FIGURE 21.15 Mantle waves. Mantle waves observed on multiple orbits around the Earth. The symbol "R" designates Rayleigh waves and "G" Love waves. Odd-numbered (1,3) arrivals correspond to minor arc arrivals plus an integer number complete number of paths around the Earth. Even-numbered wavegroups correspond to initial propagation in the major arc direction. The signal between arrivals of the fundamental mode wavegroups represents contribution of overtones. Top traces are observed seismograms; bottom traces are synthetic seismogram computed for 3-D model of upper mantle M84C; if one-dimensional model (PREM) was used, there would be significant differences between observed and computed traces.

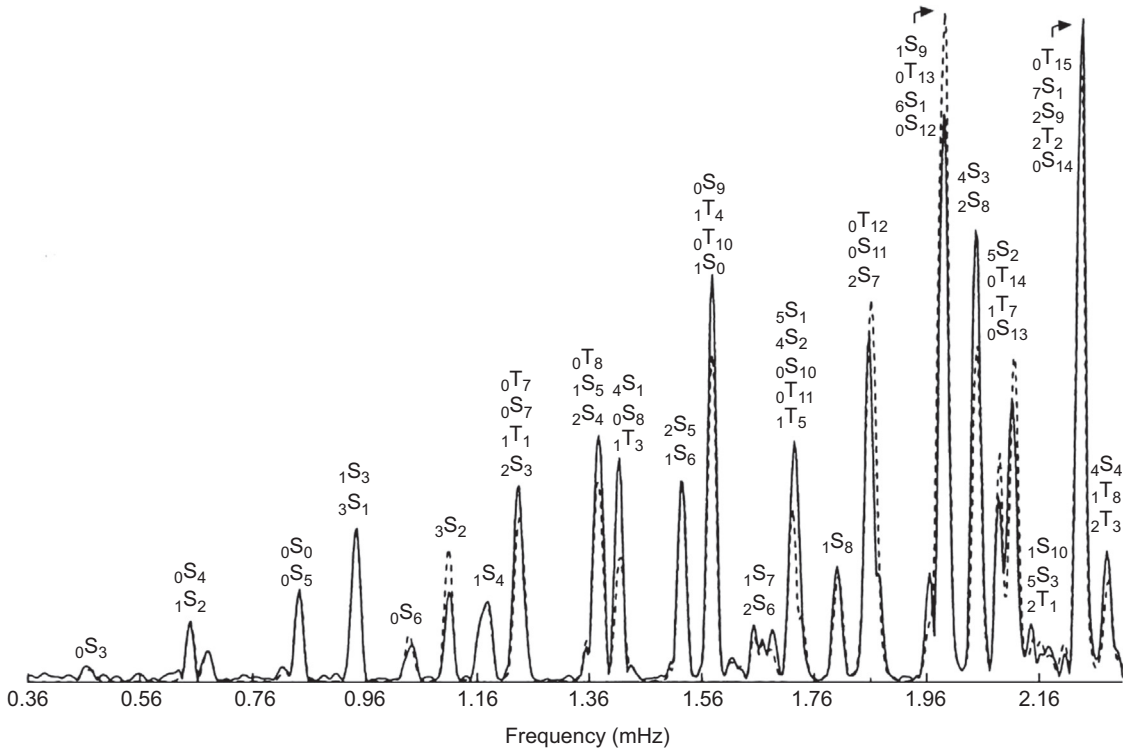

FIGURE 21.16 Amplitude spectrum. Amplitude spectrum of a vertical component seismogram of the great deep Bolivia earthquake of 1994. The peaks in the spectrum correspond to periods of free oscillations (vibrations) of the Earth. The symbols designate the specific normal modes. Some of them appear in groups, which indicate a possibility of coupling between modes close in frequency. Usually the fundamental modes (presubscript "0") are excited most strongly.

All three types of data described earlier are sensitive to the lateral heterogeneity. Travel times will be perturbed by slight variations of the structure along a particular ray path, compared to the prediction by a one-dimensional model. All we need is many observations of travel times along crisscrossing paths. Many millions of such data are available from the routine process of earthquake location; they are assembled from some 6000 stations around the world by the National Earthquake Information Center in Golden, Colorado, and by the International Seismological Centre in England (see Figure 21.13). Surface waves, mantle waves, and periods of free oscillations in a 3-D Earth also depend on the location of the source and the receiver. Progress during the last decade in global seismographic instrumentation, in terms of the quality and distribution of the observatories and exchange and accessibility of the data, makes the required observations much more readily available.

5. SEISMIC SOURCES

Even though the field of seismology can be divided into studies of seismic sources (earthquakes, explosions) and of the Earth's structure, they are not fully separable. To obtain information on an earthquake, we must know what happened to the waves along the path between the source and receiver, and this requires the knowledge of the elastic and anelastic Earth structure. The reverse is also true; in studying the Earth structure, we need information about the earthquake, at least its location in space and time, but sometimes also the model of forces acting at the epicenter.

Most of the earthquakes can be described as a process of release of shear stress on a fault plane. Sometimes the stress release can take place on a curved surface or involve multiple fault planes; the radiation of seismic waves is more complex in these cases. Also, explosions, such as those associated with nuclear tests, have a distinctly different mechanism and generate P- and S-waves in different proportions, which is the basis for distinguishing them from earthquakes.

Figure 21.17 shows three principal types of stress release, sometimes also called the earthquake mechanism. The top part of Figure 21.17(a) is a view in the horizontal plane of two blocks sliding with respect to each other in the direction shown by the arrows. Such a mechanism is called strike slip, and the sense of motion is left-lateral; there is also an auxiliary plane, indicated by a dashed line; a ground motion generated by a slip on the auxiliary plane (right lateral) cannot be distinguished from that on the principal plane. The bottom part of Figure 21.17(a) is a stereographic

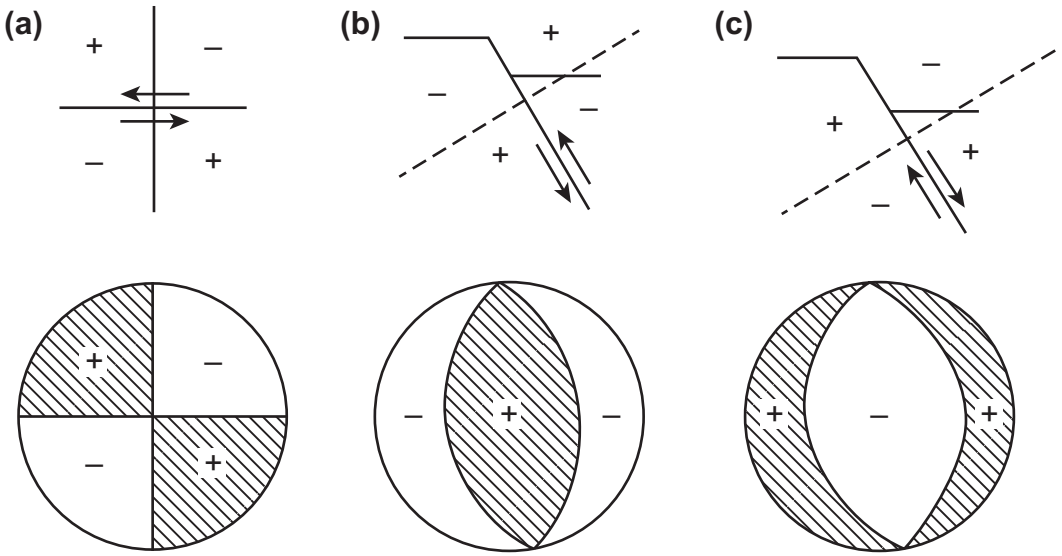

FIGURE 21.17 Classical types of earthquakes. Three classical types of earthquakes (top) and the distribution of the signs of the P-wave arrivals: (a) strike slip, (b) thrust or reverse fault, and (c) normal fault. The beach balls represent the equal area projection of the signs of first motion of the P-waves. The motion would be positive within the shaded areas. The lines separating shaded areas with the unfilled ones are called "nodal planes".

projection of the sign of P-wave motion observed on the lower hemisphere of the focal sphere (a mathematical abstraction in which we encapsulate the point source in a small uniform sphere). The plus sign corresponds to compressive arrivals and minus sign to dilatational zones; quadrants with compressive arrivals are shaded.

The top part of Figure 21.17(b) is a section in the vertical plane. In this case, the block on the right moves upward on a plane that dips at a 45° angle with respect to the block on the left; this mechanism is called thrust and is associated with compression in the horizontal plane and tension in the vertical plane and corresponds to the convergence of the material on both sides of the fault. Such processes are responsible for mountain building. The shaded central region in the bottom part of Figure 21.17(b), with the dilatational arrivals on the sides, is characteristic of the thrust—or reverse faulting—events. Figure 21.17(c) illustrates the opposite mechanism, in which tension is horizontal and compression vertical; this is called normal faulting and is associated with extension, which can lead to the development of troughs or basins.

The "beach-ball" diagrams are commonly used as a graphic code to represent the tectonic forces. Some earthquakes are a combination of two different types of motion, e.g. thrust and strike slip; in this case the point at which the two planes intersect would be moved away from either the rim or the center of the beach-ball diagram.

The size of the earthquake is measured by magnitude. There are several different magnitude scales depending on the type of a wave whose amplitude is being measured. In general, magnitude is a linear function of the logarithm of the amplitude; thus a unit magnitude increase corresponds to a 10-fold increase in amplitude. Most commonly used magnitudes are the body wave magnitude, m_b, and surface wave magnitude, M_S. The frequency of occurrence of earthquakes, i.e. a number of earthquakes per unit time (year) above a certain magnitude M, satisfies the Gutenberg—Richter law: $\log_{10} N = aM + b$. The value of a is close to -1, which means that there are, on average, 10 times more earthquakes above magnitude five than above magnitude six. A new magnitude, M_W, based on the estimates of the released seismic moment (shear modulus × fault area × offset (slip) on the fault) is becoming increasingly popular; it is more informative for very large earthquakes, for which M_S may become saturated.

Figure 21.18 is a map of the principal tectonic plates, as defined in plate tectonic theory. The direction of the arrows shows the relative motion of the plates; their length corresponds to the rate of motion. At a plate boundary where the blue arrows converge, we expect compression and, therefore, thrust faulting; one of the plates is subducted, hence the term "subduction zones". At a plate boundary where the red arrows diverge, there is normal faulting and creation of a new crust, mid-ocean ridges. For boundaries that slip past each other in the horizontal plane (green arrows), also called the transform faults, there is strike-slip faulting.

Figure 21.19 shows the source mechanism of approximately 4000 shallow earthquakes from 1993 through 1997 determined at Harvard University using the centroid-moment tensor (CMT) method; the center of each beach ball is at the epicenter—many earthquakes have been plotted on top of each other. It is easy to see that thrust faulting is dominant at the converging boundaries

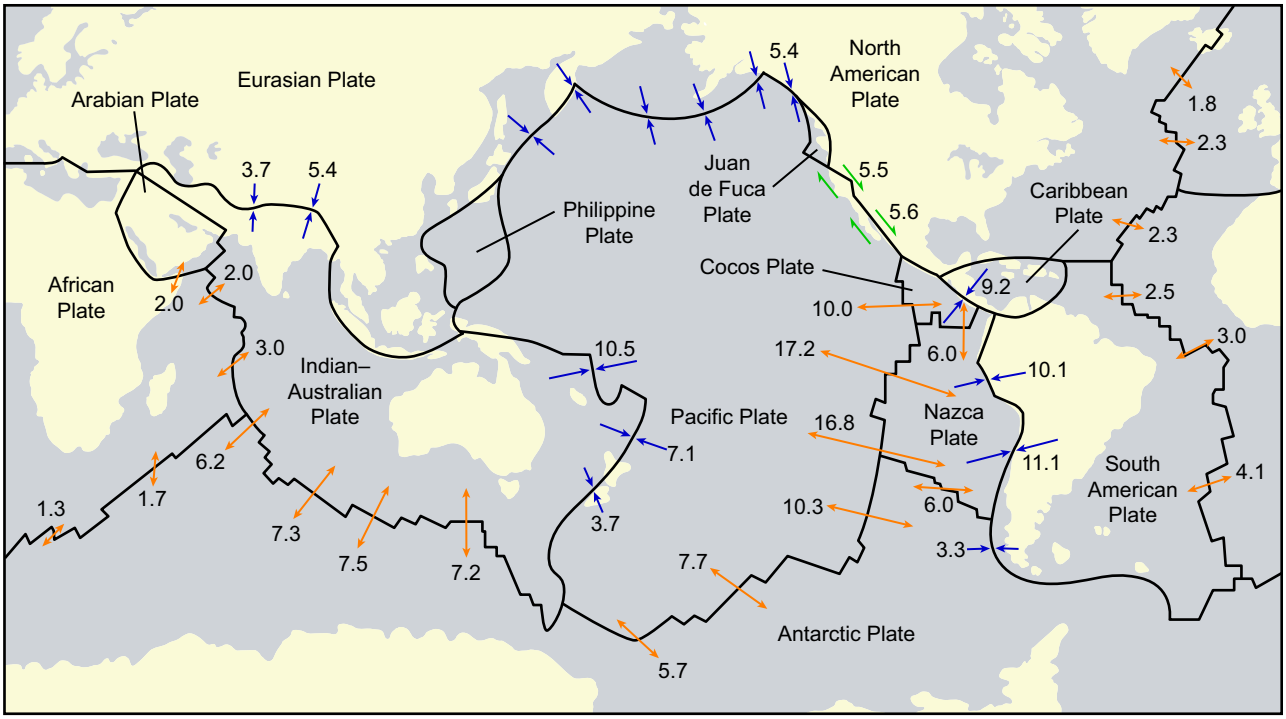

FIGURE 21.18 Motion of principal tectonic plates. Principal tectonic plates and relative plate motion rates. Red arrows signify spreading, blue arrows, convergence, and green arrows, strike-slip motion.

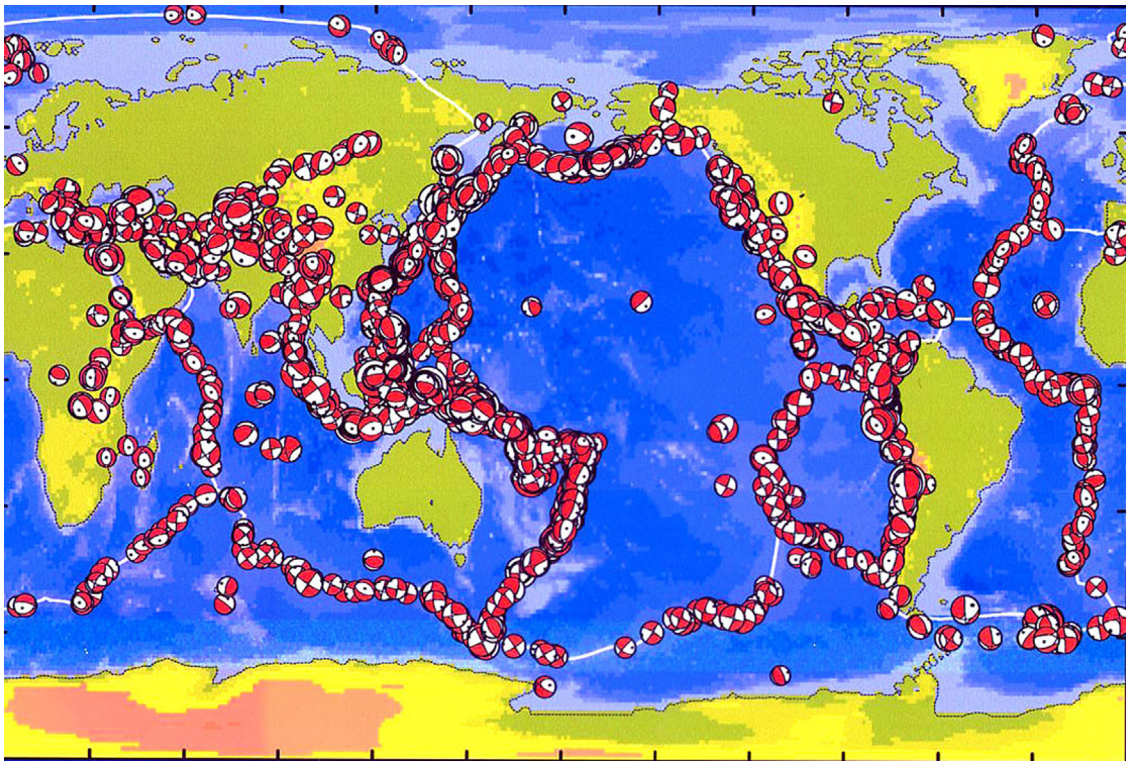

FIGURE 21.19 Earthquake source mechanisms. Source mechanisms of approximately 4000 earthquakes from 1993 to 1997 obtained through the CMT analysis. The center of a beach ball is plotted at the epicenter. Only a small fraction of earthquakes are visible. Note the preponderance of earthquakes occurring on plate boundaries (Figure 21.18) and their mechanism corresponding closely to the type of the boundary (convergent, thrust faulting; divergent, normal faulting; transform, strike-slip faulting). Some earthquakes occur away from plate boundaries. They are particularly numerous in Asia and Africa along the east African rift system, but there are some in eastern North America and the center of the Pacific.

(subduction zones), there are exceptions related to bending of the plates, plate motion oblique to the boundary, and other causes. The CMT project moved in 2006 from Harvard to Columbia; the catalog, available online (globalcmt.org) contains now over 40,000 earthquakes that occurred between 1976 and 2013.

At mid-ocean ridges, we see predominantly normal faulting, the faults where a mid-ocean ridge is offset, show strike-slip faulting, in accordance with the plate tectonic theory. The exception is where the fault is complex. Along the San Andreas Fault, the most famous transform fault, we see many complexities that led to earthquakes other than the pure strike slip. For example, the Northridge earthquake of January 1994 was a thrust, and the Loma Prieta earthquake of October 1989 was half-thrust, half-strike slip. There are also earthquakes away from the plate boundaries. These are called intraplate earthquakes and their existence demonstrates the limits of the validity of the plate tectonic theory, as there should be no deformation within the plates. A very wide zone of deformation is observed in Asia; the rare large earthquakes in eastern North America are sometimes associated with isostatic adjustment following the last glaciation. If we compare the distribution of earthquakes along a mid-ocean ridge, including its transform faults, with that of the Alpide belt, we notice that for the oceanic plates the region in which earthquakes occur is very narrow, while in Eurasia it may be 3000 km wide. A part of the reason that the theory of plate tectonics has been put forward is because of observations (bathymetry, magnetic stripes, and seismicity) in the oceans.

There are also deep earthquakes, with the deepest ones just above 700 km depth; earthquakes with a focal depth from 50 to 300 km are said to be of an intermediate depth and are called "deep" when the focal depth is greater than 300 km. Intermediate and deep earthquakes are explained as occurring in the subducted **lithosphere** and are used to map the position of the subducted slab at depth. Not all subduction zones have very deep earthquakes; for example, in Aleutians, Alaska, and Middle America the deepest earthquakes are above 300 km depth. The variability of the maximum depth and the mechanism of deep earthquakes have been attributed in the late 1960s to the variation in the resistance that the subducted plate encounters; more recent studies indicate more complex causes, often invoking the phase transformations (change in the crystal structure) that the slab material subjected to the relatively rapidly changing temperature and pressure may undergo.

6. EARTH'S RADIAL STRUCTURE

A spherically symmetric Earth model (SSEM) approximates the real Earth quite well; the relative size of the 3-D part with respect to SSEM varies from several percent in the upper mantle to a fraction of a percent in the middle mantle and increases again above the CMB.

A concept of an SSEM, often referred to as an "average" Earth model, is a necessary tool in seismology. Such models are used to compute functionals of the Earth's structure (such as travel times), and their differential kernels are needed to locate earthquakes and to determine their mechanism. Knowledge of the internal properties of the Earth is needed in geodesy and astronomy. Important inferences with respect to the chemical composition and physical conditions within the deep interior of the Earth are made using information on radial variations of the elastic and anelastic parameters and density.

An SSEM is a useful mathematical representation that is not necessarily completely representative of the real Earth. This is most obvious at the Earth's surface, where one must face the dilemma of how to reconcile the occurrence at the same depth, or elevation, of water and rocks; the systems of equations governing the wave propagation in liquid and in solid are different. The commonly adopted solution is to introduce a layer of water whose thickness is such that the total volume of water in all the oceans and that calculated for the SSEM are equal. It is a reasonable decision, but it will be necessary to introduce corrective measures even when constructing the model, as practically all seismographs that record ground motion are located on land.

This chapter uses the preliminary reference Earth model (PREM) published in 1981 by Dziewonski and Anderson as an example. It has been derived using a large assembly of body wave travel time data, surface wave dispersion, and periods of free oscillations, collected through the end of 1970s. An effort to revise it is now under way; a large body of very accurate data has been assembled in the nearly 20 years since the publication of PREM. However, with the exception of the upper mantle, no substantial differences are expected. A reference model designed to fit the travel times of body waves (ak135) has been developed by Kennett and Engdahl in 1995.

Figure 21.20(a) shows the density, compressional velocity, and shear velocity in the model PREM. To illustrate the complexities in the uppermost 800 km of the model, its expansion is shown in Figure 21.20(b). In what follows, we shall give a brief summary of our knowledge and significance of the individual shells in the Earth's structure.

6.1. Crust

This is the most variable part of the Earth's structure, both in terms of its physical properties as well as history. Large areas of the Earth's surface are covered by soils, water, and sediments. These provide support for life and economic activity. However, the vast proportion of what is called "the crust of the Earth" consists of crystalline rocks, mostly of igneous origin.

The primary division is between the continental and the oceanic crust. The former can be very old, with a significant

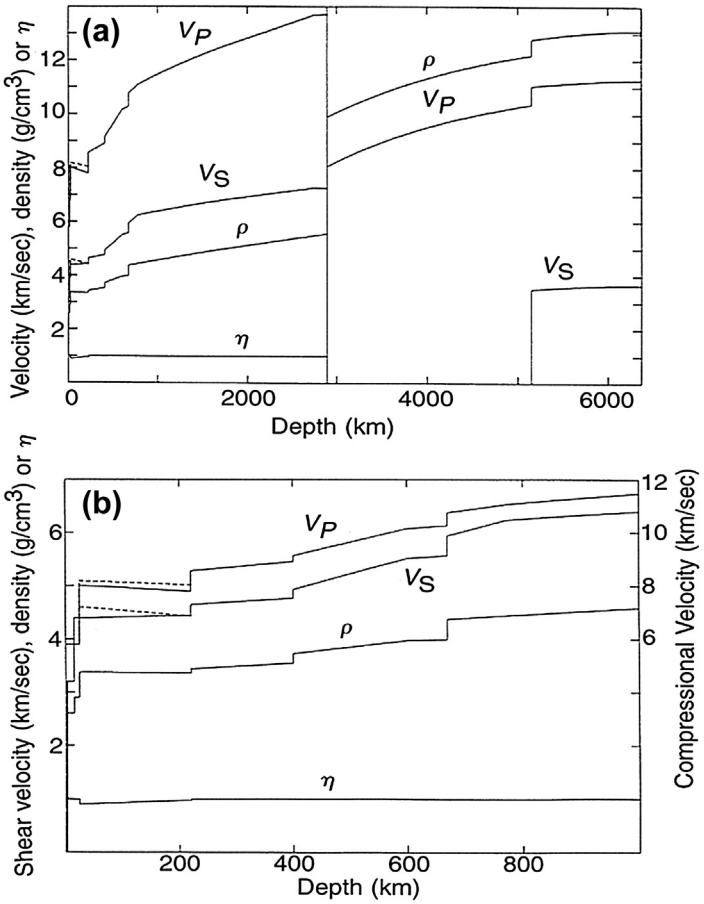

FIGURE 21.20 The Preliminary Earth Reference Model (PREM) of Dziewonski and Anderson (1981) describing the compressional velocity (v_S), shear velocity (v_S), and density (ρ). (a) Model for the entire Earth, and (b) an expansion of the uppermost 1000 km. From Moho to 220 km depth the model is characterized by transverse anisotropy, in which the waves propagating in the vertical (solid line) and horizontal (dashed lines) planes have different velocities. Parameter η, characterizing the propagation of P-waves at intermediate angles, is unity in an isotropic medium and is about 0.95, just under the Moho. Below 220 km depth the model is isotropic.

fraction being older than 1.5 Ga. It is light, with an abundance of calcium, potassium, sodium, and aluminum. Its average thickness is 40 km, but varies substantially, from about 25 km in the areas of continental thinning due to extension (the Basin and Range province in the Western United States, for example) to 70 km under Tibet, in the area of continent—continent collision.

The oceanic crust is thin (7 km, on average, covered by some 4.5 km of the ocean), young (from 0 to 200 Ma), and somewhat more dense, with a greater abundance of elements such as magnesium and iron. It is created at the mid-ocean ridges and is consumed in subduction zones, with trenches being their surficial manifestation. The difference between oceanic and continental crusts is called by some the most important fact in Earth sciences, as it is related intimately to plate tectonics. The thinner, denser oceanic crust provides conditions more favorable for initiation of the subduction process.

Overall, crustal thickness follows the Airy's hypothesis of isostasy closely, thick roots under mountains and a thin crust under "depressed" areas—oceans. The seismic velocities in the crust increase with depth. It is a subject of debate whether this increase is gradual or the crust is layered; recently, the latter view has begun to prevail. The knowledge of global crustal structure is important in studying Earth's structure at greater depths. The most recent result provides the crustal structure for each $1 \times 1^\circ$ grid (Laske et al., 2013) for a total of 648,000 entries. Each of the grid point entries contains information for up to eight crustal layers and specifies layer thickness, seismic velocities, and density.

6.2. Upper Mantle: Lithosphere and Asthenosphere (25−400 km Depth)

The boundary between the crust and the upper mantle was discovered in 1909 by a Yugoslavian geophysicist Andreiji Mohorovicic. It represents a 30% increase in seismic velocities and some 15% increase in density. It is a chemical boundary with the mantle material primarily composed of

minerals olivine and pyroxene, being much richer in heavier elements, such as magnesium and iron.

The terms **lithosphere** and **asthenosphere** refer to the rheological properties of the material. The lithosphere, strong and brittle, is characterized by very high **viscosity**. It is often modeled as an elastic layer. It includes the crust and some 30–100 km of the upper mantle. The asthenosphere is hotter (>1573 K by convention), its viscosity much lower, and in modeling is represented by yielding. Under loads, such as glacial caps, the lithosphere bends elastically, whereas the asthenosphere flows. The difference of rheological properties is explained by differences in temperature; the viscosity is an exponential function of temperature. The lithosphere is relatively cool; the transport of heat is mostly through conduction. The asthenosphere is hotter, and the convective processes are believed to become important. Low viscosity of the asthenosphere is used to explain the mechanical decoupling between the plates (in the plate tectonic theory) and the underlying mantle. The depth of this decoupling varies with position; it is shallow near mid-ocean ridges and increases as the plate cools with time and its lithosphere grows in thickness.

The continents, with their very old and cold shield regions, may be significantly different. If the hypothesis of the "tectosphere" is correct, it may have roots that are 400 km deep and move as coherent units over long periods of the Earth's history. The depth of roots is still subject to a debate (most recent results would indicate their depth extent as 200–250 km). As the seismic velocities decrease with increasing temperature, the vertical gradient of seismic velocities in the transition between the lithosphere and the asthenosphere may become negative. This is called the "low-velocity zone"; its presence creates a shadow zone in seismic wave propagation, making interpretation of data complex and nonunique.

Measurements of attenuation of seismic waves led to the determination of models of quality factor (Q) for the shear and compressional energy. Anelastic dissipation of shear energy, due to grain boundary friction, is most important. Attenuation in the range of depths corresponding to the low-velocity zone is several times stronger than in the lithosphere.

Somewhere below 200 km depth the velocities and Q (attenuation parameter) begin to increase slowly; the effect of increasing pressure begins to dominate over the increase in temperature. The so-called Lehmann discontinuity is elusive and does not appear to be a global feature; this is one of the elements of PREM, where it shows a sudden increase in both P and S velocities, that will be changed in the next version of the reference Earth model.

6.3. Transition Zone (400–660 km Depth)

Knowledge of the composition of the transition zone is essential to the understanding of the composition, evolution, and dynamics of the Earth. In seismic models, this depth range has been known for a long time to have a strong velocity gradient; much too steep for an increase under pressure of the elastic moduli and density of a homogeneous material. It was first postulated in the 1930s that this steep gradient may be due to phase transformations: changes in the crystal lattice that for a given material take place at certain temperatures and pressures.

In the 1960s, when major improvement in seismic instrumentation took place, two discontinuities were discovered: one at 400 km and the other at 670 km (the current best estimate of the global average of their depth is 410 and 660 km, respectively). Their existence has been well documented by nearly routine observations of reflected and converted waves. There is still some uncertainty of how abrupt the velocity changes are; the 410 km discontinuity is believed to be spread over some 5–10 km, whereas the 660 km discontinuity appears to be abrupt. The estimates of the velocity and density contrasts are still being studied by measuring the amplitudes of the reflected and converted waves; the values of these contrasts are important for understanding the mineralogical composition of the transition zone.

In general terms, the seismological models are consistent with the hypothesis that olivine is the main (up to 60%) constituent of the upper mantle. Laboratory experiments under pressures corresponding to depths up to 750 km show that olivine undergoes phase transformations to denser phases with higher seismic wave speeds. At pressures roughly corresponding to 400 km depth, the α-olivine transforms into β-spinel. The latter will transform to γ-spinel at about 500 km depth, with only a minor change in seismic velocities. Indeed, a seismic discontinuity at 520 km has been reported, although some studies indicate that in some parts of the world it may not be substantial enough to be detected. At 660 km γ-spinel transforms into perovskite and magnesio-wüstite.

Although olivine may be the dominant constituent, it is not the only one. The presence of other minerals complicates the issue. Also, there are other hypotheses of the bulk composition of the upper mantle, "piclogyte model", for example.

6.4. Lower Mantle (660–2890 km)

The uncertainties in the mineralogy of the upper mantle and the bulk composition of the Earth have created one of the most stubborn controversies in the Earth sciences: are the upper mantle and lower mantle chemically distinct? A "yes" answer means that there has not been an effective mixing between these two regions throughout the Earth's history, implying that the convection in the Earth is layered. The abrupt cessation of seismic activity at about 660 km depth, coinciding with the phase transformation described earlier, and geochemical arguments—mostly with respect to differences in isotopic composition of the mid-ocean ridge **basalts** and ocean island basalts—are used as

strong arguments in favor of the layered convection. New evidence, gathered within the tomographic studies to be discussed later, gives support to a significant impedance to the flow between the upper mantle and lower mantle.

The whole mantle convection is favored by geodynamicists who develop kinematic and dynamic models of the mantle flow. For example, the geometry and motions of the known motions of the plates are much easier to explain assuming whole mantle circulation. Evidence has been presented for penetration of slabs into the lower mantle, based on the presence of fast velocity anomalies in the regions of the past and current **subduction**. At the same time, there is evidence for stagnation and "ponding" in the transition zone of some of the subducted slabs. The recent results from seismic tomography seem to support the concept of at least partial separation of the upper and lower mantle flow.

In the early 1990s a model of mantle avalanches was developed; the subducted material is temporarily accumulated in the transition zone as the result of an endothermic phase transformation at the 660 km discontinuity. Once enough material with the negative buoyancy collects, however, a penetration can occur in a "flushing event", where most of the accumulated material sinks into the lower mantle. The calculations, originally performed in two-dimensional geometry, indicated the possibility of such events causing major upheavals in the Earth's history. However, when calculations were extended to 3-D spherical geometry (Tackley et al., 1993), their distribution in space and time turned out to be rather uniform.

The computer models of the mantle convection are still tentative. There are many parameters that control the process. Some, such as the generation of the plates and plate boundaries at the surface, are difficult to model. Others, such as the variation of the thermal expansion coefficient with pressure- or temperature-dependent viscosity, are poorly known; even one-dimensional viscosity variation with depth is subject to major controversies.

The lower mantle appears mineralogically uniform, with the possible exception of the uppermost and lowermost 100−150 km. There is a region of a steeper velocity gradient in the depth range of 660−800 km, which may be an expression of the residual phase transformations. Also, at the bottom of the mantle, there is a region of a nearly flat, possibly slightly negative gradient. This region, just above the CMB, known as D″, is the subject of intense research. Its strongly varying properties, both radially and horizontally, are being invoked in modeling mantle convection, chemical interaction with the core, possible chemical heterogeneity (enrichment in iron), and as evidence for partial melting. In 2004, the existence of a new phase "post-perovskite" has been proposed; its existence may affect the complexities in the D″ region. The seismic velocities and density throughout the bulk of the lower mantle appear to satisfy the Adams−Williamson law, describing the properties of the homogeneous material under an **adiabatic** increase in pressure.

6.5. Outer Core (2981−5151 km)

The outer core is liquid; it does not transmit shear waves. Consideration of the average density and the **moment of inertia** pointed to a structure with a core that would be considerably heavier, possibly made of iron, judging from cosmic abundances. We now know that the core is mostly made of iron, with some 10% admixture of lighter elements, needed to lower its density. It has formed relatively early in the Earth's history (first 50 Ma) in a melting event in which droplets of iron gravitationally moved toward the center. Although difficult to estimate, some current models place its temperature in the range of 3000−5000 K.

The presence of a liquid with a very high electrical conductivity creates conditions favorable to self-excitation of a magnetic **dynamo**. It is important to know that the magnetic field we observe at the surface is only a small fraction of the fields present in the core. Actually we see only one class of the field, the poloidal, whereas the toroidal field, possibly much stronger, is confined to the core.

Numerical models of the dynamo predicted several key phenomena observed at the surface: the primary dipolar structure with the alignment of the dipole axis close to the axis or rotation of the Earth, the westward drift of secular variations, and reversals of the polarity of the magnetic field. The later phenomenon is the cause of the magnetic anomalies on the ocean floor, which allowed estimating the rate of ocean spreading. Numerical simulations of geodynamo has begun in mid-1990s some being able to obtain the polarity reversal. Yet, the realistic parameter space has not yet been adequately sampled because of the computational challenges.

Seismological data are consistent with the model of the core as that of a homogeneous fluid under adiabatic temperature conditions. As often near major discontinuities, there is difficulty with pinning down the values near the end of the interval, just below the CMB and just above the inner core boundary (ICB). Some seismic models of the compressional velocity just under the CMB have gradient too steep for a homogeneous material. This implies chemical heterogeneity, with the intrinsically denser material at the top, which is unlikely. Also, some models contain a 100-km-thick layer just above the ICB, which has a nearly zero gradient. Using the velocity-density systematics, this would imply enrichment in iron and indicate that mixing of the material in the outer core is not as complete as the low viscosity of the fluid outer core predicts.

6.6. Inner Core (5251−6371 km)

An additional seismic discontinuity deep inside the core, which came to be called the inner core, was discovered by Inge Lehmann in 1936. The fact that it is solid was postulated soon afterward, but satisfactory proof required 35 years, when observations and modeling of the free oscillations of the Earth showed that it indeed must have finite rigidity (Dziewonski & Gilbert, 1971). However, mineral physicists have difficulty with explanation of the very high Poisson ratio of 0.44.

Estimates of the energy required to maintain geodynamo require that the inner core formed a long time after accretion of the Earth, perhaps some 2 Ga ago or even more recently. As the Earth was cooling, the temperatures at the Earth's center dropped below the melting point of iron (at the pressure of 330 GPa) and the inner core began to grow. The release of the gravitational energy associated with the precipitation of solid iron is believed to be an important source of the energy driving the dynamo. Again, estimates are difficult, but models yield a current temperature range of 5000−7500 K.

The inner core might have been considered quite uninteresting, with a very small variation of the physical parameters across the region. This all changed in the mid-1980s when it was discovered that this region is anisotropic, with the symmetry axis roughly parallel to the rotation axis. A deviation from that ray's symmetry and an observation of temporal variation of travel times through the inner core brought forward an interpretation that the inner core rotates at a slightly (1°/year) higher rate than the mantle. This could be explained by the electromagnetic coupling with the dynamo field of the other core. However, the inference of the rate of the differential rotation soon becomes very controversial. Several studies now indicate that this differential rotation must be much less. Another controversial issue is the "hemispheric asymmetry", with the western hemisphere having stronger anisotropy than the eastern one. In 2002, it was proposed that there exists an "innermost inner core", the central region with some 300 km radius in which the anisotropy is distinctly different than in the bulk of the inner core. Since then, the anomalous properties of this region have been confirmed by other studies.

It is likely that some of these controversies originate because of the insufficient, or uneven, data coverage. The inner core occupies less than 1% of the Earth's volume. Introduction of a new parameter such as the cylindrical anisotropy imposes additional requirements. Unlike in modeling an isotropic structure when travel time depends only on the bottoming depth of a ray, modeling the anisotropy requires also data coverage as a function of the location of the ray's bottoming point as well as the azimuth of the ray's path. The data requirement may be significantly reduced if simplifying assumptions are made, for example, the transverse isotropy with the symmetry axis aligns with the rotation axis. But if such an assumption turns out to be incorrect, the results may be very misleading.

7. EARTH IN THREE DIMENSIONS

Figure 21.21 is an example of results obtained using global seismic tomography (GST). It shows a triangular cut into an Earth model of the shear velocity anomalies in the Earth's mantle and shows only deviations from the average; if the Earth were radially symmetric, this picture would be entirely featureless. The surface is the top of the mantle (Mohorovicic discontinuity, or Moho) and the bottom is the CMB. Seismic wave speeds higher than average are shown with blue colors, whereas slower than average are shown as yellow and red colors. Seismic velocities decrease with increasing temperature; the inference is that the light areas are hotter than average and dark are colder. Seismic wave speeds also vary with chemical composition, but there are strong indications that the thermal effect is dominant.

Density is also a function of temperature. Material hotter than average is lighter and, in a viscous Earth, will tend to float to the surface, whereas colder material is denser and will tend to sink. Thus our picture can be thought to represent a snapshot of the temperature pattern in the convecting Earth's mantle. In particular, the picture implies a downwelling under the Indian Ocean and an upwelling originating at the CMB under Africa; sections passing through this anomaly indicate that this upwelling may continue to the surface. This "window into the Earth" shows the outer core (blue), inner core (pink), and the innermost inner core (red); the latter represents only 0.01% of the Earth's volume.

The GST is limited by the distribution of globally detected earthquakes and by the locations of seismographic stations. There is not much that we can do about the distribution of seismicity, except that now and then an earthquake occurs in an unexpected place, so the coverage is expected to improve with time. Generally, the earthquake distribution is more even in the Northern Hemisphere. Much has been done in the last decade to improve the distribution and the quality of the seismographic stations, and recent results show considerably better resolution of the details in the top 200 km, for example. However, even using the available oceanic islands (which are very noisy, because of the wave action), there are oceanic areas with dimensions of several 1000 kilometers where no land exists. A series of experiments by Japanese, French, and

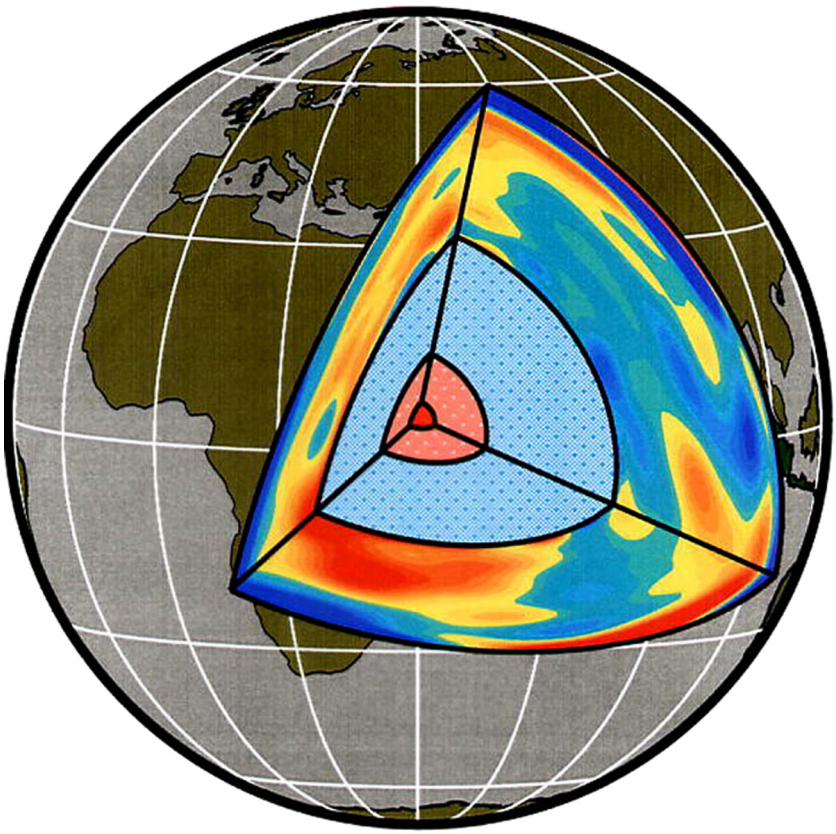

FIGURE 21.21 Three-dimensional Earth model. A 3-D model S362D1 of Gu et al. representing the lateral deviations of the shear velocities with respect to PREM. The sides represent a vertical cross-section along three different profiles. Faster than average velocities (caused by colder than normal temperature, presumably) are shown in green/blue and slower (hotter) in yellow/red colors. The scale is ±1.5%; significant saturation of the scale occurs in the upper mantle. Note the lateral and vertical consistency of the sign of the anomalies over large distances and depths. The mantle underneath Asia and Indian Ocean is fast at nearly all depths, whereas the mantle under central Africa is slow. The liquid outer core is shown in blue, inner core in red, and the innermost inner core in red.

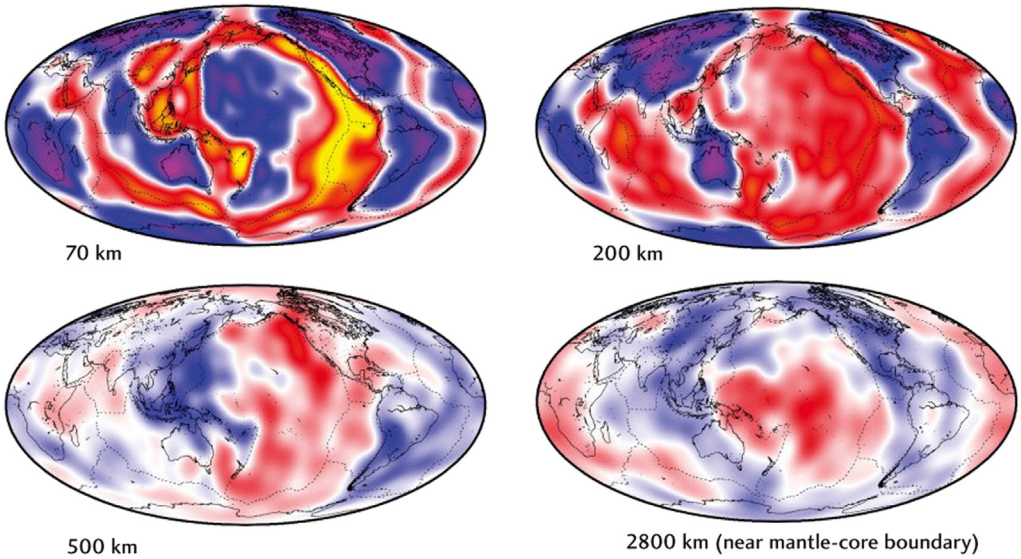

FIGURE 21.22 Lateral variations of the Earth's shear wave velocity. Maps of lateral variations of S velocities at four depths in a shear velocity model of Ekström and Dziewonski. The yellow/red colors indicate slower than average velocities and blue, the faster. The range of variations is about 7% at 70 km and 3% at near the core–mantle boundary.

American seismologists have demonstrated that the establishment of a permanent or semipermanent network of ocean bottom high-quality seismographic stations is now a real, even though expensive, possibility.

Figure 21.22 is a collection of maps of the shear velocity anomalies from a recent model of the mantle by Ekström and Dziewonski published in 1998, built using a wide range of types of data (travel times, surface wave

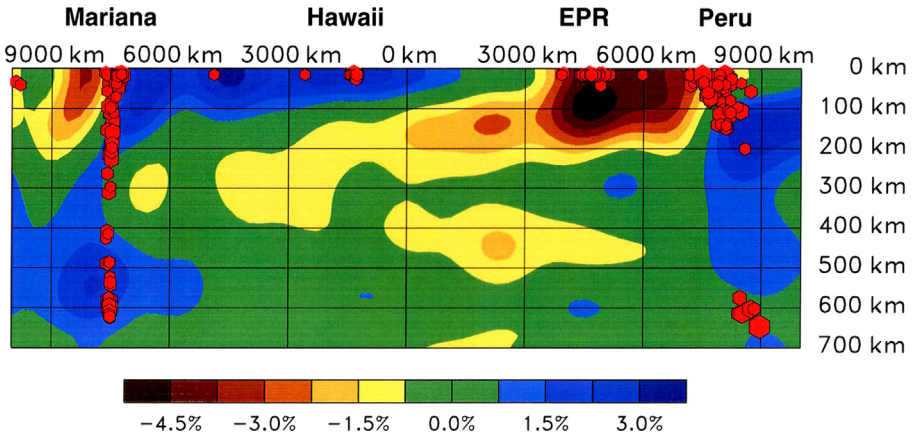

FIGURE 21.23 Cross-section of upper mantle model. Cross-section through the upper mantle of model of Ekström and Dziewonski. Note that velocities change as a function of distance from the East Pacific Rise (proportional to age of the plate) to depths greater than 200 km. Red dots indicate earthquakes. There is vertical exaggeration by a factor of about 20.

dispersion, and waveforms). The nominal resolution of this model is about 100 km in depth and 1500 km horizontally near the surface.

At 70 km depth, the model agrees with the predictions of the plate tectonics and the thermal history of the continents. The stable continental areas (old and cool) are very fast (up to +7%), whereas material under the mid-ocean ridges is much slower than normal (up to −7%). This negative anomaly decreases with the increasing age of the oceanic plate to become faster than average for ages greater than 100 Ma. The depth to which the anomalies associated with the mid-ocean ridges persists in the tomographic maps (>200 km) puzzles geodynamicists who think that mid-ocean ridges are passive features and that conditions below about 100 km depth are isothermal.

Figure 21.23 shows a cross-section through the upper mantle of the Pacific from the model of Ekström and Dziewonski; the direction of the cross-section follows the direction of motion of the Pacific plate. Going from East to West, we see higher seismic velocities associated with **subduction** under South America; very slow **lithosphere** at the East Pacific rise; increase in velocities with the distance from the ridge; and subduction under the Mariana trench; the red dots are earthquakes. It is clear that the velocities change with age to depths below 200 km. The map in Figure 21.22 at 200 km depth shows diminished variability of velocities under ocean but still very strong anomalies under the continents, the old cratons, in particular. Thus, the tomographic model is consistent with the tectosphere hypothesis, but the amplitude of the velocity anomalies decreases rapidly below 200−250 km depth.

The map in Figure 21.22 at 500 km depth represents average shear velocity anomalies in the transition zone. The most characteristic features are the fast anomalies in the western Pacific and Eastern Asia and in the east, under South America and the Atlantic, reaching to western Africa. In the western Pacific they can be associated with subduction zones, although they are much wider than an anomaly associated with a 100-km-thick slab. Studies of the topography of the 660 km discontinuity show that the areas of high seismic velocity are correlated with a depressed boundary, yielding credence to an interpretation that these anomalies are indicative of an accumulation (temporary, perhaps; see earlier discussion on the models of flow in the mantle) of the subducted material in the transition zone. Figure 21.24 shows comparison of lateral variation in velocities obtained in a model named S362D1. The two maps one just above and the other just below the 660 km discontinuity are very different; the map representing the transition zone shows features similar to that at

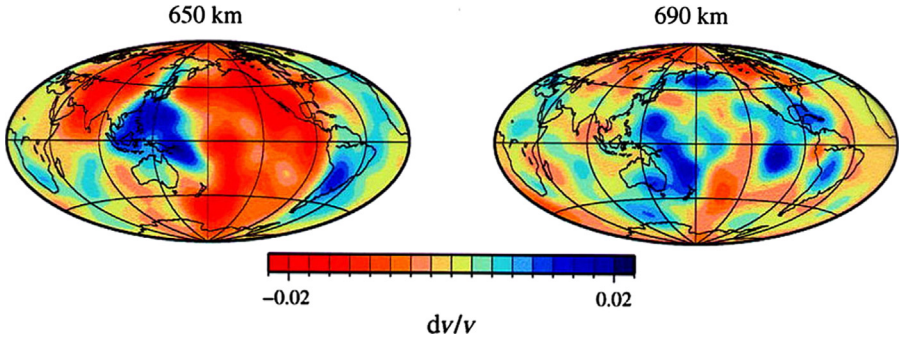

FIGURE 21.24 Shear velocity anomalies. Shear velocity anomalies just above and below the boundary between the upper mantle and lower mantle in model S262D1 of Gu et al. The differences indicate a drastic change in the pattern of the anomalies, most likely associated with a serious impedance to flow.

500 km map in Figure 21.22; the lower mantle map is quite different and has distinctly different spectral content; it is dominated by relatively short wavelength features. This result, and similar maps obtained by other modeling groups, supports the concept of a separation—perhaps not absolute—between the upper mantle and lower mantle.

In the middle mantle the anomalies are not well organized. This observation contrasts with the results of "high-resolution" tomography, which in this depth range shows two narrow high-velocity features: one stretching from the Hudson Bay to Bolivia and the other from Indonesia to the Mediterranean. Even though elements of these two structures are present in our model, they are not equally well defined. Also, there are many other features of comparable amplitude. This is also true with respect to models published by scientists at the University of California Berkeley and at Caltech/Oxford, who used parameterization similar to that in Figure 21.22. Intensive efforts are made to understand the differences between the results of two different approaches to tomography.

The map at 2800 km depth shows the velocity anomalies as the CMB is approached. The ring of high velocities circumscribing the Pacific basin is already visible at 2000 km; it strengthens considerably over the next 500 km and increases even further toward the CMB. In the wave number domain of spherical harmonics, the spectrum of lateral heterogeneities is very red, being dominated by degree 2 and 3. These two harmonics account for 70% of the variance of the heterogeneity near the CMB. The location of the ring of fast velocities corresponds to the location of subduction zones during the past 200 Ma. The large red (slow) regions are sometimes called the African and the Pacific "superplumes"; some seismologists prefer Large Low Shear Velocity Provinces. Their origin is unknown; they, most likely, represent both thermal and chemical heterogeneity. There is a good correlation between the location of the two superplumes and distribution of hot spots at the Earth's surface, indicating a degree of connection between the tectonics at the surface and conditions near the core–mantle boundary.

Figure 21.25 gives two views of low-pass filtered anomalies in the lower mantle in a model by Ritsema, van Heijst, Woodhouse (1999), plotted in Cartesian coordinates; the red is a 0.6% isosurface and blue is +0.6%. We see the circum-Pacific ring of fast anomalies and the two low-velocity anomalies: one very concentrated under the Pacific and a more diffuse one under the Atlantic and Africa. Their radial continuity throughout the lower mantle indicates that they cannot be explained by processes at the core–mantle boundary alone. The origin of this large-amplitude, very large-wavelength signal has not yet been explained by geodynamic modeling, although an assumption that the velocity and gravity anomalies are correlated leads to a good prediction of the geoid at the gravest harmonics.

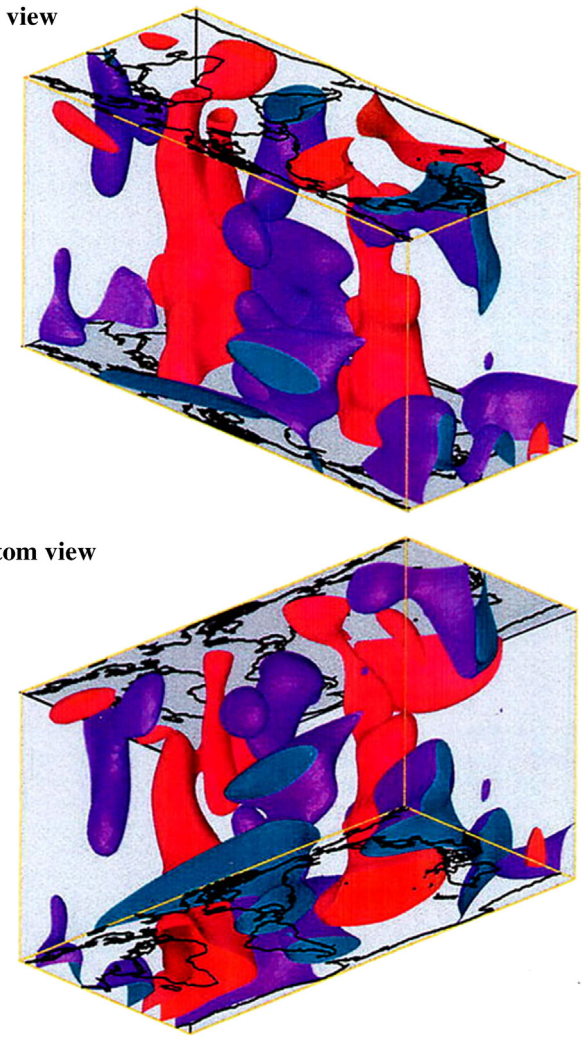

FIGURE 21.25 Low-pass filtered S-velocity model. Low-pass filtered S-velocity model of Ritsema et al. in a 3-D projection; the top 800 km of the structure is removed.

Dziewonski, Lekic, and Romanowicz (2010) hypothesized that the degrees 2 and 3 velocity anomalies in the lowermost mantle are indicative of a thermal and/or compositional heterogeneity that imposes a long-term control on the global tectonics. Close examination of the long-wavelength shear velocity signal in the lowermost mantle in the wavenumber domain ties several geophysical observations together and leads to fundamental inferences.

Figure 21.26 compares degree 2 shear velocity anomalies at 2800 km depth in three relatively recent 3-D shear velocity models; the maps for that harmonic are nearly indistinguishable. The power in this degree is more than one half of the total power contained in harmonics from 1 to 18. Even though no constraints were imposed a priori, the pattern—for all practical purposes—is described by a single spherical harmonic coefficient, the "recumbent" Y20 spherical harmonic, a Y20 with its axis of symmetry rotated

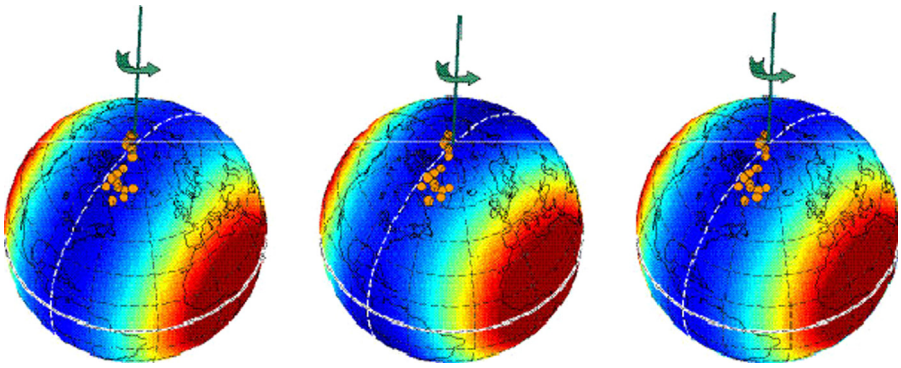

FIGURE 21.26 Comparison of shear velocity anomaly components. Comparison of degree 2 component of shear velocity anomalies at 2800 km depth for three relatively recent 3-D models published by research groups at (from the left) Harvard, Berkeley, and Caltech/Oxford. Subduction during the last 200 Ma occurred within the blue area, hot spots, over red (slow anomalies). The TPW positions of Besse and Courtillot (2002) during the last 200 Ma are indicated by small orange circles.

to the equatorial plane. There is less than 1/1000 probability that such a result could be obtained by chance. This degree 2 signal, which continues with decreasing amplitude throughout the lower mantle, is characterized by two antipodal regions of low velocities, separated by a circumpolar torus of velocities higher than average. If the slow regions are associated with net excess mass, then any axis of rotation located in the plane of the polar great circle will be the maximum moment of inertia axis; this includes, of course, the current axis of rotation. The polar great circle would be also the preferred direction of true polar wander (TPW); the open circles show the locations of the TPW axes during the most recent 200 Ma determined by Besse and Courtillot (2002). It is suggested that the recumbent Y20 is a very stable feature; once established, it is difficult to erase, and only relatively small departures from this equilibrium configuration are possible. This anomaly correlates strongly with the degree 2 terms of the residual geoid expansion, distribution of the hot spots above the slow regions, high attenuation in the transition zone, and position of subduction zones above the fast band during the last 200 Ma. Also, the preferred paths of the virtual geomagnetic pole and TPW locations for the last 200 Ma lie within the fast band. Since the nonhydrostatic perturbation of the moment of inertia tensor depends only on degree 2 anomalies in the density distribution and deformation of discontinuities, it is natural to infer that rotational dynamics of the Earth have influenced the distribution of heterogeneities in the Earth's deep interior. It is proposed that the large-scale heterogeneity at the base of the mantle, named "mantle anchor structure" may have formed early in the history of the convecting mantle, remained locked in place with respect to the Earth's rotation axis ever since, and is currently imposing the planform of flow in the mantle and—on a shorter timescale—plate tectonics at the surface.

It was believed since 1977, the time of publication of the first large-scale GST study, that 3-D images of lateral heterogeneity in the mantle will be an essential tool in addressing some of the fundamental problems in earth sciences. The results accumulated since then confirm that statement, even though much progress is still to be made. Cooperation among the different fields of Earth sciences (geodynamics, mineral physics, geochemistry, seismology, and geomagnetism) is the requisite condition to fulfill this goal.

8. EARTH AS A ROSETTA STONE

The Earth is unique among its partners in our solar system in that it has had liquid water oceans for most of its history, has a highly mobile crust, and a dynamically convecting interior. This combination means that the surface is and has been constantly driven by the movement of the interior, such that the oldest terrestrial subaerial landscapes are at most $\sim$10% of the age of the planet, and the oldest submarine landscapes are only a little more than 10% of that. Thus, the Earth not only has one of the most globally dynamic surfaces in the solar system, but its interior is also one of the most dynamic. Only the tidally wracked and volcanically incessant surface of Io, Jupiter's innermost satellite, may be younger and more active. Driven by internal forces, the periodic conglomeration and separation of continental landmasses, causing opening and closing of oceans, and construction and destruction of mountain ranges profoundly impact the global climate. The environmental stresses caused by such reshuffling of the surface may themselves have influenced the progress of evolution on the planet—evolution that was possibly reset every 100 million years or so by devastating asteroidal impacts. In the final analysis, the Earth is the only planetary body with which the human species has had intimate experience—for millennia. Thus, beyond being our home, the Earth is for us a crucial yardstick—a Rosetta stone—by which we will measure and interpret the processes, internal structure, and overall histories of other planets in this solar system and, someday, of other planets around other stars.

The Sun has profound effects on the Earth through its primarily visible and infrared photon emissions. This radiated energy, generated as a by-product of the nuclear reactions in the Sun's core (see The Sun), is absorbed or reflected at different wavelengths by the sea and land surfaces and the atmosphere. The result is the atmospheric circulation system that generates tropospheric weather through the diurnal and seasonal cycles caused by Earth's rotation and axis tilt. (See Earth: Atmosphere and Oceans). The climate of the Earth is the result of the long-term interaction of solar radiation, weather, surface, oceans, and human activity.

These influences are not the only ways the Sun affects the Earth. Ultraviolet (UV) and X-ray light from the Sun are much less intense, but more energetic and variable than the visible emissions. The UV radiation is absorbed in the stratosphere where it affects the production of the ozone layer and other atmospheric chemistry, while the extreme UV (EUV) photons and X-rays are absorbed in the thermosphere (above ~90 km), creating the ionized component of the upper atmosphere known as the **ionosphere**. Even more variable is the emission of charged particles and magnetic fields by the Sun. One form of this output is the magnetized solar wind **plasma** and its gusty counterpart, the **Coronal Mass Ejection** or CME. CMEs interact with the Earth to create major **geomagnetic storms**. These and other forms of matter, energy and momentum transfer couple the physical domains of the connected Sun–Earth system, which is illustrated in Figure 22.1. A brief summary of the subject of this chapter, whose focus is this system, follows here.

Space weather begins in the solar interior where dynamo activity (see The Sun) generates the solar magnetic field. The solar magnetic field, coupled with the mechanical and radiative energy outputs from core fusion reactions, ultimately determines both the variability of the Sun's energetic (EUV, X-ray) photon outputs, and the interplanetary conditions at the orbit of Earth. The latter include the solar wind plasma properties, the interplanetary magnetic field magnitude and orientation, and the energetic particle radiation environment. Both the energetic photon outputs and interplanetary conditions vary with the ~11-year solar cycle, which is characterized by changing frequencies of solar flares and CMEs, the two primary forms of solar activity. These in turn determine conditions in near-Earth space or **geospace**, the region composed of the **magnetosphere**, the upper atmosphere and the ionosphere. Only in the 1960s was it appreciated that the interplanetary magnetic field orientation relative to Earth's own dipolar field plays a major role in solar wind–magnetosphere couplings as described in more detail in the main text below.

The magnetosphere, the region of near-Earth space dominated by the magnetic field of the Earth and shaped by its interaction with the solar wind (see Figure 22.1), organizes geospace. Various particle populations in the magnetosphere, including the plasmas originating in the

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00022-0

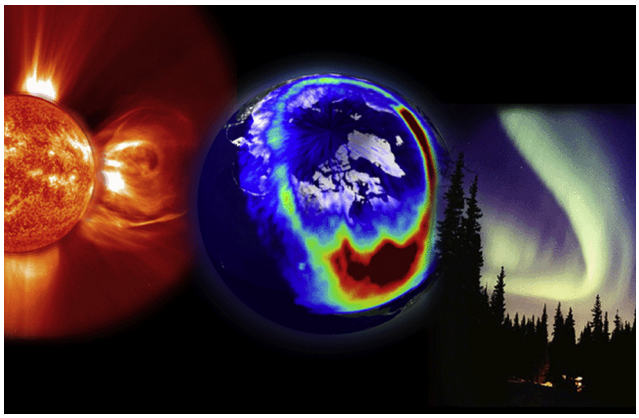

FIGURE 22.1 Triptych illustrating the coupled Sun–Earth system, showing from left to right an image of the erupting **solar corona** from the SOHO spacecraft, and images of the Earth's auroral emissions from space (center) and from the ground (right). *See http://sohowww.nascom.nasa.gov/hotshots/2003_03_14/.*

solar wind and Earth's ionosphere, and the more energetic particles trapped in the **radiation belts**, are constantly modified by changing interplanetary conditions. The ionosphere acts as a conducting inner boundary affecting the magnetosphere's response to those conditions, but is also a source of ions and electrons for the magnetosphere. Under the disturbed local interplanetary conditions following an Earth-directed CME, a collection of major magnetospheric modifications called a geomagnetic storm occurs. The population of trapped energetic particles in the radiation, or **Van Allen, belts** surrounding the Earth undergoes enhancements, losses, and redistribution. Current systems and particle exchanges couple the magnetosphere and ionosphere to a greater than normal degree. The result is enhanced solar wind energy transfer into geospace, causing **auroral** emissions and related changes in the high-latitude dynamics of the ionosphere, and the density and composition in the thermosphere. Evidence of atmospheric influences of geomagnetic storms and other solar effects down to the stratosphere has been reported, although it remains controversial. On the other hand, induced currents in conductors on the ground from storm-associated magnetic field changes are unarguable proof of the depth of influence of extreme space weather.

Studies of space weather investigate the physics that makes the Solar Wind, Magnetosphere, and Upper Atmosphere/Ionosphere, a highly coupled system. Figure 22.2 shows an attempt to diagram its various components and their relationships. There are also practical aspects to understanding the connections shown. Specifications of radiation tolerances for spacecraft electronics components, designs of protective astronaut suits and on-orbit shielding, and definitions of the surge limits for power grids on the ground can be made with a better understanding of space weather effects. Forecast models can help predict the changes in the magnetosphere that alter the radiation belts and the changes in the ionosphere that disrupt radio communications and GPS navigation. Observational and theoretical research in space weather processes also increases our understanding of other areas of Astronomy and Astrophysics such as planet–solar wind interactions, extrasolar planetary systems, stellar activity, and the acceleration of particles in the universe.

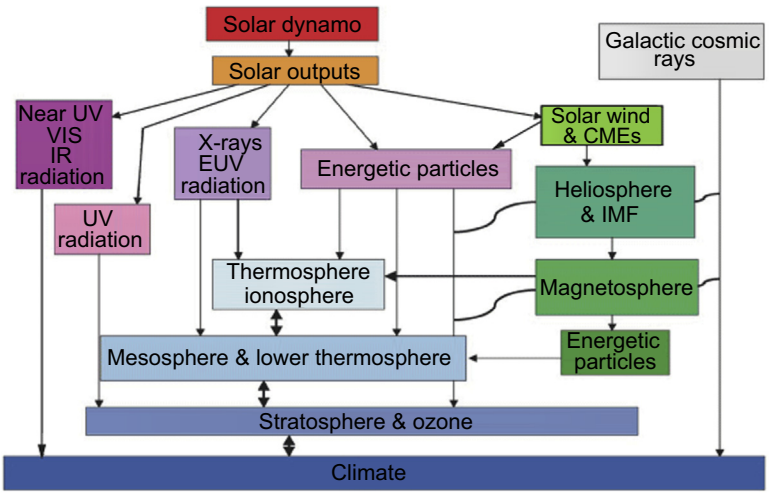

FIGURE 22.2 Flow diagram illustrating the connections in and complexity of the coupled Sun–Earth system. The solar **dynamo** (top) generates the solar magnetic field, which modulates the solar outputs of EUV and X-ray emissions, as well as the solar wind plasma. The solar wind and its gusty counterpart, CMEs (green box, upper right), directly determine the state of the local heliosphere, which controls the state of the magnetosphere (including its energetic particle or radiation belt populations). In the meantime, both solar photons (upper right boxes) and solar energetic particles directly affect the state of the upper atmosphere. The possible connection to climate, suggested at the bottom, is currently a matter of speculation. *Adapted from http://lws-trt.gsfc.nasa.gov/lika_radtg.ppt.*

1. THE SOLAR AND HELIOSPHERIC ROLES IN SPACE WEATHER

Solar radiation in the UV, EUV and X-ray wavelengths are the primary sources of ionization in the Earth's atmosphere. Of these solar EUV fluxes are the most important source of the ionosphere. Figure 22.3 illustrates the relatively large variability of this part of the solar spectrum, compared with the visible and infrared wavelengths that dominate the "solar constant". As mentioned before, this variability is a result of the control of these emissions by the solar magnetic field, which undergoes significant evolution during the course of the ~11-year solar activity cycle (see The Sun). The EUV emissions come largely from bright plage areas seen on the photosphere and from the chromospheric network, while the X-rays come mainly from hot plasma-containing coronal loops structured by the coronal magnetic field. The plages and X-ray bright loops are related to active regions, areas with the strongest photospheric magnetic fields, that are nonuniformly distributed over the solar surface. An important result of having magnetic field observations of the Sun was the appreciation that not all active regions have fields strong enough to produce sunspots on the visible disk. The changing numbers of active regions, and their areas, determine the solar activity cycle. Thus the solar EUV flux experienced at Earth undergoes variations on both the 27-day timescale of solar rotation (due to the nonuniform distribution of active regions on the surface) and the near-decadal timescale of solar activity (see The Sun). The transient brightenings in active regions called solar flares occasionally produce solar EUV and X-ray emission enhancements of up to several orders of magnitude at photon energies extending into the gamma ray range. These outbursts affect Earth's atmosphere and ionosphere at depths depending on their wavelengths as indicated in Figure 22.4. The magnetosphere responds to changes in the ionosphere and upper atmosphere, but its primary solar controller is the magnetized solar wind plasma.

The solar wind is the outflowing ionized gas or plasma of the solar upper atmosphere (see The Solar Wind). This outermost extension of the corona fills a space up to about ~100 AU in radial extent, defining the region surrounding the Sun, the **heliosphere**. The mainly hydrogen solar wind flows primarily from places in the corona that are magnetically "open" to interplanetary space. These open field regions are often called coronal holes because of their dark appearance in soft X-ray and EUV images (see The Sun). The solar wind also carries with it the stretched out coronal magnetic field that takes on an average outward or inward orientation depending on the magnetic field direction or polarity at its photospheric base. There is also a component of the quiet solar wind that comes from the edges of coronal closed magnetic field regions, producing the equivalent of a boundary layer between outflows from different open field regions. On the average the solar wind speed is slowest in these boundary layers and fastest where it flows from the center of large

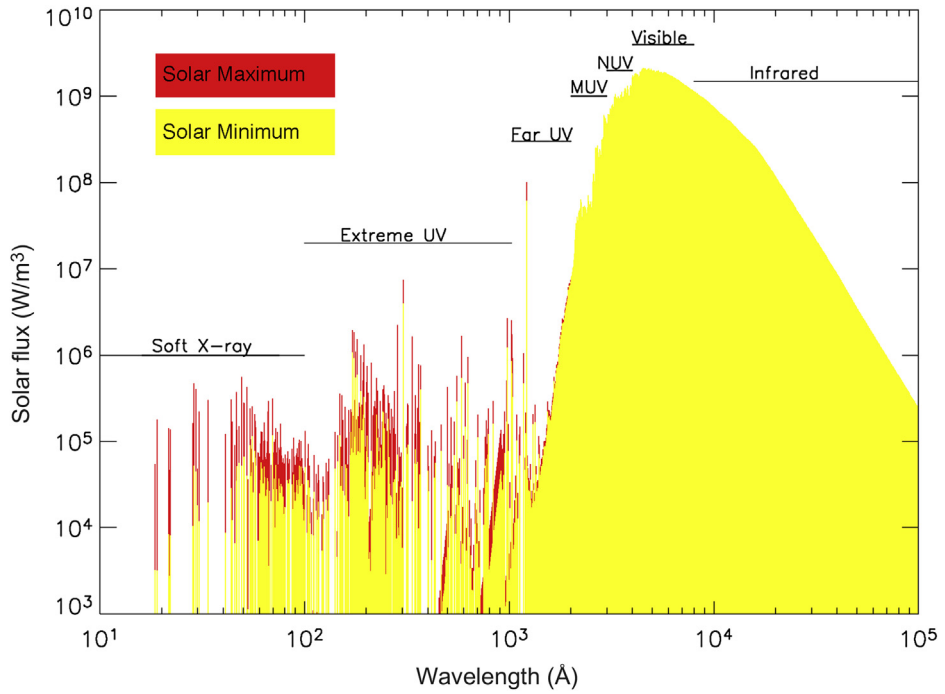

FIGURE 22.3 Illustration of the solar spectrum, showing the intensities of various wavelength emissions and their variation from active (red) to quiet times. Notice that order of magnitude variations from solar minimum to maximum occur at the short (<1000 Å) wavelengths. (1 Å is equivalent to 0.1 nm.)

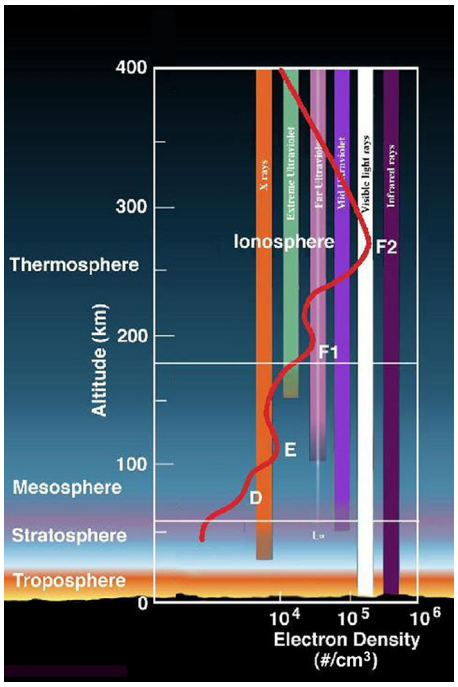

FIGURE 22.4 Atmospheric depths affected by various wavelengths in the solar spectrum. (Courtesy of Windows to the Universe, http://www.windows.ucar.edu.) The longer wavelength radiation affects mainly heating, while the shorter wavelengths can produce ionization and associated chemistry changes. The letters F1, F2, E, and D are used to designate different ionospheric layers.

open field regions. Typical solar wind speeds range from ~300 km/s to ~800 km/s and are roughly constant with radial distance. Undisturbed solar wind magnetic field strengths at 1 AU range from ~5 to 10 nT and densities from ~5 particles/cm^3 to 15 particles/cm^3. Heliospheric images that capture the faintest coronal structures indicate that coronal hole boundary outflows are at least partly in the form of small transients or "blobs", the result of the constant evolution of solar surface magnetic fields at the base of the corona. Because the open and closed field regions change with the distribution of active regions on the Sun, the solar wind stream structure and field polarity pattern evolve with the solar activity cycle. They are simplest at the quietest times of the cycle, during which the corona usually exhibits two main solar wind sources near the Sun's polar regions, one with positive (outward) and one with negative (inward) magnetic polarity. As more active regions appear on the solar surface, the coronal magnetic structure becomes more complicated and with it the distribution of open fields. In particular, low and mid-latitude coronal holes appear that can produce most of the solar wind the Earth experiences.

In fact, a critical aspect of the solar wind stream structure for the impact on geospace is Earth's location near the solar rotational equator. This region is often dominated by the presence of the slow wind and the related heliospheric current sheet that separates the solar wind from open coronal field sources with outward and inward magnetic field polarities. This circumstance, together with the rotation of the Sun, produces local interplanetary conditions that at low solar activity exhibit repeating or "corotating" 27-day variations in solar wind speed and density, and interplanetary magnetic field polarity. E. Parker, who first proposed the existence of the solar wind, also recognized that the Sun's rotation would wind up the interplanetary magnetic field into a spiral shape. Figure 22.5 illustrates this "Parker Spiral" orientation of the near-ecliptic field in the heliosphere, and its typical 45° (from radial) orientation at 1 AU (see The Solar Wind). At solar minimum, adjacent streams of different speeds from different coronal source regions may interact, producing spiral density and field ridges at their boundaries. When these ridges, which are called stream interaction regions or corotating interaction regions, rotate past the Earth, they can cause modest geomagnetic activity. At solar activity maximum the more complicated coronal field mentioned above makes the corresponding solar wind conditions more variable and structured, and less organized by solar latitude. The active phase solar wind also includes many transient disturbances caused by rapid changes in coronal structure, including CMEs, whose effects are further described below. Figure 22.6 illustrates the general morphology of solar wind characteristics from periods around solar minimum and solar maximum. These solar cycle-dependent interplanetary conditions shape the

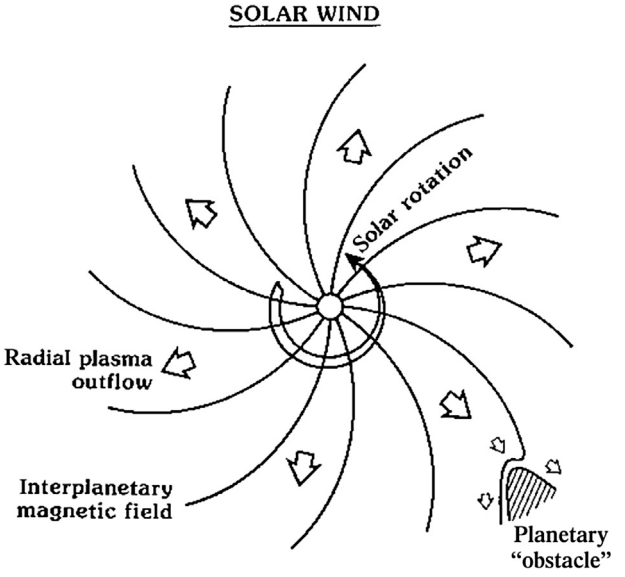

FIGURE 22.5 Illustration of the Parker Spiral interplanetary magnetic field carried in the outflowing solar wind, and wound up by solar rotation. At 1 AU the typical angle the field makes with respect to the Sun–Earth line is ~45°. *See The Solar Wind for further information.*

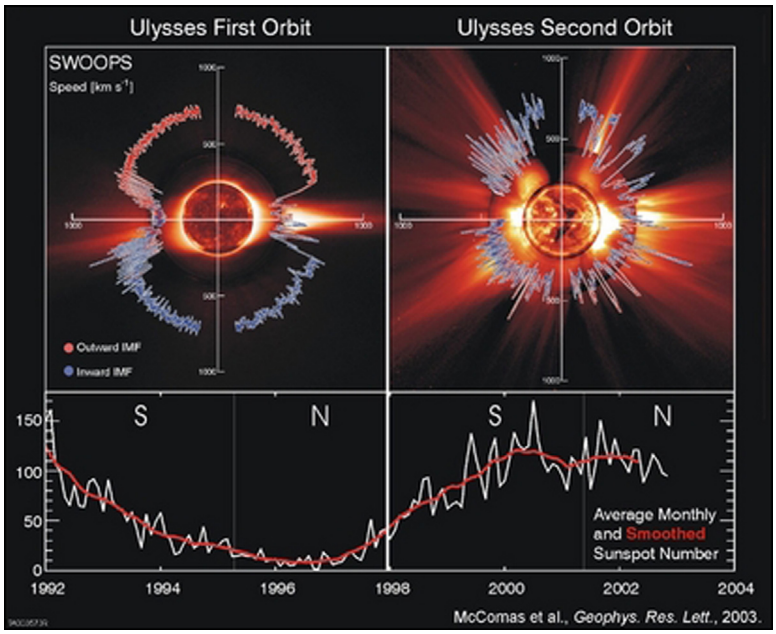

FIGURE 22.6 Solar wind velocities at solar minimum and maximum as measured on the Ulysses spacecraft which passes over the Sun's poles. The speed is shown in a polar coordinate system with zero speed at the center of the Sun. The blue and red indicate interplanetary magnetic field polarity. *McComas et al. (2003)*.

Earth's magnetosphere, and regulate its internal particles, energization, and stresses.

When the Sun is active, it produces greater numbers of both the flares mentioned earlier and CMEs. CMEs have the greatest effects on geospace, and so we focus on them here. The details of the CME initiation process, as well as CME structure, are subjects of intensive current research. As seen in white light images from coronagraphs like the SOHO LASCO instrument (an example of which is shown in Figure 22.1), CMEs appear to be eruptions of large magnetic bubbles or twisted "flux ropes" of coronal magnetic fields. These structures, referred to as drivers or ejecta, travel outward at speeds ranging from tens of km/s to several thousands of km/s. As they travel they interact with the surrounding solar wind, compressing it ahead if they are moving faster. If they move fast enough relative to their surroundings they create an interplanetary shock wave. Figure 22.7 illustrates the effect of a CME on the solar wind and interplanetary magnetic field at 1 AU. These propagating disturbances are experienced by the magnetosphere as sudden increases of solar wind density, velocity, and magnetic field at the shock passage, followed by several hours of enhanced solar wind parameters, and then the ejecta passage characterized by a period with normal densities but high magnetic field strengths and, often, high inclinations. The entire structure may take hours to days to pass Earth depending on its speed. Enhanced solar wind pressure associated with a CME is usually from the sheath portion between the shock front and the ejecta. The ejecta

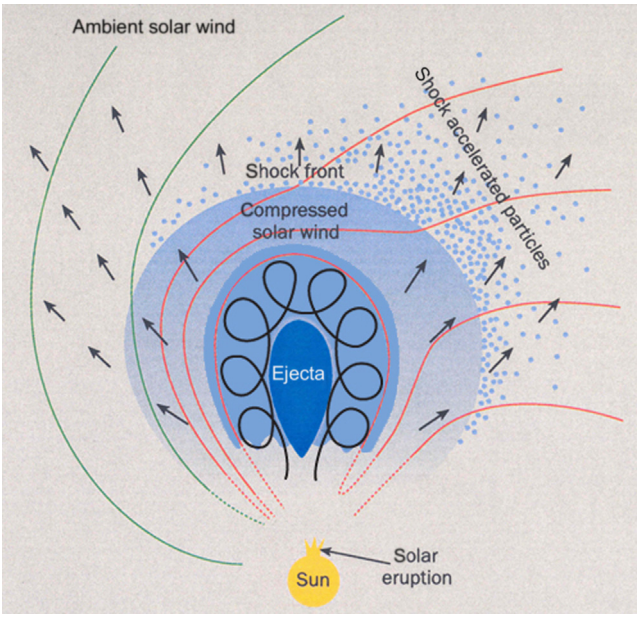

FIGURE 22.7 Illustration of the interplanetary effects of a CME. The CME produces an ejection of coronal material (ejecta) that may include a helical magnetic field structure or flux rope (illustrated by the black line). This structure plows into the ambient solar wind and may produce a shock in the solar wind plasma ahead of the ejecta. The region of compressed solar wind between the shock and ejecta is referred to as the sheath. Some solar wind particles are accelerated at the shock and speed out ahead of it along interplanetary field lines (red, green). *Luhmann (2000)*.

fields can occasionally be modeled as a passing magnetic flux rope configuration as suggested in Figure 22.7. Around the minimum of solar activity the local interplanetary medium is disturbed by one of these interplanetary CMEs or ICMEs once every few months, but at solar maximum they can occur about once a week. The most extreme (largest, fastest) ICMEs usually follow CMEs associated with large, complex active regions on the Sun that also produce solar flares.

In addition to the magnetized solar wind plasma, the heliosphere also contains a population of energetic (tens of kiloelectron Volts (keV) to hundreds of Megaelectron Volts (MeV)) charged particles that varies with time. Ions and electrons are accelerated at both flare sites on the Sun and by the shock waves formed in the corona and interplanetary space by the fast-moving CME ejecta or by interacting high- and low-speed solar wind streams. CME shocks produce the most intense and long-lived (several day) episodes. The particles race ahead of their shock source along the spiral interplanetary field lines, surrounding the magnetosphere with a sea of potentially hazardous radiation within tens of minutes of the events at the Sun. Sometimes the fluxes of these particles increase by several orders of magnitude when the CME shock itself arrives several days after the event in the corona. The contributions of **solar energetic particles** to local interplanetary conditions are related to the level of flare and CME activity on the Sun. In an interesting opposite effect of solar activity, other more permanently present energetic charged particles called cosmic rays, which arrive at Earth from the heliospheric boundary and beyond, show locally decreased fluxes when solar activity is high. These decreases are likely due to the sweeping action of the highly structured solar wind around the time of solar activity maximum, when interplanetary field disturbances carried outward present effective barriers to incoming charged particles. In fact especially notable episodes called "Forbush Decreases" can occur during the passages of CME ejecta. Under certain conditions solar energetic particles can enter the magnetosphere where they contribute to the radiation belts and produce layers of enhanced ionization deep in the Earth's polar atmosphere.

2. THE GEOSPACE ROLE IN SPACE WEATHER

The Earth's space environment is determined by its nearly dipolar internal magnetic field that forms an obstacle to the solar wind, creating the magnetosphere (see Planetary Magnetospheres). Spreiter, Summers, and Alksne (1966) and Axford and Hines (1961) were among the pioneering researchers to recognize the fluid-like aspects of the solar wind interaction with Earth's compressible field, describing it in terms of a blunt body in a hypersonic flow. The size and shape of this blunt body, the magnetopause, can be calculated from the assumption of pressure balance between the Earth's internal magnetic field pressure and the incident dynamic pressure of the solar wind. (Dynamic Pressure = mass density × velocity squared.) It typically occurs at ~10 Earth radii along the line connecting the centers of the Earth and the Sun and at ~15 Earth radii in the terminator plane. In contrast to the compressed, solar wind pressure-confined dayside, the nightside magnetosphere stretches out into an elongated structure called the magnetotail. These features, confirmed by decades of observations, are illustrated in Figure 22.8. The magnetopause separates geospace and the solar wind plasma-dominated regions outside. As seen in Figure 22.8, the outermost features associated with

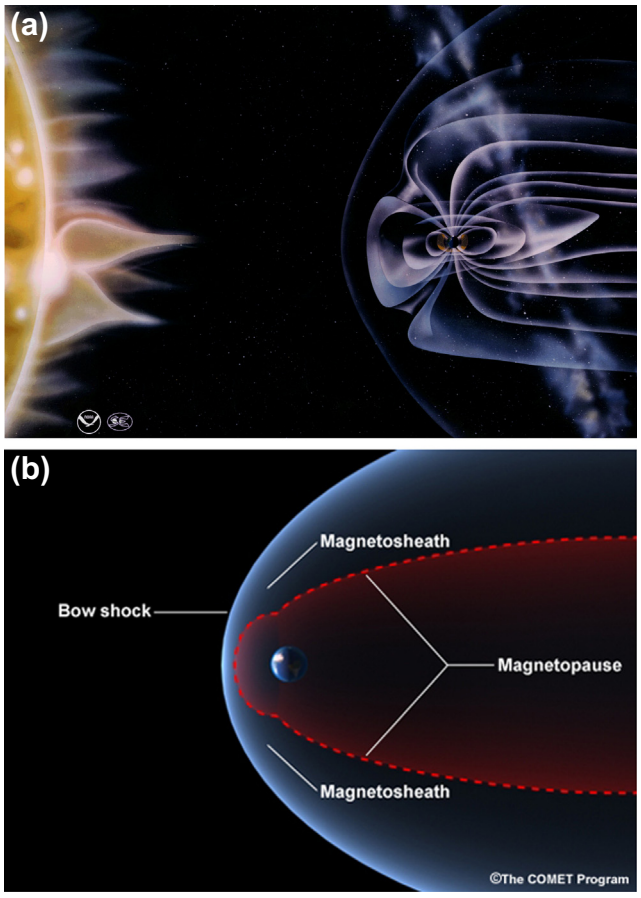

FIGURE 22.8 (a) Illustration of the blunt body shape of the magnetosphere, showing some gossamer "shells" of magnetic field surfaces along which charged particles drift, and the magnetopause (Rice University). (b) Magnetospheric boundaries described in the text. The magnetopause nominally separates solar wind and magnetospheric domains. *The source of this material is the Cooperative Program for Operational Meteorology, Education, and Training (COMET) Web site at http://meted.ucar.edu/ of the University Corporation for Atmospheric Research (UCAR) pursuant to a Cooperative Agreement with National Oceanic and Atmospheric Administration. 1997–2004 University Corporation for Atmospheric Research. © All Rights Reserved.*

the Earth's magnetic obstacle are actually the bow shock that forms in the solar wind ~5 Earth radii upstream of the dayside magnetopause, and the magnetosheath. The magnetosheath is the slowed, deflected solar wind between the bow shock and the magnetopause. Thus when the Earth's field interacts with the solar wind, it does so through the altered solar wind in the magnetosheath.

Dungey (1961) first recognized that the magnetopause is not a complete barrier to the solar wind, and that magnetospheric field topology is also controlled by its interconnection, or **reconnection**, with the interplanetary field. This leap of understanding revolutionized the study of solar-wind magnetosphere coupling and geomagnetic activity. Figure 22.9 reproduces Dungey's original cartoon suggesting the different appearances of the magnetospheric field topology for the extreme cases of steady Northward and Southward interplanetary fields. Similar pictures can be obtained by adding background uniform fields of both directions to a dipole field. The Northward interplanetary field, which is parallel to the Earth's dipole field at the equator, produces a magnetically closed magnetosphere. The Southward field, which is antiparallel to the Earth's dipole field at the equator, produces a magnetically open configuration with the polar region fields of the Earth connected to the interplanetary field. These differences greatly affect the transfer of both energy and particles from the solar wind into geospace. For the Northward case the solar wind interaction resembles a viscous boundary interaction at the magnetopause and there is minimal exchange of energy and particles. For the Southward case the charged particles in interplanetary space have access to the polar regions along interplanetary field lines. An electric field associated with solar wind convection $E = -V \times \mathbf{B}$, where V is the solar wind velocity and $\mathbf{B}$ its magnetic field, maps along open field lines into polar regions where it drives vigorous magnetosphere and ionosphere circulation as in Figure 22.10. The two-celled vortical convection pattern has been observed in the ionosphere by high-latitude radars and can be inferred from magnetometer measurements. Solar wind—magnetosphere coupling is thus greatly enhanced at times when the interplanetary magnetic field is Southward.

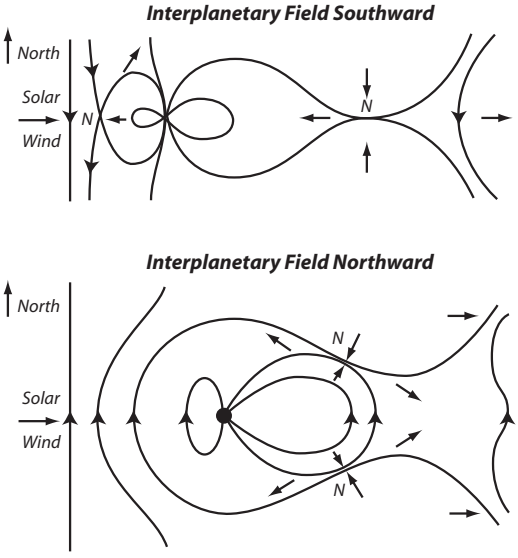

FIGURE 22.9 Dungey's original 1961 cartoon suggesting the reason for the association of greater geomagnetic activity with southward interplanetary magnetic fields Southward interplanetary fields can reconnect or merge with the Earth's dipole field at the dayside magnetopause. Another reconnection in the magnetotail returns the Earth's opened fields to their original "closed" state, so that all of the Earth's field is not permanently opened by dayside reconnection. The process of reconnection drives magnetospheric circulation (see Figure 22.10) and is thus a means by which solar wind energy is transferred to the magnetosphere. *Reprinted figure with permission from Dungey (1961). Copyright 2005 by the American Physical Society.*

The physics of the reconnection or magnetic field merging process that results in this configuration change for Southward interplanetary fields is still a subject of intensive research. Because space is not a vacuum, simple superposition of the external (interplanetary) and internal (Earth dipole) fields is not a physically correct explanation. Somehow the solar wind plasma that carries the interplanetary field "frozen" into its flow must allow the field to merge with the magnetospheric field at the magnetopause when the two have antiparallel components. The interested reader is referred to the review by Drake and Shay (2005) for further details on current theories of magnetic field reconnection in space plasmas. When CME effects reach the Earth, the solar wind dynamic pressure incident on the magnetosphere can increase by an order of magnitude or more, primarily due to the compression of the ambient solar wind plasma by the driver or ejecta from the CME. The onset of this increase may be sudden if a leading shock is present. The solar wind magnetic field is also compressed with the plasma, and can become significantly inclined with respect to the Earth's equatorial plane. The ejecta fields are also highly inclined, and often strong and steady, or slowly rotating over intervals of about a day. Thus, larger than normal Northward and/or Southward interplanetary field components result from both passing segments of the disturbance. The magnetosphere's response to these disturbed heliospheric conditions includes increased compression of the dayside magnetosphere, sometimes to within a few Earth radii of the surface, and increased reconnection between the Earth's magnetic field and interplanetary field during the passage of the southward-oriented portions. The time-dependent nature of these boundary conditions can introduce additional complexity into the solar wind—magnetosphere coupling.

Resulting geospace consequences of CMEs are numerous and varied, as illustrated by Figure 22.11. The associated magnetospheric compression is accompanied by enhancements of the energetic radiation belt particles

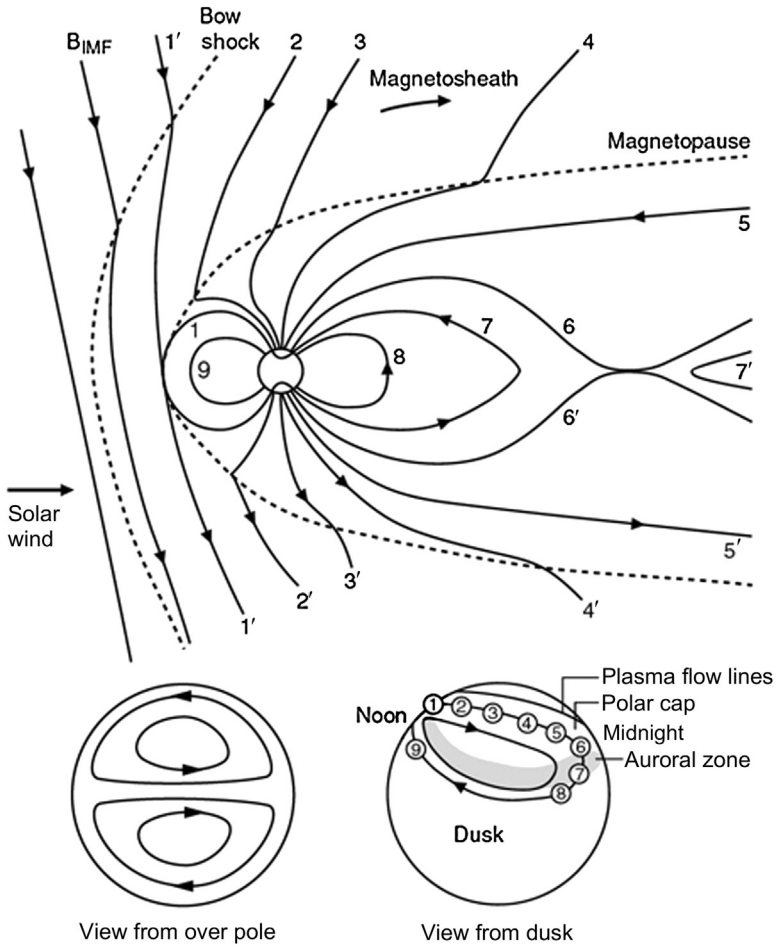

FIGURE 22.10 Illustration of magnetospheric circulation during periods of southward interplanetary magnetic field. Various key features of the solar wind interaction are shown, including magnetospheric field line connections to the interplanetary field, and their mapping to the high-altitude atmosphere. The numbers indicate a time sequence. The driven circulation occurs all the way down to the polar ionosphere as shown by the inset, which shows the dusk half of the double-celled ionosphere convection pattern. The aurora occurs mainly in the regions of convection reversals. *Kivelson & Russel (1995).*

trapped in the Earth's dipole field, due to a combination of inward diffusion and energization of the existing particle populations (see Planetary Magnetospheres). Solar energetic particles accelerated at the CME-driven shock or in associated solar flares can also leak into the magnetosphere along newly reconnected field lines at the magnetopause or along open field lines into the polar regions, as these particles tend to stream along field lines. Magnetic reconnection between the stretched out antiparallel fields in the magnetotail causes currents to flow through the high-latitude ionosphere. As magnetospheric charged particles move toward Earth with the field lines, they are accelerated in some cases by electric fields parallel to the magnetic field. These energized particles include electrons, protons, and other heavier ions. When they reach the upper atmosphere, they collide with neutral gases at altitudes of ~100 to ~200 km, causing ionization and excitation of atoms and molecules. The ionization enhances the flow of magnetosphere–ionosphere currents, and when the excited atoms and molecules decay back to their ground states they emit the light known as the aurora. (Further information about the aurora can be found in Section 3.)

