan 1969	Soviet mission, study of the atmosphere, release of a capsule into the atmosphere, data transmission on 17 May 1969 for 51 min
Venera 7	17 Aug 1970	Soviet mission, study of the atmosphere and other phenomena of the planet, release of a landing capsule on 15 Dec 1970, transmission of data for 23 min after landing
Venera 8	27 Mar 1972	Soviet probe and lander, successful landing on 22 Jul 1972, transmission of data from the surface for 50 min
Mariner 10	03 Nov 1973	NASA mission, first mission to two planets, study of the environment, atmosphere, surface, and figure parameters of Mercury and Venus, Venus flyby, and three Mercury flybys, closest approach to Venus: 5768 km, first images from Venus, end of mission: 24 Mar 1975
Venera 9	08 Jun 1975	Soviet mission, orbiter and lander, successful landing on 22 Oct 1975, operated for 53 min after landing, first images from the surface
Venera 10	14 Jun 1975	Soviet mission, orbiter and lander, successful landing on 25 Oct 1975, operated for 65 min after landing, images from the surface
Pioneer Venus 1	20 May 1978	NASA mission, study of the atmosphere, ionosphere, and surface from the orbit, end of mission: Aug 1992, spacecraft burnt up in the Venusian atmosphere on 8 Oct 1992
Pioneer Venus 2	08 Aug 1978	NASA mission, multiprobe spacecraft (five atmospheric probes), release of the probes on 16 Nov 1978 and 20 Nov 1978, transmission of data from the surface for 67 min from one of the probes
Venera 11	09 Sep 1978	Soviet mission, study of the chemical composition, the nature of the clouds and the thermal balance of the atmosphere, descent into the atmosphere on 25 Dec 1978, soft landing, transmission of data from the surface for 95 min
Venera 12	14 Sep 1978	Soviet mission, study of the chemical composition, the nature of the clouds and the thermal balance of the atmosphere, descent into the atmosphere on 21 Dec 1978, soft landing, transmission of data from the surface for 110 min

(*Continued*)

—cont'd

Mission	Launch Date	Description
Venera 13	29 Oct 1981	Soviet mission, soft landing on 1 Mar 1982, first panoramic images through several filters, examination of soil samples, operated for 127 min on the surface
Venera 14	01 Nov 1981	Soviet mission, soft landing on 3 Mar 1982, panoramic images through several filters, examination of soil samples, operated for 57 min on the surface
Venera 15	02 Jun 1983	Soviet mission, study of the surface properties with Synthetic Aperture Radar from orbit, radar images of the northern hemisphere, resolution: 1–2 km, end of mission: 10 Jul 1984
Venera 16	07 Jun 1983	Soviet mission, study of the surface properties with Synthetic Aperture Radar from orbit, radar images of the northern hemisphere, resolution: 1–2 km, end of mission: Oct 1984
Vega 1	15 Dec 1984	Soviet mission, Venus flyby in Jun 1985 and comet Halley flyby, release of a lander and balloon for studies of the central cloud cover, balloon operated in the atmosphere for 46.5 h
Vega 2	21 Dec 1984	Soviet mission, Venus flyby in Jun 1985 and comet Halley flyby, release of a lander and balloon for studies of the central cloud cover, balloon operated in the atmosphere for ~47 h
Magellan	04 May 1989	NASA mission, study of landforms and tectonics, impact processes, erosion, deposition, chemical processes, and data for modeling the interior radar mapping of 95% of the surface with Synthetic Aperture Radar, highest resolution: 75 m/pixel, contact lost on 12 Oct 1994
Galileo	18 Oct 1989	NASA mission, flyby at Venus on its way to Jupiter on 10 Feb 1990, images of the cloud cover
Cassini	15 Oct 1997	NASA–ESA mission, two flybys at Venus on its way to the Saturnian system on 26 Apr 1998 and 24 Jun 1999
MESSENGER	03 Aug 2004	"Mercury surface, space environment, geochemistry and ranging", NASA mission, images from Venus during two flybys on its way to Mercury on 24 Oct 2006 and 5 Jun 2007
Venus Express	09 Nov 2005	European Space Agency (ESA) mission, study of the complex dynamics, and chemistry of the planet and the interaction between the atmosphere and surface from orbit, orbit entry on 11 Apr 2006, still active
Akatsuki (Planet-C)	20 May 2010	Japanese Aerospace Exploration Agency (JAXA) mission, study the dynamics of the atmosphere from orbit, orbit entry failed and satellite flew by Venus, next possibility to enter orbit in 2016/2017

Missions to the Moon

Mission	Launch Date	Description
Luna 1	02 Jan 1959	Soviet mission, study of interplanetary space, flyby, closest approach: 5995 km, data transmission for 62 h after launch
Pioneer 4	03 Mar 1959	American mission, flyby of the Moon at a distance of 60,000 km
Luna 2	12 Sep 1959	Soviet mission, first impact on the Moon on 13 Sep 1959
Luna 3	04 Oct 1959	Soviet mission, 29 images from the near and the far side for the first time, after flight around the Moon spacecraft burnt up in the Earth's atmosphere on Apr 1960
Ranger 3	04 Oct 1959	NASA mission, study of the surface prior to impact, rough landing of a seismometer capsule, to collect gamma-ray data in flight and study radar reflectivity of the surface, missed lunar orbit due to malfunctions

—**cont'd**

Mission	Launch Date	Description
Ranger 4	23 Apr 1962	NASA mission, study of the surface prior to impact, rough landing of a seismometer capsule, to collect gamma-ray data in flight and study radar reflectivity of the surface, impact on 26 Apr 1962, loss of radio communication on launch day
Ranger 5	18 Oct 1962	NASA mission, study of the surface prior to impact, rough landing of a seismometer capsule, to collect gamma-ray data in flight and study radar reflectivity of the surface, malfunction during injection on the Moon trajectory, passed within 725 km of the Moon
Luna 4	02 Apr 1963	Soviet mission, astronavigation system failed, missed the Moon by about 8400 km
Ranger 6	30 Jan 1964	NASA mission, study the lunar surface in high-resolution prior impact, impact on the edge of Mare Tranquillitatis on 2 Feb 1964, due to a failure of the camera system no images were transmitted
Ranger 7	28 Jul 1964	NASA mission, study the lunar surface in high-resolution prior impact, impact in Mare Nubium on 31 Jul 1964, 4308 images during approach
Ranger 8	17 Feb 1965	NASA mission, study the lunar surface at high-resolution prior impact, impact in Mare Tranquillitatis on 20 Feb 1964, >7000 images during approach
Ranger 9	21 Mar 1965	NASA mission, study the lunar surface at high-resolution prior impact, impact in the Alphonsus crater on 24 Mar 1965, >5800 images
Luna 5	09 May 1965	Soviet mission, testing of a lunar soft landing, impact on the Moon on 12 May 1965 due to malfunctions of the main retrorocket system
Luna 6	08 Jun 1965	Soviet mission, attempted soft landing, midcourse correction failed, missed the Moon by 161,000 km on 11 Jun 1965
Zond 3	18 Jul 1965	Soviet mission, flyby at a distance of 9200 km on 20 Jul 1965, 25 images in very good quality from the far side, transmission ended in Mar 1966
Luna 7	04 Oct 1965	Soviet mission, system tests for landing, due to the loss of attitude control impact in Oceanus Procellarum on 7 Oct 1965
Luna 8	03 Dec 1965	Soviet mission, system tests for landing, soft landing failed, impact in Oceanus Procellarum on 6 Dec 1965
Luna 9	31 Jan 1966	Soviet mission, first soft landing on the Moon on 3 Feb 1966, panoramic images of the surface, end of mission: 6 Feb 1966
Luna 10	31 Mar 1966	Soviet mission, first artificial satellite of the Moon, operated for 56 days in orbit, end of mission: 30 May 1966
Surveyor 1	30 May 1966	NASA mission, soft landing after direct injection into a lunar impact trajectory, 10,338 images, 1000 using red, green, and blue filters on the first lunar day, 812 images on the second lunar day, end of mission: 13 Jul 1966
Lunar Orbiter 1	10 Aug 1966	NASA mission, study of the surface for potential Surveyor and Apollo landing sites from orbit, photographic coverage of ~5 million km^2, transmission of 229 images, mission ended with impact on 29 Oct 1966
Luna 11	24 Aug 1966	Soviet mission, study of lunar gamma- and X-ray emission and lunar gravitational anomalies from orbit, battery failed on 1 Oct 1966
Surveyor 2	20 Sep 1966	NASA mission, attempted soft landing, after unsuccessful path correction out of control, impact south of Copernicus crater on 23 Sep 1966
Luna 12	22 Oct 1966	Soviet mission, images of the surface from orbit, data transmission ended on 19 Jan 1967
Lunar Orbiter 2	06 Nov 1966	NASA mission, study of the surface for potential Surveyor and Apollo landing sites from orbit, transmission of 817 images, mission ended with impact on 11 Oct 1967

(*Continued*)

—cont'd

Mission	Launch Date	Description
Luna 13	21 Dec 1966	Soviet mission, soft landing near Seleucus crater, panoramic images at different sun angles, loss of contact: 30 Dec 1966
Lunar Orbiter 3	05 Feb 1967	NASA mission, study of the surface for potential Surveyor and Apollo landing sites from orbit, transmission of only 626 images due to failure in the image transport system, mission ended with impact on 9 Oct 1967
Surveyor 3	17 Apr 1967	NASA mission, soft landing in the eastern part of Oceanus Procellarum, transmission of 6326 images, last transmission of 4 May 1967
Lunar Orbiter 4	04 May 1967	NASA mission, broad systematic photographic survey of the surface, transmission of 546 images, 99% of the near side covered, mission ended with impact on 31 Oct 1967
Surveyor 4	14 Jul 1967	NASA mission, soft landing failed, impact on the Moon on 17 Jul 1967
Explorer 35	19 Jul 1967	NASA mission, study of interplanetary plasma, magnetic field, energetic particles, and solar X-rays from lunar orbit, end of mission on 24 Jun 1973 after successful operation for 6 years
Lunar Orbiter 5	01 Aug 1967	NASA mission, broad systematic photographic survey of the surface and imaging of additional potential Surveyor and Apollo landing sites from orbit, 844 images, mission ended with impact on 18 Aug 1967
Surveyor 5	08 Sep 1967	NASA mission, soft landing in Mare Tranquillitatis on 11 Sep 1967, 18,006 images and soil analyses during the first lunar day, 19,118 images in total over four lunar days, loss of contact: 17 Dec 1967
Surveyor 6	07 Nov 1967	NASA mission, soft landing in Sinus Medii, 14,500 images and ~55 soil analyses; 15,000 images from a new position (stereoscopic coverage), last contact: 14 Dec 1967
Surveyor 7	07 Jan 1968	NASA mission, soft landing 40 km north of the rim of Tycho crater; 21,038 images for the first time using a polarizing filter, soil analyses, transmission ended on 21 Feb 1968
Luna 14	07 Apr 1968	Soviet mission, study of the gravitational interaction of the Earth and lunar masses, lunar gravitational field, solar charged particles and cosmic rays, and the motion of the Moon, mission success is not proved
Zond 5	14 Sep 1968	Soviet mission, test of the return of a space probe with biological payload after lunar flyby, flight around the Moon and back to the Earth, closest approach to the Moon: 1950 km, first successful Soviet circumlunar Earth-return mission, mission ended on 21 Sep 1968
Zond 6	10 Nov 1968	Soviet mission, aerodynamic return of biological payload, closest approach: 2420 km, photographs of the lunar near and far side from distances of ~11,000 and 3300 km, controlled reentry on 17 Nov 1968
Apollo 8	21 Dec 1968 to 27 Dec 1968	NASA mission, first manned space flight, photographic exploration of the planned Apollo landing site and other areas, test of command module systems, 10 orbits around the Moon, extensive photography of the lunar surface and six live TV transmissions, safe return to Earth on 27 Dec 1968
Apollo 10	18 May 1969 to 26 May 1969	NASA mission, manned landing simulation in the lunar orbit, closest approach: 15,185 m, extensive photography of the lunar surface and TV images, safe return to Earth on 26 May 1969
Luna 15	13 Jul 1969	Soviet mission, study of the circumlunar space, the lunar gravitational field, and the chemical composition of lunar rocks, lunar surface photography, mission ended with impact on 21 Jul 1969
Apollo 11	16 Jul 1969 to 24 Jul 1969	NASA mission, first manned Moon landing, landing in Mare Tranquillitatis, return of soil, rock samples, and photographs, safe return to Earth on 24 Jul 1969

—**cont'd**

Mission	Launch Date	Description
Zond 7	07 Aug 1969 to 14 Aug 1969	Soviet mission, color photography of the Moon and Earth from varying distances, closest approach: 2000 km, aerodynamic return, soft landing on Earth on 14 Aug 1969
Apollo 12	14 Nov 1969 to 24 Nov 1969	NASA mission, second manned Moon landing, landing in Oceanus Procellarum, return of soil, rock samples, and photographs, safe return to Earth on 24 Nov 1969
Apollo 13	11 Apr 1970 to 17 Apr 1970	NASA mission, attempted manned Moon landing, abortion after explosion of an oxygen tank in the service module, successful return to Earth on 17 Apr 1970
Luna 16	12 Sep 1970	Soviet mission, first return of soil samples with an unmanned remote controlled semiautomatic probe, safe landing in Mare Foecunditatis, liftoff of the return capsule 26 h later back to Earth, capsule landed on 24 Sep 1970
Zond 8	20 Oct 1970	Soviet mission, closest approach: 1120 km, return trajectory over the northern hemisphere of Earth, color and black/white images from the Moon and Earth, splashdown in the Indian Ocean on 27 Oct 1970
Luna 17	10 Nov 1970	Soviet mission, soft landing in Mare Imbrium, remote controlled semiautomatic lunar rover "Lunokhod 1", >200 panoramic images, 20,000 other images, >500 soil analyses, operation ceased officially on 4 Oct 1971
Apollo 14	31 Jan 1971 to 09 Feb 1971	NASA mission, third manned Moon landing, landing near Fra Mauro crater in eastern Oceanus Procellarum, return of soil, rock samples, and photographs, safe return to Earth on 9 Feb 1971
Apollo 15	26 Jul 1971 to 07 Aug 1971	NASA mission, fourth manned Moon landing, landing in the Rima Hadley area, first manned lunar rover, return of soil, rock samples, and photographs, safe return to Earth on 7 Aug 1971
Luna 18	02 Sep 1971	Soviet mission, impact in Mare Foecunditatis after 54 orbits, signals ceased at the moment of impact
Luna 19	28 Sep 1971	Soviet mission, study of lunar gravitational field and location of mascons from lunar orbit, high-resolution images of the lunar surface, end of mission: 20 Oct 1972
Luna 20	14 Feb 1972	Soviet mission, landing at the northeastern edge of Mare Foecunditatis, return of samples, return of the capsule on 25 Feb 1972
Apollo 16	16 Apr 1972 to 27 Apr 1972	NASA mission, fifth manned Moon landing, landing in Cayley plateau near Descartes crater, manned lunar rover, return of soil, rock samples, and photographs, safe return to Earth on 27 Apr 1972
Apollo 17	07 Dec 1972 to 19 Dec 1972	NASA mission, sixth and last manned Moon landing, landing in Taurus–Littrow, manned lunar rover, return of 113 kg of lunar samples and photographs, safe return to Earth on 19 Dec 1972
Luna 21	08 Jan 1973	Soviet mission, soft landing in Le Monnier crater, remote controlled semiautomatic lunar rover "Lunokhod 2", 86 panoramic images, >80,000 TV pictures, end of mission: 4 Jun 1974
Explorer 49 (Radioastronomy Explorer B)	10 Jun 1973	NASA mission, second of a pair of Radio Astronomy Explorer satellites, lunar orbit, study low-frequency radioemissions from the planets, the Sun, and the galaxy, last contact: Aug 1977
Luna 22	29 May 1974	Soviet mission, study of the magnetic field, surface gamma-ray emissions, composition of lunar surface rocks and gravitational field from orbit at varying altitudes, end of mission: Nov 1975
Luna 23	28 Oct 1974	Soviet mission, attempted sample return, after lunar orbit landing in Mare Crisium, sample collection failed
Luna 24	14 Aug 1976	Soviet mission, landing at the southeastern edge of Mare Crisium, return of 170 g of lunar samples, return of the capsule on 22 Aug 1976

—cont'd

Mission	Launch Date	Description
Galileo	18 Oct 1989	NASA mission, flybys at the Moon on its way to Jupiter in Dec 1990 and Dec 1992, multispectral images
Hiten (Muses-A)	24 Jan 1990	Japanese mission, test and verify technologies for future missions, subsatellite "Hagaromo" released to lunar orbit but data transmission failed, several flybys at the Moon of Hiten before lunar orbit and impact on the Moon on 10 Apr 1993
Clementine	25 Jan 1994	American mission, test of sensors and spacecraft components, study of the surface mineralogy of the Moon from orbit, multispectral mapping of the whole Moon with resolutions of 125–250 m/pixel, planned flyby at asteroid 1620 Geographos failed, end of mission: Jun 1994
Lunar Prospector	07 Jan 1998	NASA mission, study of the surface composition and possible deposits of polar ice, measurements of magnetic and gravity fields and lunar outgassing events from polar orbit, end of mission with impact on 31 Jul 1999
SMART-1	27 Sep 2003	ESA mission, test of a solar powered ion engine, study of the geology, morphology, topography, mineralogy, geochemistry, and exospheric environment from orbit, end of mission with impact on 3 Sep 2005
Kaguya (SELENE)	14 Sep 2007	JAXA mission, two subsatellites "Ouna" and "Okina", study of mineralogy, topography, geography, and gravity field from orbit, end of mission with impact on 10 Jun 2009
Chang'e 1	24 Oct 2007	Chinese mission, test of technologies for future missions, mapping of lunar surface chemistry, stereo images from lunar orbit, end of mission with impact on 1 Mar 2009
Chandrayaan 1	22 Oct 2008	Indian mission with Indian and international payload, test of space technologies, global high-resolution mapping with 5m resolution, mineralogical mapping, laser ranging, release of a Moon Impact Probe on 14 Nov 2008, loss of contact: 28 Aug 2009
Lunar Reconnaissance Orbiter (LRO)	18 Jun 2009	NASA mission, mapping of the surface, characterization of future landing sites regarding terrain roughness, usable resources, and radiation environment from orbit, still active
Lunar Crater Observation and Sensing Satellite	18 Jun 2009	NASA mission, impactor, launched along with LRO, consists of a Shepherding Spacecraft (S–S/C) attached to the Centaur upper stage, search for water ice by directing the Centaur upper stage to impact the surface while observing the collision from behind, impacted on the lunar surface on 9 Oct 2009
Chang'e 2	01 Oct 2010	Chinese mission, modified backup satellite of Chang'e 1, high-resolution images of the surface, search for landing sites from orbit, left the Moon orbit to L2 Lagrangian point on 9 Jun 2011 for measurements of the solar wind, left the L2 point to asteroid 4179 Toutatis, flyby on 13 Dec 2012 at the closest distance of 3.2 km, presumably still active
GRAIL	10 Sep 2011	"Gravity Recovery and Interior Laboratory", NASA mission, consisted of two satellites launched together, high resolution and accuracy mapping of the lunar gravity field to study the structure of the crust and lithosphere, the asymmetric thermal evolution of the Moon, the subsurface structure of basins and of mascons, orbit entry in Dec 2011 and Jan 2012, end of mission with impacts of the satellites on the Moon on 17 Dec 2012
LADEE	07 Sep 2013	"Lunar Atmosphere and Dust Environment Explorer", NASA mission to study the exosphere and dust in the vicinity of the Moon with a neutral mass spectrometer, ultraviolet–visible spectrometer, and lunar dust experiment, technical demonstration of a laser communication terminal, still active
Chang'e 3	01 Dec 2013	Chinese mission, soft landing in northern Mare Imbrium on 14 Dec 2014, release of rover Yutu, still active