Magnetotail reconnection also triggers injection of particles toward Earth at low latitudes that form a **ring current** at ~4 to ~7 Earth radii. In the polar regions, protons and ions, including ionospheric oxygen ions, O^+, are driven upward from the base of open field lines and flow into the magnetosphere, changing the composition of the magnetosphere and ring current ion populations. The ring current noticeably changes the magnetic field in the magnetosphere and at Earth's surface. Altogether these phenomena characterize a geomagnetic storm, whose magnitude is characterized by the ring current-related reduction of the field at the ground, defined by the index Dst. (Another index, Kp, is also used, but is more a measure of the auroral current systems.) Eventually, the magnetosphere and ionosphere return to their pre-storm states. Most effects are gone after a few days, but some trapped particle

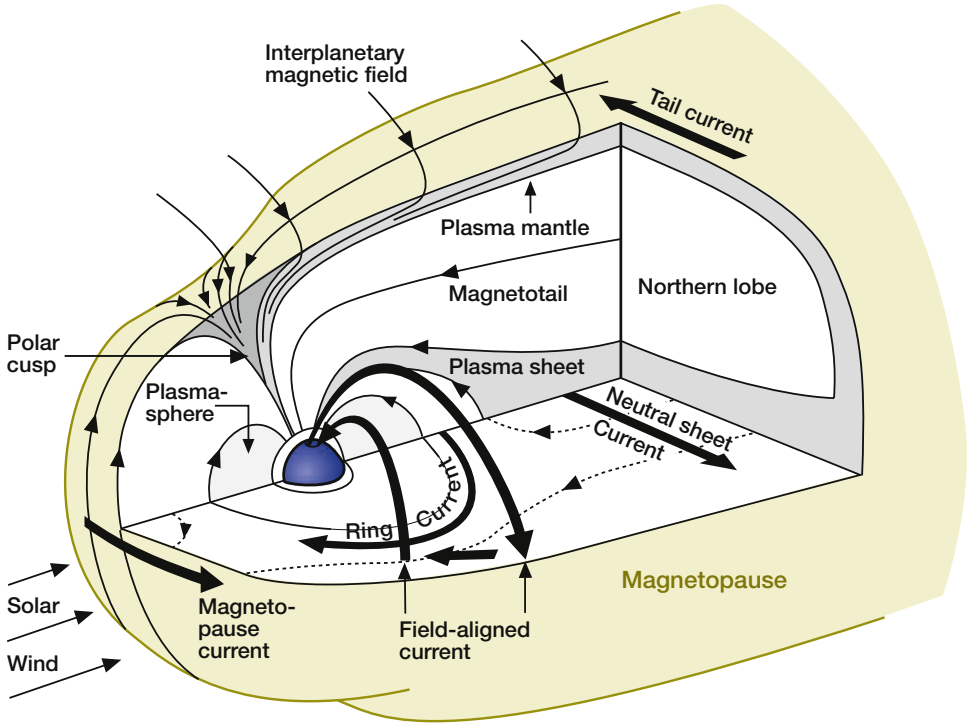

FIGURE 22.11 A more detailed illustration of the magnetosphere, showing further features mentioned in the text, such as the ring current and magnetotail current sheet. The plasmasphere is a region of denser, corotating magnetospheric plasma of ionospheric origin. The plasma sheet is a denser region of magnetotail plasma that participates in the physics of magnetotail reconnection and ring current formation (Rice University).

populations may last much longer. This complex geospace response to a CME has recently been simulated by several research groups using numerical models of geospace, with solar wind measurements defining the time-dependent boundary conditions on the magnetosphere. Some results from one of these models are illustrated in Figure 22.12.

There are also weaker, more frequent geomagnetic disturbances known as substorms. Substorms may occur during storms, as periodic enhancements of the storm−time geospace responses, or as stand-alone disturbances when the quiet interplanetary magnetic field has a southward component. In some cases they appear to follow a sudden change in the interplanetary north−south field component or a dynamic pressure pulse in the solar wind. Current ideas on the reasons for substorms, which have been debated for decades, include internal instabilities of the magnetosphere that occur in response to a variety of triggers. However, geomagnetic storms involve the largest episodic energy transfers from the solar wind, and are thus responsible for the strongest space weather effects.

3. ATMOSPHERIC EFFECTS OF SPACE WEATHER

The atmospheric responses to solar activity and its magnetospheric consequences are the closest counterparts of space weather to traditional weather. They are therefore of special interest to space weather research. Direct effects are largely confined to the thermosphere and ionosphere, above the mesopause at ∼90 km. They fall into two main categories: the effects of particles entering or "precipitating" into the atmosphere, and the effects of high-latitude ionospheric convection from magnetosphere−ionosphere coupling.

There are several types of precipitating particles: ∼1−20 keV auroral electrons, ∼10−100 keV ring current ions (protons and some oxygen ions), ∼1−10 MeV radiation belt electrons, and ∼1−100 MeV solar energetic particles (primarily protons). The more energetic the particles, the deeper they penetrate; the altitude ranges to which these various particles penetrate to deposit their energy are illustrated in Figure 22.13. As mentioned earlier, when these particles encounter atmospheric atoms and molecules, they cause impact ionization, and dissociate molecules into their atomic elements. They also excite bound electrons to unstable states, which then radiatively decay to produce photons with specific energies and thus wavelengths that give the aurora its colors. Chemical reactions caused by the interactions of ions with the dissociated and excited atomic products also excite particular emission features. The characteristic green and red auroral emissions at 557.7 and 630.0 nm are produced by the excitation of the upper atmosphere oxygen atoms; other auroral emission features in the blue and near-UV

spectral regions are formed from excitation of molecular nitrogen and its ion.

Most auroral emissions occur in an oval-shaped band just equatorward of the open field lines at high latitude, giving the auroral oval (shown in Figures 22.1 and 22.10) its name. Ring current ion precipitation can produce high-altitude red aurora at lower latitudes. In contrast, radiation belt electrons and solar energetic protons leave mainly chemical signatures. Along with other chemical by-products, all particle precipitation produces nitric oxide (NO) from molecular nitrogen dissociation. Very energetic particles can produce NO in the mesosphere (50–90 km) and even the stratosphere (15–50 km). Increases in NO affect ozone levels, because chemical reactions involving NO, ozone, nitrogen dioxide, and atomic oxygen form a catalytic cycle that reduces ozone. For some major solar proton events ~30% depletions of ozone in the mesosphere and upper stratosphere have been detected. While the reduction of mesospheric ozone does not have the biological impact of reductions in the denser lower stratospheric ozone, it can modify the temperature and thus the dynamics of the mesosphere. These alterations can in turn modify the transmission of energy from the stratosphere and troposphere to the upper atmosphere. Whether these effects have significant consequences for the lower atmosphere, especially over the long term, is unknown.

As noted above, the solar wind electric field within the open magnetospheric field regions at high latitudes typically stirs the polar ionosphere in a twin vortex pattern, illustrated in Figure 22.10. Ionospheric ions and electrons are dragged antisunward over the polar caps, and then forced into a return flow at lower latitudes. The differential motion of the ions and electrons caused by the interplay between ion–neutral collisions and the electric and magnetic fields that control their motion leads to an ionospheric current. This auroral electrojet current has a strength dependent on the combination of the solar wind electric field and the level of ionization in the auroral ionosphere. Collisional dissipation or friction within the volume occupied by the electrojet heats the auroral zone atmosphere. This resistive "joule" heating results in large density perturbations called auroral gravity waves in the upper atmosphere. These travel equatorward, in some cases depositing significant energy and modifying upper atmosphere circulation globally. Traveling ionospheric disturbances are one manifestation of the passage of these waves. Magnetic field perturbations associated with the time-varying electrojet current and the ring current mentioned earlier are detected on the ground, giving the geomagnetic storm its name. A particular geomagnetic index called AE is a widely used measure of the level of ground magnetic field modifications by the auroral electrojet currents.

Solar and magnetospheric events are not the only source of space weather in the thermosphere–ionosphere system. Wave motions and atmospheric tides propagating upward from the lower and middle atmosphere have important effects on the ionosphere, and contribute to its variability

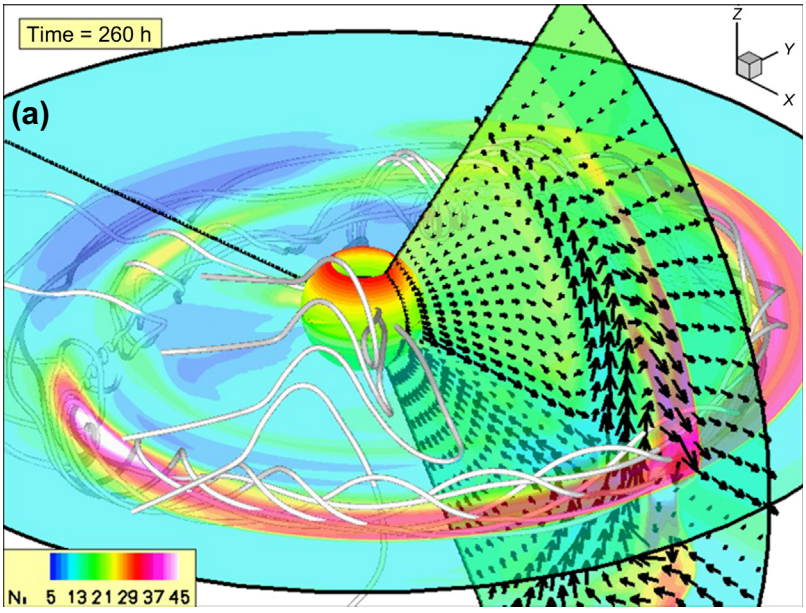

FIGURE 22.12 (a) Results from a numerical simulation of a CME, showing the distortion of the interplanetary plasma density (contours) and magnetic field (white lines) as it travels toward the Earth. even when the external space environment is very quiet. An important mechanism of atmospheric influence on the ionosphere is change in the global electric field, especially at low latitude, where atmospheric tides drive high-altitude winds that in turn generate currents in the ionosphere. Meteorological events in the troposphere—conventional weather—can disrupt these winds and currents. The turbulence above storms and frontal systems is also transmitted to high altitude, where it can alter the composition of the thermosphere and subsequently the structure of the ionosphere. These effects from the coupled atmospheric system are now recognized as an important component of space weather effects near the Earth.

4. PRACTICAL ASPECTS OF SPACE WEATHER

Space weather is a complex and fascinating physical system that also has many practical consequences. Society is increasingly dependent on space-based telecommunications and satellite systems that monitor tropospheric weather, global resources, and military activity. The satellite environment is part of the design of these spacecraft, which can suffer radiation damage to electronics if the extremes they may encounter are not taken into account. Satellite orbits are affected by drag as they pass through the upper thermosphere, where changes in density caused by EUV radiation and geomagnetic storms affect their tracking and lifetime. This is particularly true of large, relatively low-altitude vehicles such as the Hubble Space Telescope and the International Space Station. In addition, satellite orientation controls often rely on Earth's magnetic field, which can be highly variable during geomagnetic storms. Changes in the ionosphere disrupt radio communications by changing ionospheric transmission or reflection characteristics. GPS navigational signals, which pass

through and are altered by the ionosphere as they are transmitted from very high-altitude satellites to ground receivers, can degrade during disturbed conditions, giving inaccurate locations. On the ground, currents induced in power system transformers and in oil pipelines by storm-related magnetic field perturbations respectively lead to overload and corrosion.

In the era of human space flight, there is also great concern over space radiation hazards from energetic particles. Manned vehicle orbits at low latitude and low altitude are largely protected from the radiation belts and the less common but potentially dangerous major solar energetic particle events. However, the orbit of the International Space Station is sufficiently inclined with respect to Earth's equator that it is occasionally exposed to solar energetic particles at high latitudes, when the magnetosphere is disturbed as it often is during solar particle events. Astronaut radiation exposure is carefully monitored and is limited by NASA. To minimize it, plans for extravehicular activities take into account conditions on the Sun and the likelihood of a major solar event that might affect the Earth. Even commercial and military aircraft on polar routes monitor major solar events as a precaution. For future space travel outside of the effective but imperfect magnetospheric shield, protection from solar particle radiation is a major problem to be solved.

In response to both international civilian interests and military needs, the National Oceanic and Atmospheric Administration (NOAA) runs a Space Environment Center (SEC) that collects, analyzes, and distributes information on the Earth's space environment and solar activity. Space weather reports are regularly issued via the Internet (swpc.noaa.gov), where one can also find access to the archives of solar, heliospheric, magnetospheric, and upper atmosphere/ionosphere data that are used. Customers of these services seek information on subjects ranging from interference to radio transmissions by solar radio bursts or ionospheric scintillations, to satellite orbit decay rates based on solar EUV emission intensities. Alerts are posted when a forecaster interprets behavior in the relevant data to mean a solar energetic particle event, geomagnetic storm, or ionospheric disturbance will occur within the next minutes to days. One of the most useful geomagnetic storm forecasting methods takes advantage of the SOHO spacecraft, which allows the forecaster to identify CMEs and the location of active regions on the solar disk. When a CME is headed toward Earth, it sometimes appears in the SOHO coronagraph images as a ring around the Sun called a halo CME. These events are known to have an increased probability of causing a geomagnetic storm. However storm forecasts are still extremely difficult, with false alarms a major problem. For example some halo CMEs are actually heading away from the Earth, having originated on the far side of the Sun, while others have ejecta that are deflected away from Earth enroute or include mainly northward magnetic fields that are not particularly "geoeffective".

Geomagnetic indices, calculated from ground-based measurements of magnetic field perturbations, are routinely used as a measure of the level of space weather disturbance. Different indices emphasize particular Earth responses depending on how and from what stations they are calculated. Several of these were mentioned above. The auroral electrojet index AE is primarily a measure of auroral zone ionospheric currents obtained from high and mid-latitude monitors, while the ring current index Dst is mainly a measure of the ring current obtained at lower latitudes. The planetary index Kp uses ground stations in both regions. These indices were developed and have been recorded since before the space age. They are used to both parameterize empirical models (e.g. of the auroral zone ionosphere), and maintain a continuous long-term historical record of space weather in concise form.

A major goal of space weather research today is a physics-based model of the coupled heliosphere–magnetosphere–upper atmosphere/ionosphere system, including CMEs. Such a model could provide both a forecast tool for space weather events based on solar observations and a numerical experiment framework to gain greater insight into the physics of the coupled system and its extremes. For example, severe space weather events are occasionally observed, but even larger events have been inferred from records of the Earth's historical cosmic ray exposure present in ice cores. What is the worst that could happen to our planet and space assets after one or more of these greatest of solar activity episodes? It is an intriguing question. As a practical matter, the plan to again send humans into deep space, to the Moon and to Mars, also renews the concerns of space radiation hazard issues faced to a lesser degree on the International Space Station. The unpredictability of CMEs, and the fact that historically the strongest space weather events have not been at solar maximum, helps motivate applied space weather research.

For many decades there has also been research on and discussion about the connection of solar activity and Earth's climate. It is possible that the very small changes in total solar irradiance, the so-called solar constant, or changes in UV radiation can have measurable climatic effects. It is also possible that some Sun Earth connection-related phenomena can reach the troposphere. One highly cited example is the coincidence of the Maunder Minimum in solar activity with the Little Ice Age in Europe during the fifteenth to sixteenth centuries. Ideas on how nonradiative effects might play a role include mechanisms such as cloud–cover alteration by low-altitude ionization effects of energetic cosmic rays reaching Earth (Tinsley, 2000). The Maunder Minimum climate change has also inspired speculation about the climatic and other consequences of geomagnetic field reversals. Analyses of ice age records

and geomagnetic field reversals have as yet produced no definitive results, although it may be significant that the Earth's field still maintains an important higher order harmonic component (e.g. a quadrupole moment) during reversals.

5. IMPLICATIONS FOR PLANETARY ASTRONOMY AND ASTROPHYSICS

Space weather, and the physics it encompasses, is often invoked in the planetary sciences in connection with solar wind interaction issues. Our knowledge of the solar wind coupling to the Earth's magnetosphere and upper atmosphere is far greater than our comparable knowledge for any other planet due to both the wealth of available observations and the efforts that have been put into their interpretation. Planetary spacecraft found that there are magnetospheres around Mercury, Jupiter, Saturn, Uranus, and Neptune. Mars does not have a strong dipolar internal field, but it has patchy crustal magnetism that makes a rather unique obstacle to the solar wind. Venus has essentially no planetary field and thus represents another extreme contrast in solar wind interaction styles. One of the main goals of the Messenger mission to Mercury is to better observe the magnetosphere there in terms of its response to solar wind conditions, and its particle content and dynamics. Mercury has no substantial atmosphere or ionosphere; so it represents an interesting contrast to Earth that may tell us more about the atmosphere's role in space weather. In addition, the relative strengths of its internal field close to its surface and the local interplanetary field are more comparable than Earth's, making the coupling of these two fields particularly close. Mercury may represent an example of a strongly driven planet−solar wind interaction. Jupiter's giant magnetosphere was found by the Galileo spacecraft to be dominated by the internal mass content contributed by the volcanic satellite Io. Similarly, Saturn's magnetosphere, currently under scrutiny by the Cassini Orbiter, also seems to have an important internal mass source in its satellite Enceladus. The auroras at both these planets thus have different reasons than Earth's for occurring where and when they do. Torques provided by the internally produced heavy ions seem to exert considerable control over the magnetospheres' dynamics compared with the external conditions in these cases. The comparative analysis of planet−solar wind interactions and the related atmospheric effects is extremely valuable for achieving maximum understanding from necessarily limited planetary data.

In the world of astrophysics, extrasolar planetary system research strives to infer from poorly resolved observations the details of individual planets. One possibility for remote sensing is provided by the stellar wind interaction with the planets, which may produce detectable emissions from the planetary atmospheres. To be useful, these emissions must be interpretable in terms of familiar examples in our own solar system. Of particular interest is the detection of Earth-like planets. There are a range of possible remote signatures for applications to these "origins" investigations. Similarly, the identification of the effects of stellar winds around other stars is enabled in part by our own heliospheric experience. The interaction of the stellar wind and the surrounding interstellar medium produces a feature like the magnetosheath that is remotely detectable in Lyman-alpha emission. Some stellar outbursts suggest the occurrence of CMEs, and the associated space weather around remote worlds.

Finally, fundamental astrophysical processes are involved in energetic particle acceleration as well as in magnetic reconnection. Much of what has been learned about particle acceleration at shocks in plasmas has come from the analysis of the observations from the region around the Earth's bow shock. Similarly, reconnection processes at the magnetopause and in Earth's magnetotail have been examined using spacecraft data from both single spacecraft and small constellations. These difficult observations of a dynamical and nonuniform space plasma system with many scales are slowly yielding information about the process that suggests that it occurs when and where electrons are no longer controlled by the magnetic field. In addition, numerical simulations have been carried out using fluid, kinetic (particle), and hybrid (mixed particle and fluid) codes to shed light on the microphysics of how oppositely directed magnetic fields in space plasmas undergo major topological changes. Laboratory work has also contributed to these investigations, all under the umbrella of space weather research.

6. EPILOGUE

The phrase "space weather" is used to describe the physically rich and dynamic system by which processes at the Sun affect near-Earth space via other than the solar constant radiative emissions. It is necessary to use a combination of theory, measurements and modeling to study the system components: the heliosphere, the magnetosphere, and the upper atmosphere and ionosphere, to learn how they are coupled. As described above, the couplings are numerous and diverse. They are sometimes subtle like cosmic ray effects on clouds, and sometimes overt like CMEs and the related topological changes reconnection imposes on the magnetosphere in response to their associated large southward oriented interplanetary magnetic fields. The consequences of these couplings are only partly understood. Practical applications of space environment knowledge are in the meantime growing in popularity and demand. Other fields are beneficiaries of the planetary and astrophysical "laboratory". And in an era of new human

Exploration Initiatives, and a society increasingly dependent on space-based technologies, space weather may one day become part of the weather report on your local news.

1. INTRODUCTION

The Moon is the single most important planetary body for understanding not only Earth but also all **terrestrial planets** in our solar system in terms of planetary processes. Building on earlier telescopic observations, our knowledge about the Moon was drastically expanded by the wealth of information provided by Apollo and other missions of the 1960 and 1970s, as well as several recent space missions, including Smart-1, Chandrayaan, Chang'e 1-3, the Selenological and Engineering Explorer (SELENE (Kaguya)), the Lunar Reconnaissance Orbiter (LRO), the Lunar Crater Observation and Sensing Satellite (LCROSS), the Gravity Recovery and Interior Laboratory (GRAIL), and the Lunar Atmosphere and Dust Environment Explorer (LADEE).

Telescopic observations from the Earth, observations by spacecraft from lunar **orbit**, measurements on the lunar surface by manned and unmanned landed missions, the analyses of lunar samples including those returned by the Apollo and Luna missions, and lunar **meteorites** found on the Earth are important sources of information that were used to develop and test various hypotheses and models that were subsequently applied to other terrestrial bodies. Remote sensing using passive sensors in the optical wavelength range, as well as active laser and radar measurements supported by in situ field work, allow the entire lunar history to be studied with respect to its impact-related, volcanic, tectonic, and space weathering evolution. Spectral measurements in all wavelength ranges from high-energy **gamma rays** to mid-infrared provide the overall surface composition and major mineralogical content of **rocks**, whereas geochemical details and the origin, **differentiation**, and evolution of the lunar rocks have been deduced from the returned samples and geophysical data. The vast amount of knowledge gained from samples brought to the Earth by the Apollo and Luna missions and the lunar meteorites and the in situ geophysical measurements made by the Apollo Lunar Surface Experiment Packages demonstrate how valuable the Moon is for understanding our solar system. Today, the Moon is unique in that we have a rich data set for geology, geochemistry, mineralogy, petrology, chronology, and internal structure that is unequaled for any planetary body other than the Earth. These data are crucial for understanding planetary surface processes and the geologic evolution of a planet. They are also essential for linking these processes with internal and thermal evolution. Because the Moon's surface has not been affected by plate recycling, an atmosphere, water, or living organisms, the Moon recorded and preserved evidence for geologic processes such as impact cratering, magmatism, and tectonism that were active over the past 4.5 Ga and offers us the unique opportunity to look back into geologic times for which evidence on Earth has already been erased. Thus, the Moon is the Rosetta stone for understanding the fundamental processes that drive planetary formation and evolution.

With respect to impact processes, the Moon allows us to study, for example, the depths of excavation, the role of oblique impact, modification stages, composition and production of **impact melt**, **ejecta** emplacement dynamics, and the role of **volatile** element addition. The lunar samples returned from known geological units provide the calibration of crater size–frequency distribution chronologies for the entire solar system. These data are important for further understanding the importance of impact cratering in shaping planetary **crusts**, particularly early in solar system history. For example, crater counts indicate that the impactor flux was much higher in the early history of the Moon, the period of the "heavy bombardment", which lasted until ~3.8 Ga ago.

The Moon also allows us to study planetary magmatic activity in an unobscured form, that is, without the influence of plate tectonics, an atmosphere and associated erosion, and biological activity. We have detailed knowledge of many aspects of lunar volcanism (extrusion) and to a lesser amount of plutonism (**intrusion**) and can assess the role of magmatism as a major crust building and resurfacing process throughout the Moon's geologic history. For example, the ages, distribution, and volumes of volcanic materials indicate the distribution of **mantle** melting processes in space and time. In addition, the detailed magmatic record coupled with the samples permit an assessment of the processes in a manner that can be used to infer similar processes on other planets. The sample-based and remote sensing data reveal the role of magmatic activity during the heavy bombardment (intrusion, extrusion) and more recently in lunar history, the **mare** stratigraphic record, the distribution of **basalt** types, and the implied spatial and temporal distribution of mantle melting. Stratigraphic information and crater ages also provide an emerging picture of volcanic volumes and fluxes. In addition, the Moon allows us to assess a wide range of eruption styles, including **pyroclastics**, and their petrogenetic significance, owing to the existence and preservation of a diverse suite of volcanic deposits.

The Moon is also a type locality for tectonic activity on a one-plate planet. Tectonic processes and tectonic activity can be understood in the context of the complete lunar data set, including the internal structure and thermal evolution. **Graben** illustrate deformation associated with **mascon** loading, and **wrinkle ridges** appear to document the change in the net state of **stress** in the **lithosphere** from initially extensional to contractional in early lunar history. Finally small-scale scarps formed by thrust faulting probably indicate a global change in diameter and can be linked to the lunar thermal evolution, i.e., the cooling of the planetary body.

In summary, the Moon is a complex differentiated planetary object and much remains to be explored and discovered, especially regarding the origin of the Moon, the history of the Earth–Moon system, and processes that have operated in the inner solar system over the past 4.5 Ga. The Moon remains an extremely interesting target scientifically and technologically because although the current data have helped to address some of our questions about the Earth–Moon system, many questions remain unanswered. Returning to the Moon is therefore the critical next stepping-stone to further exploration and understanding of our planetary neighborhood.

In this chapter, we first discuss the astronomical aspects of the Moon, including its orbit, eclipses, and **librations** (Section 2). We briefly review the Moon's physical properties (Section 3), followed by the description of the latest understanding of the origin of the Moon (Section 4), and

the formation of the magma ocean and its related processes (Section 5). In the succeeding sections, we start with the interior and move outward to the exterior (i.e., the surface), ending with a description of the lunar atmosphere/exosphere. For example, Section 6 deals with the interior of the Moon, specifically seismicity, gravity, magnetic field, and the thermal evolution, while Section 7 describes the lunar crust and its terranes. In Section 8, we provide a review of lunar rock types, including highland rocks, the magnesian-suite rocks, mare basalts, and impact **breccias**. In Section 9 we describe the lunar surface, which is characterized by impacts, volcanism, tectonism, space weathering, erosion, and degradation. Section 10 provides information on the stratigraphy and surface ages. Here, we introduce the reader to the lunar stratigraphy, the **late heavy bombardment (LHB)**, the methods of age determination, and the age record of lunar maria. The thickness of the **regolith**, as well as its properties and sources, are discussed in Section 11. Section 12 provides detailed information on the geology of the Apollo and Luna landing sites and Section 13 discusses the significance of the landing sites for the interpretation of global data sets. The recent identification of lunar volatiles in samples and remote sensing data merits a separate section (Section 14). Finally, the lunar atmosphere and environment are presented in Section 15. In the bibliography section, we point the reader to seminal papers on various aspects of lunar research.

2. THE ORBIT OF THE MOON

2.1. General Characteristics

As seen from a north polar orientation, the Moon revolves counterclockwise around the Earth, as the Earth and the other planets do around the Sun. Moving at a velocity of 1.03 km/s along a slightly elliptical orbit ($e = 0.0549$), it takes the Moon on average 27.32166 days to revolve around the Earth (sidereal period). Because the Earth also moves along its own orbit, the synodical period of the Moon, i.e., the time between successive new moons, is longer (29.5306 days). The lunar rotation slowed down early in its history owing to tidal friction associated with deformations and became locked into a synchronous state, orienting the Moon such that the same hemisphere faces the Earth at all times. Besides locking the Moon into a **synchronous orbit**, tidal effects cause the Moon to recede from Earth at 3.79 cm/year. With respect to the ecliptic, the orbit of the Moon is inclined by 5.15°; however, the orientation of its rotation axis is tilted only 1.53° with respect to the ecliptic pole (Figure 23.1). The **inclination** of the lunar orbit to the equatorial plane of the Earth varies between 18.4° and 28.6°. On average, the Moon is 384,400 km from the Earth, which corresponds to about 60 Earth radii. However, due to the **eccentricity** of its orbit, this distance varies from 363,000 km at **perigee** to 406,000 km at **apogee**.

2.2. Lunar Phases and Eclipses

Over the course of a month, the appearance of the Moon undergoes regular changes, the so-called lunar phases. These phases are caused by the amount of illuminated lunar surface visible from Earth and thus depend on the relative orientation of the Sun, the Earth, and the Moon. Starting from new Moon when the Moon is not visible in the sky, the Moon appears to grow (wax) every night and is visible as a crescent. One week after new Moon, half of the lunar disk is visible, known as quarter Moon. During the next week, the Moon goes through the gibbous waxing phase. Two weeks after new Moon, the Moon is completely illuminated (full Moon) because the Sun and the Moon are in opposite directions from the Earth. During the next 2 weeks, the Moon appears to shrink (wane), passing through the gibbous, quarter, and crescent waning phases until it eventually becomes new again.

In rare occasions, the Sun, the Earth, and the Moon line up precisely to cause eclipses. If the Moon and the Sun are exactly in opposite directions, the Earth's shadow darkens the Moon to cause a lunar eclipse. Such lunar eclipses usually last for less than 100 min, occur typically twice a year, and can either cover the entire Moon or parts of it. If the Moon and the Sun are exactly in the same direction, the Moon casts a shadow onto the Earth, causing a solar

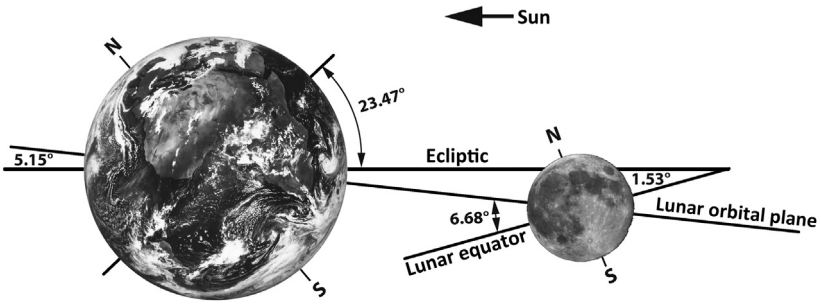

FIGURE 23.1 The orbit of the Moon. *From Hiesinger and Jaumann (2014).*

eclipse. Such solar eclipses are possible because the angular diameter of the Moon (29.3−34.1′) is close to the angular diameter of the Sun (31.6−32.7′) as seen from Earth. Consequently, the Moon can block our view of the Sun either completely or partially, resulting in total, partial, or annular eclipses.

2.3. Librations and Tidal Forces

The Moon is in **synchronous rotation** with respect to the Earth, i.e., it is in a 1:1 spin−orbit coupling. However, because of the orbital eccentricity of $e = 0.0549$ and the resulting variation of the Moon's orbital angular velocity along its elliptic trajectory around the Earth, exact synchronism is given only at two points along the orbit. Near perigee, the rotational angular velocity lags behind the orbital angular velocity, whereas near apogee, the opposite occurs. This situation causes geometric (sometimes called optical) librations in longitude of about ±8.6°. The inclination of the Moon's orbit with respect to the ecliptic plane causes latitudinal librations of about 6.9°. These geometric librations mean that we can actually see about 60% of the lunar surface from the Earth. Geometrical librations cause librational tides that are essential for the dissipation of orbital energy within the Moon. Radial tides also occur owing to the variation of the Earth−Moon distance because of the elliptical orbit.

Constraints on the rate of dissipation by tidal friction in lunar rocks are essential for calculating the long-term evolution of the lunar orbit. Tidal dissipation in the Moon tends to decrease the orbital eccentricity and the **semimajor axis**, whereas tidal torques exerted by the Earth tend to increase the Moon's orbital eccentricity and semimajor axis. Although lunar tides only contribute about 1% to the Moon's orbital acceleration, they do significantly contribute to changes in eccentricity. Better constraints on the current dissipation of tidal energy in the lunar interior are needed to fully understand the present orbital state of the Moon and the long-term orbital evolution of the Earth−Moon system.

The dissipation rate and thus the orbital evolution are closely connected to the thermal state of the lunar interior. The presence of partial melt in the deep lunar interior significantly enhances the dissipation rate and is consistent with the orbital characteristics of the Moon. Important clues on the constitution of the lunar interior can be gained by monitoring tidally induced surface deformation from orbiting and landed spacecraft, and Earth-based, highly precise lunar laser ranging observations. In addition to the Apollo lunar seismic data record, these observations provide useful constraints on mantle elasticity and size, as well as composition and physical state of a lunar **core**. The Moon is subject to physical librations because of the tidal contribution to its permanent equatorial bulge. These tidal effects are periodic variations of the Moon's rotation rate caused by torques exerted by not only the Earth but also other planetary bodies and the Sun. In addition to the free librations that depend only on the ratio of the Moon's moments of inertia, there are various forced librations that do depend on the frequency of the external forcing. Examples of forced periods are the 1-year period caused by the Sun, a 3-year period that is in resonance with the free libration period of 2.89 years, a monthly period caused by the Earth, and a 273-year term that arises from perturbations by Venus. The amplitudes of the physical librations are on the order of several tens of **arc seconds** and are thus significantly smaller than variations in longitude caused by geometrical librations. However, physical librations have a significant effect on the dissipation of energy inside the Moon.

3. PHYSICAL PROPERTIES

Within the solar system, Earth and Moon form a unique celestial system with a common center of mass. Although the large moons of Jupiter and Saturn have similar masses, the satellite/parent ratio is the largest for the Earth-Moon system—with respect to its own mass no other planet has such a large moon in orbit. With a radius of 1738 ± 0.1 km, the Moon is the fifth largest satellite in the solar system and has a surface gravity of 1.622 m/s^2, about 17% of that on Earth. Its surface area is less than one-tenth that of the Earth's surface; its volume is about 2%, and its mass is only 1.2% that of the Earth. The lunar bulk density is 3.344 ± 0.003 g/cm^3 and is considerably smaller than the bulk density of the Earth (5.52 g/cm^3). The moment of inertia is 0.3932 ± 0.0002 and indicates a small increase in density with depth. The spin **angular momentum** of the Earth−Moon system is high compared to that of Mars and Venus, which has been interpreted as evidence for some process or event such as a large impact that spun up the system.

4. ORIGIN OF THE MOON

The origin and formation of the Moon is still debated and is one of the key scientific questions because the associated conditions and processes have profound implications for both the initial thermal state of the Earth and the Moon, and for their subsequent thermal and magmatic evolution. There are also major questions about the specific implications for the Earth−Moon system with respect to the uniqueness of Earth, such as why is the Earth the only terrestrial planet with a large moon and what are the gravitational influences on the origin and evolution of life and on the stability of Earth's climate? Prior to the Apollo program, models attempted to explain the origin of the Moon by **accretion** or condensation along with the Earth as a double planetary system, by fission from a rapidly

rotating Earth, or by capture by the Earth of a body that formed elsewhere in the solar system. However, all these models fail to explain modern observations. For example, the coaccretion model is inconsistent with the angular momentum of the two bodies and their contrasting densities. Similarly, the fission model cannot account for the orbital dynamics of the Earth–Moon system and would require unrealistically large tidal forces to extract the Moon. Finally, the capture model proposed that elsewhere in the solar system a cool and relatively undifferentiated Moon was formed with a composition similar to chondritic meteorites and was captured by the Earth's gravity. However, the samples of the Apollo and Luna missions demonstrated that the Moon is not the source of **chondrites** because it is not a primitive body; it is differentiated. Furthermore, dynamical considerations argue against the capture model.

Important constraints for the formation of the Moon are its bulk composition, particularly its depletion in metallic iron (i.e., small core), the low abundances of volatiles, and the high angular momentum of the Earth–Moon system. Such constraints are best explained by a giant collision of the proto-Earth with a large object in early solar system history. This Mars-sized object, like the proto-Earth, must have already differentiated, with the iron and siderophile elements concentrated in the core. Following the collision, most of the dense material was incorporated in the Earth's mantle and core, while the outer portions of the impactor and the crust and upper mantle of the Earth were ejected into Earth orbit where the material reaccreted to form the Moon (Figure 23.2). Much work is currently aimed at understanding the chemical and isotopic **fractionations** that would accompany the giant impact and subsequent accretion of the Moon from a hot disk. Comparison of model results to measured chemical and isotopic signatures of lunar materials is a key area of ongoing work, especially in light of recent determinations of lunar indigenous H contents and stable isotope fractionation (or lack thereof) for volatile elements such as K and Zn.

Although the giant impact hypothesis is widely accepted in the scientific community, it is not perfect. For example, numerical simulations indicate that lunar accretion might be relatively inefficient in that only 10–55% of the ejected material would be available for the formation of the Moon. These simulations imply that much more than one lunar mass must be ejected into orbit by the collision. Furthermore, simulations of lunar accretion predict that the initial inclination of the lunar orbit relative to the Earth's equator had to be about 1°, whereas orbital reconstructions indicate that the initial inclination was at least 10°. In addition to uncertainties concerning the distribution of ejecta in the circumterrestrial disk from the giant impact, there are also uncertainties about the amount of time required for the disk to evolve between the giant impact and the onset of accretion.

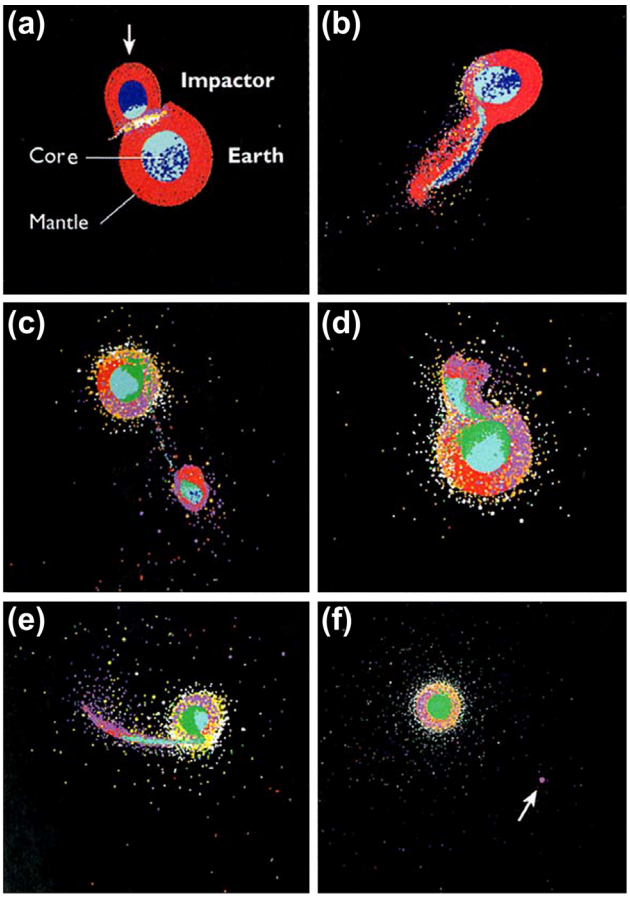

FIGURE 23.2 Mathematical simulation of the giant impact hypothesis. The model demonstrates the feasibility of the formation of the Moon by the oblique collision of a Mars-sized object with proto-Earth (a). The giant impact ejected crustal and mantle material (b–e), which later accreted to the Moon (f, white arrow). © *Alastair Cameron, Harvard-Smithsonian Center for Astrophysics and Sky Publishing.*

In summary, whether the giant impact hypothesis is capable of accurately explaining the origin of the Moon is an area of continuing investigation. However, increasingly sophisticated numerical models demonstrate that a giant impact can eject sufficient mass into Earth orbit, which accretes very quickly to form the Moon, consistent with observed orbital and compositional properties. Hence, these new numerical models strongly support the giant impact hypothesis.

5. THE MAGMA OCEAN

Geochemical evidence suggests that large parts of the Moon were initially molten to form a magma ocean (Figure 23.3) (see Chapter 8). Energy release associated with the giant impact and accretion that formed the Moon produced large-scale melting, accompanied by density segregation of crystals from the melt and the formation of a low-density, plagioclase-rich crust. While the details of the

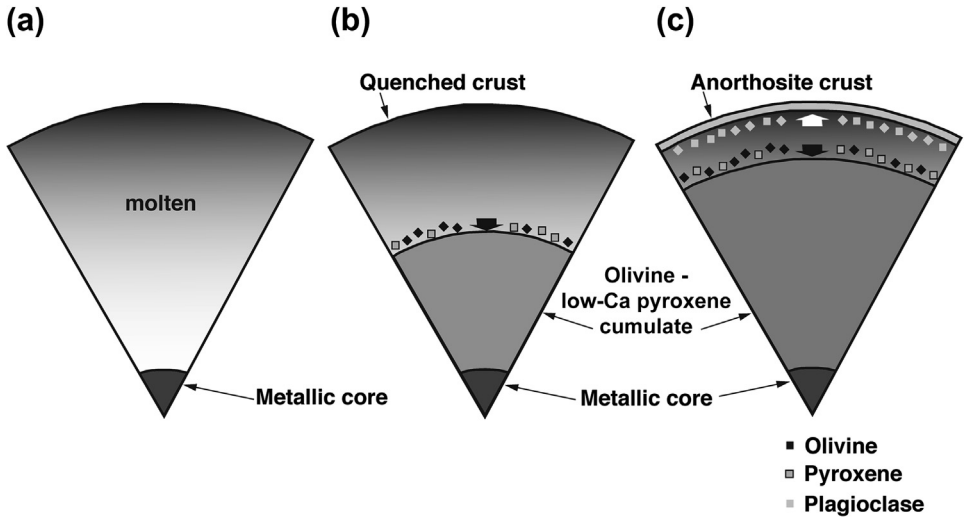

FIGURE 23.3 Schematic cross-section through the magma ocean at three different times. As the molten Moon (a) crystallized, minerals denser than the magma sank to the bottom (b). Eventually, the lighter minerals floated to the top of the magma ocean to form the primary anorthositic crust of the Moon (c). © *http://www.psrd.hawaii.edu/Aug11/LMO-crystallization.html*.

crystallization of such a magma ocean are still under debate, a likely scenario is that crystallization of olivine and orthopyroxene resulted in **cumulates** in the deeper parts of the magma ocean because they were denser than coexisting melt. As early Fe- and Mg-rich **minerals** crystallized, the melt became richer in Al and Ca, resulting in crystallization of plagioclase after about 75–80% solidification. Plagioclase had a lower density than the melt and thus accumulated upward to form the anorthositic highland crust (Figure 23.3). Rare earth element (REE) patterns of crustal rocks show the effect of crystallization of plagioclase-rich cumulates in their strongly positive Eu anomalies and low trivalent REE concentrations, and corresponding enrichment of REE^{3+} relative to Eu in the late-stage magma ocean melt (Figure 23.4). As the crystallization of the magma ocean continued, KREEP (rocks rich in K, P, and REEs) was eventually produced. The distribution of this KREEP was globally asymmetric as shown by the concentration of thorium on the lunar nearside, as determined from orbital remote sensing. The lunar samples suggest that the crystallization of the main phases of the magma ocean was probably completed by about 4.4 Ga ago and that the KREEP residue was solid at about 4.36 Ga ago (Figure 23.5). In summary, evidence for the existence of a lunar magma ocean and its fractional crystallization comes from the anorthositic flotation crust, the ages of crustal rocks, and trace elements in several suites of rocks, including KREEP formed by high degrees of fractional solidification.

Crystallization models predict that the cumulate mantle that results from solidification of a magma ocean is gravitationally unstable, with later-formed, Fe-rich and therefore denser cumulates overlying less dense, early formed

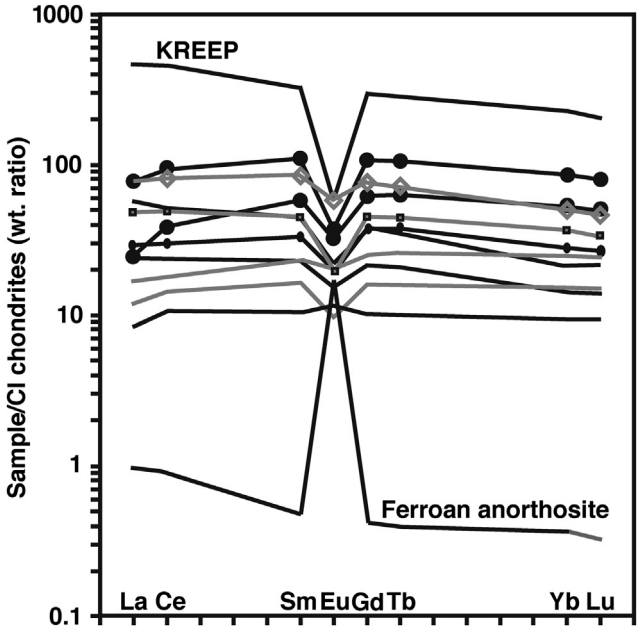

FIGURE 23.4 Chondrite-normalized REE concentrations in mare basalts, KREEP, and a representative ferroan anorthosite. *From Warren. (2003).*

Mg-rich cumulates. Geophysical models predict that the development of such instability and the overturn of the cumulate mantle might deliver cold, dense, incompatible-element-rich material to the core–mantle boundary. In these models, this situation may cause a core flux that was sufficient to drive an early magnetic **dynamo** and may have produced a long-lived dense layer at the core–mantle boundary that presumably did not (and does not) participate

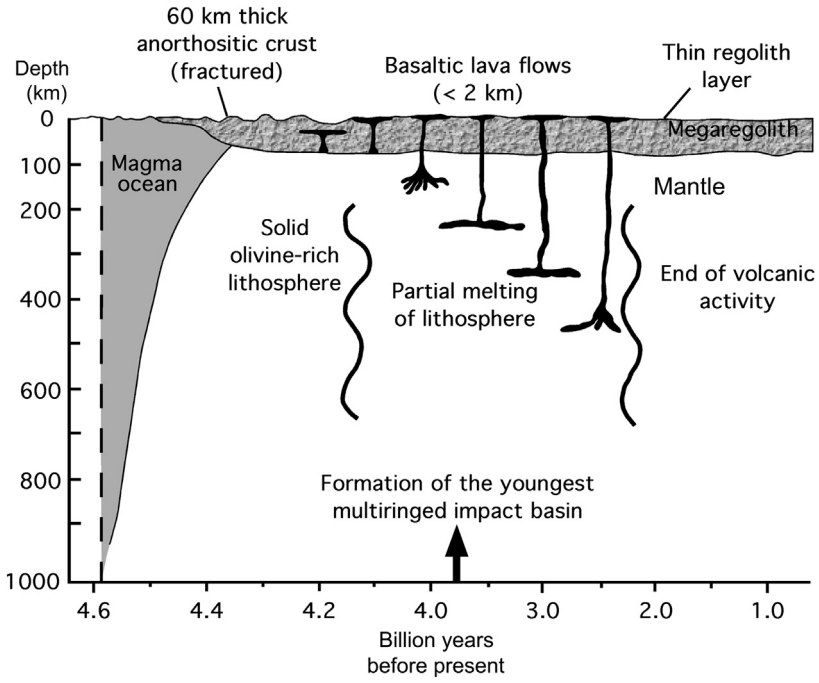

FIGURE 23.5 Evolution of lunar magma ocean, crust, and mantle as a function of time. The simplified geological cross-section of the outer 1000 km of the Moon illustrates the early formation of an olivine-rich residual mantle and plagioclase-rich flotation crust by fractional crystallization of the magma ocean and the simultaneous impact brecciation of the crust to form a megaregolith and a regolith. Later, partial melting of the mantle results in the formation of chemically distinct basaltic lavas due to mineralogical zoning of the mantle established about 4.3 Ga. Finally, volcanic activity ceases while regolith formation due to impacts continues. Timescale not linear. *From Hiesinger, H. & Head, J.W., III. (2006).*

in thermally driven **convection**. Simultaneously, hot rising **diapirs** may have melted **adiabatically** to produce the first basaltic resurfacing crust of the Moon.

6. THE INTERIOR OF THE MOON

The lunar interior is key to better understanding the formation, differentiation, and evolution of the early solar system, in general, and the Earth–Moon system, in particular. Seismic and remotely sensed data, as well as the lunar samples, suggest that the Moon differentiated into a crust, mantle, and possibly a small core (Figure 23.6). The formation of a global low-density crust coupled with a lack of prolonged and significant heating in the interior led to the absence of plate tectonics on the Moon, and a predominantly conductive cooling through the low-density crustal layer. Accordingly, the Moon has a globally continuous lithosphere (crust plus rigid part of mantle), i.e., it is a one-plate planet.

The low mean lunar density of 3344 kg/m^3 indicates that the Moon has only a small iron core compared to that of Earth or any other terrestrial planet. Geophysical data suggest that the central portion of the Moon is molten and might have a solid inner core. The core has a high electrical conductivity and is denser than the overlying mantle. Although the composition of the core is not well constrained, the moment of inertia, the k_2 Love number, the quality factor Q, and lunar rotation and magnetic induction studies are all consistent with a core of 375 km radius that

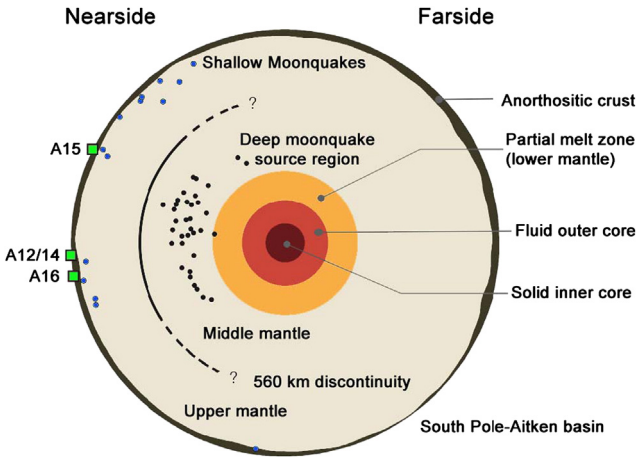

FIGURE 23.6 Cross-section of the interior of the Moon. This figure summarizes information gained by geophysical measurements performed at the landing sites and from orbit. It is believed that the lunar interior is characterized by a solid inner core, a fluid outer core, and a partially molten mantle, superposed by a rigid crust. This crust is substantially thicker on the farside compared to the nearside. Detected moonquake hypocenters (nests) are projected along the 0° meridian. *From Wieczorek, M.A., et al. (2006).*

is composed of Fe–FeS–C metallic alloy or a slightly larger core of molten silicates. Thermal models indicate that at least some portions of the core, regardless of its composition, should have crystallized over the past 4.5 Ga, thus supporting the concept of a solid inner core. Further

support for a small lunar core also comes from geochemical considerations, i.e., modeling of lunar siderophile element abundances, which suggests an iron-nickel-rich core of 260–293 km radius. Lunar laser ranging data show that the true spin axis of the Moon is displaced from the Cassini alignment (mean direction of the spin axis) by 0.26 arcsec. A possible interpretation is that internal dissipation in the presence of partially molten rock in the deep mantle and a fluid core causes this displacement. Recent reprocessing of the seismic data supports the presence of a partially molten layer at the base of the mantle and shows the presence of not only a 330-km liquid core but also a small solid inner core.

Global models of lunar topography improved considerably in terms of spatial resolution and accuracy since the availability of maps based on accurate laser altimetry and improved coverage with geometric stereo imaging. Doppler tracking of the Lunar Prospector and SELENE (Kaguya) spacecraft led to global maps of the Moon's gravitational field, as well as information on the mean moment of inertia factor and tidal potential Love number. These data were further improved by several orders of magnitude by the GRAIL spacecraft, which used two orbiters with accurate tracking and knowledge of their motions relative to each other to obtain very high resolution global gravity data.

6.1. Seismicity

To date, the Moon is the only body besides the Earth on which extensive seismological experiments have been done. The Apollo 12, 14, 15, and 16 astronauts installed a network of four three-component, long-period seismometers on the Moon, which detected more than 13,000 seismic events. Although the Apollo seismometers were highly sensitive state-of-the-art instruments and recorded lunar seismic events for almost 8 years, the relatively small network aperture and their restriction to only the nearside limited both the detection capability and the accuracy with which seismic sources could be located. Unfortunately, such location uncertainties are propagated into uncertainties of the interior structure. Nevertheless, the Apollo data revealed that lunar seismicity is different from that of the Earth due to the absence of tectonic plate movement. Sources of seismic activity on the Moon are related to deep moonquakes, shallow moonquakes, and meteoroid impacts.

Deep moonquakes occur in so-called "nests", which repeatedly release seismic energy in specific cycles correlated with lunar tides (Figure 23.6). More than 7000 individual deep moonquakes were recorded, originating from more than 250 of these nests, which are situated at depths between 700 and 1100 km. From the limited data available, neither the spatial nor the temporal patterns of deep lunar quakes are fully understood. However, it is apparent that the activity of these nests correlates with the tidal cycles caused by the Earth and the Sun. The shallow lunar quakes are even more enigmatic. Compared to the deep moonquakes, they are relatively rare; during almost 8 years of continuous data collection, only 28 such events were recorded and their epicenters were not correlated with known geologic or geographic features. One interpretation is that these moonquakes were formed by the release of thermoelastic stresses in the lunar crust or the upper mantle, possibly connected to large impact basins.

While early seismic studies favored crustal thicknesses of about 60 km beneath the Apollo network, more recent studies favor thinner crusts of only 30–45 km. The mean thickness of the lunar crust is estimated at 49 ± 15 km if an Airy-type compensation mechanism applies. These crustal thicknesses are in agreement with estimates of 34–43 km on the basis of GRAIL gravity data and assumed mantle densities of 3220 kg/m^3 and 3150 kg/m^3.

For the upper mantle, the Apollo seismic data indicate almost constant seismic velocities, whereas they are more variable in the underlying middle mantle. At about 560 km below the surface of the Moon, the seismic data suggest a discontinuity in the mantle, which might be related to a compositional change to more aluminous and MgO-rich **mafic** silicates. If this discontinuity exists globally, it may represent the initial depth of melting during the magma ocean phase of the Moon. If it only exists on the nearside, it can be interpreted as the maximum depth of melting of the mare basalt source region beneath the Procellarum KREEP Terrane (PKT). In the lower mantle below a depth of about 1150 km, seismic waves are strongly attenuated, indicating a partially molten zone extending to the core–mantle boundary.

With few exceptions, almost all recorded seismic events within the Moon occurred on the nearside, a **dichotomy** that might be either observational bias or related to geology. Because of the depth distribution of the deep moonquakes, P and S waves do not sample depths below 1200 km and thus the core region remains poorly understood. Among the ~1700 meteoroid impacts detected by Apollo seismometers, only one was at a distance great enough to allow for investigations of the deepest mantle. This observation constrains the lunar core to have a radius between 170 and 360 km.

6.2. Gravity

The gravitational field of the Moon provides important information on the spatial distribution of mass at the surface and within the lunar interior. Gravitational field investigations are commonly based on measurements of the Doppler shift in the radio tracking signal caused by accelerations acting on orbiting spacecraft and are augmented by

earthbound lunar laser ranging observations. Early Lunar Orbiter gravitational field models revealed major mass concentrations (mascons) on the lunar nearside, and Apollo 15 and 16 measurements were consistent with a thicker crust on the farside hemisphere as compared to the nearside. The first reliable global characterizations of lunar surface elevations and gravity were based on the Clementine topographic and gravity maps as well as radio tracking of the Lunar Prospector spacecraft. The first reliable gravity field determination for the lunar farside was accomplished by SELENE (Kaguya), which also considerably improved the spatial resolution of the lunar gravitational field data. Recently, the GRAIL spacecraft obtained the highest resolution global gravity data (Figure 23.7).

Gravity data reveal a 1.9-km offset of the center of mass relative to the center of figure of the Moon in the direction toward the Earth. This offset is attributed to a pronounced dichotomy between nearside and farside crustal thicknesses possibly established during the magma ocean stage. Analyses of global gravity and topography data indicate that the thickness of the farside crust exceeds that of the nearside by about 15 km on average. However, the gravity-based results are model dependent; laterally varying crustal compositions are also part of the dichotomy and may contribute to the offset.

Undulations of the current lunar geoid (or selenoid) are larger than 500 m and thus are much rougher than the geoid of the Earth (200 m). The lunar highlands appear to be nearly isostatically compensated, yet basin structures show a wide range of compensation states that are independent of their sizes or ages. Circular maria in many cases display large positive gravity anomalies (mascons) of a few 100 mGal, indicating mass surpluses, whereas some basins are surrounded by concentric gravity lows. Mascons are best explained by superisostatic uplift of the crust–mantle boundary beneath basins and the emplacement of dense mare basalts within basins.

6.3. Magnetic Field

Currently, the Moon does not have an internally generated magnetic field. However, its crust exhibits regions of weak **remanent magnetization** (Figure 23.8). The origin of this remanent magnetization might be related to an ancient internally generated magnetic field, which requires the presence of a highly conductive fluid in the lunar interior and motion within this fluid. Such motion within the core could have been driven by either thermal or chemical convection caused by core freezing. Because these processes depend on the amount of heat extracted from the lunar interior, knowledge of the rate of heat loss places important constraints on models of lunar magnetic field generation. Some thermal history calculations demonstrate that a thermal dynamo could have generated an early magnetic field for about 1 Ga. The generation of a dynamo could also be powered by the **precession** of the lunar spin axis, or by changes in spin rate of the mantle following large impact events. The recent detection of a strongly magnetized mare basalt sample is consistent with a relatively long-lived lunar core dynamo, operating roughly

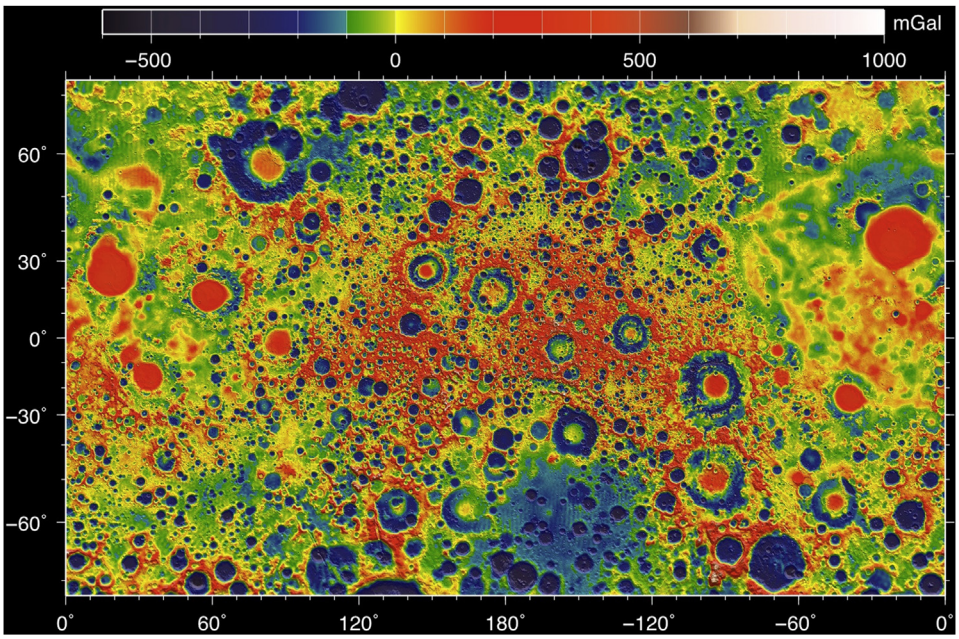

FIGURE 23.7 GRAIL lunar gravity field. Red colors correspond to mass excesses, which create areas of higher local gravity; blue colors represent mass deficits, which result in areas of lower local gravity. © *PIA 16587, NASA/JPL-Caltech/GSFC/MIT.*

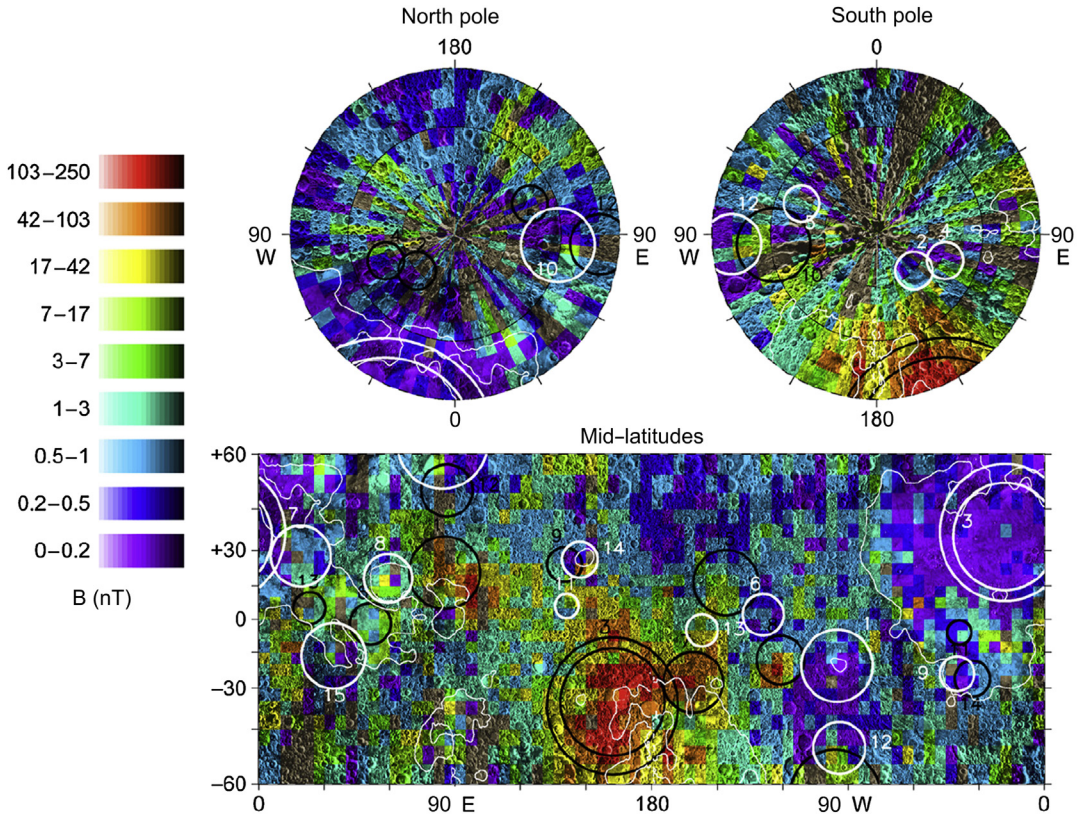

FIGURE 23.8 Lunar Prospector magnetic field strength of the lunar surface superposed onto a shaded relief map. Data are binned into 5 × 5 degree elements at the equator. Red colors indicate strong magnetization, while purple colors show weakly magnetized regions. *From Mitchell et al., (2008).*

between 4.2 and 3.7 Ga. However, the recent detection of an inner core presents a problem for models of the magnetic history of the Moon. In particular, if the inner core had been growing over an extended period until recently, chemical buoyancy in the core should have extended the lifetime of the dynamo much beyond the lifetime of the thermal dynamo.

Alternatively, an impact-related origin appears plausible. Because the strongest magnetic anomalies are often found at the antipodes of large impact structures, it has been argued that either shock-remanent magnetization or an expanding impact-generated **plasma** cloud could amplify ambient magnetic fields near the antipodes or magnetize the rocks in those locations. The patchiness of the remanent crustal magnetization indicates the presence of strong, localized magnetic fields on a regional scale, which is consistent with transient magnetic fields generated by impact events. The induced lunar magnetic moment as the Moon passes through the geomagnetic tail lobes of the Earth is consistent with a lunar core radius of 340 ± 90 km.

The depth variation of electrical conductivity from which mantle temperature and composition can be inferred hints at a partially molten mantle zone at 800−1500 km depth. This finding is in agreement with the observed attenuation of seismic waves (Figure 23.6).

6.4. Thermal Evolution

Magmatic evolution and lunar volcanism are closely related to the thermal evolution of the Moon, which is linked to the heat released by the decay of radioactive elements in the lunar interior and **secular** cooling, i.e., the loss of **primordial** heat acquired during accretion. A fundamental parameter characterizing the thermal state of the Moon is the amount of heat loss given by the surface **heat flow**. Thermal models predict that the lunar surface cooled mostly by thickening of a lithosphere, while the deep interior cooled by only a few tens of Kelvin. Seismic data from deep moonquakes may indicate the presence of a partially molten layer in the deep mantle (Figure 23.6). Although temperatures in the lunar mantle have also been calculated from magnetic studies, lunar surface heat flow measurements at the Apollo landing sites are still the most direct indicator of the thermal state of the Moon.

From the Earth it is known that heat flow varies widely owing to variations in crustal composition and thickness, tectonic activity, terrane age, climatic effects,

and hydrothermal circulation. On the Moon, gamma-ray **spectrometer** data indicate that the distribution of heat sources on the lunar surface is highly non-uniform. In particular, very high K, Th, and U abundances have been identified in a region known as the Procellarum KREEP Terrane (PKT) and a few other isolated areas.

Although the average surface heat flow of the Moon is important for understanding the thermal evolution of the Moon (Figure 23.5), only two heat flow measurements were done successfully during the Apollo missions (15 and 17). Unfortunately, several factors complicate the interpretation of these heat flow measurements. First, both the Apollo 15 and 17 sites are located at the boundary between the feldspathic highlands and the PKT, thus the measured heat flow values are likely not representative of the entire lunar surface. Second, the experimental setup in which a high-conductivity bore stem was inserted into a predrilled hole resulted in considerable shunting of heat and a change of the regolith thermal conductivity due to compaction by the rotary-concussion drill system. Accordingly, the Apollo 15 and 17 heat flow measurements vary widely between 14 and 21 mW/m^2, and this variation might be related to lateral and possibly vertical variations in the concentrations of heat-producing elements. Because of this dependency, the average surface heat flow allows one to estimate the abundances of the heat-producing elements K, Th, and U. On the basis of such calculations, bulk U contents of 20–46 ppb have been estimated. The concentration of 20 ppb is close to the estimated U content of the bulk silicates on the Earth and is thus consistent with the hypothesis that the Moon formed largely from material similar to Earth's mantle excavated during a giant impact into the proto-Earth.

The canonical view of a simplified lunar thermal evolution can be summarized as: (1) a relatively rapid accretion from vaporized and pulverized materials originating both from a Mars-sized impactor and from the proto-Earth itself; (2) development of a magma ocean whose fractional crystallization resulted in the sinking of mafic minerals to form an ultramafic cumulate mantle, and upward accumulation of plagioclase after about 75–80% crystallization to form an anorthositic rigid crust, followed by the late concentration of KREEP materials in the last zones of crystallization, presumably at the base of the crust; (3) overturn of the early formed cumulate pile due to density instability, bringing hot, magnesian cumulates to the top of the mantle; (4) extrusion of melts from this heterogeneous interior facilitated by crustal weakening and excavation due to massive impacts; and (5) generation of impact melts of various compositions dependent mostly on the make-up of target materials (Figure 23.5). Cumulate overturn (3) may have occurred prior to complete solidification of the magma ocean (2), and might have produced some of the hybrid rock suites such as KREEP-bearing, plagioclase-rich magnesian-suite materials.

7. THE LUNAR CRUST AND LUNAR TERRANES

To a first order, **albedo** differences on the Moon reflect major differences in the composition and origin of surface materials. The traditional and most likely too simple view of the lunar surface suggests that the more highly reflective lunar highlands consist mainly of anorthositic rocks and plagioclase-rich magnesian-suite rocks, including norites, gabbronorites, and troctolites. Mg-suite dunites and other magnesian rocks such as recently discovered Mg-spinel **anorthosite** are less abundant. Even rarer in the sample collection are alkali-suite rocks and KREEP basalts, which are enriched in potassium (K), REEs, and phosphorus (P). The dark mare **terrains** consist of younger basaltic rocks, including **lava flows** and pyroclastic deposits (Figure 23.9).

However, orbital gamma-ray spectrometer data allow division of the lunar crust and the underlying mantle into distinct "terranes" that possess unique geochemical, geophysical, and geological characteristics (Figure 23.10). Among those, the Procellarum KREEP Terrane (PKT) and the Feldspathic Highlands Terrane (FHT) are the two most extensive. The FHT is characterized by Th values of less than 3 ppm and covers approximately 60% of the lunar surface. This terrane consists mostly of ancient anorthositic rocks, presumably mainly of the ferroan anorthositic suite. Basaltic flows in the FHT terrane (Figure 23.10) erupted exclusively during the Imbrian period, are volumetrically small, and generally exhibit low to moderate concentrations of TiO_2 (<6 wt%). The PKT (Figure 23.10) in the Oceanus Procellarum and Mare Imbrium regions is characterized by high Th concentrations of 3–12 ppm (at the spatial resolution of orbital mapping) and extensive mare basaltic volcanism that erupted from at least 4.2 Ga to about 1 Ga. It has been argued that the high concentrations of heat-producing elements within the PKT are responsible for the longevity of extensive magmatic activity within this region. Global Th mass balance calculations indicate that as much as ~30% of the Moon's heat-producing elements may be located within the PKT, increasing the heat flow and enhancing the rates of viscous relaxation of basins within this terrane. A third terrane has been identified in association with the South Pole–Aitken (SPA) basin (Figure 23.10). The SPA terrane is characterized by FeO abundances of ~6–12 wt% and Th abundances derived from orbital data that are slightly elevated compared to the surrounding FHT (~2–3 ppm versus ~1 ppm). Spectral investigations indicate that the SPA impact mostly sampled the lower noritic crust and that mantle rocks, if excavated at all, are not abundant. Recent petrologic modeling coupled with results from the GRAIL mission suggest the possibility that the exposed interior of SPA basin reflects the upper part of a thick, differentiated impact melt body produced by the SPA impact.

8. LUNAR ROCKS

Information about the mineralogy and chemical composition of the lunar crust has been obtained from the Apollo and Luna samples, and lunar meteorites, as well as telescopic observations and orbital remote sensing. The returned samples provide first-order ground truth because they have enabled detailed studies of the age, mineralogy, chemistry, and petrology of lunar rocks, as well as their physical properties. These samples have allowed remotely sensed data to be properly calibrated, interpreted, and extrapolated to areas from which no samples have been returned.

On the basis of their textures and compositions, lunar samples can be classified into four distinct groups: (1) pristine highland rocks that are primordial igneous rocks; uncontaminated by impact mixing; (2) pristine basaltic volcanic rocks, including lava flows and pyroclastic deposits; (3) **polymict** clastic breccias, impact melt rocks, and thermally metamorphosed granulitic breccias; and (4) lunar regolith and regolith breccias.

As a consequence of the depletion of key volatiles, in particular H_2O and OH^-, the lunar surface mineralogy is relatively simple compared the mineralogy of other planetary bodies such as the Earth, Mars, and presumably Venus. In general, lunar surface mineralogy and petrology are characterized by four main mineral phases: plagioclase, pyroxene(s), olivine, and ilmenite, with other relatively rare silicates (SiO_2 **polymorphs**, K-**feldspar**, etc.), oxides, phosphates, and sulfides as accessory minerals. The relative fractions of these minerals permit classification of lunar rocks into distinct petrological groups, albeit within a

continuous compositional **spectrum**. In particular, rocks containing large fractions of plagioclase are classified according to the type and mass fraction of their mafic component, e.g., "troctolite" contains olivine, "norite" contains orthopyroxene, and "gabbro" contains clinopyroxene and orthopyroxene.

8.1. Highland Rocks

Pristine highland rocks can be divided into two chemical groups by their molar Ca/(Ca + Na + K) abundance versus the molar Mg/(Mg + Fe) abundance of their bulk rock compositions (Figure 23.11). Radiometric age determinations indicate that the ferroan anorthosites are extremely old (4.56–4.29 Ga). However, recent results based on more accurate geochronologic analyses call some of the older dates into question. Magnesian-suite rocks (high Mg/Fe) also have very old ages (4.46–4.18 Ga), overlapping with the ferroan anorthosites, but extending to somewhat younger ages. Ages determined on alkali suite rocks are younger still (4.37–3.80 Ga) and include rocks such as alkali anorthosite, norite, gabbronorite, granite, and quartz monzodiorite or monzogabbro. From these age relationships, it appears that the earliest Mg-suite magmatism occurred contemporaneously with the formation of at least some ferroan anorthosites. However, such a contemporaneous crystallization of the ferroan anorthosites and Mg-suite rocks is not consistent with the idealized magma ocean model. In such a model, ferroan anorthosites crystallized first to form the oldest crust, which was later intruded by younger Mg-suite plutonic rocks. Consequently, the complexity and overlap of the age relationship of the two lithologies have been interpreted to support an alternative crust building mechanism to the global magma ocean hypothesis, i.e., serial magmatism. However, massive, highly pure anorthosites in many regions of the lunar surface where fresh rocks from depth are exposed are indicative of a plagioclase accumulation from a magma ocean rather than from serial magmatism. Also, given the violent early impact bombardment and other events such as localized overturn of the mantle and possible concentration of Mg-suite intrusions in the PKT, or at the base of thick crust elsewhere, it appears likely that the crystallization of the magma ocean and distribution of primary crustal materials resulted in a wide variety of rocks now exposed at the lunar surface. A third alternative for explaining the overlapping ages is that some sort of reprocessing, e.g., heating owing to large impacts has modified some of the oldest ages.

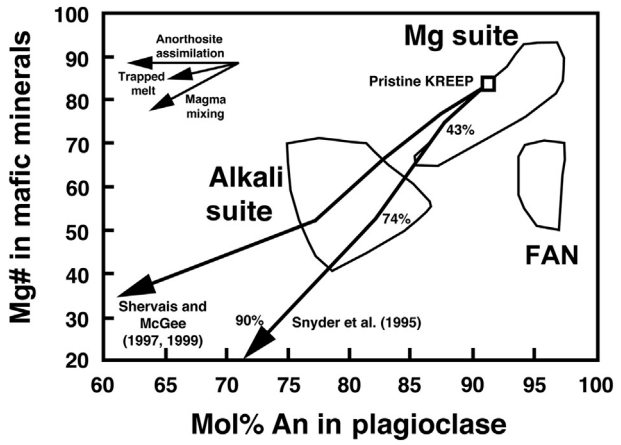

FIGURE 23.11 Composition of lunar highland plutonic rocks: anorthite content (An) in plagioclase versus Mg# of coexisting mafic silicates. *From Shearer, C.K., et al. (2006).*

Since the early inspection of Apollo samples it has been known that anorthosite is common in the lunar highlands with a plagioclase composition of typically An_{96}. In comparison to plagioclase in terrestrial rocks (e.g., An_{35} to An_{65}), such anorthitic contents are much higher and ultimately reflect the depletion of the Moon in volatile elements such as sodium. The Mg# (=MgO/MgO + FeO) of pyroxene and olivine in lunar anorthosite is more ferroan than in terrestrial rocks of such high Ca/Na ratio and any other non-mare lunar rocks, such as impact melt breccias and troctolites (En_{44-76}). For this reason, lunar anorthosite with plutonic or relic plutonic textures has been called ferroan anorthosite. The ferroan anorthositic suite consists of ferroan anorthosites (>90% plagioclase), as well as their more mafic but less common variations, ferroan noritic anorthosite and ferroan anorthositic norite. Although some ferroan anorthosites contain olivine, pyroxene is more abundant. However, geochemically, ferroan anorthosites contain little FeO and incompatible trace elements such as REE, Zr, U, Th, Ni, and Co, compared to other lunar rocks. Despite the fact that the ferroan anorthosites are usually heavily brecciated, a number of samples indicate that they are coarse-grained intrusive igneous rocks, formed during slow cooling at depth below the surface. Because the ferroan anorthosites contain high concentrations of plagioclase feldspar (Figure 23.11), they were interpreted as cumulate rocks produced by the separation and accumulation of crystals from the remaining melt. The Apollo missions returned several large nearly monomineralic plagioclase rocks and outcrops of "pure" anorthosite have been identified in Earth-based and spacecraft observations. However, the perceived importance of ferroan anorthosite to lunar crustal formation might have been overestimated. Although analyses of Apollo samples indicated a key role for ferroan anorthosite in the feldspathic lunar highlands, recent analyses of lunar meteorites suggest that more magnesian anorthosite, which is extremely rare in Apollo samples, might play a more significant role. The petrologic

significance of abundant magnesian anorthosite is not yet understood.

8.2. The Magnesian Suite

Most lunar highland rocks were presumably formed during the differentiation of a magma ocean when buoyant plagioclase accumulated in the upper crust to produce a thick anorthositic crust. Magnesian-suite rocks, once thought to make up a significant proportion of the crust, may instead be more localized products of intrusive activity within the PKT or localized to regions where overturn of mantle cumulates brought magnesian rocks to the upper mantle where melting, mixing with, and assimilation of crustal rocks produced hybrid, magnesian magmas. Some investigations indicate that magnesian-suite rocks may also (or instead) have formed as part of thick differentiated basin-formed impact melt bodies.

8.3. Mare Basalts

Geochemically, mare basalts are rich in FeO and some in TiO_2, depleted in Al_2O_3, and have higher CaO/Al_2O_3 ratios than highland rocks. Mineralogically, they contain more olivine and/or pyroxene, especially clinopyroxene, and less plagioclase than crustal rocks. Mare basalts are interpreted as products of partial melting of mantle cumulates produced during the early lunar differentiation. KREEP basalts differ from mare basalts and are thought to have formed by remelting or assimilation of mantle melts of late-stage magma ocean residua, the so-called urKREEP. Commonly, mare basalts are categorized on the basis of their petrography, mineralogy, and chemistry. Particularly useful is the subdivision using their TiO_2 contents, which distinguishes three mare basalt types: very low Ti basalts (<1.5 wt% TiO_2), low-Ti basalts (1.5–6 wt% TiO_2), and high-Ti basalts (>6 wt% TiO_2) (Figure 23.12). The TiO_2 abundances of the lunar samples have been studied extensively and the application of this knowledge to remote sensing data resulted in the derivation of global maps of the major mineralogy/chemistry of the lunar surface.

An early interpretation of the Apollo and Luna data suggested that Ti-rich basalts were generally older than Ti-poor basalts. Thus, models were proposed in which lunar mare volcanism began with high-TiO_2 content but decreased with time, and that this change was linked to the depth of melting. However, remote sensing data show that young basalts exist with high TiO_2 concentrations. Moreover, there are also some old (mostly >3 Ga) lunar basaltic meteorites that have very low TiO_2 contents. Combining iron and titanium maps determined from orbital data with crater size–frequency distribution ages across the nearside did not reveal a distinct correlation between mare ages and composition. Instead, FeO and TiO_2 concentrations vary

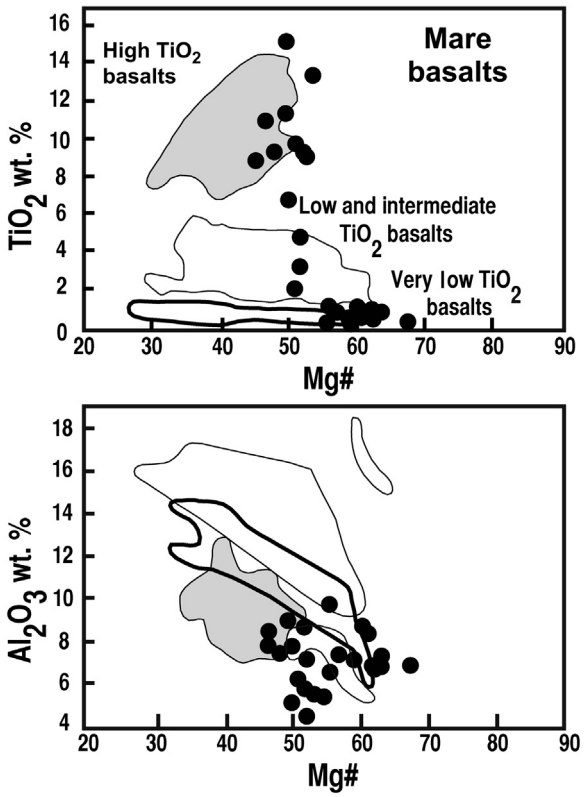

FIGURE 23.12 Mg# versus TiO_2 and Al_2O_3 for crystalline mare basalts and picritic glasses. The fields for high-Ti, low-Ti, and very low Ti basalts were derived from more than 500 analyses. The filled circles represent picritic glasses, thought to represent melt compositions. *Adapted from Papike (1998).*

independently with time, and TiO_2 (FeO)-rich and TiO_2 (FeO)-poor basalts have erupted contemporaneously. Hence, today it appears that the early interpretations were simply biased by the fact that two of the six Apollo landing sites happened to be in areas of high-Ti basalts.

8.4. Impact Breccias

Lunar impact breccias are mixtures of materials from different locations and different rock types and are produced by single or multiple impacts. Breccias contain various amounts of clastic rock fragments and impact-melted materials and show a wide variety of textures, grain sizes, and chemical compositions. On the basis of these characteristics, fragmental, glassy melt, crystalline melt, clast-poor impact melt, granulitic, dimict, and regolith breccias have been discriminated. Fragmental breccias consist of angular clasts in a porous, mostly friable clastic matrix of rocks, minerals, and rare glass debris. Glassy melt breccias are characterized by a coherent glassy or devitrified glass matrix with or without clasts. Crystalline melt breccias exhibit rock or mineral clasts or both in an igneous (extrusive)-textured matrix. Those breccias might be fine or

coarse grained, and clast-poor or clast-rich. Melt-poor impact melt breccias are igneous (extrusive)-textured rocks that contain meteoritic siderophile-element contaminations. Granulitic breccias have rock and/or mineral clasts in an equilibrated granoblastic to poikiloblastic matrix. Textures of these breccias are similar to plutonic rocks and compositions reflect siderophile-element contamination. Dimict breccias have a veined texture of intrusive, dark, fine-grained crystalline melt breccias with coarser-grained light-colored breccias consisting of plutonic or metamorphic fragments or both. Finally, regolith breccias can be described as lithified regolith. They contain regolith fragments, including impact glass, volcanic glass, and volcanic debris with glassy matrix.

9. SURFACE OF THE MOON

On a macroscopic scale there are three major geological processes that influence the lunar surface: impacts, volcanism, and tectonics.

9.1. Impact Processes

The Moon has been bombarded by **asteroids** and comets that range over 35 orders of magnitude in mass with impact velocities that in some cases exceed 30 km/s, resulting in impact craters with diameters from micrometers to ~2500 km. The final **morphology** of a crater depends on several factors, including the size of a specific crater, the rheologic properties of the surface, and erosional and degradational processes. Figure 23.13 shows size-dependent morphologies of typical lunar craters from microcraters found in lunar rock samples to large impact basins. On the Moon, fresh simple craters occur at diameters smaller than approximately 18 km and are characterized by (1) a paraboloid (or bowl-shaped) crater interior, (2) sharp rims, and (3) a well-developed ejecta blanket (Figure 23.13). With time, erosion and degradation processes, mostly related to impacts, as well as the deposition of mare lavas result in **mass wasting** and the obliteration of crater rims and ejecta.

With increasing impact energy and crater size, crater morphology becomes more complex. At crater sizes larger than the lunar simple-to-complex transition diameter at ~18 km (with a broader transition from 15 to 25 km), craters are characterized by (1) flat floors and a lower depth-to-diameter ratio compared to simple craters, (2) wall terraces, (3) central peaks, (4) well-developed continuous and discontinuous ejecta, and, (5) solidified impact melt pooled inside the crater and ejected from it (Figure 23.13). The relaxation of the compressed crust produces flat floors and central peaks. Like simple craters, resurfacing processes, which result in partial degradation of rims, central peaks, or ejecta, and partial or even complete filling by later basaltic lavas also influence the final complex crater morphologies (Figure 23.13). Craters younger than about 1 Ga often show bright, radial ejecta rays, which can extend up to several hundreds of kilometers across the lunar surface. These bright rays are either caused by differences in maturity between the ray and surrounding material or reflect compositional differences.

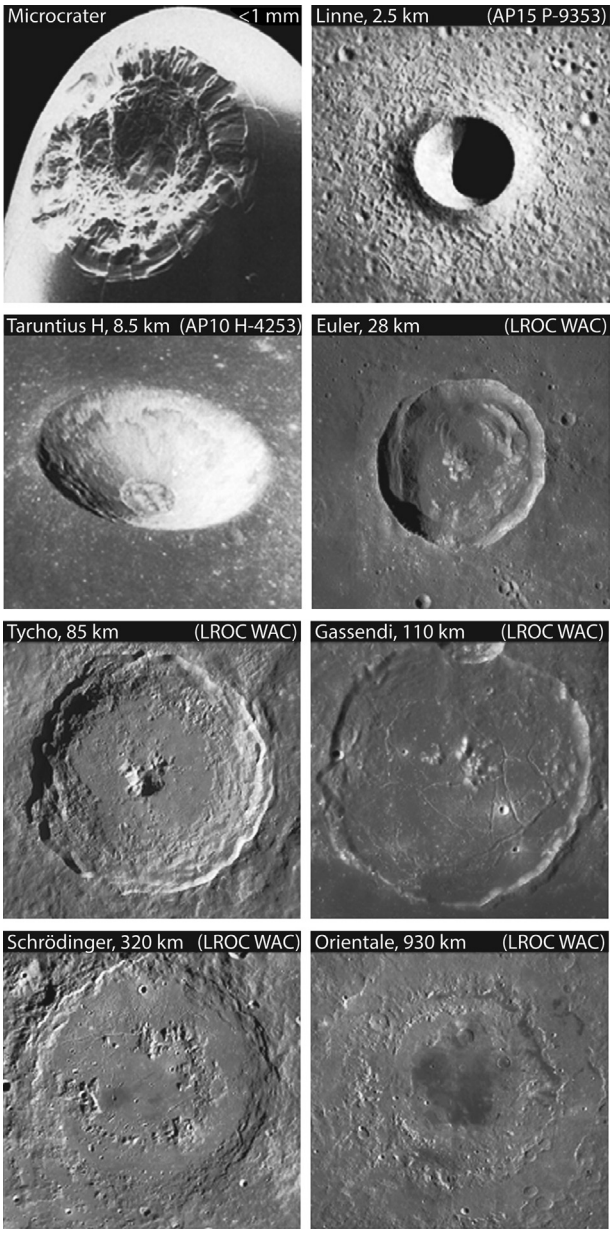

FIGURE 23.13 Size-dependent morphology of lunar impact craters. Microcrater on a lunar glass spherule. Craters Linne and Taruntius H are simple, bowl-shaped craters while craters Euler, Tycho, and Gassendi represent complex craters. Schrödinger and Orientale are multiring basins. For Orientale, the outermost (Cordillera) ring is about 930 km in diameter. All images are LROC Wide Angle Camera (WAC) images with the exception of the microcrater, Linne and Taruntius H. The latter two were imaged by the cameras on the Apollo 15 and 10 command modules. *From Jaumann et al. (2012).*

At diameters larger than 100 km, craters show a transition from central peaks to peak-rings. Two or more concentric ridges or scarps facing inward toward the crater center are characteristic of very large craters, i.e., basins that are larger than approximately 300 km (Figure 23.13). Peak-ring and **multiring basins** were formed by massive impact events during the first ~800 Ma of lunar history. While an early interpretation of Apollo radiometric ages suggested that many of these basins might have formed during a spike in the cratering rate around 3.9–4.0 Ga ago (i.e., the LHB or cataclysm), there is mounting evidence that this interpretation was influenced by a sampling bias (see Chapter 10.2).

9.2. Volcanic Processes

Because the Moon lacks plate tectonics it has preserved evidence of its long volcanic history. Lunar basalts occur preferentially on the nearside and in the interiors of many low-lying impact basins and cover about 17% or 7×10^6 km^2 of the total lunar surface amounting to ~1% of the lunar crustal volume (Figure 23.14). High volumes of low-**viscosity**, high-temperature basaltic lava flooded the topographically low-lying impact basin interiors and reshaped approximately 30% of the lunar nearside hemisphere. The radioactive decay of mainly K, U, and Th resulted in partial melts of the ultramafic mantle at depths between ~60 and 500 km, which led to the generation of basaltic magmas. Because of the enlarged concentration of heat-producing elements in the PKT of the nearside hemisphere, volcanism was active longer on the nearside than on the farside. In addition, geophysical models suggest that massive basin-forming impacts stripped away low-density upper crustal materials on the nearside, to allow dense basaltic magmas to erupt onto the surface. Individual volcanic features in areas resurfaced by mare basalts tend to be obscured by (1) the flatness of the deposits of the basalts due to the low viscosity of the lavas and (2) degradation from several billion years of impact cratering. However, within the lunar maria areas, several geomorphologic features of volcanic origin can be observed, including (1) lava flows, (2) sinuous rilles, (3) volcanic domes and cones, and (4) pyroclastic deposits (Figure 23.15). Volcanic vents in the mare regions are rarely observed. However, with the LRO imaging and topography data sets, many more are being found. Lava flow fronts several tens of kilometers long are visible, especially in low-sun and multispectral imaging, but at high resolution, flow fronts are heavily degraded by the impact cratering process (Figure 23.15). Very common in the mare areas are wrinkle ridges of presumably volcanic/tectonic origin. Meandering lava channels (i.e., sinuous rilles) are between a few tens of meters and ~3 km wide, a few kilometers to up to 300 km long, and on average ~100 m deep (Figure 23.15). One such sinuous rille (Hadley Rille) was examined in detail by the Apollo 15 mission. Geophysical modeling of sinuous rilles suggest that they were formed by high-effusion, high-temperature, low-viscosity lavas that thermally eroded into the substrate.

While already recognized, for example, in Apollo 15 images of the wall of Hadley Rille, new high-resolution imaging data reveal extensive layering within the mare basalt deposits. For example, in at least three mare regions, 100- to 150-m large holes or pits in the mare surface, presumably formed by collapse into voids created by subsurface movement of volcanic melt or by tectonism (Figure 23.16), were identified. Similar features were also observed in impact melt ponds of some craters. Within the pit walls,

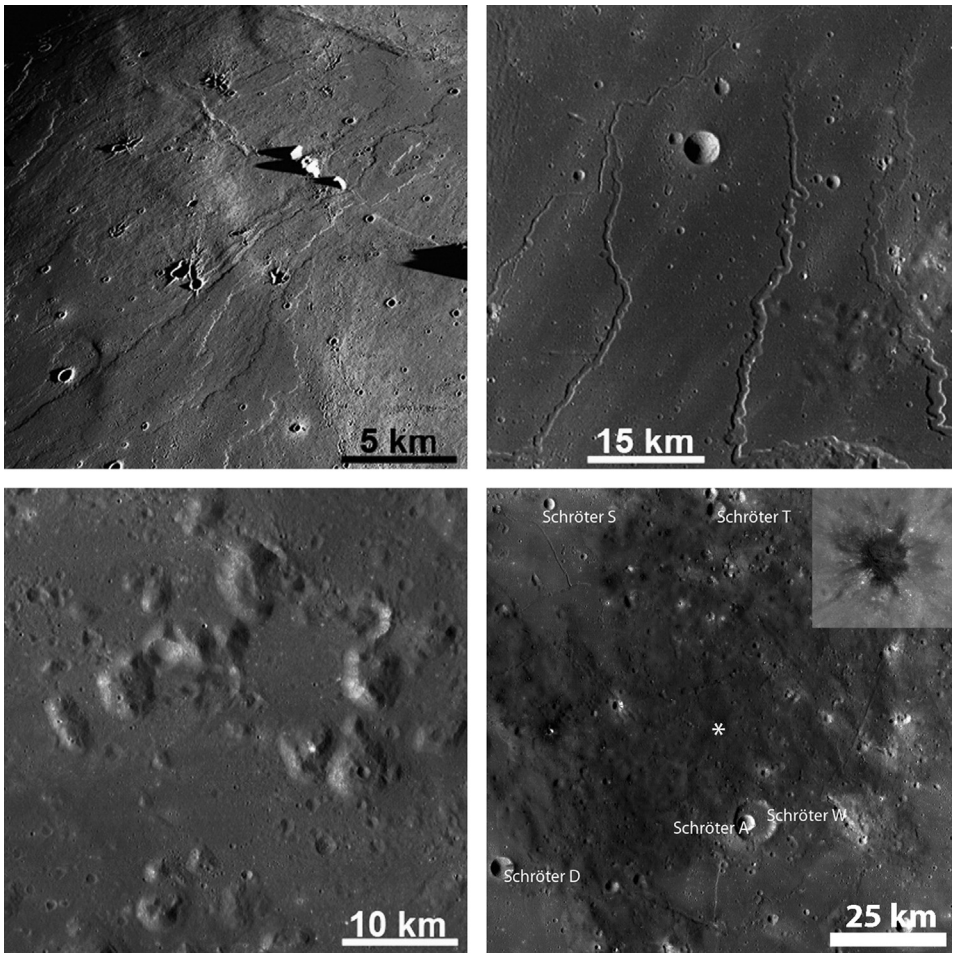

FIGURE 23.15 Volcanic landforms. Basaltic lava flow fronts in Mare Imbrium (top left; AS15-M-1556); sinuous lava channels (Rimae Prinz) in Mare Imbrium (top right, LROC WAC); basaltic domes in Mare Imbrium (bottom left, LROC WAC); and pyroclastic deposits (dark mantle deposits) south of Sinus Aestum; asterisk indicates location of insert, which shows a 170-m-diameter crater that excavated fresh pyroclastic material (bottom right, LROC Wide Angle Camera (WAC) and Narrow Angle Camera (NAC)). *From Jaumann et al. (2012).*

multiple basalt layers of several meters and up to ~15 m thickness were observed. These observations indicate that the basalts in the mare areas were emplaced by multiple thin flow events with individual flows ~10 m thick, rather than by a small number of flows of tens or hundreds of meters thickness. This interpretation is consistent with the Apollo 15 observations of the wall of Hadley Rille and observations of the interior rim walls of several craters.

Dark mantle deposits on the Moon were produced by pyroclastic eruptions, which may cover large areas on the order of >2500 km^2. Examples of such large pyroclastic deposits include the Rima Bode, Sulpicius Gallus, and Aristarchus Plateau deposits. However, most are concentrated in smaller areas, some only several kilometers in diameter; such deposits comprise the smallest currently known pyroclastic deposits on the Moon.

Mare domes, cones, and shields, which measure 3–17 km across and up to several hundred meters high, are mostly basaltic in composition and occur mostly within the extensive mare areas (Figure 23.15). For example, the Marius Hills complex in Oceanus Procellarum contains more than 100 domes and shields and exhibits a wide range of volcanic materials such as olivine-rich basalts and distinct lava flows. Changes in slope at the flanks of the domes are best explained by changes in viscosity due to effusion rate, temperature, and/or degree of crystallization. Blocks and boulders observed on the domes and cones, and along lava flow margins, are consistent with changes in flow rate or temperature. In addition, evidence in the form of layering in some of the cones suggests a mixture of lava and pyroclastic materials. Spatially much less abundant than landforms associated with basaltic volcanism are domes, which are characterized by steeper slopes, higher albedo, and strong absorption in the ultraviolet (UV) region (Figure 23.15). Known as red spots because of their specific spectral behavior in the UV, they were formed by much more viscous lava of dacitic or rhyolitic composition. In general, volcanic edifices having shallow flank slopes (<10°; e.g., in the

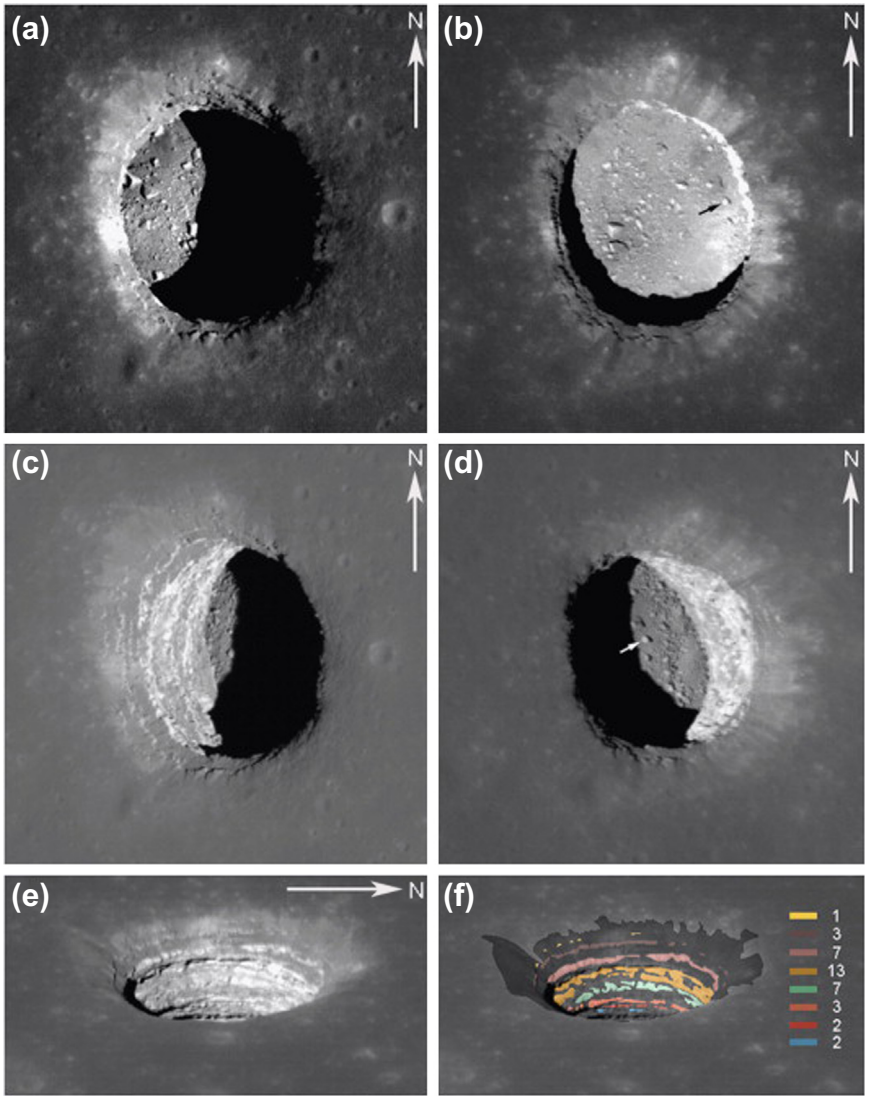

FIGURE 23.16 Pit interpreted as skylight into an underlying lava tube in Mare Tranquillitatis. The topmost images are two LROC NAC near-nadir images with opposite Sun azimuth angles: (a) M126710873R and (b) M155016845R. Together these two images show more than 90% of the pit floor; both images are approximately 175 m wide. (c) Layering in the west wall; portions of the pit floor are beneath the overhanging mare (29° emission angle; M175057326R); (d) a significant portion of the illuminated area is beneath the eastern overhanging mare (26° emission angle; M152662021R); white arrow indicates the same boulder marked with black arrow in panel b. Detailed layering is shown in (e) and (f) (M155023632R and M144395745L, respectively). Outcropping bedrock layer thickness estimates (in meters, ±1 m) are presented in (f). *Robinson et al. (2012)*.