Missions to Mars

Mission	Launch Date	Description
Marsnik 1 (Mars 1960A)	10 Oct 1960	Soviet mission, first soviet planetary probe, failure of the third stage, parking orbit not reached, highest altitude: 120 km, reentry
Marsnik 2 (Mars 1960B)	14 Oct 1960	Soviet mission, failure of the third stage, parking orbit not reached, highest altitude: 120 km, reentry
Sputnik 22 (Mars 1962A)	24 Oct 1962	Soviet mission, attempted Mars flyby, failure, upper stage exploded in the Earth orbit
Mars 1	01 Nov 1962	Soviet mission, study of the interplanetary space between Earth and Mars, flyby at Mars at a distance of 193,000 km on 19 Jun 1963, loss of contact: 21 Mar 1963
Sputnik 24 (Mars 1962B)	04 Nov 1962	Soviet mission, upper stage failed fragmenting the spacecraft, could not leave the Earth orbit, reentry on 19 Jan 1963
Mariner 3	05 Nov 1964	NASA mission, study the vicinity of Mars and obtain photographs, failure of shell separation, no Mars flyby possible, loss of contact
Mariner 4	28 Nov 1964	NASA mission, first successful flyby at Mars on 14 Jul 1965, closest approach: 9844 km, 22 images of the Martian surface, communication ceased on 21 Dec 1967
Zond 2	30 Nov 1964	Soviet mission, flyby at Mars on 6 Aug 1965, closest approach: 1500 km, failure of the communication system in early May 1965
Zond 3	18 Jul 1965	Soviet mission, flyby at the Moon at a distance of 9200 km on 20 Jul 1965, transmission ended in Mar 1966, flight to Mars orbit
Mariner 6	25 Feb 1969	NASA mission, study of the surface and atmosphere during close flyby on 31 Jul 1969 at a distance of 3431 km, 75 images returned
Mariner 7	27 Mar 1969	NASA mission, spacecraft identical to Mariner 6, study of the surface and atmosphere during close flyby at 5 Aug 1969 at a distance of 3430 km, 126 images returned
Mars 1969A	27 Mar 1969	Soviet mission, attempted Mars orbiter, explosion of the third stage 7 min after launch
Mars 1969B	02 Apr 1969	Soviet mission, attempted Mars orbiter, failure of the first stage promptly after launch
Mariner 8	08 May 1971	NASA mission, attempted Mars orbiter, malfunction of the Centaur upper stage, reentry
Cosmos 419	10 May 1971	Soviet mission, attempted Mars orbiter, reached parking orbit around the Earth, could not leave parking orbit due to upper stage failure, reentry on 12 May 1971
Mars 2	19 May 1971	Soviet mission, orbiter and lander, study of the surface, atmosphere, temperature, topography, and physical properties, reached Mars orbit on 21 Nov 1971, first release of landing capsule, soft landing failed, end of mission: 22 Aug 1972
Mars 3	28 May 1971	Soviet mission, identical to Mars 2, study of the surface, atmosphere, temperature, topography, and physical properties, reached Mars orbit on 2 Dec 1971, release of landing capsule, soft landing, lander instruments worked for 20 s only, end of mission: 22 Aug 1972
Mariner 9	30 May 1971	NASA mission, mapping of the surface and study of temporal changes of the atmosphere and surface of Mars, reached Mars orbit on 14 Nov 1971, first artificial satellite of a planet, >7000 images of the surface, maximum resolution: 100 m/pixel, end of mission: 27 Oct 1972
Mars 4	21 Jul 1973	Soviet mission, attempted orbiter, could not reach Mars orbit due to technical malfunctions, flyby at a distance of 2200 km on 10 Feb 1974
Mars 5	25 Jul 1973	Soviet mission, study the composition, structure, and properties of the Martian atmosphere and surface, reached Mars orbit on 12 Feb 1974, orbiter worked a few days only, transmission of data from the atmosphere and images of a small part of the southern hemisphere
Mars 6	05 Aug 1973	Soviet mission, flyby bus and descent module, reached Mars on 12 Mar 1974, landing in Margaritifer Sinus, contact lost

(*Continued*)

—cont'd

Mission	Launch Date	Description
Mars 7	09 Aug 1973	Soviet mission, flyby bus, and descent module, reached Mars on 9 Mar 1974, landing capsule missed its target
Viking 1	20 Aug 1975	NASA mission, orbiter and lander, high-resolution images of the surface, study of the structure and composition of the atmosphere and surface, search for evidence of life, reached Mars orbit on 19 Jul 1976, soft landing on 20 Jul 1976 in Chryse Planitia, both orbiter and landers (Viking 1 and 2) transmitted panoramic images and other data, all in all 55,000 images (including of the moons), coverage of the whole surface with resolutions from 100 to 200 m/pixel, regionally up to 30 m, some images up to 8 m/pixel, orbiter shut down: 7 Aug 1980, lander operated in the automated mode until Nov 1982
Viking 2	09 Sep 1975	NASA mission, orbiter and lander, identical to Viking 1, high-resolution images of the surface, study of the structure and composition of the atmosphere and surface, search for evidence of life, reached Mars orbit on 7 Aug 1976, soft landing on 3 Sep 1976 in Utopia Planitia, end of orbiter mission: 25 Jul 1978, lander operated until 11 Apr 1980
Phobos 1	07 Jul 1988	Soviet mission, attempted Mars orbiter and flyby at Phobos with release of small landers, loss of contact due to a fault signal on 2 Sep 1988, recovery of the probe not possible
Phobos 2	12 Jul 1988	Soviet mission, Mars orbiter and flyby at Phobos with release of a small lander, reached Mars orbit on 29 Jan 1989, thermal images of a nearly 1500-km broad strip at the equator, resolution: ~ 2 km/pixel, 9 images of Phobos, loss of communication on 27 Mar 1989 before release of probe
Mars Observer	25 Sep 1992	NASA mission, attempted Mars orbiter, study of the surface and climate, loss of communication on 21 Aug 1993 three days before orbit insertion at Mars, the most likely cause: Explosion of the engine during injection maneuver
Mars Global Surveyor	07 Nov 1996	NASA mission, replacement for Mars Observer, Mars orbit insertion started on 12 Sep 1997, one year longer aerobraking to mapping orbit due to a malfunction of one of the solar panels, >243,000 images and high-resolution global topographic map using laser altimetry, mapping of the surface magnetization, loss of contact: 2 Nov 2006
Mars-96	16 Nov 1996	Russian mission with international participation, instable Earth orbit due to a malfunction of the fourth rocket stage, loss of probe and fourth stage, reentry on 17 Nov 1996
Mars Pathfinder	04 Dec 1996	NASA mission, soft landing on 4 Jul 1997 in Ares Vallis, rover "Sojourner" was released on 6 Jul 1997, lander and rover worked until loss of contact on 27 Sep 1997, >17,000 images
Nozomi (Planet B)	03 Jul 1998	Japanese mission, study of the atmosphere from orbit, Mars orbit insertion failed, mission abandoned on 9 Dec 2003
Mars Climate Orbiter	11 Dec 1998	NASA mission, study of weather and climate, water and carbon dioxide budget from orbit, loss of probe during orbit insertion on 23 Sep 1999
Mars Polar Lander	03 Jan 1999	NASA mission, study of weather and climate, water and carbon dioxide budget, landing failed on 3 Dec 1999
Deep Space 2	03 Jan 1999	NASA mission, part of the New Millennium Program, consisted of two micropenetrators to explore the sub-surface of Mars near the South Pole, were attached to the Mars Polar Lander, landing failed on 3 Dec 1999
2001 Mars Odyssey	07 Apr 2001	NASA mission, detailed mineralogical mapping of the surface and study of the radiation environment from orbit, also communication relay for future landing missions, still active
Mars Express	02 Jun 2003	ESA mission, orbiter and lander "Beagle 2", lander separation on 19 Dec 2003, landing failed, orbit insertion on 25 Dec 2003, global high-resolution imaging, mineralogical mapping, study of atmospheric composition and processes, still active

—cont'd

Mission	Launch Date	Description
Spirit (Mars exploration Rover A)	10 Jun 2003	NASA mission, landing in Gusev crater on 4 Jan 2004, rover with scientific instrumentation and a daily range of 100 m, explore the habitability of the area, study of climate and geology, loss of contact: 22 Mar 2010
Opportunity (Mars exploration Rover B)	08 Jul 2003	NASA mission, landing in Meridiani Planum on 25 Jan 2004, rover with scientific instrumentation and a daily range of 100 m, explore the habitability of the area, study of climate and geology, still active
Mars Reconnaissance Orbiter	12 Aug 2005	NASA mission, study of the current climate, observation of the surface from orbit using a high-resolution camera and search for landing sites, orbit entry on 10 Mar 2006, still active
Phoenix	04 Aug 2007	NASA mission, small stationary lander, study of the surface at high latitudes, observation of the polar climate and weather, composition of the lower atmosphere, geomorphology, and role of water, soft landing in the north polar region at 68.15° N and 125.9° W on 25 May 2008, end of mission: 2 Nov 2008
Phobos Grunt	08 Nov 2011	Russian lander mission to Phobos, exploration of the landing site, soil sampling from the surface and return to Earth, could not reach trajectory to Mars due to a failure in the propulsive unit, loss of the spacecraft, Earth atmosphere reentry on 15 Jan 2012
Yinghuo-1	08 Nov 2011	Chinese mission, "lightning bug", tandem flight with Phobos Grunt, measurements of the gravity field for one year from orbit around Mars, loss of the satellite, Earth atmosphere reentry on 15 Jan 2012
Mars Science Laboratory	25 Nov 2011	NASA mission, rover "Curiosity", exploration of the mineralogy, geochemistry and habitability, successful landing in Gale crater on 6 Aug 2012, nominal mission duration: one Martian year (687 days), still active
Mangalyaan (Mars Orbiter mission)	05 Nov 2013	Indian mission, study of surface features, morphology, mineralogy, and atmosphere, orbit insertion planned for 24 Sep 2014, still active
MAVEN	18 Nov 2013	"Mars Atmosphere and Volatile EvolutioN", NASA mission, study the upper atmosphere, ionosphere, and interactions with the solar wind, scheduled to reach Mars on 22 Sep 2014, still active

Missions to Asteroids

Mission	Launch Date	Description
Galileo	18 Oct 1989	NASA mission, flyby at 951 Gaspra (Oct 1991) and 243 Ida (Aug 1993) on its way to Jupiter
NEAR Shoemaker	17 Feb 1996	"Near Earth Asteroid Rendezvous", NASA mission, study asteroid 433 Eros from close orbit, flyby at 253 Mathilde on 27 Jun 1997, in orbit around 433 Eros from Feb 2000 to Feb 2001, afterward controlled descent to Eros on 12 Feb 2001, contact lost: 28 Feb 2001
Cassini	15 Oct 1997	NASA mission, flyby at 2685 Masursky (Jan 2000) on its way to the Saturnian system
Deep Space 1	24 Oct 1998	NASA mission, test of new technologies (ion propulsion) for use in space, flyby at asteroid 9969 Braille (29 Jul 1999) and comet Borrelly (22 Sep 2001), end of mission: 18 Dec 2001

(*Continued*)

—cont'd

Mission	Launch Date	Description
Hayabusa (Muses-C)	09 May 2003	Japanese mission, orbiter and lander "Minerva" with sample return from the surface of asteroid 25143 Itokawa and technology demonstration, reached Itokawa in Sep 2005, lander was deployed on 12 Nov 2005, landing of the orbiter on 25 Nov 2005, sample acquisition and restart to Earth, reentry capsule with samples entered Earth's atmosphere on 13 Jul 2010
Rosetta	02 Mar 2004	ESA mission, orbiter and lander "Philae", flyby at 2867 Šteins (5 Sep 2008) and 21 Lutetia (10 Jul 2010) on its way to comet Churyumov–Gerasimenko, landing planned for Nov 11, 2014
Dawn	27 Sep 2007	NASA mission, rendezvous and orbit of asteroid 4 Vesta and dwarf planet 1 Ceres, arrival at Vesta and in orbit from 14 Aug 2011 to 5 Sep 2012, will reach 1 Ceres on 1 Feb 2015, still active

Missions to Jupiter

Mission	Launch Date	Description
Pioneer 10	03 Mar 1972	NASA mission, first spacecraft to the outer solar system, study of the planet Jupiter, flyby at Jupiter at a distance of 200,000 km on 4 Dec 1972, numerous images of the equatorial region and a few satellites, first probe which left the solar system, last contact on 23 Jan 2003
Pioneer 11	06 Apr 1973	NASA mission, second spacecraft to explore Jupiter and the outer solar system and first to explore Saturn and its main rings, flyby at Jupiter at a distance of 42,000 km on 3 Dec 1974, numerous images of Jupiter and a few satellites, last contact at a distance of 44.7 AU at the end of 1995
Voyager 2	20 Apr 1977	NASA mission, study of the outer planets, flyby at Jupiter on 9 Jul 1979, closest approach: 722,000 km, 18,000 images of Jupiter and its moons, still active on its way out of the solar system
Voyager 1	05 Sep 1977	NASA mission, study of the outer planets, flyby at Jupiter on 5 Mar 1979, closest approach: 349,000 km, 18,000 images of Jupiter and its moons, entered interstellar space on 25 Aug 2012
Ulysses	06 Oct 1990	European–American mission, study of the Sun, flyby at Jupiter on 8 Feb 1992, end of mission: 29 Jun 2009
Galileo	18 Oct 1989	NASA mission with international participation, first spacecraft with a complex trajectory with gravitational assists, orbiter, and atmospheric probe, study of Jupiter's atmosphere and magnetosphere, and the Galilean satellites, arrival at Jupiter on 7 Dec 1995, end of mission with impact into Jupiter on 21 Sep 2003
Cassini–Huygens	15 Oct 1997	NASA–ESA mission, study of the Saturnian system, flyby at Jupiter in Dec 2000 on its way to the Saturnian system
New Horizons	19 Jan 2006	NASA mission, study of Pluto and its moon Charon and continue to the Kuiper Belt, flyby at Jupiter on 28 Feb 2007 on its way to the Pluto–Charon system
Juno	05 Aug 2011	NASA mission, study of the atmosphere, magnetic field, gravity field, and magnetosphere of Jupiter from polar orbit, after Earth flyby on 9 Oct 2013 arrival at Jupiter on 5 Jul 2016, still active

Missions to Saturn

Mission	Launch Date	Description
Pioneer 11	06 Apr 1973	NASA mission, second spacecraft to explore Jupiter and the outer solar system and first to explore Saturn and its main rings, flyby at Saturn at a distance of 20,800 km on 1 Sep 1979, 440 images of Saturn and a few satellites, last contact at a distance of 44.7 AU at the end of 1995
Voyager 2	20 Aug 1977	NASA mission, study of the outer planets, flyby at Saturn on 26 Aug 1981 at a distance of 102,000 km, 16,000 images of Saturn and its moons, still active on its way out of the solar system
Voyager 1	05 Sep 1977	NASA mission, study of the outer planets, flyby at Saturn on 12 Nov 1980 at a distance of 124,000 km, about 16,000 images of Saturn and its moons, entered interstellar space on 25 Aug 2012
Cassini–Huygens	15 Oct 1997	NASA–ESA mission, study of Saturn, its rings and satellites from orbit, release of atmospheric probe "Huygens" into Titan's atmosphere in Dec 2004, still active

Missions to Uranus

Mission	Launch Date	Description
Voyager 2	20 Aug 1977	NASA mission, study of the outer planets, flyby at Uranus on 24 Jan 1986 at a distance of 107,000 km, 7000 images of Uranus and its moons, still active on its way out of the solar system

Missions to Neptune

Mission	Launch Date	Description
Voyager 2	20 Aug 1977	NASA mission, study of the outer planets, flyby at Neptune on 25 Aug 1989 at a distance of 29,240 km, 9000 images of Neptune and its moons, still active on its way out of the solar system

Missions to Dwarf Planets

Mission	Launch Date	Description
New Horizons	19 Jan 2006	NASA mission, study of Pluto and its moon Charon during flyby and continue to the Kuiper Belt, arrival at the Pluto–Charon system in Jul 2015, still active
Dawn	27 Sep 2007	NASA mission, rendezvous and orbit of the asteroid 4 Vesta and dwarf planet 1 Ceres, arrival at Vesta and in orbit from 14 Aug 2011 to 5 Sep 2012, will reach 1 Ceres on 1 Feb 2015, still active

Missions to Comets

Mission	Launch Date	Description
ISEE 3/ICE	12 Aug 1978	"International Sun Earth Explorer 3", NASA mission, renamed "International Cometary Explorer", study of the interaction between the solar wind and a cometary atmosphere, flight through the plasma tail of comet Giacobini–Zinner on 11 Sep 1985
Vega 1	15 Dec 1984	Soviet mission, flyby at comet Halley on 6 Mar 1986 after Venus flyby in Jun 1985
Vega 2	21 Dec 1984	Soviet mission, flyby at comet Halley on 9 Mar 1986 after Venus flyby in Jun 1985
Sakigake	08 Jan 1985	Japanese mission, flyby at comet Halley on 11 Mar 1986, loss of contact: 15 Nov 1995
Giotto	02 Jul 1985	ESA mission, study of comet Halley during flyby on 13 Mar 1986 at a distance of 605 km, images of the nucleus, flyby at comet Grigg–Skellerup on 10 Jul 1992 at a distance of 200 km, end of mission: 23 Jul 1992
Suisei (Planet-A)	18 Aug 1985	Japanese mission, flyby at comet Halley on 8 Mar 1986 at a distance of 151,000 km, end of mission: 22 Feb 1991
Galileo	18 Oct 1989	NASA mission with international participation, first spacecraft with a complex trajectory with gravitational assists, images from traces after impact of Shoemaker-Levy 9 fragments on Jupiter, 17–22 Apr 1994
NEAR	17 Feb 1996	"Near Earth Asteroid Rendezvous", NASA mission, study asteroid 433 Eros from close orbit, flyby at comet Hyakutake on 24 Mar 1996 on its way to asteroid 433 Eros
Deep Space 1	24 Jan 1998	NASA mission, test of new technologies (ion propulsion) for use in space, flyby at asteroid 9969 Braille (29 Jul 1999) and comet Borrelly (22 Sep 2001), end of mission: 18 Dec 2001
Stardust	07 Feb 1999	NASA mission, study of comet P/Wild 2 and collect samples of dust and volatile matter from the comet's coma during flyby on 31 Dec 2003, safe sample return to Earth on 15 Jan 2006; mission extension as Stardust/NEXT ("New exploration of Tempel 1"), study of comet Tempel 1 during flyby on 15 Feb 2011 at a distance of ~200 km, loss of contact: 25 Mar 2011
CONTOUR	03 Jul 2002	"Comet Nucleus Tour", failed NASA mission, close flybys at comets Encke and Schwassmann-Wachmann-3 and possibly comet d'Arrest, could not leave Earth orbit, loss of contact: 15 Aug 2002
Rosetta	26 Feb 2004	ESA mission, orbiter and lander "Philae", study of comet 67 P/Churyumov-Gerasimenko from "orbit" and soft landing on the nucleus, landing planned for Nov. 2014, still active
Deep Impact	12 Jan 2005	NASA mission, study of comet Tempel 1 during flyby on 3 Jul 2005, release of an impactor to the nucleus on 4 Jul 2005, observation of the impact; mission extension as EPOXI ("Extrasolar Planet Observation/Xtended Investigation of Comets"), observation of comet Hartley 2 on 4 Nov 2010 at a distance of 700 km, end of mission: 19 Sep 2013

Missions to the Kuiper Belt

Mission	Launch Date	Description
New Horizons	19 Jan 2006	NASA mission, study of Pluto and its moon Charon during flyby and continue to the Kuiper Belt, arrival at the Pluto–Charon system in Jul 2015, still active

Glossary

Aberration The shift in direction of incoming light or material flow produced by the motion of the observer. In the solar system, the aberration angle of the solar wind is approximately the tangent of V_{perp}/w, where V_{perp} is the observer's speed perpendicular to the direction from the Sun and w is the solar wind speed. This effect causes comet plasma tails and the magnetic tails of Earth and Jupiter to lag behind (in the sense of motion) the radial direction.

Ablation Removal of material. Meteors ablate during their passage through the atmosphere.

Absolute magnitude *(H)* A measure of the brightness of an object. It is defined as the brightness if the object were at 1 AU each from the Sun and the Earth, and viewed at 0 degrees phase angle. For a given albedo, smaller absolute magnitudes correspond to larger objects. A difference of 5 absolute magnitudes corresponds to a factor of 10 in radius for objects with the same albedo.

Accretion The process of building larger bodies from smaller ones through low velocity collisions where the particles stick to one another, or where the gravity of a relatively large body draws the smaller bodies to it.

Achondrite A meteorite from a body that has melted and differentiated.

Actinic flux The solar flux used in calculating photodissociation rates, corresponding to the mean intensity at a given point in the atmosphere.

Active optics The controlled deformation or displacement of optics to compensate for slowly varying effects such as flexure or temperature changes. Typical timescale for updates is longer than one second.

Active Pixel Sensor (APS) A image sensor made of an integrated circuit containing an array of pixel sensors, each of which contains a photodetector and an amplifier. APS are commonly used in digital consumer cameras.

Adaptive optics An observational technique where the phase perturbations induced by the Earth's atmospheric turbulence, responsible for the blur in the images obtained, is corrected in real-time on the incident wavefront reaching the telescope. These perturbations are measured by a wavefront sensor. Opposite phase corrections are then applied using a thin deformable mirror in the pupil plane. The timescale for updates is typically about 1/1000 of a s.

Adiabatic A process occurring without exchange of heat with the surroundings.

Adiabatically *See* adiabatic.

Adiabatic compression Compression of a gas without exchange of heat. Expansion or compression of rising or sinking air masses in planetary atmospheres is commonly assumed to be driven by adiabatic processes.

Adiabatic temperature gradient In a convective fluid where there is no heat transfer between the rising and sinking parcels with the environment, the temperature profile follows a so-called adiabat. The dry adiabatic gradient (with altitude) of the Earth's atmosphere is roughly -7 K/km. That of the Earth's mantle (with depth) about 0.3 K/km.

Adiabatic temperature lapse rate (or temperature gradient) See Adiabatic temperature gradient.

Adsorption The formation of a thin layer of gas, liquid, or solid on the surface of a solid or, more rarely, a liquid. There are two types. A single layer of molecules, atoms, or ions can be attached to a surface by chemical bonds. Alternatively, molecules can be held onto a surface by weaker physical forces.

Advected Transported by advection. Advection is the transport of a quantity, typically heat, by the bulk motion of material.

Aeolian deposits Materials deposited by the wind, such as sand dunes.

Aerosol In atmospheric physics, aerosol is a generic name for any particle (cloud, dust, haze) suspended in the air, although in the Earth science community the term is usually restricted to apply to haze rather than cloud particles.

Aerogel Synthetic porous ultralight solid material with extremely low density, most commonly made of silica gel (also called "frozen smoke"). The Stardust mission was equipped with dedicated aerogel collectors that successfully collected dust particles in the coma of comet Wild 2 and interstellar particles along the spacecraft''s interplanetary trajectory and returned them to Earth.

Agglomerate Similar to aggregate.

Age Time elapsed since some event at a discrete time, t_0.

Aggregate A collection of separate particles or units gathered into a mass or whole, e.g. a dust ball is a loose aggregate.

Agglutinate Common particle in the lunar soil, usually about 60 m in size, consisting of rock, mineral, and glass fragments bonded together by glass (that also contains submicron metal droplets) produced by meteorite impact.

Airglow The emission of light by an atmosphere. Airglow may result from resonant scattering, fluorescence, impact by charged particles, or radiative decay of atoms, ions, or molecules left in an excited state by some chemical reaction.

Albedo (p) A ratio of scattered to incident electromagnetic radiation power, most commonly light. It is a unitless measure of a surface or body's reflectivity. The geometric albedo of an astronomical body is the ratio of its total brightness at zero phase angle to that of an idealized fully reflecting, diffusively scattering (Lambertian) disk with the same cross section. The visual geometric albedo refers to this quantity when taking into account only electromagnetic radiation in the visual range. The bond albedo is the fraction of total power in the electromagnetic incident radiation that is scattered back out into space, taking into account all wavelengths. The bond albedo (A) is related to the geometric albedo (p) by the expression $A = pq$, where q is the phase integral.

Alfvén point Heliocentric distance at which the solar wind flow speed exceeds the local Alfvén speed. Usually thought to occur at a heliocentric distance of ~ 0.04 AU.

Alfvén speed The speed of propagation of disturbances in a magnetized plasma that bend a magnetic field without changing its magnitude.

Alfvén waves A wave propagating in a magnetized plasma in which the magnetic field oscillates transverse to the propagation direction. The propagation speed is given by the Alfvén speed $v_A = B/\sqrt{4\pi\rho}$, where B is the magnetic field strength and ρ is the mass density.

Algae Any of a large group of mostly aquatic organisms that contain chlorophyll and other pigments and can carry on photosynthesis, but that lack true roots, stems, or leaves; they range from microscopic unicellular organisms to very large multicellular structures.

Aliasing Overlapping of radar echos at different frequencies or at different time delays.

Alkali plagioclase An aluminum silicate mineral rich in sodium (*See* Feldspar).

Allochthonous Describes a rock unit that has been moved into its present location.

Alpha particle Helium nucleus having mass four times and charge twice that of a proton.

Amino acid Any organic compound containing an amino acid ($-NH_2$) and a carboxyl (-COOH) group; specifically, one of the so-called building blocks of life, a group of 20 such compounds from which proteins are synthesized during ribosomal translation of messenger RNA.

Amorphous Having no crystalline form.

Angrites A group of twelve basaltic achondrites with ~4.56 billion year ages.

Angle of repose The maximum slope at which loose material does not fall downhill.

Angular momentum Property of orbiting or rotating objects, usually expressed as mvr, where m is the mass, v is the velocity, and r is the distance from the center of rotation. The Earth and Moon have orbital angular momentum on account of their revolution around the Sun and spin angular momentum because of axial rotation. Angular momentum is conserved unless forces act to change it.

Anhydrous silicates Silicates lacking in water content.

Anomalistic month The time between successive passages of the Moon through perigee.

Anorthosite An igneous rock formed almost exclusively of plagioclase. It forms the outer layer of the Moon.

Antenna gain Ratio of an antenna's sensitivity in the direction toward which it is pointed to its average sensitivity in all directions.

Antipodes The opposite points on the surface of a sphere, given by a line through the center of the sphere.

Aphelion The point in the elliptical orbit of a planet, comet, or asteroid farthest from the Sun.

Aphelion distance (Q) The farthest distance from the Sun of an object in an elliptical orbit, given by $Q = a(1 + e)$, where a is the object's semimajor axis and e is its eccentricity.

Apoapse Point on an orbit farthest from the center of gravity, called aphelion for orbits about the Sun and apogee for orbits about the Earth.

Apogee The point in the orbit of the Moon or an artificial satellite, furthest away from the Earth.

Apojove The point in an orbit around Jupiter, farthest from the planet.

Apse Informal synonym for *Longitude of perihelion*.

Arc seconds, arcsec, second of arc An angle equal to 1/3600 of a degree, or 1/60 of an arc min. The Sun subtends an angle of ~1919 a s on average when viewed from the Earth.

Arc minute, arcmin, minute of arc An angle equal to 1/60th of a degree, or 60 a s.

Areocentric Sun longitude (L_s) An angular measure of the Martian year. $L_S = 0^\circ$ corresponds to the vernal equinox, marking the beginning of Spring in the northern hemisphere. $L_S = 90^\circ$, 180°, and 270° correspond to the summer solstice, autumnal equinox, and winter solstice, respectively.

Argument of perihelion (w) In an orbit around the Sun, the angle between the ascending node and the perihelion point, measured in the body's orbital plane and along its direction of motion.

Asteroid A rocky, carbonaceous, or metallic body, smaller than a planet and orbiting the Sun. Most asteroids are in semistable orbits between Mars and Jupiter, but others are thrown onto orbits crossing those of the major planets. Also called a **minor planet.**

Asteroid family Population of asteroids that share similar orbital elements, such as semi-major axis, eccentricity, and orbital inclination. The family members are thought to be fragments of asteroid collisions. About one-third of asteroids in the main belt are members of an asteroid family.

Aspect ratio The ratio between two dimensions of something; for a disk, the ratio between its vertical thickness and its diameter.

Asthenosphere A low viscosity zone that lies between the lithosphere and the mantle.

Astrology A belief system in which the future of individuals is predicted based upon the date and location of their birth and the positions of the moon and planets relative to the Sun or Earth at specific times.

Astrometry Precise measurement of an object's position in space.

Astronomical unit (AU) Commonly thought of as the mean distance of the Earth from the Sun. It is more formally the distance at which a massless particle in a circular orbit would have an orbital period of 1 Gaussian year, equal to 365.256898326 days. It is equal to 149.59787066×10^6 km, or about 92.955807×10^6 miles.

Astrophysical disk A rotating system of countless orbiting constituents in which random and/or vertical velocities are small compared to the orbital velocities (equivalently, in which all orbital **inclinations** are small).

Aurora Atmospheric emissions excited by the precipitation of energetic magnetospheric and solar particles, most frequently at high latitudes.

Autochthonous Describes a rock unit that has been formed in place.

Autotrophy Literally, self-feeding; the capacity of an organism to obtain its essential nutrients by synthesizing nonorganic materials from the environment, rather than by consuming organic materials; photosynthetic green plants and chemosynthetic bacteria are examples of autotrophic organisms.

(B-R) color A color scale for astronomical objects. Light from astronomical objects consists of all the colors of the rainbow: red, orange, yellow, green, blue, indigo, and violet (roygbiv). The (B-R) color measures the proportion of red to blue Light from an object. A red astronomical object has (B-R) ~ 2, the Sun has (B-R) = 1.03, and a blue astronomical object has (B-R) ~ 0.

Bar Unit of pressure, equal to 10^6 dyn/cm^2 or 10^5 Pa; the standard sea level pressure of the Earth's atmosphere is 1.013 bar. Typical planetary interior pressures are measured in megabars (Mbar) or 10^6 bar.

Baroclinic instability A 3-dimensional process common in the midlatitude troposphere wherein cold polar air pushes underneath hot low-latitude air, which transports heat toward the poles and produces complex circulation patterns that generate much of the winter rainfall in the midlatitudes.

Baroclinic, barotropic Barotropic is a region of uniform temperature distribution; a lack of fronts. Everyday being similar (hot and humid with no cold fronts to cool things off) would be a barotropic type of atmosphere, such as we find at tropical latitudes. In a baroclinic region, distinct air mass regions exist. Fronts separate

warmer from colder air. In a synoptic scale baroclinic environment, you will find the polar jet, troughs of low pressure (midlatitude cyclones), and frontal boundaries. There are clear density gradients in a baroclinic environment caused by the fronts. Midlatitude cyclones are found in a baroclinic environment.

Barycenter The center of mass of a system of two or more gravitationally bound (orbiting) bodies.

Basalt An igneous rock primarily composed of plagioclase and pyroxene. On Earth, oceanic crust is primarily basaltic in composition.

Beta meteoroid Small meteoroid for which the solar radiation pressure force is comparable to solar gravitational attraction and hence leaves the solar system on an unbound orbit.

Biologically available nitrogen Chemical forms of nitrogen such as NH_3 that can be used by organism as nutrients.

Birch–Murnaghan equation A complex semi-empirical equation of state for planetary mantles that relates pressure to density and temperature.

Bistatic Describes an observation that involves the use of a transmitter and a receiver at separate locations. The angle between the transmitter and receiver is known as the bistatic angle.

Blackbody A blackbody is defined as an object that absorbs all radiation that falls on it at all frequencies and all angles of incidence; none of the radiation is reflected.

Blackbody radiation Continuous spectrum of electromagnetic radiation emitted by an object that absorbs all radiation incident on it.

Body wave A seismic wave, or vibration, that travels through the interior of a planet. There are two types of body waves: P-waves, or compressional waves, have vibrational motion in the same direction as the wave is traveling, and are equivalent to sound waves in air; S-waves, or shear waves, have vibrational motion perpendicular to the direction of travel, and move somewhat more slowly than P-waves.

Bolide A meteoric fireball.

Bolometric albedo Fraction of the incident energy (at all wavelengths) reflected by the surface.

Bond albedo Ratio of the total radiation reflected in all directions from a solar system object to the total incidence flux.

Bound orbit Circular or elliptical orbit about a central body (e.g., Sun, planet).

Breccia Rock composed of fragments derived from previous generations of rocks.

Bremsstrahlung Electromagnetic radiation that is emitted when an energetic electron is deflected by an ion. It is also called free-free emission because both the electron and ion are free in an ionized plasma. The term is borrowed from German and means "braking radiation" because the deflected electron loses energy (by the emitted photon) and is slowed down.

Brightness temperature The temperature a body would have if it were a blackbody producing the same brightness as the observed object at the same wavelength. It can also be defined as the radiant intensity scaled to units of temperature by $X^2/2\,k$ where X is wavelength, and k is Boltzmann's constant.

Brittle deformation Irreversible deformation of rocks and solid materials occurring at relatively high stresses and low temperatures and resulting in the generation of cracks and faults or in frictional movement along existing fractures.

CAI: calcium-aluminum rich inclusion Minor component of primitive meteorites composed of refractory minerals.

Caloris Basin The largest recognized impact basin on Mercury, approximately 1550 km in diameter (960 miles).

Caldera Large volcanic crater, usually greater than 1 km in diameter. A caldera is many times the size of any associated vent(s). Calderas are formed either by collapse (most often) or explosion.

Carbonaceous (C-type) material Carbon-silicate material rich in simple organic compounds, such as that found in carbonaceous meteorites, which are believed to be among the most primitive (unaltered since their formation in the solar nebula) objects found in the solar system. They contain complex carbon compounds (hydrocarbons, amino acids), made mostly from the elements C, H, O, and N. C-type material is low albedo, spectrally flat and exists on the surfaces of several outer planet moons.

Catalytic cycle Series of chemical reactions facilitated by a substance that remains unchanged.

Cd-cutoff The neutron capture cross section for natural cadmium (Cd) is very high for thermal neutrons, but drops sharply for energies greater than about 0.5 eV, which is sometimes referred to as the "Cd cutoff" energy. Consequently, Cd is an excellent filter that absorbs thermal neutrons, but allows epithermal and fast neutrons to pass through.

Centaur A small body in a heliocentric orbit whose average distance from the Sun lies between the orbits of Jupiter and Neptune, and that has a Tisserand parameter with respect to Jupiter greater than three. Typically, the orbits of Centaurs also cross one or more of the orbits of the other giant planets. Centaurs are part of the population of ecliptic comets. They are most likely derived from the Kuiper belt and the Scattered disk. Eventually, some Centaurs may evolve into the terrestrial planets zone and become short-period comets.

Chaotic motion A dynamical situation in which the error in the prediction of the long-term motion of a body grows exponentially with time. This exponential growth leads to an inability to predict the location of the body. Chaotic motion can be confined to fairly narrow regions of space so that the orbit of the body will not change much over time. This is the case for the planets in our solar system. However, for most comets and some asteroids that we observe, chaotic motion leads to sudden and drastic changes in the orbit of the body.

Chaotic terrain Areas of the martian surface where the ground has collapsed to form a surface of jostled blocks standing 1–2 km below the surrounding terrain.

Charge-coupled device (CCD) A solid-state device used to record light electronically. A typical CCD has thousands to millions of tiny detectors arranged in a grid pattern. Each detector element is called a pixel. These devices record images electronically. CCDs have completely replaced photographic plates in astronomy due to their very high efficiency in capturing light.

Chasmata Term used in planetary geology to refer to long, relatively narrow, steep-sided troughs.

Chemoautotrophy The capacity of an autotrophic (self-feeding) organism to derive the energy required for its growth from certain chemical reactions (e.g., methanogenesis) rather than from photosynthesis; some bacterial forms are chemoautotrophic organisms.

Chiron-type comet A Centaur that displays cometary activity.

Chlorofluorocarbons (CFCs) Various compounds made with the halogens chlorine and fluorine. Their stability made them favored refrigerants until it was discovered that this also makes them efficient atmospheric ozone destroyers.

Chondrite A meteorite from an asteroid that never grew hot enough to melt and differentiate. It usually contains chondrules and their fragments.

Chondrule Millimetre-sized bead of rock found in large numbers in primitive meteorites.

Chromophore Any coloring material.

Chromosphere Lower atmosphere of the Sun, above the photosphere and beneath the transition region, with a vertical height extent of about 2000 km and a temperature range of 6000−20,000 K.

Circular polarization ratio Ratio of radar echo power received in the same sense of circular polarization as transmitted (the SC sense) to that received in the opposite (OC) sense.

Circular restricted three-body problem A special case of the problem of calculating the gravity-controlled motion of three bodies. In the circular restricted three-body problem, the two massive bodies follow circular orbits about each other, and the mass of the third body is negligible. The motion of comets and asteroids can often be approximated with the circular restricted three-body problem with the Sun and Jupiter, or sometimes the Sun and Neptune, as the two massive bodies.

Clathrate Clathrate compound, or cage compound **A**. chemical substance consisting of a crystalline lattice of one type of molecule trapping and containing a second type of molecule. A clathrate therefore is a material that is a weak composite, with molecules of suitable size captured in spaces left by the other crystalline molecule. Water ice often forms clathrates with more volatile molecules.

Co-latitude The co-latitude is the complementary angle of the latitude, i.e. the difference between 90° and the latitude. It increases from zero at the North Pole to 90° at the equator and 180° at the South Pole.

Column abundance The product of density (g/cm^3) and geometric thickness (cm). Measures the mass per unit area of an atmospheric or surface layer.

Column density The number of molecules above a column of unit area in an atmosphere.

Coma The freely outflowing atmosphere of gas and dust around the nucleus of a comet. The nucleus and coma of a comet together are often called the head.

Comet A body containing a significant fraction of ices, smaller than a planet or dwarf planet and orbiting the Sun, usually in a highly eccentric orbit. Most comets are stored beyond the planetary system in two large reservoirs:the Kuiper belt beyond the orbit of Neptune and the Oort cloud at near-interstellar distances. Comets become "active" when their ices sublimate and carry gas and dust into the coma.

Comet dust trail A contrail-like structure extending behind a comet close to its orbit, and sometimes a short distance ahead of the comet, consisting of large particles ($p < \sim 10^{-3}$) emitted at low velocities from the nucleus. Trails are distinguished from comet tails, which consist of much smaller particles, more sensitive to solar radiation pressure.

Cometary mantle or crust A layer of refractory material covering some or all of a comet nucleus' surface. When thick enough, a cometary mantle will choke off outgassing over that area.

Conjunction Occurs when two or more planetary bodies appear in the same area of the sky.

Conservation of angular momentum Fundamental physical law requiring that the quantity of angular momentum, p, be conserved (constant) for objects in orbit around a primary body: $p = mvr$, were m is mass, v is velocity, and r is the distance from the primary body, and for rotating objects. Angular momentum is not conserved in the presence of modifying torques.

Contact surface In the vicinity of a comet, the surface that separates outflowing cometary plasma from the slowed solar wind that is approaching the comet.

Continents Part of the Earth's crust of silicic composition that lies mostly above sea level and is less dense than both the mantle and the oceanic crust.

Convection Transport of energy by mass motion. In turbulent regions of planetary atmospheres and interiors, rising parcels of hot air (or rock) and sinking parcels of cool air (or rock) transport energy outward from the interior.

Core The central part of a differentiated planet, satellite or asteroid. Terrestrial planets have iron-rich cores. Jovian planets have rocky-iron cores.

Core accretion model A model for the formation of giant planets beginning with the growth of a solid core, followed by accretion of gas from the surrounding protoplanetary disk.

Coriolis acceleration Component of the acceleration on a rotating planet that acts perpendicular to the motion and balances the horizontal pressure gradient in an atmosphere or ocean. It causes circulation around high- and low-pressure centers. It is strongest in the polar regions and weakest in the tropics.

Corona Upper atmosphere of the Sun, extending above the transition region out into the heliosphere, with a dominant temperature of 1−2 million K in the lowest 100,000 km. The corona is visible during solar eclipses, and extends outward many solar radii.

Coronae Circular to oval feature surrounded by concentric ridges and fractures.

Coronal mass ejection (CME) Magnetic instabilities in the solar corona that lead to eruption of filaments, prominences, and magnetic flux ropes, which propagate as ejected mass out into the heliosphere, often accompanied by flare phenomenon. Known as an interplanetary coronal mass ejection (ICME) when observed in the solar wind far from the Sun.

Cosmochemistry The field of chemistry that concerns itself with the chemistry of extraterrestrial matter.

Coulomb interaction or collision The interaction of charged particles at large distances through the Coulomb force. The interaction is sometimes called a Coulomb collision because it produces a change of particle momentum similar to that in a conventional collision.

Cowling's theorem A mathematical theorem proved by Cowling that states that an axisymmetric magnetic field cannot be maintained by dynamo action.

Crater rays Diffuse, elongate geologic feature arrayed radially around relatively young, fresh impact craters on planetary surface. The rays form where dispersed cluster of impacting ejecta fragments form chains of secondary craters. The secondaries in turn excavate relatively bright regolith from the subsurface that has been less darkened by space weathering. Crater rays are most distinctive with the Sun overhead to accentuate albedo differences.

Cratering flow-field Penetration of the impactor, followed by movement of target materials in an impact event in response to the passage of the shock and rarefaction, or decompression, waves.

Cratering flow-field Movement of target materials in an impact event in response to the passage of the shock and rarefaction, or decompression, waves.

Critical point Temperature and pressure for a given material above which there is no distinction between the liquid and gas phases.

Crust The chemically distinct, less dense, outer shell of a planet or satellite formed by melting of the interior.

Cryovolcanism Volcanism where the volcanic materials are melted ices, such as water, ammonia, and methane, as distinguished from the common high-melting point volcanic materials of the terrestrial planets, such as basalt and rhyolite. The melted ices freeze on the surface, forming "lava flows" composed of ice.