Rümker and Marius Hills) were preferentially produced by low-viscosity eruptions, while steeper slopes (>20°) indicate eruptions of more silica-rich, higher viscosity lava (e.g., the Gruithuisen domes) (Figures 23.15, 23.38). Detailed morphologic and spectral studies of non-mare domes, such as the Gruithuisen domes and Hansteen Alpha, and domes in the Compton–Belkovich volcanic complex on the lunar farside, corroborated highly viscous, silicic non-mare volcanism in these areas.

9.3. Tectonic Processes

On the Moon, tectonism is associated with both impacts and volcanism and is manifested by extensional and compressional features, including faults, graben, dikes, and wrinkle ridges (Figure 23.17). Compared to the Earth, landforms created by tectonic stress are less abundant on the Moon. The large surface/volume ratio resulted in a very efficient cooling of the Moon, which rapidly produced a thickening lithosphere that today is about 800–1000 km thick. Early in its history, the Moon formed a stagnant lid from the solidification of the global magma ocean, creating a crust of low density. Hence, the Moon is a so-called one-plate or stagnant-lid planetary body with sluggish convection in its interior and has lost most of its heat through conduction as opposed to volcanism and plate tectonics.

Lunar tectonic features are mainly related to (1) impact-induced stress, (2) stress induced by load of basaltic materials within impact basins, (3) tidal forces, and (4) thermal effects. Impacts induce rock failure decreasing with distance from the impact site, creating radial and/or concentric extensional troughs or graben. At the edges of lava-filled impact basins, extensional stresses develop due to loading with basaltic deposits in the basin interior, creating arcuate

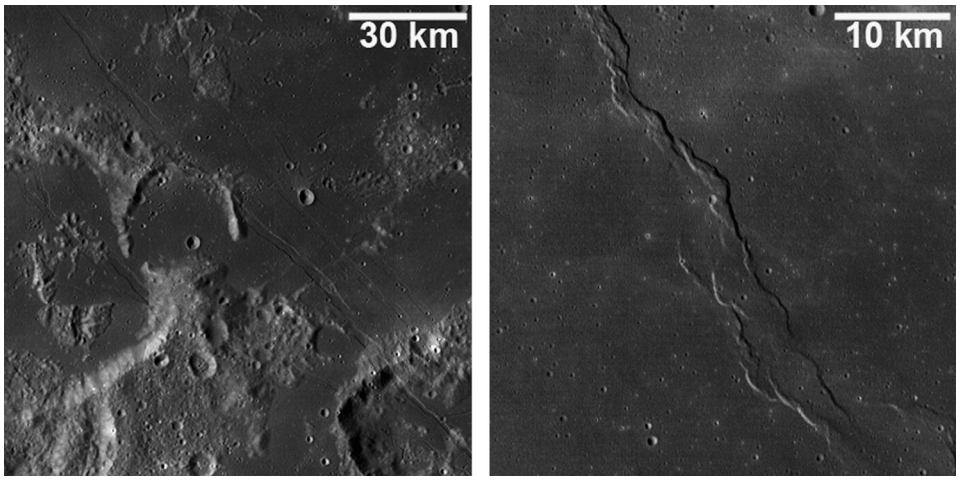

FIGURE 23.17 Tectonic landforms. Extensional graben (Rimae Goclenius) in Mare Fecunditatis (left, LROC WAC) and mare ridges (Dorsa Whiston) in Oceanus Procellarum (right, LROC WAC). © *Jaumann et al. (2012).*

troughs or rilles. Subradial and concentric ridges toward basin interiors are likely formed by compressional stress associated with the loading and inward movement of basalts. Such wrinkle ridges are common landforms in the mare areas and range from several kilometers up to 10 km in width, tens to hundreds of kilometers in length, and average heights on the order of 100 m (Figure 23.17). The origin of these wrinkle ridges is either related to lava extruding along fissures or to thrust faulting by compression in the interior of a lava-filled basin.

Craters with fractured floors have been explained by isostatic uplift of the floor or the emplacement of sills resulting in an extensional stress field, the latter being the interpretation preferred by most researchers.

On the basis of recent LRO images, a range of tectonic features not readily visible in older images has been observed, including narrow extensional troughs or graben, splay faults, and multiple low-relief terraces. **Lobate scarps** in mare as well as in the highlands, for example, have now been observed globally, including at high latitudes, suggesting a global, late-stage contraction of the Moon. These lobate scarps are among the youngest landforms on the Moon and are interpreted as compressional, low-angle thrust faults.

Earth–Moon gravitational interaction causes tides that are the main source of present-day, deeply seated moonquakes. Deformation by tidal stress was likely more intense early in lunar history when the Moon was closer to the Earth. However, today's spatial distribution of lineaments mapped on the lunar surface is similar on the nearside and farside and does not support an origin by tidal forces, i.e., the collapse of a tidal bulge. Rather, the thermal history, i.e., the shrinking diameter, has influenced the development of compressional stresses and style of tectonic deformation with time. Extensional structures (graben) on the order of 1–2 km long and 500 m wide and superimposing or cross-cutting craters only 10 m in diameter are presumably only a few millions of years up to 50 Ma old. The existence of such recent extensional structures is inconsistent with thermal history models that assume a totally molten early Moon because the models predict late-stage compressional stress that would prevent graben formation.

9.4. Space Weathering, Erosion, and Degradation

At small scales, mainly two processes, space weathering and impact "gardening", have reshaped the upper surface of the Moon. The Moon does not possess a global magnetic field and has only a negligible atmosphere, i.e., exosphere, thus the surface regolith is constantly bombarded with (1) micrometeorites, (2) energetic particles of the solar wind, (3) photons of solar radiation, and (4) cosmic rays. This particle bombardment results in physical and chemical processes that are called "space weathering". Space weathering is an important process on airless planetary bodies that is responsible for an increasing maturation of the regolith material by (1) lithification, (2) mechanical comminution, (3) melting and sublimation, (4) formation of agglutinates (partially melted soil **aggregates**), (5) implantation of ions, (6) **sputtering**, and (7) incorporation of meteoritic material. In some lunar regions with strong local magnetic anomalies, solar wind and cosmic rays may have been deflected, thus decreasing the rates of space weathering. For example, large swirl-like albedo features, such as Reiner Gamma, were likely formed by the partial standoff of the solar wind. The amount of trapped solar wind particles not only is an important maturity parameter of the lunar regolith but also records the history and evolution of the Sun over extended periods of time. In particular, areas where younger lava flows or impact ejecta have protected older regolith material ("paleoregoliths") from space weathering, it may be possible to reconstruct the evolution

of the solar wind and thus that of the Sun, and the galactic environment of the solar system, throughout much of solar system history.

On the Moon, micrometeorite impacts produce glasses that weld together small particles to form larger aggregates, termed "agglutinates". These micrometeoroid impacts, in combination with impacts of solar wind particles (primarily protons), also result in an autoreduction of FeO to metallic Fe, which increases the abundance of nanophase iron in a "mature" regolith. Maturity is a quality that is roughly proportional to the time the soil has been exposed to micrometeorite bombardment and the agglutinate abundance and varies widely across the lunar surface. The products of these continuous space weathering processes result in spectral reddening (increased reflectance toward longer wavelengths), a general darkening, and an attenuation of diagnostic absorption features. The longer any given surface material is exposed to space weathering, the more its spectral characteristics will be influenced. With the exception of a few small-scale exposures of bedrock, the lunar regolith covers more or less the entire lunar surface. Thus, for optical remote sensing techniques such as the mapping of TiO_2 and FeO concentrations it is crucially important to understand the optical properties of the lunar regolith and how they might be affected by, for example, grain size and maturity.

Impact gardening results in the abrasion of regolith material by small projectiles (micrometeorites) and the fragmentation of rock-sized material on the surface by centimeter-sized projectiles. As a result, fine-grained regolith consists mostly of poorly sorted silt to sand-sized material with variable amounts of rocky fragments and with average grain sizes of about 60–80 μm. Lunar erosion rates are generally low and depend on the size of the regolith material constituents. For example, a boulder with a mass of ~1 kg has an average survival time against impact destruction of about 10 Ma.

10. LUNAR STRATIGRAPHY AND SURFACE AGES

Cratered landscapes and impact basins are evidence of the extensive bombardment from space over time by projectiles ranging from micrometeorites to asteroids and/or comets. The lunar surface is ideally suited to study craters and the populations of solar system objects forming them. Using knowledge of the rate by which craters form over time, it is possible to date unsampled geological units by the number and size of craters that accumulated on them with time.

10.1. Lunar Stratigraphy

The lunar history is divided into five chronostratigraphic time periods: Pre-Nectarian, Nectarian, Imbrian, Eratosthenian, and Copernican. The Imbrian Period is further subdivided into the Early and Late Imbrian Epochs by the formation of the Orientale basin at the end of the Early Imbrian Epoch. However, because there are no rock samples, that unambiguously date the Orientale event, this subdivision is based on **stratigraphy** (e.g., superposition of **geologic units**) and on impact crater frequencies. Traditionally, the absolute boundaries of the lunar time periods and epochs differ among various authors because there is no unique solution to assigning a certain age of a given Apollo rock sample to a specific impact event. Commonly, more than one age may be extracted from rocks of a given landing site, and ages may vary widely even within a specific sample. Also, different radiometric systems have different closure characteristics and so date different types of events, e.g., crystallization resetting versus shock resetting. In addition, for the assignment of an absolute age to a specific basin impact, either the youngest age represented in a rock sample or the "peak age" (i.e., the age with the highest occurrence) has been chosen to represent the event. Consequently, estimates of the absolute ages of the lunar basins such as Nectaris or Imbrium and the time boundaries, which are defined by them, vary. Thus, according to the different chronostratigraphic models (Figure 23.18), the pre-Nectarian comprises the time before 3.92 or 4.1 Ga, the Nectarian Period spans the time from 3.92/4.1 to 3.85 or 3.91 Ga, the Imbrian Period lasts from 3.85/3.91–3.2 Ga, the Eratosthenian Period lasts from 3.2 to 1.0 or 0.8 Ga, and the Copernican Period comprises the time since 1.0/0.8 Ga. New cratering model ages of the young lunar craters Copernicus and Tycho derived from crater counts on LROC images are in excellent agreement with exposure ages of material collected at the Apollo 12 and 17 landing sites and are consistent with a beginning of the Copernican Period about 800 Ma ago.

Recent improvements in our understanding of the lunar sample collection, the applied dating methods, as well as, for example, a new accurate Ar decay constant have resulted in significantly better constraints of absolute ages assigned to the chronostratigraphic time periods. For example, one key recent result is the determination of 3.91 Ga formation ages of rocks that almost certainly formed during the Imbrium impact. These ages, coupled with required modifications to all Ar–Ar ages derived with the old decay constant, are critical for an accurate absolute chronostratigraphy of the Moon.

10.2. Late Heavy Bombardment

Apollo rock samples show an apparent clustering of radiometric ages at about 3.8–3.9 Ga. This clustering was interpreted as indicating a spike in the impact rate of large bolides around that time, known as the terminal lunar cataclysm or the Late Heavy Bombardment (LHB). Alternatively an exponential decay in the impact rate since the earliest times until about 3.3–3.5 Ga ago has been

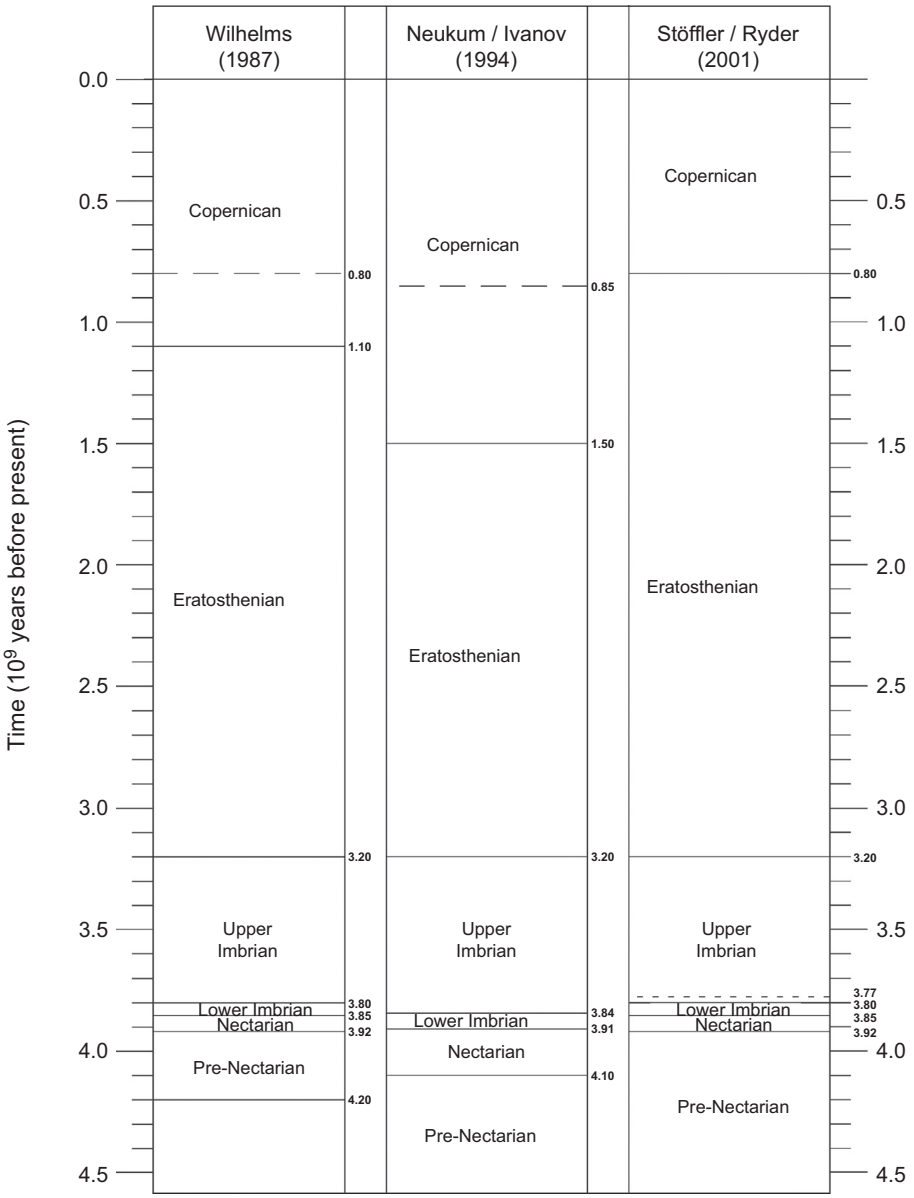

FIGURE 23.18 The stratigraphies of Wilhelms (1987), Neukum and Ivanov (1994), and Stöffler and Ryder (2001). Dashed lines in the stratigraphies of Wilhelms (1987) and Neukum and Ivanov (1994) indicate radiometric ages, which these authors attributed to the formation of the crater Copernicus. In Stöffler and Ryder (2001), two formation ages for the Imbrium basin were discussed, i.e., 3.85 Ga and 3.77 Ga (dashed line). *From Hiesinger et al. (2003).*

proposed. The so-called Nice model was initially developed by researchers at the Observatoire de la Côte d'Azur to test the plausibility of the LHB hypothesis. In order to explain an intense bombardment of the inner solar system around 3.9 Ga, the Nice model required dramatic changes in the orbits of the giant planets to cause a disruption of the primordial asteroid belt, which resulted in the ejection of many of those bodies, some out of the solar system and some into the inner solar system. Although the Nice model posits that an LHB is feasible under certain assumptions and also provides a plausible explanation of the evolution of the asteroid belt, it neither proves nor disproves this hypothesis. Hence, establishing the age of formation of the oldest and largest lunar basin, i.e., the SPA basin and other stratigraphically old basins remains key to testing the cataclysm hypothesis. In addition, careful analyses of ancient clast components of the lunar meteorites are critical to further test the LHB hypothesis. Lunar meteorites are considered to be random samples of the lunar surface and show a broad distribution of ages, thus not necessarily supporting the hypothesis of an LHB. Rather, a majority of the samples collected at the Apollo landing sites might have been influenced by the Imbrium impact, hence showing the observed spike in ages. In addition, attempts to date the SPA basin using impact crater size–frequency distributions have yielded absolute model ages of at least 4.2 Ga, and these ages are inconsistent with some models of the LHB. However, the scientific question whether an LHB existed or

not is still under debate and probably requires the return of new samples from areas unaffected by the Imbrium impact, such as from the SPA basin.

10.3. Age Determination

From the Moon we only have a small number of samples that can help to decipher its geologic history and evolution. For example, accurate radiometric ages for mare basalts are available only for the spatially restricted Apollo and Luna landing sites. Owing to the lack of samples and their radiometric ages, most mare basalts remain undated even after the Apollo and Luna missions. However, it is possible to derive relative and absolute model ages for these regions from remote sensing data. In particular, inspection and interpretation of superposition of geologic units onto one another, embayment, and cross-cutting relationships in high-resolution images can be used to obtain relative ages of lunar surface units. Furthermore, crater degradation stages and crater size-frequency distribution measurements (CSFDs) are useful for deriving relative and absolute model ages. Such studies also allow testing dynamical models of impactor populations and thus of the evolution of the solar system.

Age determinations with CSFDs are possible because for a given surface unit, the number of its impact craters correlates with the time this unit was exposed to the bombardment of asteroids and comets: the higher the crater frequency, the older the age of the unit. Thus, the number of craters superposed on a specific surface unit at a given diameter, or range of diameters, is a direct measure of the relative age of the unit. Determining the absolute age of a geologic unit with CSFD measurements is possible because the crater frequencies of key geological units could be calibrated with radiometric and exposure ages of returned Apollo and Luna samples (Figure 23.19). However, there are some uncertainties associated with this method, including the lack of calibration points for the impact flux prior to 3.9 Ga and radiometrically dated surfaces with ages between one and 3 Ga. Furthermore, while the method assumes a homogeneous distribution of impact craters across the lunar surface, there is evidence that the synchronous rotation of the Moon and the preference for asteroidal orbits to lie close to the ecliptic plane, result in spatial variations in the distribution of craters. The absolute chronology of geologic events on the Moon is based on the combination of radiometric and exposure ages of the lunar samples, regional stratigraphic relationships, and crater degradation and size–frequency distribution data. Accurate age estimates, for example, of mare basalts are crucial to constrain the duration and the flux of lunar volcanism, as well as the petrogenesis of mare basalts and its relationship to the thermal evolution of the Moon.

10.4. Age Record of Lunar Maria

Prior to and following the US and Russian lunar missions, the lunar stratigraphy was extensively investigated. This early work indicated that the lunar highlands are generally older than the mare regions; that mare volcanism did not occur within a short time interval, but shows a wide range

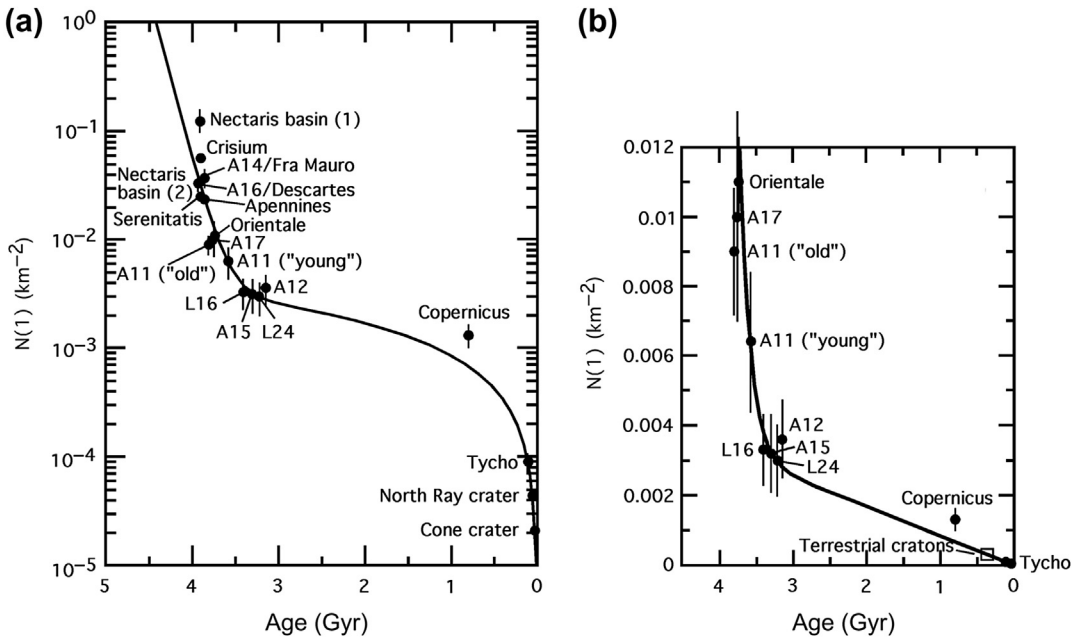

FIGURE 23.19 Lunar cratering chronology in (a) log form and (b) linear form. *From Neukum et al. (2001).*

in ages; and that there is significant variation in the mineralogy and composition of basalts of different ages.

Dating of mare basalts in extensive areas across the lunar nearside using CFSDs has shown that (1) in the investigated basins volcanism was active for almost 3 Ga, starting at about 3.9–4.0 Ga ago and ceasing at ~1.2 Ga ago; (2) most basalts erupted during the Late Imbrian Period at about 3.6–3.8 Ga ago; (3) significantly fewer basalts were emplaced during the Eratosthenian Period (3.2–1.2 Ga); and (4) basalts of possible Copernican age (~1.2 Ga) were only found in limited areas in Oceanus Procellarum (Figure 23.20). These results confirm and extend the general distribution of ages of mare basalt volcanism seen in the samples and show the preferred occurrence of older mare basalts on the eastern and southern nearside and in patches peripheral to the larger mare. In contrast, the younger basalt ages are preferentially located on the western nearside, i.e., in Oceanus Procellarum. Mare volcanism on the central lunar farside exhibits a range of absolute model ages between 3.5 and 2.7 Ga, which is well within the range of ages found for the nearside mare basalts. However, farside mare volcanism ceased earlier than on the nearside, which might be related to either a thicker crust or reduced abundances of radioactive elements in the farside mantle.

CSFDs indicate that the Gruithuisen domes in the northern Oceanus Procellarum region erupted from at least about 3.85–3.7 Ga ago. Therefore, the Gruithuisen domes postdate the Imbrium impact but predate the mare materials in the vicinity, which show ages of 3.55–2.4 Ga. Volcanic features such as the red spots in southern Oceanus Procellarum and Mare Humorum have a wider range in ages compared to the Gruithuisen domes. For example, in the region north of Mare Humorum, red spot light plains associated with a feature named "The Helmet" range in age from 3.94 Ga (Darney χ) to 2.08 Ga. The red spot dome "Hansteen Alpha" has an absolute model age range of 3.74–3.56 Ga, slightly less than the Gruithuisen domes, and postdates craters Billy (3.88 Ga) and Hansteen (3.87 Ga) but predates younger mare materials (3.51 Ga). The ages of the Gruithuisen domes and Hansteen Alpha suggest that at least in these two regions high-silica, viscous, non-mare volcanism was active only in the Late Imbrian Epoch, hence a much shorter interval than mare volcanism.

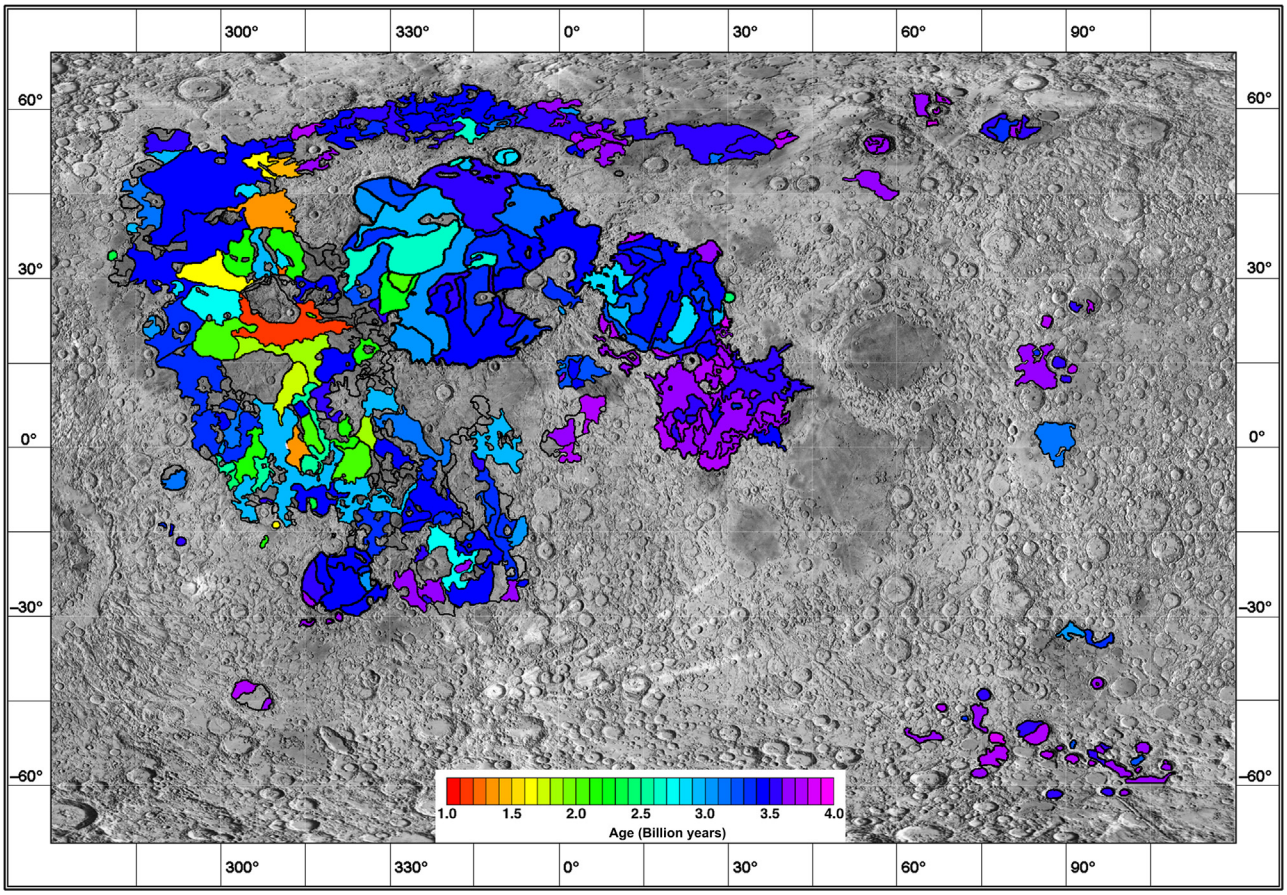

FIGURE 23.20 Ages of mare basalts derived from CSFDs on spectrally and morphologically defined mare units. *From Hiesinger et al. (2012).*

11. THE REGOLITH

The heavy lunar bombardment resulted in fracturing and fragmentation of the lunar crust down to several kilometers and produced a global layer of chaotically mixed impact debris termed the "megaregolith" (Figure 23.21). The fine-grained fraction (mostly <1 cm) of unconsolidated surface material is called "lunar regolith" or "lunar soil".

At the end of the heavy bombardment at ~3.8–3.9 Ga, the size distribution of impacting projectiles changed significantly and smaller projectiles became increasingly important for the evolution of the lunar surface. These impacts generated a layer of unconsolidated, fine-grained, and poorly sorted material, the lunar regolith. While small-sized impacts homogenized the regolith by continuously turning over the surface layer, larger impacts excavated fresh material from the subsurface resulting in layering of the regolith with numerous discontinuities. Despite the fact that the regolith is mostly produced from the lithologies of the underlying substrate, remotely sensed data of highland/mare boundary regions indicate that lateral transport of material owing to 0.1–10 m large meteorite impacts occurs as well.

The composition of the lunar regolith generally ranges from basaltic to anorthositic (with a small meteoritic component of usually <2%). The regolith consists of fragments of igneous intrusive and extrusive rocks, crystalline impact melt rocks, various types of crystalline and glassy breccias, mineral fragments, glassy and crystallized spherules of volcanic origin, impact glasses, meteorites, meteoritic metal, and agglutinates (see Section 9.4) with an average grain size of ~60–80 μm.

11.1. Regolith Thickness

On the basis of seismic data and models of the effects of large-scale impacts during the heavy bombardment, the cumulative ejecta thickness on the lunar highlands has been estimated to be on the order of 2.5–10 km, possibly up to tens of kilometers in places. While the average thickness of the mechanically disturbed lunar crust by impacts is not well known, conservative estimates imply a thickness of at least 2–3 km (megaregolith), a structural disturbance to depths of more than 10 km, and fracturing of the in situ crust down to about 25 km. Smaller impacts since the end of the heavy bombardment produced a fine-grained powdery regolith layer on the lunar surface above the megaregolith. This uppermost part is continuously "gardened" or modified by small impacts. Rare large craters play an important role because they can create a mixed regolith layer consisting of preexisting substrate plus fresh ejecta

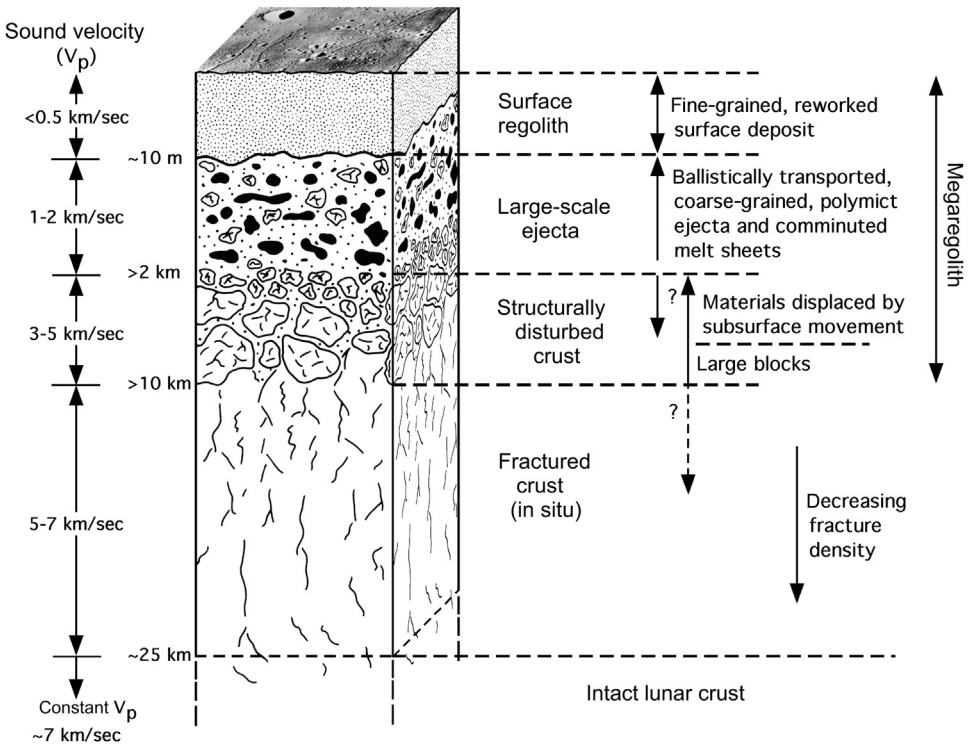

FIGURE 23.21 Idealized cross-section of the upper crust illustrating the internal structure of the megaregolith. The depth scale of this figure is debatable because regional variations are expected depending on the degree to which a region has been influenced by basin-sized impacts. *From Hiesinger, H. & Head, J.W., III. (2006) and Hörz et al. (1991).*

despite the tendency of the smaller craters to homogenize the upper parts of the regolith (Figure 23.21).

Crater morphologies, spectral information, and radar data can be used to estimate the regolith thickness. These studies show that in mare areas the regolith is typically only a few meters thick, whereas in the highlands it is ~10 m thick (Figure 23.21). Regolith thickness is roughly correlated with surface age and evidence indicates that a higher regolith production rate existed ~3.5 Ga ago. With time, the production rate of regolith decreased because the increasing regolith thickness protects underlying bedrock from being incorporated into the regolith. In areas with a thick regolith layer, only rare large craters can penetrate the regolith to incorporate "fresh" bedrock, while smaller impacts only redistribute the existing regolith.

11.2. Regolith Properties and Sources

Space weathering processes (Section 9.4) act directly on the lunar surface because the Moon does not have a magnetic field or a thick atmosphere to shield the surface from incoming charged particles and micrometeorites. Thus, the exposure of the surface to intense space weathering results in strong physical and chemical alterations or maturation of the regolith, which involves lithification, mechanical comminution, melting, vaporization, formation of agglutinates, ion implantation, and sputtering. Several products of this maturation are scientifically important and could be economically significant, including trapped solar wind particles to decipher the history of the Sun, cosmogenic nuclei resulting from galactic cosmic rays (and thus the galactic environment of the solar system), ^{3}He as a possible future energy resource, metallic iron, and hydrogen/water.

From a scientific point of view, understanding the space weathering process and its products is essential because space weathering changes the optical properties of the lunar regolith, which must be considered when analyzing remote sensing data (see Chapter 9.4). While the spectral characteristics of the main mineralogical species are well understood from detailed laboratory measurements, remote sensing spectra of the lunar surface in comparison to the laboratory spectra are influenced by several parameters, including topography (e.g., shadowing), illumination angles, grain size, thermal environment, and space weathering. In addition, lunar soils may not be entirely representative of the underlying lithologies because they are produced by impacts and mixing, which have modified their spatial and mineralogical characteristics. Finally, returned lunar samples that are used to calibrate remote sensing instruments offer a rather biased representation of surface materials because they were all collected within just 35° latitude and 95° longitude on the nearside.

12. THE APOLLO AND LUNA LANDING SITES

12.1. Overview

Between 1969 and 1976, six manned American Apollo missions (1969–1972) and three automated Soviet Luna missions (1970–1976) returned samples from the Moon (Figure 23.9). These landing sites are key for understanding

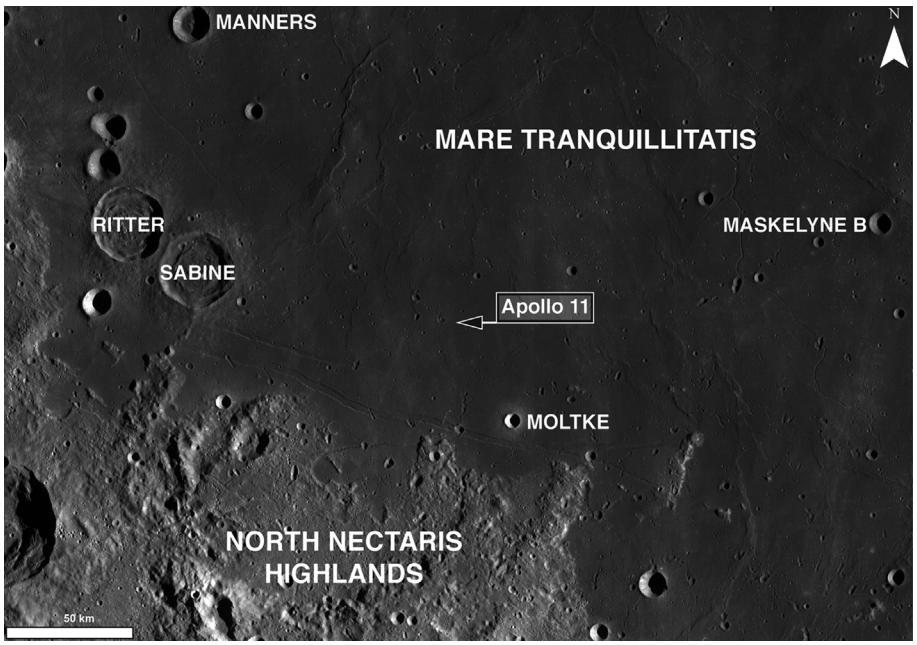

FIGURE 23.22 The geologic setting of the Apollo 11 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

and interpreting the global orbital data sets and provide ground truth for geologic investigations and experiments, data calibration, and new techniques of data reduction.

12.2. Apollo 11 (July 1969)

Apollo 11 was the first lunar mission to return samples of basalt from Mare Tranquillitatis, thereby confirming the hypothesis that extruded lavas, formed by partial melting of the lunar mantle, flooded the lunar impact basins. Compared to terrestrial standards, the returned lunar basalts are characterized by very high TiO_2 concentrations, mostly hosted in the mineral ilmenite. These high TiO_2 abundances are consistent with the spectrally "blue" character of the basalts, due to the interaction of solar irradiation with mineralogical compounds. The ages of the basalts range from 3.57 to 3.88 Ga and provided a first calibration point for the lunar chronology. In addition, they showed that lunar volcanism was ancient by terrestrial standards. In the Apollo 11 sample collection, there are also pieces of non-volcanic material, including fragments of plagioclase-rich anorthosites, and these were interpreted to be from the adjacent highlands. These pieces of highland rocks were particularly important because they indicated the general feldspathic character of the lunar crust and led to the first correct concepts of lunar differentiation. The landing site of Apollo 11 within Mare Tranquillitatis, located about 40−50 km from the nearest mare/highland boundary (0.674158° N, 23.473146° E), was chosen primarily for safety reasons (Figures 23.9, 23.22).

During their stay on the lunar surface, astronauts Neil Armstrong and Edwin "Buzz" Aldrin performed a 2.5-h-long extravehicular activity (EVA), during which they collected 21.6 kg of lunar samples about 400 m west of the West crater, a sharp-rimmed, rayed crater ∼180 m in diameter and ∼30 m deep (Figure 23.23). The thickness of the regolith at the landing site is about 3−6 m. Detailed geochemical analyses in the laboratory revealed that five

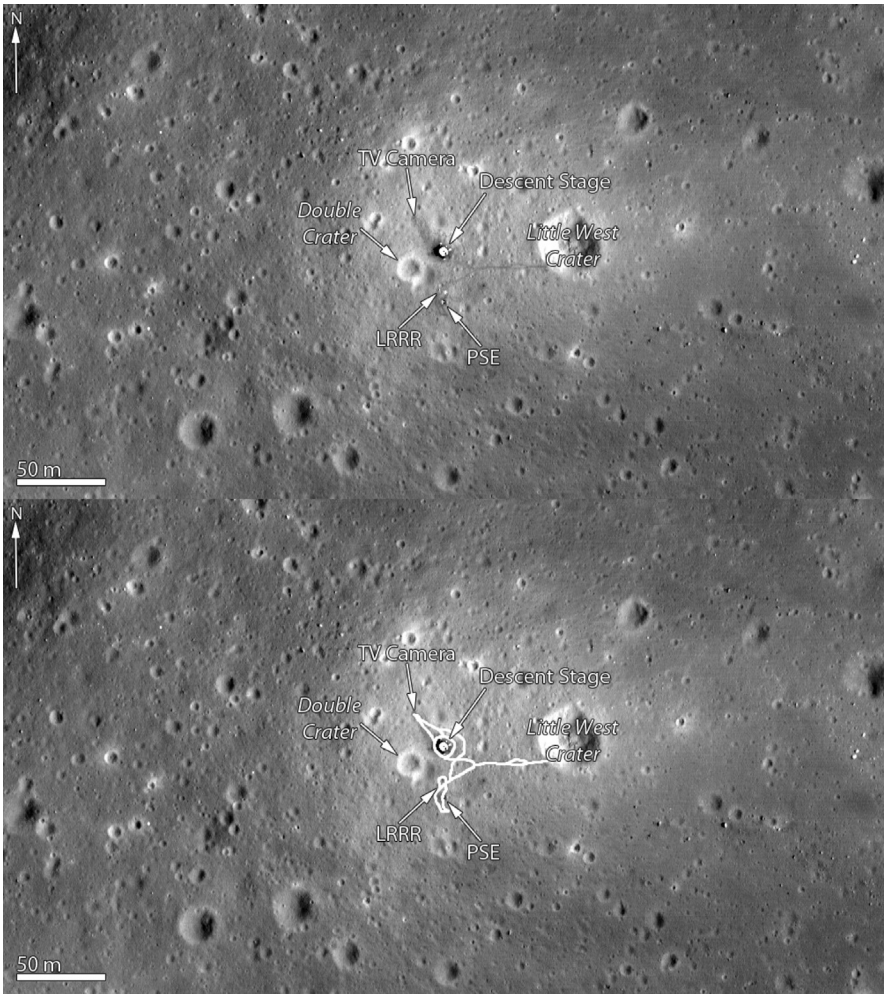

FIGURE 23.23 Detailed view of the Apollo 11 landing site and the location of experiments and traverses (top); detailed view of the EVA traverses (bottom). © *Images from the LROC webpage.*

distinctive groups of mare basalts were sampled, together with regolith samples consisting of feldspathic lithic and mineral fragments that were derived from highland regions. Situated in an extensive mare region, the Apollo 11 regolith nevertheless contains up to ~28% of non-mare material that is similar in composition to the regolith of the Cayley Plains at the Apollo 16 landing site (Section 12.6). It has been suggested that this non-mare material is most likely derived from Imbrium ejecta deposits excavated from beneath the basalt flows by subsequent impact craters.

12.3. Apollo 12 (November 1969)

Apollo 12 with astronauts Charles Conrad and Alan Bean was sent to the Surveyor 3 site, a relatively flat mare site with only a few large boulders to demonstrate the capability of pinpoint landings. This objective was successfully accomplished because Apollo 12 touched down within 200 m of the Surveyor 3 landing site in southeastern Oceanus Procellarum (3.012499° S, 336.578158° E) (Figures 23.9, 23.24). This landing site is less cratered, hence younger than the Apollo 11 site, and the sampled mare basalts differ in their composition and spectral characteristics from the Apollo 11 basalts. The differences in age and chemistry between Apollo 11 and Apollo 12 basalts were interpreted to show variability in mantle sources and basalt production processes on the Moon. Exposures of non-mare materials near the landing site, mostly part of the Fra Mauro Formation, indicate that the basalts are relatively thin, forming a complex topography. Crater counts and nominal crater degradation values or D_L values (defined as the diameter of craters with wall slopes of 1°) demonstrate that the landing site basalts are older than basalts 1 km to the east and west. Although the Apollo 12 landing site is dominated by the ejecta of several >100 m large craters (Figure 23.25), its regolith is only half as thick as the Apollo 11 regolith and craters only 3 m deep penetrate into basaltic bedrock. A prominent ray from crater Copernicus crosses the Apollo 12 location, delivering abundant non-mare materials to the site. There are probably multiple sources of the non-mare materials at the Apollo 12 site, including material mixed into the surface from impact melt formations that underlie the basalts. However, analyses of the non-mare materials show a major disturbance at about 800–900 Ma ago. This disturbance has been interpreted as being related to the emplacement of Copernicus ray material. Thus, this age is inferred to be the age of Copernicus, although no specific sample has been unambiguously related to this crater.

During two EVAs, the astronauts collected 34.3 kg of samples, mostly basalts. The radiometric ages of these basalts range between 3.29 and 3.08 Ga and at least three chemically distinctive groups of mare basalts were identified. The mare basalt flows (20–21% FeO) cover the older Fra Mauro Formation, which contains about 10% FeO. Apollo 12 was the first mission to collect KREEP (rocks and glasses enriched in potassium, rare earth

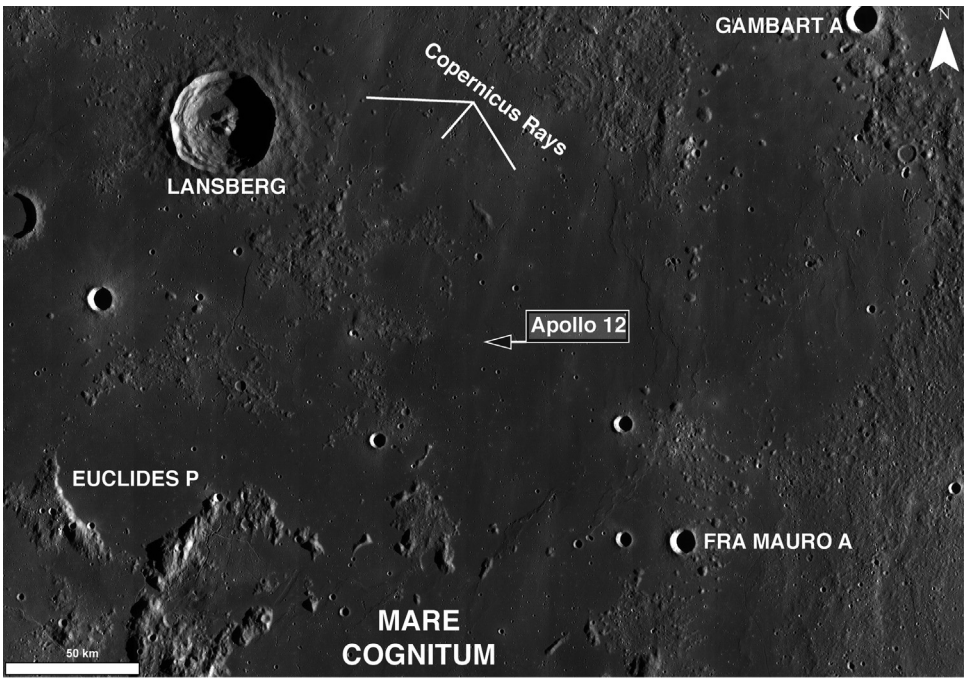

FIGURE 23.24 The geologic setting of the Apollo 12 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

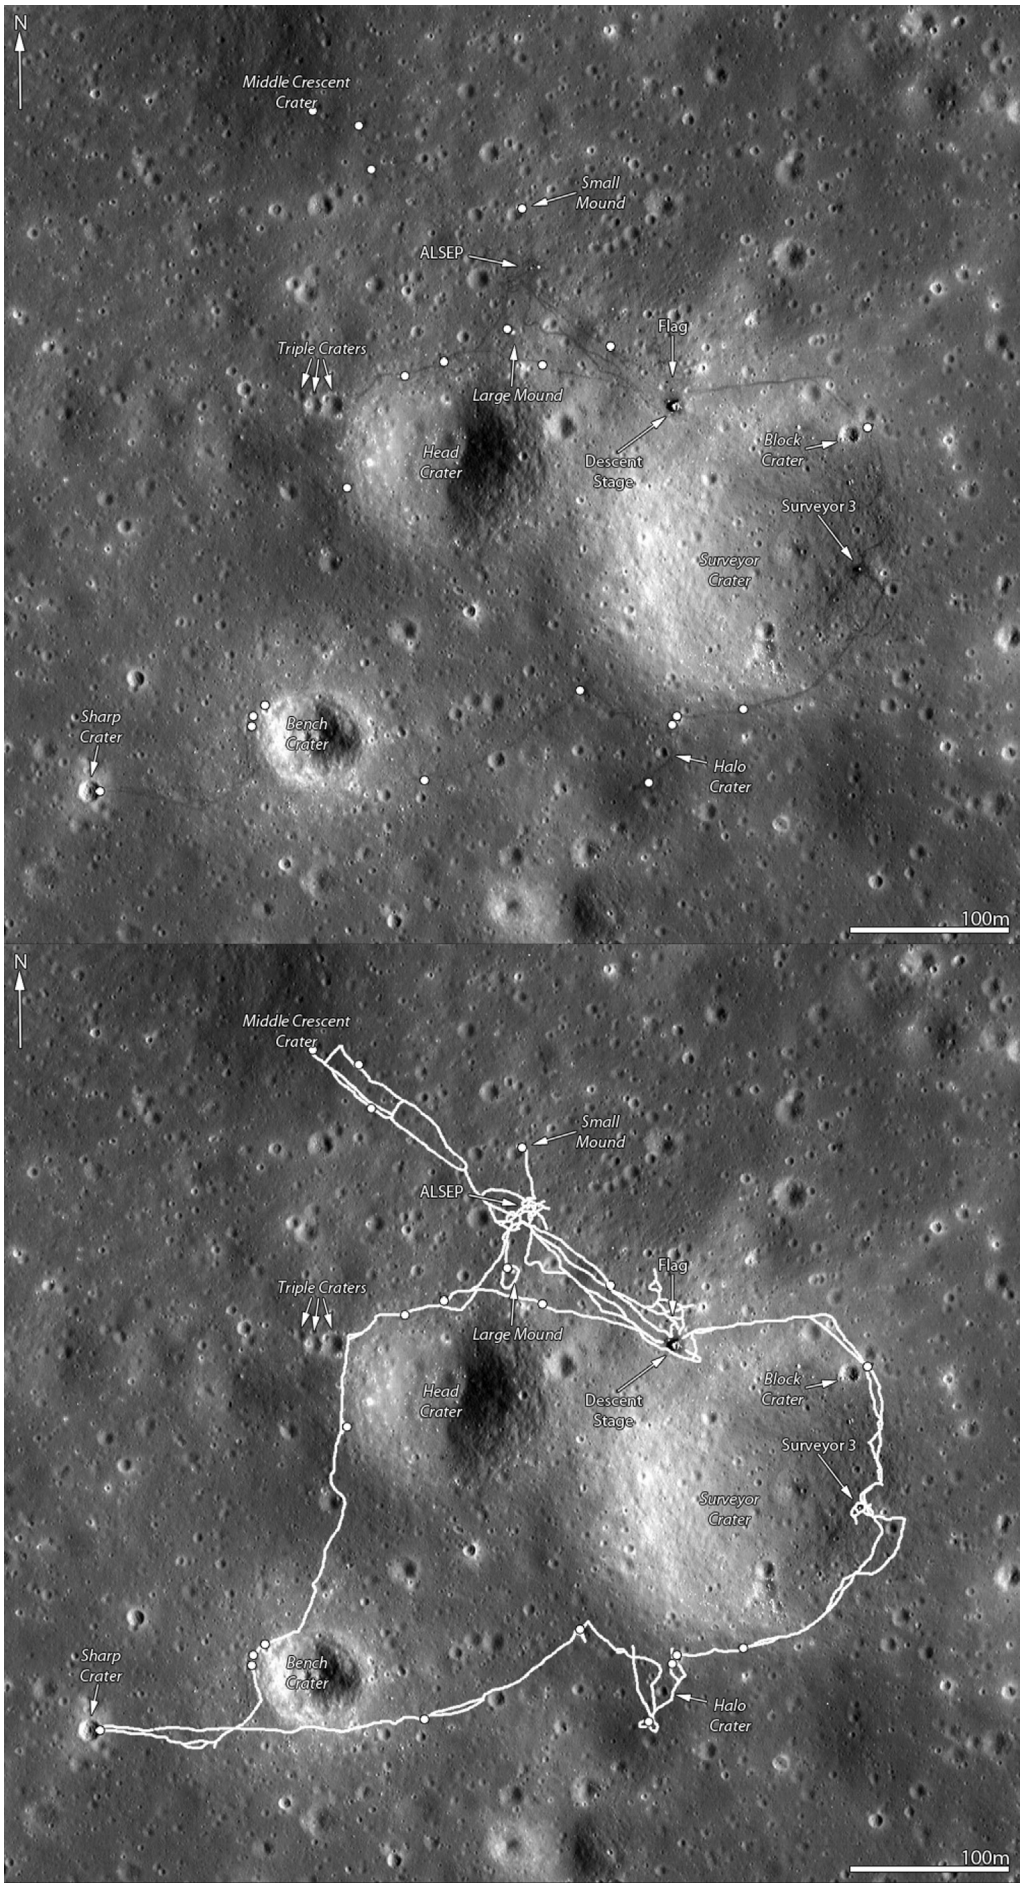

FIGURE 23.25 Detailed view of the Apollo 12 landing site and the location of experiments and traverses (top); detailed view of the EVA traverses (bottom). © *Images from the LROC webpage.*

elements, phosphorus, and other incompatible elements). The very distinct and unique geochemical signature of KREEP requires substantial magmatic differentiation, consistent with a strongly differentiated Moon. KREEP material occurs as dark, ropy glasses similar in composition to Apollo 14 soils and a subset of Apollo 14 impact glasses, and several crystalline rock and lithic fragments. These glasses appear to represent impacted surface material similar to that exposed in the Apollo 14 Fra Mauro Formation. The KREEP material is derived mostly from the PKT and was probably incorporated into the regolith of the landing site by a combination of lateral transport and vertical mixing.

12.4. Apollo 14 (January–February 1971)

By landing on a hummocky terrain north of the Fra Mauro crater (3.645890° S, 342.528050° E) ~550 km south of the Imbrium basin, Apollo 14 became the first mission to sample the lunar "highlands" (Figures 23.9, 23.26). The landing site was selected primarily to sample the Imbrium basin ejecta, which presumably came from deep crustal levels. It was also chosen to date the Imbrium event, which is a major stratigraphic marker in lunar history. During two EVAs, astronauts Alan Shepard and Edgar Mitchell collected 42.3 kg of samples, including complex fragmental breccias, impact melt breccias, and clast-poor impact melts with generally basaltic and KREEP-rich compositions. Radiometric dating revealed that these breccias were formed about 3.9–3.8 Ga ago. However, it is still under debate whether they date the Imbrium event itself, or later, smaller impacts into Imbrium ejecta. Although the Fra Mauro Formation has been interpreted to consist primarily of Imbrium ejecta, some studies suggest that it is mostly dominated by local material with only 15–20% Imbrium ejecta mixed in.

The Apollo 14 landing site is commonly considered a "highland" landing site. However, its elevation is some 3200 m below the lunar mean and, from a geochemical point of view it is neither feldspathic highlands nor mare. Rather, unknown at the time of the site selection, the Apollo 14 site is located within the PKT, which contains exceptionally high thorium concentrations. At the Apollo 14 landing site relatively aluminous basalts have been identified, some of them also enriched in K. These aluminous and high-K basalts are not found at other Apollo mare landing sites. However, one of the Soviet Luna missions, Luna 16, also returned aluminous basalts (Section 12.8). A "model" mixture of the regolith at the Apollo 14 site contains ~60% impact melt breccias, ~20–30% noritic lithologies, ~5–10% each of mare basalts and troctolitic anorthosites, and minor amounts of meteoritic components. Regolith from different stations at Apollo 14 shows little variation in composition, both vertically (tens of centimeters) and laterally (kilometers around the landing site). The landing site is situated ~1100 m west of the ~340-m-diameter and 75-m-deep Cone crater, which ejected blocks of up to ~15 m in size (Figure 23.27). In addition, the landing site

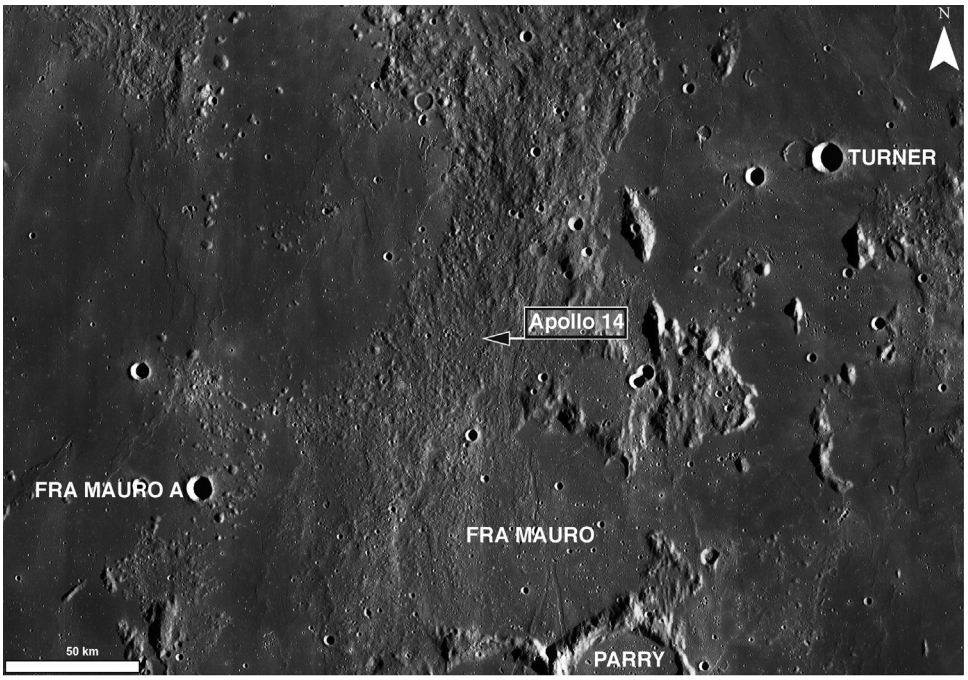

FIGURE 23.26 The geologic setting of the Apollo 14 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

shows numerous subdued craters up to several hundreds of meters across and the regolith is estimated to be 10–20 m thick.

12.5. Apollo 15 (July–August 1971)

The Apollo 15 mission was the first advanced ("J") mission that carried the Lunar Roving Vehicle (LRV). The complex multiobjective landing site in the Hadley-Apennine region (26.132379° N, 3.633303° E) (Figures 23.9, 23.28) was chosen to sample and study the massifs and highlands of the Imbrium rim, as well as the mare lavas and landforms of Palus Putredinis (e.g., Hadley Rille). The main Imbrium ring rises ~3.5 km above the plains at Hadley Delta, only 4 km south of the Apollo 15 landing site, and extensive lava plains are exposed west of the landing site. The so-called Apennine Bench Formation, a light plains unit that probably underlies the Late Imbrian basalts at the Apollo 15 landing site is exposed within a few kilometers of the landing site and is located inside the Imbrium ring. **Crater rays** from Autolycus and Aristillus cross the landing site. The regolith thickness, which varies widely depending on the local terrain is only ~5 m thick at the landing site, and the wall of Hadley Rille exposes a layered basalt flow sequence. The Apollo 15 astronauts Dave Scott and James Irwin performed three EVAs with the LRV collecting a total of 77.3 kg of mare and non-mare rocks (Figure 23.29). In particular, they collected two types of basalts (quartz normative and olivine normative), which have ages of ~3.3 Ga. Non-volcanic rocks include anorthosites, magnesian-suite plutonic rocks, impact melts, and granulites, many of which occur as individual clasts in regolith breccias. In addition, the Apollo 15 sample collection contains KREEP-rich non-mare basalts and green ultramafic volcanic glasses. Together with Apollo 14 samples, rocks from the Apollo 15 site have been interpreted to indicate that the Imbrium basin is 3.91 Ga old.

12.6. Apollo 16 (May 1972)

The objective of the Apollo 16 mission was to explore the smooth Cayley Formation and the hilly and furrowed Descartes Formation, both of which were initially thought to be volcanic in origin (Figures 23.9, 23.30). Further objectives were to sample highland material at great distance from any mare region and to study two nearby, fresh 1–2 km diameter craters. Apollo 16 landed at 8.973476° S latitude and 15.501019° E longitude near Descartes crater. Three long EVAs were performed with the LRV, and astronauts John Young and Charles Duke returned 95.7 kg of samples (Figure 23.31). The Apollo 16 landing site is the most highland-like landing site of the Apollo program, but surface morphology, vicinity to the Imbrium basin and thus possible presence of PKT material, composition of the regolith, and lithologic components of the regolith compared to those of the feldspathic regolith breccia lunar meteorites argue against Apollo 16 having landed on "typical" highlands.

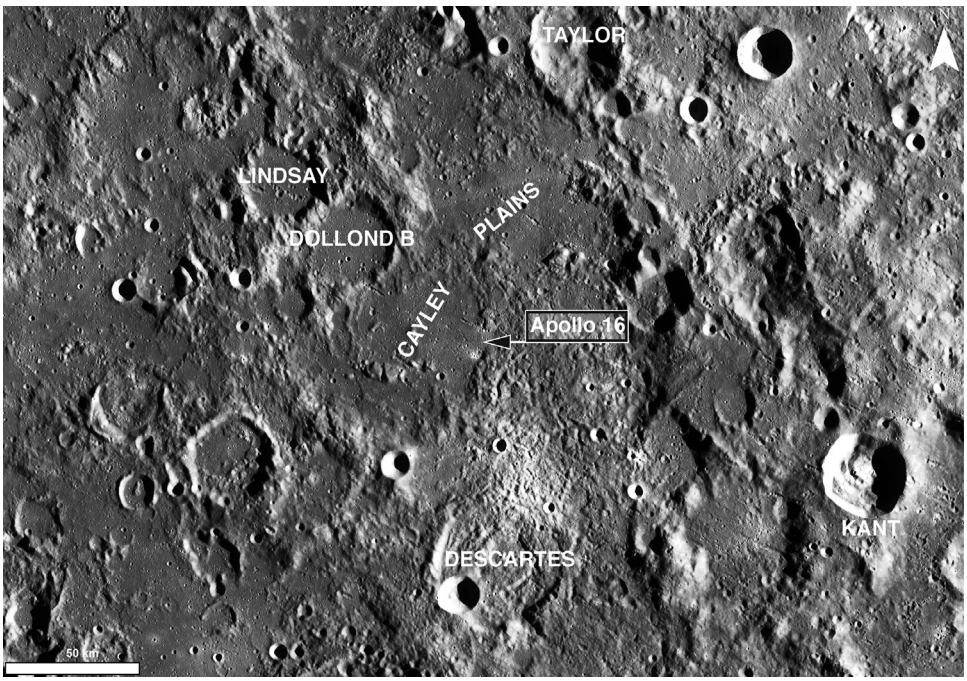

FIGURE 23.30 The geologic setting of the Apollo 16 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

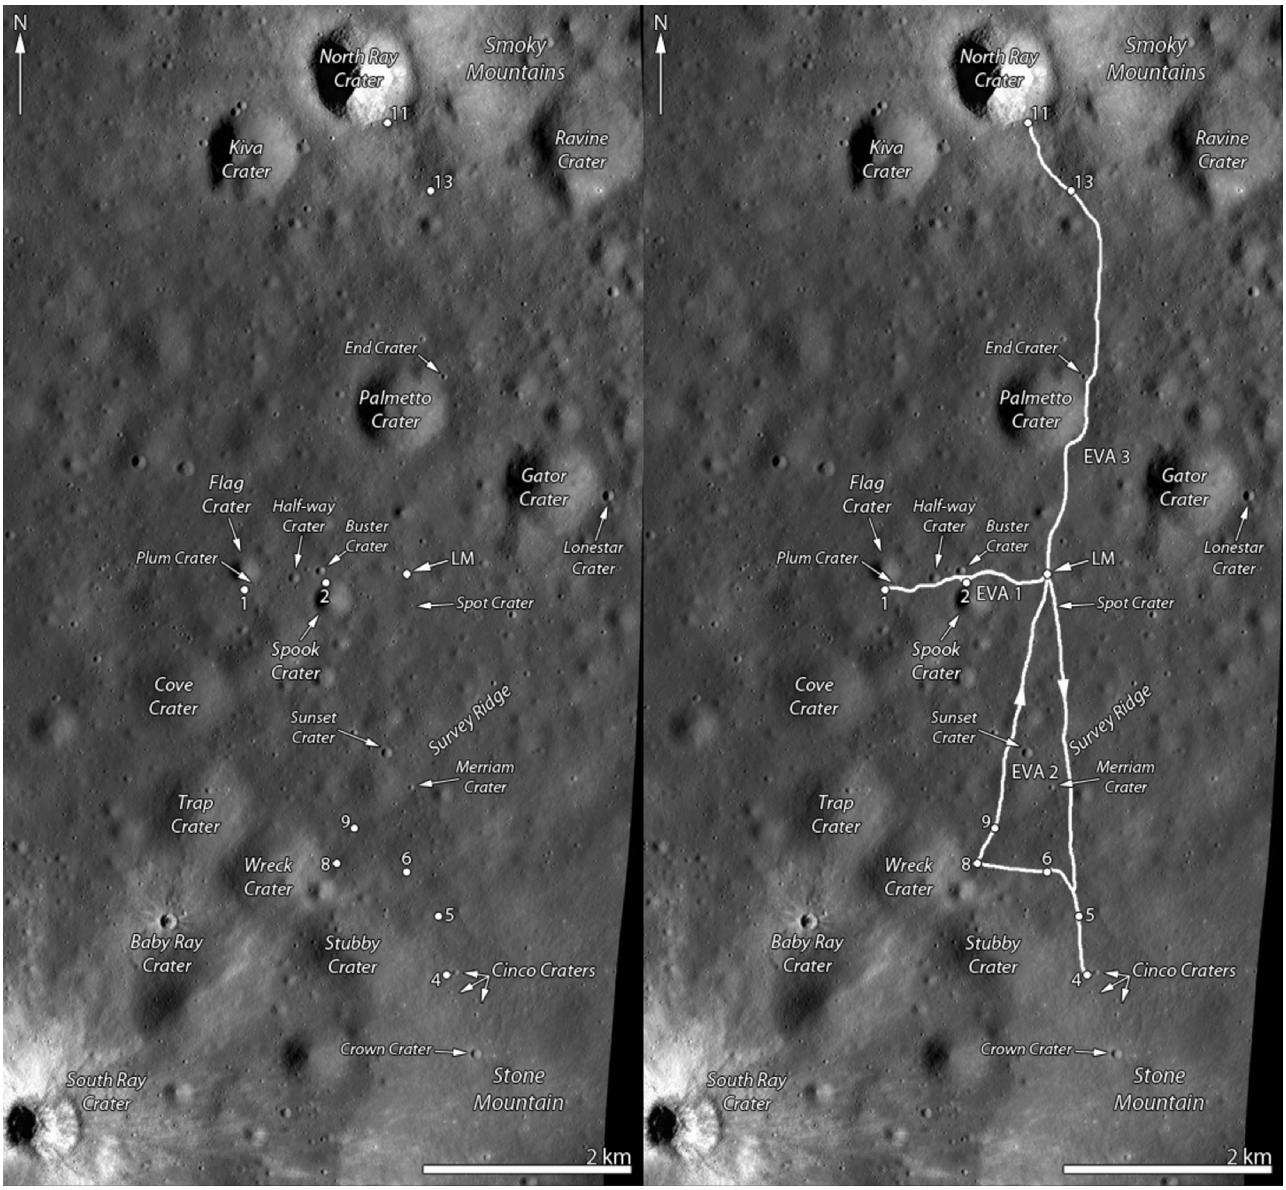

FIGURE 23.31 Detailed view of the Apollo 16 landing site and the location of experiments and traverses (left); detailed view of the EVA traverses (right). © *Images from the LROC webpage.*

The landing site includes numerous overlapping subdued craters ~500 m size; two young fresh craters, North Ray (1 km wide, 230 m deep) and South Ray (680 m wide, 135 m deep); as well as Stone Mountain (Figure 23.31). The regolith thickness on both the Cayley and the Descartes Formations varies from 3 to 15 m and averages about 6–10 m. In contrast to pre-mission interpretations, the Apollo 16 samples are mostly rocks of impact origin. Many are impact melts or fragmental breccias, but there are also some anorthositic rocks. From the returned samples it is apparent that neither the Cayley Formation nor the Descartes Formation is volcanic in origin, but instead both are related to the deposition of ejecta from the Imbrium, Serenitatis, and Nectaris basins. The relative amounts of ejecta contributed to the Apollo 16 site by each basin, however, are still under debate. Some Apollo 16 impact melts have been interpreted as products of the Nectaris event, indicating a formation of the Nectaris basin 3.92 or 4.21 Ga ago.

12.7. Apollo 17 (December 1972)

Apollo 17 was the last mission of the Apollo program and was sent to the highland/mare boundary near the southeastern rim of the Serenitatis basin, the Taurus-Littrow valley (20.190,850° N, 30.772,247° E) (Figures 23.9, 23.32). The goals of Apollo 17 were to examine

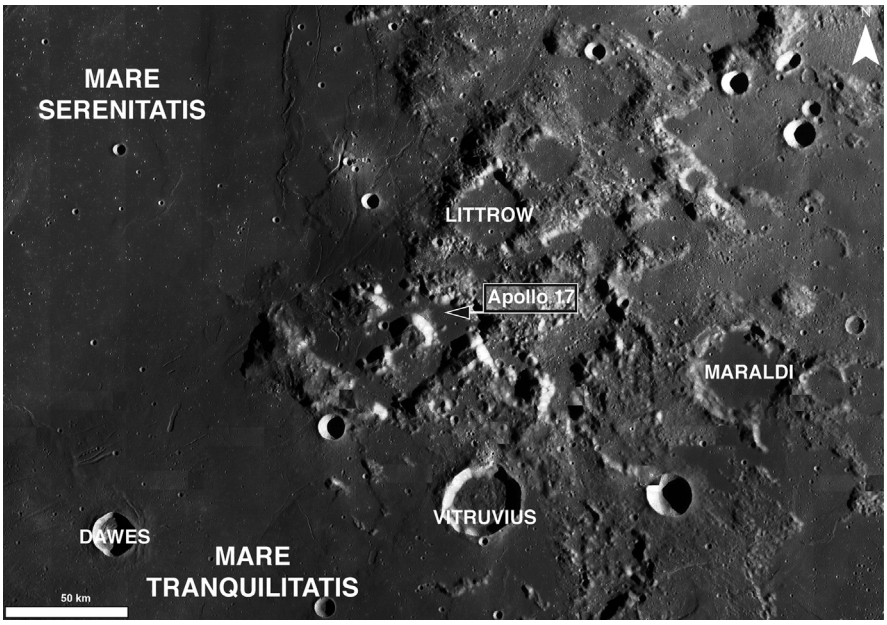

FIGURE 23.32 The geologic setting of the Apollo 17 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

two highland massifs where rocks from deep crustal levels could be collected, to investigate the presumably basaltic valley floor, and to study the low-albedo deposit that mantles both highlands and mare at the site. The Apollo 17 and 15 sites were the most geologically complex landing sites. Using the LRV, astronauts Eugene Cernan and Harrison Schmitt performed three EVAs and collected 110.5 kg of samples, bringing the total amount of samples collected by Apollo missions to 381.7 kg (Figure 23.33). Samples from this site show that the valley floor is covered with TiO_2-rich basalts. Specifically, several chemical subgroups of basalts were identified, ranging in age from 3.8 to 3.7 Ga.

It has been argued that the Apollo 17 impact melts are likely of Serenitatis origin because they were collected from thick ejecta deposits on the Serenitatis basin rim. However, some of the impact melt breccias have trace element signatures similar to some groups from Apollo 15 and Apollo 14, suggesting a minor component from the later Imbrium basin. Deep-seated magnesian-suite rocks and granulitic breccias were also identified in the highland massif regolith.

At the Apollo 17 landing site, the regolith is on the order of 15 m thick. The highlands along this part of the Serenitatis rim are relatively FeO-rich because of abundant mafic impact melt breccias and addition of basaltic material as impact debris and pyroclastic deposits. The compositions of the highland massifs are consistent with mixtures of noritic impact melt and feldspathic granulitic material, plus variable amounts of high-Ti basalts on the flanks at low elevations and pyroclastic deposits at high elevations. In summary, the highlands at the Apollo 17 site consist of complex impact melt breccias and plutonic rocks of the Mg-suite. Impact melt breccias are 3.87 Ga old and have been interpreted to indicate the age of the Serenitatis basin. Orange and black volcanic glass beads of high-Ti basaltic composition are incorporated in the dark mantling deposits, which are approximately 3.64 Ga old. A light-colored mantle unit presumably results from an avalanche at the slope of the South Massif triggered by secondary impacts from the 2200-km-distant Tycho crater (Figure 23.33). According to cosmic ray exposure ages, this landslide is ~100 Ma old and has been related to the age of the Tycho event.

12.8. Luna 16 (September 1970)

The first successful automated Soviet sample return mission, Luna 16, landed in northern Mare Fecunditatis at 0.513° S and 56.364° E (Figures 23.9, 23.34, 23.37). Luna 16 landed on a series of relatively thin basalt flows ~300 m in thickness. The landing site is geologically complex as it incorporates ejecta and ray material from Eratosthenian crater Langrenus (132 km diameter) 220 km to the southeast, Copernican crater Tauruntius (56 km diameter), and craters Theophilus and Tycho. Luna 16 samples were taken from a shallow regolith drill core, which reached a depth of 35 cm and provided 101 g of dark gray regolith with preserved stratigraphy. While no visible layering was recognized in the core, five zones of increasing grain sizes with depth were identified. Luna 16 samples consist of moderately high Ti, high-Al basalt fragments, approximately

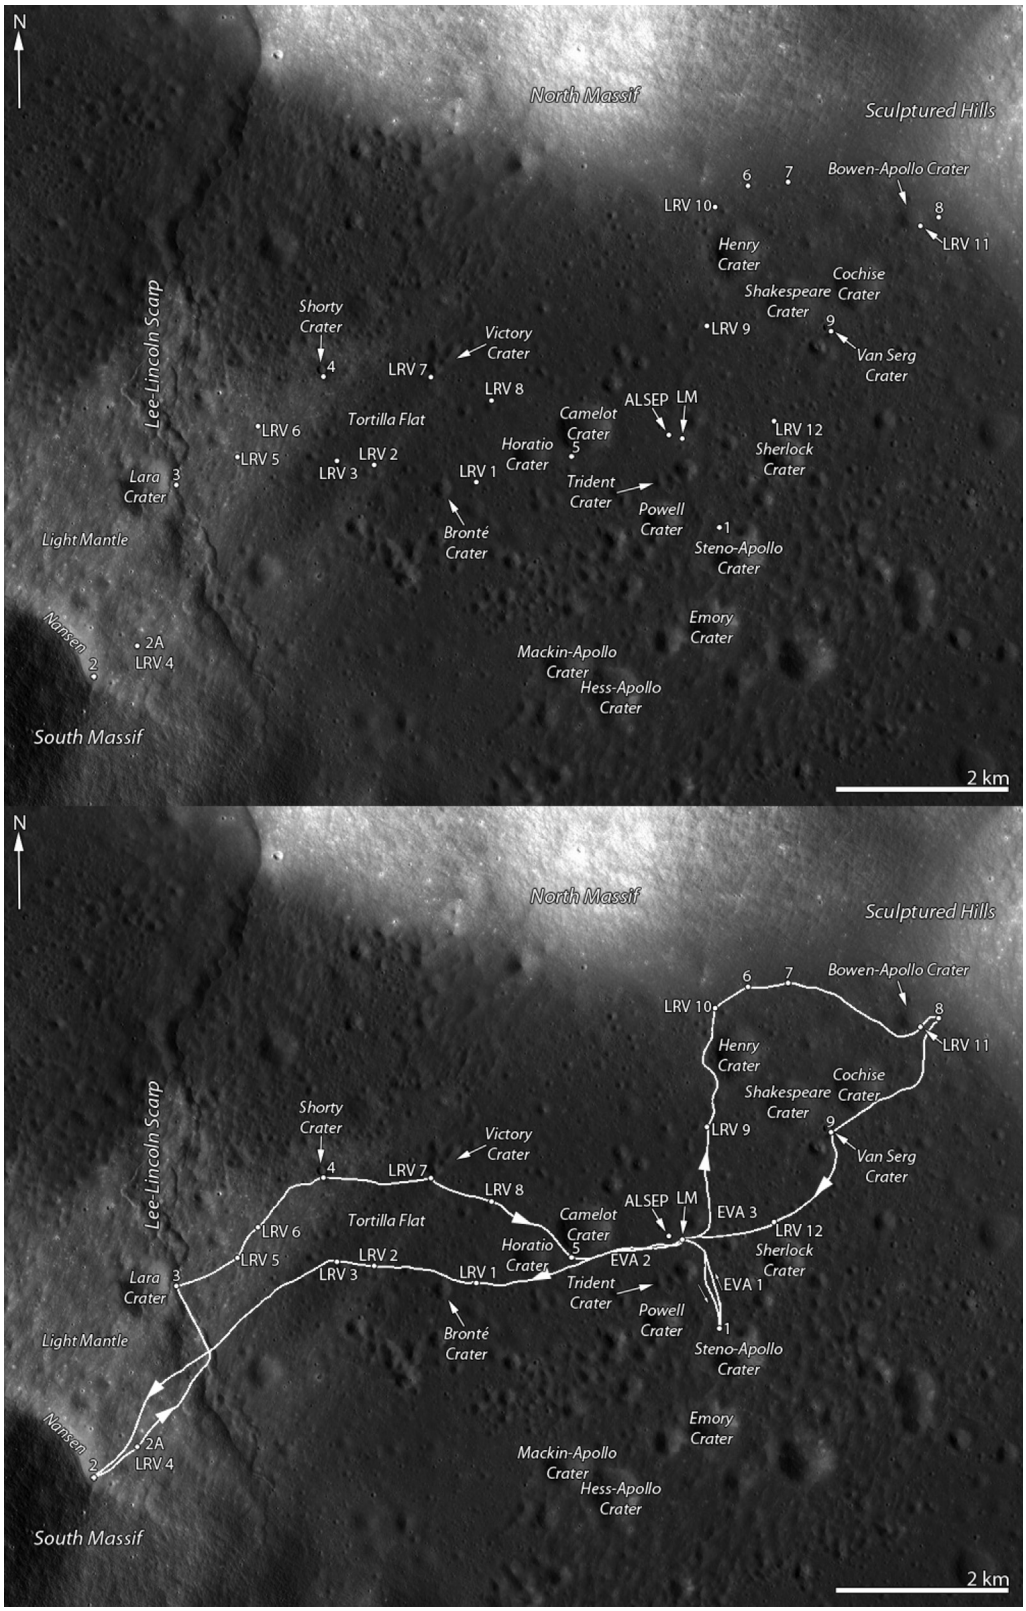

FIGURE 23.33 Detailed view of the Apollo 17 landing site and the location of experiments and traverses (top); detailed view of the EVA traverses (bottom). © *Images from the LROC webpage.*

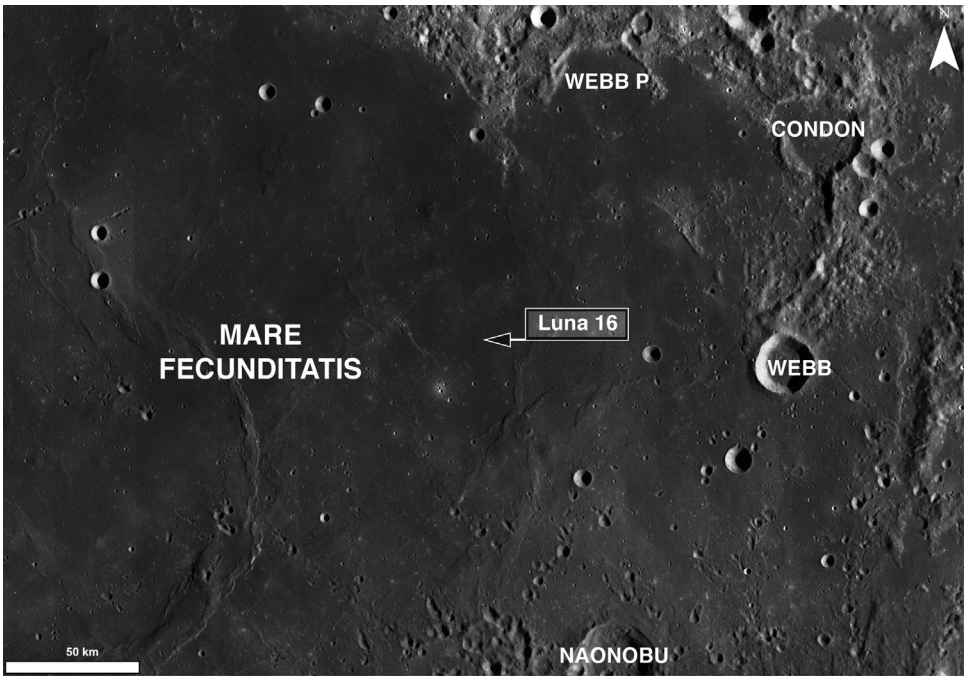

FIGURE 23.34 The geologic setting of the Luna 16 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

3.41 Ga old. While mare basalts from the Luna 16 landing site are among the most Fe- and Mg-poor lunar basalt samples, they are also the most Al-rich basalts (~13.5% Al_2O_3) yet sampled.

12.9. Luna 20 (February 1972)

Luna 20 landed in the highlands south of Mare Crisium (3.787° N, 56.625° E) and returned samples of the rim of the Nectarian-aged Crisium basin (Figures 23.9, 23.35, 23.37). The Luna 20 landing site is topographically ~1 km above the basaltic surface of Mare Fecunditatis and is influenced by Apollonius C, a 10-Ka fresh Copernican crater located only a few kilometers to the east. Morphologically, the landing site is characterized by smooth rounded hills and shallow linear valleys that give the region a hummocky appearance. Luna 20 returned a drill core that contained ~50 g of fine-grained light gray regolith. While no stratification has been observed within the core, mixing during transport to Earth cannot be excluded. The mission sampled the anorthositic highland regolith (Figures 23.9, 23.35) that contains lithic fragments of granulites, anorthosites, impact melts, and polymict breccias. Most of the lithic regolith fragments are breccias of anorthositic–noritic–troctolitic composition and impact melt rocks of noritic–basaltic composition. The Luna 20 regolith contains less K and P than the regolith at the Apollo 16 landing site, anorthosite fragments are rare, and MgO-rich spinel troctolites are common. Of particular importance are the higher concentrations of MgO because they may reflect the addition of an unknown mafic highland rock material to the Luna 20 site that is absent at the Apollo 16 landing site. Owing to the low K and P concentrations, it has been suggested that the Luna 20 samples have not been contaminated with KREEP-rich Imbrium ejecta. Instead, they may represent middle to lower crustal material ejected by the Crisium impact.

12.10. Luna 24 (August 1976)

Luna 24 was the last and most successful Luna mission. Luna 24 landed in southern Mare Crisium (12.714° N, 62.213° E) (Figures 23.9, 23.36, 23.37), about 40 km north of the main basin ring, which is ~3.5–4.0 km higher than the landing site. The landing site is characterized by wrinkle ridges, and several distinctive basalt types of Mare Crisium were identified by remote sensing techniques. The thickness of these basalts was estimated to be ~1–2 km. Several bright patches and rays imply that non-mare material has been dispersed across the basin by impacts such as Giordano Bruno and Proclus. Luna 24 returned a 1.6-m-long drill core that contained 170 g of mostly fine-grained mare regolith. In contrast to the drill cores of Luna 16 and Luna 20, stratification was well preserved in the Luna 24 core sample. On the basis of color and grain size differences, four layers were

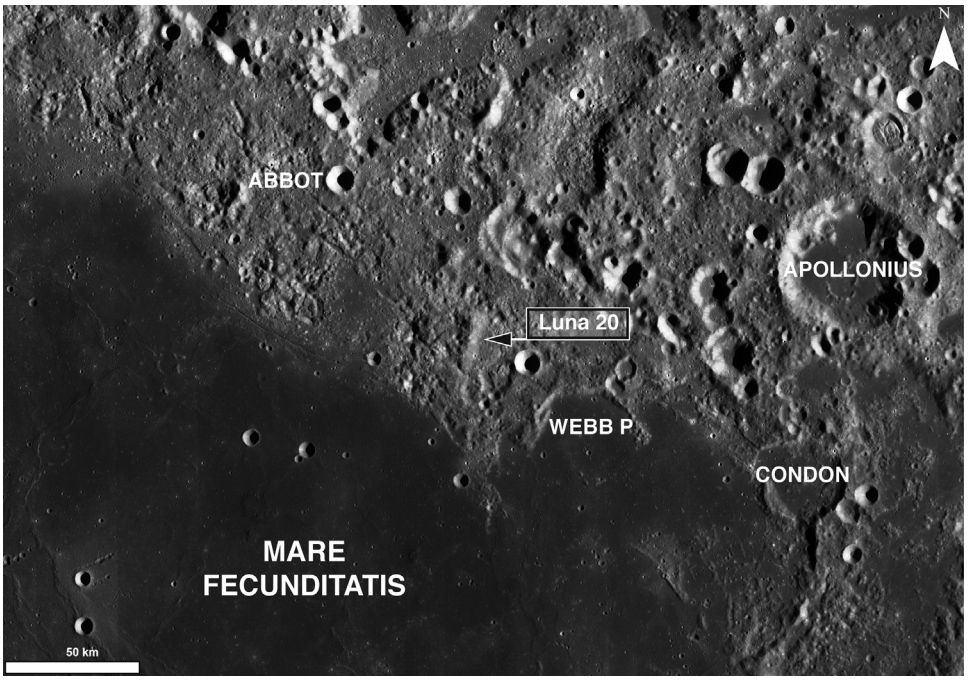

FIGURE 23.35 The geologic setting of the Luna 20 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

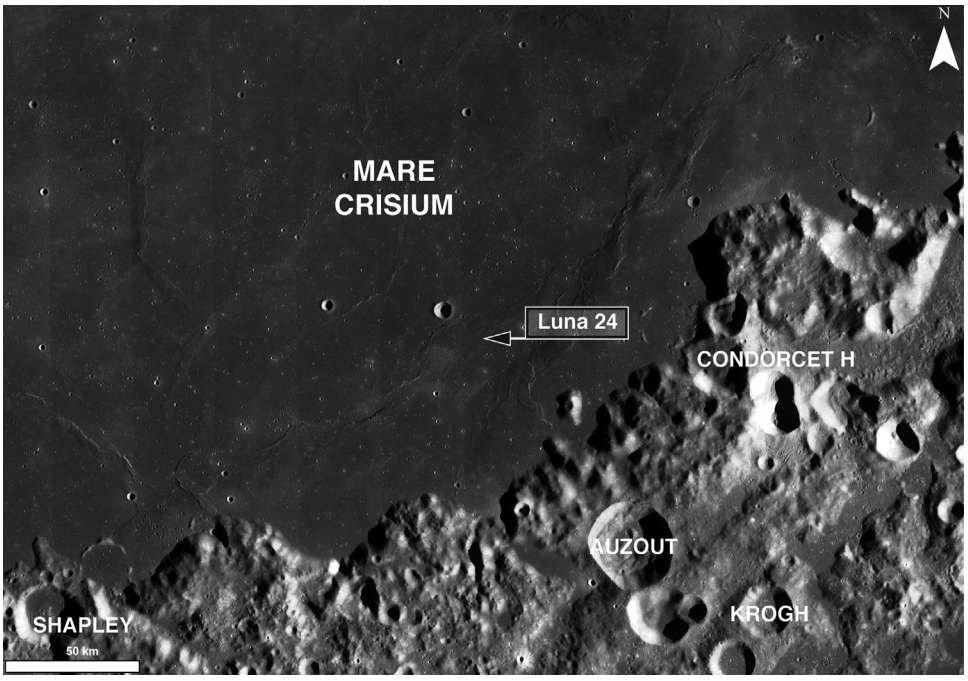

FIGURE 23.36 The geologic setting of the Luna 24 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

identified. The basaltic fragments from this core are very low in TiO_2, low in MgO, and high in Al_2O_3 and FeO and are 3.6−3.4 Ga old. Mare basalts and soils of Luna 24 contain similar concentrations of FeO and this observation indicates that only minor amounts of non-mare material occur at the landing site. In the Luna 24 drill core, there is also evidence for about 0.1 wt% of water at a depth of 143 cm. Although the abundance of water appeared to increase with depth, a possible contamination of the sample on Earth could not be excluded.

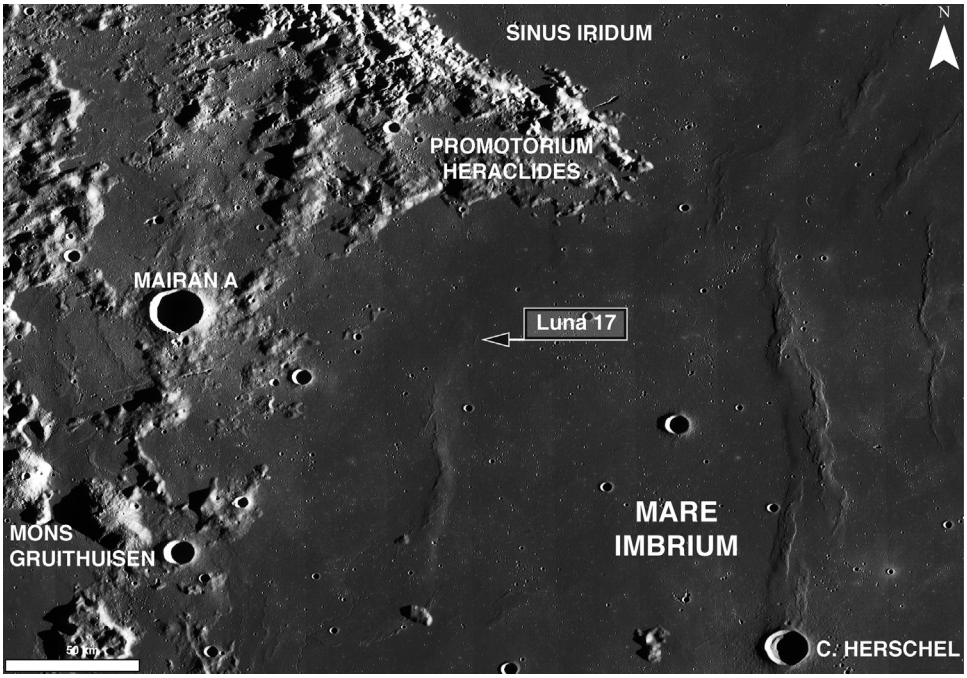

FIGURE 23.38 The geologic setting of the Luna 17/Lunokhod 1 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

12.11. Luna 17/Lunokhod 1 (November 1970–October 1971)

Lunokhod 1 was the first of two unmanned Soviet rovers. Equipped with four television cameras, an X-ray spectrometer, an X-ray telescope, cosmic ray detectors, a laser retroreflector, and a device to determine the density and mechanical characteristics of the lunar soil, Lunokhod 1 was transported to the lunar surface by the Luna 17 spacecraft. Lunokhod 1 landed in northern Mare Imbrium (Sinus Iridum, 38.238° N, 325.003° E) and operated for about 11 months, 8 months longer than originally planned. While roving about 10.5 km (Figures 23.9, 23.38, 23.39), Lunokhod 1 took about 20,000 images and 200 television panoramas and performed roughly 500 soil investigations. After losing contact with the rover in 1971, Lunokhod 1 was recently rediscovered in LRO images. Having a laser reflector on board, the position of Lunokhod 1 is now known to about 1 cm accuracy. Due to its high northern latitude and its location close to the limb, the Lunokhod 1 landing site is far from other landing sites with laser reflectors. Thus, Lunokhod 1 is particularly useful in determining the lunar librations and has become a significant new addition to lunar and gravity science.