Cryovolcano An icy volcano. See cryovolcanism.

Cumulate Plutonic igneous rock composed of crystals accumulated by floating or sinking in the silicate melt, or magma.

Curie temperature The temperature below which permanent magnetization can be maintained in a ferromagnetic material. Below the Curie temperature the individual atomic-level magnetic moments are "frozen" in place, whereas above this temperature they are largely free to realign.

Current Strictly, the product of the velocity and number density of particles. The dot product of the current and the unit normal vector of a surface yields the net number of particles crossing the surface per unit area. In the chapter "Remote Chemical Sensing Using Nuclear Spectroscopy," current is taken to be the net number of particles crossing out of a planetary surface per cosmic ray, which is dimensionless.

Cusps Features of planetary magnetospheres near the "magnetic poles", where inward closure of magnetic field lines allows plasma from the Sun direct access to the planet's surface or upper atmosphere.

Cycloidal Motion of a cycloid, which is the curve defined by a fixed point on a wheel as it rolls.

Cyclostrophic balance On Earth, the surface rotation typically surpasses the zonal winds, and the pressure gradient force generated by the unequal solar fluxes at low and high latitudes is balanced by the Coriolis force, in what is called a geostrophic balance. On Titan (and Venus), the opposite is true, and pressure gradients are balanced by strong centrifugal forces arising from the rapid rotation of the atmosphere. This balance, typical of cyclones, is called cyclostrophic.

Debris disk A disk of dust and debris in orbit around a star. Contrary to the dense protoplanetary disks, debris disks are not primordial. Rather they are secondary disks formed from debris released from planetesimals like asteroids and comets. Debris disks are considered the massive counterparts of the Zodiacal and **Kuiper** belt dust disks in our solar system.

Design reference mission Conceptual definition of a mission scenario responding to a set of mission objectives, including as a minimum the overall mission architecture, major architecture elements, and concept of operations.

Degenerate matter Matter at very high pressures where the normal atomic structure is destroyed.

Deterministic system Dynamical system in which the individual bodies move according to fixed laws described mathematically in the form of equations of motion. A deterministic system can still give rise to chaotic, unpredictable motion because of the finite precision with which any physical measurement or numerical computation can be made.

Deuterium/deuterated Heavy form of the hydrogen atom, consisting of one proton and one neutron. A deuterated molecule, such as CH_3D, deuterated methane, has one or more deuterium atoms in place of hydrogen.

Diapir A body of rock or ice that has moved upward due to buoyancy, attaining an inverted teardrop or pear shape, and piercing and displacing the overlying layers.

Diaplectic glass Glass phase produced from minerals by the destruction of internal structural order, without melting, by the passage of a shock wave.

Dichotomy A division into two opposite groups. Often used to describe the difference between the nearside mare terrain and the farside highland terrain on the Moon. Also used to describe the difference between the northern lowlands and the cratered southern highlands on Mars.

Dielectric materials Materials with few free charges, where current flows by small shifts in electrons bound to constituent atoms (as opposed to conductors, which have a large number of free electrons). Dielectric materials include most rocks, regolith, and ice.

Differentiated A body that has melted and separated into layers of different composition and density.

Differentiation Melting and fractionation of a planet, moon or asteroid into multiple layers or zones of different chemical composition; e.g., core, mantle and crust. High-density materials sink and low-density materials float.

Diffraction A physical process in which light from different parts of a mirror or lens interfere with each other. As a result of diffraction, the image of a star is not absolutely sharp; instead the full width at half maximum (FWHM) of the image is given by $\theta = 0.252^{*}\lambda/D$ a s, where the wavelength is given by λ in micrometers and D is the telescope diameter in meters. In the absence of atmospheric seeing, the image of a star would be diffraction-limited if the optics were polished sufficiently well.

Diffraction grating An object with finely and uniformly spaced grooves, commonly seen in a physics or optics laboratory; because it scatters different wavelengths of light at different angles, a diffraction grating separates light into its **spectrum** (i.e. like a prism, it creates a rainbow).

Dihedral scattering Scattering from two surfaces that form a right angle. Dihedral surfaces are commonly referred to as corner reflectors.

Dipole magnetic field The shape of the field lines around a short bar magnet. This field can be visualized by sprinkling iron filings on a piece of paper on top of a bar magnet.

Direct or prograde motion Orbital or axial motion of a body in the solar system that is counterclockwise as seen from north of the ecliptic.

Disk instability model A model for giant planet formation in which such planets form by the gravitational collapse of a portion of a protoplanetary disk.

Diurnal Occurring every day. A diurnal cycle is one that repeats daily.

Diurnal stresses Twice-daily forces exerted on a planet, which are derived from gravitational forces between the planet and a satellite.

Doppler shift Difference between the frequencies of the radar echo and the transmission, caused by the relative velocity of the target with respect to the radar. Also, the shift in frequency of spectral lines due to the motion of a light source toward or away from an observer.

Drainage basin Geomorphic entity that contains a drainage network. Typically a bowl-shaped catchment in humid areas, drainage basins in arid regions can be quite flat. Drainage patterns typically reflect the topography of the drainage basins that contain them.

D-type material Primordial, low-albedo material thought to be rich in organic compounds. It is redder than C-type material.

Ductile A ductile material is deforming under tensile stress. Ductility is an element of plasticity.

Dust bands Apparent parallel bands of dust arising from comminuted asteroid collisional debris filling a roughly Sun-centered

torus and extending past the Earth as a consequence of Poynting–Robertson drag.

Dust tail The broad, relatively featureless tail of a comet consisting of micron-sized dust particles being driven away from the nucleus and coma by solar radiation pressure. The dust particles are on independent orbits around the Sun under reduced gravity. The dust tail appears whitish or yellowish from sunlight scattered by the dust particles.

Dwarf planet A new term created by the IAU in 2006 to describe bodies orbiting the Sun that are round (in hydrostatic equilibrium) but are not massive enough to have cleared their zones. Dwarf planets include Ceres, Pluto, and Eris (2003 UB313). Other main-belt asteroids and Kuiper belt objects are potential candidates for this classification as more is learned about them.

Dynamical inertia The increase in the radiative time constant due to mixing of more massive, deeper layers of an atmosphere. The thin atmosphere at high altitudes would be expected to respond rapidly to changes in sunlight, but if there is substantial vertical circulation, the changes will occur more slowly as the mixing increases the effective mass of the layer under consideration.

Dynamo The conversion of mechanical energy into electromagnetic energy through electromagnetic induction. In a planetary dynamo, motions in an electrically conducting fluid amplify magnetic field efficiently enough to maintain it faster than it can decay through Ohmic dissipation.

Dynamo action Mechanism for the generation of magnetic fields in stars and planetary interiors resulting from convection of a rotating and electrically conducting fluid.

α-effect The process of generating magnetic field through helical motions.

ω-effect The process of generating magnetic field through large scale zonal shear flows.

Eccentricity A measure of the departure of an orbit from circular. For an elliptical orbit, the eccentricity, e, is equal to $(1-b^2/a^2)^{1/2}$, where a and b are the semimajor and semiminor axes of the ellipse, respectively. Circular orbits have $e = 0$; elliptical orbits have $0 < e < 1$; radial and parabolic orbits have $e = 1$; and hyperbolic orbits have $e > 1$.

Echo bandwidth Dispersion in Doppler frequency of a radar echo, i.e., the width of the echo power spectrum.

Ecliptic, ecliptic plane The plane of the Earth's orbit around the Sun. The planets, most asteroids, short-period comets, Kuiper belt objects and Scattered-Disk objects follow orbits with small or moderate inclinations (or tilts) relative to the ecliptic.

Ecliptic comet A comet with a Tisserand parameter with respect to Jupiter greater than 2. They generally have a small or moderate inclination to the ecliptic. The designation of such objects as comets does not necessarily imply visible cometary activity because comets typically do not become active until they pass well within Jupiter's orbit. The term "comet" assumes that the body contains a substantial fraction of water ice. Ecliptic comets include Centaurs and Jupiter-family comets.

Eddy-driven jet The jet stream occurring in the mid-latitudes, driven by eddies generated by baroclinic instabilities.

Ejecta Debris excavated from depth by an impact and deposited onto the surface outside the rim of the impact crater. The lateral extent of the ejecta depends on the gravity of the body and the velocity of the impactor.

Ekman layer Idealized model of the planetary boundary layer in which the mean flow (as in an atmosphere or ocean) is modified near the ground by friction (either laminar or turbulent). The resulting variation of flow speed and direction with height is described by the Ekman spiral.

Electromagnetic induction The generation of an electromotive force from a changing magnetic flux, governed by Faraday's Law.

Elevation angle The angle between a flat surface (such as Saturn's rings) and the observer's line of sight.

El Nino-Southern Oscillation *See* ENSO.

Elongation The angular distance between the Sun and a planet or other solar system body as viewed from the Earth.

Embays To form a protective barrier.

Embryo Differentiated protoplanet resulting from the accretion of km-sized planetesimals.

Emissivity The ratio of radiant energy flux from a material to that from a blackbody at the same temperature. A blackbody is an ideal material that absorbs all radiant energy incident upon it and emits radiant energy at the maximum possible rate per unit area at each wavelength for a given temperature. A blackbody has an emissivity of 1 across the entire spectrum. Real materials have an emissivity between 0 and 1 for a given wavelength.

Encke-type comet An ecliptic comet whose entire orbit is interior to the orbit of Jupiter and which has a Tisserand parameter with respect to Jupiter greater than 3.

Endogenic Forming from within.

ENSO El Nino, "the child," and the Southern Oscillation. El Nino is the episodic appearance of warm water off the coast of South America, often at Christmas time, that devastates Peruvian fishing (usually one fifth of the world's catch), causes drought conditions in Australia, and weakens the monsoon in India. The Southern Oscillation is the historical name for the global (not just southern) atmosphere-ocean oscillation for which El Nino years are the extreme.

Entropy Broadly, the degree of disorder, or randomness in a system; in thermodynamics, a measure of the amount of heat energy in a closed system that is not available to do work. In a condition of low entropy (high efficiency), the system will convert to energy a large portion of the heat transferred to it from an external source (no actual system can utilize 100% of the heat it receives).

Enzymes Proteins that catalyze, or accelerate, chemical reactions.

Epicenter The point on a planet's surface that is directly above the hypocenter or focus of a seismic event (or quake), the point within the planet where a quake originates.

Equal angle map For mapping, the surface of a planet is subdivided into spatial elements called pixels on which quantities such as counting rates and elemental abundances are specified. In an equal area map, all of the pixels span the same angle in latitude and longitude. Consequently, a parallel near a pole is divided into the same number of pixels as a parallel at the equator and the area of the pixels varies with latitude.

Equal area map The longitude-range for pixels at different latitudes is adjusted so that all of the pixels have approximately the same area. Consequently, a parallel near the pole is divided into fewer pixels than at the equator. The span of pixels in latitude and longitude at the equator is used to specify the map.

Equation of state Equation relating the pressure of a given material to its temperature and density, typically derived from experimental and theoretical considerations.

Equinox The passing of the Sun through a planet's equatorial plane, so that the northern and southern hemispheres receive sunlight in

equal measure; associated with the seasons of spring and autumn (cf. **solstice**).

Equilibrium vapor pressure The ambient pressure of the gas phase over a condensed phase when the gas and condensed phase are in thermodynamic equilibrium (i.e., when the rate of condensation from gas to ice equals the rate of sublimation from ice to gas). In effect, vapor pressure is a measure of the amount of gas an ice or liquid layer at a specified temperature will evolve in a closed container (or planetary atmosphere). Vapor pressures are extremely sensitive functions of temperature and are also related to the composition and structure of a given ice or liquid.

Escape velocity Minimum velocity required to escape from the surface of a body to infinity.

Europium anomaly and Eu* Because the Moon is highly reduced, europium is divalent on the Moon and hence is mostly separated from the other smaller trivalent rare earth elements because it is concentrated in plagioclase feldspar. The degree of enrichment or depletion is given by Eu/Eu*, where Eu is the measured abundance and Eu* is the abundance expected if Eu had the same relative concentration as the neighboring rare earth elements, samarium and gadolinium.

Exosphere The outermost part of an atmosphere, characterized by very low densities and very long mean-free paths, and usually isothermal.

Extended scattered disk Collection of objects with orbits with semimajor axis >50 AU, large eccentricity, and perihelion distance large enough to avoid destabilizing encounters with Neptune. The apparent similarity with the orbits of objects in the scattered disk suggests that the latter extended further in perihelion distance in the past, due to a different orbital architecture of the planets or of the environment of the solar system. The most prominent members of the extended scattered disk population are 2000 CR105 and 90377 Sedna.

External comet A returning comet with a semimajor axis greater than ∼34.2 AU. External comets have Tisserand parameters with respect to Jupiter less than 2. Also known as a **long-period comet.**

Extrasolar planet A planetary companion to a star other than the Sun.

Fault A planar fracture or discontinuity in a rock with significant displacement.

Ferrel cells The overturning circulation in the midlatitudes, poleward of the Hadley cells. Unlike the Hadley cell, the Ferrel cell is not thermally driven but rather is mechanically driven by baroclinic instabilities and wave generation in this latitude range.

Feldspar A common group of aluminum silicate minerals.

Field of view The region visible in a single image taken by a camera or telescope.

Filaments Near-horizontal magnetic field lines on the Sun suspended above magnetic inversion lines that are filled with cool and dense chromospheric mass, seen on the solar disk.

Flexural response Behavior of the elastic, near-surface portion of a planet when a load is applied.

Flares A magnetic instability in the solar corona that impulsively releases large energies that go into heating of coronal and chromospheric plasma, as well as into acceleration of high-energy particles. A flare is usually accompanied by impulsive emission in gamma rays, hard x-rays, soft x-rays, EUV, and radio emission.

Fluctus (pl., flucti) Term meaning (on Io) a volcanic flow field.

Fluorescence Photons emitted immediately after electron decay. The electron had been elevated to a higher energy state by external stimulation of their parent atoms, ions, and molecules. In planetary atmospheres, the external stimulation is usually sunlight or electrons.

Flux The flux of particles (denoted p with units of $cm^{-2}s^{-1}$) given by the product of the speed of the neutrons, v (cm/s), and the number density (particles per cm^3).

Flux density Power per unit area and per unit frequency interval received from an object. The units of flux density are Janskies: $1\ Jy = 10^{-26}\ W/m^2/Hz$.

Flux transfer event A localized spatial region in which magnetic reconnection links the solar wind magnetic field to a planetary magnetic field producing a configuration that transports flux from the day side to the night side of the planet.

Fractionation Separation of elements or isotopes based on their masses or chemistry.

Fraunhofer lines Dark lines in a radiance spectrum, produced when chemical elements in a cold gas absorb light of specific energies from a broad-spectrum photon source. In the solar spectrum, Fraunhofer lines originate from gas in the outer regions of the Sun, which are too cold to directly produce emission lines of the elements they represent.

Frequency-time spectrogram A graph of the emission intensity as a function of frequency and time. Usually the intensity is shown on a gray scale ranging from black to white or one of several color schemes, with frequency plotted along the vertical y-axis and time along the horizontal x-axis.

Galactic cosmic rays Energetic particles, including photons, electrons, protons, and heavy ions, that originate outside the heliosphere.

Galilean satellites The four major satellites of Jupiter: Io, Europa, Ganymede and Callistio, discovered by Galileo in 1610.

Gamma ray A high energy quantum of electromagnetic radiation (photon) emitted by nuclear transitions. Gamma rays originate from nuclear processes, such as radioactive decay and the de-excitation of residual nuclei produced by nuclear reactions.

Gamma-ray spectroscopy In planetary science, the estimation of abundances of elements from their emissions of gamma rays. The rays come from the natural radioactivity of uranium, thorium, or potassium, or emissions from other elements when their nuclei have been excited by cosmic rays.

Gas chromatography A chemical technique for separating gas mixtures, in which the gas is passed through a long column containing a fixed absorbent phase that separates the gas into its component parts.

Gas drag Drag force experienced by a solid object when it moves through a surrounding gas.

Gauss coefficients Radial coefficients of the spherical harmonic expansion of the scalar potential for a planetary magnetic field in an insulator.

Gauss' Theorem Gauss' theorem (also known as the divergence theorem) states that the outward flux of a vector field through a closed surface is equal to the volume integral of the divergence over the region inside the surface. Intuitively, it states that the sum of all sources minus the sum of all sinks gives the net flow out of a region. When applied to gravity, it can be restated as Gauss' law of gravitation: "The integrated gravitational flux through any closed surface is proportional to the enclosed mass."

Gaussian year The orbital period of a massless particle in a circular orbit with a semimajor axis of 1 AU, equal to 365.256898326… days. Formally, the Gaussian year is defined as $2\pi/k$, where k is the Gaussian gravitational constant, 0.01720209895.

Geochemistry The study of the chemical components of the lithosphere of the Earth and other planets, chemical processes and reactions that produce and modify rocks and soils, and the cycles of matter and energy that transport chemical components in space and time.

Geodesy The measurement and representation of Earth's topography, its gravitational field and geodynamic phenomena (e.g., polar motion, tides, and crustal motion) in 3-dimensional, time-varying space.

Geodynamo The self-sustaining process responsible for maintaining a planet's magnetic field in which the kinetic energy of convective motion of the planet's liquid core is converted into magnetic energy.

Geologic unit In planetary geology, a volume of rock (or ice) having a consistent age range, that is identifiable by distinctive morphology, surface texture, composition, or other measurable physical property that relates to the rock's origin.

Geomagnetic activity Disturbances in the magnetized plasma of a magnetosphere associated with fluctuations of the surface field, auroral activity, reconfiguration and changing flows within the magnetosphere, strong ionospheric currents, and particle precipitation into the ionosphere.

Geomagnetic storm The response of the Earth to the arrival of an interplanetary medium disturbance, usually associated with a CME.

Geomagnetism The Earth's magnetic field, which is approximately a magnetic dipole, with the magnetic poles offset from the corresponding geographic poles by approximately 11.3°, and extending several tens of thousands of kilometers into space.

Geometric albedo *See* Albedo.

Geomorphology Science of landscape analysis. Geomorphic investigations deal with the processes and timescales of landscape formation and degradation.

Geospace The Earth's magnetosphere and upper atmosphere, including the ionosphere.

Geostationary orbit An orbit around the Earth in which a satellite has an orbital period equal to the Earth's rotation period. A geostationary satellite remains above the same point on the Earth's surface at an altitude of about 36,000 km.

Geostrophic A geostrophic flow (ocean) or wind (atmosphere) results from the balance between the Coriolis effect and the pressure gradient force.

Giant Planets The giant planets in the solar system are Jupiter and Saturn. Jupiter is 300 times more massive than the Earth and about 10 times as large. Saturn is about 9 as large as Earth but only about 100 times as massive. Compare the planetary data in table 2 of the appendix. Uranus and Neptune are smaller and are usually called the sub-giants.

Global contraction Reduction in the radius of a planetary body due to cooling of its interior, placing the near-surface region under compressional stress. Global contraction is thought to be an important driver of tectonic deformation on Mercury.

Global exploration roadmap Defines technical feasible and programmatically implementable pathways toward human missions to Mars, reflecting policies and plans of space agency's and defining future mission concepts as well as required preparatory activities.

Graben A pair of conjugated normal faults that create a narrow, linear trough as the lithosphere is pulled apart under extension.

Granite Light-colored intrusive rock containing more than 50% silica. On Earth, continents are largely granite and other high silica rocks.

Grain-size Dimension of individual crystals in a rock that strongly influences its rheological properties.

Grand Tack model Model describing a hypothetical episode during the formation of the planets in which Jupiter migrated inwards and then outwards across the asteroid belt, scattering away many of the planetary building blocks from the asteroid belt and the region now occupied by Mars.

Gravitational focusing The tendency of an object's trajectory to curve toward a massive body due to gravitational attraction.

Gravitational instability Spontaneous collapse of a portion of a protoplanetary disk due to mutual gravitational attraction. This can refer to either the solid or gaseous component of the disk.

Graybody A sphere that absorbs a fraction of all light incident on it, and reemits that energy in all directions as thermal radiation. A gray body which absorbs all light incident on it is considered a "black body".

Greenhouse effect A radiative effect that occurs when the atmosphere is more transparent in the visible than infrared (IR) radiation. Visible sunlight easily penetrates through the atmosphere and is absorbed at deep levels. Because the atmosphere is relatively opaque in the IR, the atmosphere radiates IR radiation both up (to space) and down (to the surface). Since the surface receives not only sunlight but IR energy from the atmosphere, its temperature becomes higher than would occur in absence of an atmosphere. In steady state, energy balance is achieved, with escaping heat energy almost exactly equalling absorbed solar energy; in contrast to popular myth, heat is not "trapped."

Gyro radius Radius of the orbit of a charged particle gyrating in a magnetic field.

Gyrofrequency The frequency of the circular motion of a charged particle perpendicular to a magnetic field.

Habitable zone The region of space around a star in which a geologically active, rocky planet can maintain liquid water on its surface.

Hadley cell *See* Hadley circulation.

Hadley circulation A major component of atmospheric circulation driven directly by latitude-averaged heat sources and sinks. Warm air rises in regions near the equator, flows poleward at higher altitudes, and loses heat in the colder, higher latitude regions. The cooler, denser air then descends and has a flow component near the surface back toward the low-latitude heat source, which completes a circulation cell. The near-surface and high-altitude branches of the flow have eastward ("trade wind") and westward components, respectively, arising from Coriolis forces. When the heat source is located on the equator, the Hadley circulation tends to be symmetric about the equator, but the Hadley circulation is asymmetric about the equator if the heat source is located off the equator, as occurs during solstice seasons on Earth and Mars.

Half-life The time in radioactive decay in which half of the isotope has decayed to its daughter isotope.

Hall conductivity The electric conductivity in the ionosphere perpendicular to the electrical and the magnetic field.

Halley-type comet A returning comet with a semimajor axis less than ∼34.2 AU. Halley-type comets have Tisserand parameters with respect to Jupiter less than 2.

Heat flow Heat emitted (or received) at the surface of a body that is ultimately radiated to (or absorbed from) space.

Heavy elements In astrophysics, all elements other than hydrogen and helium.

HED meteorites The "howardite–eucrite–diogenite" achondrite meteorites believed to originate from the asteroid Vesta.

Heliocentric A Sun-centered coordinate system.

Heliopause Interface between the heliosphere and the interstellar plasma; the outer boundary of the heliosphere.

Heliosphere The region of space, surrounding the Sun that is carved out in the interstellar medium by the solar wind. This region extends to about 100 AU in radial distance from the Sun.

Heliospheric current sheet The surface in interplanetary space separating solar wind flows of opposite magnetic polarity; the interplanetary extension of the solar magnetic equator.

Heliospheric magnetic field Remnant of the solar magnetic field dragged into interplanetary space by the solar wind.

Helium rain The precipitation of helium droplets due to the dissociation of helium from hydrogen that occurs at the molecular-metallic hydrogen transition in Jupiter and Saturn.

Heterotrophy Literally, other-feeding; the condition of an organism that is not able to obtain nutrients by synthesizing nonorganic materials from the environment, and that therefore must consume other life forms to obtain the organic products necessary for life; e.g., animals, fungi, most bacteria.

Highlands A topographic region that stands above its surroundings. A prominent example is the lunar highlands.

High-reflectance plains (HRP) Material that dominates some of Mercury's largest deposits of smooth plains, notably in Caloris basin and in the North Polar region. HRP is higher in albedo and more red than average Mercury surface material.

Hill sphere Region around a secondary in which the secondary's gravity is more influential for the motion of a particle about the secondary than is the tidal influence of the primary.

Hilly and lineated terrain The broken-up surface of Mercury at the antipode of the Caloris impact basin.

Hirayama asteroid families Clusters of asteroids having orbits with similar semimajor axes, eccentricities, and inclinations. The most prominent of these were discovered by Kiyotsugu Hirayama in 1914.

Hohmann transfer orbit Elliptical trajectory to achieve low-energy transfer of spacecraft between two different circular orbits, involving orbital maneuvers consisting of thrust impulses tangential to the orbits at the beginning and end of the transfer ellipse.

Homopause Level in an atmosphere, above the stratosphere, at which gases cease being uniformly mixed and separate by diffusion, with the lighter elements diffusing upward.

Horseshoe orbits Librating orbits encircling the L_3, L_4, and L_5 Lagrangian points in the circular restricted three-body problem. These orbits appear to be shaped like horseshoes in the frame rotating with the mean motion of the system.

Hot Jupiter An extrasolar gas giant planet at a very small orbital separation of 0.03–0.05 AU from its host star and with an orbital period of a few days. The proximity of the discovered hot Jupiters to their host stars is probably a result of inward orbital migration.

Hot poles The alternating perihelion subsolar points on Mercury at the 0° and 180° meridians.

Hot spots Regions of enhanced thermal emission on Io, a marker of volcanic activity. The term does not imply a particular eruption mechanism.

Hugoniot elastic limit Stress at which a rock or mineral's response to shock changes from elastic to plastic. Stresses above the Hugoniot elastic limit cause the rock or mineral to deform plastically.

Human action radius The range around the Earth where humans can travel by spacecraft within the present state of technology. It includes the Moon, Venus, Mars, and near Earth objects like asteroids or comets.

Human–robotic partnership Complementarity of robotic and human capabilities in space for advancing exploration goals. It refers to the role of robotic missions in preparing human missions as well as mission concepts, which combine robotic and human capabilities in space.

Hydrated A mineral in which water molecules or hydroxyl radicals are attached to the crystalline structure.

Hydrodynamic escape A limiting case of atmospheric escape that occurs when the escape rate is so rapid that the atmosphere at high altitudes reaches an outward velocity comparable to the speed of sound. This occurs if the thermal energy of the gas molecules becomes comparable to the gravitational binding energy. Hydrodynamic escape allows the upper atmosphere of a planet to escape wholesale, as opposed to the usually slower processes of Jeans-type thermal leakage or solar wind ion pickup.

Hydrogen cloud The huge cloud of atomic hydrogen surrounding most comets. The hydrogen cloud is produced by the dissociation of water and the hydroxyl molecule (OH).

Hydrostatic equation Relationship that says pressure is equal to the weight of gas or liquid above the level of interest.

Hyperbolic orbit Unbound orbit in which the object escapes the gravitational attraction of the central body. Examples are orbits of beta meteoroids and interstellar grains.

Hypsometry Geodetic observations of terrain elevations with respect to sea level.

Hysteresis The dependence of a system not only on its current environment but also on its past environment. This is typically manifested as the lagging of an effect behind its cause, as when the change in magnetism of a body lags behind changes in the magnetic field to which it is subjected.

Ice dwarf The term given to the planetesimals believed to have been created in large numbers during the formation of the giant planets and later scattered to the Oort cloud or ejected from the solar system by close encounters with the forming giant planets. Pluto and Triton are thought to be among the largest remnants of this population.

Ice Mixture of water, ammonia, methane, and other volatile compounds in the interiors of jovian planets, not literally in the form of condensed "ice."

IDP Interplanetary dust particle, collected by aircraft in the stratosphere.

Imaging spectrometer An instrument that can take pictures of a scene at many wavelengths simultaneously, sampling a significant portion of the **spectrum** at each pixel.

Impact melt Melt of target rocks resulting from the waste heat generated in an impact event. When solidified, it can be either glassy or crystalline and contain clasts of rock and mineral debris from unmelted portions of the target.

Inclination The angle between the plane of the orbit of a planet, comet, or asteroid and the ecliptic plane, or between a satellite's orbit plane and the equatorial plane of its primary. Inclination takes on values between 0° and 180°.

Inclination (orbital) For asteroids this is the tilt of an object's orbit with respect to the solar system ecliptic.

Incompatible elements Element that upon silicate melting tends to be largely concentrated in the liquid phase.

Inertia matrix In space, inertia is defined by a symmetric 3×3 inertia matrix where the diagonal elements couple torque around one axis to acceleration about the same axis, and where the off-diagonal terms called products of inertia couple torque around one axis to acceleration about another axis.

Insolation The flux of sunlight at all wavelengths falling on a body. For the Earth this amounts to a flux of 1.368×10^6 ergs 21 cm s.

Integral of the motion Any function of the position and velocity coordinates of an object that remains constant with time along all orbits. In the circular restricted three-body problem, the Jacobi constant is an integral of the motion. The Jacobi constant can be approximated by the Tisserand parameter.

Infrared light Electromagnetic radiation with wavelengths ranging from 900 nm to about a millimeter on the **spectrum**; because it is emitted by objects at temperatures commonly experienced on Earth and other planets, infrared is commonly thought of as "heat radiation".

In-situ resource utilization (ISRU) Use of resources found or manufactured on a celestial body to advance a space mission. This could be life support (oxygen, food and water), energy, propellant, construction or other materials.

Intercrater plains The oldest plains on Mercury that occur in the highlands and formed during the period of late heavy bombardment.

Intraplate volcanism Volcanic events not associated with phenomena occurring at plate margins and generally thought to be related to magmatism generated by mantle plumes.

Intrusion Geological structure of igneous material that forces its way into an existing formation. Examples are dykes, sheet-like intrusions of magma that later solidified or diapirs, bodies of (partial) melt that intruded driven by their bouyancy relative to the solid surrounding rock.

Invariable plane The plane passing through the center of mass of the solar system, which is perpendicular to its total angular momentum vector. The invariable plane is inclined 0.5° to the orbital plane of Jupiter and 1.6° to the ecliptic.

Ionopause The surface separating ionospheric plasma and the solar wind in the vicinity of an unmagnetized planet.

Ionosphere Outer portion of an atmosphere where charged particles are abundant.

Isolation mass The mass of a planetary embryo if it sweeps up all the accessible solid material in its vicinity.

Isostasy A condition of gravitational balance (similar to floating) in which crustal rocks are buoyantly supported from below by denser mantle rocks. The crustal rocks above subside into the mantle, or the mantle rises, until the mass in each column of rock is equalized.

Isotopes variant of a given chemical element characterized by the same number of protons but a different number of neutrons.

Jacobi constant An integral of the motion in the circular restricted three-body problem. It is proportional to the total orbital energy of the small body in a reference frame rotating with the two massive bodies.

Jeans escape The process by which fast (energetic or hot) molecules of an atmosphere escape into space. The energy distribution of a gas at a given temperature has a hot tail—a few atoms moving faster than the rest. If, at an altitude where collisions between molecules are rare, the molecules in the hot tail move faster than the local escape velocity, they can escape to space. This process is fastest for hot atmospheres of light gases (hydrogen, helium) on bodies with low gravity.

Jets The observed, collimated emission of gas and dust that occurs in restricted areas on the surface of a cometary nucleus. Jets are usually active on the sunlit side of the nucleus.

Joule heating Heating that occurs when a current flows through a resistive medium. In the high atmospheres of the giant planets, it may be an important process in heating the atmosphere to high temperature as currents of charged particles driven by magnetospheric electric fields collide with the neutral atmosphere atoms, which provide resistance.

Jovian planet A planet like Jupiter, which is composed mostly of hydrogen, with helium and other gases, but possibly with a silicate/iron core. Also called a gaseous or a giant planet. The jovian planets are Jupiter, Saturn, Uranus, and Neptune.

Jupiter-family comet An ecliptic comet with a Tisserand parameter between 2 and 3. It is typically on a low to moderate inclination orbit, with a semimajor axis less than that of Jupiter's orbit. Most Jupiter-family comets are in orbits that cross or closely approach Jupiter's orbit.

Ka-Band Ka-band is the part of the microwave band of the electromagnetic spectrum that ranges from 26.5 to 40 GHz. The corresponding range of wavelengths is 0.75 to 2.5 cm. In space missions the reserved frequency band is around 34 GHz (34.2 to 34.7 GHz) for the uplink (Earth to Space) and around 32 GHz (31.8 to 32.3 GHz) for the downlink (Space to Earth).

K or kelvin Unit of absolute temperature. The freezing and boiling points of water are 273.16 K and 373.16 K, respectively. The temperature in Kelvin is calculated from the temperature in °C by adding 273,15 K.

Kepler mission A four year NASA mission using a 1 m space telescope to monitor a large target field of 160,000 stars with the transit technique. *Kepler* has the sensitivity to detect planets as small as Earth.

Keplerian orbit The path that a body would follow if it were subject only to the gravitational attraction of its primary, e.g., a planet orbiting the Sun, a satellite orbiting a planet.

Keplerian velocity The speed with which a solid body moves on a circular orbit about a larger body.

Kepler's laws Three rules that describe the unperturbed motion of planets about the Sun (and of moons about planets): (1) Planets move on elliptical paths with the Sun at one focus. (2) An imaginary line from the Sun to a planet sweeps out area at a constant rate. (3) The square of a planet's orbital period varies as the cube of the semimajor axis of its orbit.

Kirkwood gaps Zones in the asteroid belt that have been depleted of objects due to mean-motion orbital resonances with Jupiter.

Klystron Vacuum-tube amplifier used in planetary radar transmitters.

Kozai resonance A resonance where an object's nodal precession rate is equal in magnitude and direction to its periapse precession rate. Objects within a Kozai resonance undergo oscillations in eccentricity and inclination that are out of phase (i.e., when one increases, the other decreases). Kozai resonances affect the motion of Pluto and some comets and asteroids in the solar system.

Kuiper belt Generally used to refer to the population of trans-Neptunian bodies, i.e., those with semimajor axes >30 AU. In a more detailed classification, which partitions the trans-Neptunian population into the Kuiper belt, the scattered disk and the extended scattered disk, the name "Kuiper belt" is associated with a collection of bodies on essentially stable, low inclination, low eccentricity orbits. Almost all Kuiper belt objects discovered so far have semimajor axes <50 AU, which argues for the Kuiper belt having an outer edge at approximately that location. *See also*

chapters 42, 43 and 44 about Pluto, Kuiper belt dynamics and about the physical properties of Kuiper belt objects.

Lagrangian points The five locations in the circular restricted three-body problem at which the net gravitational and centrifugal forces in the frame rotating with the massive bodies is zero. The first three Lagrangian points, L_1, L_2, and L_3, lie on the line connecting the massive bodies; all three colinear Lagrangian points are unstable. The L_4 and L_5 Lagrangian points each make equilateral triangles with the two massive bodies; orbits about the triangular Lagrangian points are stable to small perturbations provided the ratio between the masses of the two bodies is ≥ 27.

Larmor radius The radius (also known as the gyroradius or cyclotron radius) of motion of a charged particle in a magnetic field. It depends on the mass of the particle, the magnetic field strength, and the speed of the particle perpendicular to the magnetic field lines.

Landforms Natural physical features of a planet's surface.

Langmuir probe Instrument used to measure electron and ion densities. The external sensor is usually a stiff wire and the current is measured as different voltages are applied.

Laplace resonance Occurs when three or more orbiting bodies have a simple integer ratio between their orbital periods.

Last universal common ancestor The hypothetical latest living organism from which all currently living organisms descend.

Late heavy bombardment (LHB) An apparent event 4.1 to 3.8 billion years ago, during which a large number of impactors collided with inner solar system planetary bodies. The record of this event exists in the crater populations of Mercury, the Moon, and Mars. The LHB happened "late" in the solar system's accretion period, when Earth and the other rocky planets formed and gained most of their mass (although this period is still early in the history of the solar system as a whole). The LHB may have happened when solar system dynamics caused the orbits of many main-belt asteroids to become elliptical and intersect inner solar system planets.

Latent heat Heat that is released or absorbed during a phase change, i.e., vapor or liquid or ice to ice or liquid or vapor. Latent heat contributes to heating and cooling the atmosphere in regions where ice and liquid clouds form and dissipate. It also contributes to the heat capacity of a parcel of gas/cloud and therefore influences the adiabatic temperature gradient.

Lava flow A body of silicate rock on a planetary surface, both while it is flowing into place and after it has come to rest.

Leading hemisphere When a moon is locked in synchronous rotation, the leading hemisphere faces in the direction of orbital motion.

Libration A small oscillation around an equilibrium configuration, such as the angular change in the face that a synchronously rotating satellite presents toward the focus of its orbit.

Lightcurve A graph of an object's brightness versus time. Since asteroids and cometary nuclei are usually not perfect spheres, the observed projected area of the object varies as the object rotates. The time difference between the peaks of the lightcurve provide a measure of the object's rotation rate and the shape of the lightcurve can be statistically modeled to derive the object's shape.

Limb-darkening The darkening of the observed edges a planetary disk or a star. This may be due to the scattering properties of the surface (if, for example, it is a strongly backscattering surface, like an icy one) or more usually to the presence of an optically thick atmosphere. It is often characterized by an exponent k, the Minnaert exponent, for a scattering law of the form $I = I_0 \mu^k / \mu_0^{k-1}$, where μ and μ_0 are the cosines of the angle between the normal at a given point and the observer and sun respectively and I_0 is the brightness of the center of the disk. $k = 0.5$ corresponds to a flat disk (rather like the moon), while $k = 1$ is a Lambertian disk with strong limb-darkening. $k < 0.5$ corresponds to limb-brightening, typical of a scattering but optically thin region above an absorbing (dark) region in the atmosphere.

Linear stability Mathematical technique used to describe the stability of a dynamical system subject to small perturbations.

Liquidus Temperature above which all minerals present in a rock are molten.

Lithophile Material made of elements that are commonly found in rocks, such as Si, O, Al, Ca, and Fe; derived from the Greek, meaning "rock-loving."

Lithosphere The rigid outer shell of a planetary body, generally including a chemically distinct crust and part of the upper mantle; For a more detailed discussion of planetary lithospheres see chapter 9 on the thermal evoluton of terrestrial planets. *See also* Thermal lithosphere.

Lobate scarp A long sinuous cliff (*See* Thrust fault)

Longitude of perihelion ($\overline{\omega}$) The sum of the longitude of the ascending node and the argument of perihelion.

Longitude of the ascending node (Ω) The nodes of an orbit are the points where the orbit crosses some reference plane, usually the ecliptic. The ascending node is where the orbit crosses the reference plane from south to north. The longitude of the ascending node is the angle between the location of the ascending node and some standard direction in the reference frame, usually the direction of the vernal equinox.

Long-period comet A comet with an orbital period of more than 200 years. Some long-period comets have orbital periods of millions of years.

Lorentz force Force exerted by a magnetic field on a moving charged particle. This force is always perpendicular to the motion of the particle.

Low Earth orbit (LEO) Spacecraft orbit with altitudes between 160 km (below this limit atmospheric drag leads to rapid orbital decay) and 2000 km above the Earth surface. All human spaceflight except the Apollo missions has taken place in LEO.

Low-reflectance material (LRM) Material that occurs on Mercury within and surrounding some craters and impact basins that have exposed material from several or more kilometers below the surface. LRM is lower in albedo and less red than average Mercury surface material.

Lyapunov exponent Measure of the rate of divergence of two nearby trajectories in a system. A positive Lyapunov exponent is associated with chaotic motion, and its inverse gives an estimate of the timescale for exponential separation of nearby orbits.

Macroscopic cross section The product of the number density (number per cm^3) of the target nuclei and the microscopic cross section. The macroscopic cross section has units of cm^{-1} and gives the probability per unit path length that a particle will undergo an interaction, for example, in a planetary surface.

Mafic Dense, Fe- and Mg-rich silicate minerals, such as those that dominate the mantle; usually refers to basalts and other refractory igneous rock types.

Magma ocean Partially or completely molten silicate mantle of a terrestrial body resulting from extreme heating due to large impacts or radioactive decay.

Magnetic flux rope A magnetic flux tube characterized by axial fields near its center and by helical fields with increasing pitch angles away from the axis of the rope near the outer edge.

Magnetic induction equation A source-diffusion equation for magnetic field generation derivable from Maxwell's equations and Ohm's law.

Magnetic reconnection A magnetic instability that can be triggered in the solar corona, where the topology and connectivity of magnetic field lines change; believed to be the primary cause of flares and coronal mass ejections.

Magnetic Reynolds number A dimensionless group of parameters that describes the ratio of magnetic induction to magnetic diffusion. A critical value must be attained for a self-sustained dynamo to occur.

Magnetic storm A prolonged interval of intense geomagnetic activity often lasting for days.

Magnetic wind Zonal flows driven by Lorenz forces.

Magnetopause The outer boundary of a magnetosphere between the solar wind region and a planets' magnetic field region, where a strong thin current generally flows.

Magnetosheath The region between a planetary bow shock and magnetopause in which the shocked solar wind plasma flows around the magnetosphere.

Magneto-rotational instability Coupling of a protoplanetary disk's magnetic field to the gas's orbital motion leading to an inward flow of mass and outward transport of angular momentum.

Magnetic secular variation Time variations of a planetary magnetic field.

Magnetic wind Zonal flows driven by Lorenz forces.

Magnetohydrodynamic limit An approximation made to Maxwell's equations and Ohm's law used in the study of dynamics of electrically conducting fluids when velocities are much smaller than the speed of light.

Magnetosphere The region of space around a planet or satellite dominated by its intrinsic magnetic field and associated charged particles.

Magnetostrophic balance It is achieved in the momentum equation when the Lorenz and Coriolis forces are dominant and balance each other.