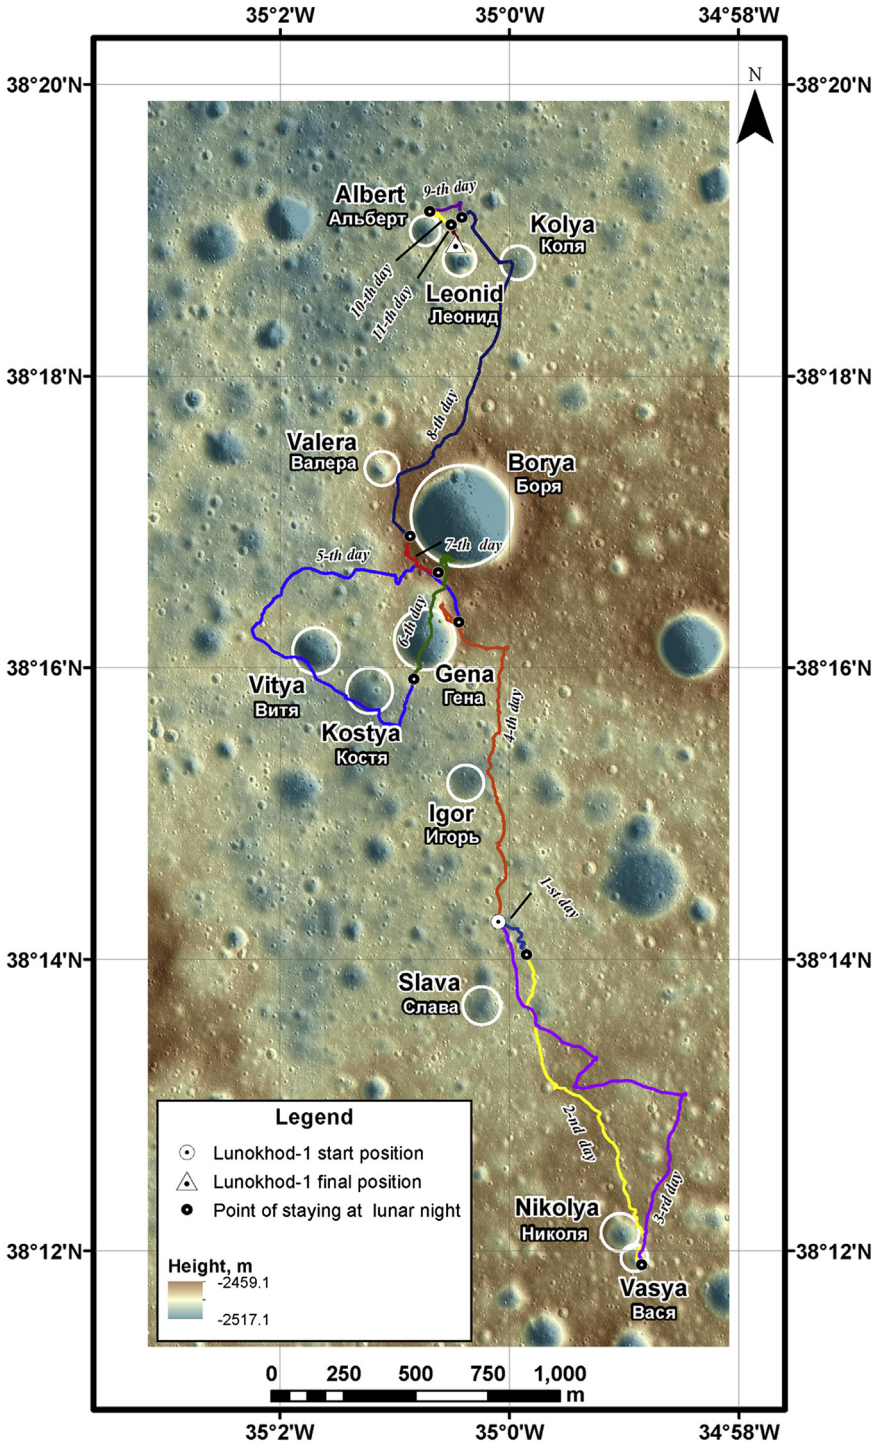

FIGURE 23.39 Detailed view of the Lunokhod 1 rover traverses with superposed topography. *Courtesy of I. Karachevtseva.*

12.12. Luna21/Lunokhod 2 (January–June 1973)

In 1973, the Soviet spacecraft Luna 21 delivered the second lunar rover, Lunokhod 2, to the surface of the Moon. Lunokhod 2 landed in crater Le Monnier (26.003° N, 30.408° E) at the northeastern edge of Mare Serenitatis. During 4 months of operation, Lunokhod 2 roved more than 42 km across the lunar surface (Figures 23.9, 23.40, 23.41). The main objective of Lunokhod 2 was to study the transitional zone between mare and highland areas and to investigate the southern part of a linear furrow located on

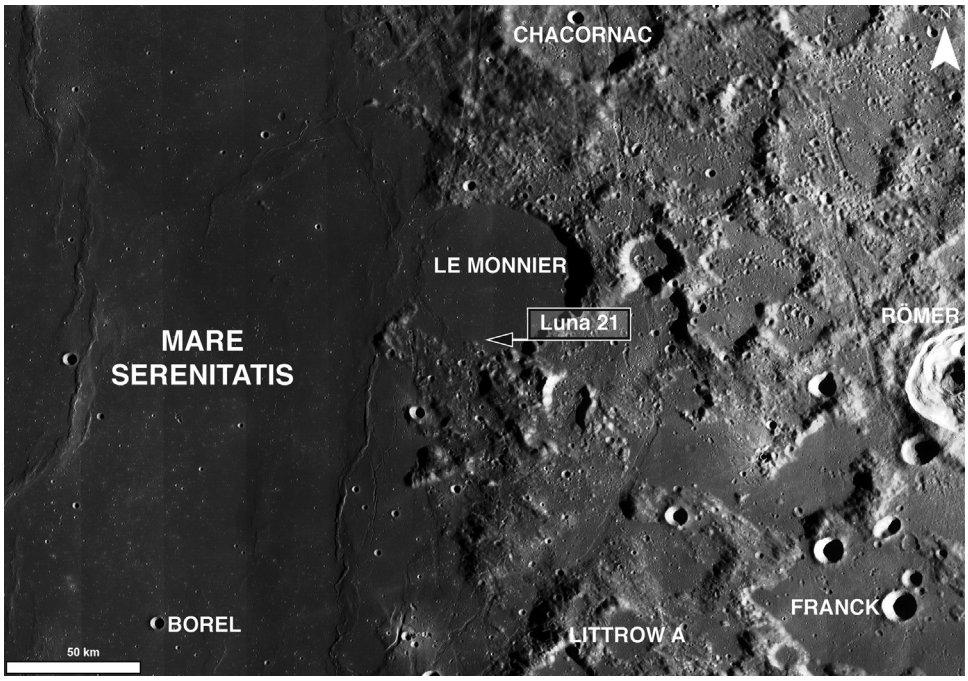

FIGURE 23.40 The geologic setting of the Luna 21/Lunokhod 2 landing site (LRO WAC mosaic). *From Hiesinger and Jaumann (2014).*

the mare surface of crater Le Monnier. The landing site consists of gently undulating terrain with numerous bowl-shaped impact craters. Around craters larger than 10 m in diameter, boulders are common. Lunokhod 2 discovered that close to the craters the wheels would sink deeper (20 cm) into the regolith compared to areas between the craters (5 cm), indicating local differences in the physical properties of the regolith. Despite the fact that the landing site is about 6 km from the highlands, even on the mare surface the X-ray spectrometer discovered a highland-like composition. Reported Al_2O_3 abundances are $\sim 9 \pm 1\%$ and FeO abundances are $\sim 6 \pm 0.6\%$. Because the composition became more highland-like the closer Lunokhod 2 approached the highlands, it was concluded that significant lateral transport of material occurs on the Moon.

13. SIGNIFICANCE OF LANDING SITES FOR THE INTERPRETATION OF GLOBAL DATA SETS

Our understanding of the geology, geophysics, history, and evolution of the Moon depends heavily on the information derived from the lunar landing sites. Landing site exploration and sample return are particularly beneficial because of the strength and synergy of having samples with known geologic context. Samples returned from the landing sites can be analyzed in detail in sophisticated laboratories with state-of-the-art techniques. In addition, portions of samples reserved for future analysis with even more sophisticated methods offer numerous advantages over in situ robotic measurements that are restricted to techniques available at the time of the mission. Numerous geophysical experiments deployed by astronauts are equally important and improved our knowledge of the physical properties and the internal structure of the Moon. In fact, laser reflectors at the landing sites are still used to accurately measure the Earth–Moon distance and to study lunar librations. Generally, the Apollo era data are still used in new innovative investigations. As a result, these data allow new models to be developed and tested long after the end of the Apollo missions. And of course, the landing sites provide important ground truth for all remote sensing experiments. In fact, the calibration of remote sensing data to the landing sites and the lunar samples allows derivation of information about unsampled areas.

The Apollo landing sites were carefully selected on the basis of safety considerations and scientific questions. In particular, the selection of each individual landing site can be viewed in the context of the scientific goal to obtain comprehensive understanding of impact basin structures and materials. This is crucial because the impact basin process is largely responsible for shaping the first-order features of the lunar surface. The schematic cross-section in Figure 23.42 illustrates the geologic setting of the Apollo and Luna landing sites relative to a multiringed impact structure, specifically in relation to morphologic features of the youngest lunar impact basin, Orientale. From this figure it is apparent that each landing site sampled very specific terrain types associated with large

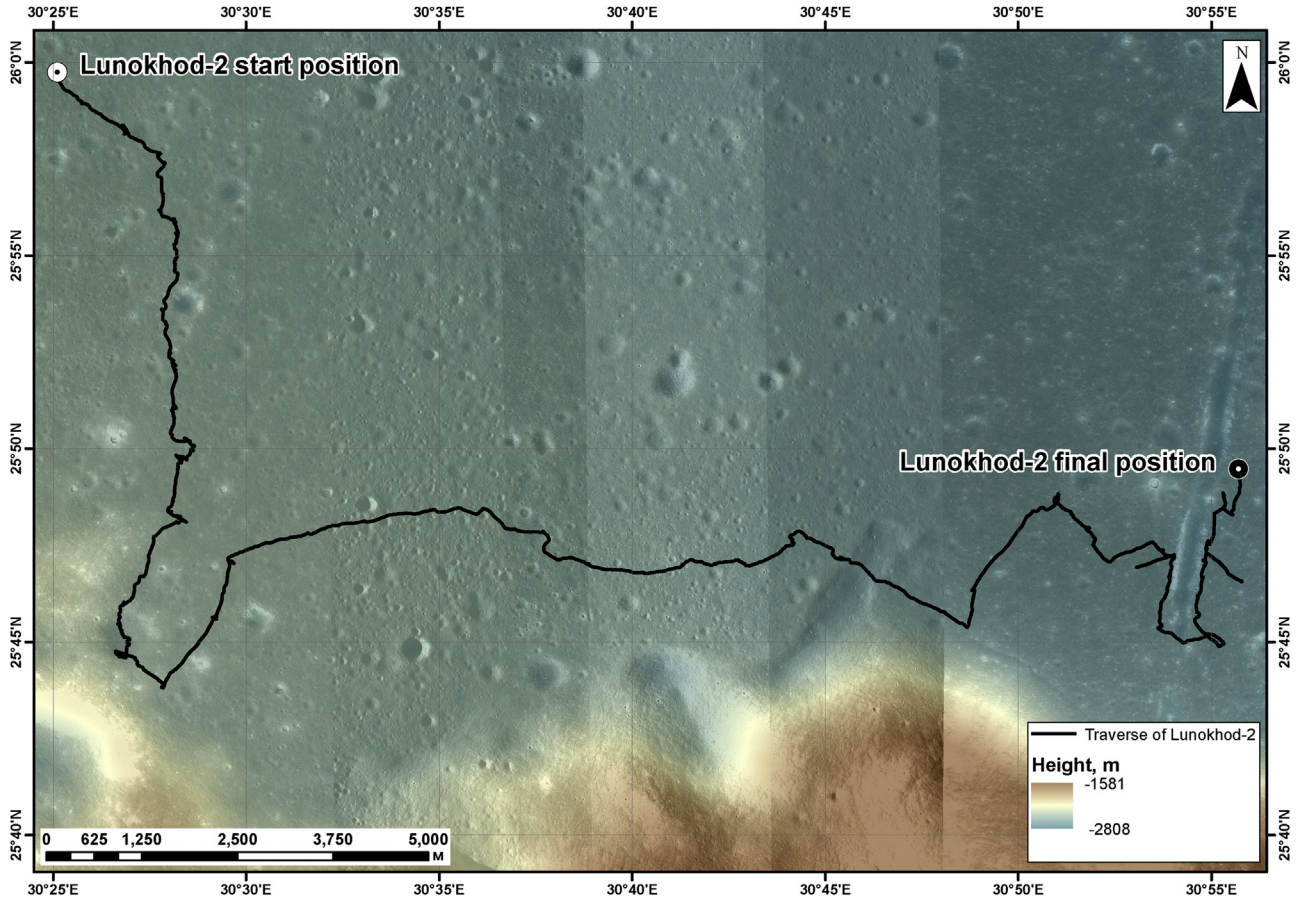

FIGURE 23.41 Detailed view of the Lunokhod 2 rover traverses with superposed topography. *Courtesy of I. Karachevtseva.*

lunar impact basins. In particular, Apollo 16 sampled old pre-basin highland terrain, Apollo 14 landed on radially textured basin ejecta deposits, and Apollo 15 samples contain polymict breccias, which were formed by a post-basin crater. Besides other investigations, Apollo 17 examined dark mantle deposits in detail, and Apollo 11 and 12 investigated different types of basalts. With the exception of Apollo 16 and Luna 20, all Apollo and Luna missions returned basaltic samples, and even these two missions returned small fragments of basaltic rock and glass in their regolith samples. As no mantle xenoliths have been identified in the returned samples, these basalts and the volcanic glasses are our best window into the lunar mantle.

In the late 1990s, Lunar Prospector identified a large area with elevated thorium concentrations on the lunar nearside. Several models for the origin of this thorium anomaly have been proposed, including accumulation of KREEP-rich magma beneath a region of thinned crust corresponding to the region of Oceanus Procellarum or accumulation above a degree-1 downwelling of dense ilmenite cumulates. While the precise carrier of the Th-rich compositional signature in broad areas of the Procellarum region cannot be identified from remote sensing alone, this question is crucial for understanding the magmatic and thermal evolution of the Moon due to radiogenic heat production. Fortunately, the landing sites of Apollo 12, 14, and 15 are located within the Procellarum KREEP Terrane (PKT) and thus allow us to study the KREEP signature from returned samples. For example, the Apollo 12 and 14 samples indicate that impact melt breccias and derivative breccias, such as regolith breccias and agglutinates, are the main carriers of KREEP. At the Apollo 15 landing site, however, basalt is an important carrier of KREEP. It has been proposed that the Imbrium basin impacted into the PKT and distributed KREEP-rich material globally across the lunar surface. This hypothesis is supported by the observation that abundant KREEP-rich material occurs in impact melt breccias of landing sites located outside the PKT, including Apollo 11, 16, and 17. In addition, smaller amounts of KREEP-rich material were found in soils from the Luna 16, 20, and 24 landing sites, which are located at greater distances from the PKT.

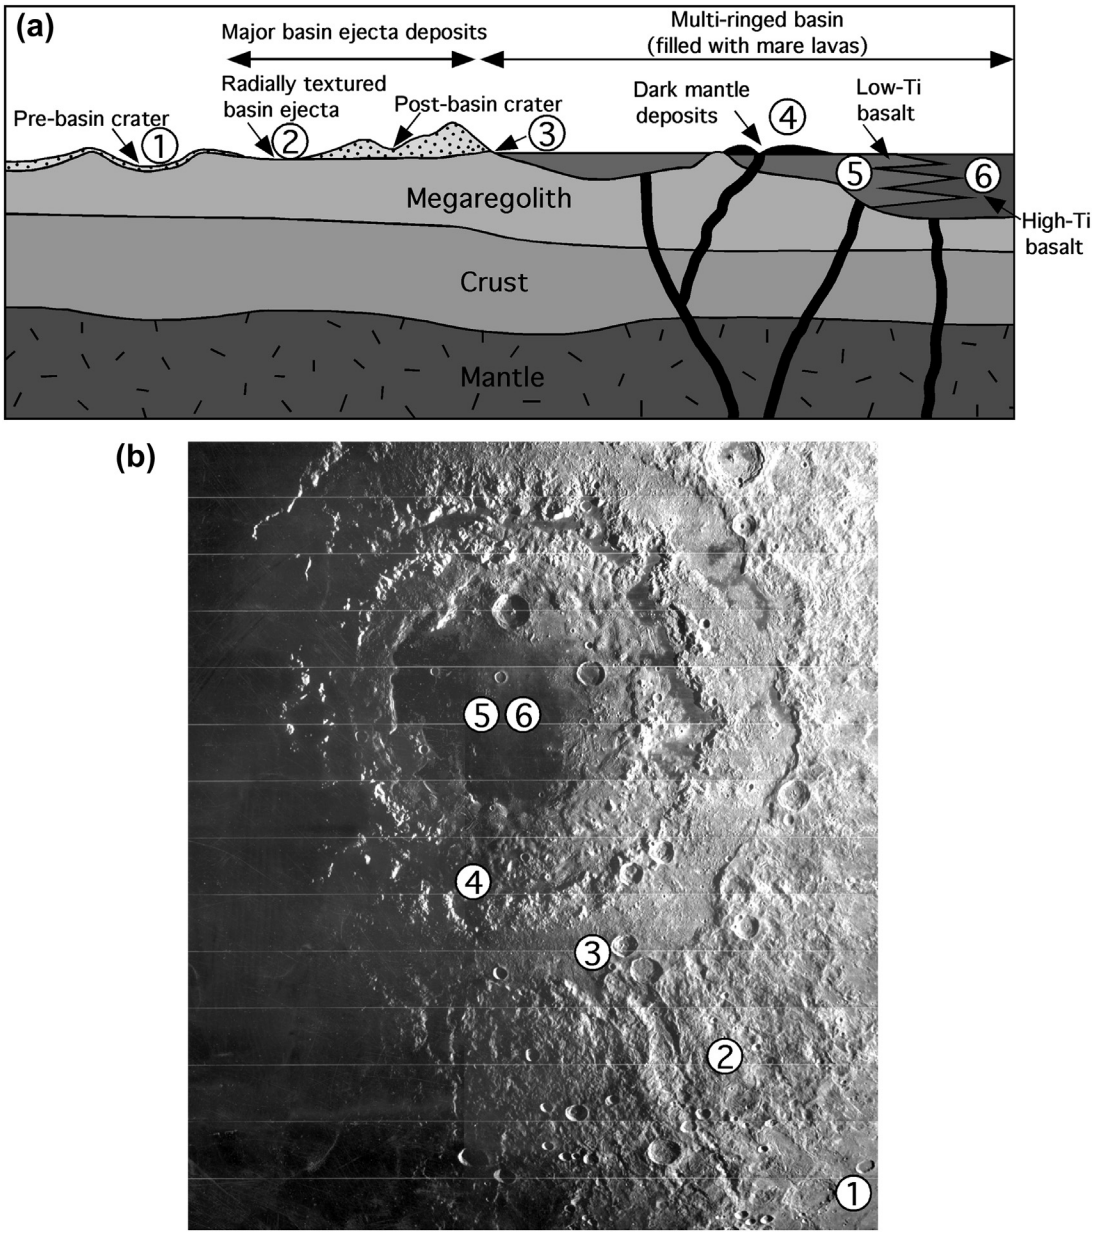

FIGURE 23.42 Schematic cross-section showing the Apollo landing sites in the context of a multiringed impact basin (a). Plan view of the Orientale basin with superposed locations similar to the Apollo landing sites (b); (1) similar to Apollo 16, (2) similar to Apollo 14, (3) similar to Apollo 15, (4) similar to Apollo 17, (5) similar to Apollo 12, (6) similar to Apollo 11. *From Hiesinger, H. & Head, J.W., III, (2006).*

In 1994, Clementine was the first spacecraft to provide high-resolution multispectral remote sensing images. These images permitted, for the first time, researchers to locate individual sampling stations at the Apollo 15, 16, and 17 landing sites. A comparison of spectra from these sampling stations with their average soil composition, revealed a strong correlation between spectral variations and compositions. On the basis of this correlation, algorithms were developed that allow calibrated global estimates of the FeO and TiO_2 concentrations on the lunar surface. Knowledge of the variability of these two compositional parameters in lunar basalts and their spatial distribution is important for understanding the petrogenesis of mare basalts and the history and evolution of magmatic processes on the Moon.

The lunar landing sites and the returned samples are essential for understanding the absolute chronology to anchor the Moon's geologic record. While the returned samples were dated radiometrically (e.g., U–Pb, Rb–Sr, Sm–Nd, and ^{40}Ar–^{39}Ar), with high accuracy, they only represent a few small areas on the Moon (i.e., the landing sites). Consequently, remote sensing techniques, i.e., CSFDs, are

required to derive absolute model ages for the vast unsampled lunar regions. In order to derive absolute model ages from crater counts for any unsampled lunar region, the radiometric ages from returned samples have to be correlated with the crater counts from the landing sites to establish the lunar cratering chronology. For this purpose, crater counts for the Apollo 11, 12, 14, 15, 16, and 17 and the Luna 16 and 24 landing sites were performed and correlated with the corresponding radiometric ages of these sites. There are several slightly different empirically derived lunar impact chronologies based on a variety of interpretations as to which radiometric sample ages are most representative for a given landing site.

Finally, the lunar landing sites are important to understand the physical properties of the lunar surface. In fact, the Moon is the only extraterrestrial body for which seismic activity, heat flow, and thermal and electric conductivity have been measured. In addition, the Apollo laser reflectors allow us even today, more than 40 years after the Apollo program, to accurately measure the distance between the Earth and the Moon and its librations. Both sets of measurements are crucial for our understanding of the lunar internal structure. The rediscovery of the Lunokhod 2 retroreflector adds to this data set.

Although it is apparent that samples and surface exploration are important as ground truth for remote sensing, information derived from orbital data provide the necessary context for the landing sites, thus feeding back into our understanding of the entire planetary body. With increasing spatial and spectral capabilities of modern remote sensing instruments, the gap between in situ exploration and orbital observations continues to close. For example, with images of the Lunar Reconnaissance Orbiter (LRO) that have a **pixel** scale on the order of 0.5 m, one can study the lunar surface on the scale approaching that of field observations on the Earth.

Some measurements are best done globally from orbit. High-resolution global gravity, topography, and magnetic field measurements all provide important input for studies of the lunar interior. From global compositional data it is apparent that the vast area of the Feldspathic Highland Terrane is not well represented by the returned samples and that the South Pole-Aitken (SPA) Terrane is not at all represented in the sample collection. The compositions of the increasing number of lunar meteorites better represent the compositional variety of the Moon than is reflected in the Apollo and Luna samples. These statistically significant and more or less random meteorite samples of the Moon are dominated by feldspathic breccias and by low- to intermediate-Ti basalts. The feldspathic breccia meteorites appear to represent the typical FHT better than Apollo 16 samples. The distribution of basalt compositions in the meteorite collection also appears to be more like what is anticipated from remote sensing, whereas the Apollo basalts disproportionately sampled high-Ti regions. In summary, an optimal understanding of the Moon comes from integration of all available data sets.

14. LUNAR VOLATILES

Compared to the Earth, the bulk Moon is significantly depleted in volatile elements, including water, and this has been interpreted to be a direct consequence of the violent impact origin of the Moon. While small amounts of water were reported in lunar soils returned from each of the Apollo missions, these were generally attributed to terrestrial contamination. Consequently, in the post-Apollo era, the consensus was that the Moon was primarily an anhydrous planetary body that contained <1 ppb H_2O. However, modern data returned by instruments onboard several *National Aeronautics and Space Administration* (NASA) missions indicate the occurrence of water ice, particularly in the permanently shadowed polar regions of the Moon (Figure 23.43). For the south polar crater Cabeus, the LCROSS mission confirmed the existence of H_2O and OH^-. On the basis of the estimated total excavated mass of regolith that was observable, the concentration of water ice in the regolith at the LCROSS impact site was calculated to be $5.6 \pm 2.9\%$ by mass. In addition, several other volatile species were detected in the impact vapor plume, including H_2S, NH_3, SO_2, C_2H_4, CO_2, CH_3OH, and CH_4. Remote sensing data also indicate that nearly the entire lunar surface, at least in the uppermost few micrometers to millimeters depth, is hydrated at least during some portions of the lunar day. This water may be present either as molecular H_2O adsorbed onto the lunar soil grains or as structurally bound OH^-. In addition, remote sensing data identified stronger absorptions at 2.8−3.0 μm at cooler high latitudes and associated with fresh feldspathic craters. These absorptions are typically attributed to OH^-- and/or H_2O-bearing materials and are thought to be the result of hydration processes at the lunar surface or else created continuously by solar wind protons interacting with oxygen-rich surfaces during the formation of lunar soil particles.

Complementing the discovery of water on the Moon by orbiting and impacting spacecraft has been the detection and quantification of water contents in lunar samples returned by Apollo missions and lunar meteorites. In addition, studies of the drill core of the Luna 24 mission revealed at least 0.1 wt% of water at depths below 143 cm. The H content and the D/H isotopic composition were measured in lunar volcanic glasses, derived from deep in the mantle, as well as apatite, the main OH^--bearing mineral in lunar samples. These estimates suggest that the lunar mantle might contain as much H as the terrestrial mantle. Some of the measured D/H ratios are high, consistent with cometary sources for at least some of the

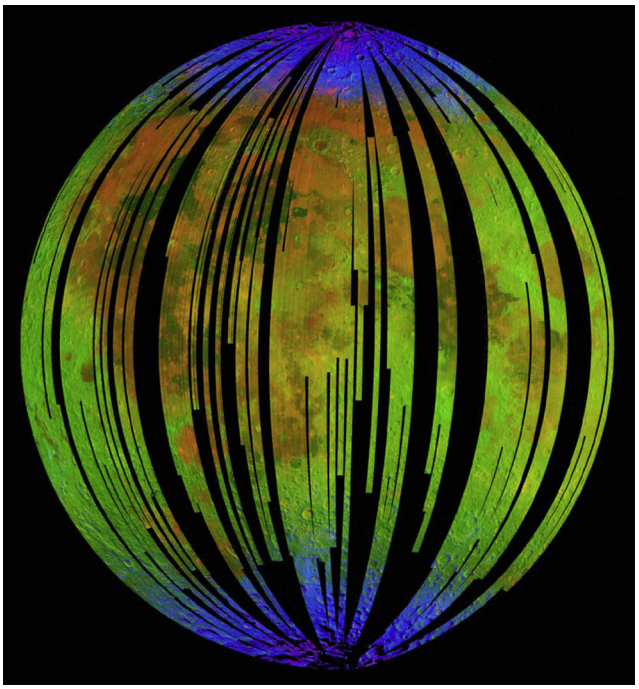

FIGURE 23.43 Moon Mineralogy Mapper (M^3) daytime near-infrared (NIR) color composite of the lunar nearside illustrating the spatial extent of diagnostic absorptions. Shown in blue is the 3-μm absorption associated with OH/H_2O; green indicates the reflected solar radiation (brightness) at 2.4 μm, and red represents the absorption at 2 μm due to the presence of iron-bearing pyroxenes. Small amounts of surficial OH/H_2O appear to be a function of the surface thermal and radiation environment and perhaps composition. During daytime, volatiles were most prominently detected at the higher, cooler latitudes. However, it cannot be excluded that a 3-μm feature at lower latitudes is masked by a minor thermal emission component. *From Pieters et al. (2009).*

water present in the lunar interior, and/or terrestrial-like original values with fractionation due to outgassing leading to high D/H values. In contrast, on the basis of chlorine isotope data from lunar samples it has been concluded that the lunar interior is dry.

Up to seven sources have been proposed for lunar volatiles including the Sun (solar wind reduction of lunar regolith), Earth (from the Moon-forming giant impact), Moon (internal degassing), comets, asteroids, interplanetary dust, and giant interstellar molecular clouds. The dominant sources of water are likely to be primordial acquisition during lunar accretion, "water ice" delivered to the Moon by cometary and asteroidal impacts after the completion of the main phase of lunar magma ocean crystallization, water produced by the interaction of solar wind hydrogen with oxygen-bearing minerals of the lunar soil, or a combination of these processes. For example, while the polar ice deposits on the Moon are most likely primarily cometary in origin, migration of solar wind-derived water from lower latitudes to polar cold traps during the **diurnal** cycle of the sunlit side of the Moon is also possible.

In the context of future lunar exploration, water is of particular interest and importance because water plays a fundamental role in planetary accretion and subsequent evolution. Finally, the discoveries of water on the Moon—in polar regions, in surface regolith, and in lunar rocks—allow investigating key astrobiological questions and enable future lunar exploration by allowing water production with in situ resource utilization techniques.

15. LUNAR ATMOSPHERE AND ENVIRONMENT

The atmosphere of the Moon is extremely tenuous. Important constituents of the lunar environment are neutral gases, plasma, and ejected dust particles that are generated by the interaction of the lunar surface with the space environment. These components and their characterization are not only of scientific interest but also have gained importance from an engineering perspective because of their effects on the proposed human and robotic activity on the lunar surface.

The atmospheric conditions on the Moon are similar to those of interplanetary space. While 10^5 to 10^7 particles/cm^3 or the total of 10^4 kg of gaseous species—14 orders of magnitude less than the atmosphere of Earth—are contained in a neutral lunar "atmosphere", interactions between particles due to collisions are negligible. Thus, the Moon has an exosphere. Known constituents are He, Ar, Na, K, and Rn that are captured from the solar wind or originate from the Moon by radioactive decay, sputtering, or micrometeorite impacts. A variety of energetic particles (particles associated with solar wind and solar **flares**, as well as galactic cosmic rays mostly consisting of protons, electrons and some heavier nuclei) also characterize the Moon's environment. The absence of a significant atmosphere and the absence of a global magnetic field cause this radiation to directly interact with the surface, yielding measurable alteration of the uppermost material as well as secondary radiation from the surface.

Recent measurements by Kaguya (SELENE), Chandrayaan 1, and LRO (i.e., the Cosmic Ray Telescope for the Effects of Radiation (CRaTER)) have shown that not all of the protons impinging on the lunar surface are absorbed or implanted. Instead, about 20% of the protons are backscattered or reflected, most of them as neutral hydrogen and only $<1\%$ as charged ions. Furthermore, reductions in the backscattered neutral hydrogen flux are observed in association with lunar magnetic anomalies, which may act as "minimagnetospheres" and reduce the impacting proton flux. Embedded in the plasma environment, the lunar surface becomes charged to an electrostatic potential, which is either positive or slightly negative on the dayside and significantly negative on the nightside. Thus, lateral changes

in the electrostatic potential especially close to the terminator may bear on the still open question of dust levitation.

Dust generated by hypervelocity impacts of fast projectiles (10−72 km/s) striking the lunar surface may also be present in the lunar environment. A total of 10^6 kg of micrometeoroids impact the lunar surface every year and each projectile excavates about 1000 times its own mass. Most of the ejecta return to the lunar surface, but a fraction could reach escape velocities forming a dust envelope around the Moon, similar to the Galilean satellites.

ACKNOWLEDGEMENT

This chapter is based on the articles "Geology, Geochemistry, and Geophysics of the Moon: Status of Current Understanding" published in the *Planetary Space Science* special issue "*Scientific Preparations For Lunar Exploration*", and "New Views of Lunar Geoscience: An Introduction and Overview", "Understanding the Lunar Surface and Space-Moon Interactions", and "Thermal and Magmatic Evolution of the Moon" published in *Reviews in Mineralogy and Geochemistry* that summarized the work of numerous lunar researchers. It is not possible to give credit to all lunar researchers whose work was included in this encyclopedia article, but we would like to refer the reader to these articles to find extensive references. The selected bibliography and the references therein further allow the reader to find the relevant primary literature, which has been used for this chapter. Particularly, we greatly appreciate the work of M. Anand, I. Antonenko, L. E. Borg, B. A. Campbell, R. M. Canup, J. Carpenter, I.A. Crawford, L. T. Elkins-Tanton, R. Elphic, B. Feldman, O. Gasnault, J. J. Gillis, M. Grott, T. L. Grove, B. H. Hager, A. N. Halliday, S. Hempel, P. C. Hess, H. Hiesinger, J. W. Head III, H. Hoffmann, L. L. Hood, D. Hunten, H. Hussmann, R. Jaumann, B. L. Jolliff, M. Knapmeyer, U. Köhler, R. L. Korotev, K. Krohn, D. Lawrence, S. Lawson, D.-C. Lee, J. Longhi, P. Lucey, S. Maurice, M. Mendillo, C. R. Neal, S. Noble, J. Oberst, J. J. Papike, E. M. Parmentier, T. Prettyman, M. E. Pritchard, R. C. Reedy, M. S. Robinson, N. Schmitz, F. Scholten, C. K. Shearer, F. Sohl, T. Spohn, L. A. Taylor, R. Wagner, U. Wiechert, and M. Wieczorek, as well as A. T. Basilevsky, C. P. Florensky, I. Karachevtseva, E. Speyerer, G. J. Taylor, and P. Warren. Special thanks to C. H. van der Bogert and J. H. Pasckert.

Last but not least, we are very thankful for Brad Jolliff's very thorough and extremely constructive review, which helped tremendously in improving the manuscript.

Chapter 24

Interior of the Moon

Renee C. Weber
NASA Marshall Space Flight Center, Huntsville, AL, USA

Chapter Outline

1. Introduction **539**
2. Bulk Lunar Properties **539**
3. Methods Used to Probe the Lunar Interior **541**
3.1. Apollo Core Samples 542
3.2. Gravity Measurements 542
3.3. Laser Ranging 543
3.4. Magnetic Techniques 544
3.5. Heat Flow 545
3.6. Compositional Studies 546
3.7. Seismology 546
4. Lunar Internal Structure **549**
4.1. Regolith 549
4.2. Crust 550
4.3. Mantle 551
4.4. Core 551
5. Implications for Lunar formation and Evolution **552**
Bibliography **554**

1. INTRODUCTION

Understanding the internal structure of the Moon is of key importance to deciphering its early history. The current consensus is that the Moon formed following the collision of a Mars-sized body with the Earth about 4.5 billion years ago. The rocky mantle of the impactor spun out to form the Moon, while the core of the impactor fell into the growing Earth. This model explains the high angular momentum of the Earth–Moon system, the low density of the Moon relative to the Earth, and the Moon's depletion of lighter **volatile** elements, which were likely lost during heating associated with the impact event. The model also provides a source of energy to melt the early Moon.

The geochemical and petrological evidence strongly supports the theory that the molten Moon floated an anorthositic crust about 4.45 billion years ago. This forms the present high-**albedo** highland crust. As the initially hot, molten Moon cooled, the mantle likely crystallized into a sequence of mineral zones by about 4.4 billion years ago. Heavier elements sank to form a small metallic core. Following the formation of the crust, major impacts on the surface produced many craters and multiring basins. The oldest basin observed is the South Pole–Aitken Basin and the youngest is the Orientale Basin, which formed 3.85 billion years ago. Some evidence suggests that a spike or "cataclysm" created many of these basins around 3.9–4.0 billion years ago.

Beginning about 4.3 billion years ago, and peaking between 3.8 and 3.2 billion years ago, partial melting occurred in the lunar interior, and basaltic lavas flooded the low-lying basins on the surface. This occurred mostly on the nearside, where the crust is thinner, resulting in the low-albedo lunar mare. Major volcanic activity ceased around 3.0 billion years ago, although minor activity may have continued until 1.0–1.3 billion years ago. The Moon has suffered only a few major impacts since that time (forming, for example, the young **rayed craters** such as Copernicus and Tycho).

An overview of the commonly accepted model of the Moon's present day internal structure, illustrating the crust, mantle, and core layers, is shown in Figure 24.1, and includes the probable depths of the interfaces between the core layers.

2. BULK LUNAR PROPERTIES

The mass of the Moon, determined from the orbital periods of various spacecrafts using **Kepler's third law**, is 7.35×10^{22} kg, which is 1/81 of the mass of the Earth. Although the Galilean satellites of Jupiter (Io, Europa, Ganymede, and Callisto), and Saturn's moon Titan are comparable in mass, the Moon/Earth ratio is the largest satellite-to-parent mass ratio in the solar system (Table 24.1). The lunar radius is 1738 ± 0.1 km, or 27% of the Earth's radius. This radius is intermediate between that of

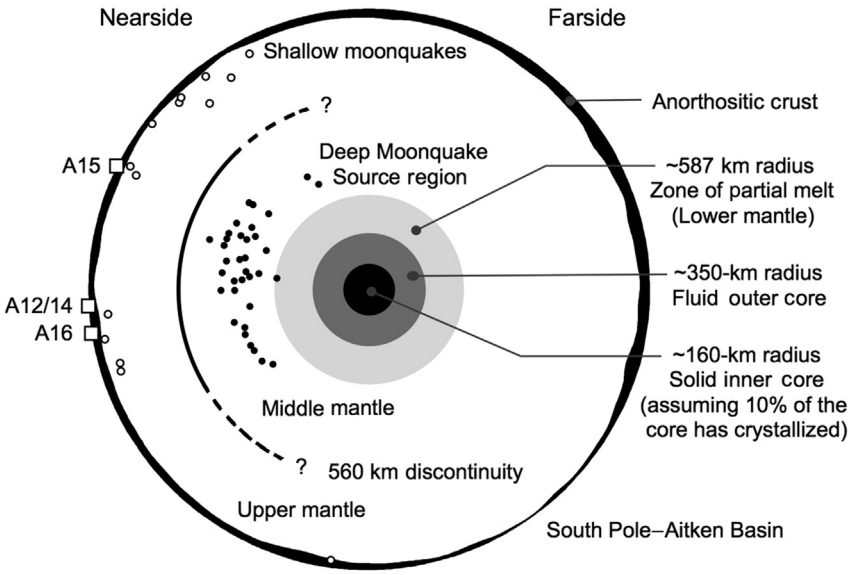

FIGURE 24.1 Schematic cross-section of the Moon showing the approximate depths of layering inferred using various geophysical methods. The nearside is to the left. The thickness of the crust is shown for a pole-to-pole profile at 0 and 180° longitude; the nearside crust is known to be thinner than the farside crust. The source regions of natural moonquakes (dots) detected by the Apollo seismometers (squares) have been projected onto the nearside hemisphere as a function of depth and latitude (see Section 3.7). *Figure reproduced from Wieczorek et al. (2006).*

TABLE 24.1 Radius, Density, and Satellite-to-Parent Mass Ratio of the Largest five Satellites in the Solar System, Sorted by Radius

Moons	Radius (km)	Density (kg/m^3)	Satellite-to-Parent Mass Ratio
Europa	1561	3014	1/39544
Moon	1738	3344	1/81
Io	1818	3529	1/21256
Callisto	2410	1834	1/17575
Titan	2576	1880	1/4225
Ganymede	2634	1942	1/12825
Materials			
Wood (pine)	–	0500	–
Water	–	1000	–
Stone (granite)	–	2700	–
Metallic iron	–	7874	–

The densities of several common earth materials are given for comparison.

Europa (radius = 1561 km) and Io (radius = 1818 km). The Moon is much smaller than Ganymede (radius = 2634 km), which is the largest satellite in the solar system. The lunar mean density is 3344 ± 0.003 kg/m^3, while the Earth has a much higher mean density of 5515 kg/m^3. The lunar density is also intermediate between that of Europa (density = 3014 kg/m^3) and Io (density = 3529 kg/m^3). Most of the other known satellites in the solar system are ice–rock mixtures and so are much less dense.

The Moon's moment of inertia (MOI) factor is related to its second-degree gravitational harmonics, which have been measured to high precision by orbiting spacecraft. Current

estimates indicate that the Moon's mean MOI is 0.3931 ± 0.0002, very close to that of a uniform density sphere, which has an MOI of 0.4. This value is met with a Moon that has a slight density increase toward its center, in addition to the presence of a low-density crust. In comparison, the mean MOI value for the Earth, with its dense metallic core that constitutes 32.5% of the Earth's total mass, is 0.3315.

The mass of the Moon is distributed in a nonsymmetrical manner, with the center of mass (CM) lying 1.9 km closer to the Earth than the geometrical center of figure (CF) (Figure 24.2). This offset is due to the presence of a thicker farside crust. This is a contributing factor in placing the Moon into synchronous orbit with the Earth, such that the Moon always presents the same face to the Earth. The gravitational influence of the Earth (and to a lesser extent, the Sun) on the Moon's asymmetric mass distribution resulted in torques that slowed down the rotation of the early Moon. These torques acted in combination with torques on the Moon's tidal bulges to slow the Moon's rotation until it became tidally locked, always presenting the same face to the Earth. However, the lunar longitudinal and latitudinal **librations** in combination allow a total of 57% of the Moon's surface to be visible at different times in the orbital cycle.

Various explanations have been advanced to account for the offset of the Moon's CM from its CF. Dense mare basalts erupted from the lunar interior cover about 17% of the lunar surface, mostly on the nearside, but they are generally less than 1 or 2 km thick and constitute only about 1% of the total volume of the crust—insufficient by about an order of magnitude to account for the effect. It has also been suggested that the offset could arise if the lunar core is displaced from the CM. However, such a displacement would generate shear stresses that could not be supported by the hot, likely molten (or partially molten) deep interior. Another suggestion is that some form of density asymmetry developed in the mantle during crystallization of the magma ocean, with a greater thickness of lower density materials being concentrated within the farside mantle. However, it is unlikely that such density irregularities would survive stress relaxation in the hot interior, unless actively maintained by convection (for which there is no present-day evidence).

The conventional explanation for the CM/CF offset is that the farside highland low-density crust is thicker, probably a consequence of an asymmetry developed during crystallization of the magma ocean. This explanation is supported by crustal thickness estimates derived from gravity mapping (see Section 3.2). The crust is massive enough and sufficiently irregular in thickness to account for the CM/CF offset. An equipotential surface is closer to the actual surface on the nearside. Magmas that originate at equal depths below the surface will thus have greater difficulty in reaching the surface on the farside, where the crust is thicker. This explains the scarcity of observed mare basalts on the farside. Lavas rise owing to the relative low density of the melt and do not possess sufficient hydrostatic head to reach the surface on the farside, except in craters in some very deep basins.

3. METHODS USED TO PROBE THE LUNAR INTERIOR

The Apollo Lunar Surface Experiments Package (ALSEP), deployed across the lunar surface by the astronauts on

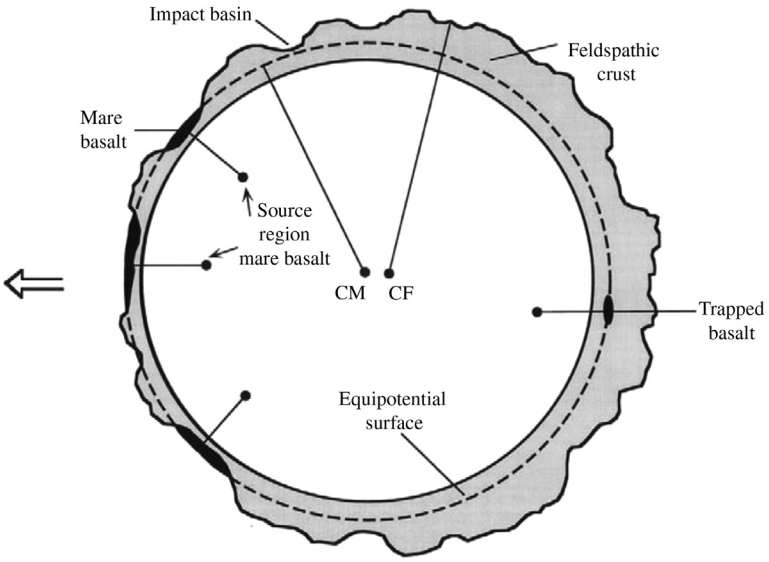

FIGURE 24.2 Schematic cross-section of the Moon in the equatorial plane showing the displacement of the Moon's center of mass toward Earth (figure left), due to the presence of a thicker farside crust (figure right). The crustal thickness is exaggerated for clarity. An equipotential surface is indicated with a dashed line. *Figure reproduced from "The Moon" chapter in the previous edition of the Encyclopedia of the Solar System.*

Apollo missions 12, 14, 15, 16, and 17, gathered several years' worth of data relevant to the lunar interior. Each ALSEP installation consisted of a set of geophysical instruments connected to a central base station. The base station acted as the command center for the entire package. It received commands and transmitted data to and from Earth, and distributed power to each experiment. The astronauts also gathered a wide collection of samples from the lunar surface, which were returned to Earth for analysis.

Instruments both onboard spacecraft in lunar orbit and Earth-bound also gather measurements that are useful for deciphering the Moon's internal structure. These include gravity and magnetic field data measured from orbit and laser ranges originating from Earth.

This section will review results of the active and passive seismic experiments and the heat flow experiment from ALSEP, analyses performed on samples gathered from the surface and shallow subsurface, and a variety of orbital and Earth-based measurements, and discuss interpretations of the lunar interior made from these data.

3.1. Apollo Core Samples

The near-surface structure of the Moon was revealed by core samples taken by the Apollo astronauts (Figure 24.3). Core tubes were either 2 or 4 cm in diameter and were pounded into the surface with a hammer. The deepest core was nearly 3 m at the Apollo 17 landing site, and a total of 24 cores were collected over all six Apollo surface sites. These cores revealed that the shallowest lunar layer, known as the regolith, is a complex array of overlapping ejecta blankets resulting from meteor bombardment on the lunar surface throughout the Moon's history. This process is known as impact gardening, and results in a shallow layer of particles of varied size and texture (see Section 4.1).

3.2. Gravity Measurements

The Moon's internal structure can be inferred through analyses of the lunar gravity field as measured from orbit (Figure 24.4). Variations in surface gravity across the Moon are caused by density heterogeneity in the subsurface, and these variations affect the position of the orbiting spacecraft. First noticed during analysis of tracking data from National Aeronautics and Space Administration (NASA)'s Lunar Orbiter program in the 1960s, the Moon's gravity field has been mapped in successively higher resolution by missions such as NASA's Lunar Prospector in the 1990s, the Japanese space agency's SELENE orbiter (Selenological and Engineering Explorer) in the 2000s, and NASA's GRAIL mission (Gravity Recovery and Interior Laboratory) in the 2010s. The GRAIL mission mapped the Moon's gravity in unprecedented detail, resulting in the highest resolution gravity map of any body in the solar system, including Earth.

The biggest features resolved in the lunar gravity field are known as **mascons**, or mass concentrations. They are associated with giant impact basins and are caused by the uplift of a central plug of dense mantle material during impact, followed by the much later addition of dense mare basalt. Smaller shallow features are also resolved in the gravity data, including tectonic structures, volcanic landforms, basin rings, complex crater central peaks, and simple bowl-shaped craters. Young ray craters have negative gravity anomalies because of the mass deficit associated with excavation of the crater, combined with the low density of the fallback rubble. Craters less than

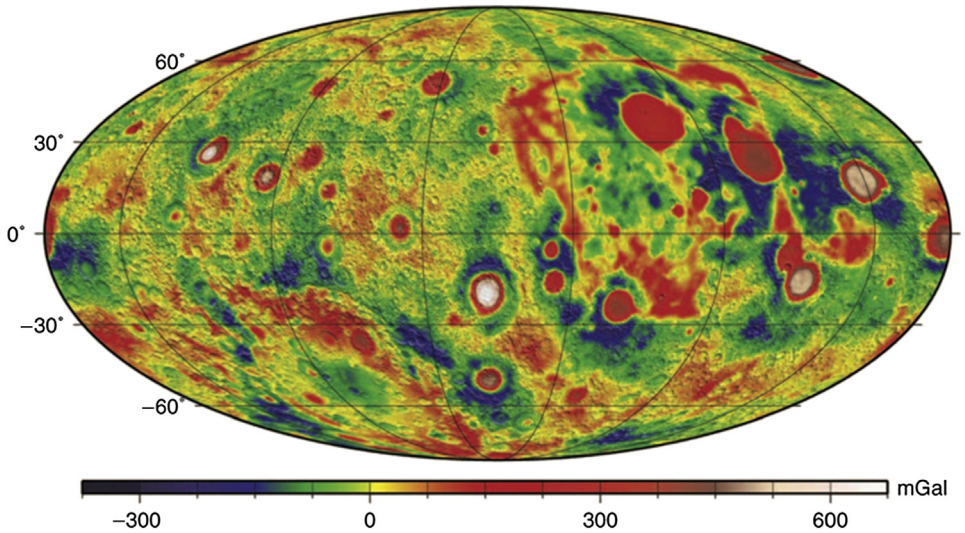

FIGURE 24.4 Bouguer gravity anomaly map from the GRAIL lunar gravity model GL0420A. The map is a Molleweide projection centered on 270° E longitude, with the nearside on the right and farside on the left. *Figure reproduced from Zuber et al. (2013).*

200 km in diameter have negative gravity anomalies for the same reason (e.g. Sinus Iridum has a negative anomaly of −90 mGal). Volcanic domes such as the Marius hills have positive anomalies (+65 mGal), indicating support by a rigid lithosphere. The gravity signature of young, large, ringed basins, such as Mare Orientale, shows a "bull's-eye" pattern with a central positive anomaly (+200 mGal) surrounded by a ring of negative anomalies (−100 mGal) with an outer positive anomaly collar (+30 to +50 mGal).

In combination with topography data, the gravity field can also be used to infer the depth of the crust−mantle interface (known as the **Moho**). The Moho deflects in response to surface loads, and the resulting flexural signature contributes to the observed gravitational field. Crustal thickness largely correlates with topography, with the exception of the lunar mare regions. These areas of low elevation were resurfaced by high-density basaltic lava flows, resulting in more complex flexural signals. The average density of the highland crust calculated from GRAIL-derived crustal thickness estimates is 2250 kg/m^3.

The lunar highland crust is strong. High mountains such as the Apennines (7 km high), formed during the Imbrium collision 3.85 billion years ago, are uncompensated and are supported by a strong cool interior. The gravity data are consistent with an initially molten Moon that cooled quickly and became rigid enough to support loads such as the circular mountainous rings around the large, younger, ringed basins as well as the mascons. Even if some farside lunar basins do not show mascons, this may merely be a consequence of the greater thickness of the farside crust. The South Pole−Aitken Basin (the largest and oldest basin, age at least 4.3 billion years) is particularly significant in this respect.

3.3. Laser Ranging

Additional information about the interior of the Moon can also be inferred from data gathered by the ongoing Lunar Laser Ranging (LLR) experiment. This experiment consists of Earth-based laser ranges to an array of retroreflectors emplaced on the lunar surface 30 years ago by both US and Russian missions.

A laser pulse is fired from the Earth to the Moon, where it bounces off a retroreflector and returns back to Earth (Figure 24.5). The round-trip travel time can be used to measure the Moon's shape and position with accuracy better than 2 cm. The analysis of LLR data provides a wealth of information concerning the dynamics and internal structure of the Moon.

The distances between the retroreflectors and the Earth change in part because of lunar rotation (physical librations) and tides. Values of the gravitational harmonics, the moments of inertia, the lunar Love number k_2 (which measures the tidal change in the Moon's moments of inertia and gravity), and variations in the lunar physical librations are related to the Moon's composition, mass distribution, and internal dynamics.

A range of internal structure models is compatible with the MOI values constrained by LLR. For example, a 60-km-thick lunar crust with density of 2750 kg/m^3, a constant-density lunar upper mantle, a lower mantle with a similar change in density relative to the upper mantle, and a variable-radius iron core with density of 7000 kg/m^3 produces an appropriate MOI. In this case the maximum

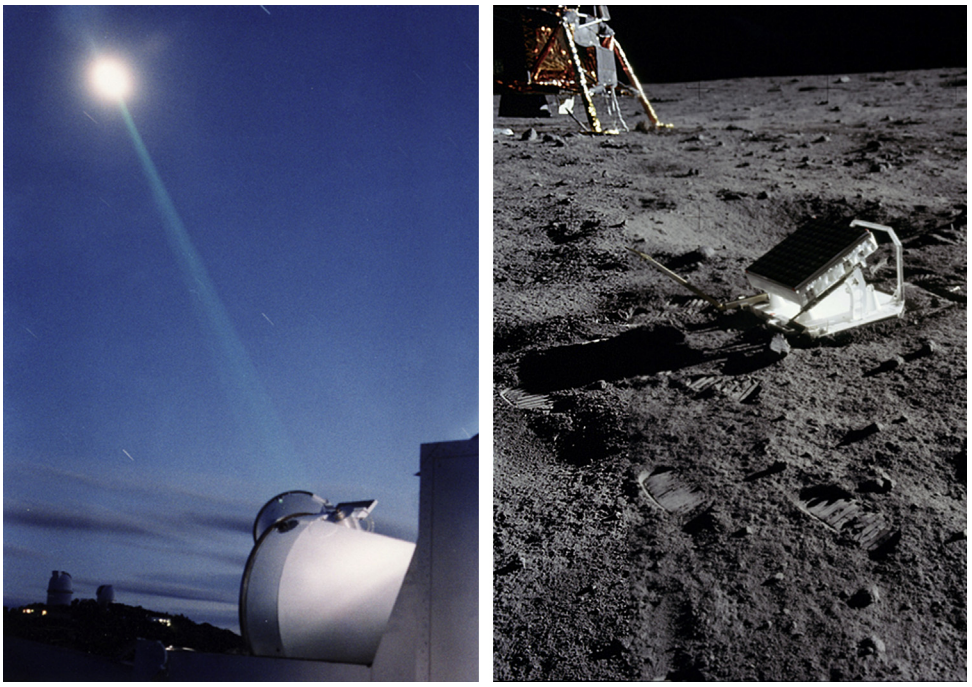

FIGURE 24.5 (Left) The Lunar Laser Ranging Station at the University of Texas McDonald Observatory. Photo by Randall L. Ricklefs. (Right) Laser retroreflector installed on the lunar surface by the Apollo 11 astronauts. *Photo AS11-40-5952 from the NASA Apollo Archive.*

core size is in the range of 220−350 km, and an increase in crustal density to 2959 kg/m^3 raises the maximum core size to 400 km, consistent with other estimates (see Section 4.4). All layers can be adjusted in thickness and density to produce a suite of plausible lunar structure models.

For a perfectly rigid Moon, the mean direction of the lunar spin axis would be expected to precess with the Earth−Moon orbit plane. The LLR data show, however, that the true spin axis of the Moon is displaced from the expected direction. This is the result of ongoing active dissipation in the lunar interior, which has been proposed to be due in part to friction at the interface between the solid lower mantle and a fluid core.

3.4. Magnetic Techniques

At present, the Moon does not possess an internally generated magnetic field. However, some samples returned by the Apollo astronauts from the lunar surface retain natural remanent magnetism. In addition, orbital estimates of surface magnetic field strength reveal regions of increased magnetic intensity (Figure 24.6), albeit with field strengths of only about 1/100th of the terrestrial field. Based on the age dating of Apollo samples, this magnetic signature suggests that between about 3.6 and 3.9 billion years ago, there was a planetary-wide magnetic field that has now vanished. The field appears to have been much weaker both before and after this period.

Although taken from the lunar surface, these observed present-day remanent magnetic anomalies are relevant to the lunar internal structure since one interpretation is that the Moon once possessed a lunar dipole field of internal origin. The favored mechanism is that the field was produced by dynamo action in a liquid iron core, similar to the way Earth's magnetic field is generated. A core about 400 km in diameter could produce a field at the lunar surface with strength comparable to the observations. In early lunar history, this magnetization would be impressed into the cooling lunar crust.

An alternative interpretation suggests that the magnetic signature may not be internally generated but rather results from shock magnetization in transient fields generated following the basin-forming impacts in lunar history. This theory is supported by the observation that the largest crustal magnetizations appear to be located at or near the antipodes of the largest impact basins. In addition, some localized strong magnetic anomalies are associated with patterns of swirls—high-albedo features that impart no observable topography. These swirls have likewise been suggested to form by some focusing effect of the seismic waves that resulted from the large basin-forming impacts. More work is clearly needed to substantiate this hypothesis and to understand the association of swirls and magnetic fields.

The internal structure of the Moon can also be inferred by measuring the lunar-induced magnetic dipole moment. This is the residual response of the lunar interior to the

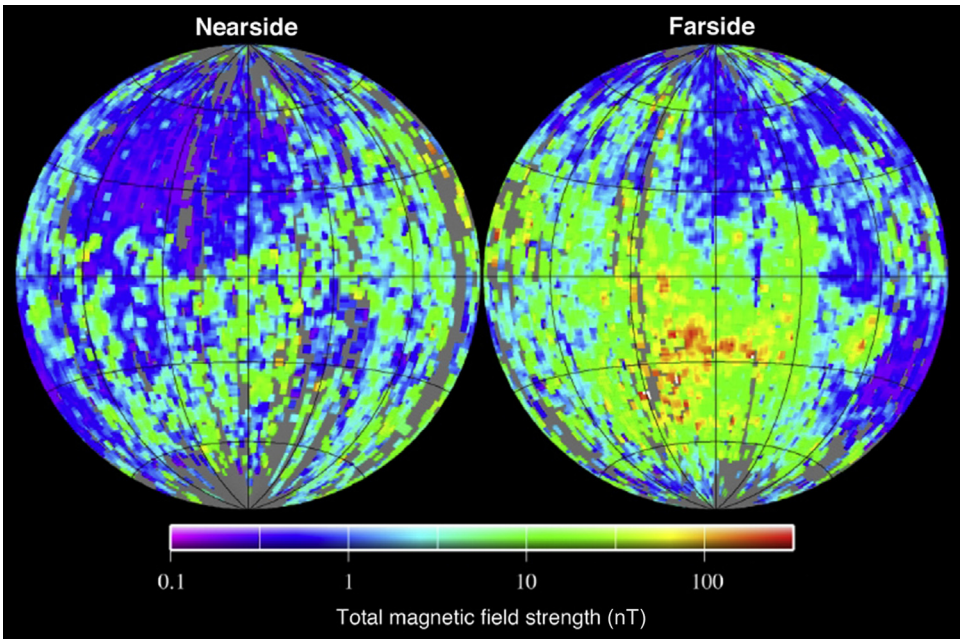

FIGURE 24.6 Total magnetic field strength at the surface of the Moon as derived from the Lunar Prospector electron reflectometer experiment, which was in orbit around the Moon during the years 1998–1999. *Figure courtesy of M. Wieczorek.*

sudden exposure of the Moon to a uniform magnetic field in a near-vacuum environment, which happens every month as the Moon passes through the Earth's geomagnetic tail. The external field is perturbed by an induced magnetic field caused by currents at the surface of a highly electrically conducting (iron) core, and these perturbations can be measured by orbiting spacecraft. Data gathered by the Lunar Prospector magnetometer were analyzed to conclude that the Moon likely does possess an iron-rich core, with a preferred radius of 340 ± 90 km.

3.5. Heat Flow

The rate at which a planetary body loses heat to space is an important indicator of the level of tectonism and volcanic activity on that planet. Two measurements of the lunar heat flow are available, as measured by the ALSEP's Heat Flow Experiment during the Apollo 15 and Apollo 17 mission's surface operations. The Heat Flow Experiment involved drilling a hole into the lunar regolith and inserting a probe that measured temperature at several depths within the hole. The rate at which temperature increases with depth provides a measure of the total heat flowing from the Moon's interior: 21 mW/m^2 at the Apollo 15 site and 16 mW/m^2 at the Apollo 17 site, respectively. These surface heat flow measurements are close to Earth-based estimates from microwave observations.

Unlike the Earth, which dissipates most of its heat by convective volcanism at the midocean ridges, the Moon transports its heat to the surface by conduction. A lack of observed present-day active volcanism or tectonism on the Moon indicates that most of its original internal heat has been lost, so any observed heat flow must be instead predominantly due to the radioactive decay of heat-producing elements, with a small percent of the total heat flow consisting of the loss of residual heat from lunar formation.

If the Apollo heat flow measurements are considered to represent the average heat loss characteristic of the entire Moon, they can be used to provide constraints on the bulk lunar abundances of elements that release heat through radioactive decay. The heat-producing elements K, U, and Th were concentrated just below the crust by differentiation during lunar formation. However, the constraints on these abundances are only mild, as the distribution of heat-producing elements is not symmetric across the lunar surface.

The heat flow measurements made by Apollo could indicate bulk lunar uranium values as high as 45 ppb, over twice the terrestrial abundances. A more likely scenario is that uranium and other heat-producing elements are concentrated beneath the lunar crust. This is a consequence of magma crystallization. Potassium (K), rare earth elements (REE), and phosphorus (P) (KREEP), along with thorium and uranium, are among the last trace elements to crystallize from a melt. As the early molten Moon cooled, various minerals crystallized from the melt. Heavy olivines sank to the bottom, while lighter anorthosites floated to the top. The remaining incompatible trace elements probably remained molten for a much longer period of time and were eventually exposed to the surface through impact processes. It is unknown whether KREEP is globally

distributed in the Moon. It is only exposed on the nearside, but large impact basins did not excavate below the thick farside crust to the same extent. It is possible that KREEP is a global layer; it is also possible it was somehow concentrated on the nearside, which may help explain the asymmetric distribution of lunar mare.

3.6. Compositional Studies

The Moon is depleted of volatile elements compared to the Earth. It also lacks ferric iron, as determined by both orbital measurements and sample analyses. This lack of iron is reflected in the low lunar density. The Earth contains about 25% metallic Fe; the Moon, less than about 2–3%. However, the bulk Moon contains between 12 and 13% FeO, or 50% more than current estimates of 8% FeO in the terrestrial mantle. Along with its depletion in iron, the Moon also has a low abundance of **siderophile** or "metal-seeking" elements. These elements are extracted into metallic phases according to their metal/silicate partition coefficients during accretion. The lunar depletion of these elements has been used to argue that they have likely been segregated into a metallic core.

The other major element abundances are mostly model-dependent. Si/Mg ratios are commonly assumed to be **chondritic** (CI), although the Earth and many meteorite classes differ from this value. The lunar Mg value is generally estimated to be about 0.80, lower than that of the terrestrial mantle value of 0.89.

The Moon is probably enriched in refractory elements such as Ti, U, Al, and Ca, a conclusion consistent with geophysical studies of the lunar interior. This conclusion is reinforced by the data from the Galileo, Clementine, and Lunar Prospector missions, which indicate that the highland crust is dominated by anorthositic rocks. This requires that the bulk lunar composition contains about 5–6% Al_2O_3, compared with a value of about 3.6% for the terrestrial mantle and so is probably enriched in refractory elements (e.g. Ca, Al, Ti, and U) by a factor of about 1.5 compared to the Earth. Both the Cr and O isotopic compositions are identical in the Earth and Moon, probably indicating an origin in the same part of the nebula, consistent with the single-impact hypothesis that derives most of the Moon from the silicate mantle of the impactor.

The Moon has a composition that is unlikely to have been made by any single-stage process from the material of the primordial solar nebula. The compositional differences from the primitive solar nebula, from the Earth, from Phobos and Deimos (almost certainly of carbonaceous chondritic composition), and from the satellites of the outer planets (rock/ice mixtures, with the exception of Io) thus call for a distinctive mode of origin (see Section 5).

3.7. Seismology

The Apollo astronauts deployed four seismometers on the lunar surface between 1969 and 1972 (Figure 24.7). These

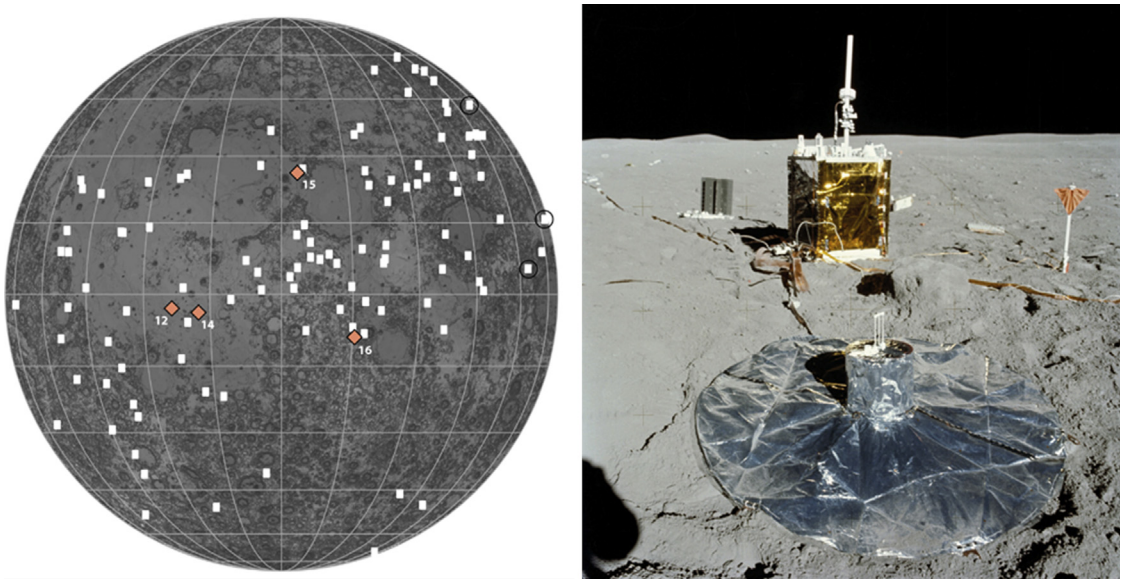

FIGURE 24.7 (Left) Map of the lunar nearside (15° increments of latitude and longitude) showing the locations of the four seismometers that comprised the Apollo Passive Seismic Experiment (red diamonds) and the nominal epicenter locations of the deep moonquake source regions (white rectangles). Farside source regions (outer black circles) are projected on the nearside. The deep moonquakes are roughly constrained to a wide swath trending northeast–southwest across the entire nearside of the Moon. (Right) Photograph of the Apollo 16 seismometer as installed on the lunar surface. It is covered with a mylar shield that was intended to thermally protect the instrument. Other instruments from the Apollo Lunar Surface Experiments Package can be seen in the background, as well as the central station that telemetered data continuously to Earth. *Photo AS16-113-18,347 from the NASA Apollo Archive.*

instruments gathered data continuously until 1977, making the Moon the only extraterrestrial body for which extensive seismic data has been gathered.

The Moon is much less seismically active than the Earth, due to its lack of oceans and plate tectonics. Still, the Apollo network recorded several types of both naturally occurring and artificial seismic events, resulting in a total number of approximately 13,000 catalogued events over the 8-year span of the experiment. Because the Moon has no atmosphere to burn off potential impactors, there were a significant number of meteoroid impacts on the surface that registered on the seismic array. The booster rockets and lunar modules from the Apollo spacecraft were also purposely impacted onto the surface, in part to test and calibrate the seismic array. Observed naturally occurring moonquakes include the relatively large but rare shallow moonquakes of unknown origin (similar to intraplate earthquakes), and the relatively small but frequent deep moonquakes, (triggered with monthly periodicity by the lunar tides). Observed deep moonquakes generally had body wave equivalent magnitudes less than three, with most less than magnitude one; shallow moonquakes were larger, with the larger recorded events having moment magnitudes ranging between 2.4 and 4.1. In addition, the network detected many noiselike thermal events that were associated with the large temperature fluctuations between lunar day and night.

Deep moonquakes are the most numerous type of seismic event, comprising approximately half of the event catalog. They are known to originate from distinct source regions located in a wide swath across the nearside, at depths between approximately 700 and 1200 km (Figure 24.7). Events from a single source are periodic at monthly (tidal) periods, and exhibit high degrees of waveform similarity, likely representing repeated failure on existing fault structures at depth.

Compared to terrestrial seismograms, lunar seismic signals exhibit characteristics typical of a large degree of wave scattering and very low attenuation, due in part to the fractured nature of the upper few hundred meters of lunar regolith. During events, seismic energy reverberates within the Moon, resulting in recorded signals of extremely long duration, sometimes an hour or more, with P- and S-wave codas that mask secondary arrivals. The small number of seismic stations and lack of high-quality seismic events limited the types of analyses that could be performed. Despite these limitations, data from the Apollo passive seismic network have been extensively analyzed to reveal details on the Moon's internal structure, confirming the presence of separate crust, mantle, and core layers (Figure 24.8).

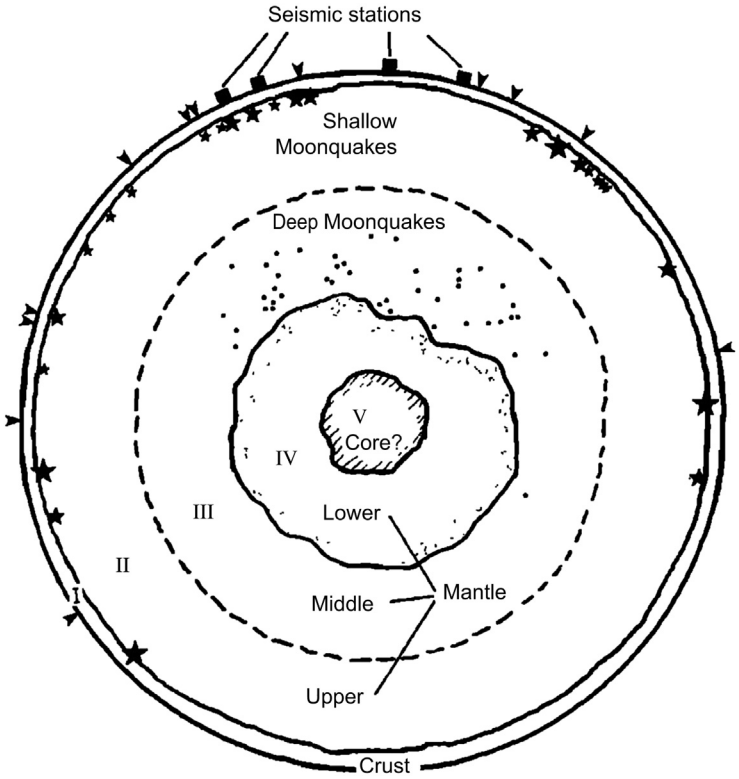

FIGURE 24.8 Schematic cross-section of the Moon showing the crust, mantle, and core layers inferred through analyses of the Apollo seismic data. The Apollo station locations and seismically active regions are indicated; arrowheads show a sample of meteoroid impact locations. *Figure reproduced from Nakamura, Latham, and Dorman (1982).*

The detailed structure of the upper kilometer of the lunar crust was determined by two additional seismic experiments: the Active Seismic Experiment on Apollo 14 and 16, and the Lunar Seismic Profiling Experiment on Apollo 17. In both experiments, the astronauts detonated a series of small explosives on the lunar surface (Figure 24.9). A network of geophones then recorded the ground motions generated by these explosions. On Apollo 14 and 16, up to 19 explosions were detonated by an astronaut using a "thumper" device along a 90-m-long geophone line. Additionally, on Apollo 16, three mortar shells were used to launch explosive charges to distances of up to 900 m from the ALSEP. On Apollo 17, the astronauts were able to position eight explosive charges at distances of up to 3.5 km from the Lunar Module, with the assistance of the Lunar Roving Vehicle. Both the Apollo 16 mortar shells and the Apollo 17 explosives were detonated by radio control after the astronauts left the lunar surface.

These experiments showed that the seismic P-wave velocity is between 0.1 and 0.3 km/s in the upper few hundred meters of the crust at all three landing sites. These velocities are much lower than observed for intact rock on Earth, but are consistent with a highly fractured material produced by the prolonged meteoritic bombardment of the Moon. At the Apollo 17 landing site, the surface basalt layer was determined to have a thickness of 1.4 km.

The lower crust and mantle seismic velocities have been estimated using the classical nonlinear inversion of compressional and shear wave arrival time readings made from the Apollo seismograms (Table 24.2). Shallow structure is constrained largely using surface and near-surface events (impacts and shallow moonquakes), while deep structure is constrained using midmantle and deeper

TABLE 24.2 Lunar Seismic P- and S-wave Velocity and Density Structure with Depth

events (deep moonquakes). Seismic velocities increase steadily down to approximately 20 km. At that depth, there is a change in velocities within the crust that probably represents the depth to which extensive fracturing, due to massive impacts, has occurred (see Figure 24.11 and Section 4.1). At an earlier stage of seismic data analysis, this velocity change was thought to represent the base of the mare basalts, but these are now known to be much thinner. The main section of unbroken crust has rather uniform velocities that correspond to the velocities expected from the average anorthositic composition of the lunar samples.

Very few seismic rays detected by Apollo traverse the region below the deep moonquake zone. Evidence for a highly attenuating region in the deep interior such as a layer of partial melt or a fluid lunar core is implied in part by a lack of observation of seismic signals originating from the farside of the Moon (Figure 24.10). Since deep moonquakes are generally small, their energy cannot penetrate the attenuating region to reach the nearside Apollo array. An additional interpretation of the lack of farside signals is that the farside is aseismic, which, given the other global nearside/farside asymmetries (e.g. crustal thickness and mare distribution), is not outside the realm of possibility. Further seismic exploration is needed to resolve this issue.

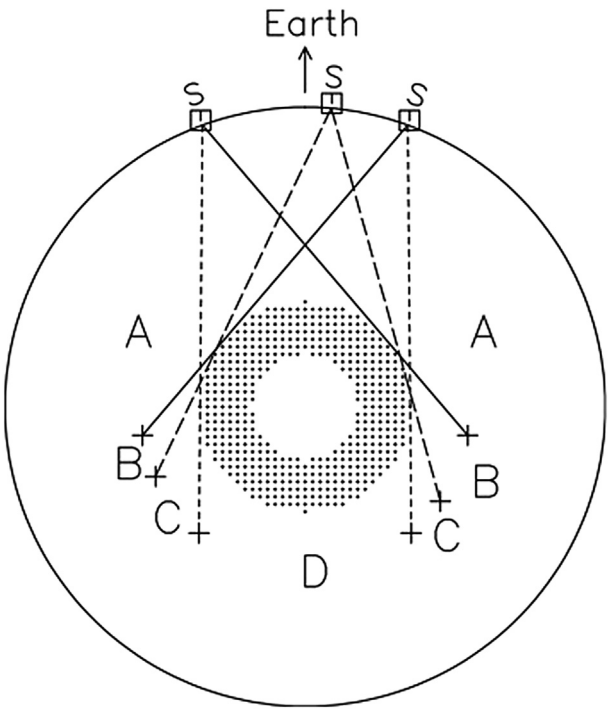

FIGURE 24.10 Schematic cross-section of the Moon showing the bounding seismic rays for shear wave shadows from the deep attenuating region. The direction to Earth is indicated. Small squares denote the Apollo seismic station locations (Apollo 12 and 14 are approximately colocated, so only one square is shown for clarity). The crosses mark the locations of hypothetical deep moonquake hypocenters for which the seismic rays to a station at a corner of the triangular station network graze the lower mantle, in which shear waves are severely attenuated. For events in Zone A, clear shear wave arrivals may be observed at all three corners of the network, i.e. none of the seismic stations are in the S-wave shadow. For events in Zone B, clear shear wave arrivals may be observable at two corners of the network, i.e. one corner of the array is in the S-wave shadow. For events in Zone C, clear shear wave arrivals may be observable only at one corner of the network, i.e. two corners of the array are in the S-wave shadow. For events in Zone D, no clear S-wave arrivals are observable at all three corners of the network, i.e. all corners of the array are in the S-wave shadow. *Figure reproduced from Nakamura (2005).*

4. LUNAR INTERNAL STRUCTURE

Decades of research following the Apollo era has led to a model of the lunar interior that consists of a silicate crust and mantle, and a small iron core (Figure 24.1). Overlying the crust is a very thin layer of extremely pulverized material known as the regolith, resulting from the initial heavy and continued bombardment of meteorites on the lunar surface. As discussed previously, the crust is globally asymmetric in thickness, with the nearside on average thinner than the farside. The mantle is considered to be largely homogeneous, with increases in seismic velocity and density of only a few percent from the base of the crust down to the partial melt boundary layer between the mantle and core. The core itself likely consists of a fluid outer layer and a solid inner layer. This section will provide details on the structure of the lunar interior.

4.1. Regolith

The surface of the Moon is covered with a debris blanket, called the regolith, produced by the impacts of meteorites (Figure 24.11). It ranges in scale from fine dust to blocks several meters across. Although there is much local variation, the average regolith thickness on the maria is 4–5 m, whereas the highland regolith is about 10 m thick.

Seismic velocities are only about 100 m/s at the surface, but increase to 4.7 km/s at a depth of 1.4 km at the Apollo 17 site. The density is about 1.5 g/cm^3 at the surface, increasing with compaction to about 1.7 g/cm^3 at a depth of 60 cm. The porosity at the surface is about 50% but is strongly compacted at depth. The individual crater ejecta blankets that comprise the regolith typically range in thickness from a few millimeters up to about 10 cm, derived from the multitude of meteorite impacts at all scales. These have little lateral continuity even on scales of a few meters. Most of the regolith is of local origin: lateral mixing occurs only on a local scale so that the mare–highland contacts are relatively sharp over a kilometer or so. The rate of growth of the regolith is very slow, averaging about 1.5 mm/million years or 15 Å/year, but it was more rapid between 3.5 and 4 billion years ago during the late heavy bombardment.

The regolith consists of fragments of minerals, crystalline rocks, and **breccias**, as well as impact glasses and

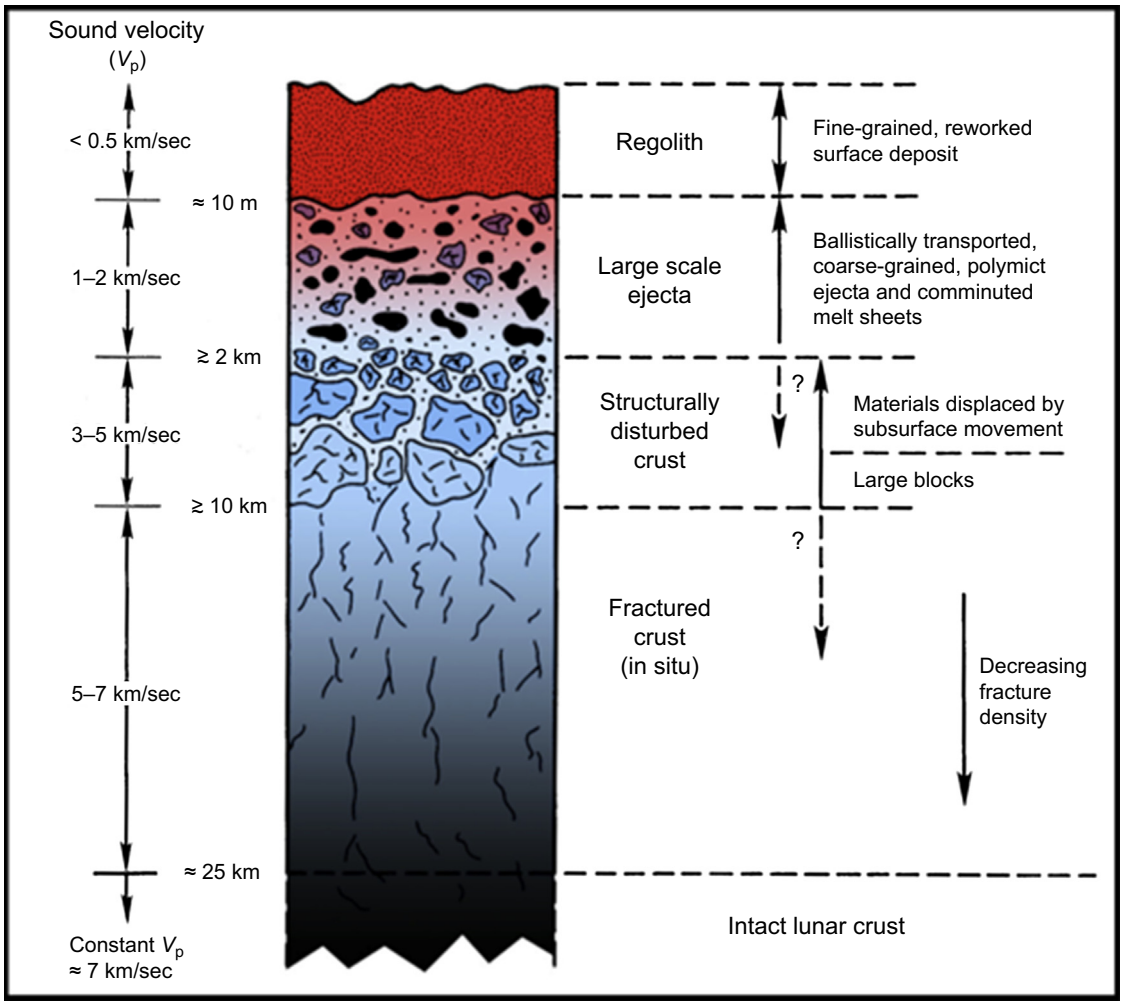

FIGURE 24.11 Schematic cross-section of the upper 25 km of the lunar surface, illustrating the effects of large-scale cratering on the structure of the lunar crust. *Figure reproduced from the Lunar Source Book.*

agglutinates. The latter are aggregates of smaller particles welded together by glasses. They may compose 25−30% of a typical regolith sample and tend to an equilibrium size of about 60 μm. Their abundance in a sample is a measure of its maturity, or length of exposure to meteoritic bombardment. Most lunar regolith samples reached a steady state in particle size and thickness. Agglutinates contain metallic iron droplets (typically 30−100 Å) referred to as "nanophase" iron, produced by surface interaction with the solar wind during melting of the regolith by meteorite impact.

A "megaregolith" of uncertain thickness covers the heavily cratered lunar highlands. This term refers to the debris sheets from the craters and particularly those from the large impact basins that have saturated the highland crust. The aggregate volume of ejecta from the presently observable lunar craters amounts to a layer about 2.5 km thick. Earlier bombardment may well have produced megaregolith thicknesses in excess of 10 km. Related to this question is the degree of fracturing and brecciation of the deeper crust due to the large basin collisions (Figure 24.11). Some estimates equate this fracturing with the leveling off in seismic compression-wave velocities (v_p) to an approximately constant 7 km/s at 20−25 km depth. In contrast to the highlands, bedrock is present at relatively shallow depths (tens of meters) in the lightly cratered maria.

4.2. Crust

Recent analyses of both seismic and gravimetric data from the Moon indicate that the average crustal thickness lies between 34 and 43 km. The farside crust averages about 15 km thicker than that of the nearside. The crust thus constitutes about 9% of lunar volume. The maximum relief on the lunar surface is over 16 km. The deepest basin (South Pole−Aitken) has a 12 km relief.

The mare basalts cover 17% of the lunar surface, mostly on the nearside (Figure 24.12). Although prominent

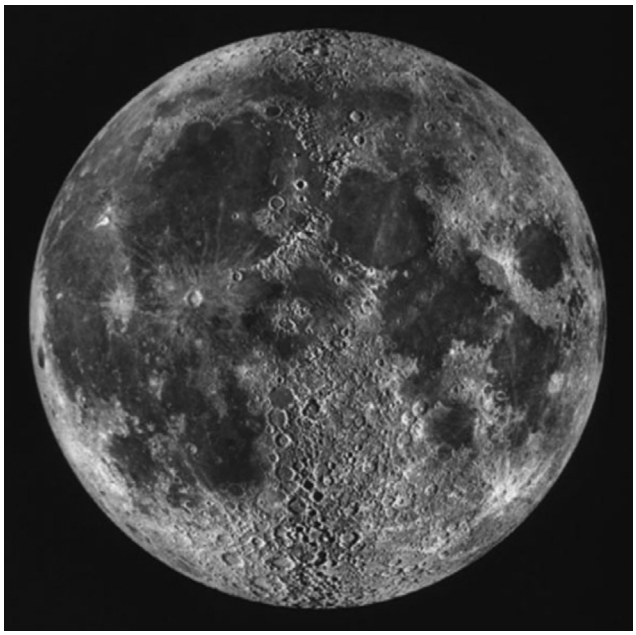

FIGURE 24.12 A composite full-Moon photograph that shows the contrast between the heavily cratered highlands and the smooth, dark basaltic plains of the maria. Mare Imbrium is prominent in the northwest quadrant. The dark, irregular, basalt-flooded area on the west is Oceanus Procellarum. Mare Crisium is the dark circular basalt patch on the eastern edge. *Figure courtesy of UCO/Lick Observatory, photograph L9.*

visually, they are usually less than 1 or 2 km thick, except near the centers of the basins. These basalts constitute only about 1% of the volume of the crust and make up less than 0.1% of the volume of the Moon.

Seismic velocities increase steadily down to around 25 km. At that depth, there is a change in velocities within the crust, which probably represents the depth to which extensive fracturing due to massive impacts has occurred (Figure 24.11). At an earlier stage, this velocity change was thought to represent the base of the mare basalts, but these are now known to be much thinner. The main section of the crust from approximately 20–40 km has rather uniform shear (S) and compression (P) wave velocities, corresponding to the velocities expected from the average anorthositic composition of the lunar samples.

4.3. Mantle

The structure of the mantle has been difficult to evaluate on account of the complexity of interpreting the lunar seismograms. From MOI considerations alone we know it is largely homogeneous at least in density. The average P-wave velocity is 7.7 km/s and the average S-wave velocity is 4.45 km/s down to about 1200 km. Most models postulate a pyroxene-rich upper mantle that is distinct from an olivine-rich lower mantle beneath about a depth of 500–600 km. Seismic data are ambiguous regarding the nature of the lunar mantle below 500 km. They may be interpreted as representing magnesium-rich olivines or indicate the presence of garnet. If the latter is present, this implies that the Moon has a larger bulk aluminum content than has been predicted previously, which has important implications for reconstructing the early evolution of the Moon. However, this distinction cannot be made on the basis of the Apollo seismic data alone.

The seismically active deep moonquake zone lies deep within the lower mantle at about 800–1000 km depth (Figure 24.8). The very low seismic attenuation observed in the outer 800 km of the mantle is indicative of a volatile-free rigid lithosphere. Solid-state mantle convection is thus extremely unlikely in the Moon.

Below about 800 km, P- and S-waves become attenuated ($v_S = 2.5$ km/s). P-waves are transmitted through the center of the Moon, but S-waves are missing, possibly suggesting the presence of a melt phase (Figure 24.10). It is unclear, however, whether the S-waves were not transmitted or were so highly attenuated that they were not recorded by the nearside Apollo array.

4.4. Core

The evidence for a metallic core is suggestive but inconclusive. As discussed previously, current (indirect) constraints on core properties arise from MOI considerations, the LLR experiment, magnetic field strength studies, and analyses of elemental abundances in mare basalts. These estimates are varied, and the presence of a lunar core (and its properties, if existent) is a topic of debate among the planetary science community.

Electromagnetic sounding can also constrain deep lunar structure by estimating the electrical conductivity as a function of depth. This approach applied to data from the Apollo orbital magnetometers results in an upper limit of 400–500 km radius for a highly conducting (e.g. metallic) core. The MOI value of 0.3931 ± 0.0002 is low enough to require a small density increase in the deep interior, in addition to the low-density crust. Although a metallic core with a radius of about 400 km (4% of lunar volume) is consistent with the available data, denser silicate phases might be present. The resolution of these problems requires improved seismic data.

A direct seismic constraint on the size and state of the lunar core (through observation of reflected and/or converted core phases on Apollo seismograms) has not been achieved, due in part to the strong scattering of seismic energy in the lunar regolith and the limited sensitivity of the instruments. Many deep moonquake signals occurred at or just slightly above the Apollo instrument detection threshold (approximately 5.4×10^{-9} cm of ground motion at 1 Hz), and if any seismic phases were observed at all, these were typically the main P- and S-wave arrivals. Since

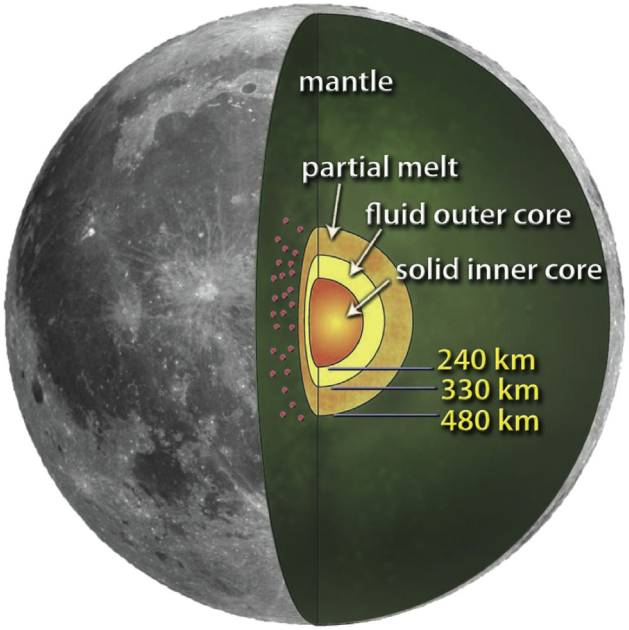

FIGURE 24.13 Schematic meridional cross-section of the Moon showing the approximate distribution of deep moonquakes (red circles) and the radii of physical layers in the deepest lunar interior, as resolved from recent reanalyses of the Apollo seismic data. *Figure reproduced from Weber, et al. (2011).*

the predicted amplitudes of the lunar core phases are many times smaller, the extended coda of the primary arrivals obscured their identification on individual Apollo seismograms. However, recent application of a terrestrial seismology technique known as "array stacking" revealed the presence of several core-reflected phases, arguing strongly for a solid inner core, a fluid outer core, and a partial melt boundary layer that likely accounts for the lack of observed farside deep moonquake signals (Figure 24.13).

5. IMPLICATIONS FOR LUNAR FORMATION AND EVOLUTION

A practical model for lunar formation must result in a Moon with present-day internal structure that is consistent with the observations presented in this chapter. In addition, it must be able to explain the high value for the angular momentum of the Earth–Moon system, the lunar orbit inclined at 5.09° to the plane of the ecliptic, the high mass relative to that of its primary planet, and the low bulk density of the Moon, much less than that of the Earth or the other inner planets. The chemical age and isotopic data revealed by the returned lunar samples added additional complexities to these classic problems because the lunar composition is unusual by either cosmic or terrestrial standards. It is perhaps not surprising that previous theories for the origin of the Moon failed to account for this diverse set of properties and that only recently has something approaching a consensus been reached.

Hypotheses for lunar origin can be separated into five categories:

1. Capture of an intact Moon from an independent orbit
2. Simultaneous Earth–Moon formation as a double planet (or "coaccretion")
3. Fission of the Moon from a rapidly rotating Earth
4. Disintegration of incoming planetesimals
5. Earth impact by a Mars-sized planetesimal and capture of the resulting debris into Earth orbit

These are not all mutually exclusive, and elements of some hypotheses occur in others. For example,

1. Capture of an already formed Moon from an independent orbit has been shown to be highly unlikely on dynamic grounds. The hypothesis provides no explanation for the peculiar composition of our satellite. In addition, it could be expected that the Moon might be an example of a common and primitive early solar system object, similar to the captured rock-ice satellites of the outer planets, particularly since the Moon's density is similar to that of primitive carbonaceous chondrites. It would, however, be an extraordinary coincidence if the Earth had captured an object with a unique composition, in contrast to the many examples of icy satellites captured by the giant planets.
2. Formation of the Earth and the Moon in association as a double-planet system immediately encounters the problems of differing density and composition of the two bodies. Various attempts to overcome the density problem led to coaccretion scenarios in which disruption of incoming differentiated planetesimals formed from a ring of low-density silicate debris. Popular models to provide this ring involved the breakup of differentiated planetesimals as they come within a **Roche limit** (about three Earth radii). The denser and tougher metallic cores of the planetesimals survived and accreted to the Earth, while their mantles formed a circumterrestrial ring of broken-up silicate debris from which the Moon could accumulate. This attractive scenario has been shown to be flawed because the proposed breakup of planetesimals close to the Earth is unlikely to occur. It is also difficult to achieve the required high value for the angular momentum in this model. Such a process might be expected to have been common during the formation of the terrestrial planets, and Venus, in particular, could be expected to have a satellite.
3. In 1879, George Darwin proposed that the Moon was derived from the terrestrial mantle by rotational fission (see cartoon illustration in Figure 24.14). Such fission hypotheses have been popular since they produced a

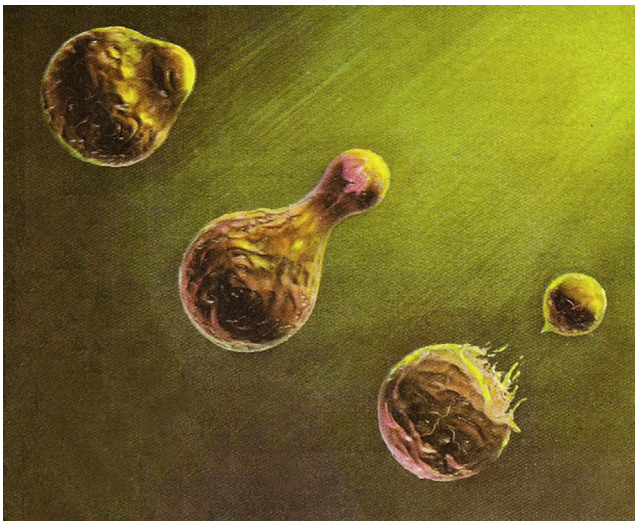

FIGURE 24.14 Artist's rendition of the fission theory of lunar formation, in which the Moon was formed from the mantle of a hot, early Earth. In this theory, the molten Earth rotates rapidly, causing a blob of material to spin out, which later rounded into the Moon. *Figure reproduced from Binder (1961).*

low-density, metal-poor Moon. The lunar sample return provided an opportunity to test these hypotheses because they predicted that the bulk composition of the Moon should provide some identifiable signature of the terrestrial mantle. The O and Cr isotopic compositions are similar, and this is sometimes used to argue for a lunar origin from the Earth's mantle. However, other significant chemical differences remain. The Moon contains, for example, 50% more FeO and has distinctly different trace siderophile element signatures. It also contains higher concentrations of refractory elements (e.g. Al and U) and lower amounts of volatile elements (e.g. Bi and Pb). The similarity in V, Cr, and Mn abundances in the Moon and the Earth is nonunique since CM, CO, and CV chondrites show the same pattern. These differences between the chemical compositions of the Earth's mantle and the Moon are fatal to theories that wish to derive the Moon from the Earth. But perhaps more importantly, the angular momentum of the Earth–Moon system, although large, is insufficient by a factor of about four to allow for rotational fission. If the Earth had been spinning fast enough for fission to occur, there is no available mechanism for removing the excess angular momentum following lunar formation.

4. One proposed modification of the fission hypothesis uses multiple small impacts to place terrestrial mantle material into orbit that sequentially accretes into a moon. However, it is exceedingly difficult to obtain the required high angular momentum by such processes because multiple impacts are random in both direction and energy, and the angular momentum they impart to the Earth over time should average out.

Most of these Moon-forming hypotheses should be general features of planetary and satellite formation and should produce Moon-like satellites around the other terrestrial planets. They either fail to account for the high angular momentum (relative to the other terrestrial planets) of the Earth–Moon system and the volatile-depleted composition of the Moon, or they do not account for the differences between the lunar composition and that of the terrestrial mantle.

The single-impact hypothesis was developed to solve the angular momentum problem, but, in the manner of successful hypotheses, it has accounted for other parameters as well and has become a consensus in the lunar science community. The theory proposes that, during the final stages of accretion of the terrestrial planets, a body about the size of Mars collided with the Earth and spun out a disk of material from which the Moon formed. This giant impact theory resolves many of the problems associated with the origin of the Moon and its orbit. The following scenario is one of several possible, although restricted, variations on the theme.

In the closing stages of the accretion of the terrestrial planets from the protoplanetary disk surrounding our Sun, the Earth suffered a grazing impact with an object of about 0.10 Earth mass. This body is assumed to have been differentiated into a silicate mantle and a metallic core. Because the oxygen and chromium signatures of the Earth and Moon are identical and the impact velocities are required to be low in the formation models, the impactor likely came from the same general region of the initial planet-forming nebula as the Earth.

The impactor was disrupted by the collision and the resulting debris mostly went into orbit about the Earth. Gravitational torques, due to the asymmetrical shape of the Earth following the impact, assisted in accelerating material into orbit. Expanding gases from the vaporized part of the impactor also promoted material into orbit. Following the impact, the mantle material from the impactor was accelerated, but its metallic core remained as a coherent mass and was decelerated relative to the Earth, so that it fell into the Earth within about 4 h. A metal-poor mass of silicate material, mostly from the mantle of the impactor, remained in orbit.

In some variants of this hypothesis, the orbiting material immediately coalesced to form a totally molten Moon. In others, it broke up into several "moonlets" that subsequently accreted to form a partly molten Moon. This highly energetic event accounts for the geochemical evidence that indicates that at least half the Moon was molten shortly after accretion. Figure 24.15 illustrates several stages of a computer simulation of the formation of the Moon

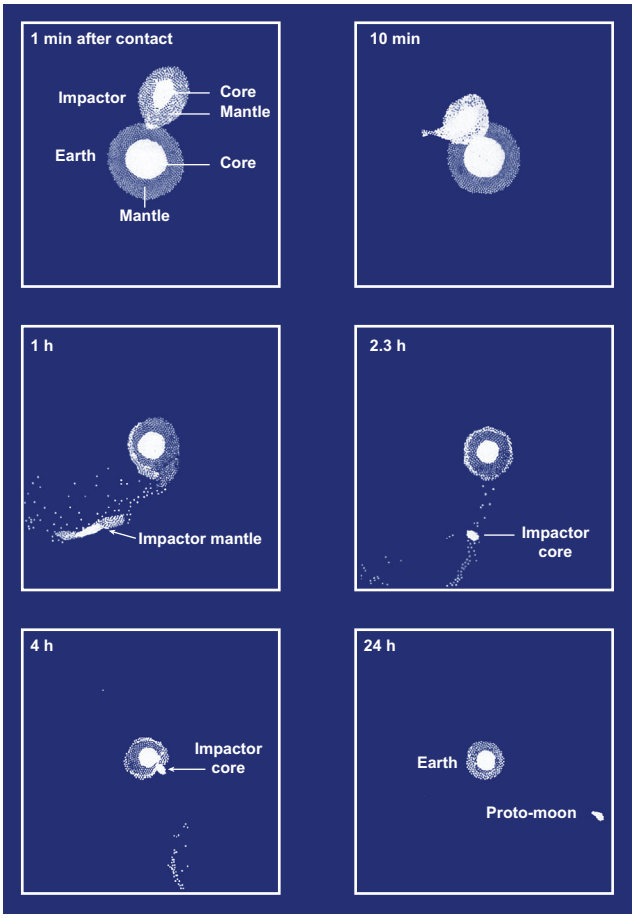

FIGURE 24.15 A computer simulation of the origin of the Moon by a glancing impact of a body approximately the same size of Mars with the early Earth. This event occurred about 4.5 billion years ago during the final stages of accretion of the terrestrial planets. By that time, both the impactor and the Earth had differentiated into a metallic core and rocky silicate mantle. Following the collision, the mantle of the impactor is ejected into orbit. In this simulation, the metallic core of the impactor clumps together and falls into the Earth within about 4 h. Most terrestrial mantle material ejected by the impact follows a ballistic trajectory and is eventually reaccreted by the Earth. The metal-poor, low-density Moon is thus derived mainly from the silicate mantle of the impactor. *Figure courtesy of A. G. W. Cameron.*

according to one version of the single giant impact hypothesis.