Magnitude A logarithmic unit of brightness. Large magnitude values correspond to faint objects. The Sun, the faintest star visible with the unaided eye, and the faintest Kuiper belt object seen with the *Hubble Space Telescope* have magnitude values of $-26.74, +6$, and $+28$, respectively. For every change by five magnitudes, the brightness changes by a factor of 100. One magnitude equals a factor of $100^{1/5}$ or ~ 2.5119 in brightness. All magnitudes are scaled to the flux of Alpha Lyrae, also named Vega, which is designated as magnitude 0.

Magnetotail The part of a planetary magnetosphere that is pushed antisunward into a tail-like feature by the pressure of the solar wind.

Main sequence When stars are plotted on a graph of their luminosity versus their surface temperature (or color), most stars fall along a line extending from high-luminosity, high-surface temperature stars, to low- luminosity, low-surface temperature stars. This plot is known as the Hertzsprung-Russell diagram, and the line is known as the main sequence. Stars spend the majority of their lifetimes on the main sequence, during which they produce energy by hydrogen fusion within their cores.

Mantle The interior of a generic Earthlike (terrestrial) planet consists of an iron-rich core surrounded by a rock mantle underneath a rock crust. The crust forms by partial melting and extrusion of mantle rock. Mantle and crustal rock is solid but may flow over geologic timescales of hundreds of million years.

Mantle convection Movement of material within the Earth's mantle occurs because the density of constituent rock is related to temperature. Buoyant hot material thus tends to rise and cooler material tends to sink over time. In our experience, convection is most commonly associated with liquids or gases, however, deep within the Earth, plastic and even solid rock under pressure can convect, and thus transport heat away from the core, through the mantle, and ultimately toward the surface.

Mare (pl., maria) Latin word for "sea," used first by Galileo to refer to the dark patches on the lunar surface, now known to be basaltic lava flows.

Mascons Regions of the Moon of excess mass concentrations per unit area, identified by positive gravity anomalies and associated with basalt-filled multiring basins.

Mass wasting The downslope movement of rock, regolith, and soil under the influence of gravity.

Maxwellian distribution The distribution of particle velocities for a gas in thermal equilibrium.

Mean anomaly The mean anomaly is an angle that defines the position of a fictive body moving with a uniform velocity along an orbit and with the same orbital period as the true body.

Mean motion The mean motion is the mean value of the angular velocity of a planet or a satellite while progressing around its elliptical orbit.

Mean-motion resonance An orbital resonance in which the orbital periods of the bodies involved are in a simple integer ratio. For example, Pluto is in a 2:3 mean-motion resonance with Neptune; it completes two orbits around the Sun for every three of Neptune.

Meridional circulation Motions of the atmosphere in the plane defined by the vertical and latitudinal coordinates. Atmospheric motions in the vertical and north-south directions participate in the meridional circulation.

Meridional mixing Mixing of the atmosphere along meridians (lines of constant longitude), for example, between polar regions and mid-latitudes.

Mesosphere The layer of the atmosphere overlying the stratosphere and below the mesopause. In the mesosphere and stratosphere - collectively called the middle atmosphere – radiative heat transfer dominates over convection.

Metallic hydrogen High-pressure ($\geq$1.4 Mbar) metallic form of hydrogen found in the interiors of Jupiter and Saturn.

Meteor Light phenomenon that results from the entry of a meteoroid from space into Earth's atmosphere.

Meteorite Meteoroid that has reached the surface of Earth or another planet without being completely vaporized.

Meteoroid A small fragment of an asteroid or comet that is in interplanetary space. When a meteoroid enters a planetary atmosphere and begins to glow from friction with the atmosphere, it is called a **meteor**. A fragment that survives atmospheric entry and can be recovered on the ground is called a **meteorite**.

Methane clathrate A clathrate consisting of methane ice. *See* clathrate.

Micrometeoroid Meteoroid smaller than about 0.1 mm in size.

Micron, micrometer, or μm One millionth of a meter.

Microscopic cross section An effective area that gives the probability that a particle (for example, a neutron or gamma ray) will undergo a reaction with a target nucleus (or atom). The microscopic cross section has units of barns per nucleus. One barn is 10^{-24} cm^2.

Mid-ocean ridges Active undersea volcanic chain at which the Earth's oceanic crust is generated by magma solidification.

Mie scattering The scattering of sunlight by atmospheric particles such as aerosols.

Miller-Urey experiments Laboratory experiments in which mixtures of gases representing the composition of planetary atmospheres or the Earth's early atmosphere were placed in sealed vessels and exposed to various forms of energy such as UV and energetic particles. In general the experiments tended to produce more complex combinations of molecules from the initial gases.

Mineral Naturally-occurring substance of specified chemical composition and physical properties having a characteristic atomic structure and/or crystalline form.

Minor planet Another term for an asteroid.

Mixing ratio Fractional mass of a particular component of an intimate mixture.

Moho Short form for Mohorovicic discontinuity. A discontinuity in seismic velocity (and density) that characterizes the boundary between the Earth's cust and the mantle. Named after discoverer Andrija Mohorovicic (1857−1936).

Molecular cloud Cold, dense, region of the interstellar medium containing molecular hydrogen: H_2, often the site of star formation.

Moment magnitude A measure of the size of earthquakes in terms of the energy released, on a logarithmic scale. The magnitude is based on the seismic moment of the earthquake, which is equal to the rigidity of the Earth multiplied by the average amount of slip on the fault and the size of the area that slipped. The moment magnitude scale is similar to the more famous Richter scale, but is preferred by seismologists due to its direct relationship to the physics of an earthquake.

Moment of inertia The moment of inertia is the inertia for rotational motion. For a larger moment of inertia of a given principal axis of inertia a larger torque along that axis is needed for a given rotational response.

Moon A body in orbit around another larger body, known as the primary, such as a planet, dwarf planet, or asteroid. Also called a **satellite**.

Morphology Study of the shape of landforms on a planetary surface.

Multiringed basin The largest category of impact features, characterized by multiple, concentric rings of massifs in their interiors. Smaller features have a single peak ring; still smaller ones have a single central peak near the center of the crater; and the smallest craters are "simple" and lack an elevated central region.

Near-Earth asteroid *See* Near Earth object.

Near-Earth object (NEO) Any object, such as an asteroid or comet, orbiting the Sun with a perihelion distance less than 1.3 AU.

Nearly isotropic comet (NIC) A population of comets with orbits that are randomly inclined to the ecliptic plane. By definition, the Tisserand parameter of NICs is less than 2. Also known as a **long-period comet**.

Neutron A neutral particle with mass similar to that of the proton. Neutrons and protons are the primary constituents of the atomic nucleus. Neutrons liberated from the nucleus by nuclear reactions decay by beta emission with a mean lifetime of 900 s.

New comet A nearly isotropic or long-period comet that is entering the planetary region for the first time since it was placed in the Oort cloud. Dynamically new comets are usually taken to be nearly isotropic comets with original semimajor axes greater than 10,000 AU.

Newton's laws Three laws of motion and one of gravity that describe aspects of the physical world: (1) A body remains at rest or in uniform motion unless it is acted upon by an external force. (2) The acceleration of a body is directly proportional to the force acting upon it and inversely proportional to its mass. (3) For every action, there exists an equal and opposite reaction. (Gravity) The gravitational attraction between any two spherically symmetric objects is proportional to the product of their masses and inversely proportional to the square of the distance between their centers.

Nice model A model designed to explain the orbital architecture of the outer Solar System based on early migration of the orbits of the giant planets as they gravitationally scattered numerous smaller planetesimals. *See* chapter 2 on the Origin of the Solar System for more detail.

Near Infrared Mapping Spectrometer (NIMS) A near infrared mapping spectrometer on the Galileo Mission to make multispectral images for atmospheric and moon surface chemical analysis. The NIMS instrument was sensitive to 0.7−5.2 micrometer wavelength IR light. The telescope associated with NIMS with an aperture of 229 mm used only mirrors and no lenses. The spectrometer of NIMS used a grating to disperse the light collected by the telescope. The dispersed spectrum of light was focused on detectors of indium antmonide and silicon.

Node One of the two points where a body's orbit crosses a reference plane, such as the ecliptic.

Nongravitational force A force not due to gravity that acts on comets and asteroids and that can significantly alter their orbits. The most important nongravitational force for comets is the reaction force due to the outgassing of volatile materials from the day side of the nucleus.

Nonsynchronous rotation The state of a satellite whose rotation period is not equal to its orbital period.

Nonthermal escape Atmospheric escape of gases in processes that do not depend on the temperature of the bulk upper atmosphere. Nonthermal escape can occur when a neutral species is photoionized by solar extreme ultraviolet radiation and recombines with an electron to form a fast neutral atom. This is called photochemical escape. Alternatively, a fast ion can impart its charge to a neutral atom through collision or charge exchange, and become a fast neutral atom with escape velocity. Today, photochemical escape is important for the loss of carbon, oxygen, and nitrogen from Mars.

Nonthermal radio emission Radio emission produced by processes other than those which produce thermal emission. In particular, in planetary science we are concerned with cyclotron and synchrotron radiation. Cyclotron radiation is emitted by (nonrelativistic) electrons, often in the auroral (near-polar) regions of a planet's magnetic field at the frequency of gyration around the magnetic field lines (cyclotron frequency). The emission is like a hollow cone pattern. Synchrotron radiation is produced by relativistic (i.e., particle velocity approaches the speed of light) electrons. This radiation is strongly beamed in the direction in which the particle is moving. There are other types of nonthermal radio emissions that involve coupling from various plasma wave modes to radio waves.

Normal modes A particular type of oscillation in a system that maintains a constant amplitude and frequency.

Nucleosynthesis The creation of stable and unstable isotopes in stars.

Nucleus The central cometary body that is the source of all the other cometary features. The nucleus is composed of volatile

materials, primarily water ice, and dust particles composed of both silicates and organics. Sublimation produces molecular gases and releases the dust particles. The nucleus has a typical radius of 1−10 km.

Nutation Nutation is the periodic change in the orientation of a planet due to gravitational torques exerted by other solar system bodies. The tip of the rotation axis describes a periodic motion, superimposed on the precession motion, with periods related to the periods of the orbital elements of the bodies involved in the gravitational torque. Nutation causes the motion in the direction of precession to be faster or slower (called nutation in longitude) and also periodically changes the obliquity (called nutation in obliquity). *See* chapter 8 on Planetary Rotation for more detail.

Oblateness A measure of the amount to which the shape of a planet or other body differs from a perfect sphere.

Obliquity The angle between a planet's equator and its orbital plane. Earth's current obliquity of 23.5° is sufficient to cause seasons.

Observational bias The effect that some astronomical objects are easier to discover and observe than others, generally because they are brighter. The observed sample of comets suffers from severe bias because, in general, only those comets that pass well within the orbit of Jupiter become bright enough to be observable.

Occultation Obscuration of a body brought about by the passage of another body in front of it. Occultations of stars by planets or by planetary rings allow the observer to probe the atmospheric structure of the planet or the structure of the rings. Occultation of stars by asteroids allow the observer to determine the size of the asteroid.

Ohmic dissipation Dissipation of energy due to electrical resistance.

Oersted Unit of magnetic intensity in the centimeter-gram-second system, equivalent to the gauss.

Oligarchic growth Self-regulated stage of planet formation that follows runaway growth.

Olivine A mineral with chemical formula $(Mg,Fe)_2SiO_4$ that is abundant in the Earth's upper mantle (to 670 km depth). Its properties are often used to characterize the upper mantle.

Oort cloud A large reservoir of several times 10^{12} cometary nuclei surrounding the planetary system and extending from a few thousand AU to about 100,000 AU from the Sun. The outer Oort cloud, beyond ∼10,000 AU, is roughly spherical; the inner Oort cloud is flattened toward the ecliptic plane. The existence of the Oort cloud is inferred from the semimajor axis distribution of long-period comets.

Opacity The ability of an atmosphere to absorb (or sometimes scatter) radiation. Also called optical depth. A beam of monochromatic radiation passing through an atmosphere with an optical depth of one will have its intensity reduced by a factor of e (= 2.718), while an optical depth of four absorbs or scatters 98% of the radiation. Opacity is a function of wavelength as well as of the pressure, temperature, and composition of the region of the atmosphere under consideration.

Opposition effect Nonlinear surge in brightness as a celestial object approaches being viewed at zero phase angle.

Opposition The position of a superior planet, a comet or an asteroid when it is opposite the Sun in the sky, i.e., when its elongation approaches 180°.

Optical depth Measure of the integrated extinction of light along a path through a medium, such as an atmosphere or the disk of particles forming a ring. Normal optical depth refers to the extinction along a path perpendicular to the ring plane.

Orbit The path of a planet, asteroid, or comet around the Sun, or of a satellite around its primary. Most bodies are in closed elliptical orbits. Some comets and asteroids are thrown on to hyperbolic orbits, which are not closed and which will escape the solar system.

Orbital elements The six parameters that uniquely specify an object's orbit and it location within the orbit. Two parameters, semimajor axis and eccentricity, enumerate the size and shape of the orbit. Three angles, inclination, longitude of the ascending node, and argument of perihelion, describe the orbit's orientation in space. Finally, the mean anomaly specifies the position of the object along the orbit.

Orbital phase angle Angular position of a satellite in orbit about its primary object, measured counterclockwise when viewed from the north.

Orbital inclination (of a solar system body) The angle between the plane of the body's orbit and the ecliptic plane.

Orbit-orbit resonance Condition in which two objects have orbital periods in the ratio of small integers. Orbit-orbit resonances are commonly found between Jupiter and minor planets in the asteroid belt, between Neptune and bodies in the Kuiper belt, and in the satellite systems of Jupiter and Saturn. Also known as a **mean-motion resonance**.

Orogenic, orogeny Process of mountain building, with uplift generally occurring as a result of tectonic plate collisions.

Orphan trail A dust trail that does not appear to be connected to any cometary source. This might arise as a consequence of planetary perturbations causing a shift in a comet's orbit and disconnecting it from a more distant portion of its dust trail.

Outflow channels Large channels that start full size and have few if any tributaries. They may be up to several tens of kilometers across and thousands of kilometers long and are believed to have been formed by large floods.

Oxidants Chemical compound that readily transfers oxygen atoms.

Paleomagnetism The study of the record of a planet's magnetic field through the remanent magnetism in rocks.

Palimpsest Flattened, circular bright patches on Ganymede and Callisto that are believed to be the remnants of ancient large impact structures.

Panspermia A theory by which life spreads through the solar system and the galaxy by spores carried on dust grains or small particles.

Parallax The apparent change in the position of a nearby star on the celestial sphere when measured from opposite sides of the Earth's orbit, usually given in seconds of arc.

Parautochthonous Describes a rock unit that has been moved only slightly into its present location.

Partial melting Melting of one or more minerals composing a rock.

Particle-size distribution The function that specifies the number of particles of different sizes in a given population.

Parsec The distance at which a star would have a parallax of 1 a s, equal to 206,264.8 AU, or 3.261631 lightyears, abbreviated: pc. One thousand parsecs are equal to a kiloparsec, abbreviated: kpc.

Patera (pl., paterae) A collective term for a variety of unusual, saucer-shaped, shallow volcanic constructs that often have a central crater or caldera.

Peak ring A ring of mountains or massifs near the center of a small impact basin. Smaller impact features have a single central peak near the center of the crater; still smaller craters are "simple" and

lack an elevated central region. Larger impact features have multiple, concentric rings of massifs in their interiors.

Periapse Point on an orbit closest to the central body, called **perihelion** for orbits about the Sun and **perigee** for orbits about the Earth.

Perigee The closest point to the Earth of the elliptical orbit of the Moon or an artificial satellite.

Perihelion distance (q) The closest distance to the Sun an object reaches in its orbit, given by $q = a(1—e)$, where a is the object's semimajor axis and e is its eccentricity.

Perihelion Point in a heliocentric orbit when it is closest to the Sun.

Perijove The point in an orbit around Jupiter when the object is closest to the planet.

Periodic comet Traditionally, a comet with an orbital period of less than 200 years; also known as a short-period comet.

Permafrost zone Near-surface zone within which temperatures are always below 0° C. It may or may not contain ground ice.

Petrology The study of the nature and history of mineralogic phases and chemical compositions of rocks, and conclusions regarding their origins. One aim of mineralogy and petrology is to decipher the history of igneous and metamorphic rocks.

Phase angle Angle between the illumination source (the Sun), a given object, and the observer with the object at the vertex.

Phase function The curve describing the change in brightness of a body as a function of the phase angle, the angle between the observer, the body, and the Sun. Usually expressed in astronomical magnitudes per degree.

Phase integral Integrated value of the function that describes the directional scattering properties of a surface.

Phase space Multidimensional space in which the coordinates are, for example, the positions and the velocities.

Photoautotrophy The capacity of an autotrophic (self-feeding) organism to derive the energy required for its growth from sunlight by means of photosynthesis; green plants are photoautotrophic.

Photodissociation A chemical reaction in which a chemical compound is broken down by photons.

Photolysis Process that occurs when a molecule absorbs light of sufficiently high energy (usually ultraviolet light) and breaks apart.

Photosphere A thin, 300 km thick layer above the solar surface from where most of the optical emission (white light) is irradiated, with a temperature of $\sim$6000 K.

Photon-stimulated desorption A process that liberates atoms from a planetary surface, whereby a photon breaks bonds holding the surface molecules together, and ejects one or more atoms.

Phototactic/phototaxis The movement of an organism in response to light, either toward or away from the source; e.g., certain microorganisms are phototactic and will migrate in the direction of sunlight.

Phylogenetic Refers to organisms that are related to each other through evolution.

Physiographic Referring to the physical appearance of the landscape.

Pixel A "picture element." One element in a CCD or infrared detector array.

Plagioclase A mineral of the Feldspar group with chemical formula $NaAlSi_3O_8—CaAl_2Si_2O_8$ that has a relatively low melting temperature and is thus typically found in crustal rock.

Planar deformation features Planar, micrometer-sized bands of intense deformation or glass that occur in minerals due to the passage of a shock wave.

Planetary protection The guiding principle in space missions to celestial bodies ensuring avoidance of their harmful contamination and also adverse changes in the environment of the Earth resulting from the introduction of extraterrestrial matter. Planetary Protection is included in the United Nations Outer Space Treaty of 1967, signed by 101 nations.

Planet According to the new IAU definition passed in 2006, a planet must have three qualities: (1) it must be round, indicating its interior is in hydrostatic equilibrium; (2) it must orbit the Sun; and (3) it must have gravitationally cleared its zone of other debris. According to the definition, our solar system has eight planets: Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus and Neptune. Although most astronomers have accepted the new definition, some are campaigning to have it changed. See The Solar System and Its Place in the Galaxy and Pluto and Charon for more discussion.

Planetary embryo Large solid body formed by runaway and oligarchic growth.

Planetesimal A small solid body formed in the early solar system by accretion of dust and ice (if present) near the central plane of the solar nebula. The terrestrial planets, asteroids, comets, and cores of the giant planets are generally thought to have formed through the accretion and aggregation of planetesimals.

Planetary rings An **astrophysical disk** adorning a planetary body.

Plasma Ionized medium in which electrons have been stripped from neutral matter to make a gas of charged ions and electrons.

Plasma beta Ratio of gas pressure to magnetic field pressure within a plasma.

Plasma tail The narrow, highly structured tail consisting of molecular ions (and electrons) confined to magnetic field lines wrapped around the head of the comet. The plasma tail is normally attached to the head region. The exception is when disconnection events occur. The orientation of the tail, approximately antisunward, is produced by the solar wind interaction. The plasma tail appears blue because of resonance scattering of sunlight from ionized carbon monoxide molecules.

Plasmoid A region within a magnetosphere in which plasma is confined by a magnetic structure that is not directly linked to the planet.

Plate tectonics Theory describing the motion of rigid plates over the Earth's surface driven by subduction of oceanic lithosphere and, to a lesser extent, by spreading of mid-ocean ridges.

Plume A hot blob or column of material that rises through the mantle, typically causing uplift of the surface and volcanism.

Poloidal field Component of a solenoidal field that can be written as the curl of a curl of a function in the radial direction. The term was coined by Elsasser to refer to magnetic field in the direction "toward the poles".

Polar wandering Changes in the direction of the magnetic pole relative to its orientation in space.

Polymict A rock unit consisting of fragments of various preexisting rock units.

Polymorph Crystal form of a mineral that has a different crystal structure from that of the original mineral.

Polysaccharide Any of a group of carbohydrates consisting of long chains of simple sugars; e.g., starch, glycogen.

Power spectra Graphs of the radar backscatter power versus frequency. Measuring the received power in each frequency bin allows for one to derive the mean radial velocity and albedo of an object.

Poynting-Robertson effect, P-R drag Drag on interplanetary particles caused by their interaction with solar radiation, which causes

the particles to lose orbital angular momentum and to spiral in towards the Sun.

Precession Precession is the slow change in the orientation of a planet due to gravitational torques exerted by other solar system bodies in which the tip of the rotation axis describes a large circle on the celestial sphere around the normal to the orbital plane. *See* chapter 8 Rotation of Planets for more detail.

Precession of the equinoxes The slow rotation of the equinoxes with respect to the stars. It has a period of about 26,000 years for the Earth.

Primary body Celestial body (usually the Sun or a planet) around which a planet or a moon, respectively, or secondary body, orbits.

Primitive meteorite *See* Chondrite.

Primordial The original form, e.g. the primordial solar nebula would be the original, unaltered state.

Principle axis of inertia Each (celestial) body has a set of mutually perpendicular axes, called principal axes of inertia, for which the off-diagonal terms of the **inertia matrix** are zero. A torque along a principal axis only affects the rotational acceleration about that axis.

Prominences Cool and dense mass structures suspended above the chromosphere, observed above the solar limb, which are called filaments when seen on the solar disk.

Protoplanetary nebula A disk of gas and dust that surrounds a newborn star, from which the planets, asteroids, and comets are thought to form.

Protostar A star in the process of formation, which is luminous due to the release of gravitational potential energy from the infall of nebula material.

P-wave velocity Seismic body wave velocity associated with particle motion (alternating compression and expansion) in the direction of wave propagation.

Pyroclastic materials Fragmented materials ejected during an explosive volcanic eruption, including ash, pumice, and rock fragments.

Pyroclastic vent A typically rimless, scalloped-rimmed depression formed by the explosive eruption of pyroclastic volcanic materials.

Pyroxene A mineral of chemical formula (Mg, Fe, Ca)SiO_3 that is typically found in mantle rock.

Radar albedo Ratio of a target's radar cross section in a specified polarization to its projected area, hence a measure of the target's radar reflectivity.

Radar cross section Most common measure of a target's scattering efficiency, equal to the projected area of that perfect metal sphere that would give the same echo power as the target if observed at the target's location.

Radial velocity technique Observational method used to detect stellar reflex motions by measuring the line-of-sight component of a star's space velocity vector. If the radial velocity can be measured with a precision of a few m/s then the reflex motion due to planetary companions become detectable. Today, this is the most successful method for finding extrasolar planets.

Radiation belts Toroidal zones containing charged particles that are magnetically trapped in a planetary dipole field. The Van Allen belts around the Earth include ions and electrons with energies from hundreds of keV to tens of MeV.

Radiation pressure The force per unit area an object feels due to solar photons hitting its surface.

Radio interferometric synthesis The addition of signals from a set of smaller telescopes, used to produce an image with the same angular resolution of a much larger telescope.

Radio spectrum A graph of the brightness temperature as a function of wavelength or frequency.

Radiolysis The dissociation of molecules by high-energy radiation.

Radiometric modeling Interpretation of the measured thermal emission of an asteroid by modeling to provide an estimate of the asteroid's surface temperature distribution and albedo. A dark asteroid, for instance, would absorb more of the visible sunlight since it has a low albedo, but would radiate that additional energy in thermal wavelengths, showing a warmer surface temperature. Combining data on thermal "temperature" and visible reflectance can thus provide both the albedo of an object and an estimate of its size. The accuracy of the model depends on various assumptions made about the nature of the surface.

Radiometric modeling Measures the thermal emission of an asteroid to provide an estimate of the asteroid's surface temperature and albedo. A dark asteroid, for example, would absorb more of the visible sunlight because it has a low albedo, but it would radiate that additional energy at thermal wavelengths, showing a warmer surface temperature. Combined data on thermal "temperature," and visible reflectance can provide the albedo of an object and an estimate of its size.

Radio occultation The passing of a radio beam through a planet's atmosphere. Attenuation and refraction (bending) of the beam, generally by phase delay, can be used to measure the density of electrons in the planet's ionosphere and the density of the gas in its atmosphere. The abrupt cutoff of the signal can also be used to make a precise measurement of the planet's radius.

Raman scattering Inelastic scattering of sunlight by gas molecules in an atmosphere, such that the scattered photon is shifted in frequency.

Random walk A series of movements in which the direction and size of each move is randomly determined.

Rayed crater *See* Crater rays.

Rayleigh number Non-dimensional parameter characterizing the vigor of convection in a convecting fluid. It can be interpreted as the ratio between the bouyancy forces driving the flow to the viscous forces that retard the flow and the loss of bouyancy through diffusion.

Rayleigh scattering The scattering of sunlight by gas molecules in an atmosphere.

Reaction notation The notation for nuclear reactions given by T (**i**, p) **R**, where T is the target nucleus, i is the incident particle, p indicates the particles(s) produced by the reaction, and R is the product nucleus. For example, the notation for neutron inelastic scattering with ^{56}Fe is ^{56}Fe(n,n'y), where n' is the scattered neutron and y is the associated gamma ray. Similarly, neutron capture with ^{56}Fe is denoted ^{56}Fe(n,y)^{57}Fe, where the product isotope has been appended.

Reaction rate The rate (R) at which gamma rays or neutrons interact with nuclei is given by the product of the flux (0), the number density of the target nuclei (N nuclei per cm^3) and the microscopic cross section (0) for the selected reaction: $R = yNa$ (interactions per unit time).

Reconnection A process in which the magnetic configuration changes as if two field lines were broken and reconnected in a new configuration. This can occur when two plasmas containing oppositely directed magnetic fields flow toward each other.

Red slope A increase in albedo with increasing wavelength that is common in the visible to near-infrared portion of the spectrum of sunlight reflected from silicate planetary surfaces.

Reductants Compounds or catalysts that result in the loss of an electron.

Reflectance spectroscopy The study of the physical and mineralogical properties of materials over the wavelength range of reflected electromagnetic radiation. Light interacts with the atoms and crystal structure of materials producing a diagnostic set of absorptions and reflectances.

Refracted The manner in which the path of a wave is bent when it passes from one medium to another in which its speed is different. This is commonly observed in optics as light passes from air into glass or water, but is a general property of all wave phenomena.

Refraction Bending of a light ray as it traverses a boundary, for example, between air and glass or between space and an atmosphere.

Refractories Materials not deformed or damaged by high temperatures. Classic refractories are high-melting oxides, like silica and alumina, but also carbides, nitrides, sulfides, and pure carbon. In our terminology, refractories are materials that are not modified by space conditions (temperature and vacuum) in the inner solar system. The opposite are volatile materials, e.g., ices that rapidly sublimate close to the Sun.

Refractory element In planetary science, an element that has a strong chemical bonds causing it to remain in the solid phase at relatively high temperatures.

Refractory inclusion See **CAI**.

Regolith The outermost unconsolidated fragmental layer on some airless planets, satellites and asteroids that results from the breakup of rocks by repeated impacts of meteoroids.

Regular motion A trajectory that does not display chaos.

Regular satellite A satellite with low orbital eccentricity and inclination.

Remanent magnetization Permanent magnetism in a rock after removal of the magnetizing field.

Remnant magnetic field The field generated by the permanent magnetization left behind in a ferromagnetic material (such as iron) after an external magnetic field is removed.

Rendezvous mission A space mission in which the spacecraft visits the target object, e.g. an asteroid, and may enter orbit around it, "hover" close to it, or touch down on its surface.

Resonance A situation in which two orbiting bodies have orbital frequencies (related to the time they take to complete their orbits or for their orbits to precess) that are in a simple integer ratio. Objects in resonance exert a regular gravitational influence on each other. Depending upon the particular resonance involved, resonance can either stabilize an orbit, as in the case of Pluto, or destabilize an orbit as near the Kirkwood gaps in the asteroid belt. Strong satellite resonances open gaps at particular locations in broad planetary rings; weaker ones drive radial and vertical wave trains.

Resonant emission A quantum process in which photons of specific energies or wavelengths are absorbed by an atom or ion and then reemitted at the same wavelength.

Resurfacing The process of renewing a planetary surface by volcanism, cratering, erosion and sedimentation.

Retrograde, retrograde motion Orbital or rotational motion in the solar system that is clockwise as seen from north of the ecliptic. Nearly isotropic comets with inclinations greater than 90° have retrograde orbits. Triton is in a retrograde orbit around Neptune. Venus is in retrograde rotation.

Returning comet A nearly isotropic or long-period comet that is returning to the planetary region for at least the second time. Returning comets are usually taken to be nearly isotropic comets with semimajor axes less than 10,000 AU.

Reynolds number Dimensionless number that governs the conditions for the occurrence of turbulence in fluids.

Reynolds stress Transfer of momentum to the axisymmetric zonal velocity field from the correlation of small-scale zonal and radial velocity fields through the nonlinear inertial force.

Rheology The characteristics of the response of material in response to an applied force, under conditions in which they respond with plastic or viscous flow rather than deforming elastically. For example, a commonly used rheological parameter is viscosity.

Ring current A current carried by energetic particles that flows at radial distances beyond a few planetary radii in the near-equatorial regions of a planetary magnetosphere.

Roche limit, Roche zone The distance from a planet or the Sun, within which another body will be disrupted because tidal forces from the planet exceed the self-gravity of the smaller body, unless the material strength of the body is strong enough to hold it together. For nonrotating bodies of equal density and zero strength, the Roche limit is about 2.2 planetary radii.

Rock A rock is a solid usually microscopically heterogeneous mixture of minerals, glass, and rock fragments and may contain remnants of organisms. The crust and the mantle of terrestrial (Earthlike) planets are composed of rock. Rock understood as a mixture of iron, silicon, magnesium and other refractory elements may also be found in the deep interiors of giant planets.

Rotational lightcurve A graph depicting the variation in brightness of an object verus time as it rotates on its axis. This variation can be caused by nonsphericity (i.e., shape effects) or albedo markings; for objects as large as Pluto and Charon, albedo markings usually dominate. *See also* lightcurve.

Runaway growth Stage of planetary growth in which the largest planetesimals grow rapidly while most others remain small.

Satellite A body in orbit around a planet, dwarf planet, or an asteroid. Also called a **moon**.

Scale height The vertical distance over which atmospheric pressure or density falls by $1/e = 0.368$; equal to kT/mg, where k is Boltzmann's constant, T is temperature, m is the mean mass of the gas, and g is the acceleration of gravity.

Scattered disk A collection of $\sim 10^9$ icy planetesimals in high-eccentricity, low-to-moderate inclination orbits beyond Neptune. Scattered disk objects typically have semimajor axes of order 50−100 AU. The scattered disk is probably the primary source of the Jupiter-family comets. Scattered disk objects may have escaped the Kuiper belt billions of years ago, and/or may be scattered Uranus-Neptune planetesimals.

Scattering law Function giving the dependence of a surface element's radar cross section on viewing angle.

S-band S-band is the part of the microwave band of the electromagnetic spectrum that ranges from 1.55 to 5.2 GHz. The corresponding range of wavelengths is 7.5 to 15 cm. In space missions the reserved frequency band is around 2.1 GHz (2.0 to 2.15 GHz) for the uplink (Earth to Space) and around 2.3 GHz (2.2 to 2.45 GHz) for the downlink (Space to Earth).

Scintillator A Transparent material that coverts the kinetic energy of charged particles, such as electrons produced by gamma ray interactions or alpha particles and recoil protons produced by neutron reactions, into flashes of light detectable by a photomultiplier tube or photodiode. A wide variety of organic and

inorganic materials scintillate and can be used for radiation detection and spectroscopy.

Secondary crater A crater produced by the impact of blocks of ejecta from a primary impact by a comet or asteroid.

Secular Continuing or changing over a long period of time.

Secular cooling Loss of heat from the interior of a planetary body occurring over geological timescales.

Secular perturbations Long-term changes to the orbit of a body caused by the distant gravitational perturbations of the planets and other bodies.

Secular resonance Near-commensurability among the frequencies associated with the precessions of the line of nodes and/or apsides.

Seeing Blurringof the image of an astronomical object caused by turbulence in the Earth's atmosphere Atmospheric seeing at the very best observatory sites, such as Mauna Kea, is about 0.5 arcsec and can be as good as 0.25 arcsec. Seeing can be improved using adaptive optics.

Seismic normal mode As a consequence of a strong earthquake free oscillation of the Earth can be induced. The oscillation resembles the resonant oscillation of a bell. The normal mode oscillation can be recorded by a seismometer and used to measure the elastic properties of the Earth's interior.

Seismic tomography Technique that uses information on the travel times of elastic waves generated by earthquakes to infer the three-dimensional structure of the Earth's interior.

Seismic velocities The velocities by which seismic (acoustic) waves propagate through the Earth and other planetary interiors. Because the seismic velocities are related to the density and the elastic moduli, the seismic velocities can be used to calculate the three-dimensional structure of the Earth's interior. The seismic velocities are inversely related to the travel times of seismic waves.

Seismometer The instrument by which seismic events (Earthquakes) are recorded. A seismometer in its simplest form is a pendulum that records the motion of the ground.

Semiconductor Semiconductors, such as germanium, silicon, and CdZnTe, can be used to detect gamma rays. Swift electrons produced by Compton and photoelectric interactions ionize the semiconductor, producing electron-hole pairs. The electrons and holes drift under the influence of an applied electric field to electrical contacts. As they drift, the electrons and holes induce charge on contacts, which can be measured by a charge-sensitive preamplifier. The amplitude of the charge pulse is proportional to the energy deposited by the gamma ray, which enables semiconductors to be used for spectroscopy.

Semimajor axis (a) Commonly thought of as the mean distance of the orbit of a body from its primary. More formally, it is one half of the longer of the two axes of an ellipse describing the orbit, that passes through both foci of the ellipse.

Semiminor axis (b) One half of the minor axis (short diameter) of an elliptical orbit.

Sensitivity to initial conditions A situation in which a tiny change in an object's initial state (position and/or velocity) will make a big change in its final trajectory. Sensitivity to initial conditions is a necessary condition for chaos.

Separatrix Boundary of a resonance, separating resonant or librating motion inside the resonance from nonresonant or circulating motion outside.

Shield volcano Broad volcano with a large summit pit formed by collapse and gently sloping flanks, built mainly from overlapping, fluid, basaltic lava flows.

Shock A discontinuous, nonlinear change in pressure commonly associated with supersonic motion in a gas, plasma, or solid.

Shock metamorphism Permanent physical, chemical, and mineralogical changes in rocks, resulting from the passage of a shock wave.

Shock wave Compressional wave, resulting from an impact or explosion, which travels at supersonic velocities.

Short-lived isotopes Radioactive isotopes with half-lives much shorter than the age of the solar system.

Short-period comet A comet with an orbital period $<$200 years. Short-period comets include **Jupiter-family** and **Halley-type** comets.

Sidereal Relative to the fixed stars. A sidereal period is the orbital period of a planet around the Sun relative to the stars. A sidereal year is the orbital period of the Earth around the Sun relative to the stars.

Siderophile element Element that tends to join with iron and is predominantly found in a planet's core.

Silicate A compound containing silicon and oxygen.

Smooth plains The youngest plains on Mercury with a relatively low impact crater abundance.

SNC meteorites Group of meteorites (Shergotty-Nakhla-Chassigny) believed to be derived from Mars because of their young ages, basaltic composition, and inclusion of gases with the same composition as the Martian atmosphere.

Solar activity cycle Cycle of $\sim$11 year duration characterized by waxing and waning of various forms of solar activity such as sunspots, flares, and coronal mass ejections.

Solar corona The hot, tenuous outer atmosphere of the Sun from which the solar wind originates.

Solar energetic particles Ions (usually protons) and electrons generated in solar flares and in the corona and solar wind by shock waves, with energies above hundreds of keV for electrons and above an MeV per nucleon for ions.

Solar flare A disturbance in the solar atmosphere characterized by a sudden, localized enhancement in electromagnetic emission from visible to x-ray wavelengths.

Solar nebula The cloud of dust and gas out of which the Sun and planetary system formed.

Solar phase angle See **phase angle**.

Solar flux The radiant energy received per unit area per second from the Sun.

Solar wind A magnetized, highly ionized plasma that flows radially out from the solar corona at supersonic and super-Alfvenic speed.

Solstice The passing of the Sun to its farthest latitude away from a planet's equatorial plane, so that the northern or southern hemisphere (as the case may be) receives maximum sunlight; associated with the seasons of summer and winter (cf. **equinox**).

Solidus Line or surface in a phase diagram below which the system is completely solid.

Solidus Temperature above which the mineral with the lowest melting temperature among those that form a rock melts.

Space debris Man-made particulates littered in space.

Space exploration The extension of human reach beyond the Earth's atmosphere using spacecraft to access unknown terrains and environments, and to acquire knowledge about space, planets, stars, or other celestial bodies by human and robotic means.

Space ultraviolet That part of the ultraviolet electromagnetic spectrum that can only be observed from space because the Earth's atmosphere is opaque at those wavelengths; commonly thought of as the region below wavelengths of 3000 Angstrom.

Space weather The variable level of geomagnetic activity controlled by the conditions in the solar wind.

Space weathering A process acting on the surface of planetary and asteroidal bodies that changes their surface optical properties over time.

Spectral absorption A particular wavelength of light that is selectively absorbed by a particular material. Patterns of absorptions can serve as "fingerprints" to remotely identify surface or atmospheric materials.

Spectrometer An instrument that measures the profile of light scattered or emitted by an object as a function of wavelength (i.e. the intensity of light at different points of the **spectrum**).

Spectrum The range of wavelengths (equivalently, colors, though the concept extends beyond **visible light**) that characterize electromagnetic radiation (i.e. light); sometimes, the profile of brightnesses at each of those wavelengths.

Spheroid A spheroid is a body that is approximately spherical but not perfectly round. More strictly it can be defined as an ellipsoid of revolution (or biaxial ellipsoids). Fast rotating planets can be well approximated by an oblate spheroid, which is flattened at the poles, and can be generated by revolving an ellipse around its major axis (the equator is a perfect circle but any meridian circle passing through the poles is an ellipse flattened at the equator). A better representation of the shape of a planet is that of a triaxial ellipsoid, where also the equator is an ellipse.

Spiral bending wave A transverse wave propagating through an **astrophysical disk**, generated by a **resonance** that pumps up the orbital **inclinations** of individual disk particles.

Spiral density wave A compression wave propagating through an **astrophysical disk**, generated by a **resonance** that pumps up the orbital **eccentricities** of individual disk particles.

Spin-orbit resonance Simple numerical relationship between the spin period of a planet or satellite and its orbital period. Most natural satellites in the solar system are in the 1:1 spin-orbit resonance, also called the synchronous spin state.

Sputtering An atmospheric loss process that occurs when ions that have been picked up by the magnetic field embedded in the solar wind impact a planetary atmosphere and undergo charge exchange. Charge exchange neutralizes the ions, which can impart their large energies to surrounding particles by collision. Upward-directed energetic particles can then escape. This process may have been important on Mars after it lost its magnetic field and its upper atmosphere was no longer shielded from the solar wind. Sputtering can also occur when energetic particles from the solar wind or a planetary magnetosphere strike the surface of an airless planet or satellite and cause atoms of the surface materials to escape.

Stagnant lid Immobile and stiff layer comprising the crust and the uppermost mantle of all terrestrial planets other than Earth and of the Moon.

Stellar metallicity The amount of chemical elements, heavier than hydrogen and helium, contained in a star. Observations indicate that stellar metallicity is a critical factor in the efficiency of the formation and/or orbital migration of extrasolar planets.

Stellar occultation When a planet or asteroid passes in front of a star and the star is briefly hidden from view. Such events can be used to probe the size and also the atmospheric structure of the planet (or asteroid) doing the occulting, or the structure of rings around a planet.

Stellar reflex motion The movement of a star along its orbit around the barycenter of a star/companion system. If a star has no companions (stars or planets), the barycenter coincides with the star's own center of mass, and no reflex motion exists.

Strain Measure of the deformation representing the relative displacement between particles in a stressed body.

Stratification A layered configuration in which each layer has a distinct composition or physical property, such as density.

Stratigraphy Study of rock layers.

Stratosphere Region in an atmosphere overlying the troposphere that is strongly stabilized against convection by heating because of the absorption of ultraviolet radiation from the Sun. *Stratum* is Latin for "layer."

Stream structure Pattern of alternating flows of low- and high-speed solar wind.

Streaming instability A positive feedback in which small particles drifting inwards in a protoplanetary disk begin to accumulate at a particular location, slowing their drift rate as a result, allowing more particles to catch up and further enhancing their number.

Stress The forces acting within a body of material as a result of external forces tending to change the shape or volume of the body.

Stromatolite A geological feature formed by the conversion of loose, unconsolidated sediment into a coherent layer, as a result of the growth, movement, or activity of microorganisms; e.g., blue-green algae. Microfossils associated with stromatolite formation are an important form of evidence for early life on Earth, and thus a search for stromatolites could undertaken on other planets in sites where liquid water might have accumulated.

Subaerial Referring to landscapes, such as islands or continents, that are exposed to the air.