Unique events are notoriously difficult to accommodate in most scientific disciplines. An obvious requirement in this model is that a suitable population of impactors existed in the early solar system. Evidence in support of the previous existence of large objects in the early solar system comes from the ubiquitous presence of heavily cratered ancient planetary surfaces, from the large number of impact basins with diameters up to 2000 km or so, and from the obliquities or tilts of the planets, all of which demand collisions with large objects in the final stages of accretion. The extreme example is that an encounter between Uranus and an Earth-sized body is required to tip that planet on its side. Thus, the possibility of many large collisions in the early solar system is well established, one of which had the right parameters to form the Moon. The single-impact scenario is thus consistent with the planetesimal hypothesis for the formation of the planets from a hierarchical sequence of smaller bodies.

1. INTRODUCTION

Owing to the Moon's relative proximity to the Earth, lunar exploration has played a pivotal role in the exploration of the solar system. This was true of Galileo's first telescopic observations, through to the first spacecraft to orbit, land on, and return samples from another celestial body. And, of course, the Moon was the first, and is to date the only, celestial body that human beings have explored in person—during the Apollo program between 1969 and 1972. During the Apollo missions, samples were collected, measurements were made, and instruments were deployed that have revolutionized lunar and planetary science, and which continue to have a major scientific impact today. And although Apollo was followed by a 20-year hiatus in lunar missions, the past two decades have seen a renaissance in lunar exploration conducted from orbit. This has resulted in a wealth of new data which have in many ways revolutionized our knowledge of the Moon and has also taught us much about the early history of the solar system, the geological evolution of rocky planets, and the near-Earth cosmic environment throughout solar system history. It has also become clear that the Moon still has much more to tell us about all these areas of planetary science and that strong arguments exist for a

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00025-6

renewed program of lunar exploration in the twenty-first century.

2. TELESCOPIC EXPLORATION OF THE MOON

The scientific exploration of the Moon essentially began with Galileo's first telescopic observations in 1609, as reported in his book *Sidereus Nuncius*. For the first time these observations demonstrated that the Moon is an essentially Earth-like planetary body, with mountains and valleys, rather than being a perfect sphere made of special celestial material (Figure 25.1). Galileo was also able to estimate the heights of lunar features by measuring the lengths of shadows and thus initiated a program of the quantitative measurement of lunar topography which continues to this day. It was also from this early period that the smooth, low-lying, dark areas of the lunar surface became identified with seas ("maria"), and the rougher, higher, brighter areas with land ("terrae"), introducing the top-level lunar geographical nomenclature that is still in use.

In the decades following Galileo's initial telescopic observations, European astronomers began mapping the nearside of the Moon in earnest. Essentially all the major maria, and most of the prominent craters, had been mapped and assigned their current names by the middle of the seventeenth century, when Giovanni Riccioli published his influential lunar map. Telescopic cartography of the lunar nearside continued for more than 300 years, employing increasingly sophisticated techniques, and indeed played an important part in planning the Apollo missions during the 1960s. Especially during the latter part of this period, telescopic observations were used to make geological maps of the nearside and to address key questions in lunar geology. These included studies of the origin of craters and the nature of lunar volcanism, the identification and interpretation of tectonic features such as faults and graben, and, perhaps most importantly, the definition of the lunar stratigraphic column which still underpins much of lunar geology.

More recently, the recognition that different minerals have different reflectance spectra provided another tool for telescopic lunar geology. This technique made it possible to identify dominant surface rock types spectroscopically and to explore subsurface compositional variations by observing the ejecta from large craters. However, the relatively low spatial resolution achievable with ground-based telescopes, and the fact that only the nearside is accessible from the Earth, means that spectral studies of this kind have now largely been superseded by remote sensing from orbiting spacecraft. Indeed, despite the advances made by telescopic observations over the centuries, most of our knowledge about the Moon has been obtained

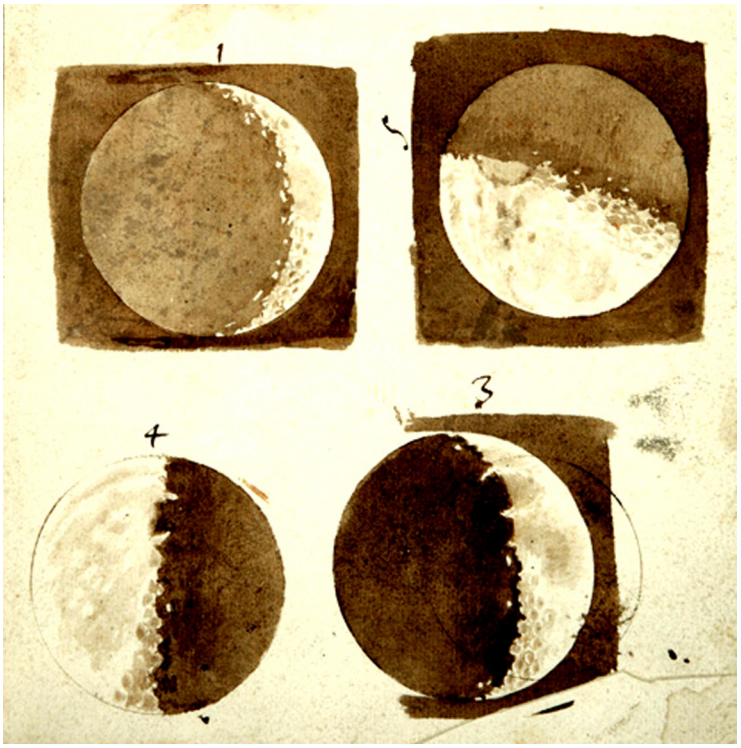

FIGURE 25.1 A set of Galileo's Moon drawings based on his early telescopic observations. Note the correct rendition of the heavily cratered lunar surface, and the "islands" of illuminated mountain peaks beyond the terminator (most easily seen in 3), from which Galileo calculated the heights of lunar mountains. *Biblioteca Nazionale Centrale, Florence.*

since space technology made it possible to conduct observations from lunar orbit, make in situ measurements on the surface, and collect rock samples for analysis in terrestrial laboratories.

3. THE EARLY SPACE AGE

A summary of the most important spacecraft to have visited the Moon is given in Table 25.1. The first spacecraft to reach the Moon was the Soviet Luna 2, which impacted the lunar surface on September 13, 1959. Luna 2 also made the first attempt to measure the lunar magnetic field (which it failed to detect), and the charged particle and micrometeoroid environments around the Moon. Of greater significance for lunar geology was the flight of Luna 3, in October that same year, which completed the first flyby of the Moon and obtained the first ever images of the farside (Figure 25.2). Even these first observations were sufficient to show that the surface of the farside is different from that of the nearside, with

TABLE 25.1 Highlights of Lunar Exploration by Spacecraft

Spacecraft/Program Name	Nationality	Launch Year	Mission Description
Luna 2	USSR	1959	First lunar impact
Luna 3	USSR	1959	Flyby: first farside images
Ranger probes (3/7)*	USA	1962–1965	Impact probes: near-surface imagery
Luna 9	USSR	1966	Soft lander: first surface images
Luna 10	USSR	1966	First lunar orbiter
Surveyor landers (5/7)	USA	1966–1968	Soft landers: surface properties
Lunar orbiters (5/5)	USA	1966–1967	Orbiters: orbital photography
Apollo 8, 10	USA	1968	Manned lunar orbiters: orbital photography
Apollo 11, 12, 14–17	USA	1969–1972	Manned landings: surface and interior properties, sample return, orbital remote sensing
Lunokhod 1, 2 (Luna 17, 21)	USSR	1970, 1973	Robotic rovers: surface properties
Luna 16, 20, 24	USSR	1970, 1972, 1976	Robotic sample return
Hiten (MUSES-A)	Japan	1990	Lunar orbiter: dust detection
Clementine	USA	1994	Orbital remote sensing
Lunar Prospector	USA	1998	Orbital remote sensing
SMART-1	Europe	2003	Orbital remote sensing
Kaguya	Japan	2007	Orbital remote sensing
Chang'e 1	China	2007	Orbital remote sensing
Chandrayaan-1	India	2008	Orbital remote sensing
Lunar Reconnaissance Orbiter	USA	2009	Orbital remote sensing
Lunar Crater Observation and Sensing Satellite (LCROSS)	USA	2009	Impact probe, polar volatile detection
Chang'e 2	China	2010	Orbital remote sensing
Gravity Recovery and Interior Laboratory (GRAIL)	USA	2011	Orbital gravity mapping
Lunar Atmosphere and Dust Environment Explorer (LADEE)	USA	2013	Orbital exospheric gas and dust characterization
Chang'e 3	China	2013	Soft lander with rover: surface properties

**For programs consisting of several spacecraft, the numbers in parentheses denote the fraction of successful missions.*

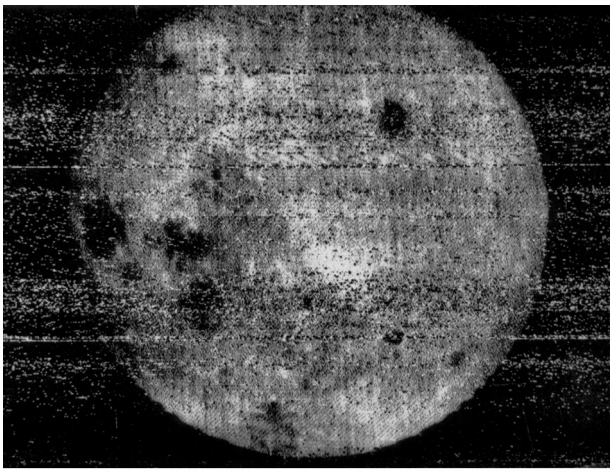

FIGURE 25.2 The first image ever taken of the lunar farside by Luna 3 on October 7, 1959, from a distance of 63,500 km. It showed that the farside is different from the nearside in lacking extensive areas of dark maria. Although noisy, many features can be recognized: the dark spot at upper right is Mare Moscoviense, the two dark areas in the lower left are Mare Marginis and Mare Smythii, and the small dark feature at lower right with the white dot in the center is the crater Tsiolkovsky and its central peak. *NASA NSSDC Data Set ID 59-008A-01A.*

few of the large, dark expanses of basaltic lava that dominate the latter.

There was a gap of over 6 years until the next two major milestones in lunar exploration, both in 1966 and both again by Soviet space probes: on February 3, 1966, Luna 9 successfully soft landed and obtained the first surface images (Figure 25.3), and on April 3, Luna 10 became the first spacecraft to enter orbit about the Moon. During this apparent hiatus, however, the US lunar exploration program started ramping up, initially with the Ranger series of "hard landers", designed to take ever increasing resolution images of the surface before crashing into it. Although the Ranger project had limited success (with only three of the seven probes launched functioning as intended), it paved the way for the much more successful Surveyor program which soft landed five robotic landers (of the seven attempts) on the lunar surface between 1966 and 1968 (Figure 25.4). These vehicles used a variety of instruments to measure regolith properties and composition.

In parallel, between 1966 and 1967 the United States flew a highly successful series of Lunar Orbiter spacecraft that were designed to obtain high-resolution images of the lunar surface. With surface resolutions of several tens of meters (occasionally as high as 2 m) for some areas of the Moon, these images long remained unsurpassed as a resource for lunar geology (although they are rapidly becoming superseded by images obtained by the Lunar Reconnaissance Orbiter (LRO) Camera discussed below). To a large extent, the Lunar Orbiter missions were designed to identify potential landing sites for the manned Apollo missions then under development, just as the Surveyors were designed to provide knowledge of the surface environment with the manned landings in mind.

The Apollo program is discussed in detail in Section 4 owing to its pivotal importance in lunar exploration. However, before leaving the discussion of this early phase of lunar exploration, it is necessary to highlight two important Soviet robotic programs that overlapped with it. These were the two "Lunokhod" rovers (Luna 17 and 21) that landed on the Moon in November 1970 and January

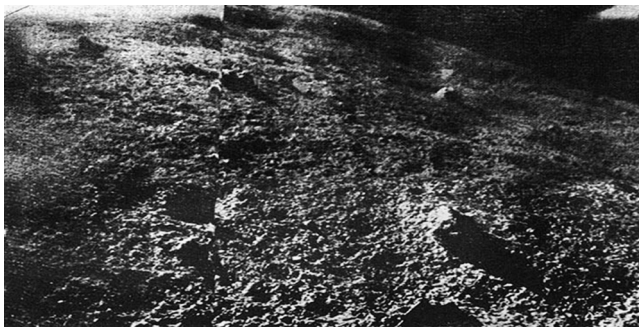

FIGURE 25.3 Mosaic of images of the lunar surface obtained by Luna 9 in February 1966 from its landing site in Oceanus Procellarum (at approximately 7.08° N, 64.37° W). The horizon is approximately 1.4 km away. *'First Panoramas of the Lunar Surface According to the Material from the Automatic Station Luna-9', NASA NSSDC/Akademiia nauk SSSR.*

Conrad's right arm is pointing to the Surveyor III camera system, and the soil sampling scoop passes in front of his knees; the Apollo 12 Lunar Module is in the background. *NASA image AS12-48-7134.*

1973, respectively. These were the first teleoperated robotic rovers to operate on another planetary body. Lunokhod 1 operated for 322 days and traversed a total distance of 10.5 km; the corresponding numbers for Lunokhod 2 were 115 days and 37 km. During their traverses, the Lunokhods made measurements of the regolith properties and composition, as well as the surface radiation environment. They also carried laser reflector panels which, similar to those deployed by the Apollo 11, 14, and 15 missions, have been used to measure the Earth–Moon distance and the Moon's physical librations (from which information about its internal structure can be inferred).

The other significant Soviet missions during this period were the three successful robotic sample return missions Luna 16, 20, and 24. These collected, and returned to the Earth, a total of approximately 320 g from three sites close to the eastern limb of the nearside. Although the quantity of material collected was small compared to that returned by *Apollo* (see below), their geographical separation from the Apollo landing sites (Figure 25.5) makes them important for our understanding of lunar geological diversity and the calibration of remote sensing measurements.

4. THE APOLLO PROGRAM

On May 25, 1961, the US President John F. Kennedy announced before a joint session of Congress his proposal to land a man on the Moon by the end of the 1960s. This initiated the Apollo program, which, at the peak of its development phase in 1965 consumed almost 4% of the US federal budget and which succeeded in landing Neil Armstrong and Edwin "Buzz" Aldrin on the surface of Mare Tranquillitatis with Apollo 11 on July 20, 1969. In the three and a half years between Armstrong's "one small step" in 1969 and the departure of the Apollo 17 astronauts, Gene Cernan and Harrison "Jack" Schmitt, from the Moon in December 1972, a total of 12 astronauts explored the lunar surface in the immediate vicinity of six Apollo landing sites (Figure 25.5). The total cumulative time spent on the lunar surface was 12.5 days, with just 3.4 days spent performing extravehicular activities (EVAs) outside the lunar modules. Yet during this short time samples were collected, measurements made, and instruments deployed which have revolutionized lunar and planetary science and which continue to have a major scientific impact today.

In their cumulative 12.5 days (25 man-days) on the lunar surface, the 12 Apollo moonwalkers traversed a total distance of 95.5 km from their landing sites (heavily weighted to the last three missions that were equipped with the Lunar Roving Vehicle; Figure 25.6), collected and returned to Earth 382 kg of rock and soil samples (from over 2000 discrete sampling localities), drilled three geological sample cores to depths greater than 2 m, obtained over 6000 surface images, and deployed over 2100 kg of scientific equipment. These surface experiments were supplemented by wide-ranging remote sensing observations conducted from the orbiting Command and Service Modules (CSM; Figure 25.7), which are equally part of the Apollo scientific legacy. Table 25.2 lists the Apollo surface and orbital science experiments.

4.1. Apollo Samples and Their Analysis

The most important scientific legacy of Apollo has resulted from analysis of the 382 kg of rock (Figure 25.8(a)–(e)) and

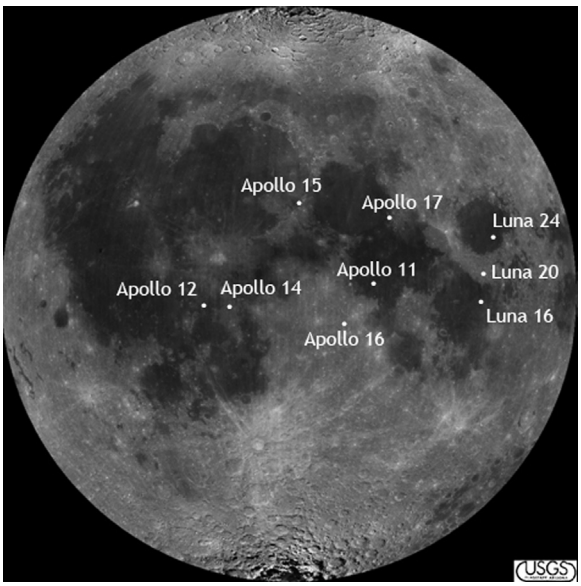

FIGURE 25.5 Nearside lunar mosaic constructed from Clementine 750-nm albedo data, with the landing sites of the six Apollo and three Luna sample return missions indicated. *USGS/K.H. Joy*

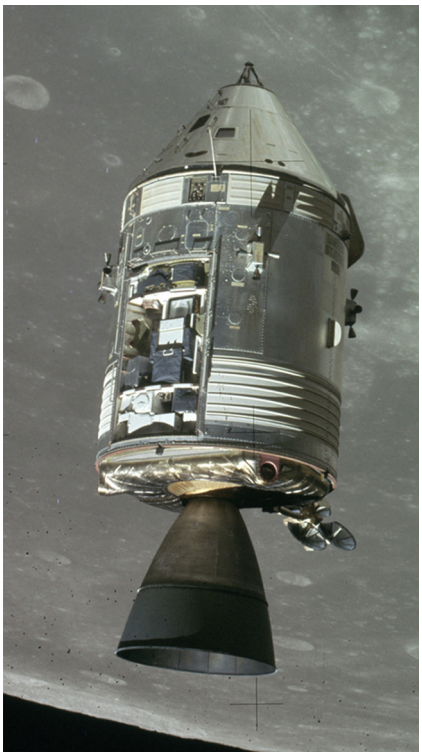

FIGURE 25.7 The Scientific Instrumentation Module (SIM) bay of the Apollo 15 Command and Service Module (CSM). On Apollo 15, the SIM included mapping cameras, a laser altimeter, a mass spectrometer for exosphere composition measurements, X-ray and gamma ray spectrometers for surface composition studies, and a subsatellite for measuring charged particles and magnetic fields (see Table 25.2). *NASA image AS15-88-11971.*

soil (Figure 25.9) samples returned to Earth. These samples have been analyzed in laboratories around the world to address many questions about the Moon's formation, differentiation, geological evolution, resource potential, and the records that they contain of wider solar system processes. Analytical techniques that have been employed to study lunar materials are summarized in Table 25.3.

Probably the most important result based on the returned samples has been the calibration of the lunar cratering rate. Not only has this facilitated the dating of lunar surfaces from which samples have yet to be obtained, but it is used, with assumptions, to estimate the ages of cratered surfaces throughout the solar system from Mercury to the moons of the outer planets.

Perhaps the next most important result of Apollo sample analysis from a planetary science point of view has been the evidence provided for the origin of the Moon. In particular, the discovery that lunar materials have compositions broadly similar to those of the Earth's mantle (including nearly identical isotope ratios for oxygen and several other elements), but that the Moon is highly depleted of volatiles compared to the Earth and has only a small iron core, led to the current paradigm that the Moon formed from debris resulting from a giant impact of a Mars-sized (or possibly larger) planetesimal with the early Earth. Constraining theories of lunar origins are of wide significance for planetary science because they inform our understanding of the general processes of planet formation through the merger of planetesimals in the early solar system. It is very doubtful that we would have sufficient geochemical evidence usefully to constrain theories of lunar origins without the quantity and diversity of samples provided by Apollo.

Beyond this, the Apollo samples have been vital to our understanding of the Moon's geological history and evolution, and have, therefore, helped elucidate important geological processes (including core formation, magma ocean evolution, and primary and secondary crust formation through magmatic and volcanic activity) that are of general relevance to our understanding of terrestrial planet evolution. In addition, Apollo samples of the lunar regolith have demonstrated the importance of the lunar surface layers as an archive of material that has impacted the Moon throughout its history. These include records of solar wind particles, the cosmogenic products of cosmic ray impacts, and meteoritic debris (Figure 25.9(f)). Extracting meteoritic records from lunar regolith samples is especially important for planetary science as it potentially provides a means of determining how the flux and composition of asteroidal material in the inner solar system has evolved through time.

4.2. Apollo Surface Experiments

Although the study of the Apollo samples has been, and continues to be, important for lunar and planetary science, many other areas of scientific investigation were also performed by the Apollo missions. Many of these were conducted as part of the Apollo Lunar Surface Experiment Packages (ALSEPs), which were deployed at all the Apollo landing sites apart from Apollo 11 (which deployed a cut down version). The ALSEPs consisted of a central communications hub and radioisotope power source (so as to permit operation during the lunar night) connected to a variety of instruments. The instruments varied between missions, but typically included some combination of seismometers, magnetometers, heat flow probes and atmospheric and ionospheric detectors. These instruments were supplemented by a variety of non-ALSEP instruments and experiments (Table 25.2).

Probably the most influential set of Apollo surface experiments were those related to various geophysical investigations, including both passive (Figure 25.10) and active (Figure 25.11) seismology studies, surface gravimetry and magnetometry, heat flow measurements (Figure 25.12), and the deployment of laser reflectors to measure the changing Earth–Moon distance and the

Notes: Acronyms are the official NASA designations for these experiments. As is well known, Apollo 13 did not land on the Moon, but did acquire 112 frames of orbital Hasselblad imagery. The Apollo 16 heat flow experiment (HFE) was rendered inactive before any data could be collected when its cable became detached from the central ALSEP station; the Apollo 17 surface gravimeter (LSG) also did not work as intended, owing to a design flaw, but did return useful data acting as a pseudoseismometer.

Moon's physical librations (Figure 25.13). With the exception of an ineffective seismic experiment sent to Mars on the Viking landers in 1976, the Moon remains the only planetary body apart from the Earth on which these geophysical techniques have been applied in situ at the surface.

Key results of the Apollo geophysics experiments include the discovery of natural moonquakes and their exploitation to probe the structure of the nearside crust and mantle, geophysical constraints on the existence and physical state of the lunar core (from both seismic data and laser reflection studies of lunar rotation), the use of active seismic profiling to determine the near-surface structure (Figure 25.11), and measurements of the lunar heat flow at the Apollo 15 and 17 localities. It is important to recognize that although these data are for the most part over 30 years old (the ALSEPs were switched off on September 30, 1977), advances in interpretation, and especially in computing power and numerical computational techniques, means that they continue to give new insights into the interior structure of the Moon. For example, in 2011, an apparently definitive seismic detection of the Moon's core, and strong evidence that, like the Earth's, it consists of solid inner and liquid outer layers, was made by a reexamination of Apollo seismic data.

4.3. Apollo Orbital Remote Sensing

Supplemental to the Apollo surface scientific payloads (see above) were a series of remote sensing experiments mounted onto the Scientific Instrumentation Module (SIM)

on the orbiting CSM of the later J-class missions (Figure 25.7). These instruments varied between the Apollo 15, 16 and 17 missions but typically included some combination of panoramic and mapping cameras, laser altimeters, gamma ray and X-ray spectrometers, and, for Apollo 17, a ground-penetrating radar sounder. Apollo 15 and 16 also carried small subsatellites to permit more accurate measurements of charged particles and magnetic

TABLE 25.3 Examples of Some Common Analytical Techniques Used in Laboratories to Investigate Lunar Samples

Investigation	Method/Laboratory Technique	Information Obtained	Type of Sample Studied or Requirement for Measurement
Mineralogy and bulk-sample chemistry	X-ray fluorescence (XRF)	Bulk-sample chemistry	Powdered samples often dissolved in strong acids and analyzed in solution.
	Instrumental neutron activation analysis (INAA)	Bulk-sample chemistry	
	Inductively coupled plasma mass spectrometry (ICP-MS)	Bulk-sample trace element chemistry	
	Inductively coupled atomic emission spectrometry (ICP-AES)	Bulk-sample major and trace element chemistry	
	Accelerator mass spectrometry	Radionuclides (exposure information)	
	X-ray diffraction (XRD	Mineral crystal structure	
	Gas chromatography mass spectrometry (GC–MS)	Concentration of light elements (e.g. H, C, N), organic compounds and their isotopic composition	
	Thermal ionization mass spectrometry (TIMS), and multicollector ICP-MS (MC-ICP-MS)	Mainly used for acquiring high-precision isotopic composition	
Mineral/phase chemistry	Electron probe microanalysis (EPMA) and secondary electron microscopy (SEM)	X-ray elemental maps, concentrations of major elements, some minor, and trace elements	Typically performed on polished thin section (30 μm thick) or polished thick sections (>30 μm thick) or polished blocks
	Secondary ion mass spectrometry (SIMS) including nanoSIMS and time of flight (TOF)–SIMS	Trace element concentrations and isotopic composition at high spatial resolutions	
	Laser ablation ICP-MS (LA-ICP-MS)	Trace element concentrations and isotopic composition	
	Raman spectroscopy	Mineral structure and composition	
	Transmission electron microscope (TEM)	Nanoscale detail of minerals	
	Fourier transform infrared (FTIR) microscopy	H and C abundances and their speciation in minerals	
Age dating (radioisotopes)	Potassium–argon (K–Ar)	Isotopic information used to infer formation or reset ages of a sample	Requires knowledge of K content of sample
	Argon–argon (Ar–Ar)		Requires irradiation in a reactor prior to analysis
	Samarium–neodymium (Sm–Nd)		Ideally requires analysis on bulk sample as well as its mineral constituents
	Rubidium–strontium (Rb–Sr)		
	Uranium–lead (U–Pb)		Can be a bulk measurement or performed using in situ (e.g. by SIMS or LA-ICP-MS techniques)
	Lead–lead (Pb–Pb)		
	Hafnium–tungsten (Hf–W)	Used to infer timing of core–mantle separation	Requires analysis on bulk samples
Magnetic properties	Magnetometer	Detection of remanent magnetization and paleointensity of magnetic field	Chip–collection orientation ideally known

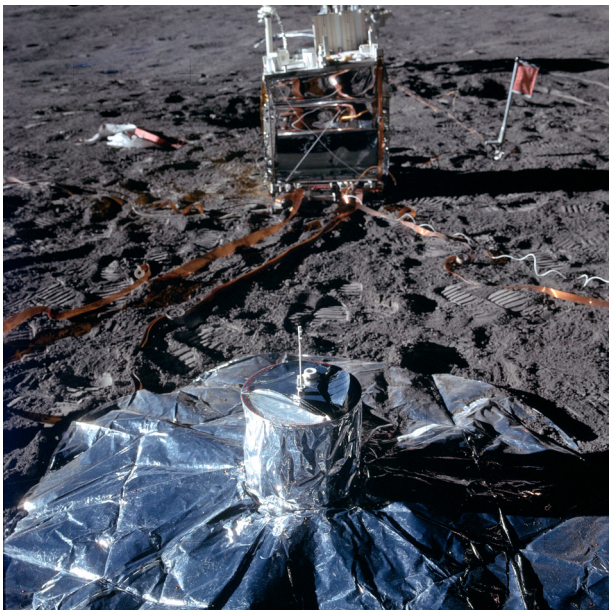

FIGURE 25.10 Apollo 14 seismometer deployed on the lunar surface; the silvery skirt provided thermal stability. These instruments, also deployed at the Apollo 12, 15, and 16 landing sites, constituted the Apollo passive seismic network which remained active until 1978. *NASA image AS14-67-9363.*

fields. These orbital instruments are summarized in Table 25.2.

4.4. Apollo and the Benefits of Human Exploration

The Apollo program was the first, and to date the only, planetary exploration program involving astronauts, and its

success has some lessons for future exploration policy. In particular, the collection of a large quantity of diverse geological samples by Apollo, as well as its deployment of an extensive range of massive and bulky geophysical instrumentation, was a direct beneficiary of the relatively generous mass budgets that are an inherent feature of human space missions compared to robotic ones. It seems most unlikely that our geological and geophysical knowledge of the Moon would be as developed as it is had the Apollo missions not taken place. Looking forward, the efficiency demonstrated by the Apollo astronauts augurs well for the scientific returns which may be anticipated from future human expeditions to the Moon, as discussed in Section 7.

5. POST-APOLLO EXPLORATION

After the Apollo program came to an end in 1972, and the last Soviet mission to the Moon (Luna 24 in 1976), there was a long gap in lunar exploration. This was only broken in the 1990s, when the Clementine and Lunar Prospector missions flew to the Moon and heralded a renewed era of lunar exploration.

5.1. Clementine

The Clementine mission was a small (140 kg) satellite launched on January 25, 1994. Clementine was designed to enter lunar orbit, map the Moon's surface, and then travel onto an asteroid. The spacecraft successfully completed two months of mapping at the Moon, but upon leaving the lunar orbit on May 3, 1994, a software failure resulted in the firing of the altitude-control thrusters, causing the spacecraft to spin uncontrollably. The mission was finally abandoned and Clementine did not rendezvous with its asteroid target.

Clementine carried a suite of instruments designed to investigate the mineralogy and topography of the lunar surface. These included:

- Multispectral cameras operating in the ultraviolet–visible (UV–VIS) and near-infrared (IR) spectral ranges. Near-complete global multispectral mapping was completed at an average resolution of 100 m/pixel (UV–VIS) and 200 m/pixel (near IR). The Clementine spectral bands were sensitive to the dominant mineralogy within each pixel (for example, among mafic minerals they may discriminate between low- and high-calcium pyroxenes and olivine), and to the iron and titanium oxide (FeO and TiO_2) concentrations in the surface. The resulting global maps (e.g. Figure 25.14) reveal the compositional diversity of the lunar crust and have been particularly important in determining the crustal composition outside sampled areas (especially high latitudes and the farside).
- The Clementine laser altimeter successfully mapped lunar topography at a resolution of 1–2 km along track with 40 m height resolution. This was the first accurate lunar topographic map to be obtained and, among other things, it revealed the true extent of many lunar craters and basins, including the giant ($\sim$2400 $\times$ 2000 km diameter and $\sim$13 km deep) farside South Pole - Aitken basin.
- The Clementine bistatic radar experiment aimed radio signals at the lunar surface, which were reflected and collected back on the Earth by ground-based radio telescopes. Scattered reflections from the lunar poles suggested the presence of icy materials within some permanently shadowed craters.

5.2. Lunar Prospector

The NASA Lunar Prospector mission was launched on January 6, 1998, and orbited the Moon for a year at an

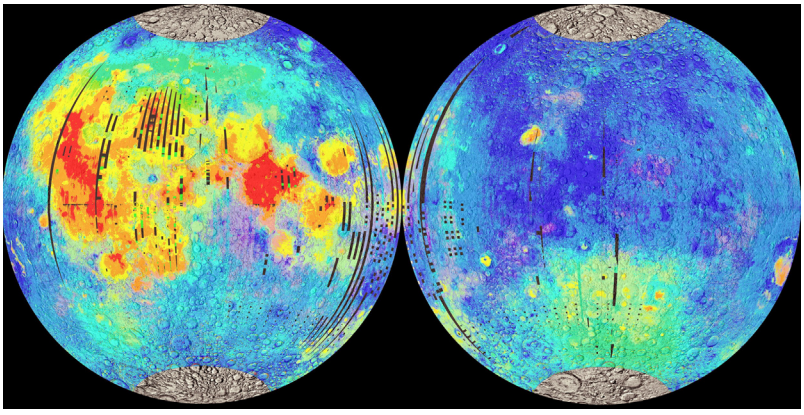

FIGURE 25.14 Distribution of rock types on the lunar nearside (left) and the farside (right) based on Clementine multispectral imaging data. Blue: anorthositic highlands; yellow: low-Ti basalts; red: high-Ti basalts. The large yellow/greenish area in the southern hemisphere of the farside is the South Pole-Aitken Basin, where the colors mostly reflect the more Fe-rich nature of the lower crust exposed by the basin rather than basaltic material. *Image courtesy of Dr Paul Spudis/LPI; LPSC 33, 1104, 2002.*

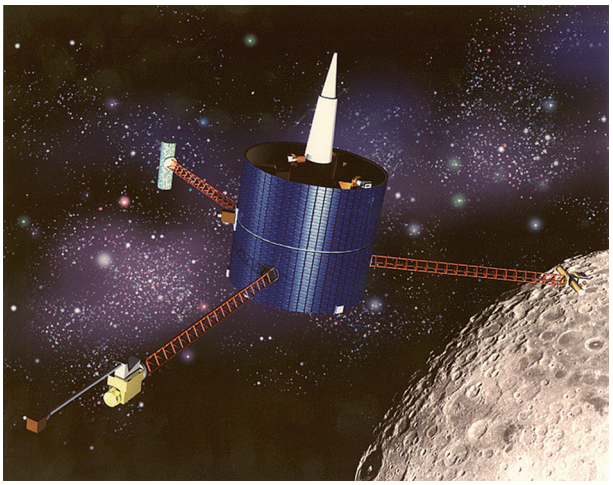

FIGURE 25.15 Artist's drawing of the Lunar Prospector spacecraft, showing instrument booms.

altitude of 100 km before being dropped into two lower orbits of 30 km and 10 km. The satellite was crashed into a south polar crater in a controlled experiment on July 31, 1999, in an attempt to see if ejected material was ice rich, although the results were inconclusive.

Lunar Prospector carried five experiments on three radial science booms (Figure 25.15), including a gamma ray spectrometer, a neutron spectrometer, a magnetometer, an electron reflectometer, and an alpha particle spectrometer (damaged at launch); spacecraft tracking also provided gravity data. The key results from the mission were:

- Gamma ray spectra were used to determine the abundance of major elements (O, Mg, Al, Si, Ca, Ti, and Fe) and radioactive elements (K, Th, and U) globally across the lunar surface. In particular, the Th distribution clearly showed that the northwest nearside of the Moon around the Imbrium Basin is compositionally unusual, with an enhanced abundance of Th (and, thus, other incompatible trace elements). This region has been dubbed the Procellarum KREEP Terrane (PKT). The term KREEP is used to describe lithologies that are enriched in potassium (K), rare earth elements (REE), and potassium (P). As these lithologies are also the dominant carriers of radioactive elements, this suggests that a large portion of the Moon's heat-producing elements may be concentrated in this region of the Moon.
- The neutron spectrometer provided independent evidence for ice at the lunar poles. Neutrons are produced by cosmic ray interaction with atoms about a meter below the regolith surface. If, on their route back through the regolith toward the surface, these neutrons encounter hydrogen nuclei an attenuated signal will be recorded by an orbiting neutron spectrometer. Such a signal was observed by Lunar Prospector, apparently supporting the Clementine bistatic radar results that ice may be present at the lunar poles. However, the data lacked sufficient spatial resolution to confirm that the areas of attenuated neutron flux correspond to permanently shadowed craters, and not all workers agree that the results prove that water ice is present in these areas (an alternative possibility could be that enhanced concentrations of solar wind-implanted hydrogen preferentially retained in the cold polar regolith).
- The Lunar Prospector magnetometer made detailed investigations of lunar crustal remanent magnetization, confirming the presence of isolated magnetic anomalies discovered by earlier missions. Combined with electron reflectometer measurements, these observations indicate that lunar crustal magnetic anomalies create mini-magnetospheres that give some protection to the underlying surface from the solar wind.

5.3. Small Missions for Advanced Research in Technology-1

Following Lunar Prospector, there was another 5-year gap in lunar exploration, until the European Space Agency's (ESA's) Small Missions for Advanced Research in Technology-1 (SMART-1) mission initiated a burst of activity in the early years of the twenty-first century. SMART-1 was ESA's first mission to the Moon. It was launched on September 27, 2003, and traveled to the Moon over a 14-month cruise period while testing an innovative solar electric propulsion (ion) drive, arriving in lunar orbit on November 15, 2004. The spacecraft carried seven technology demonstrator miniaturized instruments, designed for scientific investigations of the Moon and the surrounding space environment. SMART-1 spent almost 2 years mapping the surface of the Moon before being crashed onto its surface on September 3, 2006, when its impact into Lacus Excellentiae (34° 24′ S, 46° 12′ W) was observed from Earth.

The Advanced Moon Micro-Imager Experiment camera obtained intermediate-resolution (about 250 m/pixel globally, but better than 50 m/pixel at perilune) images of the lunar surface. The highest resolution images were of the south polar region and proved to be especially valuable in mapping the changing illumination conditions around the pole over the course of almost 2 years. These illumination maps will be useful in landing site selection for future missions designed to land at the lunar South Pole. SMART-1 also carried two instruments designed to investigate the chemical and mineralogical composition of the lunar surface. These were the SMART-1 infrared spectrometer (SIR) and demonstration of a compact X-ray spectrometer (D-CIXS). Intended primarily as technology demonstrators, these pioneering instruments resulted in greatly improved instruments flown on the Chandrayaan-1 mission (see below).

5.4. Kaguya

The Kaguya mission, known as Selene prior to launch on September 14, 2007, was the Japanese Aerospace Exploration Agency's (JAXA's) second mission to the Moon (Japan had previously sent the small (197.4 kg) Hiten-Hagoromo probe into lunar orbit in 1990 to measure the ambient dust density). Kaguya was a much larger (nearly 3 t) spacecraft and included two subsatellites designed for radio science and Doppler tracking experiments. In all, 13 instruments were carried by Kaguya, including a high-resolution television camera for public engagement. The latter has resulted in some truly spectacular images (e.g. Figure 25.16). Scientific packages included a terrain mapping camera, multiband imager and spectral profiler for mineral identification and mapping, X-ray and gamma ray spectrometers for compositional mapping, a laser altimeter for measuring lunar topography, and plasma analyzers and a charged particle detector for exosphere measurements. The two relay radio satellites helped to map lunar gravity variations, notably improving our understanding of farside gravity anomalies and crustal thickness. The Kaguya mission ended on June 10, 2009, when the main spacecraft impacted the lunar nearside surface at ~65° 5′ S, 80° 4′ E.

Key results from Kaguya included:

- A greatly improved topographic map based on the laser altimeter measurements (Figure 25.17).
- The detection of a diverse set of as yet unsampled lunar lithologies, including outcrops of pure anorthosite (which may represent pristine magma ocean flotation cumulates) and olivine-rich outcrops (which may sample mantle material).
- Measurements of the farside gravity field. This cannot be determined by tracking spacecraft directly from the Earth, but was possible with Kaguya by using the subsatellites as relays.

FIGURE 25.16 The Earth over the South Pole of the Moon, imaged by the high-definition television camera onboard Japan's Kaguya spacecraft on November 7, 2007. The 21-km-diameter crater Shackleton, almost entirely filled with shadow, lies in the right foreground *JAXA/NHK*

5.5. Chandrayaan-1

India's first mission to the Moon, Chandrayaan-1, was launched on October 22, 2008. The mission was lost prematurely on August 29, 2009, when Chandrayaan-1 ceased communication with the Earth. The spacecraft included 11 instrument packages, five of which were provided by Indian institutes and six by overseas space agencies, including two from NASA, three from ESA, and one from Bulgaria. The Indian contributions included a small Moon Impact Probe that separated from the main satellite and hard-landed near to the lunar South Pole on November 14, 2008. This probe carried a mass spectrometer (known as CHACE), which

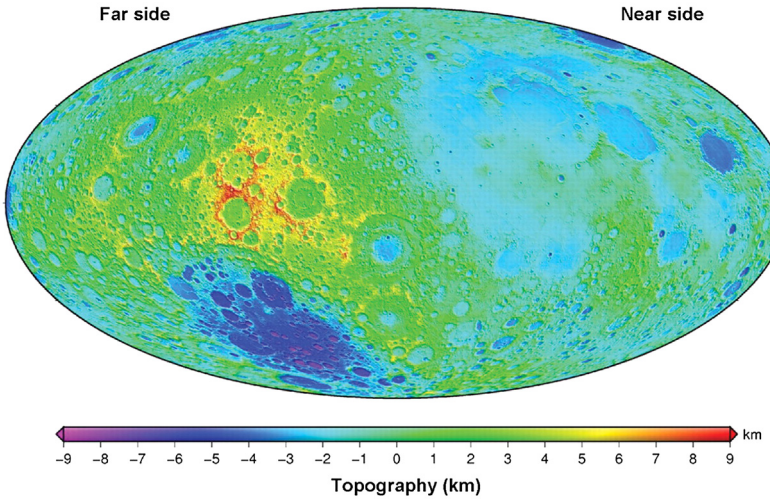

FIGURE 25.17 Lunar global topographic map obtained from Kaguya laser altimetry. *Araki et al. (2009); AAAS©*.

measured the composition of the lunar exosphere during descent, in the process detecting the presence of small quantities of atmospheric water molecules.

Other instruments on board included the Moon Mineralogy Mapper (M^3) imaging spectrometer, the Miniature Synthetic Aperture Radar (Mini-SAR), the Chandrayaan-1 X-ray Spectrometer (C1XS), and an IR spectrometer (SIR-2). Key results include:

- The discovery by M^3 of apparently hydrated minerals in high-latitude regoliths (Figure 25.18). It is hypothesized that this OH/H_2O, which cannot exist as ice in these diurnally sunlit areas, is produced by the reduction of iron oxides in the regolith by solar wind-implanted hydrogen, with OH/H_2O being retained in the relatively cold high-latitude regolith. It is, however, possible that, over time, this high-latitude OH/H_2O may migrate to permanently shadowed polar craters and contribute to ice deposits there.
- The M^3 instrument also discovered the presence of spinel-bearing lunar lithologies, in addition to those rich in olivine and pyroxene.
- The possible discovery of ice deposits in (some) permanently shadowed lunar craters by Mini-SAR. However, this interpretation, while broadly consistent with the Clementine bistatic radar and Lunar Prospector neutron spectrometer results, is inconsistent with some Earth-based radar observations and requires confirmation by future missions.
- C1XS, while benefiting from experience gained on D-CIXS on SMART-1, suffered from a low level of solar activity during the mission (solar flares are required to produce the X-rays that excite surface fluorescence). Nevertheless, the instrument was able to make compositional measurements over several Chandrayaan-1 ground tracks with a surface resolution of about 50 km.

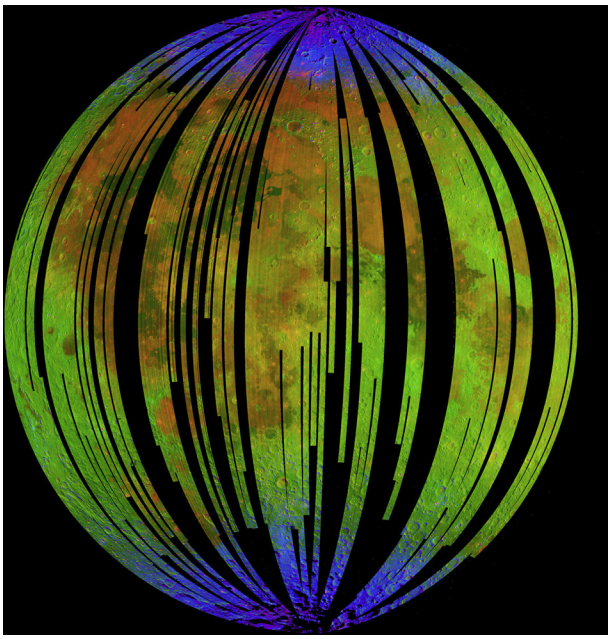

FIGURE 25.18 False color image of the lunar nearside based on data obtained by the M^3 instrument on India's Chandrayaan-1 mission. Blue represents areas where a 2.8- to 3.0-μm absorption band attributed to bound H_2O/OH was detected; red represents areas where the 1-μm band of the mineral pyroxene is strong, and picks out the basaltic maria; and green represents albedo. Note that evidence for hydration is restricted to high latitudes, but is much more extensive than areas of permanent shadow at the poles. *ISRO/NASA/JPL-Caltech/Brown Univ./USGS*

5.6. Chang'e 1 and 2

The Chinese Lunar Exploration Program (also known as the Chang'e series) was initiated on October 24, 2007, with the launch of the Chang'e 1 spacecraft. A follow-up mission, Chang'e 2, followed on October 1, 2010. The two spacecraft served as the first phase of an ambitious Chinese lunar exploration program to move from an orbiter series, to soft landers to robotic sample return, with the long-term goal of sending people to the Moon. Chang'e 1 orbited in a 200-km orbit, conducting scientific experiments to image and map the composition of the lunar surface and space environment, including a microwave radiometer to map global temperatures at different depths down to several meters. Chang'e 2 operated in a lower 100-km orbit and included similar instrument suite as Chang'e 1, but with improved spatial resolution to perform detailed analysis of future landing sites for the planned future landers and investigations of lunar resources. Key results included:

- The derivation of global major element maps.
- Publication of the first global microwave maps of the lunar surface.

The Chang'e 1 mission concluded on March 1, 2009, with a controlled crash on the lunar nearside in Mare Fecunditatis (1° 30′ S, 52° 22′ E). The Chang'e 2 spacecraft at the end of its mission was transferred successfully from lunar orbit to the Earth–Sun L2 Lagrangian point, the first satellite successfully to make this maneuver, and was subsequently sent on an extended mission to rendezvous with a near-Earth asteroid.

5.7. Lunar Reconnaissance Orbiter

LRO was launched on the June 18, 2009, as a joint launch with the Lunar Crater Observation and Sensing Satellite (LCROSS) mission (see Section 5.8). LRO was designed initially to be an exploration mission to map and study the Moon in preparation for future human exploration efforts, but after 1 year it entered an extended scientific mapping

phase. The payload included seven scientific instruments: (1) the Lunar Reconnaissance Orbiter Camera (LROC), composed of three separate elements: the wide-angle camera fitted with seven color bands with a spatial resolution of 100 m/pixel and two narrow-angle cameras (NACs) that provide panchromatic images down to a spatial resolution of ~0.5 m/pixel; (2) the Lunar Orbital Laser Altimeter (LOLA), designed to produce the most accurate lunar topographic map to date; (3) the Diviner radiometer, designed to measure surface temperatures; (4) the Lunar Exploration Neutron Detector (LEND), a neutron spectrometer designed to search for possible near-surface water ice deposits at the lunar poles; (5) the Lyman-Alpha Mapping Project (LAMP), designed to image the interiors of permanently shadowed regions in reflected ultraviolet (UV) starlight; (6) the Cosmic Ray Telescope for the Effects of Radiation (CRaTER) instrument designed to characterize the lunar radiation environment; and (7) the Miniature Radio Frequency (Mini-RF) technology demonstration of an advanced synthetic aperture radar capable of detecting ice deposits at the lunar poles.

Key results include:

- LROC NACs have yielded many insightful images of the lunar surface. These include images of fine-scale layering within lava flows (Figure 25.19), which will be exciting targets for future exploration because in situ sampling will enable studies of the temporal evolution of lunar magmatism and the search for buried paleoregolith deposits (see below). The LROC NACs have also imaged the Apollo (Figure 25.20), Luna, and Lunokhod landing sites. The location of the Lunokhod 1 laser reflector has made it possible to expand the Lunar Laser Ranging (LLR) network. Moreover, the identification of the precise landing sites of Luna 16, 20, and 24 has provided local geological context for the samples returned by these missions that was previously poorly constrained.
- LOLA has produced extremely detailed and high-resolution topographic data with a horizontal resolution of 10 m and a vertical resolution of about 2 m, along the ground tracks. Owing to the polar orbit of LRO, the poles now have essentially complete

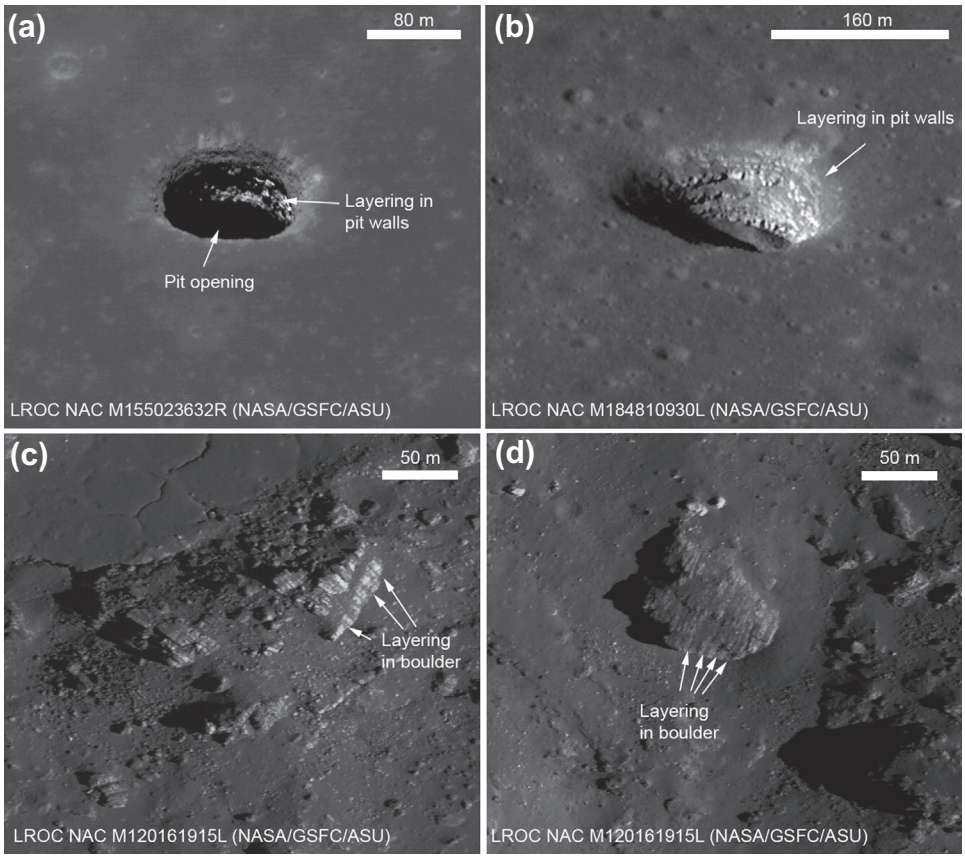

FIGURE 25.19 Oblique LROC NAC view of lunar pits with layered walls found in (a) Mare Tranquillitatis and (b) Mare Ingenii. Features are annotated based on the USGS published traverse maps. *Images: NASA/GSFC/Arizona State University, modified by K.H. Joy*

topographic coverage at this resolution, with coverage of lower latitudes constantly improving as the mission progresses.

- Diviner has measured global surface temperatures and has demonstrated that permanently shadowed regions at the poles have temperatures as low as 40 K (with some areas possibly as low as 29 K, which would be the coldest surfaces yet measured in the solar system). Water ice is stable at these low temperatures.
- The LEND instrument has confirmed the attenuation of epithermal neutrons at high latitudes first discovered by Lunar Prospector, but not the one-to-one correlation with permanently shadowed regions which would be expected if subsurface ice is responsible.
- Mini-RF, the next-generation model of the Mini-SAR radar that flew on Chandrayaan-1, has returned data about the structure of the lunar regolith and possibly detected ice-bearing deposits in permanently shadowed polar craters (but, as for the Mini-SAR results, there are alternative interpretations and the presence of polar ice deposits cannot yet be considered to have been unambiguously proved).

Many of the instruments on board LRO were used to help in mission planning for the impact of the LCROSS mission (see below) and were also involved in collecting data from the impact site.

5.8. LCROSS

The LCROSS mission was co-launched with LRO. It was designed to detect volatiles in the ejecta plume caused by the impact of the launch vehicle's spent Centaur upper stage into a permanently shadowed near-polar crater. The target selected was a region of Cabeus crater (84° 42′ S, 48° 42′ W), and impact occurred on the October 9, 2009. The Centaur rocket stage had a nominal impact mass of about 2300 kg and an impact velocity of about 2800 m/s, releasing the kinetic energy equivalent of detonating approximately 2 t of TNT (9 GJ). The LCROSS Shepherding Spacecraft passed through the resulting ejecta plume and collected and relayed data before itself impacting the surface 6 min later.

The Shepherding Spacecraft instrument payload consisted of a total of nine instruments: one visible, two near-IR, and two mid-IR cameras; one visible and two near-IR spectrometers; as well as a photometer. Near-IR spectral features attributed to water vapor and ice, and UV emissions attributed to hydroxyl radicals, were observed, and supported the presence of water in the near subsurface of Cabeus. The maximum total water vapor and water ice within the instrument field of view was estimated to be 155 ± 12 kg. Given the estimated mass of the excavated regolith, the concentration of water ice at the LCROSS impact site was estimated to be $5.6 \pm 2.9\%$ by mass. In addition to H_2O and OH, spectral bands of a number of other volatile compounds were observed, including NH_3, CO_2, sulfur-bearing compounds (H_2S, SO_2), and light hydrocarbons (CH_4, C_2H_4, and CH_3OH), although the column densities of the latter have large uncertainties associated with them.

5.9. Gravity Recovery and Interior Laboratory

Gravity Recovery and Interior Laboratory (GRAIL) was a NASA mission that was launched on September 10, 2011. The mission consisted of two small satellites GRAIL-A (known as Ebb) and GRAIL-B (known as Flow) to map the gravity field of the Moon using high-precision range-rate measurements of the distance change between the two spacecraft. Ebb and Flow were placed in circular polar orbits, with a mean altitude of 55 km above the lunar surface, and very precise tracking

of these spacecraft has produced the most accurate map of the lunar gravity field yet obtained. Key results included:

- Measurement of the mean density of the lunar crust to be only 2550 kg/m^3, which indicates significant porosity (~12%) to depths of several kilometers as a result of intense bombardment.
- Determination of the thickness of the lunar crust, which with an average thickness of 34–43 km was found to be substantially thinner than previously thought. This in turn implies that the bulk abundance of aluminum in Moon is nearly the same as that in the Earth, consistent with the hypothesis that the Moon is largely constituted of material derived from the Earth (as predicted by some versions of the giant impact hypothesis of lunar origin).
- Discovery of large (i.e. hundreds of kilometers long, tens of kilometers wide) magmatic intrusions (dikes) deep within the lunar crust, and possibly associated with an early expansion of the Moon as predicted by some thermal models.

The GRAIL mission ended on December 17, 2012, when the Ebb and Flow spacecraft crashed onto an unnamed mountain at 75.62° N, 26.63° W.

5.10. Lunar Atmosphere and Dust Environment Explorer

Lunar Atmosphere and Dust Environment Explorer (LADEE) is a NASA mission launched on 7 September 2013. The mission is designed to measure the composition of the lunar exosphere and dust environment and carries an UV ultraviolet spectrometer, a neutral mass spectrometer, and the Lunar Dust Experiment.

5.11. Chang'e 3 Lunar Lander and Rover

The Chinese Chang'e 3 mission was launched on 1 December 2013 and successfully landed in northern Mare Imbrium (approximate coordinates: 44.12 degrees north; 19.51 degrees west) on 14 December 2013. This marked the first controlled soft landing of a spacecraft on the lunar surface since Luna 24 in 1976. Chang'e 3 carried a rover which made in situ measurements of regolith structure and composition in the vicinity of the landing site. Instrumentation included a ground-penetrating radar, allowing for the first direct measurement of the structure of the regolith down to a depth of about 30 m, and an alpha particle X-ray spectrometer for compositional measurements.

6. LETTING THE MOON COME TO US: THE IMPORTANCE OF LUNAR METEORITES FOR LUNAR EXPLORATION

The Apollo and Luna collection has been supplemented by the discovery of lunar meteorites (Figure 25.21). These are pieces of lunar rocks that have been launched off the Moon at >2.4 km/s (lunar escape velocity) during the impact of an asteroid or comet projectile and that have been transported to the Earth, surviving entry through the atmosphere and found as meteorites in hot and cold (i.e. Antarctica) deserts on Earth. The first lunar meteorite, collected in November 1979, was Yamato 791197 but its lunar origin was not recognized at the time. It was not until Allan Hills (ALHA) 81005 was collected in January 1982, and classified as being lunar in origin, that meteorites became an important addition to the lunar sample collection.

Radionuclide studies indicate that the majority of known lunar meteorites have been launched from the Moon

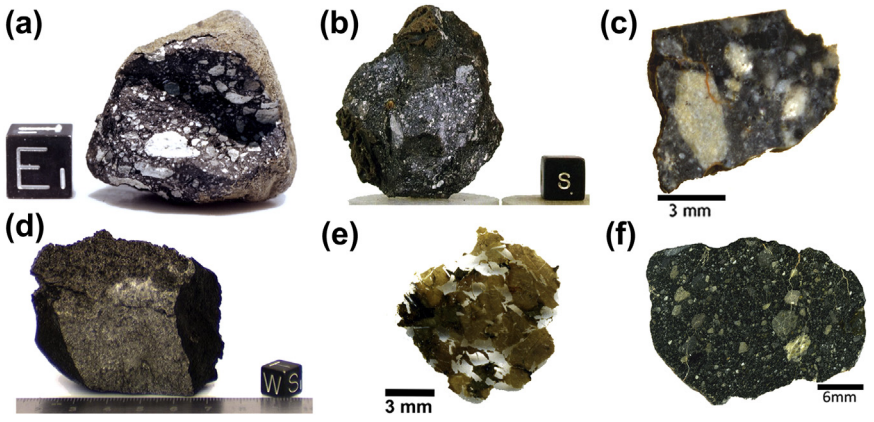

FIGURE 25.21 Examples of lunar meteorites. (a) Antarctic feldspathic regolith breccia ALHA 81005 showing clast-rich interior and brown fusion crust (Photo: NASA). (b) Antarctic feldspathic regolith breccia 791197 (Photo: NIPR). (c) Polished slab of hot desert (Libya) feldspathic regolith breccia Dar al Gani 400 (Photo: K.H. Joy). Joy). (f) Polished face of hot desert KREEP-rich regolith breccia North West Africa (NWA) 4472 (Photo: K.H. Joy). Cube scale is 1 cm and other scale bars are denoted on images.

within the past 10 million years and that all have been launched within the past 20 million years. As no large lunar craters are believed to have formed in this time period, it has been theorized that lunar meteorites are launched from small craters of only a few kilometers or less in diameter. The meteorites potentially have been launched from anywhere on the lunar surface and so arguably represent a global sampling of lunar rock types. There are currently (as of January 2014) 177 named stones, which, when paired or grouped together, represent ~85 separate meteorite arrivals on the Earth with a collective mass of ~70 kg.

Mineralogical, chemical, and isotopic studies of lunar meteorites, using the same techniques applied to study other lunar samples (Table 25.3), have helped to advance our knowledge of lunar geology. In particular, the random sampling of the lunar surface by the meteorites implies that many of them will be derived from previously unsampled regions, including the farside. They therefore give us a better understanding of the *diversity* of lunar crustal rocks than do the Apollo and Luna samples, even though generally we do not know the source region of any given lunar meteorite. Important discoveries include evidence for Mg-rich anorthosites in the farside crust, which may challenge the prevailing global flotation cumulate model for the origin of the lunar crust, and the presence of very-low-titanium basalt clasts in highland breccias. Discoveries of such basalt samples may imply that some areas of the lunar limbs and farside are underlain by mare material (as the so-called cryptomaria) that were erupted or intruded into the crust early in lunar history.

Careful comparisons between lunar meteorite compositions and crustal compositions determined by orbital remote sensing measurements are now making it possible for the source regions for some lunar meteorites to be geographically constrained. This is important because, once we know where a given meteorite comes from, it's detailed mineralogical, geochemical, and isotopic composition, which can only be measured in laboratories on Earth, can be related to a specific geological context on the Moon.

7. FUTURE LUNAR EXPLORATION OBJECTIVES

Future lunar exploration objectives can logically be divided into three categories: (1) science of the Moon (i.e. studies of the Moon itself), (2) science on the Moon (i.e. studies using the lunar surface as a platform for scientific investigations not directly related to the Moon itself), and (3) science from the Moon (i.e. studies utilizing the lunar surface as a platform for astronomical observations). These scientific objectives, with detailed recommendations for how to achieve them, are described in more detail in the Lunar Exploration Roadmap maintained by the Lunar Exploration Analysis Group (LEAG), an advisory body chartered by NASA to assist in planning for future lunar exploration.

7.1. Science of the Moon

In 2007, a US National Research Council Report on "The Scientific Context for Exploration of the Moon" identified, and prioritized, eight top-level scientific "concepts" (each of which can be broken down into multiple individual science goals) and identified the capabilities that would be required of space missions designed to address them. We summarize these here, and then describe how future surface exploration (human and/or robotic) will aid in meeting these scientific objectives.

- The Bombardment History of the Inner Solar System

The vast majority of lunar terrains have never been directly sampled, and their ages are based on the observed density of impact craters calibrated against the ages of Apollo and Luna samples. However, the current calibration of the cratering rate, used to covert crater densities to absolute ages, is not as complete as it is often made out to be. For example, there are no calibration points that are older than about 3.85 Ga, and crater ages younger than about 3 Ga are also uncertain. Improving the calibration of the lunar cratering rate would be of great value for planetary science for the following three reasons: (1) it would provide better estimates for the ages of unsampled regions of the lunar surface; (2) it would provide us with a more reliable estimate of the impact history of the inner solar system, including that of the Earth; and (3) the lunar impact rate is used, with various assumptions, to date the surfaces of other planets for which samples have not been obtained. Obtaining an improved cratering chronology is straightforward in principle: it requires the sampling, and radiometric dating, of surfaces having a wide range of crater densities, supplemented where possible by dating of impact melt deposits from individual craters and basins. However, in practice, this is likely to require the implementation of multiple missions to many different sites. These might be robotic missions, ideally involving rover-facilitated mobility and either in situ radiometric dating or, preferably, a sample return capability.

- The structure and composition of the lunar interior

The structure of the lunar interior provides fundamental information on the evolution of differentiated planetary bodies. Despite data from the Apollo geophysical instruments, key aspects of the Moon's interior structure, composition, and evolution are left unresolved. The two heat flow measurements made during Apollo were obtained near the edge of the atypical PKT, so they may not be

representative of the Moon as a whole. Resolving these questions will require making further geophysical measurements. While a few such measurements can be made from orbit (such as the measurement of the Moon's gravity and magnetic fields), most require geophysical instruments to be placed on, or below, the lunar surface. These should be configured to give global coverage and should be located at least 100 km from major terrain boundaries. Key instruments in this respect are seismometers to probe the structure of the deep interior, heat flow probes to measure the heat loss from the lunar interior, and magnetometers to measure remanent magnetizations and internal electrical conductivity variations.

- The diversity of lunar crustal rocks

Quantifying and understanding the diversity of the lunar crust will require detailed chemical and mineralogical analysis of rocks and soils from as yet unsampled regions of the lunar surface. In particular, no sample has yet been returned from the polar regions or the farside, greatly limiting our knowledge of lunar geological processes. Although, statistically, many of the lunar meteorites discussed in Section 6 presumably originate from these areas, the value of these materials is limited by lack of knowledge of their source regions and thus geological context. The diversity of lunar crustal materials has been demonstrated most recently by the orbital remote sensing instruments (see Section 5), and it is important to confirm the interpretation of these remote sensing observations. It is also important to obtain measurements of minor and trace elements in these materials, which cannot be detected by orbital remote sensing but which would help discriminate between different suggested origins and formation mechanisms. Sample return missions to currently unsampled regions would be the preferred means of furthering our knowledge of lunar geological diversity, although an alternative would be to make robotic in situ geochemical measurements.

- Volatiles at the lunar poles

The lunar poles potentially bear witness to the flux of volatiles present in the inner solar system throughout much of solar system history. As discussed in Section 5, a range of remote sensing observations suggest the presence of water ice in the floors of permanently shadowed polar craters, an interpretation supported by the LCROSS impact experiment. It seems likely that this water is ultimately derived from the impacts of comets and hydrated asteroids with the lunar surface, although solar wind implantation and endogenic sources might also contribute. However, the inferred quantity of water is sensitive to a number of assumptions and ideally needs to be confirmed by future in situ measurements. The confirmation of significant quantities of water and other volatiles at the lunar poles would help facilitate future human exploration of the Moon and of the inner solar system more generally (see Section 7.4 below).

- Lunar volcanism

The characterization of lunar volcanism is a high lunar science priority because of the window it provides into the thermal and compositional evolution of the lunar mantle. Recent remote sensing observations have demonstrated two very important points: (1) that the samples of volcanic products returned by the Apollo and Luna missions are not fully representative of all the types of volcanism present on the Moon and (2) that the presence of nonmare silicic volcanism on both the near- and farsides of the Moon shows that lunar magmatic processes are able to produce high-silica magmas in addition to the more common mare basalts. There is no doubt that these as yet unsampled areas would benefit from in situ field investigations. However, from a lunar exploration perspective, this is just one aspect of the wider requirement to sample a diverse set of lunar rocks (described above) and the implications for exploration capabilities are essentially the same.

- Impact processes

Impact cratering is a fundamental planetary process, an understanding of which is essential for our knowledge of planetary evolution. Yet our knowledge of impact processes is based on a combination of theoretical modeling, small-scale laboratory hypervelocity impact experiments, and field geological studies of generally poorly preserved terrestrial impact craters. The Moon provides a unique record of essentially pristine impact craters of all sizes (from micron-sized pits up to $>$300 km impact basins). Field studies, combining sample collection (including drill cores) and in situ geophysical studies of the ejecta blankets and subfloor structures of pristine lunar craters of a range of sizes would greatly aid in our understanding of the impact cratering process.

- Regolith processes

The lunar surface is a natural laboratory for understanding regolith processes and space weathering on airless bodies throughout the solar system. The nature of cold high-latitude regoliths, which have never been sampled or studied in situ, and which may contain a volatile component, are of particular interest. Another important aspect of the lunar regolith is the record it contains of the early solar system history. Studies of Apollo samples have revealed that solar wind particles are efficiently implanted in the lunar regolith and therefore contain a record of the composition and evolution of the Sun throughout the solar system history. Recently, it has been suggested that samples of Earth's early crust may also be preserved in the lunar regolith in the form of terrestrial meteorites. Meteorites

derived from elsewhere in the solar system have already been found on the Moon, preserving a record of the dynamical evolution of small bodies throughout solar system history. Last but not least, the lunar regolith may contain a record of galactic events, by preserving the signatures of ancient cosmic ray fluxes and the possible accumulation of interstellar dust particles during passages of the Sun through interstellar clouds. From the point of view of accessing the ancient solar system history it will be especially desirable to find layers of ancient regoliths (*paleoregoliths*) that were formed and buried billions of years ago and thus protected from more recent geological processes (Figure 25.22). Locating and sampling such deposits will likely be an important objective of future lunar exploration activities.

- Atmospheric and dust environment

The extent to which transient releases of gasses into the lunar exosphere may occur is of interest because this may correlate with ongoing low-level geological activity. The surface dust environment, and especially the extent to which dust grains may become electrostatically charged and transported, is another important research topic, one which will require surface instruments to be deployed. The processes involved are likely to be common on other airless bodies, and quantifying them on the relatively accessible lunar surface will give us better insight into regolith/exosphere interactions throughout the solar system. It is, however, important to note that landed missions have the potential to significantly disturb the tenuous lunar atmospheric environment, and it is therefore important that the lunar atmosphere/exosphere be properly characterized before renewed surface operations are initiated; the orbital LADEE mission (Section 5.10) is designed with this objective in mind.

7.2. Science on the Moon

The lunar surface is a potential platform for a number of scientific investigations unrelated to the Moon itself (see, for example, the LEAG Roadmap referred to above). These include investigations in the life sciences, human physiology, astrobiology, and fundamental physics.

- Life sciences and astrobiology

Although the Moon has, almost certainly, never supported any life of its own, lunar exploration will nevertheless inform our searches for life elsewhere. Organic molecules delivered to the inner solar system by comets and asteroids, and protected either in the lunar subsurface or in permanently shadowed craters, could provide insights into the inventory of organic material in the inner solar system. Insofar as these organics may have provided an exogenous source of prebiotic organics necessary to initiate life on the

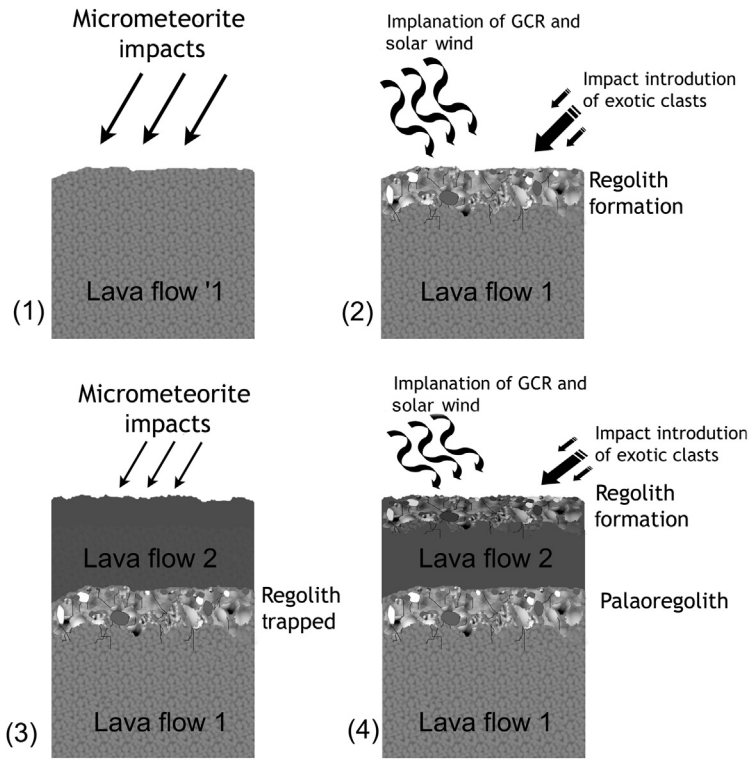

FIGURE 25.22 Schematic representation of the formation of a paleoregolith layer: (1) a new lava flow is emplaced, and meteorite impacts immediately begin to develop a surficial regolith; (2) solar wind particles, galactic cosmic ray particles, and "exotic" material derived from elsewhere on the Moon (and perhaps elsewhere) are implanted; (3) the regolith layer, with its embedded historical record, is buried by a more recent lava flow, forming a paleoregolith; (4) the process begins again on the upper surface. *Royal Astronomical Society /K.H. Joy, reproduced with permission*©.

Earth, investigating organics on the Moon has important contributions to make to understanding the origin of life on the Earth. Indigenous organic processing on the Moon may also yield insights into the origin and fate of organics in interplanetary space. Moreover, the lunar surface now contains the crashed remains of a large number unsterilized spacecraft and the study of microorganisms, or microbial spores, found within these spacecraft would answer many questions about the survivability of microorganisms in the space environment.

- Human physiology

There is medical interest in the long-term effects of reduced gravity and enhanced radiation environments on the human body. This research is needed partly to enhance our understanding of fundamental biological processes, with potential feedback into the design of medical therapies for use on Earth, and partly to support future human space operations. With regard to potential medical applications, human adaptation to prolonged exposure to partial gravity, such as exists on the Moon, may offer significant insights into vestibular disorders, cardiovascular disease, and a range of processes associated with aging. Physiological research in lunar gravity would thus supplement the knowledge accrued by microgravity exposure of astronauts in low Earth orbit. With regard to paving the way for future space exploration, for example, sending astronauts to Mars (see below) or near-Earth asteroids, research into the long-term health of a human crew operating under reduced gravity, and after a long period in microgravity, will be required. A lunar base, perhaps in combination with microgravity research on the International Space Station, is probably the only location where such research could be safely conducted.

- Fundamental physics

Although not a major driver for lunar exploration, it is recognized that a number of research fields in the area of fundamental physics may also benefit from the ability to place scientific instruments on the lunar surface. These include tests of general relativity through improved LLR measurements, tests of quantum entanglement over large baselines, and searches for exotic subatomic particles (including dark matter candidates).

7.3. Science from the Moon: Lunar-Based Astronomy

The Moon is a potentially valuable platform for astronomical observation. The lunar farside, in particular, is probably the best site in the inner solar system for radio astronomy, as it is continuously shielded from the Earth. The Moon is especially attractive as a site for low-frequency radio astronomy, because at frequencies below 30–100 MHz radio waves are seriously distorted by the Earth's ionosphere. As a consequence, the low-frequency universe is the last uncharted part of the electromagnetic spectrum. Of particular importance would be the investigation of the so-called cosmic dark ages, dating from several hundred million years after the Big Bang but before the formation of the first stars, when the cosmos was mainly filled with dark matter and neutral hydrogen. This epoch, which will contain important information on the early universe, can only be studied through radio emission from atomic hydrogen red shifted to a frequency of several tens of megahertz and would greatly benefit from radio telescopes on the Moon.

The lunar surface also lends itself to cosmic ray astronomy (as it lacks an atmosphere and lies outside the Earth's magnetosphere); other astronomies requiring large, bulky detectors (e.g. gamma ray and neutrino astronomy); and of course to observations of the Earth itself and its magnetosphere. For optical and IR astronomy, there is an argument that free-flying spacecraft offer better observing platforms than the lunar surface. Nevertheless, in the context of future human exploration of the Moon, it is important to note that the maintenance and upgrading of astronomical instruments is likely to benefit from the proximity to a human infrastructure. Thus, when and if a lunar base is established, the Moon may become a *more* attractive astronomical location than free-flying locations precisely because a human-tended infrastructure will exist to transport, service, and upgrade the instruments.

7.4. Lunar Resources

Exploration of space is an expensive undertaking in purely economic terms, with return on investment mostly measured in terms of scientific output. Identification of extraterrestrial resources, and the development of techniques to use them, could reduce our dependence on Earth-based resources and aid in the establishment of financially sustainable space exploration programs. In situ resource utilization (ISRU) is the term used to refer to the generation of consumables for autonomous or human activities from raw materials found in situ on the Moon or other planetary bodies.

Currently, the most important ISRU processes for future lunar exploration are perceived to be the production of O_2 and H_2O for life support, and/or H_2 and O_2 for fuel and propellant. At least 20 different processes have been put forward to produce oxygen from indigenous lunar resources. The most widely studied oxygen production process is ilmenite ($FeTiO_3$) reduction in the presence of hydrogen. Moreover, if ilmenite is exposed at the lunar surface (e.g. in high-Ti mare basalts) over time it accumulates solar wind-implanted species, especially hydrogen nuclei (ilmenite appears to be especially

conducive to retaining such volatiles). Lunar regolith exposed at the surface for a long time is said to be "mature" and this can be seen in the reflected spectra observed from orbit, which shifts to the longer wavelengths (i.e. it becomes "redder") the more mature the regolith is. Correlation of Ti concentration with "maturity" maps will therefore help guide future resource exploration. Moreover, as our knowledge and understanding of lunar resources improves, other elements and compounds on the Moon may become equally attractive for ISRU activities, enabling sustainable lunar exploration in the longer term.

- Regolith as a resource

The lunar regolith is the most likely primary feedstock in processes aimed at extraction of in situ resources on the Moon. The regolith particles, composed of a variety of mineral assemblages and glass, have been processed by millions to billions of years of (micro-) meteoroid impacts, with subsequent space weathering by thermal cycling, solar wind erosion, and implantation, and impacts leading to their comminution and agglutination. In general, the basaltic terrains of lunar mare tend to be richer in the minerals ilmenite, olivine, and pyroxene, while the lunar highlands are dominated by the mineral plagioclase. The actual composition of lunar soils is, however, observed to be very localized, even on the scale of a few kilometers, indicating a limited extent of lateral mixing. Within this complex mixture of materials and minerals lie several possible resources, including metal oxides, solar wind-implanted volatiles and, at high latitudes, possible water ice and/or hydrated minerals.

- Water ice in permanently shadowed craters

The possible presence of large quantities of water in the permanently shadowed regions near the lunar poles has major implications for ISRU as a potential source of water and oxygen for life support and hydrogen for fuel. As a first step, the extent, quantity, distribution, and nature of this potential ice resource must be better constrained and this will require in situ surface exploration. It is recognized that accessing permanently dark craters and identifying the presence or otherwise of in situ ice as a potential resource poses major technical challenges. Nevertheless, confirmation of exploitable quantities of water at the lunar poles would undoubtedly be a major boost for lunar ISRU, especially in the context of developing a space-faring infrastructure.

- Water on the lunar surface away from the polar regions and in the lunar interior

The recent discoveries of OH/H_2O on and near the lunar surface by infrared remote sensing measurements (Figure 25.18) have been complemented by a number of new ground-based findings of OH/H_2O in lunar samples that originated at depth within the Moon, although the sources of these species are almost certainly quite different in the two cases. The extent to which these deposits have practical utility remains to be determined, and dedicated lander/rover or sample return missions will be required to better constrain this issue.

- Solar wind-implanted volatiles

Solar wind-implanted volatiles are another potential resource, with the advantage that their extraction from the regolith can be achieved by heating alone. These volatiles have a number of potential applications, including their use as a feed product for the reduction of metal oxides such as FeO for the production of O and H_2O. The main solar wind-implanted volatiles include the elements H, N, C, and He. These elements can be important for various aspects of lunar exploration and the maintenance of a lunar outpost, and volatile extraction from the regolith may reduce the requirements for replenishment of these elements from terrestrial sources. Volatile extraction is probably the simplest example of potential ISRU, but because the abundance of volatile elements in the regolith is in general fairly low (e.g. of the order of 50 ppm by mass in the case of H), their practical application to future exploration requires further investigation.

Much previous speculation has centered on the possible use of ^3He in the lunar regolith as a fuel for future nuclear fusion reactors. However, the concentration of ^3He in the regolith samples returned by Apollo is very low (in the range 2−10 parts per billion by mass) and it is far from clear whether significant exploitation could ever be economic in terms of mining it on the Moon and exporting it back to the Earth.

- Future outlook

Lunar oxygen, hydrogen, and water may be the most crucial resources in the near-term human exploration of the Moon, but other chemical and mineral resources such as metals and rare gases could also become valuable resources (especially if they are produced as by-products of other metallurgical processes). Continued innovation in mining, processing, and manufacturing techniques could further increase the resource potential of the Moon. The existing lunar sample collection provides unprecedented access to lunar materials for improving our understanding of the chemical/mineralogical makeup of the Moon and for devising experiments to develop and test new technologies for extracting lunar resources. High-resolution global (ideally meter-scale) mapping of lunar surface elemental and mineralogical compositions, complemented by in situ measurements by landed spacecraft (including rover-enabled mobility) and sample return missions, is needed to identify the optimal locations for

lunar ISRU. In the current phase of expanding global exploration initiatives, ISRU is likely to benefit from a synergistic approach between governmental and commercial sectors.

7.5. The Moon as a Stepping Stone for the Exploration of Mars and other Solar System Destinations

Future human operations on the Moon may pave the way for the eventual, and far more challenging, human exploration of Mars, near-Earth asteroids, and other inner solar system destinations. In the case of Mars, while there remains much essential reconnaissance work to be performed robotically, in the longer term, Mars exploration would benefit from a human presence for the same reasons discussed here in the context of lunar exploration. This is likely to be especially true if evidence for past or present life is found on Mars, because the subsequent demand for follow-up investigations is likely to outstrip the limited capabilities of robotic exploration.

That said, there is still much to learn about human physiological and psychological responses to long-term immersion in the space environment before astronauts could safely be sent to Mars, and much of the required knowledge could be built up in the course of a human lunar exploration program. In addition, many of the operational techniques that will be required for exploring Mars (such as field geology using space-suited astronauts, the use of pressurized rovers, and the development of planetary drilling technologies) could also be perfected on the Moon, where they will be required to address the scientific issues discussed above. For these reasons, lunar exploration can be seen as a stepping stone for the scientific exploration of Mars and other locations in the inner solar system.

8. CONCLUSION

The Moon's proximity to the Earth has historically placed lunar exploration at the forefront of solar system exploration. This was true of Galileo's first telescopic observations (when the Moon was the only "planet" large enough to be properly resolved by the instrumentation available at the time), right through to the first spacecraft to orbit, land on, and return samples from another celestial body. Moreover, the Moon was the first, and is to date the only, celestial body that human beings have explored in person. The past two decades have seen a renaissance in lunar exploration conducted from orbit, and continued studies of the Apollo and Luna samples, supplemented by studies of lunar meteorites. This has resulted in a wealth of new data which has in many ways revolutionized our knowledge of Earth's natural satellite and has also taught us much about the early history of the solar system (including the origin and evolution of the Earth–Moon system), the geological evolution of rocky planets more generally, and the near-Earth cosmic environment throughout solar system history.

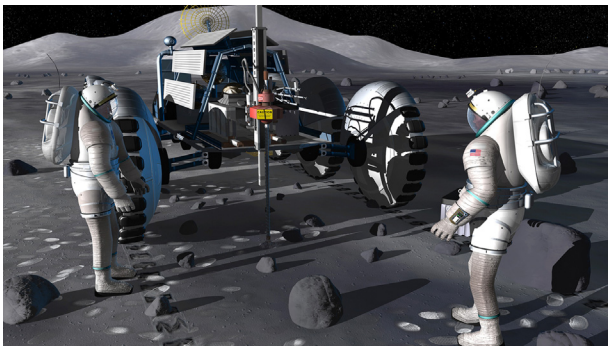

FIGURE 25.23 Artist's concept of astronauts supervising a drill. Such a capability would permit access to the subsurface, for example, to extract buried paleoregolith samples containing ancient solar wind and galactic cosmic ray records, and is an example of how science will benefit from returning humans to the Moon.

However, it is also clear that the Moon still has much more to tell us about all these areas of planetary science. In addition, the Moon also offers outstanding opportunities for research in astronomy, astrobiology, fundamental physics, life sciences, and human physiology and medicine. Addressing these objectives will require an end to the 40-year hiatus of lunar surface exploration with the placing of scientific instruments on, and the return of samples from, the surface of the Moon. Some of these scientific objectives can be addressed, at least partially, by a new generation of robotic spacecraft dispatched to the lunar surface. However, for many lunar exploration objectives, the requirements for mobility, deployment of complex instrumentation, subsurface drilling (Figure 25.23), and sample return capacity are likely to outstrip the capabilities of robotic or telerobotic exploration. Insofar as these aspects of lunar exploration would benefit from renewed human operations on the Moon, lunar exploration may once again fulfill its historical role by helping to lay the foundations for the future human exploration of the entire solar system.

ACKNOWLEDGMENTS

1. INTRODUCTION TO ASTEROIDS

1.1. What are Asteroids?

Asteroids (or more properly, minor planets) are small, naturally formed solid bodies that orbit the Sun, are airless, and show no detectable outflow of gas or dust. Shown in Figure 26.1 are eight asteroids that have been imaged in detail by spacecraft. The difference between asteroids and the other naturally formed Sun-orbiting bodies — planets, dwarf planets, and comets — is largely historical and to some extent arbitrary. To the ancient Greeks and other peoples, there were three kinds of bright objects populating the heavens. The first and most important group was the stars, or *astron* in Greek, which are fixed relative to each other. The English word star is an Old English and Germanic derivation of the Indo-European base word *stêr*, which provided the source of the Greek *astron* and the Latin *astrum*. The terms for the study of stars were based on the Greek root, i.e. astronomy or astrophysics. The second group of objects is planets, or Greek *planetos,* meaning "wanderer" since the planets were not fixed but moved relative to the background of the stars. For the ancients *planetos* included the Sun, Moon, Mercury, Venus, Mars, Jupiter, and Saturn. The final group is comets or *kometes* meaning "long haired" because of their long tails or comas and their unpredictable paths and appearances.

Asteroids were not known to the ancients and the first asteroid, 1 Ceres, was discovered in 1801 by the Sicilian astronomer Giuseppe Piazzi. While observing stellar positions he noticed a slowly moving object, which he originally reported as a comet but suggested might be "more than a comet". Its relatively slow apparent orbital motion suggested that it orbited in the gap between Mars and Jupiter, where theorists at the time had speculated would be the location of a "missing planet". The asteroid 1 Ceres was thought initially to be this new planet. However, other astronomers disputed this designation because of Ceres' apparently small size. Soon after William Olbers discovered the second such object, Pallas, in 1802, Sir William Herschel (who had discovered Uranus 20 years earlier)

proposed that, because these new objects were planetlike in their sun-centered orbits, but starlike in that they were unresolvable points of light in a telescope, the disused Greek root for a single star, "aster" should be used to describe this new addition to the celestial population. However, this term was not universally adopted at that time. By the mid-1800s, after several dozen of these bodies had been discovered, the French and Germans referred to them as "small" (*petit* or *kleine*) planets, while the British Royal Astronomical Society officially called them "minor planets". Until modern times, the term "asteroid" was only used by astronomers in America.

In 2006, the International Astronomical Union (IAU) added additional terms to the mix by defining a group of "dwarf planets". The IAU was attempting to precisely define a planet given the increasing evidence that Pluto was just one of the larger members of the **Kuiper Belt** (See also Kuiper Belt: Dynamics, Kuiper Belt: Physical Studies, and Pluto) and substantially different from the terrestrial or gas giant planets. A dwarf planet orbits the Sun, is not a satellite of another body, has sufficient mass to assume a hydrostatic equilibrium (nearly spheroidal) shape, but does not have sufficient mass to have "cleared its neighborhood" of small bodies. Under this definition 1 Ceres joins Pluto as a dwarf planet. However, for the purposes of this chapter, both Ceres and Pluto can also be considered large asteroids.

Although asteroids share many of the characteristics of planets (Sun-centered orbits, seemingly solid bodies), the primary distinction is that they are simply much smaller than the known planets or dwarf planets. Similarly, the distinction between asteroids and comets is also based on their observational qualities rather than any inherent difference in physical properties or composition. Comets are characterized by their coma, or cloud of sublimating gas and expelled dust. This gives them their characteristic diffuse "fuzzy" halo and long streaming tail (see chapter Comets). Compared to the fuzzy look of comets, an asteroid is a "starlike" sharp point of light. But comets only become "cometary" when they enter the inner solar system and are heated sufficiently by the Sun to vaporize their volatile materials. The point at which frozen volatiles begin to sublimate can vary depending on composition, but for most comets this is approximately at 4 **astronomical units (AU)**. A number of outer solar system objects that could be called asteroids may be composed of the same collection of volatile ices, dust, metal, and carbonaceous organics as comets. Since their orbits are less eccentric than currently active comets, they never travel close enough to the Sun to warm their surfaces, cause their ices to flash into gas, and thus appear cometary. These objects are "solid" bodies because their surfaces stay cold enough to keep their gases frozen.

Fundamentally both asteroids and comets are "small bodies", whose stable lifetimes depend on their location in the solar system.

In the final analysis, asteroids are defined by what they are not. They move against the celestial background so they are not stars. They are not large enough to be planets, dwarf, or otherwise. They are not actively shedding gas and dust so are not comets.

1.2. Discoveries, Numbers, and Names

Because asteroids appear as relatively small and dim points of light moving slowly against the stellar background, finding and identifying an object as an asteroid is fundamentally a question of observation coupled with precise "bookkeeping". The field of view seen through a telescope at any one moment may be filled with hundreds of points of light and rarely will one be an asteroid. The asteroid may move a small amount relative to the stars during the course of a night's observations, but the trick is to know the relative positions of all the viewed stars precisely enough to know when one of the points of light is out of place. Today the viewing through the telescope is done by extremely sensitive charge-coupled devices (CCD) that feed their digital data directly to computers to do the "bookkeeping" of the stars and known asteroids. In the days when Giuseppe Piazzi discovered 1 Ceres, all the observations were done with an eye to the telescope, and the bookkeeping was done by hand drawings of the star fields. Discoveries were made by visually comparing each point of light in the telescope field with a chart that was drawn on a previous observation (there was a premium on being able to draw accurately in the dark when cold). With these methods it is not surprising that only four more asteroids were found in the 45 years after Piazzi found 1 Ceres.

The application of photography to astronomy revolutionized the search for asteroids in the last half of the nineteenth century and the early part of the twentieth century. A photographic plate is essentially an instant and precise local star chart that is far more light sensitive than the human eye, far more accurate than what could be drawn by hand, and able to take advantage of long exposures that compensate for the Earth's rotation. As a result stars appear as fixed as bright dots, and asteroids become streaks that stand out since they move relative to the stars. Modern searches have replaced photographic plates with highly sensitive electronic imaging and computers.

A newly discovered asteroid is given a temporary "name" based on the date of discovery. The first four characters are the year of discovery, followed by a letter indicating which half month of the year the discovery took place. The final character is a letter assigned sequentially to the asteroids discovered in the half month in question. Thus, asteroid 2006 CE would be the fifth asteroid discovered in the first two weeks of February in 2006. If a half month has more than 25 discoveries (the letter "I" is not used), then the letter sequence starts over with additional numerical characters, usually added as a subscript. The 26th object discovered in the first half of February would be 2006 CA_1.

However, discovery is just the first step. Unless an asteroid is tracked and its orbit reliability determined, it will be "lost". This tracking process takes weeks and sometimes months of additional observations. Once an object has an accurate orbit, it is given a permanent number. The numbers are not assigned in order of discovery, but sequentially by order of orbit determination. As of the beginning of 2013 there were 353,926 numbered asteroids and another 251,384 awaiting an accurate-enough orbit to merit a number. With the assignment of a number, the asteroid's discoverer has the right to suggest a name for the object. There are rules, of course, set by the IAU and asteroids are properly referred to by their number and the name (if unnamed, by the temporary date-based name). Asteroids are unique in that they can be named after persons or things living (for example, the authors of this chapter: 4395 Danbritt, 4597 Consolmagno, and 3439 Lebofsky) or dead (2272 Montezuma), real (4457 van Gogh, 12838 Adamsmith) or imaginary (2598 Merlin), mythological characters (5731 Zeus) or characters in operas (558 Carmen), and in several cases, pets (although this is now discouraged); however, political and military leaders must have been dead 100 years before an asteroid can bear their names, and asteroids cannot be named to advertise commercial products. As of the beginning of 2013 there were 17,698 named asteroids.

1.3. Sizes and Shapes

Shown in Figure 26.2 are the 20 largest main-belt asteroids. Asteroid sizes drop rapidly, with the largest asteroid 1 Ceres being almost twice as large as the next largest. There are only four asteroids with diameters greater than 400 km and only three with diameters between 400 and 300 km. The asteroid population becomes relatively abundant only below 300 km diameter.

The number of asteroids increases exponentially as the size decreases in a "power-law" size distribution. This is consistent with an initial population of strong, solid bodies that have been ground down by repeated impacts over the age of the solar system. Today most asteroids are fragments of larger parent bodies that have been collisionally shattered into much smaller pieces. This power law is seen not only in the sizes of asteroids but also in the sizes of the craters on the Moon, Mars, and the asteroids themselves, as well as the moons of the Jupiter and Saturn, reflecting the population of the asteroids whose impacts made those craters.

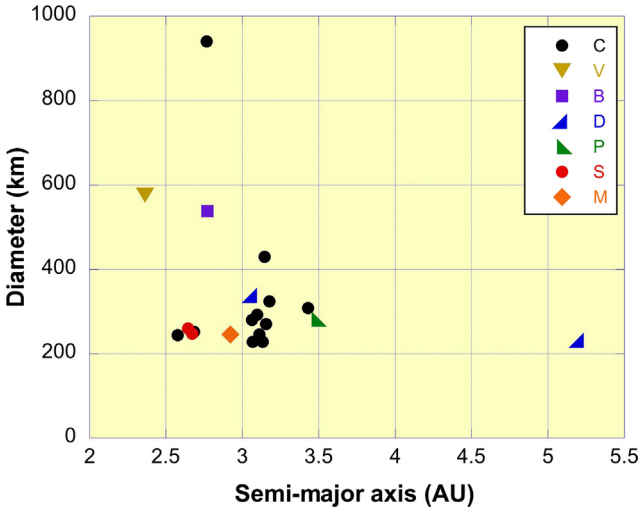

FIGURE 26.2 The 20 largest asteroids by location in the solar system and compositional type. Note that the sizes of asteroids drop rapidly with only four asteroids larger than 400 km diameter.

Given the conditions in the asteroid belt today, only the largest asteroids are large enough to have survived from the beginning of the solar system. The power law predicts, and observations confirm, that by far the most common asteroids are the smallest. Asteroid search programs using powerful telescopes, extremely sensitive CCD sensors, and state-of-the-art software regularly find asteroids in near-Earth space with diameters as small as only 5−10 m. The primary limitation on our ability to find asteroids is their apparent brightness. Smaller (and more distant) objects reflect less light and, after a point, a small object is not observable because the light it reflects drops below the limiting sensitivity of the telescopic system trying to detect it. The good news is that we have probably discovered and tracked all asteroids in the main asteroid belt larger than 20 km and all those in near-Earth space larger than 4 km. The bad news is that there are thousands of smaller asteroids in Earth-crossing orbits, a few as large as several kilometers in diameter, that remain undiscovered and potential threats to Earth (see chapter Near-Earth Objects).

Since most asteroids are presumably collisionally produced fragments of larger asteroids it should not be a surprise that they are not perfect spheres. Many asteroids that have been directly imaged optically or by radar tend to show very irregular shapes (Figure 26.1). The exception is the largest asteroids (or dwarf planets), 1 Ceres and 4 Vesta, which are (or once were) large enough for hydrodynamic forces to maintain a spheroidal shape. The asteroid 4 Vesta, the only large asteroid known to have been formed of molten lava, is an interesting boundary case. When it was molten it could form itself into a sphere. But after its lava was completely frozen it became rigid and today it appears as a flattened spheroid due to a large crater near its south pole.

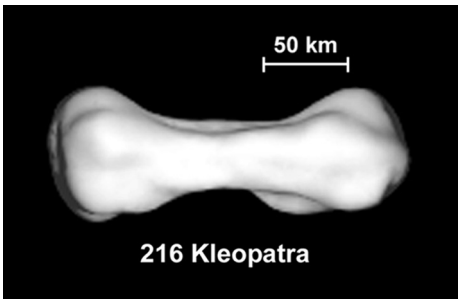

FIGURE 26.3 Radar image of the asteroid 216 Kleopatra. This irregularly shaped object resembles a 200-km-long dog bone. *Image courtesy of NASA/JPL-Caltech.*

Other large asteroids are far from spherical. For example, shown in Figure 26.3 is a radar image of the asteroid 216 Kleopatra, which has a strong resemblance to a 200-km long bone. Most asteroid shapes can be approximated as triaxial ellipsoids, which are objects that have different dimensions on each of their principal axes. In the case of Kleopatra the long dimension is over four times greater than the short dimension.

Star/asteroid **occultation** provides a direct measurement of an asteroid's shape and an opportunity for amateur astronomers to become involved in significant scientific research. The principle is simple: when an asteroid passes through (or "occults") the light from a star, the asteroid creates a "shadow" in the starlight projected on the Earth. Observers in different locations time the disappearance of the occulted star and trace out the shape of this shadow by reconstructing their "chords" or time-tagged observations of the star disappearing behind the asteroid and reappearing on the other side. This is illustrated in Figure 26.4. When done skillfully with modern equipment such as CCD detectors, computer-driven imaging systems, precise time, and the global positioning system, these measurements can be taken with very high accuracy and provide an excellent "snapshot" of the projected two-dimensional shape of the asteroid at the moment of occultation.