Subduction The process by which convective forces cause lithospheric plates to be carried into the mantle.

Sublimation The phase change of a solid directly to gas, as in the conversion of ice directly into vapor.

Subsolidus convection The convection of material at temperatures below its freezing point. This can occur because a solid material can often act as a fluid over long time scales, particularly at temperatures near its melting point.

Substorm The elementary disturbance of the magnetosphere that produces geomagnetic activity.

Subtropical jet The jet stream occurring at the poleward edges of the Hadley cell.

Sulfur allotropes Sulfur cooled rapidly from different temperatures, resulting in different colors.

Super-Earth A newly discovered class of planets. Typically, a super-Earth has a larger radius and higher mass as Earth, but is smaller and less massive as icy giants like Uranus and Neptune.

Superior geocentric conjunction The point in a planetary satellite's orbit where it is directly opposite Earth, such that the satellite lies on a straight line connecting Earth, the planet, and the satellite.

Surface of section Means of studying the regular or chaotic nature of an orbit by plotting a sequence of points in two dimensions that can represent all or part of the coordinates of the orbit in phase space.

Synchronous orbit An orbit whose period is equal to the rotation period of the primary.

Synchronous orbit distance The average distance of a body to its primary on a synchronous orbit.

Synchronous rotation Dynamical state caused by tidal interactions in which a satellite presents the same face toward the primary, because the satellite's rotation period is equal to its orbital period.

Synodic period The time required for a body in the solar system to return to the same position relative to the Sun (i.e. elongation) as seen by an observer on the Earth.

Synodic rotation period Apparent rotation period of a target that is moving relative to the observer (who may also be moving), to be distinguished from the sidereal rotation period measured with respect to the fixed stars.

Tadpole orbits Orbits that librate about the stable L_4 or L_5 triangular Lagrangian points in the restricted three-body problem. These orbits appear to be shaped like tadpoles in the frame rotating with the mean-motion of the massive bodies.

Taxon Grouping of organisms or bodies with similar characteristics.

Taylor–Proudman Theorem Mathematical theorem stating that for a fluid dominated by Coriolis and gradient forces, the fluid velocity will be uniform in the direction parallel to the rotation axis.

Tectonic framework The global or large-scale pattern of fractures and folds formed by crustal deformation.

Tensile stresses A stress defined (*See* stress) as the internal forces in a continuum resulting from external forces can be compressional, tensional and shearing. The latter is termed the shear stress while the former two are termed normal stresses, compressional and tensile.

Tephra Generic term for all volcanic fragments that are explosively ejected from a volcano.

Tension fractures Fractures that propagate near-vertically into previously unfractured brittle surface material in response to tensile stress.

Termination shock A discontinuity in the outer heliosphere where the solar wind slows from supersonic to subsonic as it interacts with the interstellar plasma.

Terminator The boundary between the illuminated and non-illuminated parts of a planet, satellite, asteroid, or cometary nuclei.

Terrane A particular type of terrain. Generally used to denote the kind of terrain dominated or formed by a particular geomorphic process regime, such as a volcanic terrane or an aeolian terrane.

Terrestrial planet A planet like the Earth with an iron core and a silicate mantle and crust. The terrestrial planets are Mercury, Venus, Earth, and Mars.

Tessera (pl. tesserae) Tile-like, polygonal terrain interpreted to be intensely deformed and cut by at least two directions of ridges and/or grooves.

Thermal boundary layer The layer next to the surface confining a convecting fluid across which heat is transferred by conduction and across which the temperature gradient is steep. Examples are the so-called planetary boundary layer in the atmosphere, the air layer near the ground, and the thermal lithosphere in a planetary mantle.

Thermal desorption Process of heating to drive off volatile gases.

Thermal lithosphere The outermost layer of a planet that is cooled by conduction, in contrast to the hotter, inner layers that are cooled by convection.

Thermal diffusion Transport of heat resulting from a temperature gradient and caused by microscopic transfer of internal energy.

Thermal emission Electromagnetic radiation emitted by a body, typically at infrared wavelengths, due to its temperature.

Thermal inertia A material property that is a measure of the time it takes for the material to respond to temperature changes. Thermal inertia is mathematically defined in terms of the physical properties of the material as $(\mathrm{kp\ C})^{1/2}$, where k is the thermal conductivity, p is the bulk density, and C is the specific heat capacity.

Thermal radio emission Continuous radio emission from an object that results from the object's temperature. Blackbody radiation is a form of thermal radio emission.

Thermal wind A wind shear developed in one direction due to a temperature gradient in an orthogonal direction.

Thermosphere, exosphere Outer parts of an atmosphere, heated by ionizing radiation and cooled by conduction. The exosphere is essentially isothermal and is also characterized by very long mean free paths.

Tholeiitic Referring to basaltic rocks generally found on the ocean floor, erupted from oceanic ridge zones or from shield volcanoes. Such rocks are considered in the mafic family.

Tholus (pl., tholi) Dome or shield. Small tholi are scattered across Io.

Three-body problem Problem of the motion of three bodies moving under their mutual gravitational attraction. In the restricted three-body problem, the third body is considered to have negligible mass such that it does not affect the motion of the other two bodies.

Thrust fault A fault where the block on one side of the fault plane has been thrust up and over the opposite block by horizontal compressive forces.

Tidal despinning The reduction in rotation rate of a satellite or planet due to energy dissipation by friction in the tidal bulge raised by the parent planet or star. Ultimately the despinning body becomes tidally locked, with on side always facing the parent body.

Tidal heating Energy deposited in a satellite due to the dissipation of energy from tidal deformation.

Time delay Time between transmission of a radar signal and reception of the echo.

Tisserand parameter A nearly-conserved quantity in the circular restricted three-body problem. The Tisserand parameter for comets with respect to Jupiter is used to recognize returning comets even if their orbits were changed by a close approach to Jupiter, and to classify their orbits.

TNT An explosive that releases approximately 4.184 GJ of energy per ton. The explosive energy of nuclear weapons is normally expressed in terms of kilotons or megatons of TNT. These units are also used to express the energy released in fireball events and asteroid impacts.

Toroidal field Component of a solenoidal field that can be written as the curl of a function in the radial direction and hence has no radial component.

Trailing hemisphere When a moon is locked in synchronous rotation, the trailing hemisphere faces away from the direction of orbital motion.

Transit photometry technique An observational method to find extrasolar planets by the periodic dimming of the host star when the planet crosses in front of it and blocks some of the light of the star. A radius for the planet can be calculated from the amount of the observed dimming.

Transit An event in which a smaller object passes in front of a larger object, blocking some of the light from the larger object.

Transient crater The crater excavated in a hyper-velocity impact, prior to the collapse of the surrounding crater walls.

Transition region The vertical zone in the Sun where the temperature climbs from 20,000 K above the cool chromosphere to 1 million K in the hot corona.

Triaxial ellipsoid A 3-dimensional surface defined by three axes that are elliptical in cross section and used to describe the shape of a body.

Troposphere Lowest level of an atmosphere dominated by vertical mixing and often containing clouds, where temperature falls off with height at close to the neutrally stable (adiabatic) lapse rate. Earth's troposphere contains 80% of the mass of its atmosphere and most of the water vapor, and consequently most of the weather. Terminated at the top by the **tropopause.** On Earth, the troposphere extends to 14 km (equatorial) and 9 km (polar); on Venus, to 65 km. *Tropos* is Greek for "turning."

True anomaly The true anomaly is an angle that defines the actual position of a body moving along an orbit. It is the angle between the direction of periapsis and the position of the body, as seen from the main focus of the ellipse.

Turbulent concentration The concentration of large numbers of similarly sized particles in stagnant regions in a turbulent gas.

Type I migration Gradual inward spiraling of a planet as it loses angular momentum via gravitational interactions with nebular gas. This affects planetary embryos and rocky planets.

Type II migration Change in the size of a planet's orbit when the planet is massive enough to clear a gap in the disk. Migration is typically inward.

Ultraviolet light Electromagnetic radiation with wavelengths between 10 and 300 nm on the **spectrum**, emitted by energetic objects such as stars or fluorescing gas.

Urey ratio Non-dimensional number indicating the ratio between internal heat production and surface heat loss in a planetary body.

Van Allen belts Region in the Earth's magnetic field, inside of ~ 4 Earth's radii, filled with energetic particles. Other magnetized planets have similar radiation belts.

Vernal equinox The direction of the Sun as viewed from the Earth as it crosses the celestial equator moving northward. On Earth, the vernal equinox denotes the beginning of spring in the northern hemisphere.

Very long baseline interferometry (VLBI) A type of astronomical interferometry in which a signal from an astronomical radio source is collected at multiple radio telescopes on Earth. This allows observations of an object that are made simultaneously by many radio telescopes to be combined, emulating a telescope with a size equal to the maximum separation between the telescopes.

Viscoelastic heating Heating (such as tidal heating) produced by nonrecoverable (permanent) deformation in the viscous portion of a viscoelastic body, i.e., a body that behaves with both viscous and elastic components of deformation.

Viscosity Property of a fluid that resists flow; fluid dynamic stiffness or, in a sense, internal friction. For lava flows that typically have remarkably little excess energy above their solidus, viscosity can be the determining factor for the magnitude and morphology of lava flow fields associated with volcanoes and is often exponentially dependent on the core temperature of the flow.

Viscous overstability A phenomenon that can occur under certain conditions in **planetary rings**, in which collisions among the ring particles cause small density fluctuations to grow into large, oscillation density variations.

Viscous relaxation Process whereby topographic features become subdued over time due to the flow of the surrounding geologic material.

Visible light Electromagnetic radiation with wavelengths between about 300 and 900 nm on the **spectrum**, emitted prolifically by our Sun and readily detected by human eyes.

Volatile Any substance that outgasses or produces a significant vapor pressure at a given temperature. Ice is a volatile on Earth ($T = 270-300$ K), but involatile in the outer solar system ($T < 100$ K). By contrast, the ices of CH_4, CO, and N_2 are volatile throughout the planetary region wherever $T > 30$ K. Also, chemical compounds or elements contained in magmas that are generally released as gases to the atmosphere during a volcanic eruption.

Volatile element In planetary science, an element that has weak chemical bonds causing it to enter a gas phase at relatively low temperature.

Volcano A positive topographic feature on a planetary surface consisting of rocks that have been erupted from the interior and accumulated around the eruption site.

Vorticity A measure of the circulation of a region of the atmosphere. Spots having cyclonic vorticity rotate counterclockwise in the northern hemisphere and clockwise in the southern hemisphere. Terrestrial hurricanes have cyclonic vorticity. The large stable spots on the giant planets are anticyclones.

Warm poles The alternating aphelion subsolar points on the surface of Mercury at the 90° and 270° meridians.

Water ice The primary volatile constituent of comets. Water ice comes in three forms:amorphous, cubic, and hexagonal. Amorphous ice, believed to be the form in the deep interior of cometary nuclei, is characteristic of ices formed at very low temperatures. It has no crystalline structure. At higher temperatures, typically 100−150 K, energy is available to convert the ice to the lower energy cubic form; this transition releases energy. A similar transition from cubic ice to hexagonal ice also releases energy at ~ 180 K. Cubic ice and hexagonal ice are collectively known as crystalline ice. The water ice nearest to the surface of the cometary nucleus is thought to be hexagonal.

Water-equivalent hydrogen (WEH) Gamma ray and neutron spectrometers are sensitive only to the abundance of hydrogen, which is sometimes expressed as the equivalent weight fraction of water. If all of the hydrogen is in the form of H_2O, then the relationship between the weight fraction of hydrogen (w_H) and the weight fraction of water (w_{water}) is ${}^{w}\text{water} = {}^{9w}\text{H}$.

Wavelength, wavenumber Wavenumber is the inverse of wavelength, having units of inverse length. In spectroscopy, the wavenumber ν of electromagnetic radiation is defined as $\nu = 1/\lambda$, where λ is the wavelength in vacuum. This quantity is commonly specified in cm^{-1}, called a reciprocal centimeter, or inverse centimeter.

Western boundary current Strong ocean current that runs along the western edge of an ocean basin as a result of the much slower eastward group velocity of Rossby waves (planetary waves) relative to the westward group velocity. The Gulf Stream is a well-known example.

Window A spectral region in a planetary atmosphere that is relatively transparent between two regions that have higher opacity. A window region can be important for remote sensing of a planetary surface and for limiting the extent of a greenhouse effect.

Wrinkle ridge A low, sinuous ridge formed on lava plains that can extend for up to several hundred kilometers. Wrinkle ridges are tectonic features thought to have formed when basaltic lava cooled and contracted. They commonly occur overlying ring structures in lava-filled impact basins.

X-Band X-band is the part of the microwave band of the electromagnetic spectrum that ranges from 5.2 to 10.9 GHz (one fines

sometimes up to 12 GHz). The corresponding range of wavelengths is 2.4 to 3.75 cm. In space missions the reserved frequency band is around 7.2 GHz (7.1 to 7.25 GHz) for the uplink (Earth to Space) and around 8.4 GHz (8.4 to 8.5 GHz) for the downlink (Space to Earth).

X-ray spectroscopy In planetary science, the estimation of abundances of elements from their emissions of X-rays. The rays come from the fluorescence of atomic nuclei in low-energy X-rays, when the nuclei have been stimulated by high-energy X-rays such as from the Sun.

Yardang A streamlined hill carved from rock through wind abrasion.

Yarkovsky effect A nongravitational force that arises from the asymmetric thermal reradiation of incident sunlight on the surface of a rotating body, that can lead to significant orbital evolution of kilometer-sized and smaller objects.

Yield stress The yield stress is the stress beyond which a material begins to deform plastically instead of elastically. An elastic deformation will be completely reversed after the stress is removed. A plastic deformation is (in part) irreversible.

Zodiacal cloud The cloud of interplanetary dust in the solar system, lying close to the ecliptic plane. The dust in the zodiacal cloud comes from both comets and asteroids.

Zodiacal light Diffuse glow seen on the Earth in the west after twilight and in the east before dawn, that appears wedge-shaped and lies along the ecliptic. It is widest near the horizon and is caused by the reflection of sunlight from the myriads of interplanetary dust particles concentrated in the ecliptic plane.

Vega spacecraft (1 and 2)
space missions to comet by, 683, 685t
Venus exploration by, 307–308, 1211–1212, 1212f
Venera 4, 983f
Venera 9, 983f
Veneras 4 Through 16, Venus exploration by, 307–308, 1211
Venus
astrobiological potential for, 220
atmospheres observations with UV for, 1050–1051, 1051f
density of, 380f
exploration missions, 1211–1212
Magellan, 1212, 1212f
Mariner 2, 307–308, 1211
Mariner 5, 307–308, 1211–1212
Mariner 10, 307–308, 1212
Pioneer Venus, 1212
Vega 1 and 2, 1212, 1212f
Veneras 4 Through 16 and Vega, 1211
Venus Express, 1212
Venus Flyby, 1212
history of exploration of, 324–325
magnetic field highlights from missions to, 122t
magnetospheres with, 141t
19th century studies on, 1008
radar imaging for, 1147–1149
Magellan surface imaging, 1147–1148, 1148f
post-Magellan radar imaging, 1148–1149
radio wavelengths thermal emission from, 1111–1112, 1111f–1112f
1761 and 1769 transits of, 1006
solar wind properties with, 141t
20th century studies on, 1013
volcanic features of, 105–106, 105f
X-ray emissions, 1020f, 1025–1027, 1026f
Venus, atmosphere, 305–322
circulation and dynamics of, 316–319
meridional wind field, 317
meteorology, 318
polar vortex, 318–319, 318f
surface and lower atmosphere wind profiles, 316–317, 317f
tides, 319
upper atmosphere, 319
zonal winds and superrotation, 317
clouds and hazes in, 314–316
appearance and motions, 314
cloud chemistry, 316
global variability, 315, 315f
lightning, 316
vertical layering, 314–315, 315f
composition of, 307t, 311–314, 311f
carbon dioxide, 311
carbon monoxide, 313
D/H ratio, 312
ionosphere, 313–314, 314f
isotopes, 313
nitrogen, 311
noble gases, 313
oxygen and ozone, 311–312
sulfur dioxide, 312–313
water vapor, 312, 313t
evolution of atmosphere and climate, 319–322
atmospheric gases sources, 319–320
escape processes, 320–321
evolutionary climate models, 321–322, 322f
surface pressure and CO2 budget, 320
volcanism, 319–320
water loss, 320–321
observations, 306–308
earth-based, 306–307, 307t
near-IR images, 306, 307f
space missions, 307–308
UV images of clouds, 306f
temperatures, 308–311, 309f
lower atmosphere, 309–310, 309f
middle atmosphere, 309f, 310
surface, 308–309
upper atmosphere, 310–311
Venus, surface and interior, 323–342
composition, 332–335
global implications, 332–334, 332t–333t, 334f
surface weathering, 334–335
general characteristics, 325–326
orbital rotations and motions, 325
physiography, 325–326
radius, 325–326
surface conditions, 326
topography, 325–326, 326f–327f
views of surface, 326, 327f
impact craters and resurfacing history, 326–329, 327f–328f
interior processes, 329–332, 331f–332f

Venus, surface and interior (*Continued*)
radar for improved understanding of, 1135f
tectonics, 337–341
chasmata, 339, 339f
coronae, 339–340, 339f
crustal plateaus, 338–339, 338f
fracture belts, 339, 339f
plains fractures, grids, and polygons, 340–341
ridge belts, 340, 340f
tessera terrains, 338–339, 338f
wrinkle ridges, 340
volcanism, 335–337, 335f–337f
Venus Express
Venus exploration with, 1212
Venus space missions by, 307–308
Venus Flyby, Venus exploration with, 1212
Venus space missions
Akatsuki, 325
Cassini, 307–308
Galileo, 307–308, 325
Langmuir probe, 308
Magellan, 307–308
Mariner 2, 5, and 10, 307–308, 325
flyby by Mariner 2, 324
Mariner 10 on way to Mercury., 324
Pioneer Venus Multiprobe and Orbiter, 307–308
Pioneer Venus probes, 307–308, 324
Vega 1 and 2, 307–308, 325
Venera 4-16, 307–308, 324
Venus Express, 307–308, 325
Very Large Array, New Mexico, 1108f
Very Large Telescope (VLT), 833
Viking mission
flyby missions to satellites by, 764t
Mars exploration with, 360t, 405, 405f
Mars reconnaissance by, 220–222, 221f, 221t
Viking 1, 983f
Viking 1 and 2, Mars exploration by, 1218
VIRTIS. *See* Visible and infrared thermal imaging spectrometer
Viscosity, 190–191, 457, 471, 896
Viscous accretion, 32
Viscous overstability, 892
Viscous relaxation, 190–191
Visible and infrared thermal imaging spectrometer (VIRTIS), 325
Visible light, 885
VLT. *See* Very Large Telescope
Vogel, Hermann, 1008
Volatile element, 289
Volcanic eruptions
classification of processes in, 108–109
effusive, 109–111
explosive, 111–117
basic considerations, 111
Hawaiian activity, 114–115, 114f–115f
Phreato-Magmatic activity, 116–117
Plinian activity, 115–116, 116f
pyroclast dispersal (into vacuum), 117
Strombolian activity, 111–112, 112f
Vulcanian activity, 112–114, 113f
on Io, 787–788
Lokian eruptions, 788, 789f
Pillanian eruptions, 786f, 787–788
Promethean eruptions, 788, 788f
lava flows with, 109–111
Volcanic features, 101–108
differentiated asteroids, 108
Earth, 101–103, 102f
icy satellites: cryo-volcanism, 107–108
Io, 106–107, 107f
Mars, 104–105, 104f
Mercury, 106, 106f
Moon, 103–104, 103f
Venus, 105–106, 105f
Volcanic history, 199–201, 200f
Volcanic plains, Mercury, 294–296, 295f–296f
Volcanic rocks, 101
Volcanic vents, Mercury, 294–296, 295f–296f
Volcanism, 101–120
Ganymede and Callisto, 825–828
intraplate, 200
Mars, 365–367, 366f
Moon, 574
Moon (Earth), 509–511, 509f–511f
planetary interiors inferred from, 117–118
Venus, 335–337, 335f–337f
Venus atmosphere with, 319–320
Volcanoes, 101
Io
Loki plume, 782, 782f
Pele plume, 782, 782f
Prometheus plume, 788f
Ra Patera, 783–785, 785f
Thor, 784f
Voyager spacecraft (1 and 2), 983f
flyby missions to satellites by, 764t
Ganymede and Callisto exploration by, 815
giant planets viewed by, 733–734
Io flyby, 782, 782f
magnetic field highlights from, 122t
planetary satellites observation with, 768
Titan surface viewed by, 842, 843f
Triton encounter with, 865, 865f
Vulcan, 19th century studies on, 1007–1008
Vulcanian activity, 112–114, 113f