1.4. Asteroid Density, Porosity, and Rotation Rates

A fundamental physical property of an asteroid is its density. To first order, asteroid density is related to its composition and should be similar to the densities of meteorites thought to be derived from those asteroids (see chapter Meteorites). However, as is often the case, such expectations can be frustrated by unexpected results from actual measurements. Asteroids in general appear to be significantly underdense relative to their meteorite analogs.

The primary complication is porosity. Asteroids appear to have significant porosity; some may be as much as 50% empty space while their meteorite analogs have only small

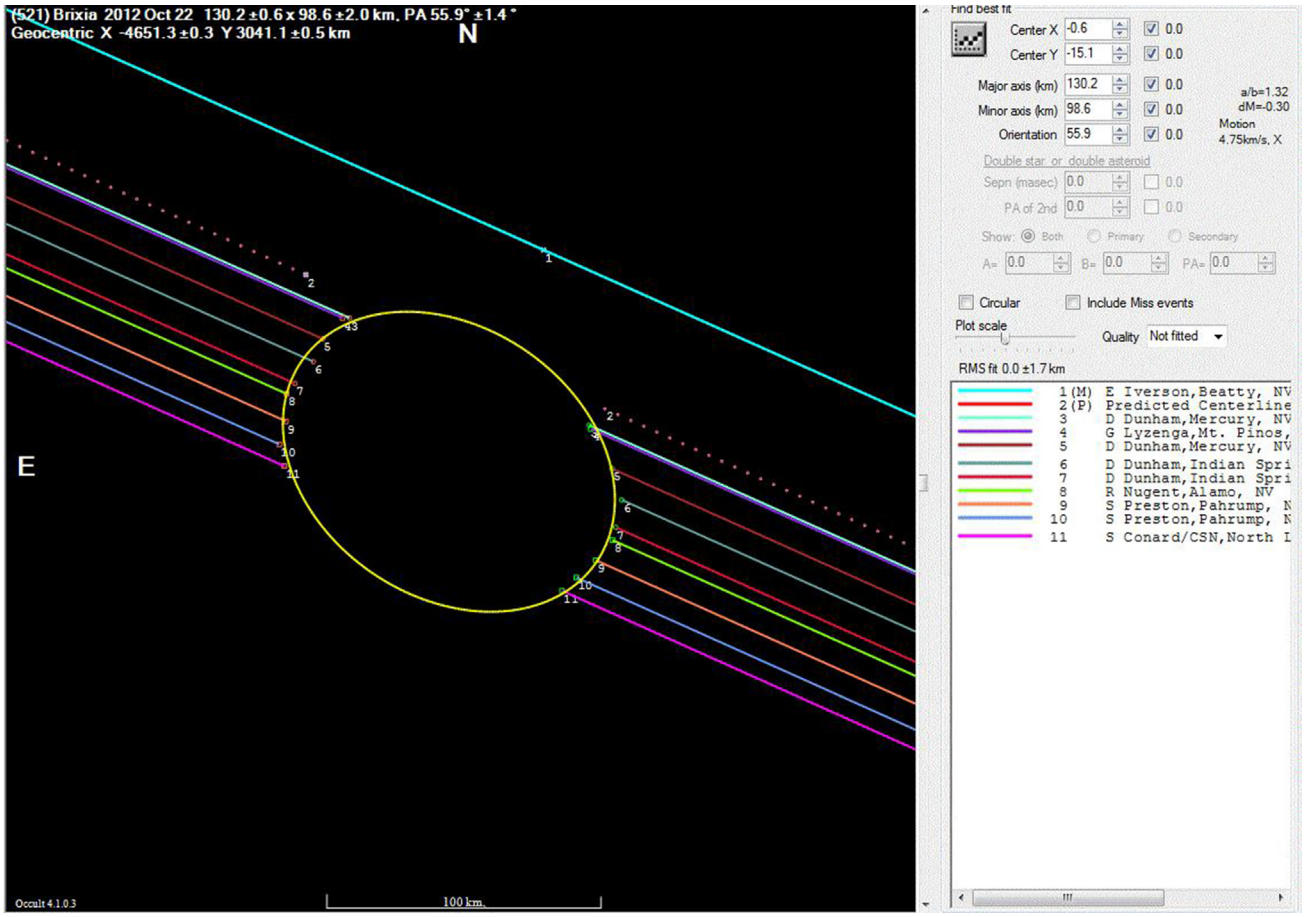

FIGURE 26.4 Occultation observation of asteroid 521 Brixia. The asteroid blocks out the star as viewed by observers at different locations on the Earth. The sum of the observations yields the shape of the asteroid. *Image courtesy of the International Occultation Timing Association.*

to moderate porosities. The observed power law of asteroid sizes, and studies of the collisional dynamics of the asteroid belt, has suggested a history of intense collisional evolution that resulted in only a few of the largest asteroids retaining their primordial masses and surfaces. Asteroids below 300 km in diameter have been shattered by energetic collisions. Some objects reaccrete to form gravitationally bound rubble piles, while the rest are broken into smaller fragments to be further shattered or fragmented. Thus, most asteroids appear to be shattered heaps of loosely bound rubble with significant porosity in the form of large fractures, vast internal voids, and loose-fitting joints between major fragments. Thus, it is not surprising that the average asteroid would have a very large porosity.

Another line of evidence supporting the rubble pile model for asteroids are the images of 253 Mathilde. This object, whose density is only half the density of typical meteorite material, has six identified impact craters that are larger than the size necessary to shatter the asteroid. The only way that Mathilde could have survived these repeated huge impacts is if it were already a shattered rubble pile that dissipates much of the energy of large impacts in the friction of the pieces of rubble grinding against each other.

On the opposite extreme are small rapidly rotating asteroids that are also rubble piles. Shown in Figure 26.5 is asteroid (66391) 1999 KW_4, which is about 1.5 km in diameter and spins with a period of 2.8 h. The bulk porosity of this object is approximately 50% and the rapid spin forces the loose material to assume a shape reminiscent of a spinning top that narrows at the ends and bulges at the equator. The rapid spin forces material from the poles and deposits it at the equator resulting in this remarkable shape.

2. LOCATIONS AND ORBITS

2.1. Zones, Orbits, and Distributions

Minor planets can be found in almost any region of the solar system, but as shown in Figure 26.6(a), one of the largest concentrations of asteroids is located in the "belt" between 1.8 and 4.0 AU. Figure 26.6(b), showing the outer solar system, gives the distribution of known short-period

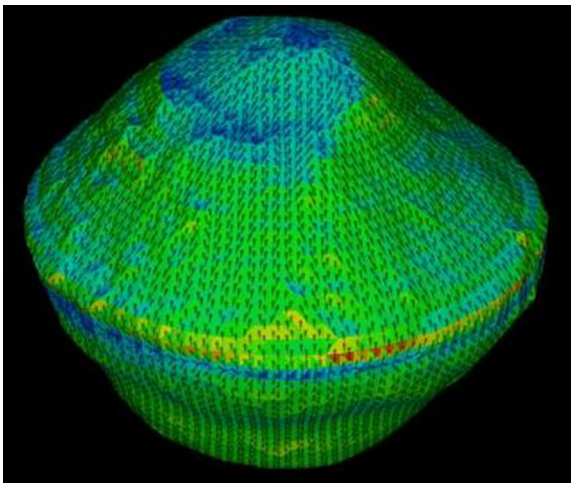

FIGURE 26.5 Asteroid (66391) 1999 KW_4. The rapid spin forces material from the poles to the equator, producing a pronounced bulge as material accumulates. *Image courtesy of NASA/JPL-Caltech.*

comets, Centaurs, and Kuiper Belt objects as well as the Trojan asteroids (discussed below).

A more detailed analysis of the average distances of asteroids from the Sun (the asteroids' **semimajor axes**) as shown in Figure 26.7 reveals a subtle structure to the asteroid belt. First, there appears to be a sharp inner boundary to the asteroid belt at about 2.2 AU. But note that this boundary curves to higher AU for asteroids with higher orbital **inclinations**. Second, there is a sharp gap in the number of asteroids whose average distance from the Sun (semimajor axis) is 3.28 AU. Asteroids orbiting here would have exactly half the orbital period of Jupiter and are said to be in a 1:2 mean-motion resonance with Jupiter. Similar gaps can be seen elsewhere in the asteroid population as well, most notably at the locations of the 1:3 and 2:5 mean-motion resonances. The gaps in the distribution of asteroid semimajor axes are called **Kirkwood gaps** for Daniel Kirkwood who first pointed them out in 1886. Unlike the gaps in Saturn's rings, however, these gaps are not directly visible within the asteroid belt in Figure 26.6(a) because asteroid orbits have a wide range of eccentricities and are constantly crossing through the region of these gaps. Third, there is a dearth of asteroids in orbits with semimajor axes beyond 3.5 AU, with two exceptions; there are clusters of asteroids at 3.97 AU, corresponding to the 2:3 mean-motion resonance with Jupiter, and at 5.2 AU, where asteroids share the same orbit as Jupiter (especially visible in Figure 26.6(b)).

These boundaries and gaps are formed by the steady influence of the gravitational attraction of the planets on the orbits of the asteroids. These interactions are strongest when a planet is closest to an asteroid, which normally occurs at random time intervals and at random locations of the asteroid's orbit; on average they cancel out without causing a significant change in the asteroid's orbit. However, an asteroid whose orbital period is a simple fraction of Jupiter's 11.86-year period will be in resonance with Jupiter and have a close approach in the same place in its orbit over and over again. For an asteroid with a 6-year period (in a 1:2 resonance), this closest approach will occur at the same place every other asteroid orbit. (Similarly, asteroids in the 1:3 resonance encounter Jupiter at the same place in their orbits, every third orbit, and so forth with higher resonances.) Jupiter's pull at this point, imparting some energy to the asteroid's orbit, will then compound itself rather than cancel out. The largest effect of

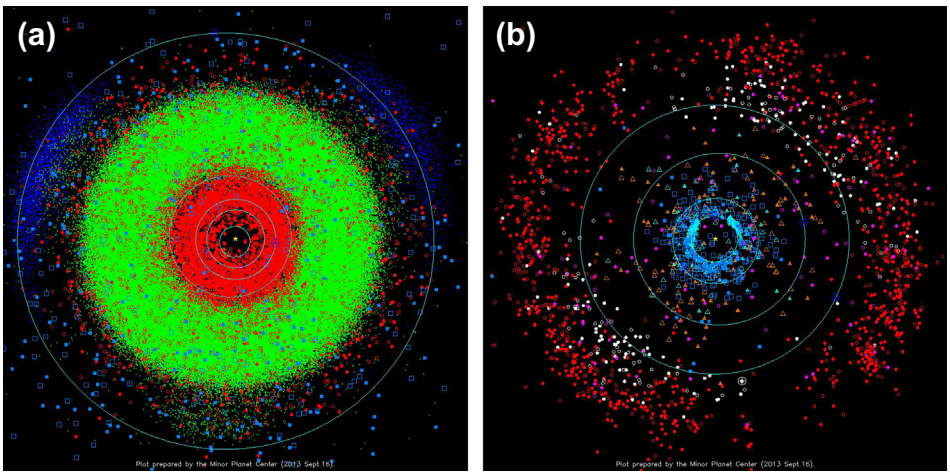

FIGURE 26.6 (a) The location of asteroids in the inner solar system. The outer circle is the orbit of Jupiter. The thick main asteroid belt (green) is readily visible just outside the orbit of Mars; the "swarms" before and after Jupiter are the Trojans. (b) The location of asteroids in the outer solar system (at or beyond Jupiter). The outer circle is the orbit of Neptune; the well-populated region outside of Neptune is the Kuiper Belt. *Image courtesy of Gareth Williams/Minor Planet Center.*

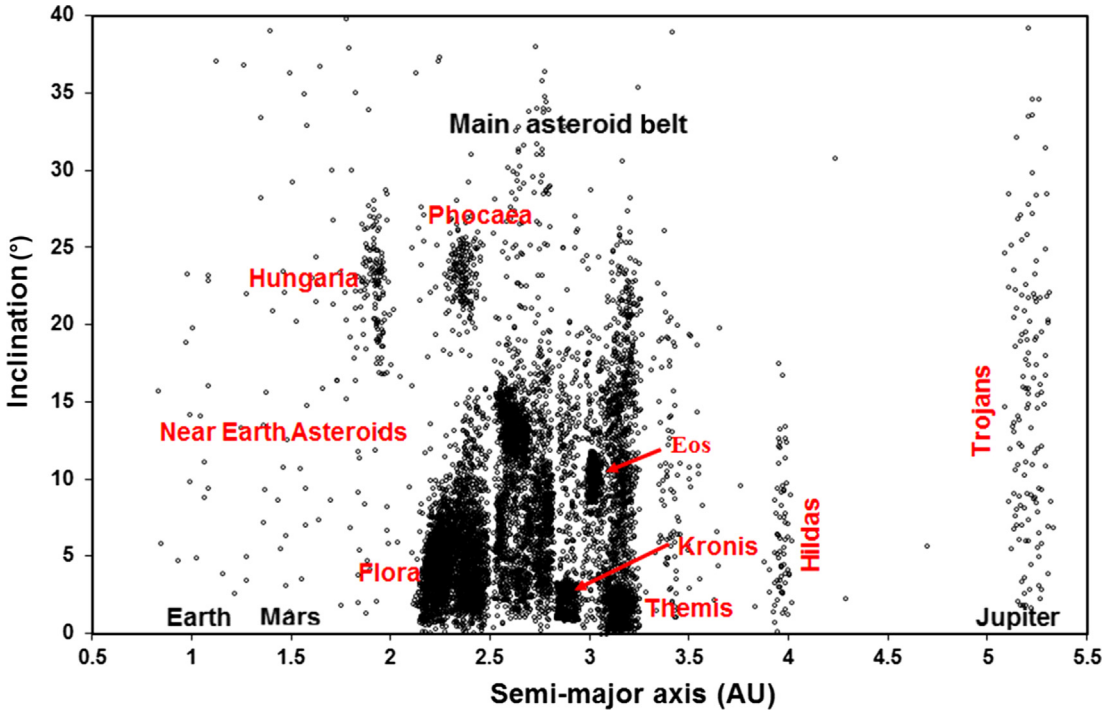

FIGURE 26.7 Plot of orbital parameters of numbered asteroids in semimajor axis vs. inclination space. The major asteroid families and the planets are identified in the plot.

this sort of perturbation is to increase the **eccentricity** of the asteroid's orbit. This does not change its average distance from the Sun, but it makes the perihelion move closer to the Sun, and the aphelion move farther out. Once its eccentricity reaches a value of about 0.3, a main-belt asteroid's orbit begins to approach or even cross the orbit of Mars. Close encounters with Mars can further alter its orbit, leading to interactions with the other inner planets or with Jupiter, which eventually results in a collision with either a planet or the Sun, or ejection from the solar system. For asteroids, orbital life in the Kirkwood gaps is (relatively) short, but exciting.

This kind of resonance explains the Kirkwood gaps. But it does not explain the inner boundary and its dependence on the inclination of the asteroid orbit, the lack of asteroids with semimajor axes outside 3.5 AU, or the concentration of asteroids at the outer resonances. More indirect effects give rise to these patterns. The shape of the inner boundary is the result of a subtle but surprisingly powerful effect. Every asteroid has an orbit that is at least slightly eccentric, and the orientation of its perihelion slowly drifts with time. This precession of the perihelion is caused by the perturbations of the other planets. Likewise, the orientations of the major planets' orbits, which are not perfectly circular, also drift with time. A subtle interaction arises when the precession of Saturn's orbit is in resonance with the precession of an asteroid's orbit. This secular resonance (so called because it builds up in the same direction over time, regardless of where the asteroid and Saturn are in their orbits) is called the ν_6 resonance; ν is the Greek letter that represents the precession rate, and the 6 represents Saturn, the sixth planet from the Sun. Its effect is to increase an asteroid orbit's eccentricity, as with the Jupiter mean-motion resonances. The position of this resonance depends on both the location and the inclination of the asteroid orbit. For asteroids orbiting in the plane of the planets, it occurs at around 2.2 AU; as the inclination of the asteroid orbit increases, the location of this resonance moves further from the Sun. This resonance sculpts the inner edge of the asteroid belt.

The lack of asteroids in the outer regions of the asteroid belt may be the result of the migration of Jupiter's orbit early in the history of the solar system. Models and observations of disks around nearby young stars suggest that the planets were formed from a relatively smooth cloud of gas and dust called the **solar nebula**. (See chapter Origin of the Solar System.) Jupiter, the innermost gas giant, may have been the first planet formed, and as we have seen, planetesimals in resonance with Jupiter would have been ejected from the inner solar system by Jupiter's gravity. The motion of these objects outward would have caused Jupiter to move inward, sweeping the location of its resonances (especially the strongest resonance, 2:1) across that region of the nebula and ejecting yet more material, effectively depleting material outside the present location of the 2:1 resonance. (Some of that material may today be residing in

the far-distant **Oort Cloud** (see Physics and Chemistry of Comets).) Asteroids in the 2:3 resonance would be stabilized against ejection and thus carried along with Jupiter as it moves.

It is possible, however, that the motion of Jupiter may have been sufficiently great that the entire region of the asteroid belt (and much of the material that would have gone into Mars) was completely removed (as described below, in Section 4.2). In this case, the material in the asteroid belt today would have migrated into this region from elsewhere in the solar system after this sweeping was complete. In this case, the resonances noted above would mark the boundaries of stable orbits for this migrating material.

2.2. Special Orbital Classes

While most asteroids are found in the main asteroid belt between Jupiter and Mars, there are a number of other asteroid groups. The "asteroids" beyond the orbit of Jupiter are probably volatile-rich and would become cometary if they were moved to the inner solar system, but for the purposes of this discussion we will list these groups of small bodies as asteroids here. The asteroids that circle the Sun at the same orbital distance as Jupiter are called Trojan asteroids. They reside in dynamically stable zones 60° ahead and behind Jupiter. These positions are the last two of the five "Lagrangian points", named by the nineteenth-century mathematician J. L. Lagrange. He first described the orbital behavior of small bodies affected by the gravitation pull of two large objects such as the Sun and any planet. He found that along with three unstable equilibrium points (L_1 through L_3), a small body like an asteroid could share a planet's orbit so long as both formed an equilateral triangle with the Sun. There are two such points; the L_4 point lies ahead of the planet, while L_5 trails behind it. In theory, any planet can have Trojan asteroids, but in practice the powerful gravitational pull of Jupiter means that it absolutely dominates the Trojan population.

The Trojans derive their name from the first such asteroid discovered in Jupiter's orbit, named Achilles after the hero of the Trojan War. For Jupiter Trojans, the L_4 region asteroids are named after Greek heroes of the Iliad, while Trojan heroes populate the L_5 region. (The exceptions, named before this rule was adopted, include two of the largest Trojans: 617 Patroclus, named for the Greek hero, orbits among the Trojans at L_5, while 624 Hektor, the largest Trojan and a hero of Troy, orbits at L_4 with the Greeks.) A total of 5928 Jupiter Trojans have been discovered to date; oddly, the L_4 region is nearly twice as populated as the L_5 region. Remember that any planet can, in theory have Trojans; as of the beginning of 2013, the census includes one suspected Earth Trojan, three Mars Trojans, and nine Neptune Trojans (and again the Neptune L_4 population is twice as large as the L_5).

Another major group of minor planets is the Centaurs. Named as a class after the discovery of Chiron, a small body orbiting between Saturn and Uranus, the term has eventually grown to include any noncometary body beyond Saturn whose orbit crosses the orbit of a major planet, and even the noncomet part must be relaxed, as Chiron itself has been seen on occasion to have a cometlike coma. These "asteroids" are most likely large, volatile-rich objects (i.e. comets) perturbed inward from the Kuiper Belt. But since the Centaurs orbit deep in the outer solar system, they cannot warm sufficiently to allow volatiles to sublimate off and show cometary activity, so they are considered asteroids until proven otherwise. In terms of their orbits, this group includes the classical Centaurs (some two dozen objects known to orbit like Chiron between Saturn and Uranus), roughly 50 objects whose orbits cross Uranus' or Neptune's orbit, and the 448 objects (discovered as of 2013) that lie in highly eccentric orbits ranging out beyond the Kuiper Belt. All are considered "scattered disk objects", which have been dynamically scattered by Neptune's gravity out of the disk of the Kuiper Belt. (See chapter Kuiper Belt: Dynamics.)

The Kuiper Belt itself is the outermost set of minor bodies. It is made up of objects populating space beyond the orbit of Neptune but inside about 1000 AU. The first object was discovered in 1992 (1992 QB_1) with a semimajor axis of 44 AU and an estimated diameter of several 100 kilometers. Besides the scattered disk objects noted above, other dynamical classes of Kuiper Belt objects include others like 1992 QB_1 in low-inclination, low-eccentricity orbits (sometimes called "cubewanos" after their first example) and others orbiting like Pluto (and so-called plutinos) in a 2:3 resonance with Neptune. Again, all these objects are probably cometary. In fact the existence of a belt of material like this was first suggested in 1949 as a source area for short-period comets. Given the nearly 1300 Kuiper Belt "asteroids" discovered as of 2013, there are probably hundreds of thousands of objects larger than a kilometer populating this belt (see chapter Kuiper Belt: Dynamics).

Inward from the main asteroid belt are the asteroids that cross the orbits of the inner planets: the Amor, Apollo, and Aten asteroids. Amor asteroids are asteroids whose eccentric orbits dip in from the asteroid belt to cross the orbit of Mars, but without reaching the orbit of the Earth. Apollos are those that do cross Earth's orbit, but whose semimajor axis is always $\geq$1 AU. This differentiates them from Atens, which also cross the Earth's orbit but have semimajor axes inside of Earth's orbit. The Apollo, Aten, and Amor objects are collectively called **Near-Earth Objects** or NEOs (See Near Earth Objects). They are relatively small objects; the largest known NEO is the Amor object 1036 Ganymed, with a diameter of 38.5 km. NEOs are also subject to a power-law distribution, so as their sizes drop the population increases rapidly. As of 2013, there are roughly 850 NEOs with diameters greater than 1 km out of

a population of approximately 9600 known NEOs. It is estimated that there are approximately 920 total NEOs that are larger than 1 km. These are the objects that can and (in the course of geologic time) do frequently collide with Earth. Indeed, computer calculations indicate that most NEOs could only survive in their present orbits for roughly 10 million years before falling into the Sun, colliding with a planet, or being ejected. Thus, the NEO population must be continually replenished from the asteroid belt. Compositional data indicates that NEOs are drawn from every zone of the asteroid belt and have been perturbed into the inner solar system by a variety of mechanisms including the Yarkovsky effect described below. (See chapter Near-Earth Objects.)

2.3. The Evolution of Orbits: Yarkovsky and YORP

The gravitational perturbations of the planets are not the only forces acting on the asteroids. Although the Kirkwood gaps show that resonances are the most effective way to clear material from the asteroid belt, the generally low population of asteroids throughout the belt (even in its most heavily-populated regions), the replenishment of asteroids into short-lived NEO orbits, and the constant delivery of meteorites from the asteroid belt to the Earth (see below) all indicate that some other forces must be moving material from the main belt to the resonance regions.

One early hypothesis was that collisions between asteroids could impart enough momentum to scatter the collision products into a wide variety of new orbits, some of which would lie in resonance with Jupiter and thus be delivered out of the asteroid belt. However, detailed computer modeling of both the collisions and the ensuing orbits of the collisional products conclusively shows that this process alone fails by many orders of magnitude to move nearly enough material from the asteroid belt to match the observed population of NEOs or the meteorite flux. Some other force or forces must be involved.

Another early suggestion first proposed by the Russian theorist I. O. Yarkovsky in the late nineteenth century is that sunlight itself could provide a surprisingly effective way of changing the orbits of asteroids. The general idea is simple enough. Since light carries momentum, as sunlight is absorbed or reflected by an asteroid there is a small momentum transfer from the light to the asteroid. However, since sunlight comes from the same direction as the force of the Sun's gravity (and, like gravity, varies as $1/r^2$) this effect by itself will merely change the effective pull of the Sun, without changing the energy (or semimajor axis) of an asteroid's orbit. (There is a small relativistic effect called "Poynting-Robertson" drag, but it is ineffectual for anything larger than small grains of dust.) However, when an asteroid absorbs sunlight, the energy of that light heats the asteroid and that heat must eventually be reradiated to space as infrared photons. When each infrared photon is emitted, it exerts a tiny amount of recoil momentum to the asteroid itself. And, unlike the direct reflection of sunlight, this recoil is not necessarily in the same direction as the pull of the Sun's gravity, since there is always a small time lag between the absorption and the reradiation of the energy.

For example, the afternoon side of a spinning body will always be slightly warmer than the morning side. This means that more infrared energy is radiated from the afternoon side; that side of the asteroid experiences greater recoil from those photons' emissions than the morning side does. The way the spin axis is tilted or the differences in heating between perihelion and aphelion are other examples of situations that will lead to the asymmetric radiation of infrared photons. Depending on how the asteroid spins, this difference can add or subtract energy from the asteroid's orbit and thus continually change its semimajor axis. It can also change the way the asteroid itself spins. An elaborate theory based on the work of Yarkovsky, as further elaborated by O'Keefe, Radzievskii, and Paddack, dubbed the "YORP" effect, suggests a number of ways in which the momentum of emitted radiation can alter both the speed and the direction of an asteroid's spin. More than just a mathematical curiosity, the predictions of this work have been confirmed in a number of cases, including asteroids whose spin rates have been observed to change or be aligned in a way predicted by this theory.

2.4. Asteroid Families

As discoveries of asteroids accumulated in the early part of the twentieth century astronomers noted that it was common for several asteroids to have very similar orbital elements and that asteroids tended to cluster together in semimajor axis, eccentricity, and inclination space. In 1918, K. Hirayama suggested that these clusters were "families" of asteroids. Hirayama suggested five families, and this number has been greatly increased by the work of generations of orbital dynamicists.

These families are probably the result of the collisional breakup of a large parent asteroid into a cloud of smaller fragments sometime in the distant past. Time and the gravitational influence of other solar system objects have gradually dispersed the orbits of these fragments, but not enough to erase the characteristic clustering of families.

It has been suggested that families could provide a glimpse at geologic units that are usually deeply hidden in the interiors of planets. If a differentiated asteroid were broken into family members, for example, that family should have members that represent the metallic core, others coming from the metal–rock transition zone called the core–mantle boundary, yet others made of the dense,

iron-rich units in the mantle, and others originating from the crust of the former planetesimal. In fact, however, no such elaborate collection of different asteroid types has been seen in a family.

Families may, in fact, be relatively short lived. The Yarkovsky effect described above has proved to be very effective in moving family members out of their original orbits. Understanding and defining the dynamics of asteroid families remains an active and rapidly changing field of study.

2.5. Asteroids and Meteorites

There are a number of lines of evidence that show the ultimate source region for meteorites is the asteroid belt. (See chapter Meteorites.) As will be discussed in more detail later (Section 3.3), meteorite **reflectance spectra** can be matched with several classes of asteroids. In addition, camera networks, or many well-separated video images of fireballs, have recorded the falls of about a dozen recovered meteorites with sufficient detail that their orbits before hitting the atmosphere can be calculated; each of these meteorites have eccentric orbits that reach back into the main asteroid belt.

The physical state of the meteorites themselves also indicates an origin in the asteroid belt. Cosmic ray exposure ages of meteorites show that they have spent most of their existence shielded from cosmic rays, deep in asteroid-sized parent meteoroids. A brecciated meteorite of one given type often contains fragments of other meteorite types, called xenoliths, which require that the source region have the mineralogical diversity found in the asteroid belt. And solar-wind implanted gases found in **regolith** meteorites indicate that implantation took place at a distance from the Sun consistent with the location of the asteroid belt.

Meteorites do not automatically provide the location and taxonomic class of particular parent bodies, however. The very fact that a meteorite is "in our hands" suggests the occurrence of some violent event that may have fragmented and perhaps destroyed the parent body. Usually, the best that can be done is to link individual asteroid spectral classes with meteorite compositional groups.

One exception is the relatively rare basaltic meteorites of the interrelated howardite, eucrite, diogenite (HED) classes. (All have similar ages and isotope abundances, and howardites are clearly a mixture of eucrites and diogenites.) Their spectra are very well matched by the spectra of asteroid 4 Vesta, and the composition of the surface of Vesta as determined by the Dawn spacecraft confirms this match between the asteroid and the HEDs. Since these meteorites are igneous rocks, one can use standard geochemical models to compute that they were made from lavas in equilibrium with a large mantle of dunite. However, while hundreds of HEDs are known, no corresponding dunite meteorites have been found, suggesting that these meteorites are sampling the surface of an otherwise intact asteroid. Thus, we infer that Vesta (perhaps via smaller asteroids chipped from the surface of Vesta) can be identified as the source of the HED meteorites.

The task of correlating other asteroid spectra with meteorite composition is less certain. Not only are there many possible candidate asteroids for any given meteorite type, but there is also no certainty that the spectra we see of asteroid surfaces is necessarily correlated with that of meteorites. Most meteorites were originally buried beneath the surface of an asteroid, the actual asteroid surface conditions are unknown, and the effects of space weathering on asteroids are poorly understood. Thus, spectral matches between asteroids and meteorites, including the ones detailed here, should be viewed with healthy skepticism.

Still, the return in 2010 of a few thousand tiny fragments (less than 100 microns diameter) from asteroid 25143 Itokawa by the Japanese Hyabusa mission, as shown in Figure 26.8, has provided the first confirmation that such identification may well be accurate. Spectra of Itokawa had been interpreted as indicating its composition was matched by LL-class ordinary chondritic material. The iron oxide, trace element, and isotope abundances of the returned samples were also well matched by LL chondrite material. In addition, some of these small particles had evidence of nanometer metal and sulfide particles, just as models of "space weathering" had predicted. The fact that LL chondrites are the least common of the ordinary chondrite classes suggests the match is more than just coincidence, and gives us confidence that other spectral identifications may also be reliable.

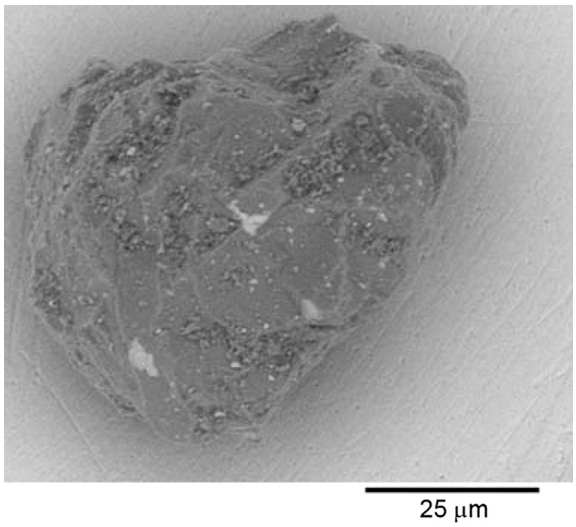

FIGURE 26.8 A fragment of the Itokawa asteroid returned to Earth by the Hayabusa spacecraft. Its composition is similar to LL chondrites and it shows evidence of space weathering. *From Noguchi et al. (2011).*

An event in 2008 showed both the connection between meteorites and asteroids, and the complications that simple spectra identification may mask. A near-Earth asteroid, designated 2008 TC_3, was discovered and observed just hours before it hit the Earth, scattering meteorites across the desert in northern Sudan. Spectra at that time suggested it had a dark and relatively featureless spectrum consistent with an F or B type; no meteorite type had been definitively identified with such asteroids, but they were thought to represent primitive material. The first meteorites collected from the strewn field near Almahata Sitta were identified as belonging to the rare ureilite class, which is unusual for having an igneous texture while being rich in carbon. As more samples were recovered from the desert, however, it was found that a number of samples actually represented other classes of meteorites, including a variety of different ordinary, carbonaceous, and enstatite chondrite meteorites, and samples that are chemically unique among meteorites. By testing samples for radioactive elements produced by cosmic rays, it has been shown convincingly that samples of these many different types nonetheless landed on the Earth at the same time, in the fall of this asteroid, and may have been incorporated together in the same asteroid for at least the past 3.8 billion years. Thus, while confirming that meteorites come from asteroids, it is not at all clear that a given asteroid can necessarily be identified with only one particular meteorite type.

In addition to the complication of multiple meteorite types coming from a given asteroid, there are also several factors that bias the population of meteorites arriving on Earth and therefore limit our sample of the asteroid belt. First, the dynamical processes that deliver meteorites from the asteroid belt to Earth are probably strongly biased toward sampling relatively narrow zones in the asteroid belt. Calculations demonstrate that the vast majority of meteorites and planet-crossing asteroids originate from just two resonances in the belt, the 1:3 Kirkwood gap and ν_6 resonance. Both these zones are in the inner asteroid belt where the asteroid population is dominated by S-type asteroids. However, the Yarkovsky effect significantly increases the chances of fragments from anywhere in the asteroid belt working their way into Earth-crossing orbits. A second factor is the relative strength of the meteorites. To survive the stress of impact, acceleration, and then deceleration when hitting the Earth's atmosphere, without being crushed into dust, the meteorite must have substantial cohesive strength. Large iron meteorites are more likely to survive until they hit the surface of the Earth; they may form a crater (like Meteor Crater in Arizona) when they hit, but in that process most of the iron is vaporized and lost. The Earth's atmosphere is probably the most potent filter for meteorites. The relatively weak, volatile-rich meteorites from the outer asteroid belt stand little chance of surviving the stress and heating of atmospheric entry. It is very likely that the meteorites available to us represent only a small fraction of the asteroids, and it is possible that most asteroids either cannot or only rarely contribute to the meteorite collections.

3. PHYSICAL CHARACTERISTICS AND COMPOSITION

3.1. The Surfaces of Asteroids

As shown in Figures 26.1, 26.9, and 26.10 the surfaces of asteroids appear cratered, lined with fractures, and covered

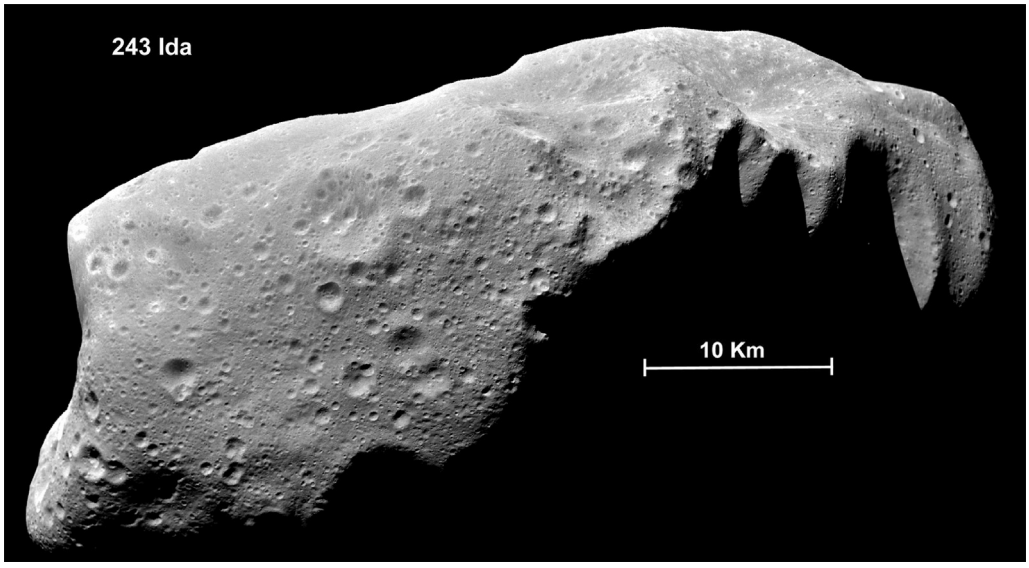

FIGURE 26.9 The surface of asteroid 243 Ida. *Image courtesy of NASA/JPL-Caltech.*

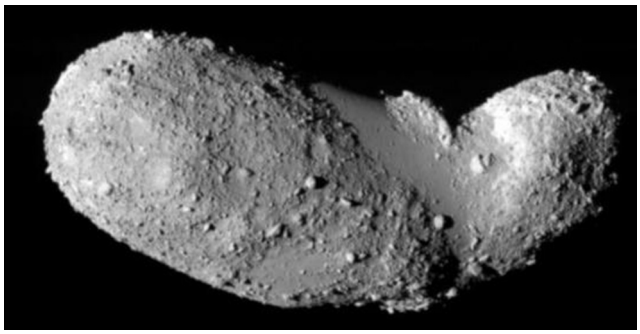

FIGURE 26.10 Asteroid 25143 Itokawa. The asteroid is approximately 700 m in it longest dimension. The smooth areas in the center and on the lower left center are examples of "ponding" of fine regolith. *Image courtesy of ISAS/JAXA.*

with regolith. These surfaces are dominated by impact processes. As discussed in earlier sections, asteroids are strongly affected by collisional disruption and have a complex history of impact fracturing and fragmentation. Objects in the size range shown in the figures are probably formed as disrupted fragments from larger objects and some are likely rubble piles themselves. Since asteroids are far too small to retain an atmosphere that could offer some protection from the exposure to space, the surfaces of asteroids are exposed to an extremely harsh environment. There is a range of processes associated with exposure to the space environment; high levels of hard radiation, high-energy cosmic rays, ions and charged particles from the solar wind, impacts by micrometeorites, impacts by crater-forming objects, and finally impacts by other asteroids large enough to destroy the parent asteroid. The overall result of these processes is threefold. First, large impacts shatter the parent asteroid creating substantial internal fracturing, porosity, and an extremely rough and irregular surface. Second, small impacts and micrometeorites create a regolith that blankets the asteroid in a fine soil of debris from the bedrock. Finally, micrometeorites, radiation, and solar wind produce chemical and spectral alterations in the regolith soil and exposed bedrock that "weather" the surface of the asteroids.

All the small asteroids viewed by spacecraft show significant regoliths, and the power of radar waves reflected by asteroids large and small (especially those passing near the Earth, and so more easily observed by radar) also shows that their surfaces are comparable to dry soil or sand (see chapter Planetary Radar). On several of these asteroids the regoliths appear to have been altered by space weathering processes, although just how this alteration affects asteroidal material is still not completely understood. In the asteroid population, there are general spectral trends that appear to be associated with the age of an asteroid's surface, with younger less altered surfaces tending to be less red. This effect is seen in the meteorite population. Meteorites that have evidence of residing on the surfaces of asteroids have strong spectral differences from meteorites that were not exposed on asteroid surfaces.

Another major surface effect is the development of small "ponds" of regolith material as shown in Figure 26.10. These ponds have been seen on Eros and Itokawa and consist of ground-up material that has been somehow mobilized on the surface and accumulated in local "depressions" or gravitational lows. The actual magnitude and direction of gravity on a body as small and irregularly shaped as an asteroid is not at all intuitive, but the effect is still strong enough to drive surface processes. Ponds appear to develop over time and appear to bury the boulders and cobbles within them.

Another process that affects the surfaces of asteroids is the reaccretion of ejecta debris. Impacts of other small asteroids produce the abundant craters seen on all these objects. While much of the impact debris escapes the low gravity of an asteroid, a large amount is reaccreted by the asteroid. The abundance and location of boulders on objects such as Eros and Itokawa (Figure 26.9) have been explained by the low-velocity ejecta debris slowly "falling" back onto the rotating asteroid.

3.2. Asteroid Satellites

While it had been long suspected that some asteroids had satellites, this was spectacularly confirmed when the Galileo spacecraft flew by asteroid 243 Ida and discovered its moon Dactyl. As of 2013, a total of 232 asteroid satellites have been announced in 209 systems including at least three triple systems and one sextuple. Figure 26.11 is an image of asteroid 22 Kalliope and its satellite Linus.

NEOs tend to have small separation distances from their satellites, which are probably the result of formation by "fission". Many NEOs have rotation rates close to the fission limit and additional collisions or the YORP effect can enhance asteroid spin enough to cause fission. Once fission occurs the new satellite carries away some of the primary's angular momentum, thus dropping the rotation

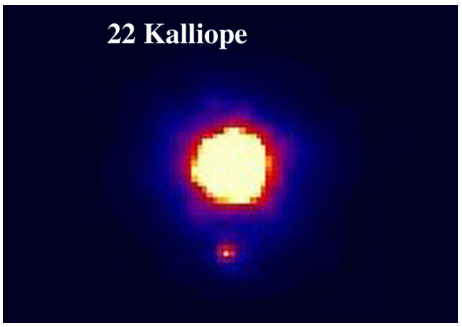

FIGURE 26.11 Asteroid 22 Kalliope and its satellite Linus. *Image courtesy of SWRI/W. Merline.*

back below the fission limit. The lack of distant NEO companions may be the result of gravitational encounters with planets. Distant satellites would be much more likely to be stripped from their primaries during close planetary encounters common with NEOs.

Although only about 209 have been discovered, asteroid satellites are thought to be fairly common with a small percentage of all asteroids having satellites. With over 350,000 numbered asteroids, a large number of satellites remain to be discovered. This is another area where amateur astronomers can make a significant contribution to science. While some satellites have been discovered by direct imaging, either from spacecraft or **adaptive optics** (i.e. Figure 26.11), most main-belt asteroid satellites are discovered by analysis of asteroid **lightcurves**. The principle is that the satellite in its orbit will periodically add or subtract its illumination from the brightness of the asteroid. By precisely tracking the change in brightness, it is possible to identify the satellite and determine its orbit and period. With CCD imagers available commercially and modest-sized telescopes, a skilled amateur can successfully compete in discovering asteroid satellites.

3.3. Telescopic Observations of Composition

Our understanding of the composition of asteroids rests on two pillars: the detailed study of meteorite mineralogy and geochemistry, and the use of remote sensing techniques to analyze asteroids. The meteorites provide, as discussed in a previous section, an invaluable but limited sample of asteroidal mineralogy. To extend this sample to what are effectively unreachable objects, remote sensing uses a variety of techniques to determine asteroid composition, size, shape, rotation, and surface properties. The best available technique for the remote study of asteroid composition is visible and near-infrared **reflectance spectroscopy** using ground-based and Earth-orbiting telescopes.

Reflectance spectroscopy is fundamentally the analysis of the "color" of asteroids over the wavelength range 0.2−3.6 μm. An experienced rock hound limited to the three colors of the human eye can identify a surprisingly wide variety of minerals. For example, the silicate olivine is green, and important copper minerals such as azurite (blue) and malachite (green) are vividly colored. These colors are a fundamental diagnostic property of the mineralogy because the atoms of a mineral's crystal lattice interact with light and absorb specific wavelengths depending on its structural, ionic, and molecular makeup, producing a unique reflectance spectrum. The reflectance spectrum is essentially a set of colors, but instead of three colors our remote sensing instruments "see" very precisely in 8, 52, or even several thousand colors. What can be seen are the details of the major rock-forming minerals olivine, pyroxene, spinel, the presence of phyllosilicates, organic compounds, hydrated minerals, and the abundance of free iron and opaque minerals.

In addition to a spectroscopic inventory of minerals, telescopic measurements yield several other critical pieces of information. The **albedo** or reflectivity of the asteroid can be determined by measurements of the visible reflected light and the thermal emission radiated at longer wavelengths. A dark asteroid will absorb much more sunlight than it reflects, but will heat up and radiate that extra absorbed energy at thermal wavelengths. Finding the ratio of the reflected and emitted flux at critical wavelengths provides an estimate of just how dark that asteroid is, its albedo. Measuring how the reflectance properties of the surface change as we observe sunlight reflecting off it at different angles (the "solar phase angle") can be used to model the photometric properties of the surface material and estimate physical properties like the surface roughness, surface soil compaction, and the light-scattering properties of the asteroidal material. Measurements of polarization as a function of solar phase angle can be used to infer albedo and also provide insight into the texture and mineralogy of the surface.

3.4. Composition, Taxonomy, and the Distribution of Classes

Our basic knowledge of asteroids is primarily limited to ground-based telescopic data, usually broadband colors in the visible and near-infrared wavelengths and albedo that is indicative of composition; this forms the basis of asteroid taxonomy. Asteroids that have similar color and albedo characteristics are grouped together in a class denoted by a letter or group of letters. Asteroids in particularly large classes tend to be broken into subgroups with the first letter denoting the dominant group and the succeeding letters denoting less prominent spectral affinities or subgroups.

Asteroid taxonomy has developed in tandem with the increase in the range and detail of asteroid observational data sets. Early observations were often limited in scope to the larger and brighter asteroids, and in wavelength range, to filter sets originally designed to be used for stellar astronomy. As observations widened in scope and more specialized filter sets and observational techniques were applied to asteroids, our appreciation of the variety and complexity of asteroid spectra has also increased. The asteroid classification system has evolved to reflect this complexity, and the number of spectral classes has steadily increased. Shown in Table 26.1 is a listing of the expanded "Tholen" asteroid classes and the current mineralogical interpretation of their reflectance spectra. While the Tholen classification is widely used it is not by any means the only asteroid classification system. Other widely accepted

TABLE 26.1 Meteorite Parent Bodies

Asteroid Class	Inferred Major Surface Minerals	Meteorite Analogs
D	Organics + anhydrous silicates? (+ice??)	None (cosmic dust?)
P	Anhydrous silicates + organics? (+ice??)	None (cosmic dust?)
C (dry)	Olivine, pyroxene, carbon (+ice??)	"CM3" chondrites, gas-rich/black chondrites?
K	Olivine, orthopyroxene, opaques	CV3, CO3 chondrites
Q	Olivine, pyroxene, metal	H, L, LL chondrites
C (wet)	Clays, carbon, organics	CI1, CM2 chondrites
B	Clays, carbon, organics	None (highly altered CI1, CM2??)
G	Clays, carbon, organics	None (highly altered CI1, CM2??)
F	Clays, opaques, organics	None (altered CI1, CM2??)
W	Clays, salts????	None (opaque-poor CI1, CM2??)
V	Pyroxene, feldspar	Basaltic achondrites
R	Olivine, pyroxene	None (olivine-rich achondrites?)
A	Olivine	Brachinites, Pallasites
M	Metal, enstatite	Irons (+EH, EL chondrites?)
T	Troilite?	Troilite-rich irons (Mundrabilla)?
E	Mg-pyroxene	Enstatite achondrites
S	Olivine, pyroxene, metal	Stony irons, irons, lodranites, winonites, siderophyres, ureilites, H, L, LL chondrites

classifications include the Barucci system, the Bus-DeMeo system, and the Howell system.

To explain the compositional meaning of asteroid reflectance spectra and color data, we can treat the asteroid belt as a series of zoned geologic units, starting at the outer zones of the main belt and working inward toward the Sun. This is illustrated in the distribution of asteroid classes shown in Figure 26.12. The outer asteroid belt is dominated by the low-albedo P and D classes. The analogs most commonly cited are cosmic dust or carbonaceous chondrites that are enriched in organics like CI chondrites or the Tagish Lake meteorite. However, the spectral characteristics of these asteroids are difficult to duplicate with material that is delivered to the inner solar system. Probably P and D asteroids are composed of primitive materials that have experienced a somewhat different geochemical evolution than cosmic dust or CI chondrites. Their spectra indicate increasing amounts of complex organic molecules with increasing distance from the Sun. These objects are also probably very rich in volatiles including water ice.

Dark inner asteroid belt asteroids include the B, C, F, and G classes whose meteorite analogs are the dark CI and CM carbonaceous chondrite meteorites. The spectral differences between these classes are thought to represent varying histories of aqueous alteration or thermal metamorphism. The CI carbonaceous chondrites are rich in water, clay minerals, volatiles, and carbon; they represent primitive material that has been mildly heated and altered by the action of water (for more details on all the meteorites see chapter Meteorites).

Sunward of 3 AU, bright rocky asteroids become much more common. This zone was strongly affected by the early solar system heating event and contains those classes most likely to represent differentiated and metamorphosed meteorites. The best asteroid/meteorite spectral match is that of the V-class asteroids with the basaltic achondrite meteorites. V types are interpreted to be a differentiated assemblage of primarily orthopyroxene with varying amounts of plagioclase, which makes them very close analogs to the basaltic HED association of meteorites. These meteorites are basaltic partial melts, essentially surface lava flows and near-surface intrusions originating on an asteroid (like Vesta) that underwent extensive heating, melting, and differentiation.

While the V-class asteroids represent the surface and near-surface lava flows of a differentiated asteroid, the A-class asteroids are thought to represent the next zone deeper. These rare asteroids are interpreted to be nearly

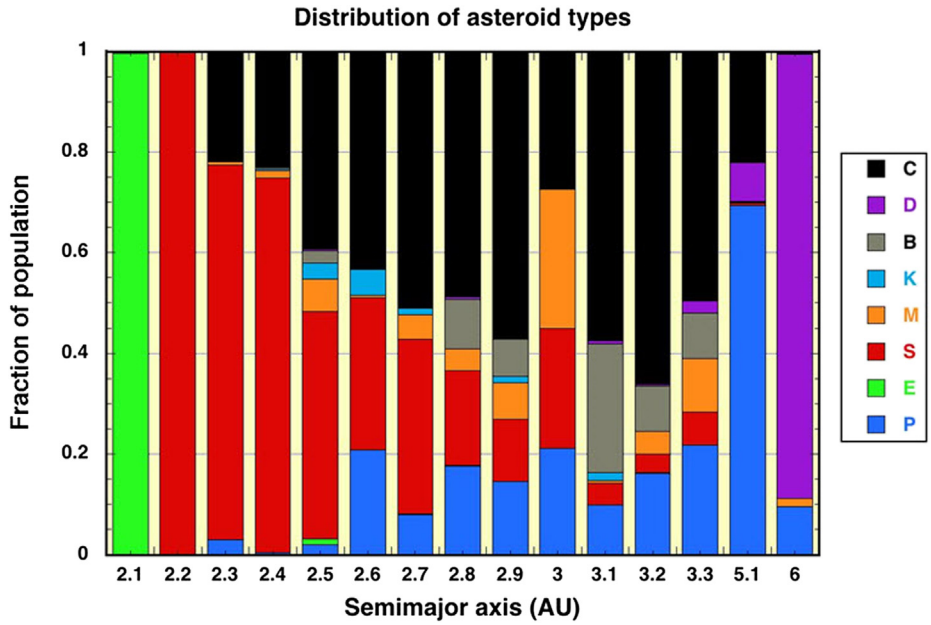

FIGURE 26.12 The distribution of asteroids by spectral class; each color represents the volume fraction of asteroids of a given class orbiting (within 0.1 AU) at the same average distance from the Sun. (The largest four asteroids, Ceres, Vesta, Pallas, and Hebe, are not included as their volumes would dominate the regions where they orbit.) Stony classes (red and green) dominate the inner belt; the darker and more volatile-rich classes (blue, purple, and black) dominate the outer belt.

pure olivine and may be derived from the mantle of extensively differentiated parent bodies. The Earth's mantle is dominated by olivine and theoretical studies show that differentiation of asteroids with a bulk composition similar to ordinary chondrite meteorites should produce olivine-rich mantles. Another possible mantle-derived asteroid is the R class, which is a single-member class made up of the asteroid 349 Dembowska. Analysis of its reflectance spectra suggests a mineralogy that contains both olivine and pyroxene and may be a partial melt residue of incomplete differentiation.

A more common asteroid class is the M class, which has the spectral characteristics of almost pure iron–nickel metal; several of them show high radar reflections consistent with metal. These objects are thought to be direct analogs to the metallic meteorites and may represent the cores of differentiated asteroids. Isotopic and chemical studies indicate that iron meteorites could come from as many as 60 different parent bodies indicating a wide variety of differentiated bodies in the asteroid belt. However, some M-class asteroids have been shown to have hydrated minerals on their surfaces and others have low radar reflections that are inconsistent with metallic compositions. The spectral characteristics of M asteroids can also be consistent with some clay-rich silicates and this raises the possibility that the "wet" M asteroids are assemblages of clays, like the CI carbonaceous chondrites, but without the carbon-rich opaques that darken the CIs. The W (or "wet") class—think of the W as an upside-down M—was coined to classify these unusual objects.

The E-class asteroids are another example of the perils of extrapolation from limited information to a convenient meteorite analog. Looking at the spectrum of the "type" asteroid for the E class, 44 Nysa, it was easy to assume that these asteroids were excellent analogs for the enstatite achondrites. The only problem was that enstatite meteorites are entirely anhydrous, and 44 Nysa was later observed to be strongly hydrated. Although some E-class asteroids are probably composed of the same differentiated enstatite assemblages as the enstatite achondrites, about half of the observed E asteroids are hydrated and cannot be composed of anhydrous enstatite. The "wet" E asteroids like Nysa may be related to the W asteroids and have surfaces rich in hydrated silicate clays. Making matters worse, the E, M, and P classes have essentially the same reflectance spectrum. What makes it possible to tell them apart is their albedo: E's are very bright, P's very dark, and M's, in the middle. But, as discussed above, these asteroids are thought to represent radically different mineralogies with E's being the high-temperature silicate enstatite, M's being metal, and P's being rich primitive organics and clays. This does show the limitations of remote sensing.

Perhaps the most complex class of asteroids is the very large S class. S-class spectra, on average, indicate varying amounts of olivine and pyroxene with a substantial metallic component but the mineralogy of these asteroids varies from almost pure olivine to almost pure pyroxene, to a variety of mixtures of these two end members. With this wide range of mineralogies comes a wide range of meteorite analogs and possible formation scenarios. The S class

could represent a range of asteroid material from the core–mantle boundary, the mantle, and the lower crust of differentiated asteroids—material not represented in any meteorite class—as well as including undifferentiated but metamorphosed asteroids that are the parent bodies of ordinary chondrite meteorites.

Ordinary chondrites are by far the largest meteorite type, accounting for approximately 80% of observed meteorite falls, but so far only a few small asteroids have been identified as Q class, direct analogs for ordinary chondrites. A number of S-class asteroids have spectral absorption bands roughly similar to those of ordinary chondrites, but S asteroids typically have a moderate spectral red slope that is not seen in ordinary chondrites. However, it has been shown in laboratory experiments that ordinary chondrite material can redden in response to "space weathering" by micrometeorite bombardment. The small ordinary chondrite parent bodies are probably relatively young fragments that have not had enough time to redden their surfaces. The larger ordinary chondrite parents have older, reddened surfaces and are members of the S class. This explanation has been strengthened by the return of ordinary chondrite (LL class) material sampled from the S-class asteroid Itokawa, as described above.

In general, the differentiated asteroids of the V, A, R, S, and M classes may represent examples of a geologic transect from the crust to the core of differentiated asteroids and can tell us a great deal about the geochemical evolution of a differentiated body. In this scenario, the V-class asteroids would be the surface and crustal material. The A asteroids would be from a completely differentiated mantle, while the R asteroids would represent a mantle that experienced only partial differentiation. Some S asteroids, particularly the olivine-rich members, would be either material from some region in the mantle or the core–mantle boundary. And finally, M-class materials represent samples of the metallic cores of these asteroids. However, as noted above, this attractive interpretation is weakened by the fact that no asteroid family, presumably made of fragments from the breakup of a larger body, shows anything like this range of spectral types among its members.

From the preceding discussion it is clear that the asteroid classes were not uniformly distributed throughout the asteroid belt. The S class dominates the inner asteroid belt while the C class is far more abundant in the outer asteroid belt. The most populous taxonomic classes (the E, S, C, P, and D classes) peak in abundance at different heliocentric distances. If we assume that the spectral and albedo differences between the asteroid classes reflect real differences in mineralogy, then we are seeing rough compositional zones in the asteroid belt. According to models of solar system condensation the high-to-moderate-temperature silicate minerals would tend to dominate the inner solar system, while lower temperature carbonaceous minerals would be common in the cooler, outer regions of the solar system. The transition between moderate and low-temperature nebular condensates is apparently what we are seeing in the taxonomic zonation of the asteroid belt. The innermost major group of asteroids, peaking at 2 AU, is the E class, which is rich in iron-free silicate enstatite, indicating formation under high-temperature, relatively reducing conditions. The next group out is the S class, thought to be rich in the moderate temperature silicates olivine and pyroxene, which contain substantial amounts of iron oxide, which indicate more oxidizing conditions; however, they still also have significant amounts of free iron–nickel. The C class, which peaks in abundance at 3 AU, shows a major transition in asteroid mineralogy to less free metal, more oxidized silicates, important low-temperature carbon minerals, and significant amounts of volatiles such as water. The P asteroids peak at about 4 AU, and the D asteroids at 5.2 AU; they are probably richer in low-temperature materials such as carbon compounds, complex organics, clays, water, and volatiles and represent the transition between the rocky asteroids of the main belt and the volatile-rich comets in the Kuiper Belt and the Oort Cloud.

Several processes have blurred the taxonomic imprint from the original condensation. Apparently, a thermal event heated much of the asteroid belt soon after accretion. Evidence from meteorites shows that some parent asteroids were completely melted (basaltic achondrites, irons, and stony irons), some asteroids were strongly metamorphosed (ordinary chondrites), and some were heated only enough to boil off volatiles and produce aqueous alteration (CI and CM carbonaceous chondrites). This event seems to have been much more intense in the inner asteroid belt and strongly affected the E- S-, A-, R-, V-, and M-class asteroids. The dynamical interaction of asteroids with each other and the planets, particularly Jupiter, has altered and blurred the original orbital distribution of the asteroids and cleared whole sections of the belt. The net result probably has been to expand the original compositional zones and produce orbital overlaps of zones that once may have been distinct from each other.

The recent flyby of 21 Lutetia by the Rosetta spacecraft points up the difficulty of characterizing asteroid mineralogy and the complexity of asteroid evolution. Lutetia has a spectrum that puts it firmly in the M class, but has a low radar reflectivity suggesting a metal-poor surface. The rich collection of flyby data included a confirmation of the flat, featureless spectrum, a measurement of the asteroid's bulk density that is higher than the densities of the possible meteorite analogs, and a structure that shows intense collisional evolution. One interpretation of these data is that Lutetia had a complex, multistage history that began with the melting and differentiation of the inner part of the

asteroid, the formation of an iron core, the preservation of a primitive low-iron silicate mantle and crust made of enstatite chondritelike material, and then the "stripping" of some portion of the crust and mantle from a major impact, leaving the higher density core intact. This points up that all but the largest asteroids are most likely fragments of originally larger bodies. Many of these bodies (and perhaps most) have survived as gravitationally bound loose piles of rubble. Lutetia is a stark reminder of how little we yet know about this dazzling array of thousands of small planets we call asteroids.

4. PUZZLES AND PROMISE

4.1. Asteroids and Earth

It is a rare but exciting event in science when a single idea by a small group of scientists ignites an entirely new field of study and redefines the scientific debate. That is exactly what happened to such diverse fields as impact physics, asteroid observations, and paleontology after Alvarez and their colleagues hypothesized that the iridium anomaly found in Cretaceous-Tertiary (K/T) boundary sediments was the mark of an impact event that destroyed the dinosaurs (see chapter Planetary Impacts).

Asteroid impacts are a consistent and steady state fact in the solar system. One just has to look at the extensively cratered surface of any solid body to realize that impacts happen. To some extent, the fact that the Earth has active geological processes that erase the scars of impact craters rapidly and a thick atmosphere that filters out the smaller impactors, has lulled us into a false sense of security.

The real question is not whether asteroids hit the Earth, but rather how often it happens. Before they hit, these impactors are comets and asteroids with the same power-law distribution of sizes that we see in the asteroid belt, so small impacts will be more frequent and large "species-killing" impacts will be much rarer. However, as those who live near dormant volcanoes should realize, rare events on human timescales can be common and frequent events on geologic timescales.

There is plenty of evidence in the geologic and fossil record for repeated major impacts, some of which are associated with mass extinctions. For instance, there were 5 mass extinctions during the last 600 million years, about what would be predicted by a purely impact-driven extinction model. The bottom line is that asteroid impacts should be treated as one of the steady state processes that result from a dynamic solar system. Although the chances of a cratering event like the one that dug the almost 1-mile-diameter Meteor Crater in Arizona happening on any random day are small, the probability is 100% that it will happen sometime. The only question is, when? When faced with predictable dangers, it is sensible to take precautions. In the same way that people who live on the Gulf coast of North America track hurricanes and people who live in tornado-prone Oklahoma build houses with cellars, it seems a reasonable precaution to identify, track, and study the asteroids in near-Earth space. The telescope search programs that are engaged in this activity are detailed in the Near-Earth Objects chapter.

4.2. Origins of Asteroids

As pieces of material left over from the accretion of the planets, the asteroids represent important chemical and physical clues about the origin of the planets. But these clues can only be interpreted by having a reliable theory for how the asteroids themselves were formed. What processes shaped both the structure of the individual asteroids and the characteristics of the asteroid belt as a whole? Where did the material in the asteroid belt today come from originally?

We do have a reasonably complete census of asteroids in the main belt, down to a size of a few kilometers, and from that we can infer (see Section 2.5) how the perturbing gravity of Jupiter and Saturn has shaped the distribution of asteroids today. And we know that asteroids come in distinct spectral classes, and that there is a tendency for S-type asteroids to be found in the inner belt and C types to be found in the outer belt. But while we recognize that those inferences are very uncertain, and that there could well be material in the asteroid belt that is not sampled in our meteorite collections, we can sketch out a testable scenario for the formation and evolution of the asteroid belt. This is not a final answer but rather a best guess, which we will continue to test and refine as we learn more about the asteroids.

The solar system formed in a solar nebula of gas and dust that smoothly varied in density and temperature from the hot, dense center where the Sun was forming to the thin, cold outer edges where the nebula bordered interstellar space. (See chapter The Origin of the Solar System.) It is possible to calculate the rate at which dust in this cloud would encounter and stick to other bits of dust. These calculations indicate that it is possible in the early solar nebula for very loose balls of dust (more than 90% empty space) as large as a kilometer across to be formed. Relatively low-speed collisions between such dust balls would lead to further compression and accretion into objects big enough to not be carried away with the gas when the last of the solar nebula was pulled into the Sun or ejected in a massive early solar wind. But it seems probable that these planetesimals were very different from the asteroids we see today.

If one takes the present-day masses of the planets, adding a solar proportion of hydrogen and helium to the rocky planets' compositions, and then imagines spreading this material in a disk around the Sun to simulate the

smallest possible nebula capable of making planets, one can see that the amount of material in such a nebula varies smoothly from the Sun to the outer reaches of the solar system, with boundaries to the nebula inside Mercury and outside Neptune. But in the region of Mars and the asteroid belt, there should have been a significant amount of mass that appears to be missing today.

We saw in Section 2 how Jupiter and Saturn perturb asteroids out of the asteroid belt. But modeling the early solar nebula allows us to estimate just how much material was so perturbed. It suggests that Mars is made up of less than 10% of the material originally available in its region of the solar nebula, while the mass of the asteroid belt is less than 0.1% of the inferred original material present. The perturbations of asteroidal material by Jupiter and Saturn must have been extremely efficient, at least in the earliest stages of the solar system's history.

Indeed, as material in resonance with Jupiter was ejected to the outer solar system, the effect on Jupiter would be to drag it into the inner part, eventually sweeping out much if not all of the material in this region. Recent calculations based on this concept, the Nice Model, suggest that interactions between Jupiter and Saturn at this time may have resulted in the wide-scale reshuffling of the gas giant planets. These radical changes would have scattered material into the Kuiper Belt, and removed nearly all the original material between Mars and Jupiter.

Thus, it has been suggested that the asteroids today could represent material scattered into this region from elsewhere. It is possible that the high-temperature, differentiated asteroids like 4 Vesta or the metallic M-class asteroids were part of a group of asteroids that formed in the region of the terrestrial planets (near Earth) and were perturbed into the asteroid belt, ending up near objects with much different mineralogies and histories. Conversely, the darker, low-temperature, carbonaceous asteroids may have come originally from the outer solar system and were likewise perturbed into the belt, creating the wildly varying collection we see today. Other variants on this theory suggest that as Jupiter and the other giant planets migrate, material originally formed between Mars and Jupiter was first scattered out, but then scattered back into the area we now call the asteroid belt.

One inevitable result of having the mass of the asteroid belt excited into such orbits is that there must have been a very high collision rate among asteroids in the early solar system. These collisions would break larger asteroids into smaller pieces and destroy the smaller pieces entirely. For the largest asteroids—many tens of kilometers in radius—impacts energetic enough to shatter them may not have enough energy to disperse the pieces completely. Instead, the fragments were likely to reaccrete into piles of rubble, consistent with the structure that asteroids are inferred to have today.

As the population of the asteroid belt dissipated, the rate of collision likewise would have dropped. Given the present-day population, collisions that are capable of breaking pieces of an asteroid into Earth-crossing orbits or creating families of asteroids where one asteroid once orbited still do occur. We do see young families of asteroids today. Likewise, by measuring short-lived radioactive isotopes formed in meteorites by cosmic rays, we can see peaks in the ages of certain meteorite classes that imply they were broken off a parent body at a specific moment some tens to hundreds of millions of years ago. But these events must be many, many times less frequent today than when the asteroid belt was much more heavily populated.

One result of this scattering of asteroids by Jupiter and Saturn may have been that a few rare bodies originally from the asteroid belt may have been captured into orbits around other planets. Among the moons suspected of being captured asteroids are the Martian moons Phobos and Deimos, the irregular moons of the gas giant planets, and even Neptune's large moon Triton.

4.3. Spacecraft Missions to Asteroids

Although telescopic studies are by far the most prolific source of data on asteroids, critical science questions on asteroid composition, structure, and surface processes can only be addressed by spacecraft missions getting close to these objects. The range of spacecraft encounters includes flybys, rendezvous, and sample return missions, which provide information of ever-increasing detail and reliability. As shown in Table 26.2 we have now seen the results of 10 missions (color coded green), one is currently on the way (colored red), and two more are awaiting launch (colored orange).

The Near-Earth Asteroid Rendezvous spacecraft, the first dedicated asteroid mission, flew past asteroid 253 Mathilde and arrived in orbit around 433 Eros in 2001. After orbiting Eros for 1 year and mapping its morphology, elemental abundances, and mineralogy with an X-ray/gamma ray spectrometer, imaging camera, near-infrared reflectance spectrometer, a laser range finder and a magnetometer, the spacecraft ended its mission by landing on the surface of Eros (see chapter Near-Earth Objects).

In late 2005, the ambitious Hayabusa asteroid sample return mission of the Japanese Aerospace Exploration Agency (JAXA) rendezvoused with asteroid 25143 Itokawa. This NEO turned out to have an extremely rough surface, as shown in Figure 26.10. After several months of mapping and analysis, the spacecraft collected samples by shooting a small projectile into the surface and collecting some of the fragments that splashed off, and successfully returned its load of tiny fragments to Earth (Figure 26.8), parachuting its sample pod onto the Australian desert in 2010.

TABLE 26.2 Spacecraft Missions to Asteroids. The 10 missions already flown are color coded green, one currently on the way is colored red, and two more awaiting launch are colored orange

Asteroid	Mission	Encounter
101955 Bennu	OSIRIS-REx	Sample return
162173 1999 JU_3	Hayabusa 2	Sample return
1 Ceres	DAWN	Orbit
4 Vesta	DAWN	Orbit
21 Lutetia	Rosetta	Flyby
2867 Steins	Rosetta	Flyby
25143 Itokawa	Hayabusa	Sample return
5535 Annefrank	Stardust	Flyby
433 Eros	NEAR	Orbit
9969 Braille	Deep space 1	Flyby
253 Mathilde	NEAR	Flyby
243 Ida	Galileo	Flyby
951 Gaspra	Galileo	Flyby

There are three exciting missions "on the way" or awaiting launch to asteroid encounters. The DAWN spacecraft has spent 15 months in orbit mapping 4 Vesta during 2011–2012 and is currently on its way to orbit 1 Ceres starting in early 2015. JAXA is planning to launch another sample return, Hayabusa 2 to asteroid 162173 (1999 JU_3), in July 2014. National Aeronautics and Space Administration is in the final stages of development in the OSIRIS-REx sample return mission. This mission is planned for a 2016 launch to encounter asteroid 101955 Bennu (1999 RQ_{36}).

While we have made great strides in exploring asteroids they are still largely unexplored; indeed, in the case of the smaller NEOs, still largely undiscovered. They have great potential for science, for destruction, as resources in space, and for exploration. We are only just starting to understand these numerous objects that share our solar system.

1. INTRODUCTION

A **near-Earth object (NEO)** is an asteroid or comet orbiting the Sun with a perihelion distance of less than 1.3 AU (1 AU, an "astronomical unit", is the mean distance between the Earth and the Sun, around 150 million km). If the orbit of an NEO can bring it to within 0.05 AU of the Earth's orbit, and it is larger than about 120 m, it is termed a potentially hazardous object (PHO); an object of this size is likely to survive passage through the atmosphere and cause extensive damage on impact. (The acronyms NEA and PHA are used when referring specifically to asteroids.)

The recognition that a giant asteroid or comet perhaps 5–10 km across most likely caused, or at least contributed to, the extinction of the dinosaurs in a geological episode known as the Cretaceous–Tertiary Event has highlighted the hazard to our civilization presented by NEOs. The energy involved in collisions of NEOs with the Earth can be much larger than that released in the detonation of nuclear weapons or naturally occurring phenomena on Earth (e.g. volcanoes, earthquakes, or tsunamis).

Scientists cannot accurately predict what effects a major NEO impact would have on today's technically sophisticated and highly networked world. Computer simulations of impacts provide some insight but natural phenomena

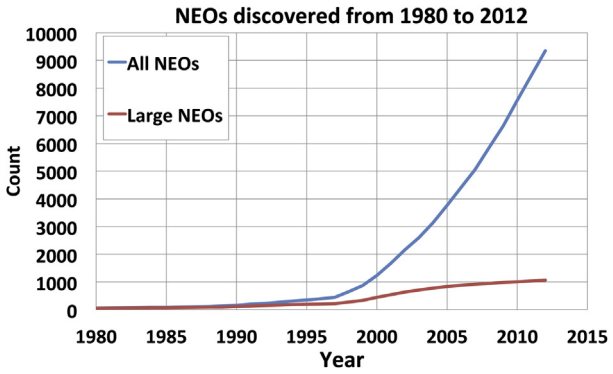

FIGURE 27.1 Cumulative total of discovered NEOs versus time. Large NEOs are defined as those with a diameter of at least 1 km.

elsewhere in the solar system provide real proof of the destructive potential of collisions between planets and small bodies. The collision of comet Shoemaker-Levy 9 with Jupiter, observed worldwide through telescopes in 1994, created scars in Jupiter's atmosphere larger than the Earth.

Even relatively small impactors can cause considerable damage on Earth. The object that exploded over the Russian city of Chelyabinsk in February 2013 had a diameter of only 17–20 m, yet it produced a blast wave that damaged buildings and injured some 1500 people. The potentially devastating effects on Earth of a collision with a large asteroid or comet are now well recognized by scientists and policy makers.

One of the pioneering programs in the search for NEOs, Spacewatch, founded by Tom Gehrels and Robert McMillan at the University of Arizona, started to detect NEOs in earnest in 1990, with the first automatic detection of a NEO. More programs have since joined in, using sensitive **charge-coupled devices (CCDs)** and sophisticated software to automate the process of identifying moving objects. These programs, mainly US-based, have increased the number of known NEOs to around 10,000 at the time of this writing, compared to 56 known in 1980 (Figure 27.1). Currently, there are some 1400 known objects qualifying as PHOs, although the total population of such objects is estimated to be around 4700.

It is now certain that most of the NEOs originated in the Main Asteroid Belt, located between the orbits of Mars and Jupiter. The range of composition and physical characteristics of NEOs spans those found among asteroids in the main belt. However, some NEOs probably evolved into their current orbits from the reservoir of short-period comets extending beyond Jupiter and into the outer solar system and may be extinct or dormant cometary nuclei.

NEOs are assigned to one of four subgroups according to their orbital types (Figures 27.2 and 27.3):

- Amors whose orbits are completely outside the Earth's orbit.
- Apollos whose orbits cross the Earth's orbit but are mostly outside it.
- Atens, whose orbits also cross the Earth's orbit but are mostly inside it.
- Atiras (also termed inner Earth objects or Apohele asteroids), which have orbits entirely inside the Earth's orbit.

Only Apollos and Atens can collide with the Earth at the present time, although the orbits of all NEOs evolve as a result of planetary perturbations and may intersect the Earth's orbit at some time in the future.

The Amor asteroid (433) Eros was the first NEO to be discovered. Gustav Witt of Berlin, Germany, recorded its position on a photographic plate in 1898. It is also one of the largest NEOs, having a longest dimension of 33 km and a cross-section of 10.2×10.2 km. Since then some 4000 Amors have been discovered. The group's namesake, (1221) Amor, was discovered in 1932. In the same year, the first Earth-crossing asteroid, (1862) Apollo, was discovered. Around 4700 Apollos have been discovered since. It was not until 44 years later that (2062) Aten was discovered

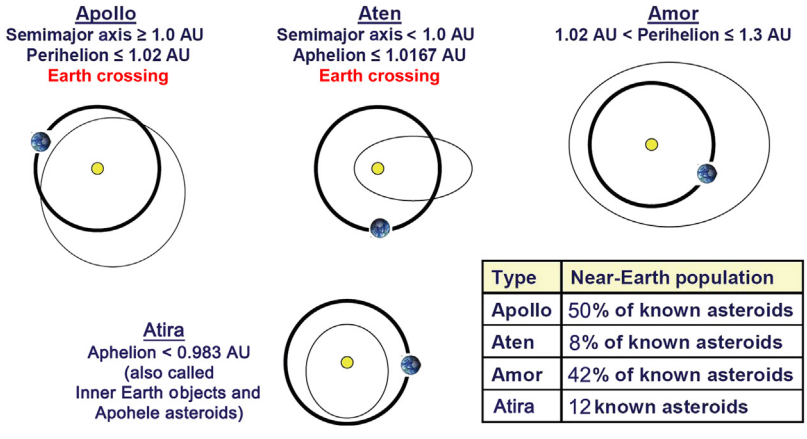

FIGURE 27.2 Apollo orbits cross that of the Earth but most of the orbit is external to the Earth's orbit. Atens are also Earth crossers but with orbits largely inside that of the Earth. Amor orbits are external to that of the Earth. Atira asteroids have orbits entirely inside the Earth's orbit. The perihelion and aphelion are the points in an orbit that have the shortest and longest distances from the Sun, respectively.

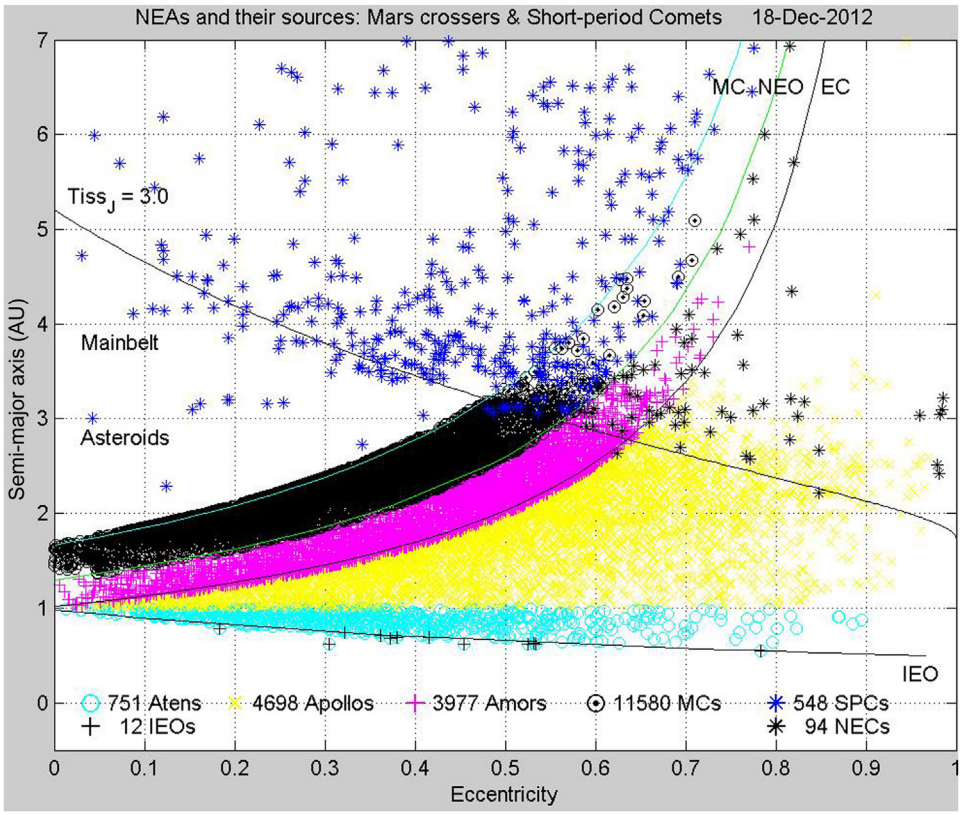

FIGURE 27.3 Plot of **semimajor axis** versus **eccentricity** of the near-Earth asteroid population, together with populations of related objects: Mars crossers (MC), short-period comets (SPC), and near-Earth comets (NEC). The Earth's orbit has a **semimajor axis** of 1 AU. The Atens are just below the 1 AU line, the Apollos just above, and the Amors fall above the Apollos as they do not cross the orbit of the Earth at all. The curves labeled MC, NEO, and EC mark the upper boundaries of the populations of Mars crossers, NEOs, and Earth crossers, respectively. The Tisserand parameter, Tiss_j, is explained in Section 3.5.1. *Credit G. Hahn/EARN, DLR Institute of Planetary Research.*

by Eleanor Helin, still using photographic plates for the search. Over 750 Atens have been discovered to date. In 1998, the first Atira or inner Earth object, 1998 DK_{36}, was discovered. Atiras are difficult to detect because they orbit inside the Earth's orbit and are therefore not normally observable in the night sky. For this reason, only about 12 Atiras have been observed to date. Several space telescope missions for NEO search and discovery have been proposed that can observe the daytime sky, unlike Earth-bound observers. Such telescopes would be better placed to detect the elusive Atiras.

Figure 27.3 is a plot of semimajor axis against eccentricity, illustrating the orbital distributions of the different dynamic classes of NEO, together with the orbital characteristics of related objects.

In 2005, the asteroid (1862) Apollo was found to be a binary system: two asteroids orbiting around a common center of mass, in this case with diameters of 1.5 km and 75 m. Of the known NEOs, only about 40 have been found to be binary objects, but it is expected that many more await discovery. According to recent estimates, some 15% of all NEOs with a diameter larger than 300 m are binary or multiple asteroid systems. Binary asteroids are scientifically fascinating objects, providing clues to some puzzling aspects of NEO physical properties.

To date, there have been two **rendezvous** missions to NEOs. National Aeronautics and Space Administration's (NASA's) Near-Earth Asteroid Rendezvous-Shoemaker (NEAR Shoemaker) mission was the first designed to orbit an asteroid. The NEAR Shoemaker spacecraft orbited its target, (433) Eros, for 1 year from February 2000. The mission ended with a descent of the spacecraft to the asteroid's surface. The Japanese Hayabusa spacecraft was launched on May 9, 2003, on a mission to investigate asteroid (25143) Itokawa and to demonstrate the technology necessary to return samples to Earth. The spacecraft arrived at Itokawa in September 2005 and performed remote sensing measurements for 3 months. In November 2005, there were two scheduled touchdowns in which some grains of surface material were collected. After a journey back to Earth lasting more than 3 years, the return capsule was released from the main spacecraft a couple of hours before both entered the Earth's atmosphere. The Hayabusa spacecraft disintegrated on reentry in a fireball, while the

thermally shielded capsule containing the grains from Itokawa was recovered in the south Australian outback on June 13, 2010.

2. SIGNIFICANCE

2.1. Remnants of the Early Solar System

From a scientific point of view, NEOs are studied for the same reason as comets and main-belt asteroids: they are remnants of the early solar system (Figure 27.4). As such, they contain information that has been lost in the planets through large-scale, planetary processes such as accretion, tectonism, volcanism, and metamorphism. Asteroids and comets have undergone less processing since their formation in the early solar nebula; therefore, knowledge of them derived from astronomical observations and studies of direct samples in the form of meteorites or collected by space missions is critical to piecing together a scenario for the formation of the solar system. (See The Origin of the Solar System.)

Most NEOs are asteroid-like in their nature, being derived from the Main Asteroid Belt. The Asteroid Belt forms an important boundary in the solar system; the planets that formed closer to the Sun, the terrestrial planets, are dominated by rocky, lithophile materials. Beyond the Asteroid Belt, the planets are composed predominately of nebula gases. Some NEOs almost certainly originated elsewhere in the solar system, such as in the cometary reservoirs lying at great distances from the Sun, beyond the gaseous planets. Knowledge of the materials in these reservoirs provides insight into the chemical and physical processes that were active in the outer regions of the solar system, both in the near and distant past. A major objective of the scientific study of NEOs is to determine the proportions of the population that derive from various regions of the asteroidal and cometary reservoirs.

2.2. Hazard Assessment

The phenomenon of collisions in the history of our solar system is very fundamental, having played the major role in forming the planets we observe today. Asteroids may have contributed to the delivery of water and organic materials to the early Earth necessary for the development of life, but later impacts of asteroids probably played a role in mass extinctions, and they currently pose a small but significant threat to the future of our civilization. Collisions of asteroids with the Earth have taken place frequently over geological history, and it is an undeniable fact that major collisions of asteroids and comets with the Earth will continue to occur at irregular, unpredictable intervals in the future. The risk of a comet impact is thought to be much lower than that of an NEA impact, although given the potentially high relative velocities, the effects in the case of a comet impact could be much more devastating.

As a result of modern observing techniques and directed efforts, thousands of NEOs have been discovered over the past 20 years, and the reality of the impact hazard has been laid bare. Future observation programs and space missions will be crucial for a better understanding of the orbits, composition, and physical nature of asteroids, and the techniques that would be most effective in preventing a collision of an asteroid with the Earth. (See Planetary Impacts; Cometary Dynamics.)

2.3. Exploration Destinations and Resource Potential

NEOs come closer to Earth than any other planetary bodies, and those with low orbital inclinations are very accessible targets for spacecraft and are considered attractive as training venues for missions to Mars. As civilization moves beyond the Earth, knowledge of materials in space is critical to their efficient use in situ. It could eventually become more

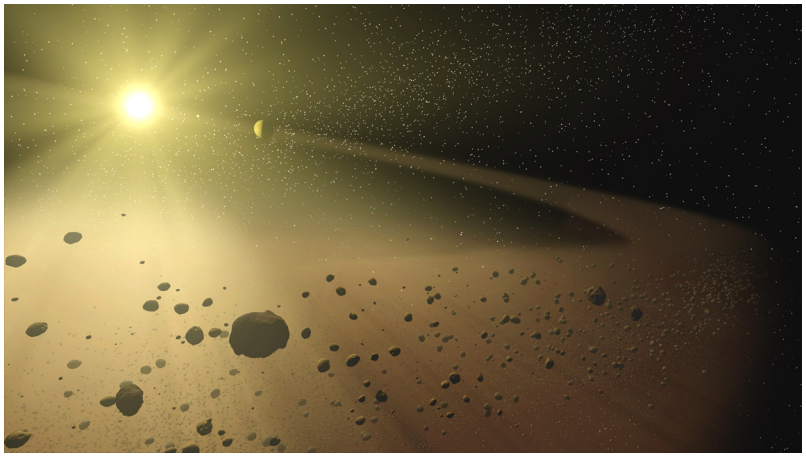

FIGURE 27.4 Artist's impression of planets forming in a young planetary system. According to theory, collisions between dust grains and small bodies at the dawn of our solar system led to the formation of "planetesimals" with diameters of up to several hundred kilometers. The significant gravitational fields of the planetesimals caused more material to be accreted and led in some cases to the growth of planets. On the other hand, dramatic collisions between bodies at the time of planet formation led to the release of countless fragments, many of which are still present in the solar system as asteroids and comets. *Credit: NASA/JPL-Caltech/T. Pyle, SSC.*

economical to use space resources than transporting material from the Earth. A number of groups have been formed over the years, including commercial companies, with the aim of eventually extracting valuable materials, such as platinum and other precious metals, from the Moon, Mars, and NEOs. For future human space exploration, water is also a precious resource that may be retrievable from certain types of NEO, both for human consumption and for the production of hydrogen and oxygen as rocket propellant.

3. ORIGINS

In the widely accepted scenario of the formation of the solar system 4.6 billion years ago, a cloud of gas and dust collapsed into a disk-shaped nebula from which planetesimals and eventually planets formed (Figure 27.4). The process of planet formation started with molecules and dust grains colliding and combining with each other. **Aggregates** and clumps grew in size by sweeping up smaller dust and ice grains. Further growth continued via collisions and accretion of material forming objects with diameters of up to a few hundred kilometers, called planetesimals. Both electromagnetic and gravitational forces came into play to oppose the destructive forces of erosion from collisions. Some planetesimals continued to increase in mass, attracting ever more material via their gravitational fields. It was primarily the strong gravitational field of the forming Jupiter that disrupted neighboring planetesimals so much that a planet never formed between the orbits of Mars and Jupiter, in the region of the so-called Main Asteroid Belt. Some large main-belt asteroids may be original planetesimals that were prevented from growing to the size of the major planets by the effects of collisions. Smaller asteroids are most likely fragments produced in collisions. The largest object that formed in the main belt, Ceres, has a diameter of 950 km and a volume of only one-fiftieth that of the Moon; Ceres constitutes one-third of the mass in this region. Over time, collisions between asteroids together with various dynamical processes have led to many objects being ejected from the Main Asteroid Belt.

3.1. Relationship to Main-Belt Asteroids

In the late 1970s it became clear from telescope observations that asteroid composition changes as a function of the distance from the Sun, and hence temperature. Therefore, the exact nature of asteroidal material holds clues to the temperature and location where the material formed, valuable information for scientists attempting to understand the processes that led to the formation of our solar system and are possibly involved in the formation of extrasolar planetary systems.

Studies of the composition of NEOs led to the conclusion that NEO composition spans the range found in the Main Asteroid Belt, thus establishing that most NEOs are derived from the main belt. Therefore physical information derived from NEOs can be reasonably considered to apply to main-belt asteroids.

Statistical analysis of the evolution of many asteroid orbits over the age of the solar system indicates that the lifetime of an Earth-crossing body against gravitational perturbations is relatively short, on the order of 10 million years or less. Within this time frame, the bodies will collide with a planet, fall into the Sun, or be dynamically ejected from the solar system. This time interval applies to the average of the entire population and does not refer to the exact lifetime of any particular asteroid. It turns out that the orbital evolution of a specific **NEO** cannot actually be determined very far into the future or the past (i.e. more than a few hundred years) owing to the difficulty of knowing the exact starting conditions and accurately predicting frequent close approaches between the NEO and the planets. (See Solar System Dynamics: Regular and Chaotic motion.)

3.2. Dynamical History

Dynamicists have simulated the pathways that objects might take from unstable regions of the Asteroid Belt using computations of dynamical forces acting in the solar system. In some cases, fragments from asteroid collisions may be violently cast into these regions of instability. However, a softer touch may play an even bigger role. Constant warming by the Sun causes asteroids of all sizes to reradiate their heat back into space. Since all asteroids rotate, the reradiation does not occur in the same direction as the incoming sunlight, resulting in a small force acting on the asteroid. This force acts as a very gentle push on the asteroid, which over many millions of years can cause the asteroid to slowly drift inward or outward from its original main-belt location. The phenomenon is called Yarkovsky drift and is especially effective on small objects; it may be particularly important for supplying meteoroids to Earth. An object undergoing Yarkovsky drift may eventually enter regions where resonances with Jupiter's orbit are particularly strong, such as the Kirkwood gaps, located where an asteroid's orbital period is shorter than Jupiter's by the ratio of two small integers, such as 3:1, 5:2, or 2:1 (see Figure 27.6 below). Any asteroid or debris that migrates into such a region finds Jupiter to be especially effective in increasing its orbital **eccentricity**. As the orbit becomes increasingly elongated, it can intersect the orbit of the Earth. There are regions of chaotic motion associated with resonances with both Jupiter and Saturn. The two gas giant planets are believed to play a significant role in directing meteoroids to Earth, and presumably also many of the NEOs.

Other NEOs evolve from Jupiter-family comets or Halley-type short-period comets. Life as a Jupiter-family comet is not long, as Jupiter imparts changes to the orbits

on timescales of 10^4–10^6 years. Leaving Jupiter's gravitational sphere of influence, the soon-to-be NEOs may sometimes be perturbed by Mars and other terrestrial planets and also affected by the influences of nongravitational forces, such as volatile outgassing or splitting of the cometary nucleus. Nongravitational forces also contribute to orbital changes that result in planet-crossing orbits.

3.3. Relationship to Meteorites

Small rocky fragments, hand-sized chunks, and large boulders continually fall to Earth from space; most fall unnoticed in the oceans or in remote areas, but occasionally one is found lying on the ground as a meteorite. Exploring the relationship between NEOs and meteorites is motivated by the possibility of making insightful connections between the geochemical, isotopic, and structural information on meteorites available from laboratory studies and the NEOs.

In January 2000, an exceptionally bright **bolide** was seen by eyewitnesses in the Yukon, Northern British Columbia, parts of Alaska, and the Canadian Northwest Territories. Nearly 10 kg of precious samples were recovered from the surface of frozen Tagish Lake. On the basis of eyewitness reports and the **bolide's** detection by military satellites, the orbit of the impacting body was traced back to the Main Asteroid Belt. Prior to striking the Earth, the body is estimated to have been about 4 m across with a mass of 56 metric tons. The determination of meteorite orbits also serves as a constraint on the mechanisms that result in meteoroid delivery to Earth.

October 2008 marked the first time that a NEO was discovered by a search program and found to be on collision course with the Earth. The NEO, 2008 TC_3, was discovered at 6:39 UT on the morning of October 6, 2008, by Richard Kowalski of the Catalina Sky Survey, using the Mt Lemmon 1.5-m-aperture telescope near Tucson, Arizona. The International Astronomical Union's Minor Planet Center (MPC) houses the world's repository of asteroid observations and uses them to automatically compute orbits for each potential discovery. Upon receiving the discovery data for 2008 TC_3, the MPC calculated a preliminary orbit that showed the object to be heading for a collision with the Earth the very next day! Dynamics experts at the NASA/JPL Near-Earth Object Program Office determined that 2008 TC_3 would enter the Earth's atmosphere above northern Sudan around 02:46 UT on October 7. Luckily, although its speed as it entered the Earth's atmosphere was calculated to be 12.4 km/s, the estimated diameter of the object was only around 4 m, too small to leave any mark on the ground, save for a scattering of meteorites. Nevertheless, the event produced a spectacular fireball. Predictions of the location of entry into the atmosphere were quite accurate, as witnessed by US government satellites, images from the Meteosat 8 weather satellite, and a sighting by an airline pilot flying over Chad. Some 280 small chunks of 2008 TC_3 have since been retrieved from the Nubian Desert in Sudan (Figure 27.5). Scientific investigations of the meteorites, named "Almahata Sitta", will continue for many years, aided by the fact that some very alert observers were able to acquire spectroscopic and light curve observations of 2008 TC_3 while it was still in orbit, in the few hours between discovery and entry into the atmosphere.

FIGURE 27.5 Peter Jenniskens, meteor expert and member of the Almahata Sitta meteorite recovery team, finds a piece of the ex-asteroid 2008 TC_3, during a search on February 28, 2009. *Credit: Peter Jenniskens, SETI Institute.*

At the time of writing the most recent case of an asteroid being discovered and subsequently impacting the Earth is that of 2014 AA, the first asteroid to be discovered in 2014. The car-sized object entered the Earth's atmosphere over the Atlantic Ocean at about 03:00 UT on January 2, 2014, less than a day after being discovered by the Catalina Sky Survey. The object presumably disintegrated harmlessly in the atmosphere.

The fireball over Chelyabinsk on February 15, 2013, was caught on many security cameras, allowing the circumstances of the event to be investigated in unprecedented detail. Information on the trajectory and brightness of the **bolide** and the orbit of the original 18-m-diameter asteroid, combined with details of the composition and internal structure of the resulting meteorites, will allow a very complete picture to be constructed of this event, providing unique insight into the nature and origin of the object that caused the worst damage on the ground since the Tunguska event of 1908 (see Section 7). (See Meteorites.)

3.4. Meteor Shower Associations

Streams of material can develop in the orbits of comets and asteroids that eject particles as they orbit the Sun. If such a

stream of particles crosses the Earth's orbit, it can give rise to a meteor shower at the same time each year, as particles in the stream are swept into the Earth's atmosphere. An icy comet nucleus warmed by the Sun ejects material in the form of gas molecules and dust grains, which feed its coma and tail in a process called outgassing. Comet nuclei are generally fragile bodies that can spontaneously lose large fragments or even disintegrate altogether. Asteroids can also lose material as a result of collisions or an increase in rotation rate caused, for example, by a close encounter with a planet. Many asteroids may be loosely bound **agglomerates** of collisional fragments that formed by gravitational reaccumulation of debris after a dramatic collision between two larger objects. Such objects are termed "rubble piles" (see Sections 5.3 and 6.2); it is easy to understand how such an object can lose material if it spins rapidly. Other mechanisms potentially causing the loss of particles from an asteroid include surface cracking and dehydration under thermal stress, which may occur if the object approaches very close to the Sun.

In 1983, Fred Whipple recognized the orbital elements of an asteroid found by an Earth-orbiting infrared telescope to be essentially the same as the Geminid meteor shower, which occurs in mid-December. (See Infrared Views of the Solar System from space.) There is little doubt that this asteroid, (3200) Phaethon, is the parent body of the Geminid meteors. While Phaethon has never exhibited a coma or tail, it has orbital, and some physical, characteristics that resemble those expected of a dormant or extinct comet nucleus. The perihelion distance of Phaethon's orbit is very small (0.14 AU), implying that surface temperatures rise to around 1000 °C at its closest approach to the Sun. Some researchers suspect that the ejection of particles via thermal fracturing and the dehydration of certain minerals may be the mechanisms by which Phaethon feeds the Geminid meteor stream. There are several other NEOs with orbital elements implying associations with the paths of existing meteor showers.

3.5. Relationship to Comets

Comets are icy and dusty objects that come from the outer reaches of the solar system. In contrast to asteroids, which are predominantly mixtures of rock and metals, a comet nucleus is a rocky body that contains frozen volatile materials, such as water, carbon monoxide, carbon dioxide, and methane, which give rise to a halo and coma when the object approaches the Sun. The orbital periods of comets are long, their orbital eccentricities are high, and they may have large or small orbital inclinations. What is their relationship to NEOs? In the 1950s, Ernst Öpik concluded that comets must be a partial source of NEOs because he could not produce the number of observed meteorites from the Asteroid Belt alone via his calculations. Building on Öpik's work, George Wetherill predicted that 20% of the NEO population consists of extinct cometary nuclei. Some now find evidence that the fraction of comets is smaller, closer to 5%. (See Cometary Dynamics; Physics and Chemistry of Comets.)

Are there hints that any particular NEO that looks like an asteroid was once a comet? If an object sometimes has a tail like a comet and sometimes looks just like an asteroid (no coma or tail), what is it: an asteroid or a comet? There is both dynamical and physical evidence that addresses this question:

3.5.1. Tisserand Parameter

A strong hint that an asteroid-like object may be a comet in disguise comes from its orbit. The orbital elements of asteroids and comets tend to occupy different regions in a plot of **semimajor axis** against orbital **eccentricity** (Figure 27.6). Another way to characterize an orbit is to calculate its Tisserand parameter from the equation:

$$T = \frac{a_J}{a} + 2\sqrt{\frac{a}{a_J}(1-e^2)}\ \cos i$$

In this equation, a and a_J refer to the **semimajor axis** values for the object and Jupiter, respectively. The parameters i and e are the **inclination** and **eccentricity** of the object's orbit. The Tisserand parameter is useful because it is a constant even if the comet's orbit is perturbed by Jupiter. Also, it helps to determine whether an object is in an orbit

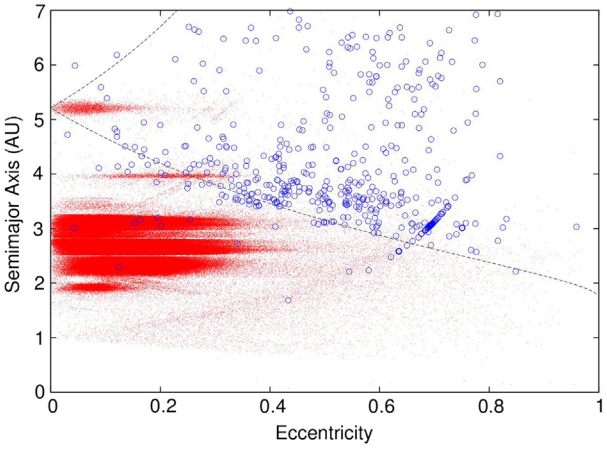

FIGURE 27.6 Tisserand parameter. The dashed line represents the Tisserand parameter with a value of 3. To the left of the line, T is greater than 3 and to the right, T is less than 3. Red dots and blue circles represent known asteroids and comets, respectively. The curved string of circles centered near **eccentricity** = 0.7, **semimajor axis** = 3, represents fragments of comet 73P/Schwassmann–Wachmann, which began to disintegrate in 1995. The Kirkwood gaps (see Section 3.2) are clearly evident in the distribution of asteroid **semimajor axes** between 2 and 3.5 AU. *Credit: Michael Mommert, DLR Institute of Planetary Research.*

that is strongly controlled by Jupiter or not. Most objects that display the characteristics of comets have a value $T < 3$, while most objects that are asteroid-like have $T > 3$. The value of $T = 3$ is represented by the dashed line in Figure 27.6. Due to diverse influences on the orbits of asteroids and comets, the value $T = 3$ does not represent a hard boundary, but "asteroids" with $T < 3$ are good candidates for being comets in disguise; the reason they do not currently display any tell-tale coma or tail is their dormancy or depletion of volatile materials.

3.5.2. Dynamical and Physical Evidence For Extinct Comets

A powerful way to investigate the mystery of how many extinct comets reside in the NEO population is to explore both dynamical factors and physical measurements to identify possible candidates. For example, numerical simulations of the orbits of short-period comets can reveal how likely it is that gravitational interactions with Jupiter and the other planets can send them into the NEO population. In these simulations, many thousands of hypothetical comets, each with slightly different initial orbits, can be tracked for millions of years to see how they are tossed around chaotically by the gravitational tugs and pulls of the planets. In the same way, thousands of different starting places for main-belt asteroid orbits can be modeled to reveal the effectiveness of resonances for sending asteroids into near-Earth space. Alessandro Morbidelli, William Bottke, and coworkers have done extensive computer calculations to assess the relative effectiveness of these dynamical processes. Their calculations suggest that, when considering NEOs with diameters of 250 m or larger, about 6% of them have a cometary origin.

Spacecraft and telescopic measurements of known comets reveal what characteristics to look for when trying to determine if a given asteroid-like NEO is an inactive comet nucleus. For example, spacecraft data show that surface regions of comets Halley, Borrelly, Wild 2, and Tempel 1 that are not actively outgassing are very dark (low albedo) and have gray color. Some other comets go through periods of very low activity, allowing astronomers to measure the albedos and colors of the nucleus unobscured by the gas and dust of a coma. All these measurements consistently show low albedos (the surface reflects back only about 4% or less of the incoming light) and gray or reddish colors. Spectroscopic analysis of reflected sunlight reveals no major absorption bands, indicating an absence of the minerals olivine or pyroxene, commonly observed in asteroid spectra, on their surfaces.

Recent estimates that combine dynamical information with albedo and color measurements indicate that perhaps a few to 10% of NEOs are in fact inactive comet nuclei.

4. POPULATION

4.1. Search Programs and Techniques

Organized, telescopic search programs for NEOs have led to a steady increase in discoveries over the past 15 years (Figure 27.7). The search programs supported by NASA include the Lincoln Near-Earth Asteroid Research program, the Panoramic Survey Telescope and Rapid Response System, the Near-Earth Asteroid Tracking system, Lowell

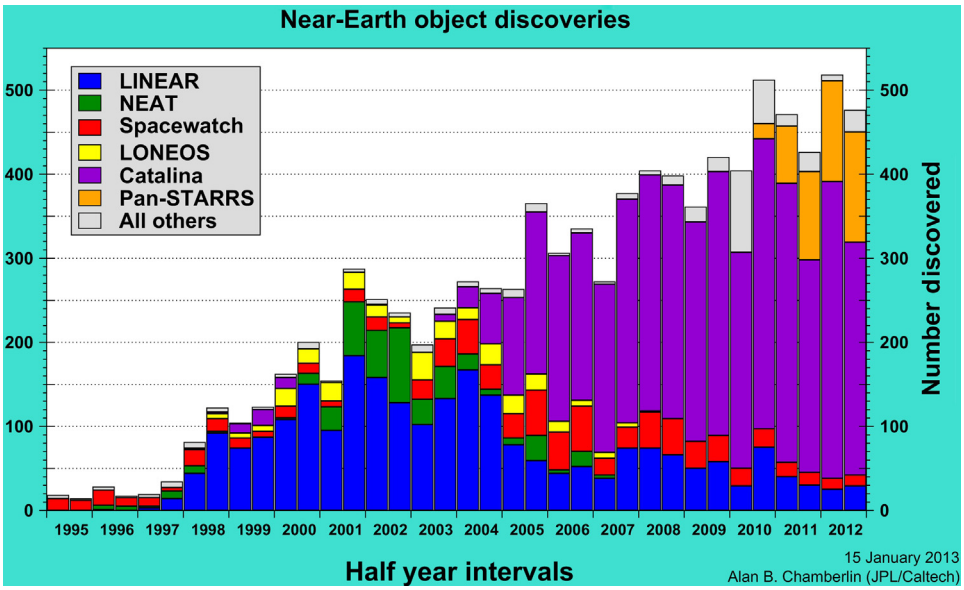

FIGURE 27.7 Numbers of NEO discoveries made by the various search programs. Improvements in detector technology and computing capabilities have led to a dramatic increase in the discovery rate since 1997. *Credit: Alan Chamberlin, JPL.*

Observatory's Near-Earth Object Search, the Wide-field Infrared Survey Explorer's (WISE) NEO search project, and the University of Arizona's Catalina Sky Survey and Spacewatch programs. Although the objectives of these programs are all similar, to inventory the objects in the vicinity of Earth, each has its own design and approach. Modern ground-based search programs employ digital imaging devices known as **CCDs** that cover large areas of the sky in a single exposure. Typically, a given area of sky is imaged and re-imaged three to five times at intervals of 10 min−1 h. With digital images, fast computers can compare the images and identify and subtract all the "uninteresting" objects that remain fixed, leaving behind the tracks of moving asteroids or comets. By rapidly repeating this process for many patches of sky throughout a night, nearly the whole sky can be scanned in the course of about 1 or 2 weeks. More sensitive and rapid search systems are under study that could significantly expand the capability to discover small NEOs, even down to diameters of 100 m or less.

When an NEO is first discovered, astronomers initially trace only a short piece of its orbit as measured over a few hours or even over a few weeks. With each new NEO discovery, astronomers wish to assess whether the object poses any immediate or future impact threat. Orbit calculations for most objects can be made reliably for many decades into the future, but of course if only a tiny part of the orbit has been observed, the extrapolation into the future is very uncertain. Sometimes this extrapolation shows that the Earth itself resides within the overall uncertainty region for a NEO's future position. If the cross-section of the Earth occupies 1/10,000th of this space, then there is a 1 in 10,000 chance of an impact with the Earth. Even though headlines may proclaim the end of the world, statistically speaking, the odds are actually 10,000 to 1 in our favor that continued observations refining the orbit will show a collision is ultimately ruled out.

There are currently two automatic systems operating that independently update the orbital parameters of NEOs and calculate future close Earth approaches and impact probabilities. Sentry is run by NASA's Jet Propulsion Laboratory in Pasadena, California, and NEODyS by the University of Pisa in Italy. Although independent, the two systems are designed to be complementary, and there is constant communication between the two sites to enable cross-checking of their results.

Two scales have been developed to facilitate assessment and comparison of impact probabilities of NEOs: The Palermo Technical Impact Hazard Scale and the Torino Scale. The Palermo Scale was developed to assess whether any NEO discovery merits concern or response. The Palermo Scale value (PS) is a measure of how much more likely an impact is than the general "background" risk of an impact from all such objects, or larger, over the period preceding the potential impact. For each potential impact of an NEO, the PS is simply the impact probability (P_i) divided by the background risk (P_b) on a logarithmic scale: $PS = \log_{10}(P_i/P_b)$. Pb is given by $0.03 \times T \times E^{-0.8}$, where T is the time in years until the potential impact, and E is the energy release in megatons of **trinitrotoluene (TNT)** associated with the potential impact, which depends on the object's size and its velocity at impact. For example, PS of +2 indicates that an impact is 100 times more likely than the general background risk, which would merit serious concern. On the other hand, $PS = -2$ indicates that the likelihood of an impact is only 1% of the background risk. $PS = 0$ implies that the risk associated with the potential impact is identical to the background risk.

The less technical Torino Scale is a 10-point scale designed for use by the media and for communicating impact risks to the public. On the Torino Scale, 0 indicates no likelihood of impact, or the impact presents no hazard (e.g. a small object that will burn up in the atmosphere), 1 indicates that an impact is extremely unlikely and there is no cause for concern, 2 indicates that the object merits attention by astronomers, and 10 implies that a collision is certain and will result in a global catastrophe.

At the time of this writing, the highest values on the Palermo and Torino Scales are −1.5 and 1, respectively. For more information on the Palermo and Torino Scales and to check the latest list of possible impactors see http://neo.jpl.nasa.gov/risk/.

4.2. How Many?

A frequently asked question is: how many NEOs are there in total? Being products of collisions, small NEOs are much more numerous than large ones. As only a small fraction of the total population has been discovered to date by the various survey programs, the observed samples must be extrapolated to determine the total number of NEOs. The largest NEO has a diameter of about 40 km. There are some 30 NEOs with diameters above 5 km, about 1000 with diameters above 1 km, and estimates run to several tens of thousands for objects with diameters above 100 m. But the size distribution does not stop there: there are billions of NEOs with diameters around 1 m (Figure 27.8). Small objects of around 1 m diameter enter the Earth's atmosphere every week and disintegrate harmlessly as they shoot Earthwards. Search programs are constantly adding to the inventory of NEOs and have found about 10,000 NEOs of all sizes to date, some 1400 of which are PHOs. The biggest objects appear brightest and are most easily found. So far the inventory is complete down to about 2 km, but only about 25% of the total population of NEOs with diameters of 100 m or more have been discovered. For sizes comparable to the Chelyabinsk impactor (17−20 m), it is estimated that less than 1% of the population has been discovered to date.

The frequency of new discoveries compared to the frequency at which already discovered objects turn up again in

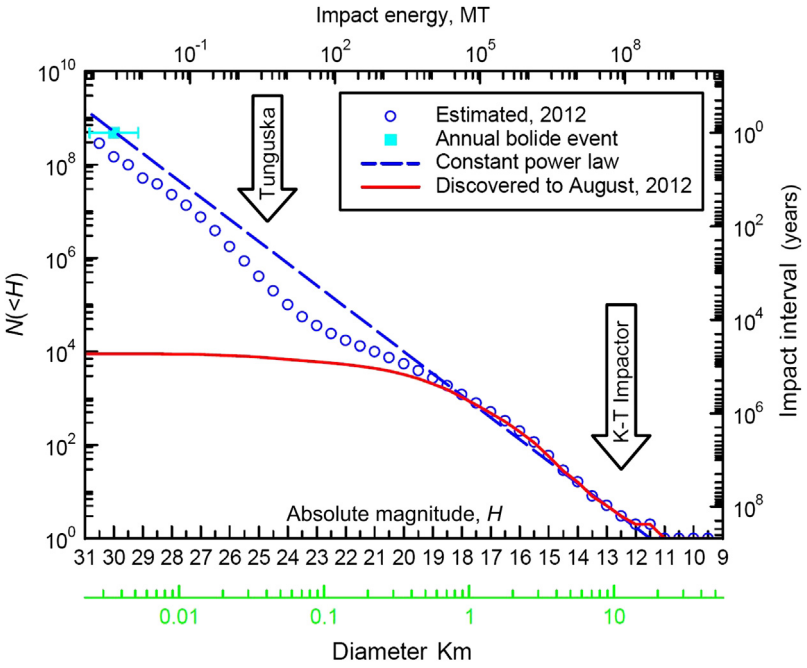

FIGURE 27.8 Estimated number of NEOs larger than a given diameter/brighter than a given absolute magnitude. (Absolute magnitude, *H*, is a log-scale measure of absolute brightness, on which *H* decreases as the brightness increases; see Section 5.1.) The red curve represents discoveries to August 2012; the blue circles represent the estimated total number of objects in the NEO population. The estimated mean interval between impacts of objects larger than a given diameter can be read off on the right-hand scale using the curve traced by the blue circles. *Credit: Alan W. Harris the elder, no relation to the significantly younger first author.*

the searches provides an estimate of how near the search is to completion, to the sensitivity limit of the telescope system. From knowledge of the sky-coverage characteristics of the search programs and how sensitive the searches are, it is possible to estimate how many objects are left to find.

When considering impact hazards on Earth, most scientists consider 1 km as the size large enough for an impact to present a global threat to human survival. Thus, the most immediate goal of search efforts was to find all objects larger than 1 km, a task that is almost complete (see Section 5.4). In the process, many smaller objects are found, and these contribute to the long-term goal of completeness to all sizes of NEOs that could cause significant damage on impact. Searchers have a long way to go to complete the survey of all the estimated hundreds of thousands of objects with diameters down to about 50 m. Even NEOs with diameters of only 30–50 m are capable of destroying a city or an urban region. The task of completing the surveys down to these sizes would benefit from new, large, specialized telescopes with huge **CCD** arrays, capable of scanning the skies more frequently and with greater sensitivity. Another possibility would be to conduct the search using telescopes in space, such as more capable versions of the Wide-field Infrared Survey Explorer (WISE) and Spitzer space telescopes discussed below in Section 5.4.

5. PHYSICAL PROPERTIES

The most accurate data on the physical nature of individual asteroids are provided by **rendezvous** missions. The NEAR mission studied the physical and chemical properties of asteroid (433) Eros from orbit and at the spacecraft's landing site. From its shape and surface morphology, astronomers deduced information about its global structure; an X-ray and gamma ray spectrometer provided information about its surface chemistry. The Japanese mission Hayabusa, which touched down briefly on the surface of the NEO (25143) Itokawa, provided valuable insight into that object's mineralogy, structure, and history. Hayabusa successfully returned a small quantity of material from the surface of Itokawa for investigation on Earth, which was the first time that material from a solar system body other than the Moon has been brought to Earth by a space mission. See Section 6 for details.

Space missions to asteroids are not only scientifically extremely productive but also extremely costly. An alternative means of providing information on the physical characteristics of NEOs is astronomical observations with telescopes (either on the ground or in orbit). While telescopic observations cannot match the results of **rendezvous** missions in terms of the wealth and accuracy of information on any particular object, they enable a significant fraction of the NEO population in all its diversity to be investigated. The first physical measurement an astronomer might make, after the position of an NEO has been established, is its brightness measured on the astronomical **magnitude** scale. The changing cross-section of an object as viewed from the Earth affects its brightness and with time reflects the shape and rotation rate of the object. Analysis of this changing brightness in the form of a so-called light curve

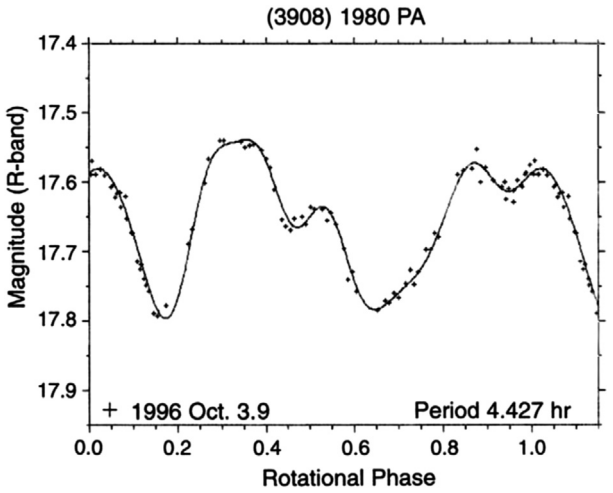

FIGURE 27.9 Light curve for Amor asteroid (3908) Nyx indicating its irregular shape. *Courtesy of Petr Pravec, Astronomical Institute, Academy of Sciences of the Czech Republic.*

(see Figure 27.9), accounting for the observational geometry, results in constraints on its shape and the determination of its rotation rate and orientation of the spin axis in space. From analyses of sunlight reflected off asteroid surfaces at different wavelengths, NEO colors are classified into different taxonomic types. (See Main-Belt Asteroids.) Further analysis can determine surface mineralogy, and, from that, constraints can be placed on the temperatures and locations in the solar system at which these objects formed.

5.1. Brightness

An asteroid's spectrum consists of reflected sunlight as well as heat that it emits as a result of being warmed by the Sun. The standard asteroid photometric magnitude system compensates for the distance and **phase angle** at which the object is observed at visible wavelengths (the solar phase angle is the angle between the observer and the Sun as seen from the asteroid). The magnitude scales by the inverse square law: as the distance from both the Sun and the observer increases, the brightness decreases by a factor equal to the inverse square of those distances. Scattering properties of the surface are expressed in the so-called phase function, which is compensated for by extrapolating the magnitude to 0° phase angle. For comparison purposes, a magnitude measurement is converted to an absolute scale, H, which is defined as the brightness of an object at a distance of 1.0 AU from both the Earth and Sun, and viewed at 0° phase angle (note that the scale is logarithmic and defined such that smaller H values correspond to brighter objects). The relation between an object's brightness and the solar phase angle at which it is observed has been measured for some of the brighter NEOs. Large changes in magnitude with changing phase angle indicate a very rough surface with significant effects due to shadowing. A relatively small dependence of brightness on phase angle indicates either a very dark surface, against which the impact of shadows is not significant, or that the surface is relatively smooth with minimal shadowing. When observations are made over a range of phase angles, fits to theoretical models with multiple variables can be made. Combined with other observational techniques (e.g. radar, polarimetry), constraints on the physical characteristics of the surface regolith can be made. A further parameter that contributes to brightness, the reflectivity of the surface expressed in terms of albedo, is discussed in Section 5.4.

5.2. Shape

Light curves are measurements of brightness as a function of time (Figure 27.9). If the object is perfectly spherical, such that its cross-section does not change with time, there is no variation and the light curve is flat. There are no such objects known, although there are light curves with very small amplitudes (not commonly found among NEOs, however). Light curves of NEOs often show two or more maxima and minima, often with inflections embedded within them. The shape of an NEO in terms of a **triaxial ellipsoid** can be modeled on the basis of observational data. Inflections in the light curves represent changes in the object's cross-section that reflect either the large-scale shape or albedo variations across the surface, or both.

Radar measurements are also analyzed to produce images that reveal the shape of asteroids. Coded wave packets transmitted from Earth to an asteroid reflect back and are received as a radar echo. The bandwidth of the echo power spectrum is proportional to the cross-section of the asteroid presented to the Earth and normal to the line of sight at the time of interaction with the surface, convolved with Doppler shifts in the returned signals caused by the object's rotation. The signal can be built up as the asteroid rotates, producing an image that represents its shape. For objects that have approached the Earth at close enough range to employ this technique, such as (4769) Castalia, (4179) Toutatis, (1627) Ivar, (1620) Geographos, and (433) Eros, the results show shapes varying from slightly nonspherical to very irregular (Figure 27.10). (See Planetary Radar.)

Knowledge of the objects' shapes provides clues to the collisional history of this population. The fact that many NEOs are irregularly shaped implies that they are products of collisions that have knocked off significant chunks of material from a larger body. Images of (433) Eros (Figure 27.11) show it as an ellipsoid measuring $33 \times 10.2 \times 10.2$ km. Its shape is irregular and dominated by large impact craters.

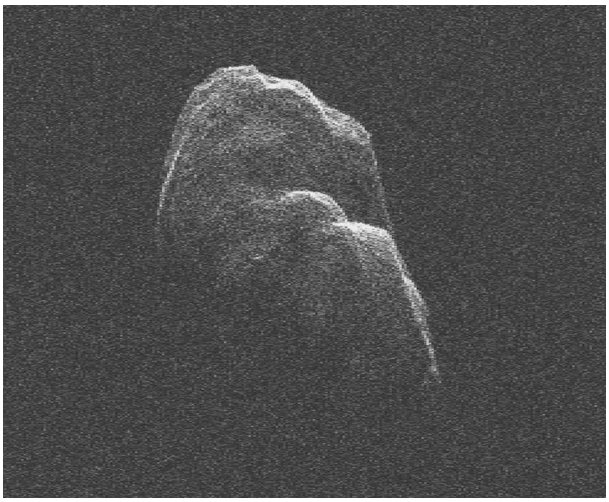

FIGURE 27.10 Radar image of NEO (4179) Toutatis from observations with the 70-m Goldstone Solar System Radar in December 2012 when Toutatis was 6.9 million km from the Earth. The elongated asteroid is about 5 km in length. *Credit: NASA/JPL-Caltech.*

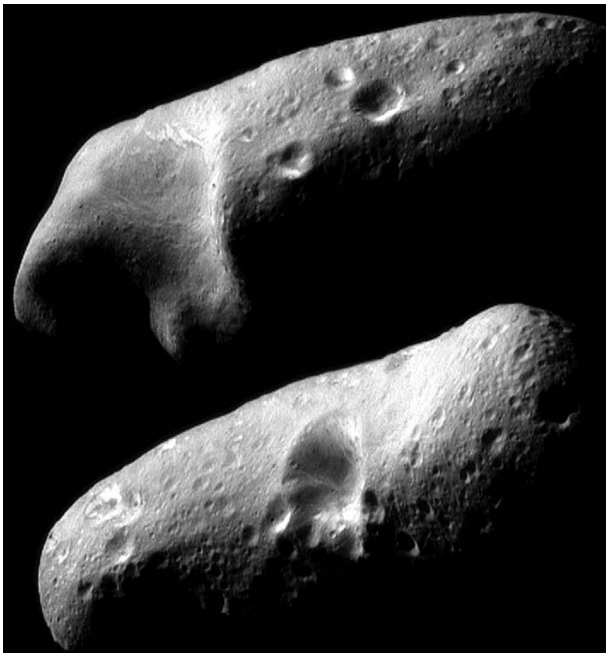

FIGURE 27.11 Asteroid (433) Eros's eastern and western hemispheres. Two mosaics created from six images when the NEAR spacecraft was orbiting 355 km above the surface. Smallest detail is 35 m across. The large depression on the top image is Himeros (10 km across). In the bottom image, the 5.3-km crater Psyche is prominent. Bright exposures can be seen on interior walls of craters. *Credit: NASA/JHU/APL.*

5.3. Rotation Rate

As a result of their proximity to Earth, NEOs are the smallest objects in space for which we can measure rotational properties. In some cases, the rotation rates for NEOs smaller than about 150 m are 100 revolutions per day or faster (i.e. they have rotation periods of just a few minutes). These objects are likely to be relatively strong and intact rock fragments. Larger objects that spin substantially slower may be less strong "rubble piles" composed of individual fragments or fractured rock held together only by gravity. A rubble pile without any cohesion must spin at a rate slower than once every 2.2 h (the so-called "spin barrier"), or else it will fly apart (Figure 27.12). Recent results indicate that dust particles between the components of a rubble pile may provide some cohesion, in which case some rubble piles may spin faster than the 2.2-h limit. Interestingly, the primary bodies of binary NEOs tend to have spin rates close to the spin barrier, consistent with the idea that a binary NEO forms when the spin rate of a rubble pile increases to the point of partial breakup (see Section 5.5). Thus, studies of the rotation rates of NEOs provide insight into the likely range of internal structures occurring within small bodies in our solar system.

5.4. Size and Albedo

Size and albedo are two of the most fundamental physical properties of asteroids, especially for considerations of the impact hazard. The albedo of a surface is a measure of its reflectivity. The so-called visual geometric albedo, normally denoted p, with a subscript for the photometric band (e.g. p_V for visual geometric albedo), is the ratio of the body's brightness at zero solar phase angle (i.e. as seen from the direction of the Sun) to the brightness of a perfectly diffusing disk with the same apparent size and at the same position as the body. The albedos of planetary surfaces depend on their compositions and physical properties. A crude method of estimating the sizes of asteroids uses their measured brightness and an assumed albedo. This method is referred to as a photometric diameter. It is used when only visual magnitudes are available. The diameter, D, is given by the equation

$$D(\text{km}) = 1329 \times 10^{-H/5} / \sqrt{p_v}$$

where p_V, the visual geometric albedo, is assumed, and H is the magnitude defined by the International Astronomical Union magnitude system for asteroids in the V, or visual bandpass. Unfortunately, the range of asteroid albedos is large, from only a few percent up to 50% or more, producing considerable uncertainty in diameters thus derived. Observations in the thermal infrared ("heat radiation") part of the spectrum allow more accurate determinations of size and albedo to be made. For an object illuminated by the Sun alone, the sum of the reflected and emitted (thermal) radiation from the object (assuming no internal energy sources or sinks) is equal to the total solar radiation on its surface. If the object's distance from the Sun is known, the amount of incident energy on the object's surface can be calculated

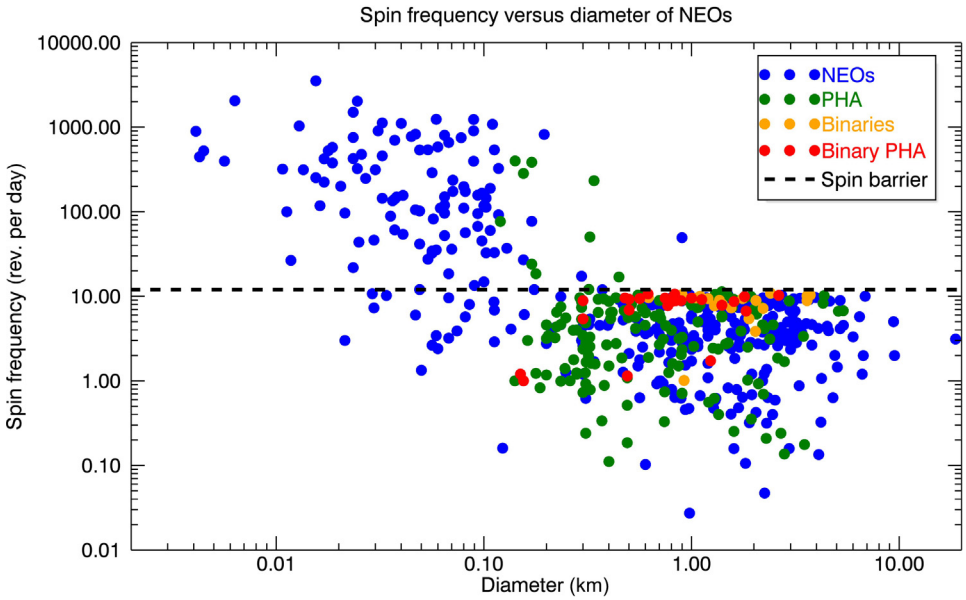

FIGURE 27.12 NEO rotation rates versus size. Very few objects with diameters larger than 200 m spin faster than one rotation per 2.2 h or 10.9 rev. per day, suggesting that the majority have insufficient cohesion to prevent break up at faster spin rates and may be rubble piles or monolithic objects with low tensile strength.

from knowledge of the Sun's radiation output. By measuring the reflected (visible) and reemitted (thermal infrared) components of radiation, and with some assumptions on the body's shape and physical characteristics of its surface, one can derive its diameter and estimate its albedo (Figure 27.13). The two parameters, diameter and albedo, are derived in tandem, with the requirement that the sum of the reflected and emitted components is equal to the incident **solar flux**. The albedo is an important indicator of the mineralogical composition of an asteroid.

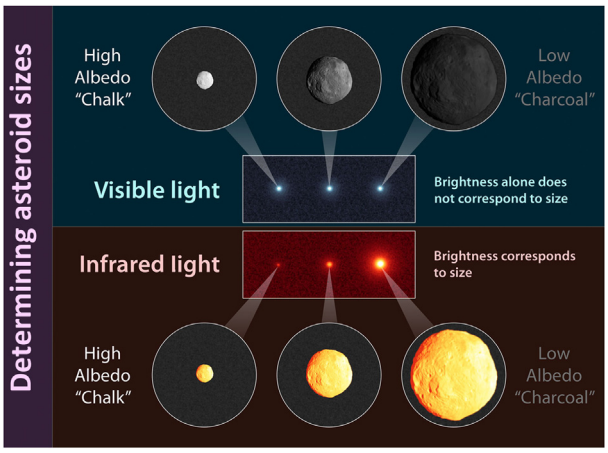

FIGURE 27.13 Upper frame: seen from a distance in a telescope, a large dark asteroid appears as a point source of light with the same brightness as a small, light one. The brightness of an asteroid viewed in visible light is the result of both its albedo and size. Lower frame: in infrared light, the brightness of the object is mainly determined by its size and is not strongly affected by its albedo, i.e. how light or dark its surface is. When visible and infrared measurements are combined, the sizes and albedos of asteroids can be more accurately determined. *Credit: NASA/JPL-Caltech.*

For main-belt asteroids, two models incorporating the above procedure have proved to be useful. The asteroid standard thermal model (STM) assumes that the asteroid is spherical and slowly rotating (and/or has practically no thermal inertia, as would be the case for a surface of fine dust). The so-called fast rotating model (FRM) caters to the other extreme, in which the object rotates rapidly (and/or has a large thermal inertia, as would be the case for solid rock). For most large main-belt asteroids, the STM appears to be applicable and gives reasonably accurate diameters and albedos. However, due to their proximity to the Earth, observed NEOs tend to be smaller than most observed main-belt asteroids and many appear to have surfaces dominated by rubble rather than dust (e.g. see the image of Itokawa in Figure 27.17 below).

Furthermore, in contrast to main-belt asteroids, NEOs are often observed at large solar phase angles, which cause much of the thermal emission to be directed away from the observer. It was found that the simple approach to size and albedo measurements based on the STM and FRM often gave large errors when applied to NEOs. A more sophisticated approach is offered by the near-Earth asteroid thermal model (NEATM), developed by one of us (AWH), which more accurately accounts for the observing geometry and allows an additional adjustment to the model surface temperature resulting in better agreement with the observed infrared thermal emission.

Surveys of the sizes and albedos of hundreds of NEOs using the NEATM have been carried out by the NASA

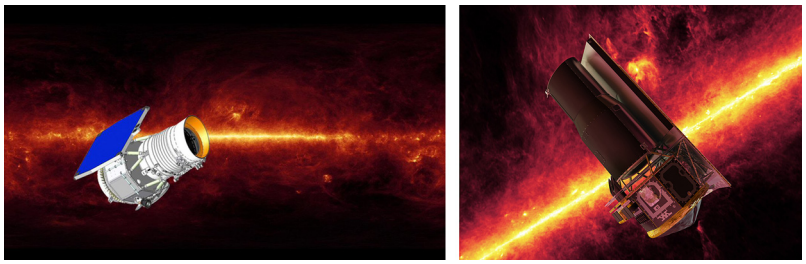

FIGURE 27.14 Artist's impressions of the WISE (left) and Spitzer Space Telescopes (right). *Credit: NASA/JPL-Caltech/R. Hurt, SSC.*

WISE and Spitzer (Figure 27.14) infrared space telescopes. WISE was launched to Earth orbit in December 2009 carrying a 40-cm-diameter telescope and infrared detectors. WISE surveyed the sky for 12 months and observed a total of at least 584 NEOs, of which more than 130 were new discoveries. Spitzer, carrying an 85-cm-diameter telescope, was launched in August 2003 and inserted into an Earth-trailing orbit (i.e. it orbits the Sun just outside the Earth's orbit and thus trails behind the Earth in space). Spitzer has been used to observe some 600 previously detected NEOs to study the size and albedo distributions of the NEO population and identify NEOs that may have a cometary origin (see Section 3.3.2) or that could serve as accessible and scientifically interesting targets for future robotic or manned space missions.

Extrapolation of the WISE data implies that there are a total of 981 NEOs with a diameter of 1 km or more in the NEO population, of which nearly all have been found. The number of objects rises dramatically with decreasing size (see Figure 27.8): the number of objects with diameters larger than 100 m is estimated to be 20,500, of which approximately 25% have been found.

5.5. Density

Knowledge of the bulk density of an asteroid can provide insight into its internal structure. Many asteroids are known to have bulk densities much lower than the densities of the minerals of which they are composed, as evidenced by the relatively high densities of meteorites. The commonly accepted reason is that there are voids and cavities between the individual fragments making up rubble pile asteroids and/or the highly porous nature of some types of asteroid.

There are various methods of determining asteroid densities, which in effect all require measurement of the object's mass and size, or their ratio. Asteroid masses can be determined by means of, for example, a spacecraft, observations of the perturbations of the orbits of other asteroids or Mars (applicable to large asteroids only), or observations of a satellite or companion asteroid in a binary system by means of precision optical or radar observations. Asteroid sizes can be determined from, for example, spacecraft, thermal-infrared measurements (Section 5.4), radar observations, and **occultation** observations. In the special case of a binary asteroid, the density, ρ, can be estimated from telescope observations using Kepler's third law. For example, if we assume for simplicity that the moon's mass is much smaller than that of the primary asteroid, and the latter is spherical, $\rho = 24\pi a^3/D^3GP^2$ where P is the period of revolution, G is the universal gravitational constant, and a/D is the ratio of the **semimajor axis** of the moon's orbit to the diameter of the primary. Both the period, P, and the ratio a/D can be derived from observations of the light curve of an eclipsing binary system. Using this method, the densities of a number of asteroids in binary systems have been estimated, including that of the NEO 1996 FG_3, which at 1.4 g/cm^3 is very low compared to values of 3–5 g/cm^3 typical of most meteorites. Similar density results for other binary systems suggest that rubble pile structures may be a characteristic of binary systems and, indeed, a necessary prerequisite for their formation: a rubble pile that is spun up by the gravitational effects of a close approach to a planet, for example, may partially break up with the result that a large fragment ends up in orbit around the primary mass.

5.6. Color and Taxonomy

Since the early part of the twentieth century, astronomers have recognized that small bodies come in different colors. As observational techniques evolved and the ability to investigate them improved, the number of observable characteristics increased. Sorting objects into meaningful groups is the process of classification or taxonomy. Asteroid taxonomy developed in response to advances in observing techniques and new technology in the field of stellar photometric astronomy. The intention of a classification scheme is to reflect the compositional variations and thus provide clues on a body's origin and evolution. Astronomers are constantly attempting to test and refine the asteroid taxonomy by employing new statistical methods and extending the number of meaningful parameters that are included in the classification process, while eliminating meaningless or redundant parameters. Today, the alphabet soup of asteroid taxonomy extends to about 13 main types

denoted by letters and about the same number of subtypes denoted by subscripted letters. The taxonomy too has evolved, and it is important to be aware of which system is being referred to and what its exact definitions are. (See Asteroids.)

NEOs have representatives from practically all taxonomic types, indicating that many locations in the Asteroid Belt feed the near-Earth population. About 90% of known NEOs fall in the S-, Q-, C-, and X-complexes (a complex is a grouping of taxa from different instrument types and different taxonomies combined into a general category that can encompass all available observations). Some 65% of observed NEOs are bright and members of the S- (40%) or Q- (25%) complexes. When considering the observed ratio of dark objects to bright, there are around twice as many bright objects observed compared to dark ones in the NEO population. However, darker objects are more difficult for visible light telescopes to discover and measure. Accounting for discovery biases is important when studying NEOs using an incomplete sample.

5.7. Mineralogy

By measuring the relative amount of reflected sunlight from the surface of an object as a function of wavelength of the light (a reflectance spectrum), it is possible to constrain its surface mineralogy. Astronomers find that the spectra of some 80% of NEOs studied spectroscopically contain two strong absorption bands, one in the ultraviolet (UV) with a band centered below 0.35 μm and the other in the near infrared near 1 μm. Sometimes a second near-infrared band is observed at a wavelength of 2 μm. Other objects do not display prominent absorption bands: they are found to be featureless and either flat or sloped. Most often an object with a featureless spectrum also has a low albedo. Figure 27.15 shows spectral reflectance measurements of some NEOs. Three spectra have prominent UV and near-infrared absorption bands that are common in silicate minerals. The broad band at 1 μm of asteroid (5641) McCleese is diagnostic of a mineral called olivine. Subtle differences in the position of the center of the band constrain the chemistry of the olivine, which can accommodate a range of magnesium and iron in its mineralogical structure. The presence of a second absorption near 2 μm indicates that a second silicate, pyroxene, is present.

The spectrum of (433) Eros contains both olivine and two types of pyroxene. Detailed spectral analysis and modeling suggest the presence of an additional component that may be a glassy material, or possibly vapor-deposited coatings of nanometer-sized iron grains. They are inferred because the brightness of the spectrum is lower than that of mixtures of only crystalline silicates. These mineral

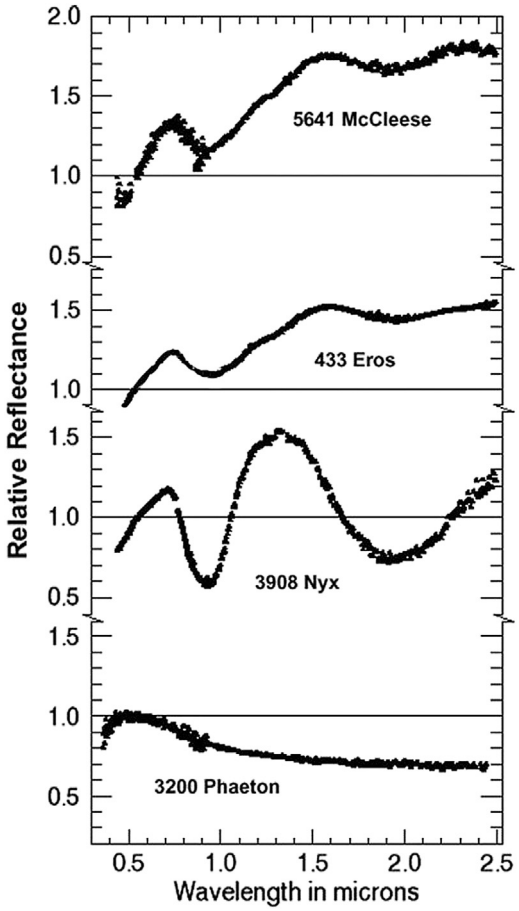

FIGURE 27.15 Spectral reflectance measurements of four NEOs. The range of spectra reflects the range of surface characteristics, including mineralogy and particle sizes, of the surface material.

constituents are present in ordinary chondrite meteorites (See Meteorites.); the deviation from ordinary chondritic composition and the processes controlling it have been studied and ascribed to **space weathering** and/or partial melting.

The spectrum of asteroid (3908) Nyx in Figure 27.15 is dominated by pyroxene and has the same spectral characteristics as the basaltic achondrite meteorites. This asteroid may be a fragment of the large main-belt asteroid, (4) Vesta. (See Main-Belt Asteroids.)

The lower spectrum in Figure 27.15 is characteristic of a subgroup of C types, labeled B. There is no UV absorption and not much of an infrared absorption. Interpretation of this spectrum is uncertain. This asteroid, (3200) Phaethon, is a candidate for an extinct comet, although its albedo (about 10%) is higher than most comets observed to date (about 4%). The range of variations in the mineral composition of NEOs reflects that seen in the Main Asteroid Belt, indicating that NEOs are mostly derived from the main belt.

A ridge winding almost around the entire asteroid is called Rahe Dorsum; fractures are at the end of Rahe Dorsum, and grooves are evenly spaced and may have raised rims. *Credit: NASA/JHU/APL.*

6. IN SITU STUDIES

6.1. NEAR Shoemaker

The NEAR Shoemaker spacecraft, named in honor of planetary scientist Gene Shoemaker, was launched from Cape Canaveral, Florida, in February 1996, on a 3-year journey to asteroid (433) Eros. NEAR orbited Eros for 1 year in 2000–2001, training its six scientific instruments on the asteroid's surface. It provided the first detailed characterization of an NEO's chemical and physical properties. The objective was to study Eros' relationship to meteorites, the nature of its surface and collisional history, as well as aspects of its interior state and structure.

Orbital imaging of Eros revealed an irregularly shaped body dominated at the global scale by both convex and concave forms, including a 10-km-diameter depression named Himeros, and a 5.3-km bowl-shaped crater named Psyche. At scales of 1 km–100 m, (Figure 27.16) there are grooves and ridge patterns superimposed on a heavily cratered surface, mostly covered by overlapping craters. At the <100-m scale, the surface is dominated by boulders, evidence of downslope movement, and ponding of material in crater bottoms, all of which indicate regolith accumulation and transport. There are not many craters with diameters less than 100 m. Evidence of structural strength on the asteroid includes chains of craters, sinuous and linear depressions, ridges and scarps, and rectilinear craters.

Eros is not a gravitationally bound rubble pile. Rather, it is a fragment of a once larger body, possessing cohesive strength throughout. Both gravitational forces and mechanical strength play a role in the formation and evolution of Eros. Its density of 2670 ± 30 kg/m^3 is low compared to ordinary chondrite meteorites of 3400 kg/m^3 that have approximately the same composition as Eros. By considering the porosity of each meteorite and its relation to a much larger asteroid, the macroporosity of Eros is determined to be 20%, most likely due to collisional fragmentation throughout Eros' interior.

Figure 27.17 shows an image of Eros from the NEAR mission alongside the much smaller NEO (25143) Itokawa. Itokawa was the target of the Japanese **rendezvous** mission Hayabusa.

6.2. Hayabusa

The Japanese Hayabusa spacecraft was launched in 2003 and started its 3-month **rendezvous** with the NEO Itokawa in 2005. It observed Itokawa with four instruments: an imaging camera with eight filters, a near-infrared spectrometer, a laser ranging instrument, and an X-ray fluorescence spectrometer. At the end of this period, the spacecraft collected a sample from the surface of Itokawa and returned it back to the Earth, where the sample capsule containing ~1500 grains (mostly in the 10–50 μm size range) landed in 2010. Since then these grains have undergone analysis in laboratories around the world.

Itokawa is a stony-type (=S-type) asteroid with a 12.1-h rotation period. The size of the asteroid is $535 \times 294 \times 209$ m. The science team remarked that it was shaped like a

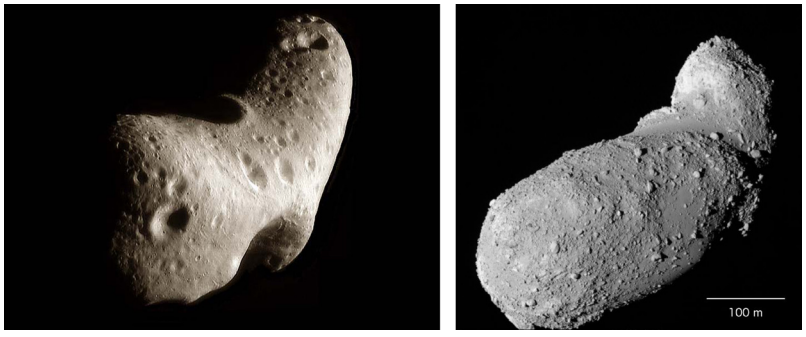

FIGURE 27.17 Near-Earth asteroid (433) Eros (left) was the target of the NASA NEAR Shoemaker spacecraft in 2000–2001. Eros is 34 km in length. The large number of impact craters indicates an age of 1–2 billion years. (Credit: JHUAPL, NASA.) Near-Earth asteroid (25143) Itokawa (right) was the target of the Japanese Hayabusa spacecraft in 2005–2006. Itokawa is 535 m in length. Itokawa, which lacks craters, is much younger than Eros and may be an **aggregate** of components weakly bound by gravity ("rubble pile"). *Credit: JAXA.*

sea otter with a head and a body (Figure 27.17). About 80% of the surface is considered to be rough terrain, with many boulders ranging in size from a few meters to 50 m; the largest, named Yoshinodai, is one-tenth the size of the whole asteroid. It has been proposed that Itokawa is the result of a gravitational reaccumulation of some of the pieces of a larger parent body that underwent a collisional breakup, i.e. a rubble pile. Scientists count boulders, rather than craters, on Itokawa to understand its impact history.

The rough terrains of Itokawa have experienced less processing, e.g. less breaking up, sorting, and transporting of material over its lifetime, than other small bodies such as Eros and the Martian moon Phobos. The smooth terrain (called seas) covers 20% of the body, is featureless, and has few boulders. At closest range, the spacecraft resolved centimeter- to millimeter-sized grains, the size of pebbles, in the smooth areas. Itokawa has few craters, although the remnants of some are just visible, almost erased by debris from both impacts and global shaking, which has filled in craters with fine material over time. Evidence of grain migration can be seen in the shapes of the particles returned to the Earth by Hayabusa: some of them have rounded edges, in contrast to the shapes of lunar grains. The composition of the grains is 64% olivine, 22% pyroxene, 11% plagioclase, and 3% other minerals.

One of the main mission goals was to test the theory that the most common meteorite type found on the Earth, the ordinary chondrites (See Meteorites), comes from S-type asteroids, and that the differences in the spectra of ordinary chondrite meteorites and S-type asteroids are due to "**space weathering**", i.e. the action of solar radiation and micrometeorite bombardment on the optical characteristics of the surface material. Analyses of the grains from Itokawa in the laboratory are in agreement with the theory. The mineral chemistry of the grains is very similar to that of thermally processed ordinary chondrites, and half the grains tested showed the surface modification expected from **space weathering**.

With a mass of 3.510×10^{10} kg and a volume of 1.840×10^{7} m^3, Itokawa's density is 1900 kg/m^3, which is lower than that of other S-type asteroids. Based on the measured bulk density of ordinary chondrites, the macroporosity of Itokawa is estimated to be 39%, twice as high as that of Eros and, in fact, soils on the Earth. The absence of linear features extending the length of the body, the presence of local flat areas tens of meters long, and the high porosity are consistent with the assessment that Itokawa is a rubble pile asteroid.

7. IMPACT HAZARDS

While this chapter was in preparation, an asteroid with a diameter of about 17−20 m entered the Earth's atmosphere over Russia at a speed of 18 km/s producing a brilliant fireball and a blast wave that injured some 1500 people in the town of Chelyabinsk and caused considerable damage to buildings (Figure 27.18). The event, which occurred on February 15, 2013, was estimated to have an explosive energy equivalent to 500 kt of **TNT** and was the most damaging of its kind since June 1908, when a somewhat larger object exploded in the atmosphere, destroying 80 million trees in the Tunguska region of Siberia. It is a rather unsettling coincidence that the Chelyabinsk event should happen on the very same day that a 30-m-diameter asteroid, 2012 DA_{14}, passed exceptionally close to the Earth at a distance from the surface of only 28,000 km! It has since been established that there is no connection between the Chelyabinsk asteroid and 2012 DA_{14}, which were on completely different orbits around the Sun and of different taxonomic types. The Chelyabinsk asteroid was not detected prior to its appearance as a fireball due to the fact that it approached from a direction too close to the Sun (Figure 27.19). In contrast, the nature of the orbit of 2012 DA_{14}, and its larger size, enabled it to be discovered 12 months before its close approach. The events of February 15, 2013, were a dramatic reminder that space near the Earth is not empty, and that NEOs can cause devastation on our planet.

FIGURE 27.18 The trail left by the Chelyabinsk **bolide**. The left part of the image shows the condensation trail of at least two pieces of the original **bolide**. One piece apparently disintegrated near the center of the image. *Credit: Wikimedia Commons.*

Much larger objects frequently pass uncomfortably close to our planet: (99942) Apophis, a potentially hazardous asteroid with a diameter of about 300 m discovered in June, 2004, is scheduled to miss the Earth's surface by only about 31,000 km in April 2029. Apophis will pass by at a lower altitude than that of **geostationary** communications and television satellites, as did 2012 DA_{14}. Furthermore, the presence of large impact craters on the Earth's surface (around 180 have been confirmed to date) serve to warn us that occasionally very large objects strike the Earth. There are two aspects of the collision hazard to be considered: the magnitude of the collisions and their frequency.

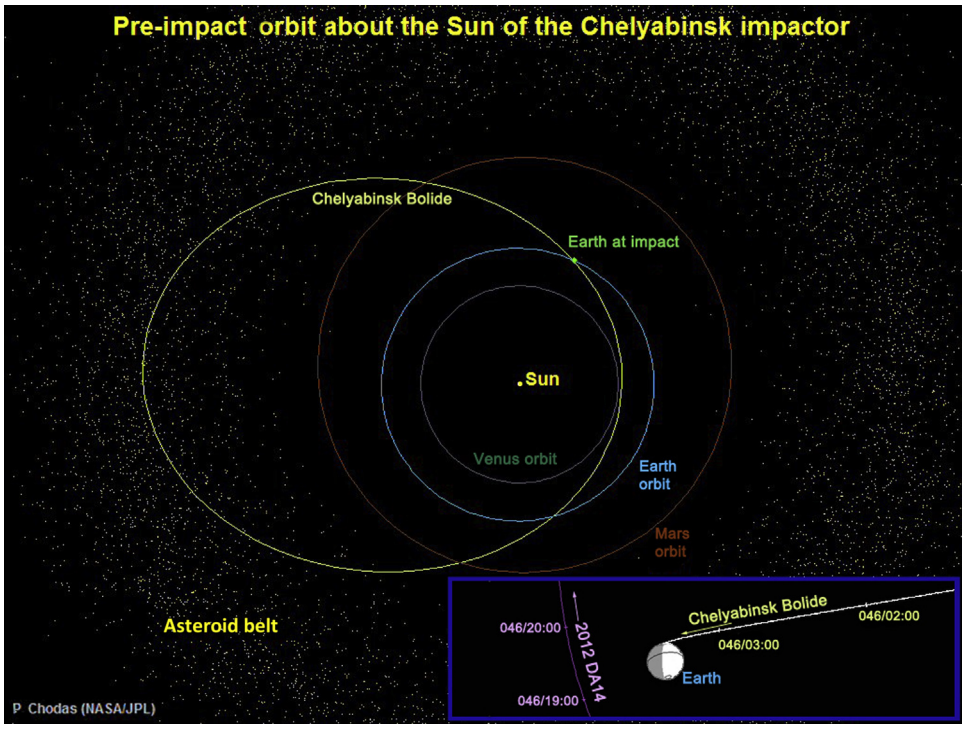

FIGURE 27.19 Heliocentric orbit of the asteroid that impacted near Chelyabinsk, Russia, on February 15, 2013. The fact that the object approached the Earth from the daylight sky prevented it from being discovered prior to its entry into the atmosphere. The inset, bottom right, shows the tracks of the Chelyabinsk bolide and 2012 DA_{14} near the Earth on February 15, 2013 (day 46). The tick marks on the tracks give the positions of the objects at various Universal Times. The inset demonstrates that the two objects had completely different orbits, implying that they were unrelated. *Credit: Paul Chodas, Courtesy NASA/JPL-Caltech; inset adapted from a diagram by Dan Adamo. Both figures are taken from the NASA/JPL Near-Earth Object Program website: http://neo.jpl.nasa.gov/news/fireball_130301.html.*

7.1. Collision Magnitude

The primary physical parameter of concern is the energy of the collision and particularly the kinetic energy transferred to the Earth. The controlling parameters are mass and velocity, according to the relation

$$E = 1/2\ mv^2$$

The energy of an impact is proportional to the mass of the impactor. Objects that are larger than a kilometer in diameter can cause significant damage on a global scale by triggering changes in the climate that would affect vital human activities such as agriculture. Objects smaller than a kilometer, down to 30–50 m in diameter, still pose a significant regional threat, having the potential to lay waste to large cities or urban areas.

Energy is also proportional to the square of the velocity, so a high-velocity object will have considerably higher impact energy than relatively slow-moving objects. Most NEOs have orbital velocities similar to that of the Earth when nearby, about 30 km/s, but because their orbits are often inclined or more eccentric than the Earth's orbit, there is still a significant relative velocity. Objects in highly eccentric and/or inclined orbits, such as comets, can have tremendous impact energy.

Any object approaching the Earth is accelerated by the Earth's gravity. The minimum velocity of any object entering the Earth's atmosphere is equal to the Earth's escape velocity, 11.8 km/s. So even NEOs with an orbital velocity differing little from that of the Earth's will have quite significant kinetic energy when they hit the ground. Assessment of the damage that a particular impact will impart to the Earth is based on how much energy any particular location can absorb and whether or not that location can recover from an impact. Small objects, in the size range of a meter to a few tens of meters, normally break up in the Earth's atmosphere, leaving perhaps only scattered fragments.

Craters are produced by impacts with energies greater than about 4.2×10^{16} J, or 10 Mt of **TNT**. (See Planetary Impacts; Meteorites.) Impacts with energies of an order of magnitude greater, corresponding roughly to an impactor diameter of 100 m (and the energy released in the largest H bomb detonation), can impart regional damage, potentially destroying areas within a 25 km radius. Of further concern is that an impact into the ocean might induce tsunamis that would destroy coastal areas. The Cretaceous–Tertiary Event 65 million years ago has been estimated at $>4.2 \times 10^{23}$ J, or 100,000,000 Mt!

Such large impacts occur very infrequently, but they have occurred continuously over the lifetime of the Earth and will continue to occur in the future. Most of the energy from the Tunguska and Chelyabinsk impactors was dissipated in the form of an air burst; it was the shock waves from both objects being torn apart high in the Earth's atmosphere that produced the bulk of the ground damage.

7.2. Collision Frequency

A complete assessment of the situation requires knowledge of the frequency of collisions by objects of different sizes. Objects in the range of hundreds of kilometers in diameter were swept up and incorporated into the planets or dynamically ejected as the solar system formed during the period called the Late Heavy Bombardment. The lunar basins formed during this time, which ended ~3.8 billion years ago. No terrestrial collisions are expected from such large objects today. (See The Moon.)

The impact in the Tunguska region of Siberia in 1908 was most likely a NEO with a diameter of 30–50 m. Interestingly, the Tunguska object did not make a crater because it probably was a weak (heavily cracked) rocky body that broke apart in the atmosphere. Only the shock wave of air from the ~12-Mt explosion reached the ground, felling thousands of square kilometers of remote forest. The frequency of impacts increases exponentially with decreasing size and energy (see Figure 27.8). Small objects a few meters in diameter, such as 2008 TC_3 or 2014 AA (see Section 3.3), enter the atmosphere once or twice a year. Conversely, for larger objects the frequency decreases. On the basis of present, albeit incomplete, knowledge of NEO numbers, we should reckon with an impact that could cause serious damage on the ground (comparable to the Tunguska event) every several hundred years. Present data on the NEO population suggest that the average time interval between impacts of NEOs with diameters of 1 km or more (a catastrophic impact with global consequences) is around 600,000 years. A civilization-threatening impact, such as the one to which the extinction of the dinosaurs 65 million years ago is attributed (diameter of some 10 km, see K-T impactor arrow in Fig. 27.8), would be expected only about every 100 million years. It should be remembered that these estimates are statistical and based on incomplete knowledge of the NEO population and are continually being revised. To assess the overall impact risk, it is imperative to have accurate knowledge of the numbers, sizes, and orbits of NEOs. An object's orbit bears directly on its velocity relative to the Earth in its motion around the Sun. PHOs are monitored closely, worldwide.

There is no need for individuals (except perhaps astronomers) to lose sleep over the impact risk, but preventing occasional serious disruption to our very complex and highly networked society will depend on us developing techniques to deal with the impact hazard. While major impacts in the past have probably altered the evolutionary course of life on the Earth, and paved the way for the dominance of mankind, we would now rather not remain at the mercy of this natural process. Can we protect our civilization from the next serious impact?

Our surveys for NEOs at present remain incomplete, and once an object is discovered, it must be observed over a sufficiently long period for its orbit to be characterized with enough precision to allow it to be tracked into the future. While more than 90% of 1 km and larger near-Earth asteroids have been discovered at present, less than 1% of Chelyabinsk-sized objects have been found, so more work remains to discover, track, and characterize the majority of NEOs. Research into developing improved survey and follow-up systems is ongoing.

7.3. Mitigation Measures

At present, there is no general agreement on the most effective strategy to adopt in the case of a predicted impact. In the case of an object with a diameter below 50 m, the best course of action may be to simply evacuate the region around the predicted impact point, assuming there would be sufficient advance warning (only a small fraction of the asteroids in this size category have been discovered to date). For objects larger than 100 m, serious scientific and technological research is in progress to investigate methods of mitigation. A technique that has been the subject of several studies is the so-called kinetic impactor (Figure 27.20), which involves accurately guiding a massive spacecraft to the target at a high relative velocity, causing a transfer of momentum to it. Such an impactor would thereby slightly change the velocity and orbit of the NEO so that it misses the Earth. The change of momentum of the target asteroid would depend on its structure (rubble pile?) and the amount of ejecta produced in the impact, predictions of which would require some prior knowledge of the asteroid's physical properties. A second spacecraft could be used for reconnaissance purposes, to study the mitigation-relevant physical properties of the asteroid prior to the collision and to monitor the course of the asteroid afterward.

Alternative approaches include the "gravity tractor". The gravity tractor relies on the force of gravity between the target asteroid and a spacecraft hovering under power in close proximity to gradually modify the asteroid's orbit. A significant advantage of the gravity tractor is that no contact with the target is required, and the deflection process is largely independent of the structural properties of the NEO.

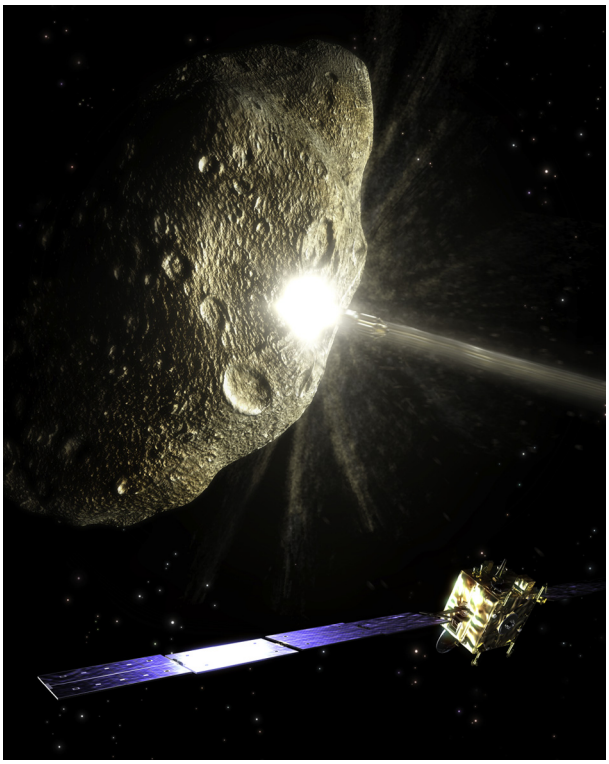

FIGURE 27.20 Artist's impression of a kinetic impactor spacecraft deployed to modify the orbit of a near-Earth asteroid. The second spacecraft at the bottom of the picture is orbiting the asteroid or "hovering" near it to observe the effects of the impact and monitor the altered trajectory of the asteroid. The scenario depicted derives from the Don Quijote mission studies commissioned by ESA in 2006 (ESA-AOES Medialab).

It should be noted that the frequency at which a political decision will be taken to launch a space mission to modify the orbit of a NEO may far exceed the estimated frequency of impacts on the Earth. The distribution of NEOs in near-Earth space is random: For every direct hit there will inevitably be many uncomfortable near misses. Predicting the exact course of a NEO years or decades ahead is subject to considerable uncertainty, therefore decision makers may wish to play safe and deflect a NEO before a direct hit becomes a certainty.

A unique research program funded by the European Commission and involving 13 partner organizations in six countries, including Russia and the United States, was established in 2012 to investigate mitigation techniques in detail. The project, called NEOShield (Figure 27.21), aims to provide solutions to scientific and technical issues that will enable the feasibility of promising mitigation options to be demonstrated in the future via test missions. Research into the mitigation-relevant physical properties of NEOs, including laboratory experiments and associated modeling, is aimed at supporting technological development work leading to the detailed design of demonstration missions.

APPENDIX

Asteroid Numbering and Naming Conventions

Once at least two nights of observations of a newly discovered object are available, the Minor Planet Center (MPC) assigns a provisional designation consisting of the year of discovery followed by a two-letter code (often with a numerical appendage). The first letter of the code indicates the half-month period (Universal Time) in which the object was discovered (A = January 1−15, B = January 16−31, C = February 1−15, etc.; the letters I and Z are not used in this sequence); the second letter is a sequential counter incremented for each discovery made in the same half-month period. Due to the productivity of modern search programs, the number of objects discovered in a half-month period can run into hundreds. To enable provisional designations to be assigned to the 26th, 27th, etc. discoveries in the same half-month period, the sequential part of the designation may contain a numerical appendix. If more than 50 discoveries are made in a half-month period, the second letter is recycled again with the number 2 appended, etc. The appended numbers should, wherever possible, be written as subscript characters, e.g. 1998 SF_{36}. Once an object has been redetected during several subsequent oppositions, it may be assigned a permanent designation, i.e. a number, which is normally enclosed in parentheses and precedes the provisional designation, e.g. (25143) 1998 SF_{36}. As of the end of 2012, there were about 350,000 numbered asteroids. The discoverer of a

numbered asteroid may suggest a name and an accompanying citation, briefly describing the significance of the name. The name and citation have to be approved by the Committee for Small Body Nomenclature of the International Astronomical Union, established in 1994. The assigned name replaces the provisional designation, e.g. (25143) Itokawa (the parentheses are often dropped).

1. INTRODUCTION

1.1. General

In the Western world, 1492 marked the discovery of the New World by the Old, the Spanish Expulsion, and, the oldest documented, preserved, and scientifically studied meteorite fall, a 127-kg stone, which fell in 1492 at Ensisheim in Alsace. A meteorite is named for the nearest post office or geographic feature. The oldest preserved meteorite fall might be Nogata (Japan), an L6, which allegedly fell in 861 (but all associated documentation is more recent) and is in a Shinto shrine there. Recovered meteorites, whose fall was unobserved, are finds, some having been discovered (occasionally artificially reworked) in archaeological excavations in such Old World locations as Ur, Egypt, and Poland, and in New World burial sites. Obviously, prehistoric and early historic man recognized meteorites as unusual, even venerable, objects.

Despite this history, and direct evidence for meteorite falls, scientists began to generally accept them as genuine samples of other planetary bodies only at the beginning of the nineteenth century, initiated by a book published by E. F. F. Chladni in 1794. Earlier, acceptance of meteorites as being extraterrestrial, and thus of great scientific interest, was spotty. One might laboriously assemble a meteorite collection only to have someone later dispose of this invaluable material. This occurred, for example, when the noted mineralogist, Ignaz Edler von Born, discarded the imperial collection in Vienna as "useless rubbish" in the latter part of the eighteenth century. With the recognition

that meteorites sample extraterrestrial planetary bodies, collections of them proved particularly important. In 1943, with the imminent invasion of Germany, the Russian Government planned for "trophy brigades" to accompany their armies and collect artistic, scientific, and production materials as restitution for Russian property seized or destroyed by Nazi armies during their occupation of parts of Russia. Meteorites that fell in Russia, fragments of which were acquired by and housed in German collections, were explicitly identified as material to be seized.

Apart from its recovery and preservation, Ensisheim is a typical fall. For finds, some peculiarity must promote recognition, hence, the high proportion of high-density iron meteorites outside of Antarctica (Table 28.1). Observed falls are taken to best approximate the contemporary population of near-Earth meteoroids.

A meteoroid's minimum initial entry velocity into the Earth's atmosphere is 11.2 km/s. While its maximum velocity could reach 70 km/s, the observed average value is 17 km/s. During atmospheric passage, the meteoroid's surface melts and ablates by frictional heating. Heat generation and **ablation** rates are rapid and nearly equivalent, so detectable heat effects only affect a few millimeters below the surface. The meteorite's interior is preserved in its cool, preterrestrial state. Ablation and fragmentation—causing substantial mass loss and deceleration, often to terminal velocity—leave a dark brown-to-black, sculpted fusion crust as the surface, diagnostic of a meteorite on Earth (Figure 28.1(a)). If it is appropriately shaped perhaps by ablation, a meteoroid may assume a quasi-stable orientation late in its atmospheric traversal. In this case, material ablated from the front can redeposit as delicate droplets or streamlets on its sides and rear (Figure 28.1(b)). The delicate droplets on Lafayette's fusion crust would have been erased in a few days' weathering: it must have been recovered almost immediately after it fell.

The majority of meteorites derive from **asteroids** and, less commonly, from larger parent bodies. In 2012, about 160 individual samples representing about 76 separate falls are known to come from Earth's Moon and about 60 others (120 individual specimens) from planet Mars. Some interplanetary dust particles may also come from these sources, and/or **comets**. Meteorites are rocks and therefore polymineralic (Table 28.2), with each of the 100 or so known meteoritic minerals generally having some chemical compositional range, reflecting its formation and/or subsequent alteration processes. Important episodes during meteorite genesis are shown in Figure 28.2.

1.2. From Parent Body to Earth

If a meteoroid is small enough to be decelerated significantly during atmospheric passage, it may land as an individual or as a shower. A recovered individual can have a mass of a gram or less (as the 1965 fall of the Revelstoke stone (CI) in British Columbia), or up to 60 metric tons (e.g. the Namibian Hoba iron meteorite found in 1920). A meteorite shower results from a meteoroid fragmenting high in the atmosphere, usually leaving a particle trail down to dust size. Shower fragments striking the earth define an ellipse whose long axis—perhaps extending for tens of kilometers—is a projection of the original trajectory. Typically, the most massive fragments travel farthest and fall at the farthest end of the ellipse.

Some falls are signaled by both light and sound displays, others, like the Peekskill meteorite (Figure 28.3(a)),

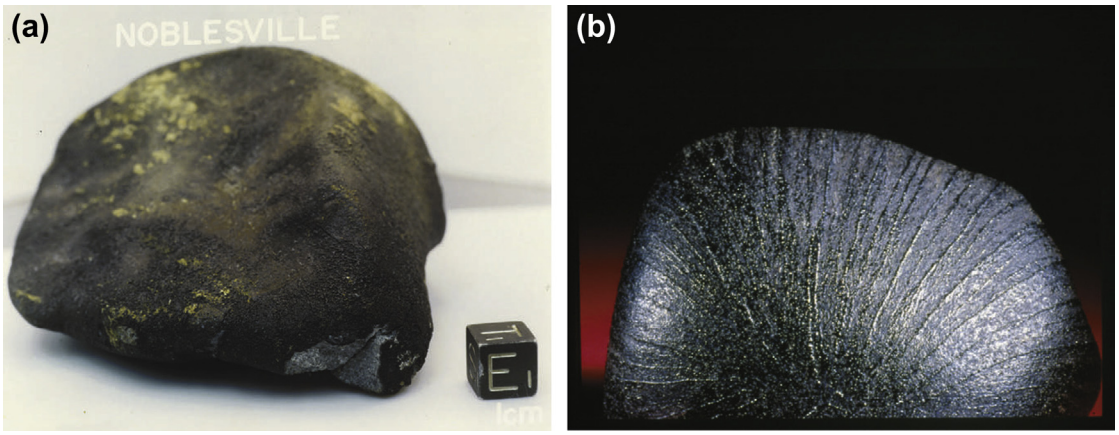

FIGURE 28.1 Fusion crusts: (a) Noblesville H chondrite; (b) Lafayette Martian meteorite. Noblesville, which fell on 31 August, 1991, has nearly complete fusion crust but exposed surface at lower right next to the 1-cm cube shows a genomict (H6 in H4) breccia. (Photo courtesy of NASA Johnson Space Center.) Lafayette exhibits very delicate, redeposited droplets on its sides, indicating an orientation with its top pointing Earthward late in atmospheric traversal. *Photo courtesy of the Smithsonian Institution.*

exhibit a spectacular fireball trail observed over many states. Small falls, like Noblesville (Figure 28.1(a)) fall silently and unspectacularly, and, when recovered immediately after fall, have cold to slightly warm surfaces. The temperature of the interior of a meteorite is not affected by the passage through the atmosphere.

Large meteoroids—tens of meters or larger—are not decelerated much by atmospheric transit and, with an appropriate trajectory, may ricochet off the Earth's atmosphere (Figure 28.3(b)) or strike it at full velocity, which is >11.2 km/s. Such explosive, crater-forming impacts can do considerable damage. The 1.2-km-diameter Meteor Crater (Figure 28.3(c)) in northern Arizona formed about 50,000 years ago by the impact of a 30- to 40-m-diameter meteoroid, yielded fragments now surviving as Canyon Diablo iron meteorites. At least 180 terrestrial craters exhibit

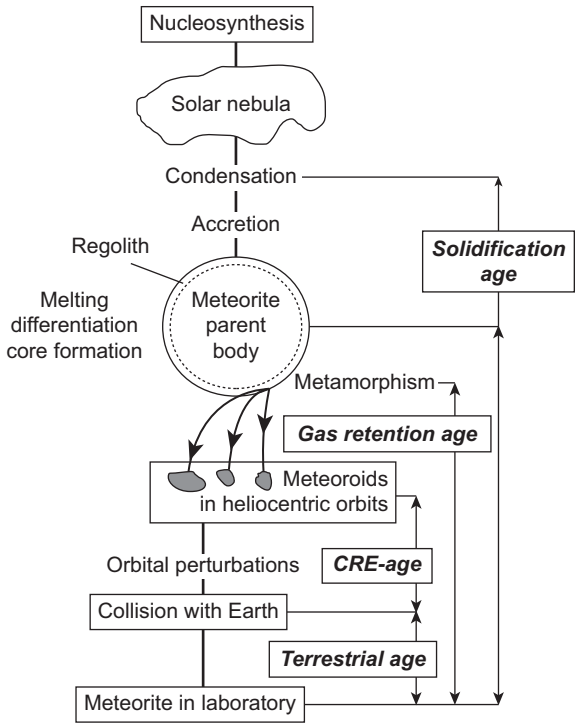

FIGURE 28.2 From nebula to meteorite: genetic processes and the corresponding age determinable for each process. Nuclides of nearly all elements were formed by nuclear reactions in interiors of large stars, which then ejected them in very energetic supernova events. Ejected nebular gas and dust subsequently nucleated, condensed, and accreted into primitive bodies. Source bodies for most meteorites were heated, causing solid state metamorphism or, at higher temperatures, differentiation involving separation of solids, liquids, and gases. As a body evolved, it suffered numerous impacts and, if atmosphere-free, its surface was irradiated by solar and galactic particles that embedded in the skins of small grains and/or caused nuclear reactions. Larger impacts ejected fragments that orbited the Sun. Subsequently, orbital changes caused by large-body gravitational attraction placed meteoroids into Earth-crossing orbits allowing their landing and immediate recovery (as a fall) or later (as a find). Each process can alter elemental and/or isotopic contents: which affected a given meteorite and the time elapsed since it occurred are definable.

features believed to be produced only by intensive explosive impact of a large meteoroid or perhaps even a comet nucleus. The 180-km-diameter Chicxulub feature in Yucatan, Mexico, is the impact site of a 10-km meteoroid. By consensus, this impact generated the climatic consequences responsible for the extinction of ~60% of then-known species of biota—including dinosaurs—ending the Cretaceous period and beginning the Tertiary, 65 Ma ago. Other, less well-established events are suggested as having caused extinctions at other times.

Some meteorites have struck man-made objects. The Peekskill stone meteorite with a recovered mass of 12.4 kg ended its journey in a car trunk (Figure 28.3(d)). Its descent in1992 was videotaped over a five-state area of the eastern United States by many at Friday evening high school football games (Figure 28.3(d)), yielding a well-determined **orbit** (see Figure 28.13). Two authenticated reports of humans hit by meteorite falls exist. The first involved a 3.9-kg stone (the larger of two fragments), which, after passing through her roof in Sylacauga, Alabama, in 1954 struck a recumbent woman's thigh, badly bruising her. The second involved a 3.6-g piece of the Mbale (Uganda) meteorite shower in 1992, which bounced off a banana tree and hit a boy on the head. An undocumented report tells of a dog being killed by a piece of the 40-kg Nakhla meteorite shower in 1911 near Alexandria, Egypt. This, incidentally, is one of the martian meteorites.

Meteorites may impact anywhere on Earth and, as of April 2012, the numbers of known falls and isolated, non-desert-cluster finds are 1100 and 3534, respectively (cf. Table 28.1). For these, it is readily established whether meteorite fragments found nearby are from the same meteoroid. Such linkages are difficult for the very numerous meteorite pieces found clustered in hot or cold (Antarctic) deserts since 1969. So far, starting in 1969, but mainly since 1976, Antarctica yielded about 30,000 fragments, hot desert clusters in Australia, North Africa (mainly Algeria, Libya, and Morocco), and Oman about 10,000 more. These discoveries are possible in these areas because dark meteorites can be readily distinguished from the local, light-colored terrestrial rocks, "meteorwrongs". The 14 million km^2 ancient Antarctic ice sheet is a meteorite trove because of the continent's unique topography and its effect on ice motion, which promotes the meteorites' collection, preservation, transportation, and concentration (Figure 28.4). Assuming four fragments per meteoroid, Antarctic meteorites recovered thus far correspond to more than 8000 different impact events.

After **chondrites** fall on Earth, their survival times as recognizable objects are limited by oxidation, mainly of small metal grains in them. Antarctic survival times are longer than those of other desert finds because most of their terrestrial residence is spent frozen in the ice sheet, where chemical reaction rates are much slower. The high number of desert finds is also the result of slower weathering rates.

2. METEORITE CLASSIFICATION

2.1. General

Meteorites, like all solar system matter, ultimately derive from primitive materials that condensed and accreted from the gas- and dust-containing presolar disk. Most primitive materials were altered by postaccretionary processes—as in lunar, terrestrial, and martian samples—but some survived essentially intact, as specific chondrites or inclusions in them. Some primitive materials are recognizable unambiguously (albeit with considerable effort), usually from isotopic abundance peculiarities; others are conjectured as unaltered primary materials. Postaccretionary

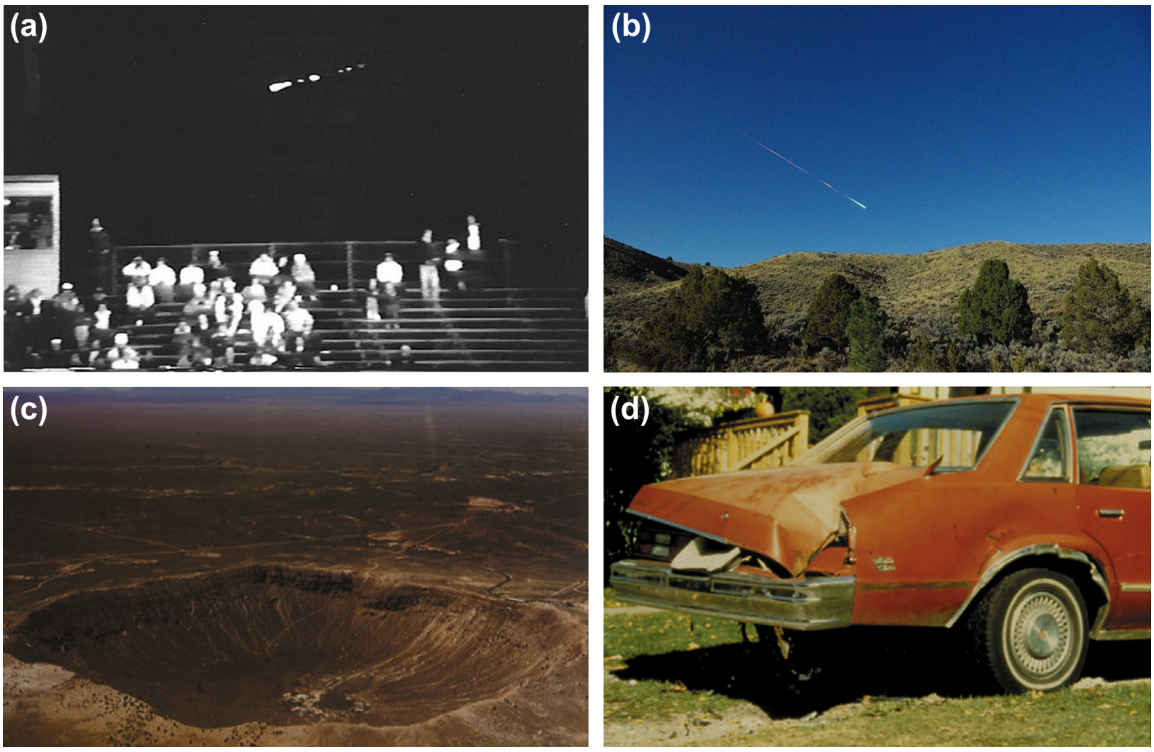

FIGURE 28.3 Large meteoroids: (a) From the videotape record of the Peekskill meteoroid during its atmospheric traverse on 9 October, 1992. During fragmentation episodes such as this one (over Washington D.C.), large amounts of material fell but none were recovered. (b) Meteor of the Sutter's Mill carbonaceous chondrite that fell on May 3, 2012. (c) The 1-km diameter Meteor Crater in Arizona formed by the explosive impact of the Canyon Diablo IA octahedrite meteoroid about 50 ka ago (photo by Allan E. Morton). FIGURE 28.4 Cross-section of Antarctic ice sheet and sub-ice topography: meteorites fall (1), are collected by the ice sheet and buried (i.e. preserved), transported, and concentrated near a barrier to the ice sheet (2), and exposed by strong South Polar winds that ablates the stagnant ice (3). *Reprinted from Workshop on Antarctic Glaciology and Meteorites, C. Bull and M. E. Lipschutz (Eds.) LPI Tech. Rept. 82-03, 57 pp. Copyright 1982 with kind permission from the LPI, Houston, TX.*

processes produced obvious characteristics that permit classification of the thousands of known meteorites into a much smaller number of types. Many classification criteria contain genetic implications, which we now summarize.

At the coarsest level, we class meteorites as irons, stones, or stony-irons from their predominant constituent (Figure 28.5(a)); each can then be classified by a scheme with genetic implications (Figure 28.5(b)). Stones include the very numerous, more-or-less primitive chondrites (Figures. 28.6(a) and (b)) and the **achondrites** (Figure 28.6(d)), of igneous origin. Irons (Figure 28.6(e)), stony-irons (Figure 28.6(c)), and achondrites are differentiated meteorites, formed from melted chondritic precursors by secondary processes in parent bodies. During melting, physical (and chemical) separation occurred, with high-density iron sinking to form pools or a core below the lower density achondritic parent magma. Ultimately, these liquids crystallized as parents of the differentiated meteorites, the irons forming parent body cores or, perhaps, dispersed "raisins" within their parent.

Stony-iron meteorites are taken to represent metal-silicate interface regions. Pallasites (Figure 28.6(c)), having large (centimeter-sized) rounded olivines embedded in well-crystallized metal, resemble an "equilibrium" assemblage that may have solidified within a few years but that

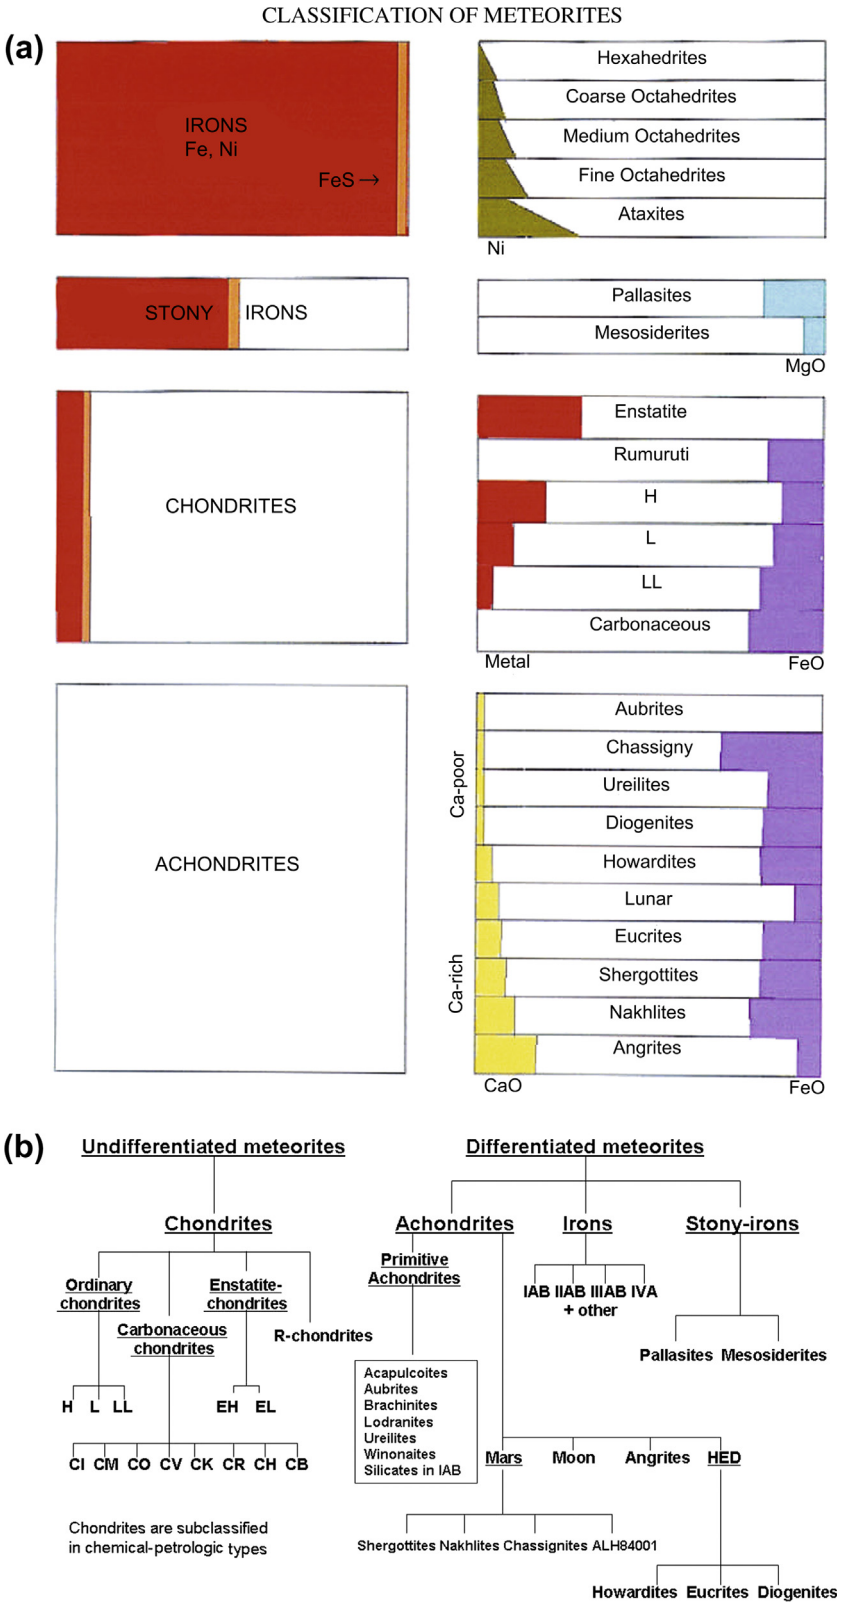

FIGURE 28.5 Meteorite classifications: (a) the most common classes and some chemical-petrologic classification criteria; (b) genetic associations involving meteorites.

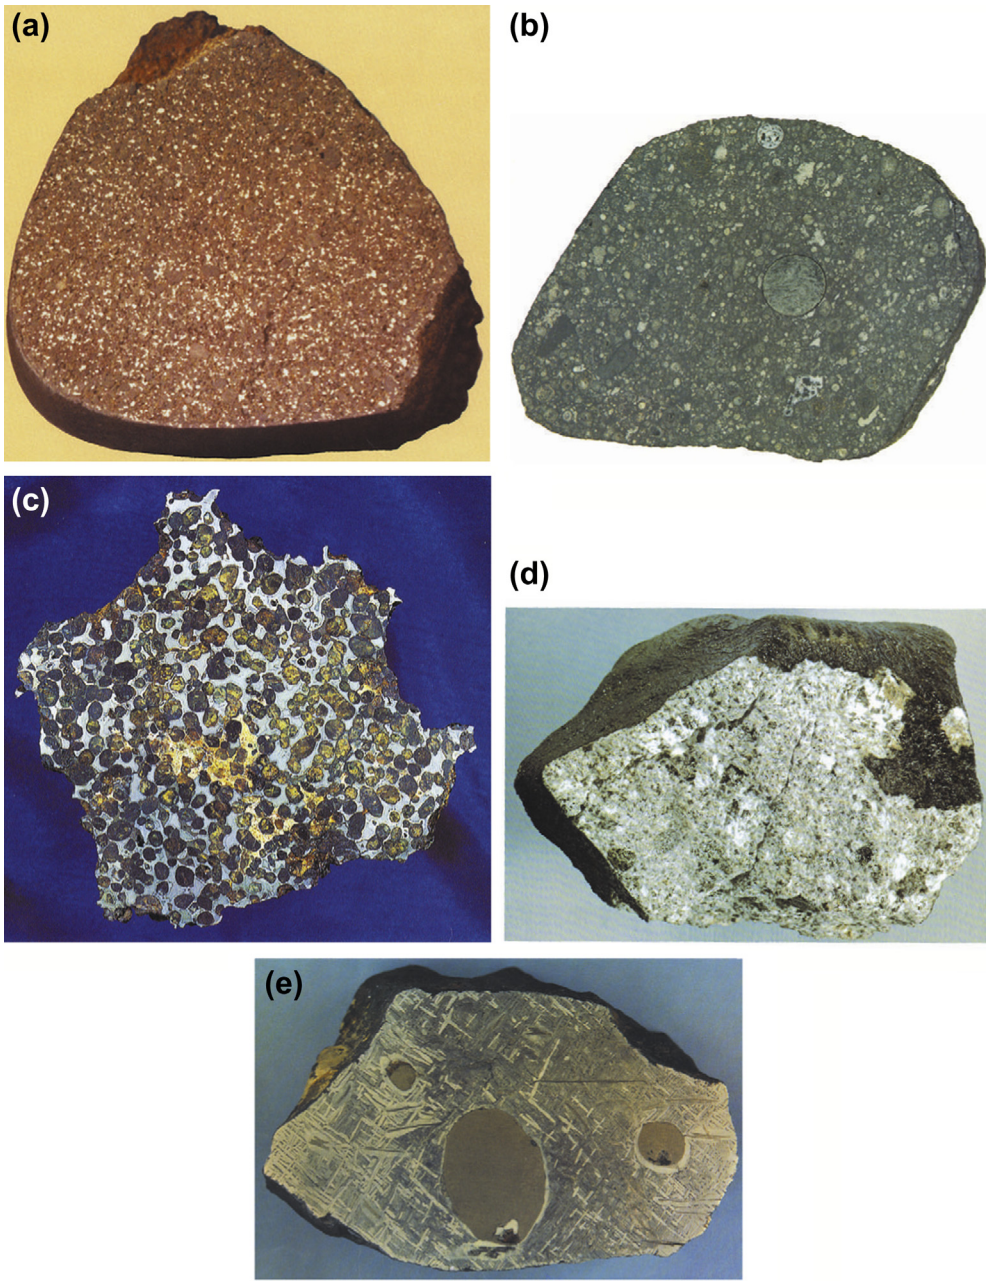

FIGURE 28.6 Common meteorite types (approximate longest dimension, in centimeters): (a) Whitman, H5 (6 cm); (b) Allende; C3V (8 cm)—note 1 cm chondrule in center, (c) Springwater pallasite (18 cm); (d) Sioux Co. eucrite (8 cm); (e) Sanderson IIIB medium octahedrite (13 cm)—note large FeS inclusions.

cooled slowly at iron meteorite formation rates, a few degrees per million years. Mesosiderite structures suggest more rapid and violent metal and silicate mixing, possibly by impacts.

During **differentiation**, siderophilic elements follow metallic iron geochemically and combine with iron into metal alloys. Such elements (e.g. Ga, Ge, Ni, or Ir) are thus depleted in silicates and enriched in metal to concentrations well above those in precursor chondrites. Conversely, magmas become enriched in **lithophilic** elements—like rare earth elements (REE), Ca, Cr, Al, or Mg – above chondritic levels: concentrations of such elements approach zero in metallic iron. During substantial heating, noble gases and other atmophile elements—like carbon and nitrogen—are vaporized and lost from metallic or siliceous regions. Chalcophilic elements that geochemically form sulfides, like troilite, include Se, Te, Tl, or Bi. Chalcophiles and a few siderophiles and lithophiles are also often quite

easily mobilized (i.e. vaporized from condensed states of matter) so that they may be enriched in sulfides in the parent body or lost from it. Concentrations of these elements in specific meteorites then depend in part on the fractionation histories of their parents and are markers of heating.

2.2. Characteristics of Specific Classes

It is obvious, even to the naked eye, that most iron meteorites consist of large metallic iron and nickel crystals, which are usually single-crystal α-Fe (kamacite) lamellae 0.2−50 mm thick with decimeter to meter lengths (Figure 28.6(e)). These relatively wide Ni-poor lamellae are bounded by thin, Ni-rich γ-Fe (taenite). The solid-state nucleation and diffusive growth process by which kamacite grew at slow cooling rates from taenite, previously nucleated from melt, is well understood. The 1-atm Fe-Ni phase diagram and measurement of Ni-partitioning between kamacite and taenite permits cooling rate estimation between 900 and 400 °C. These typically are a few degrees or so per million years, depending on iron meteorite group, consistent with formation in objects of asteroidal size. The Ni concentration in the melt determines the temperature of incipient crystallization and this, in turn, establishes kamacite orientation in the final meteorite. These orientations are revealed in iron meteorites by brief etching (with nitric acid in alcohol or ferric chloride) of highly polished cut surfaces: Baron Alois von Widmanstätten discovered this in the eighteenth century and the etched structure is called the "Widmanstätten pattern". Quite independently, an Englishman in Italy, William or Guglielmo Thomsen, simultaneously discovered this but his contribution was unrecognized.

Meteorites containing <6% Ni are called hexahedrites because they yield a hexahedral etch pattern of large, single-crystal (centimeter-thick) kamacite. Iron meteorites containing 6−16% Ni crystallize in an octahedral pattern and are octahedrites. Lower Ni meteorites have the thickest kamacite lamellae (>3.3 mm) and yield the very coarsest Widmanstätten pattern, while those highest in Ni are composed of very thin (<0.2 mm) kamacite lamellae and are called very fine octahedrites. Iron meteorites containing >16% Ni nucleate kamacite at such low temperatures that large single crystals could not form over the 4.55 billion years of solar system history; they lack a Widmanstätten pattern and are called Ni-rich ataxites (i.e. without structure). The Ni-poor ataxites are hexahedrites or octahedrites reheated in massive impacts, or artificially after they fell on Earth.

When primitive parent bodies differentiated, siderophilic elements were extracted into molten metal. During melt crystallization, fractionation or separation of siderophiles could occur. About 60 years ago, Ga and Ge contents of iron meteorites were found to be quantized, not continuous: they could then be used to classify irons into groups denoted as I to IV. Originally, these Ga-Ge groups, which correlate well with Ni content and Widmanstätten pattern, were thought to sample core materials from a very few parent bodies. Subsequent studies of many additional meteorites and some additional elements, especially Ni and Ir, modified this view. At present, the chemical groups (Figure 28.7) suggest that iron meteorites sample perhaps 120 parent bodies, although many, if not most, irons derive from but five parents represented by the IAB, IIAB, IIIABCD, IVA, and IVB irons. (The earlier Roman numeral notation for Ga-Ge groups was retained to semi-quantitatively indicate the meteorite's Ga or Ge content. However, a letter suffix was added to indicate whether siderophiles fractionated from each other.) In addition to the major minerals (kamacite, taenite, and mixtures of them) minor amounts of other minerals like troilite and graphite may be present. Also, silicates or other oxygen-containing inclusions exist in some iron meteorites.

In most cases, chondrites contain spherical millimeter-sized chondrules or their fragments. These chondrules were silicates that melted rapidly at temperatures near 1600 °C and rapidly cooled, early in the solar system's history, some ~1000 °C/h, others more slowly at 10−100 °C/h. Rapid heating and cooling are relatively easy to do in the laboratory, but are difficult on a much larger solar system scale. Yet, large volumes of chondrules must have existed in the solar system because chondrites are numerous. Chondrites (and many achondrites) date back to the solar system's formation—indeed provide chronometers for it (see Sections 7.4 and 7.5)—and represent

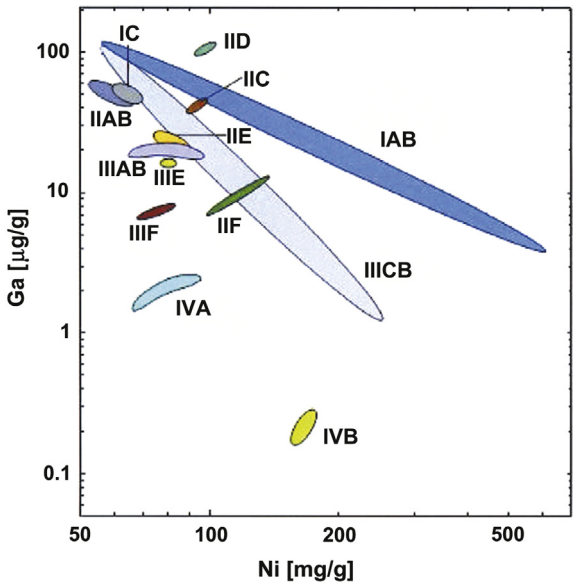

FIGURE 28.7 Contents of Ni and Ga in iron meteorites; some larger chemical groups are indicated by Roman numerals and letters.

accumulated primary nebular condensate and accretionary products. A portion of this condensate formed from the hot nebula as millimeter-sized Ca-Al-rich inclusions (CAI), mineral aggregates predicted as vapor-deposition products by thermodynamic calculations. These CAI, found mainly in chondrites rich in carbonaceous material, exhibit many isotopic anomalies and contain atoms with distinct nucleosynthetic histories. Other inclusions (like SiC and extremely fine diamond) represent relict presolar material. Other condensates formed at much lower temperatures. Some—perhaps even many—CAI may be refractory residues, not condensates.

Although most chondrites contain the same minerals, the proportions of these and their compositions differ in the principal chondritic chemical groups. The primary bases for chondrite classification involve proportions of iron as metal and silicate (in which oxidized iron—expressed as FeO—may be present), and total iron (from Fe, FeO, and FeS) content. The last (Figure 28.8) defines meteorites with high and low total iron (H and L, respectively) or low total iron and low metal (LL). Numbers of H, L, and LL chondrites are so large (see Table 28.1) that these are called the ordinary chondrites. Obviously, chondrite compositions (typically, as in Table 28.3, with elements apportioned by chemical form) are not continuous but, rather, quantized. Table 28.3 lists also major element ratios diagnostic of specific chondritic groups. The total iron in some enstatite (E) chondrites exceeds that in the H group of ordinary chondrites, denoting them as EH chondrites, the EL chondrite designation is self-evident.

Achondrites, formed at high temperatures, contain essentially no metal or sulfide and are enriched in refractory lithophiles, which, with their constituent minerals, allow classification into specific groups. Most groups are named for a specific prototypical meteorite, others—howardites, eucrites, and diogenites (HED meteorites)—were named nonsystematically. Some achondrite groups were associated in the same parent body but derive from different regions: the HED and the Shergottites-Nakhlites-Chassigny (SNC) associations. The HED meteorites are thought to come from 4 Vesta, and/or other V class asteroids produced from it. SNC meteorites and the orthopyroxenite ALHA 84001 come from Mars and are often called martian meteorites.

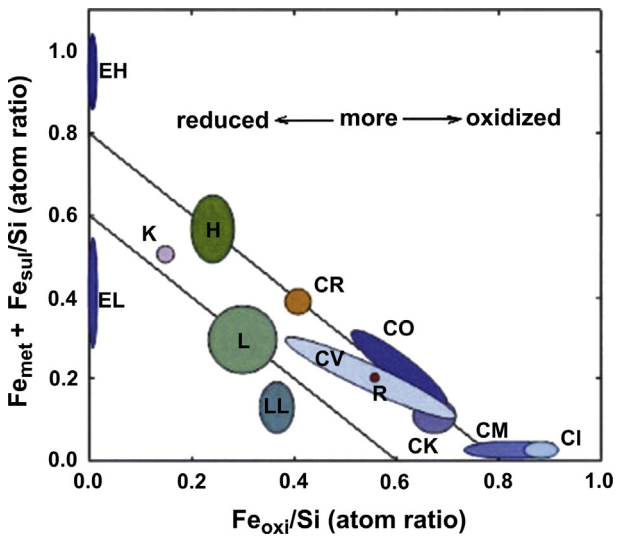

FIGURE 28.8 Silicon-normalized contents of Fe as metal and in FeS (ordinate) vs Fe in ferromagnesian silicates (abscissa) in various chondritic groups; each diagonal defines constant total iron content.

2.3. Oxygen Isotopes and Their Interpretation

Meteorites "map" the solar system by isotopic composition of oxygen (Figure 28.9), a major element in all but the irons. Since its high chemical reactivity causes oxygen to form numerous compounds, it exists in many meteoritic minerals, even in silicate inclusions in iron meteorites. In standard references, such as the Chart of the Nuclides, the terrestrial composition of its three stable (i.e. nonradioactive) isotopes is given as 99.762% ^{16}O, 0.038% ^{17}O, and 0.200% ^{18}O. In fact, any physical or chemical reaction alters its isotopic composition slightly by mass fractionation. Since the mass difference between ^{16}O and ^{18}O is about twice that existing between ^{16}O and ^{17}O, a mass-dependent reaction (e.g. physical changes and most chemical reactions) increases or decreases the $^{18}O/^{16}O$ ratio by some amount, and will alter the $^{17}O/^{16}O$ ratio in the same direction, but by about half as much. Accordingly, in a plot of $^{17}O/^{16}O$ vs $^{18}O/^{16}O$ or units derived from these ratios (i.e. $\delta^{17}O$ and $\delta^{18}O$; cf. Figure 28.9 caption), all mass-fractionated samples derived by chemical or physical processes from an oxygen reservoir with a fixed initial isotopic composition will lie along a line of slope $\sim 1/2$.

Data from terrestrial samples define the terrestrial fractionation line (TFL) in Figure 28.9, whose axes are like those described above, but normalized to a terrestrial reference material, standard mean ocean water. Not only do all terrestrial data lie along the TFL line, but so too do the oxygen isotopic compositions of lunar samples, which occupy a small part of it. The single Earth–Moon line (defined by data covering the solid line's full length) suggests that both bodies sampled a common oxygen isotopic reservoir, thus supporting the idea that the Moon's matter spun off during the massive impact of a Mars-sized projectile with a proto-Earth.

One important feature of Figure 28.9 is that many chondrite and achondrite groups defined by major element composition and mineralogy occupy their own regions in oxygen isotope space. These data suggest that the major chondritic groups (H, L, LL, R, CH, CI, CM, CR, and E) and

acapulcoites, brachinites, the two achondrite associations (SNC and HED), ureilites (U), and the silicate inclusions in group IAB iron meteorites derive from different "batches" of nebular material. The HED region also includes data for most pallasites and many mesosiderites suggesting derivation from a common parent body. Extension of the HED region by a line with slope 1/2 passes through the isotopic region of the oxygen-containing silicate inclusions from IIIAB irons, suggesting that they, too, may be related to the HED association. Perhaps these irons come from deeper in the HED parent body but this would imply complete disruption than V-class asteroids, like 4 Vesta exhibit (see also Section 3). While oxygen isotopic compositions of the rare angrites and brachinites resemble those of the HED association, differences in other properties weaken the connection. Other possible links indicating common nebular reservoirs (based upon limited oxygen isotopic data) are silicate inclusions in IIE irons with H chondrites; silicates in IVA irons with L or LL chondrites; aubrites with E chondrites; winonaites (primitive meteorites modified at high-temperatures) with silicates from IAB and IIICD irons; and the very rare, highly metamorphosed—even melted—primitive acapulcoites and lodranites.

One interpretation of Figure 28.9 is that the solar system was isotopically inhomogeneous, since each "batch" of nebular matter seems to have its characteristic oxygen isotopic composition. Isotopic homogenization of gases is more facile than is chemical homogenization, so that the isotopic inhomogeneity demonstrated by Figure 28.9 implies that the solar system condensed and accreted from a chemically inhomogeneous presolar nebula.

The other important feature to be noted from Figure 28.9 is the "carbonaceous chondrite anhydrous minerals line", with slope near 1. A feature distinguishing

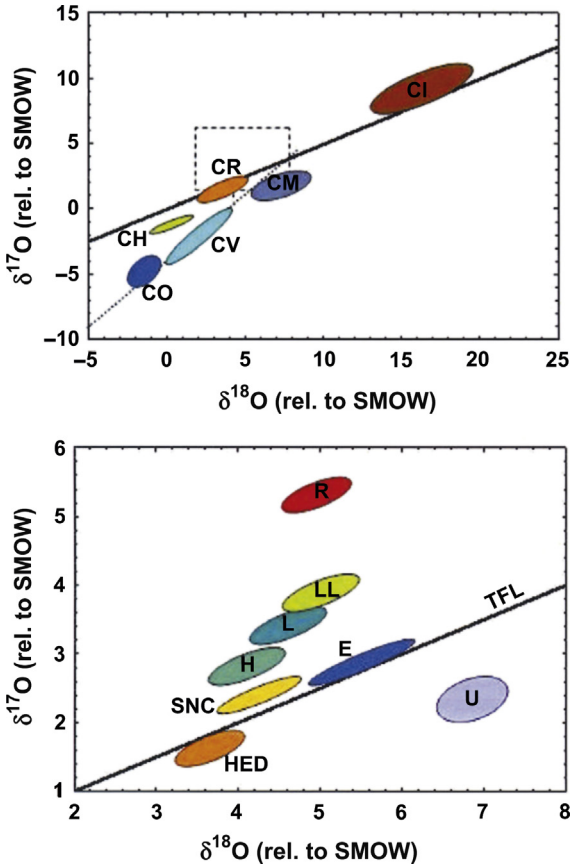

FIGURE 28.9 Relation between oxygen isotopic compositions in whole-rock and separated mineral samples from the Earth, Moon, and various meteorite classes. Units, $\delta^{17}O$ (‰) and $\delta^{18}O$ (‰), are those used by mass spectrometrists and are, in effect, $^{17}O/^{16}O$ and $^{18}O/^{16}O$ ratios, respectively. The $\delta^{17}O$ (‰) is referenced to Standard Mean Ocean Water (SMOW), as $\delta^{18}O$ is defined analogously. Oxygen isotopic compositions for carbonaceous chondrites are much more variable than for other meteorite classes (dashed box in the upper part expanded in the lower one).

C1 and C2 chondrites from all others is evidence for preterrestrial aqueous alteration or hydrolysis of some phases in them. Evidence for hydrous alteration of minerals is also observed in some unequilibrated ordinary chondrites (UOC). Anhydrous minerals (including CAI) in carbonaceous chondrites were seemingly never exposed to water, so that these chondrites are regarded as a mixture of materials with different histories. As seen from Figure 28.9, oxygen isotopic compositions of anhydrous minerals in CM, CV, and CO chondrites are consistent with a line defined by CAI whose slope cannot reflect the mass-fractionation process indicated by a slope 1/2 line like TFL. Instead, the anhydrous minerals line seems to represent a mixture of two end-members (batches of nebular material), which, at the ^{16}O-rich (i.e. low ^{17}O, ^{18}O) end lie at or beyond the CO region. Ureilite oxygen isotopic compositions lie on an anhydrous minerals line near CM, suggesting a link. These achondrites contain carbon (as graphite−diamond mixtures) in amounts intermediate to those of CV or CO chondrites and CM. Ureilite data do not indicate formation by differentiation of material with uniform oxygen isotopic composition. Rather, ureilite formation may reflect carbonaceous chondritelike components mixed in various proportions.

As originally interpreted, the anhydrous minerals line represented a mixture of nebular material containing pure ^{16}O with others higher in ^{17}O and ^{18}O. If so, the former reflected a unique nucleosynthetic history, perhaps material condensed from an expanding, He- and C-burning supernova shell. Subsequently, photochemical reactions of molecular oxygen with a given isotopic composition were shown to yield oxygen molecules with isotopic composition defining a slope 1 line as in Figure 28.9.

Which process—nebular or photochemical—produced the trends in Figure 28.9 is unknown. Even so, Figure 28.9 still serves to link meteorites or groups of them produced from one batch of solar system matter. Moreover, the position of any sample(s) could reflect some combination of the mass-fractionated and mixing (slope 1) lines. For example, primary matter that ultimately yielded L chondrites (or any ordinary chondrite group) and HED meteorites could have had a single initial composition, subsequently mass fractionated and/or mixed or reacted photochemically to produce meteorite groups with very different oxygen isotopic compositions. However, suitable meteorites with intermediate oxygen isotopic compositions are unknown.

2.4. Chondrites

The available data suggest that heat sources for melting primitive bodies (presumably compositionally chondritic) that formed differentiated meteorites were within rather than external to parent bodies. Important sources include radioactive heating from radionuclides—both extant (^{40}K, ^{232}Th, ^{235}U, and ^{238}U) and extinct (e.g. ^{26}Al)—that were more abundant in the early solar system, and impact heating. Calculations show that ^{26}Al was important in heating small (a few kilometers) primitive parents; other heat sources were effective in differentiating larger ones.

2.4.1. Petrographic Properties

Major element and/or oxygen isotope data demonstrate that differences between parent materials of chondrites of the various chemical groups (e.g. H, CM, or EH) are of primary nebular—preaccretionary origin. Parent body differentiation, on the other hand, is secondary (postaccretionary). Such heating does not necessarily melt the entire parent body and it is thus reasonable to expect an intermediate region between the primitive surface, and the molten differentiated interior. Properties of many chondrites

support this expectation and suggest that solid-state alteration of primary chondritic parent material (similar to type 3 chondrites) occurred during secondary heating. Eight characteristics observed during petrographic study of optically thin sections (Figure 28.10) serve to estimate the degree of thermal metamorphism experienced by a chondrite and to categorize it into the major three to seven types (Table 28.4). The absence of chondrules and the presence of abnormally large ($\geq$100 μm) **feldspar** characterize rare type 7. These pigeon holes approximate a chondritic thermal metamorphic continuum. Petrographic properties (with bulk carbon and water contents) suggest increasing aqueous alteration of type 3 material into types 2 and 1.

Two of these characteristics are illustrated in Figure 28.10: the opaque matrix and distinct chondrules of the type 3 chondrite Sharps (Figure 28.10(a)) should be contrasted with the recrystallized matrix and poorly defined chondrules of extensively metamorphosed (type 6) Kernouve (Figure 28.10b). Chemically, Fe^{2+}contents of the ferromagnesian silicates—olivine and pyroxene—are almost completely random in a chondrite like Sharps and quite uniform in one like Kernouve. Chondrites of higher numerical types could acquire their petrographic characteristics by extended thermal metamorphism of a more primitive, i.e. lower type, chondrite of the same chemical group.

The petrography of achondrites, like the martian meteorite Nakhla, clearly indicate igneous processes in parent bodies at temperatures >1000 °C. The resultant melting and differentiation erased all textural characteristics of the presumed chondritic precursor (Figure 28.10c) so its nature can only be inferred.

Chemical changes involving loss of a constituent, like carbon or water in chondrites, require an open system; other changes in Table 28.4 could occur in open or closed systems. We emphasize that thermal metamorphism can only affect secondary (parent body) characteristics—those listed horizontally in Table 28.4—not primary ones. Post-accretionary processes by which H chondritelike material can form from L or vice versa are unknown.

Because properties of a given chondrite reflect both its primary and subsequent histories, a chondritic classification scheme reflecting both is used: chondrites already mentioned are Ensisheim, LL6; Nogata, L6; Sharps, H3

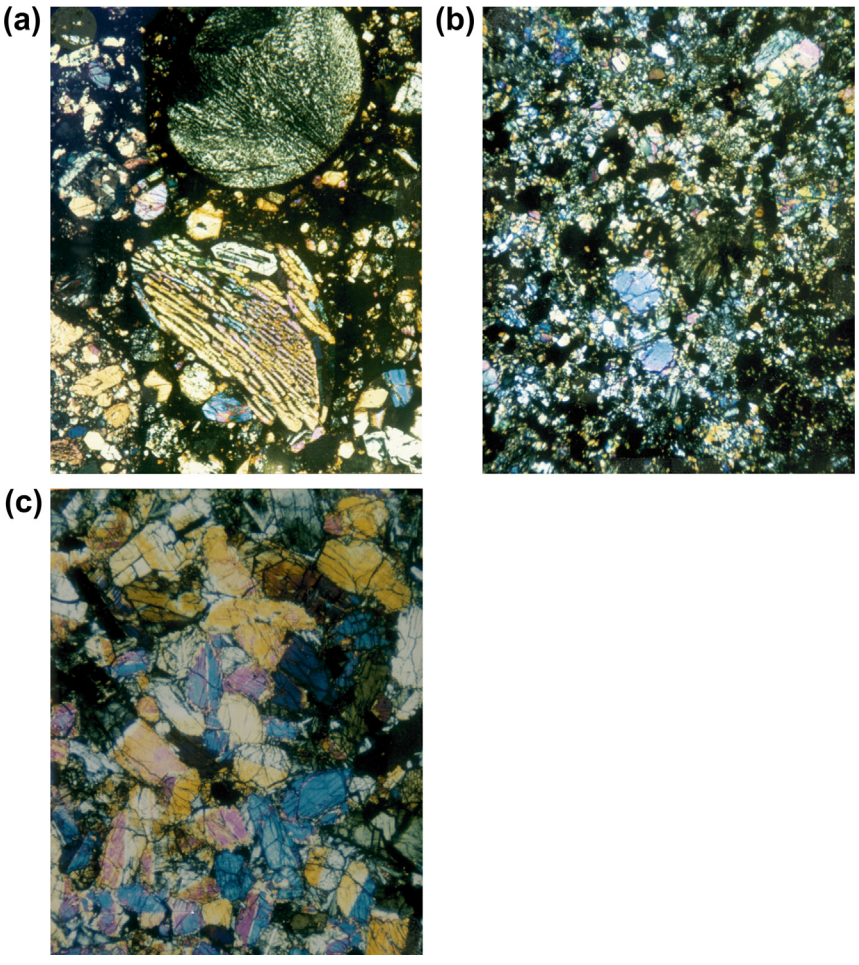

FIGURE 28.10 Petrographic (2.5 mm wide) thin sections in polarized transmitted light. Partial large chondrules are obvious in the H3 chondrite Sharps (a) but barely recognizable in the H6 chondrite Kernouve. (b) (H6); Nakhla, (c) is of Martian origin. *Photos courtesy of R. Hutchison, Natural History Museum, London.*

TABLE 28.4 Definitions of Chondrite Petrographic Types*

	1	2	3	4	5	6	7
Homogeneity of olivine composition	—	>5% mean deviations		>5% mean deviations to uniform	Uniform		
Structural state of low-Ca pyroxene	—	Predominantly monoclinic		Monoclinic		Orthorhombic	
				>20%	<20%		
Feldspar	—	Minor primary grains		Secondary <2 μm	Secondary <50 μm	Secondary >50 μm	
Chondrule glass	—	Mostly altered	Clear isotropic	Devitrified	Absent		
Metal: Maximum Ni content (wt%)	—	<20 (taenite absent or very minor)	>20 kamacite and taenite present				
Sulfide minerals: Average Ni content (wt%)	—	>0.5%	<0.5%				
Chondrule-matrix integration	No chondrules	Very sharply defined chondrules		Well-defined chondrules	Chondrules readily delineated	Poorly defined chondrules	Primary textures destroyed
Matrix	Fine grained, opaque	Mostly fine grained, opaque	Opaque to transparent	Transparent, recrystallized			
Carbon (wt%)	3–5	0.8–2.6	0.2–1.0	<0.2			
Water (wt%)	18–22	2–16	0.3–3	<1.5			

**According to Weisberg et al. (2006) in Meteorites and the early solar system (eds. Lauretta D.S. & McSween Jr. H.Y.)*

(Figure 28.10(a)); Sylacauga, H4; and Kernouve and Peekskill, H6 (Figure 28.10(b)). No ordinary (or enstatite) type 1 or 2 chondrite is known. Type 3 ordinary chondrites, the UOC, vary the most among themselves and from chondrites of other petrographic types. Within UOC, a variety of properties—for example, the chemical heterogeneity of ferromagnesian silicates, highly volatile trace element (mainly Bi, Tl, In, and noble gases) contents, and thermoluminescence sensitivity—subdivide UOC into subtypes 3.0 to 3.9. Sharps is a very primitive H chondrite, being an H3.0 or H3.4, depending on the classification criteria used. A similar subclassification of CO chondrites also exists.

Many properties of ordinary chondrites demonstrate that each group has its special history, even in something as simple as the numbers of each chemical-petrographic type (Figure 28.11), e.g. the plurality of H falls are H5, while type 6 dominates L and LL chondrites. Stony-iron and, especially, iron finds are very numerous because they are obviously "strange", hence more likely to be brought to someone knowledgeable enough to identify them as meteoritic. Achondrites grossly resemble terrestrial igneous rocks and are less likely to be picked up. Only their fusion crust permits ready recognition of their origin.

2.4.2. Breccias

Even though most chondrites are readily pigeonholed, a few consist of two or more meteorite types, each readily identifiable in the lithified breccia. Noblesville, for example, consists of light H6 clasts embedded in dark H4 matrix. Such an assemblage—two petrographic types of the same chondritic chemical group—is a genomict breccia. A polymict breccia contains two or more chemically distinct meteorite types, implying the mixing of materials from two (or more) parent bodies, each with its own history.

Of the other sorts of breccias, perhaps the most important is the regolith breccia. Noblesville is such a meteorite, and its typically dark and fine-grained matrix contains large quantities of light noble gases—He and Ne—of solar origin (cf. Section 5.2). In addition to these gases, radiation damage is present as **solar-flare** tracks (linear solid-state dislocations) in a 10-nm-thick rim on the myriad matrix crystals. However, solar gases and flare tracks are absent in the larger, lighter colored clasts of regolith breccias. Clearly, dark matrix is lithified fine dust originally dispersed on the very surface of the meter-thick regolith or fragmental rocky debris layer produced by repeated impacts on bodies with no protective atmosphere. The lunar regolith is both thicker, ~1 km, and more mature and gardened, or better mixed by impacts than are asteroidal regoliths. This dust acquired its gas- and track-component from particles with kiloelectron volt/nucleon energies streaming outward as **solar wind** or solar flares with megaelectron volt energies, so that the dust sampled the solar photospheric composition. The irradiated dust, often quite rich in volatile trace elements from another source, was mixed with coarser, unirradiated pebblelike material and formed into a breccia by mild impacts that did not heat or degas the breccia to any great extent. Regolith breccias occur in many meteoritic types but are especially encountered as R and H chondrites, aubrites, and howardites.

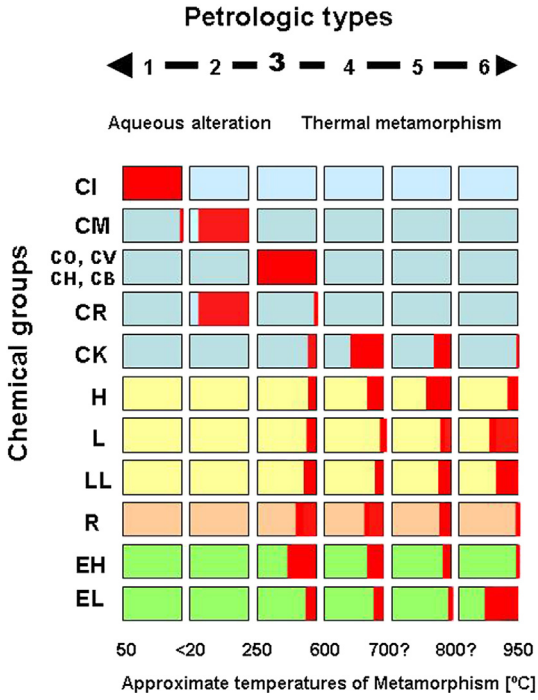

FIGURE 28.11 The relative abundance of petrologic types of chondrites; estimated temperatures of metamorphism or alteration are shown. *Adapted from McSween and Huss (2010).*

2.4.3. Carbonaceous Chondrites

2.4.3.1. Composition

The only type 1 or 2 chondrites are carbonaceous chondrites, nearly all non-Antarctic ones being observed falls. A dominant process recorded in them involves hydrolysis, the action of liquid water (in the nebula or on parent bodies) that altered preexisting grains, producing various hydrated, claylike minerals. The chondrites' petrography and the decidedly nonterrestrial $^{2}H/^{1}H$ ratios in water from them show that this hydrolysis was preterrestrial. As noted earlier, oxygen isotopic compositions of hydrated minerals demonstrate that the two groups derive from different batches of nebular matter: thus, C1 (or CI) could not form C2 (or CM) by thermal metamorphism nor could C1 have formed by hydrolysis of C2 parent material. For this reason some specialists prefer the CM designation: others prefer a hybrid classification like C2M or CM2 because other C2-like chondrites exist. Tagish Lake, although very primitive, is unique.

C1 chondrites contain no chondrules, but their obvious compositional and mineralogic similarities to chondrule-containing meteorites prompt this classification. Compositionally, C1 chondrites closely resemble the solar photosphere, but a few differences exist (Figure 28.12). Elements depleted in C1 chondrites relative to the Sun's surface (e.g. hydrogen, noble gases, or carbon) are gaseous or easily form volatile compounds that largely remained as vapor in the nebular region where C1 chondrite parent material condensed and accreted. Other elements (e.g. lithium, beryllium, and boron) are easily destroyed by low-temperature nuclear reactions during pre-main-sequence stellar evolution; consequently, they are depleted in the solar photosphere relative to C1 chondrites.

Because chemical analysis of C1 chondrites (or any planetary material) on Earth is more precise and accurate than is spectral analysis of the solar photosphere, "cosmic abundance" tables of chemical and isotopic data for most elements mainly derive from C1 chondrite analyses. Generally these data are used to estimate our solar system's composition. Only where such processes, as incomplete nebular condensation, are suspected, do such compilations adopt solar photosphere values. Recall, however, that earlier we inferred that chemical heterogeneity of the presolar nebula existed, so cosmic abundances may not have been the same in all nebular regions.

2.4.3.2. Organic Constituents

Although chondrites are depleted in carbon, hydrogen, and nitrogen relative to the solar photosphere, C1 and, to a lesser extent, C2 chondrites contain large amounts of organic matter (Table 28.3). They are visible in situ (as globules) only in the unique carbonaceous chondrite, Tagish Lake. Over 400 different extraterrestrial organic compounds have been identified in C1 and C2 chondrites, but their concentrations are very low. Molecular characteristics demonstrate that many are preterrestrial, but the problem of terrestrial contamination is ever-present.

Polyaromatic hydrocarbons (PAH) were found inside two martian meteorites, but not near their surfaces, suggesting that the PAH are not terrestrial contaminants but, rather, originated on Mars. Particles identified as microfossils were reported in at least one martian meteorite and, decades earlier, in CI and CM chondrites. Some advocate biogenic formation of these, but their arguments fail to alter the consensus view that meteoritic organics formed abiogenically.

Since many organic compounds in meteorites can be altered or destroyed by even brief exposure to temperatures of 200−300 °C, their presence in meteorites constitute a thermometer for postaccretionary heating during metamorphism, shock, or atmospheric transit.

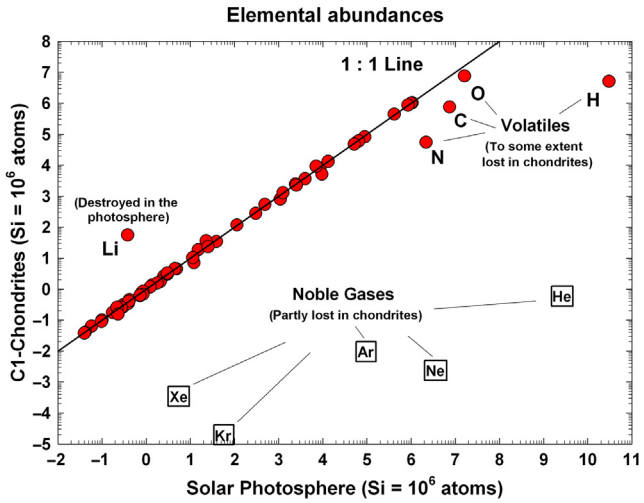

FIGURE 28.12 Elemental abundances in C1-chondrites and the solar photosphere both normalized to 10^6 atoms of silicon; the 1:1 line describes equal abundances. Most elements agree within 10%; exceptions are the volatile noble gases and other volatiles like H, C, N, and O, which are not completely retained in C1-chondrites. Li is destroyed in the Sun by nuclear processes.

2.4.4. Shock

A meteorite parent body cannot be disrupted by internal processes, but only by collision with another similarly sized object. Accordingly, many meteorites evidence exposure to significant shock. A few decades ago, chondrites were qualitatively classed "shocked" if the hand-specimen interior exhibited blackening, veining, or brecciation. Now, petrographic and mineralogic characteristics provide a semiquantitative estimate of the shock-exposure level. Such characteristics reflect changes induced directly, by the peak pressure wave, or indirectly, by the shock-associated, high residual temperature. Specific shock-pressure indicators ("shock barometers") have been calibrated against characteristics produced by laboratory shock-loading experiments. Using these criteria, the degree of shock-loading is known for almost all ordinary chondrites (Table 28.5).

The current scheme to estimate shock histories of equilibrated ordinary chondrites and enstatite chondrites involves the addition of S1, S2,…S6 to its chemical-petrographic classification. It relies upon shock effects observed in olivine and plagioclase. The shock pressures to produce these criteria are S1: <5 GPa; S2: 5−10 GPa; S3: 10−15 GPa; S4: 30−35 GPa; S5: 45−60 GPa; S6: 75−90 GPa. Shock pressures higher than S6 will melt the meteorite. Thus, the Noblesville H4 regolith breccia is S1 as a whole with some H6 clasts being S2. Other chondritic compositional data (radiogenic gases and thermally mobile trace elements, i.e. easily volatilized and lost in an open system) also give information on shock histories. Equilibrated L chondrites exhibit the highest proportion of heavily shocked chondrites, almost half having been shocked above 20 GPa.

TABLE 28.5 Degrees of Shock Loading in Chondrites as Function of Chemical-Petrological Type*

Type (Total)	S1	S2	S3	S4	S5	S6

**Data from METBASE 7.3 in percent of total number of chondrites listed with each type. Desert meteorites not corrected for pairing. Dual classifications like S3/4 or H4/5 are doubly counted, e.g. in each respective member.*

Lesser but significant proportions of H and LL chondrites show substantial degrees of shock loading (Table 28.5). The mineralogy (really, metallography) of iron meteorites is relatively simple. For shock studies, kamacite and troilite phases give the most information. Etched kamacite usually show shock features called Neumann bands, which indicate relatively low levels of shock (about 1 GPa), however, about half of all iron meteorites were shocked at $\geq$13 GPa, nearly all during collisions that disrupted their parent bodies. Only large meteoroids that formed terrestrial explosion craters can generate pressures as high as 13 GPa when they hit Earth.

The best preserved, perhaps the only, case of strong shock loading during terrestrial impact involves the Canyon Diablo meteoroid that produced Meteor Crater, Arizona. Some Canyon Diablo fragments contain millimeter- to centimeter-sized graphite–diamond aggregates, indicating partial transformation of graphite to diamond. Highly unequilibrated chondrites contain very tiny ($\sim$0.002 μm) vapor-deposited diamond grains that do not have a high-pressure origin; see Section 6.3. These aggregates contain lonsdaleite, a hexagonal diamond **polymorph** produced, so far as known, only by shock transformation of graphite, which also is hexagonal. Diamond-containing Canyon Diablo specimens always show metallographic evidence for exposure to shock $\geq$13 GPa. They are mainly found on the crater rim, not in the surrounding plain, and contain low levels of cosmogenic stable and radionuclides indicating derivation from the interior, but near the front of the impacting meteoroid where the greater explosive shock existed. The mutual correlations between degree of shock loading, depth in the impacting meteoroid, and geographic locations around Meteor Crater, argue that strongly shocked Canyon Diablo specimens experienced this during terrestrial impact.

The percentages of strongly shocked (i.e. $\geq$13 GPa) members of iron meteorite chemical groups differ widely. The IIIAB irons have virtually all been shocked preterrestrially in the 13–75 GPa range. Nearly 60% of IVA irons, the next largest group, show such shock. A similar proportion of IIB iron meteorites have been shocked at $\geq$13 GPa but this group is small. No other chemical group of iron meteorites shows an especially high proportion of shocked members. Shock-loading experiments show that pressures of 13–75 GPa acting on metallic Fe impart a free-surface velocity of 1–3 km/s. This shock impulse was important, maybe essential, in bringing large numbers of strongly shocked meteorites to Earth.

Semiquantitative petrographic shock indicators in **basaltic** achondrites, i.e. mainly the HED association and shergottites, suggest also a six-stage shock scale. The full range is seen in HED samples—primarily in clasts in howardites. These and other data, mainly compositional, suggest that howardites are a shock-produced, near-surface mixture of two deeper eucritic and diogenitic igneous layers in the HED parent body.

Shergottites have been heavily shocked, in keeping with their accepted derivation from a massive object, like Mars with its 5 km/s **escape velocity**. Nakhlites are less shocked. Lunar meteorites are breccias in most cases. Otherwise, they show no unusual evidence for shock greater than that evident in rocks returned by the Apollo programs.

Nearly all ureilites show petrographic evidence for very substantial shock. Most also contain large graphite–diamond aggregates generally believed to have formed during preterrestrial impacts.

Shock indices of olivine and kamacite in pallasites correspond to moderate shock intensities, but their parent body or bodies suffered at least one strong shock, which produced these stony-iron meteoroids. Most mesosiderites have not been shocked to more than 10 GPa, but some mineral fragments show shock stages S3 to S6. Apparently, the mesosiderites formed by intrusion of shock-loaded silicates into or onto preexisting, generally unshocked metal, possibly after excavation from parent body interiors.

2.4.5. Weathering

Meteoritic material survived in space for billions of years in near vacuum and without contact with water or oxygen. The terrestrial environment has therefore severely altered the chemistry of stone meteorite finds by oxidation or leaching of mobile elements. Also, fresh falls can experience alterations during long exposure under "normal" conditions. For Antarctic meteorites, a simple three-class-system is used based on the degree of rustiness, from minor to severe rustiness. A more detailed weathering scale for chondrites was developed in 1993 and is now generally applied to new finds. This scale designates seven progressive weathering stages from W0 (no visible oxidation) to W6 (extensive replacement of mafic minerals by iron oxides and clay minerals). This classification scheme is, however, qualitative and somewhat subjective. Different observers may come to different classifications, and within one meteorite different weathering stages may occur.

Today, the complete classification of a chondrite will contain class and type, as well as shock and weathering grade, e.g. the Canadian fall, Grimsby, in 2006 is classified as H5, S2, W0-W1; the Saharan find Dar al Gani 001, is LL6, S3, W4.

3. METEORITES OF ASTEROIDAL ORIGIN

3.1. The Meteorite–Asteroid Connection

Several arguments suggest or imply an asteroidal origin for most meteorites: (1) Instrumentally determined orbits (Figure 28.13) for most meteorites—chondrites, and achondrites—pass into the asteroidal belt, indicating that their parent bodies are located in this region of the solar system. (2) Mineralogic evidence indicates the origin of meteorites in asteroidal-sized objects. This includes iron meteorite cooling rates (implying formation depths of asteroidal dimensions), the presence of minerals (e.g. tridymite) and phase relations (e.g. the Widmanstätten pattern), and the absence of any mineral indicating high lithostatic (generated by the rocky overburden) – rather than shock pressures.

Another property linking meteorites and certain asteroids is spectral reflectance. The reflectivity (**albedo**) wavelength variation for an asteroid, involving white solar incident light, can characterize its mineralogy and mineral chemistry. To uncover possible links, asteroidal spectral reflectance are compared with possible meteoritic candidates, both as-recovered or treated in the laboratory to simulate effects of extraterrestrial processes. According to reflection spectra, asteroids are classified into different types, which are not randomly distributed in the asteroidal belt. For example, the E-type asteroids with the highest albedo are mainly found in the inner belt, the most abundant C-type asteroids with the lowest albedo occupy the middle belt to the outer edge. Most S-type asteroids, with medium albedo values, are found in the inner belt at about 2.4 AU.

The best matches (Figure 28.14) exist between the HED association and rare V-type asteroids (4 Vesta and its smaller progeny), iron meteorites, and M-type asteroids;

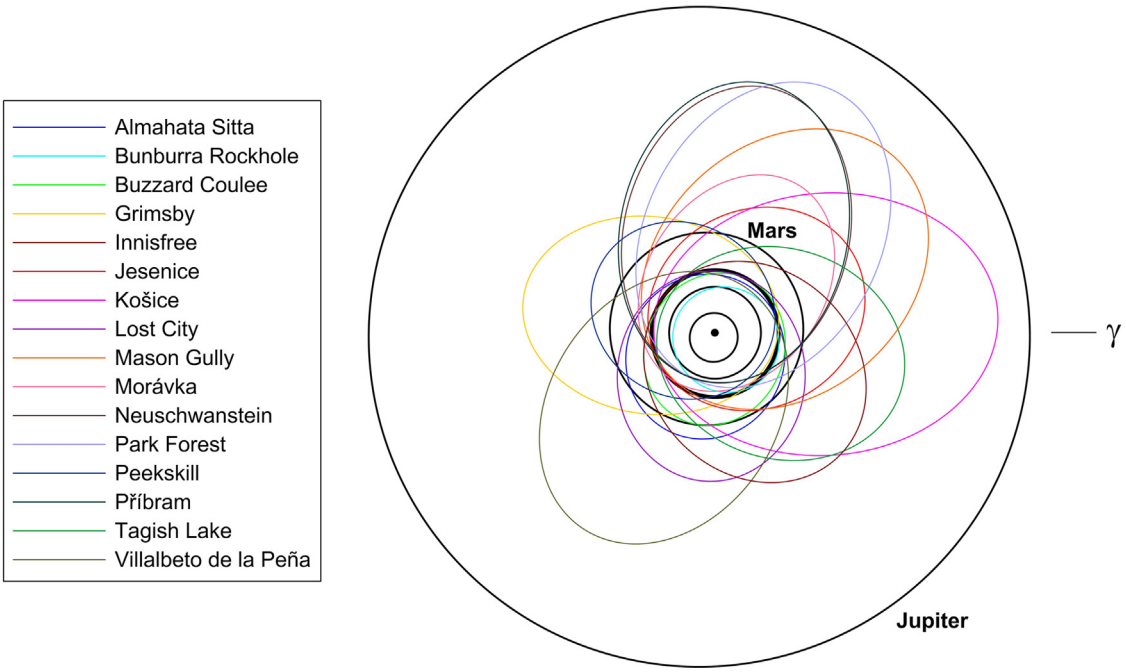

FIGURE 28.13 Instrumentally determined orbits for 16 recovered meteorite falls, as a projection into the ecliptic plane (orbits of the terrestrial planets and Jupiter are included with γ, the vernal equinox). *Figure courtesy of J. Borovicka, Ostrava, The Czech Republic.*

The albedo scale for all but Coopertown is on the left: Coopertown's is at right. Solid and dashed lines delineate meteorite and asteroid spectra, respectively. *Courtesy of Dr Lucy-Ann McFadden, University of Maryland.*

CI and CM chondrites thermally metamorphosed at temperatures up to 900 °C with the numerous C-class and related (B-, F-, and G-) asteroids. Aubrites match with the somewhat unusual E-class asteroids and pallasites with a few of the very abundant and diverse S class.

Unfortunately, relative frequencies with which meteorites of a given type and asteroids of a supposedly similar type are encountered do not agree. Specifically, there is the ordinary chondrite-S-asteroid paradox: why are there so few asteroidal candidates for the very numerous ordinary chondrites and so few olivine-dominated stony-irons from the very numerous S asteroids? One possible answer is that "space weathering" by energetic dust impingement on an asteroid's surface—causing metal reduction and dispersion—as well as the action of solar wind ions on mineral surfaces, change their surface reflectivity. This effect could mask ordinary chondrite-like interiors. Another is that Earth collects a biased meteorite sampling compared with the asteroid population, in either near-Earth space or in the asteroid belt. Alternatively, most meteoroids from some organic-rich and friable asteroids might not survive atmospheric passage. For example, Tagish Lake and Sutter's Mill, two unusual carbonaceous chondrites, are extremely friable.

A direct approach to match meteoritic samples with asteroidal material was carried out by the Japanese Spacecraft Hayabusa ("Peregrine Falcon"). Launched in 2003, it rendezvoused with the near-Earth asteroid 25143 Itokawa in 2005 and a lander collected about 2000 tiny dust particles, which were returned to Earth in 2010. Itokawa is an S-type asteroid and the first measurements (oxygen isotopic composition and model mineral abundances) show that the surface matter of this asteroid is consistent with LL-chondrite material.

The NASA spacecraft Dawn was launched in 2007 and reached 4 Vesta in July 2011: orbits of this asteroid strengthen its proposed connection to the HED meteorites. First results reveal a giant impact basin that is sufficiently large to have produced the smaller asteroids of the Vesta family (Vestoids). Furthermore, it was confirmed that Vesta is a differentiated asteroid. Both support the suggestion that the HED meteorites originated from Vesta and/or from the Vestoids.

3.2. Have Meteorite Populations Changed through Time?

The mass of extraterrestrial material falling on Earth is estimated at 40,000−60,000 t/year, most arriving as small dust grains. The number and size distribution of meteorites landing on Earth can be determined from fireball observations, and many attempts have been made to determine the flux from finds in cold and hot desert accumulation zones. The latter, however, requires the determination of terrestrial ages, weathering rates, and pairing in the respective area. In particular, data from the Meteorite Observation and Recovery Project suggest a flux of about nine meteorite falls greater than 1 kg per year and million km^2. The desert find estimates, covering the last 50,000 years, agree within a factor of two to three with this value.

The contemporary flux of meteorites, however, may be biased and unrepresentative of the meteoroid population in near-Earth space. It has been argued that compositional and mineralogical differences exist between recent meteorite falls and finds and older finds in Antarctica. Chemical differences are reported between Antarctic H4-6 and L4-6 chondrites with terrestrial ages >50,000 years and those that are younger. Other studies of Antarctic meteorites reveal more preterrestrial genetic differences between them and falls, but detailed interpretations of these differences remain controversial.

Evidence from fossil meteorites, however, shows clearly that the flux of meteoroids has changed during the geological time of the Earth. About 470 million years ago, during the Ordovician period, a shallow sea covered the area what is now southern Sweden. Limestone beds formed, which have been quarried for many centuries because it is a decorative building stone with beautifully preserved fossils. Among these fossils, ~80 meteorites were also found, as well as some remnants in the form of chromite minerals. Their chemical composition and structure show that all these fossil meteorites and grains derive from L-chondrites. Precise noble gas analyses allow

calculation of their exposure ages (see 7.2), which are only a few 100,000 years—much smaller than those of other meteorites. Based on the abundance and distribution of the fossil meteorites and the geological setting, the meteorite flux 470 million years ago could be estimated. Compared to today, this flux in the mass range 10−1000 g is enhanced by a factor of at least 100—and all these meteorites were L-chondrites. Today only about 40% of all stony meteorite falls belong to this group (Table 28.1).

It is suggested that the fossil meteorites are the result of a massive collision in the asteroid belt 470 million years ago producing a huge amount of debris of different sizes. Part of the smaller bodies arrived on Earth as an early surge and was cached in the sea sediments. Modern falls of L-chondrites, excavated later from larger parent bodies, also show the result of the 470-million-year collision in their radiogenic noble gases (see Figure 28.25).

4. METEORITES FROM LARGER BODIES

4.1. Historical Remarks

Through the first half of the twentieth century, it was assumed that the lunar craters were of volcanic origin. The only terrestrial circular structures familiar to geologists were volcanoes. Before Chladni's pioneering paper in 1794, it was suggested that meteorites might come from lunar volcanic eruptions. In that case, large lunar "volcanoes" might have been able to eject stones out of the lunar gravitational field. Some 60−70 years ago it became clear that the craters on the Moon were impact craters and ejecta from their formation could have been accelerated to the Moon's escape velocity of 2.38 km/s and beyond.

The Moon is the only astronomical body on which humans have landed and returned samples that are extensively investigated on Earth. When the first lunar rocks were returned in 1969, no meteorite was known that match their chemistry and mineralogy. Nine years after the last Apollo mission to the moon, during the 1981−82 field season of the US Antarctic Search for Meteorites, a 31-g stone was collected, known as ALHA (Allan Hills) 81005 (Figure 28.15(a)). Its identification as a lunar meteorite was uncontroversial. In the1979/80 season, three lunar meteorites had been recovered in Antarctica by Japanese teams (Yamato 791197, 793169, and 793274), but their lunar origin was not recognized then. Today, more than 160 lunar meteorites are known, mainly found in hot deserts and Antarctica. No falls are observed.

There are two kinds of martian meteorites. (1) In 2005, the Mars Rover, Opportunity, discovered an IAB iron meteorite on the surface of Mars and (2) martian meteorites have reached the Earth after impacts ejected rocks from the surface layers of that planet. This latter group of achondrites was named SNC meteorites after the three falls Shergotty, Nakhla, and Chassigny. They have similar oxygen isotopic compositions, and—with one exception—have unusually low crystallization ages as igneous rocks (0.6−1.3 billion years), uncommon for chondrites and other achondrites. The young ages were suggestive of a large parent body, since only a planetary body with relatively low surface/volume could retain interior temperatures sufficient to maintain igneous melts that recently. Asteroidal-sized objects could have been differentiated early but would have cooled rapidly. However, without lunar meteorites it seemed unlikely that a rock could have been ejected by an impact on Mars (escape velocity: 5.03 km/s).

But the SNC meteorites are linked to Mars specifically by gases (Ne, Ar, Ar, Kr, Xe, N_2, and CO_2) trapped in shock-formed glass in the Antarctic meteorite Elephant Moraine (EET) A79001 (Figure 28.15(b)), the only meteorite showing a contact between two igneous regions. Contents of these gases in EET A79001 match those in the

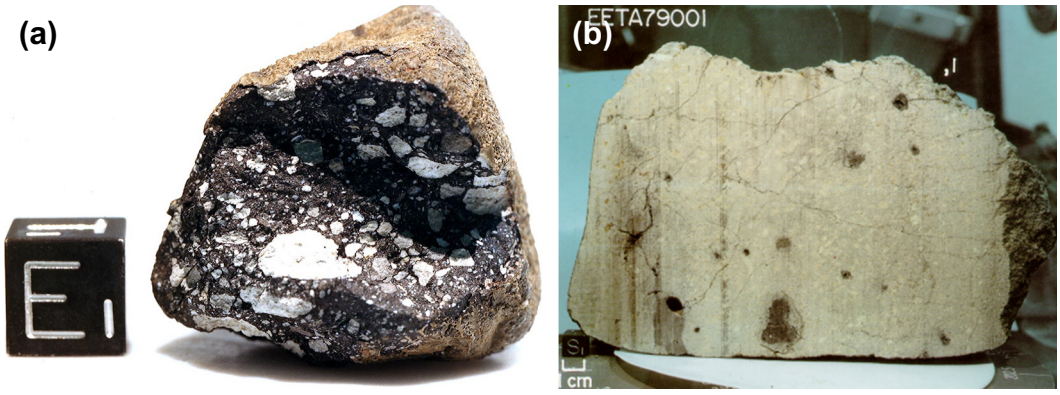

FIGURE 28.15 a) The first recognized lunar meteorite Allan Hills (ALH) A 81005. It is a regolith breccia, the white inclusions are anorthositic rock fragments. The cube is 1 cm on each side. (b) A cut face of the martian meteorite Elephant Moraine (EET) A 79001. The dark melt pockets are glass in which gases of the atmosphere of the planet are trapped. These gases are compositionally identical to the atmospheric gases measured by the Viking spacecrafts. The meteorite is 15 cm across.

martian atmosphere measured in 1976 by the Viking landers. These data and the first lunar meteorite find were the reasons that the martian origin of these achondrites became widely accepted.

4.2. Lunar Meteorites

The minerals, textures, chemical compositions, and isotope ratios of these about 160 individuals, belonging to about 75 falls, are similar to those of samples brought to Earth by the Apollo and Luna missions and unlike those of terrestrial rocks or martian and other meteorites. All were ejected from unknown locations on the Moon by meteoroid impacts, while the Apollo and Luna samples were all collected from globally unrepresentative areas. The lunar meteorites, however, more closely match the geochemical composition of the Moon's nearside and farside. Indeed, when compared with lunar orbital geochemical analyses from the Lunar Prospector or Clementine spacecrafts (e.g. distribution of FeO contents), lunar meteorites themselves parallel the overall lunar geochemical character.

Most lunar meteorites are polymict breccias, the majority being regolith and fragmental breccias, consisting of lithified surface material from the upper few meters. As a consequence, regolith breccias contain the products of solar particle radiation (e.g. solar wind gases) and of micrometeorite impacts (e.g. glass-welded aggregates, called agglutinates). Other breccias are dominated by feldspathic material, the major minerals of the lunar highlands. Several lunar meteorites are not brecciated, but are basalts. By terrestrial standards their crystallization ages are great and range from 2.8−3.9 billion years.

Transfer times from the Moon to Earth ("exposure age") are rather short for lunar meteorites compared with other meteorites. Most lunar meteorites were ejected less than 0.5 million years ago. Extreme values are a few 100 years (Kalahari 008 and 009) and about 8 million years (the paired Yamato 82192/3 and 86032). Some lunar meteorites seem to come from the same impact but arrive on Earth at different times (crater- or launch-paired).

The returned Apollo and lunar samples amount to about 383 kg, the total mass of all recovered lunar meteorites is about 62 kg. The largest lunar meteorites are Kalahari 009 (13.5 kg) and Northwest Africa 5000 (11.5 kg); the smallest is Groves Nunatak 06157 at 0.79 g. Many lunar meteorites from hot deserts have been subdivided into small pieces and sold at prices that are much higher per gram than the price of gold.

4.3. Martian Meteorites

According to mineral composition and texture, the 108 martian meteorites represent ~60 igneous rocks of basaltic and ultramafic origin. They are classified as shergottites (subdivided as basaltic [22], lherzolitic [13], and olivine-phyric shergottites [15]), nakhlites [8], chassignites [2], and orthopyroxenites [1] (in brackets are the number of falls and finds known). The main minerals in basaltic shergottites are pyroxenes and plagioclase (converted to maskelynite by shock), olivine-phyric shergottites are similar but they also contain olivine. Lherzolites are similar to gabbros, composed mainly of olivine and pyroxene. Nakhlites are augite-rich basaltic rocks, chassignites are olivine cumulates, and the unique orthopyroxenite ALHA 84001 consists mostly of orthopyroxene crystals.

The ejection from the planet's surface must have been by large-scale impacts, which produced craters with diameters >3 km. A special spallation mechanism provides escape velocities >5 km/s. Therefore, all martian meteorites are metamorphosed by moderate to strong shock pressures (15−45 GPa), which also produced local melts.

The cosmic-ray exposure (CRE) ages (see Section 7.2) show that the martian meteorites were ejected in discrete events. There is a good correlation between exposure age and petrographic class: nakhlites and chassignites have exposure ages of 10.5 Ma, all lherzolites lie between 3.8 and 4.7 Ma, basaltic shergottites between 2.4 and 3.0 Ma and five of six olivine-phyric shergottites cluster around 1.2 Ma. Only three meteorites have other ages: EETA 79001 (0.7 Ma), ALHA 84001 (15 Ma), and Dhofar 019 (20 Ma).

In 1996, ALHA 84001 became the object of hot debate, which continues today. This meteorite contains carbonates, which are associated with very small, submicron size magnetite and sulfide formations. The carbonates are complex in their chemistry and shape and their origin is still argued. A team of scientists reported tiny structures that resembling fossilized bacteria in shape, together with organic compounds. The organics have proved to be terrestrial contamination, but these reports have triggered a new research area—astrobiology—which proved very influential for the Mars Exploration Program during the past decade. The question of possible biological activity in the history of Mars is still debated. However, it is not likely that live martian microbes (if they exist) will be found in any sample on Earth since they would be destroyed by the high temperatures produced by the high shock pressures that launched the rocks earthward.

5. CHEMICAL AND ISOTOPIC SIGNATURES

5.1. Chemical Elements

5.1.1. Cosmochemical Fractionations

Earlier, we summarized meteorite compositions and genetic processes necessary to understand general meteoritic properties. Here, we focus upon these topics in greater detail.

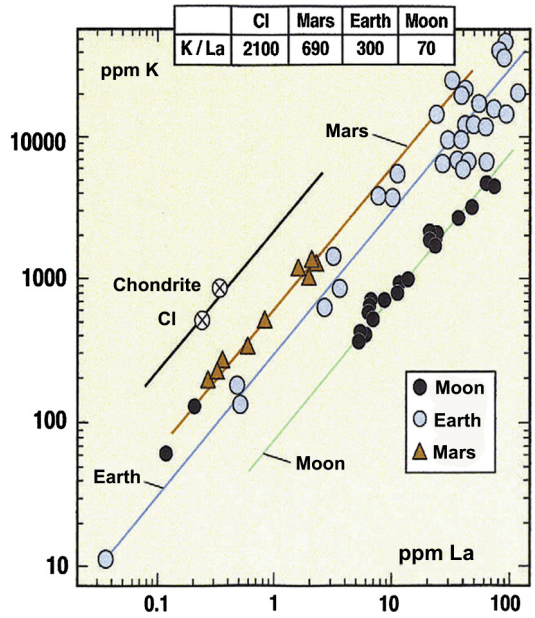

FIGURE 28.16 Lithophile element concentrations (K vs La) in ordinary (chondrites) and Cl chondrites and samples of evolved bodies: Lunar samples from various Apollo missions, and lunar meteorites, terrestrial rocks, and martian meteorites. Data for HED achondrites parallel and lie between the Earth and Moon lines.

The solar system formed from a cloud of gas and dust. The bulk chemical composition is most likely given by the solar abundances (Figure 28.12). The processes that produced the individual chemical composition of planets, asteroids, and meteorites fractionated or separated at least some of the original elements. Such chemical and isotopic fractionations are studied in detail on Earth but conditions for forming meteoritic material may well have been different from terrestrial analogs.

Many of the chemical fractionations observed in meteorites took place in the early solar system. The condensation of each element from vapor to liquid or solid phases takes place over a limited temperature range and is the reason for major chemical fractionation. The volatility of an element plays an essential role here. Elements that condense at high temperatures are called refractory elements; volatile elements condense at much lower temperatures. Other processes that fractionate elements are crystallization of minerals from melts, physical sorting of solids during the building of larger bodies, or planetary differentiation in a mantle and core. Meteorites are the result of all these fractionations and some elemental ratios are characteristic for individual classes (Figure 28.16). Several cosmochemical models try to understand these processes, which converted the originally solar material into that of individual meteorite classes.

5.1.2. Meteorites

Most elements in the periodic table are present in a meteorite at very low levels—microgram per gram (parts per million), nanogram per gram (parts per billion), or picogram per gram (parts per trillion) concentrations. Such low concentrations exist because nucleosynthesis produced stable isotopes of trace elements in only small amounts, and because their geochemical and/or physical properties prevent enrichment during genetic episodes or may even cause significant depletions. Their geochemistry (cosmochemistry) may cause some trace elements to be sited in specific hosts of particular meteorites—e.g. siderophiles like Ir, Ga, or Ge are enriched relative to Cl levels in iron meteorites—while others are dispersed among a variety of minerals. The same element may be dispersed in one meteorite class, but sited in a particular host in another. For example, REE are found in phosphates in achondrites, but some are dispersed elements in chondrites. They concentrate in whitlockite grains in eucrites, and are even more enriched in CAI (see 6.2). Trace elements convey important information because a small absolute concentration change induced by a genetic process will result in a large relative effect.

An example is the element iridium in the Cretaceous-Tertiary (K-T) boundary layer around the Earth. The fall of a massive iron meteorite enriched in siderophiles like Ir, will distribute this element around the globe and redeposit it in a thin layer. Enrichments in the K-T boundary layer suggests that dinosaurs (and many other biota) died off from sudden severe environmental changes created by a large meteoroid impact 65 Ma ago. The resulting "bullet hole" is identified as the 180-km Chicxulub crater in the Gulf of Mexico. While initially controversial, this idea is now generally accepted. In other instances, enrichments of siderophile elements in impact-breccias at an explosion crater on Earth or Moon provide a "fingerprint" of the meteoritic type that created the crater.

Volatile elements condensable at very low temperatures (like the noble gases) may not have similar contents in C1 chondrites and the solar photosphere (Figure 28.12). Meteorite compositions are referenced to readily condensable material by normalization to a refractory lithophile element—most commonly Si (as in Figure 28.8), sometimes Mg or Al—rather than hydrogen as in the astronomical scale for the solar photosphere. For meteorites, normalized ratios can be on a weight or atom basis: in the latter, trace element contents are usually referred to as atomic abundances and are often normalized to C1 contents. In some meteorites, particular C1-normalized abundances can approach or exceed C1 levels. On this basis, we say that moderately to highly refractory siderophiles are enriched in iron meteorites, or that refractory lithophiles are enriched in achondrites. Contents of the more refractory trace elements are characteristic of, hence can define, achondrite associations.

A priori identification of a trace element as refractory or volatile is impossible since its chemical form in a meteorite

is usually unknown. For example, indium metal or gaseous oxygen are each quite volatile as elements, but more refractory when chemically bonded in InO. Because In exists only at parts per billion levels in even the most volatile-rich meteorites, neither InO nor any other In compound is identifiable. Several approaches have been used to obtain at least a qualitative elemental volatility order. Criteria used include calculation of theoretical condensation temperatures in a nebular gas of solar composition at pressures of 10^{-3}–10^{-6} atm, determination of C1-normalized atomic abundances in equilibrated (petrographic type 5 and 6) ordinary chondrites, and laboratory studies of elemental mobility (ease of vaporization and loss) during long heating of primitive chondrites under conditions simulating parent body metamorphism (400–1000 °C, 10^{-4} atm H_2). By these criteria, elements considered as moderately volatile include (in increasing order) Ni, Co, Au, Mn, As, P, Rb, Cu, K, Na, Ga, and Sb, while strongly volatile ones include Ag, Se, Cs, Te, Zn, Cd, Bi, Tl, and In.

More volatile elements exhibit great variability in stony meteorites. Concentrations of the three to four most volatile elements are several orders of magnitude higher in UOC than in their equilibrated analogues and decrease by one to two orders of magnitude with increasing homogenization of ferromagnesian silicates in UOC. Contents of most strongly volatile elements in L chondrites of petrographic types 4–6 are highly variable and do not correlate with petrographic type. However, in H chondrites, concentrations of many moderately volatile elements vary as H4 > H5 > H6, consistent with loss at progressively higher metamorphic temperatures in stratified parent(s).

Such a model cannot be established for the L chondrites because late shock affected thermometric characteristics, thus obscuring earlier histories. In addition to the petrographic evidence, strongly shocked L4-6 chondrites exhibit loss of some noble gases, highly mobile elements and siderophiles, and lithophile enrichments.

The H chondrite regolith breccias, like Noblesville, differ from "normal" H chondrites in that the dark, gas-rich portions of the breccias are also quite rich in volatile trace elements, sometimes exceeding C1 levels. These volatiles, distributed very heterogeneously in the dark matrix, were apparently not implanted by the solar wind but rather occur in black clasts. During exposure on the asteroidal surface, these dark clasts and light ones (containing "normal" levels of volatiles) were apparently gardened by repeated impacts, ultimately forming the regolith breccia.

In contrast to ordinary chondrites, volatile trace elements in carbonaceous chondrites are very homogeneously distributed. These elements are unfractionated from each other in almost all carbonaceous chondrites, implying that their parent material incorporated greater or lesser amounts of C1-like matter during **accretion**. The proportions define a continuum from 100% C1 down to about 20% in C5 or C6. As in enstatite chondrites, volatile-rich samples have higher proportions of more siderophile trace elements. These trends accord with oxygen isotope data implying a continuum of formation conditions for parent materials of carbonaceous chondrites. Contents of mobile trace elements and noble gases, and the petrography of some C1 to C3 chondrites provide evidence for open-system thermal metamorphism in their parent bodies.

For meteorites of less common types, meteorites from hot deserts and, particularly Antarctica, provide a broader sampling of extraterrestrial materials than do contemporary falls. Systematic and reproducible differences involving moderately to highly volatile elements suggest that differences between falls and Antarctic meteorites may exist and may reflect variations in the near-Earth meteoroid flux with time. However, these suggestions remain controversial (cf. Section 3.2).

5.2. Noble Gases

The chemical inertness of noble gases allows their ready separation from all other chemical elements. Thus, gas mass spectrometers can determine very small noble gas concentrations in a meteorite and, in addition, measure the isotopic composition. Most analyses are carried out on meteorite samples of <100 mg but with effort, samples as small as 5 μg provide essential data.

Noble (rare) gases in meteorites have different origins and each component has a specific isotopic or elemental composition. Some components like the *radiogenic* gases were produced in situ in meteorites, e.g. radiogenic ^{40}Ar is produced by spontaneous, radioactive decay of long-lived, naturally occurring ^{40}K, while ^{4}He is produced mainly from Th and U decay. Fission Kr and Xe components derive from spontaneous or induced fission of heavy nuclei, e.g. stable U isotopes—each with a characteristic fission-fragment distribution. In addition, decay products of extinct radionuclides (e.g. ^{129}I or ^{244}Pu: $t_{1/2} = 15.7$ and 81 Ma, respectively) exist in meteorites.

Other in situ produced gases are cosmogenic nuclides formed by nuclear reactions of high energy galactic or solar particles with meteoroids. Cosmogenic nuclides are limited to the surface (<1 m depth) of larger bodies and to meter-sized objects in space. Inert gases found in iron meteorites are mainly cosmogenic, but stony meteorites contain a mix of many components.

Trapped gases include a whole family of noble gas components, which were not produced in situ but incorporated in the meteoroid when it formed. Trapped gases are of three main varieties, solar, planetary, and "exotic". Elemental solar gas ratios are similar to those observed in the Sun and are introduced into meteoritic mineral grains by direct implantation of solar-wind ions in the regolith of asteroids or the Moon. The planetary noble gas pattern

shows a systematic fractionation in which the lightest noble gases—He and Ne—are depleted relative to Ar, Kr, and Xe.

As an example, let us consider the element Ne. Because a meteorite can sample Ne from any or all of above-mentioned sources, its isotopic composition represents a weighted average of the isotopic compositions of its component sources. These can be recognized on a three-isotope plot (Figure 28.17). A sample consisting of essentially one component is represented by one point in such a diagram, while a neon mix of two components will lie on a line connecting the isotopic compositions of these components. Included in Figure 28.17, as an example, is the Ne isotopic composition of samples of the meteoritic breccia ALH 85151, which contains solar and cosmogenic gases. Lunar soils also contain solar Ne with variable isotopic composition. The proposed SEP component (Solar Energetic Particles) are interpreted now as implantation-fractionated solar wind.

Addition of Ne from other sources, like Ne-E from the decay of extinct ^{22}Na, can complicate this picture. A mixture of three Ne components will fall within a triangle whose apexes each have the Ne isotopic composition of a pure component. In addition, many chondrites contain one or more trapped Ne components, examples of which are in Figure 28.17 inset.

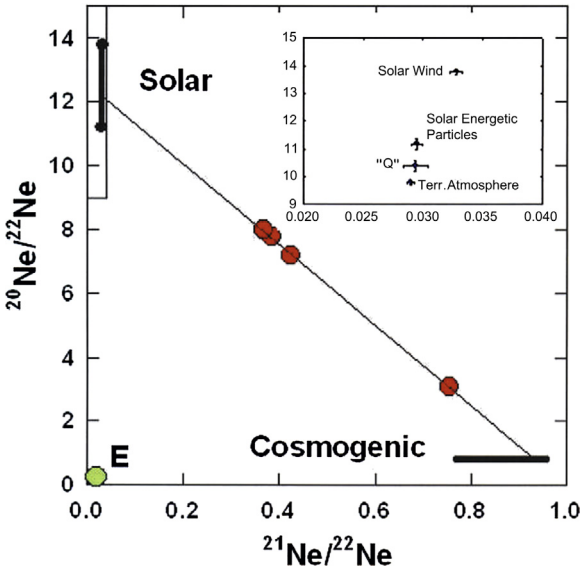

FIGURE 28.17 Three-isotope plot for stable Ne isotopes in ALH 85151 chondrite. Data for grain size separates lie on lines connecting solar Ne (composed of kiloelectron volts/nucleon solar wind particles) with cosmogenic Ne produced by gigaelectron volt galactic cosmic rays. The box in the upper left is expanded to show isotopic compositions of individual Ne components in meteorites. The inset depicts isotopic compositions of Ne from solar wind, solar energetic particles (recently interpreted as implantation-fractionated solar wind), the terrestrial atmosphere, and a trapped (planetary) component [Q]. Pure ^{22}Ne (so-called Ne-E) is formed by radioactive decay of very short-lived ^{22}Na in the protoplanetary nebula or presolar grains.

Krypton and Xe systematics are more complicated for several reasons. The Kr and Xe isotopes derive from several nucleosynthetic sources, two of which are especially important. One is now-extinct ^{129}I, which decayed to produce ^{129}Xe and gives chronometric information (cf. Section 7.5). The second involved fission of now-extinct ^{244}Pu, which produced a Xe component with a characteristic fission–yield curve. In addition to induced and spontaneous U fission products, different trapped components exist. Kr and Xe in presolar grains provide almost pure gas from individual nucleosynthetic events.

Each solar system body has its particular formation history and, thus, its own noble gas isotopic "fingerprint". Gases on the Earth, Moon, Venus, and Mars are distinguishable from each other and from those in chondrites. As discussed in Section 4.1, glass in the EET A79001 shergottite contains Martian atmospheric gas, providing incontrovertible proof that it (and the other martian meteorites) formed there.

Our brief Ne discussion outlined, in principle, how to disentangle several noble gas components from an average meteoritic datum. Actually, the situation is more complicated because each "component" may, in fact, be resolvable into constituents from specific sources, each with reproducible isotopic patterns involving more than one noble gas. Ingenious laboratory treatments can yield a phase enriched in one true gaseous constituent from others. These include investigation of individual grains, selective acid dissolution of specific minerals, enrichment by mineral density using heavy liquids, stepwise heating and mass analysis of gases evolved in some temperature interval or some combination of these steps.

6. COMPONENTS OF CHONDRITES

Chondrites are a mixture in varying proportions of chondrules, metal, sulfides, refractory inclusions, and matrix material. Because of postaccretionary alteration by thermal metamorphism, aqueous alteration, or shock, the original texture has changed. Additionally, in many cases, new minerals have been formed. Chondrules and refractory inclusions are of special interest because of their origin and their memory of processes in the early solar system. A very minor component of some meteorite classes turns out to be presolar grains that have formed in and around stars.

6.1. Chondrules

Chondrules exhibit a large variety of compositions and textures. Most chondrules, 0.1- to 1-mm-sized spherules (Figures 28.6(b) and 28.10(a)), consist primarily of pyroxene and olivine but other minerals may also be present.

Chondrules are often surrounded by small grains that accreted to them before the meteoritic rock formed.

Since their first description about 200 years ago, the formation of chondrules has been fiercely debated. There is agreement that they were once molten or partly molten droplets that rapidly cooled "like drops of fiery rain". Decay products of extinct radionuclides (see Section 7.5) suggest that chondrules are formed early in the solar system from melts initially at temperatures around 1800 °C. Cooling rates were between 100 and 2000 °C/hour. However, no consensus has been reached as to the cause that produced the liquids necessary for chondrule formation, or the necessary energy source.

Generally, two types of models have been developed: (1) Direct condensation from the material of the hot solar nebula; (2) Manufacture from preexisting solids. Processes suggested include collisions in space between asteroids or planetesimals, lightning in the solar nebula, shock waves and formation in the vicinity of the young Sun. After 200 years of research and numerous special conferences on this topic, no generally accepted theory has resulted.

6.2. Ca-Al-Rich Inclusions

In addition to low-temperature materials, like the matrix of C1 chondrites, refractory grains like CAI record early solar history. The CAI are millimeter- to centimeter-sized refractory inclusions especially recognizable in C2 and C3 chondrites, but also identifiable in some UOC and in R and E3 chondrites. They were first described in the Allende chondrite, which fell in 1969.

Typically, CAI consist of refractory silicate and oxide mineral assemblages, mainly hibonite, perovskite, melilite, spinel, diopside, and anorthite. The refractory mineralogy of CAI makes them unique among cosmochemical samples. Several isotope systems indicate that CAI are the oldest objects to have formed in the solar system (see Section 7.5).

Major-element compositions of CAI agree with calculations by equilibrium vapor-deposition evaporation models to represent the first 5% of condensable nebular matter solidifying at $\geq$1400 K from a gas of solar composition at a pressure of 10^{-3} atm, or at 0.3 atm, if the dust/gas ratio is 40-fold enriched. Most individual CAI contain tiny particles (usually $<$50 μm) very rich in refractory siderophiles (Re, W, Mo, Pt, Pd, Os, Ir, and Rh) and, occasionally, refractory lithophiles like Zr and Sc. Sometimes, even smaller (micrometer-sized) refractory metal nuggets are found, consisting of single-phase pure noble metals or their alloys.

The textural and mineralogic complexities of CAI indicate a variety of formation and alteration processes in their history. Undoubtedly, CAI formed at high temperatures; properties of some suggest vapor condensation as crystalline solids, while others seemingly reflect liquid or **amorphous** intermediates. Volatilization, melting, solid-state metamorphism, and/or alteration in the nebula or after accretion may also have affected some/many CAI. Clearly, CIA had complicated histories that obscured their primary textural properties but left their chemical and isotopic properties relatively unaltered.

Volumetrically, fine-grained CAI are encountered more often than coarse-grained ones but the latter are more easily studied. Coarse-grained CAI are grouped into different types, defined mainly by mineralogy, formed at progressively lower temperatures, from a melilite-dominated type that apparently condensed as solid from vapor, to other types formed from partly molten mixtures or melt droplets. Compositionally, CAI reflect a high-temperature origin, refractory lithophiles like REE are generally enriched 20 times or more relative to C1 compositions.

Many to all of these CAI exhibit isotopic anomalies (both in positive and/or negative directions) for O, Ca, Ti, and Cr. A few CAI, mineralogically and textually indistinguishable from others, are called FUN inclusions because they exhibit *F*ractionated and *U*nidentified *N*uclear isotopic effects involving not only Kr and Xe but also elements like Mg, Si, Sr, Ba, Nd, and Sm. Six FUN inclusions contain mass-fractionated oxygen (i.e. follow slope 1/2 lines in Figure 28.9); two of these six exhibit isotopic anomalies for every element thus far studied.

Another type of refractory-element-rich inclusions are amoeboid olivine aggregates (AOA). Like CAI, they are depleted in volatile and moderately volatile elements. AOA are interpreted as aggregates of grains that condensed from the solar nebula gas.

6.3. Interstellar Grains

Until about 1970, the solar system was considered "isotopically homogeneous", objects in it having formed from a well-mixed and chemically and isotopically homogenized primordial nebula. The later discovery of oxygen isotopic variations, e.g. Figure 28.9, disproved this. However, even then, rare samples extracted from meteorites exhibited anomalous isotopic compositions of, for example, Ne or Xe isotopes. These anomalies cannot be explained by well-established processes like decay of naturally occurring radionuclides, cosmic ray interaction with matter, or mass-dependent physical or chemical fractionation.

These isotopic anomalies, usually orders of magnitude larger than in other solar system materials, are associated with very minor mineral phases of primitive chondrites distributed irregularly in unequilibrated meteorites. These minerals include diamond, graphite, silicon carbide, and aluminum oxide, with typical grain sizes being 0.1−10 μm, with diamond being much smaller ($\sim$0.002 μm). All these minerals are rare in meteorites: e.g. SiC is about 10−15 ppm

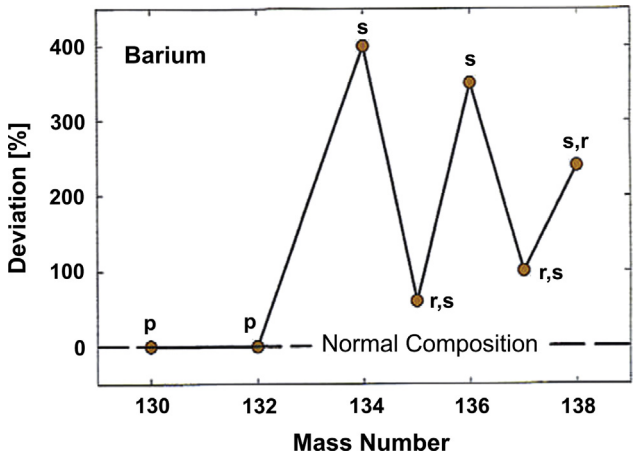

FIGURE 28.18 Stable Ba isotopes in a SiC separate from the Murchison CM chondrite normalized to those in normal terrestrial Ba. Letters indicate nucleosynthetic processes by which individual isotopes are produced. It is presolar neutron-capture isotopes (on slow s, and rapid, r, timescales that formed in presupernova and supernova stages, respectively), which are anomalously high, by up to a factor of four.

by mass, diamond about 1500 ppm. Figure 28.18 depicts such an anomaly, the Ba isotopic composition in presolar SiC separated from the carbonaceous chondrite Murchison. The data are normalized to terrestrial values of ^{130}Ba and ^{132}Ba, the anomalous s- and r-process isotopes (see below) lying far above the horizontal line.

Since the isotopic composition of these grains differs wildly from those of ordinary solar system matter, they must derive from outside our solar system. These grains were incorporated into the solar nebula with intact memories of their individual nucleosynthetic sources, then accreted into meteoritic matter and obviously survived all later episodes in their parent bodies' histories. The isotopic anomalies identified thus far point at specific genetic processes. Most SiC grains probably formed in stars on the Asymptotic Giant Branch (i.e. AGB stars) in the Hertzsprung–Russell diagram. This is the source of isotopes produced by neutron capture on a slow timescale (or so-called s-process) nuclides, with rapid neutron capture (r-process) nuclides forming immediately prior to the supernova stage. Supernovae also seem required to explain the isotopic anomalies in tiny diamonds.

Isotopic anomalies of many trace elements in these presolar grains provide a wealth of unique information regarding the evolution of stars and nucleosynthetic processes. This information is only obtainable by exhaustive, detailed, highly sensitive and highly accurate analyses of rare interstellar grains from primitive samples in terrestrial laboratories. Undoubtedly, isotopic anomalies in these rare meteoritic constituents tell us many details about stellar formation and evolution, and the formation and early history of the solar system.

7. METEORITE CHRONOMETRY

How old are meteorites? What is the "age" of the solar system? Modern cosmochronological methods give answers using naturally occurring radioactive nuclides. An age is a time interval between two events marked by specific chronometers. The "clock" starts by an event beginning the time interval and its end must be clearly and sharply recorded. Chronometers used in modern geo- and cosmochronology usually involve radioactive isotopes such as the U-isotopes, ^{87}Rb or ^{40}K. Radioactive decay allows calculation of an age if the concentrations of both parent and daughter nuclide are known, the time interval beginning is defined and—an important condition—the system is not disturbed (i.e. it is a "closed system") during the time interval. Some meteorite ages involve production of particular stable or radioactive nuclides, or decay of the latter. Typically, the chronometer's half-life should be comparable with the time interval being measured.

Meteoritic matter yield a variety of ages, each reflecting a specific episode in its history. Some of these are shown in Figure 28.2: the first formation of solids in the solar system, melt crystallization in parent bodies, excavation of meteoroids from these bodies, and the meteorite's fall to Earth. Other events, like volcanism or metamorphism on parent objects can be established, as can dating of processes in the early solar system (based on extinct radionuclides). CRE ages date the exposure of a meteoroid as a small body (about 1 m radius) in interplanetary space, as well as the meteorite's terrestrial age, the time elapsed since it landed on the Earth's surface (Figure 28.19). In the following

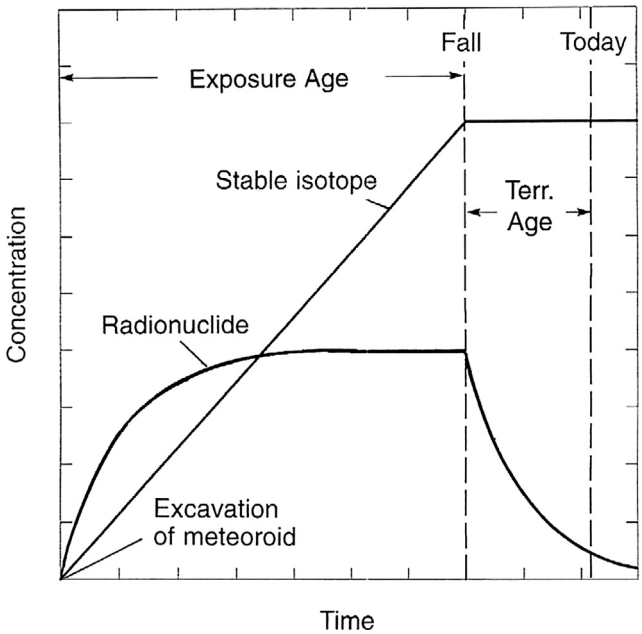

FIGURE 28.19 Concentrations of cosmic ray produced radioactive and stable nuclides during cosmic ray exposure and after the meteorite's fall on Earth.

sections we discuss some of these different ages, starting with the most recent one.

7.1. Terrestrial Ages

Terrestrial ages are determined from amounts of cosmogenic radionuclides found in meteorite falls and finds, ^{14}C ($t_{1/2} = 5.73$ ka), ^{81}Kr ($t_{1/2} = 200$ ka), ^{36}Cl ($t_{1/2} = 301$ ka), and ^{26}Al ($t_{1/2} = 730$ ka) being the nuclides most frequently employed for this purpose. In Section 3.2, we mentioned possible changes of meteorite populations with time. Terrestrial ages are important for this question. A meteorite's survival time during terrestrial residence is determined by the weathering conditions where the meteorite resides. Survival times (terrestrial ages) for meteorites are much lower for warm and/or wet areas than for the arid ones.

Stony meteorites in Antarctica have terrestrial ages in excess of 2 Ma (Figure 28.20) and age distributions depend on their locations, presumably reflecting ice sheet dynamic differences. Terrestrial ages of meteorites from the Allan Hills average ~300 ka, while those from Frontier Mountain have younger ages (<100 ka). For Antarctic iron meteorites, however, much longer terrestrial ages have been reported (Derrick Peak: ~1 Ma; Lazarev: ~2.4 Ma).

Meteorites from hot deserts generally have terrestrial ages up to 50 ka (Figure 28.21) but the terrestrial age distributions depend on the hot desert recovery site. A few stony meteorites, especially those without metal grains, can survive longer on the Earth's surface: e.g. the lunar meteorite Dhofar 025 from Oman has a terrestrial age of about 500 ka.

7.2. Cosmic-Ray Exposure Ages

The transit of a meteoroid from the asteroidal belt to the Earth takes place in several steps, dynamical aspects and orbital evolution considerations are required for its understanding. The asymmetrical heating of the meteoroid by solar radiation (**Yarkovsky effect**) may change its orbit into a resonance with that of Jupiter. This process is rather slow and may take tens of millions of years. Due to their optical properties, iron meteorites are affected less by this effect. Calculations show that once a meteoroid's orbit is in resonance, it quickly evolves into an Earth-crossing orbit.

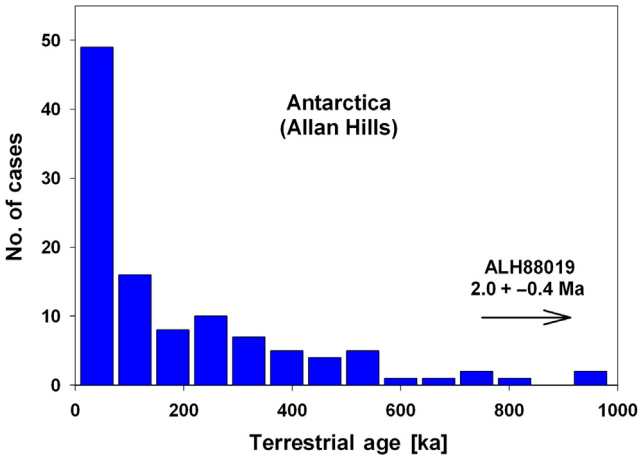

FIGURE 28.20 Terrestrial age distributions of meteorites from the Allan Hills region of Victoria Land (Antarctica), which, on average, are older than meteorites from any other part of Antarctica.

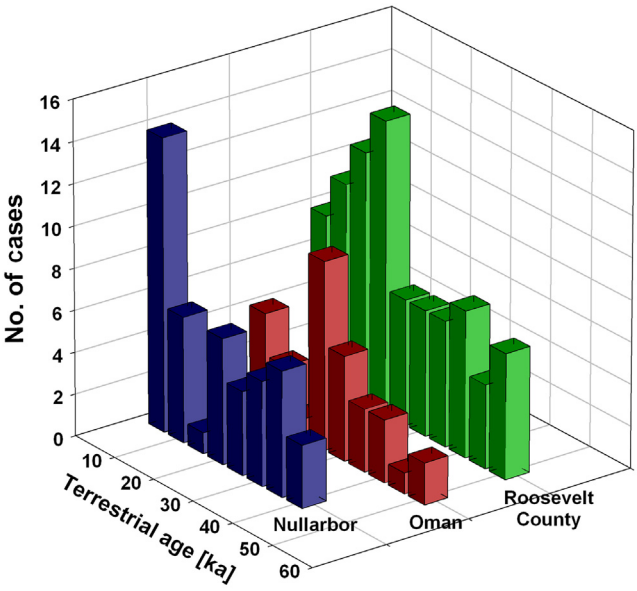

FIGURE 28.21 Terrestrial ages of chondrites from hot deserts. Data for the Saharan samples are from Welten et al. (2004); the others are from Jull (pers. commun.). Age distributions tend to vary in the four sites and, while most maximum ages are 40–50 ka, those for lunar and martian meteorites tend to be somewhat older (~150 ka).

In principle, we need to determine both a cosmogenic radionuclide and a stable nuclide to establish a CRE age, assuming constant cosmic-ray fluxes. In practice, however, production rates of stable cosmogenic noble gas nuclides in stony meteorites (e.g. ^{3}He, ^{21}Ne or ^{38}Ar) are well known as a function of their chemical composition. It usually suffices to measure just their concentrations with appropriate corrections. An especially useful and precise method is based on the measurement of cosmogenic krypton. $^{81}Kr/Kr$ CRE ages are almost independent of the chemical composition and location of the measured sample within the meteoroid. However, the concentrations of ^{81}Kr are small and Kr analyses are a challenge in noble gas spectrometry.

Absent contrary evidence, we generally assume that irradiation by cosmic rays of solar and galactic origin is simple, that is, the meteoroid was completely shielded in a parent body until an impact ejected it as a meter-sized object, remaining essentially undisturbed until collision with Earth. Some stones (e.g. the chondrite Jilin) and irons (e.g. Canyon Diablo) exhibit complex irradiation histories involving pre-irradiation on the parent body surface. In such cases, different samples of a meteorite exhibit different CRE ages.

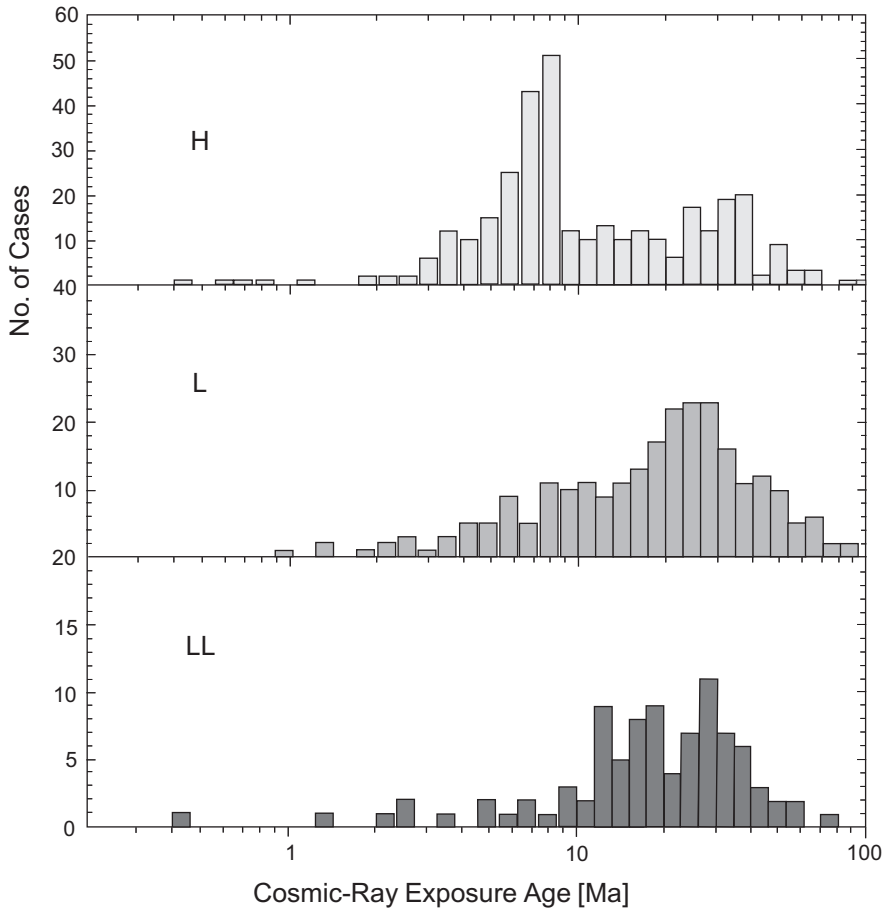

FIGURE 28.22 Cosmic ray exposure ages for ordinary H, L, and LL chondrites. Peaks in the histograms indicate major collisional events on parent bodies that generated many meter-sized fragments.

The data for ordinary chondrites in Figure 28.22 show that all groups have CRE ages ranging up to 100 Ma, but the distributions differ markedly. For H-chondrites, there is one major peak, at ~7 Ma and a smaller one at ~33 Ma. For L chondrites, major peaks are not obvious, but clusters occur at 20–30 Ma and 40 Ma. Contrary to the H-chondrite situation, nearly 2/3 of the L chondrites have CRE ages >10 Ma. For LL chondrites, the major peak at 15 Ma includes ~30% of all measured samples, and another is at 30 Ma. Major peaks correspond to major collisional breakups on/of chondrite parent bodies. The distributions of these CRE ages imply that meteoroids are not continuously produced from their parent bodies but reflect a limited number of impacts.

Most CRE ages for CI and CM chondrites tend to be short (<5 Ma). These ages are mainly based on data from cosmogenic radioisotopes alone. Either their parent bodies are close to a resonance or already in an Earth-crossing orbit. Also, most lunar meteorites have very short exposure times of <1 Ma but a few highland breccias have longer CRE-ages. Although lunar meteorites fell at different locations at different times, they may originate from the same impact on the Moon (source-crater pairing). Clustering of exposure ages is also observed for other meteorite groups, like E or R chondrites. HED meteorites display clustering for diogenites at 22 and 39 Ma, coincident with those of eucrites, and howardites. Most specimens of the acapulcoites/lodranites cluster around 5 Ma.

The martian meteorites were ejected from the planet in a number of discrete events (Figure 28.23). All nakhlites have ejection ages (exposure age + terrestrial age) of 10.5 ± 1.1 Ma. This cluster also includes the two chassignites. An ejection age of about 2.7 ± 0.4 Ma is observed for the eight basaltic shergottites measured: possibly all lherzolithic shergottites were ejected about 4 ± 0.7 Ma ago. Nine olivine-phyric shergottites measured have ages close to 1.1 ± 0.2 Ma; there are, however, three "outliers" with different ejection ages. The only orthopyroxenite has an ejection age unlike that of any other martian meteorite. At least eight individual impacts delivered all these meteorites to Earth.

The first reliable CRE age method for iron meteorites was a difficult, tedious, and no longer practiced technique involving ^{40}K ($t_{1/2} = 1.28$ Ga) and stable ^{39}K and ^{41}K.

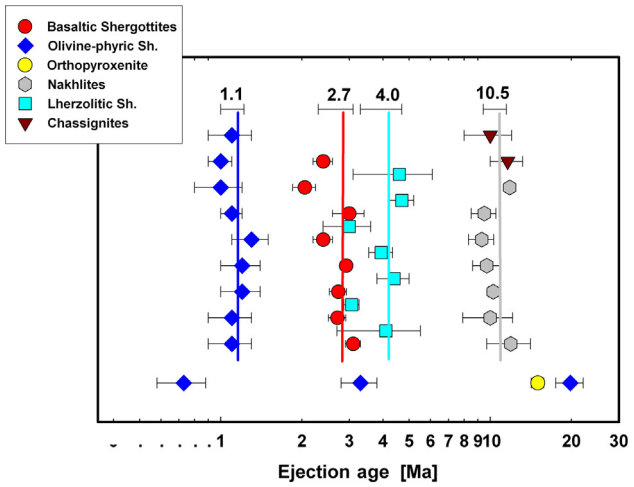

FIGURE 28.23 Ejection ages (CRE age + terrestrial age) for martian meteorites. Most meteorite types cluster at specific values, indicating distinct ejections by impacts on Mars. Only the olivine-pyric shergottites have "outliers". This group of SNC meteorites was ejected in at least four impacts.

About 70 iron meteorites were dated by the $^{40}K/^{41}K$ method and the resulting ages range from 100 Ma to 1.2 Ga (Figure 28.24). These data disagree with those determined using a stable isotope and radioactive nuclides with different half-lives (e.g. $^{36}Cl/^{36}Ar$). These discrepancies have been interpreted as time variations in the galactic cosmic ray flux. However, also complex irradiation histories as well as destructive collisions (so-called space erosion) must also be taken into account.

CRE exposure age peaks are evident for a few chemical groups, e.g. for group IIIAB a cluster around 650 Ma, for IVA around 450 Ma, both suggesting major collisional events involving the parents of the chemical groups III and IV irons. CRE ages of stony-iron meteorites are somewhat longer than those of chondrites but show no obvious clustering.

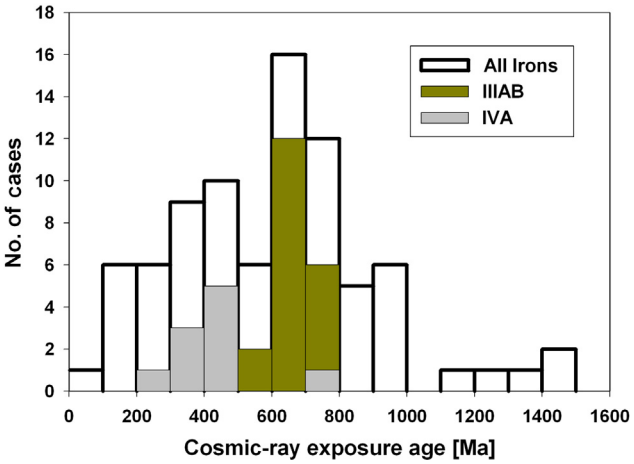

FIGURE 28.24 Cosmic-ray exposure (CRE) ages determined by the ^{40}K-^{41}K method for iron meteorites. The group IIIAB irons nearly all apparently produced by a single, massive collision on their parent body 650 ± 60 Ma ago. CRE ages for IV A irons are more diverse but average 400 ± 60 Ma.

7.3. Gas Retention Ages

From measurements of U, Th, and radiogenic ^4He or of ^{40}K and radiogenic ^{40}Ar, one can calculate a gas retention age or the time elapsed since a meteorite sample cooled sufficiently low to retain these noble gases, if the system was closed during this period. This radiogenic age records primary formation of the meteorite's parent material, but, in most cases, subsequent episodes (metamorphic and/or shock) accompanied by substantial heating, partially or completely degassed the primary material. A variant of the K/Ar age, the ^{40}Ar–^{39}Ar method, involves conversion of some stable ^{39}K to ^{39}Ar by fast-neutron bombardment, i.e. $^{39}K(n,p)^{39}Ar$, in a nuclear reactor followed by stepwise heating and mass spectrometric analysis. From the $^{39}Ar/^{40}Ar$ ratios in different temperature steps, it is possible to correct for gas loss. This method has several advantages over the conventional $^{40}K/^{40}Ar$ method: it eliminates the need for a separate measurement of potassium and the effect of argon loss can be detected.

Gas retention ages of chondrites, achondrites, and silicate inclusions in iron meteorites range up to about 4.5 Ga. Many meteorites, particularly L chondrites, have young gas retention ages, ~500 Ma, while H chondrites cluster at higher ages (Figure 28.25). The discovery of many fossil meteorites in limestone beds in Swedish quarries (see Section 3.2) imply that the meteorite flux on Earth ~470 Ma ago was much higher than the contemporary flux. A major collisional breakup at that time and the subsequent loss of gases in parts of the parent body may explain the many L-chondrites showing deficits of radiogenic helium and argon. Furthermore, meteorites with young gas retention ages generally exhibit petrographic evidence for strong shock loading, implying diffusive gas loss from material that experienced quite high residual temperatures generated in major destructive collisions. Almost always, meteorites having young K/Ar ages have lower U,Th/He ages. This occurs because He is more easily lost from most minerals than is Ar.

7.4. Crystallization Ages

Crystallization or solidification ages establish the time elapsed since the last homogenization of parent and daughter nuclides, normally by forming a mineral or rock. Nuclides used to establish crystallization ages are long-lived radioisotopes and their decay products that might have not be affected by later geological events. Some

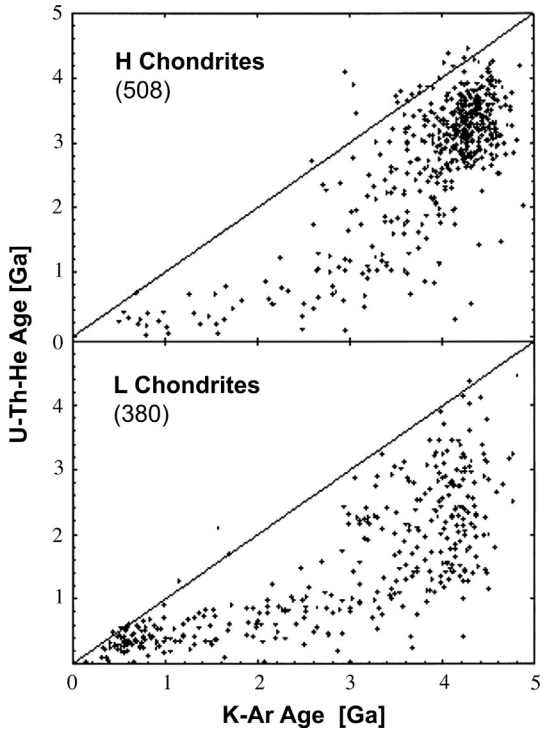

FIGURE 28.25 Gas retention ages of 508 H and 380 L chondrites. Data from the U, Th-He, and K-Ar methods are plotted against each other. The 45° line represents concordant ages. The two major chondrite types exhibit strong thermal history differences. The dominant concordant long ages of H chondrites suggest that their parent bodies generally remained thermally unaltered since forming 4–4.5 Ga ago. The concentration of data defining concordant short ages of L chondrites suggests strong shock heating in a major collision(s) about 0.6 Ga ago. Nearly all discordant meteorites lie below the 45° lines because radiogenic ^{4}He is lost far more easily than is radiogenic ^{40}Ar.

techniques, as the Pb/Pb system, which involves the ultimate decay products of U and Th isotopes, is based upon relatively mobile Pb that is more easily redistributed than nuclides of other dating systems. However, these effects are detectable since a comparison with other dating systems (e.g. Sm–Nd) can yield somewhat different ages, depending upon the sample's postformation thermal history.

Common systems found to yield useful solidification ages include a number of nuclide pairs (Table 28.6). In most cases, it is difficult to determine the age of a rock just from measurements of the concentrations of a radioactive nuclide and its daughter isotope alone, because a nonradiogenic contribution can be present. However, by measuring mother and daughter isotopes in various minerals of a rock it is possible to establish a crystallization age and determine the initial isotopic ratio of the daughter element. Figure 28.26 shows as an example the evolution diagram (also known as isochron diagram) of Sm-Nd measurements in different separates of the martian meteorite, Governador Valaderes. The slope of the isochron establishes the age of the meteorite. Such isochrons can also be constructed from whole

TABLE 28.6 Long-Lived Radionuclides Used Mostly in Cosmochronology

Radionuclide	Half-life (years)	Daughter
^{40}K	1.27×10^{9}	^{40}Ar/^{40}Ca
^{87}Rb	4.88×10^{10}	^{87}Sr
^{147}Sm	1.06×10^{11}	^{143}Nd
^{176}Lu	3.75×10^{10}	^{176}Hf
^{187}Re	4.12×10^{10}	^{187}Os
^{238}U	4.47×10^{9}	^{206}Pb
^{235}U	7.04×10^{8}	^{207}Pb
^{232}Th	1.40×10^{10}	^{208}Pb

rock samples of different meteorites, which formed from the same source material. The Rb-Sr system, for example, defines a line for basaltic achondrites that gives an age of about 4.3 Ga and provides an initial $(^{87}Sr/^{86}Sr)_0$ isotope ratio at the time their parent body differentiated. The most "primitive" value of $(^{87}Sr/^{86}Sr)_0$ was found in the chondrite Allende; those of Angra dos Reis, an angrite, and the basaltic achondrites are somewhat larger. This indicates a time difference in the formation of their parent bodies. The Re-Os system provides good isochrons for iron meteorites of 4.537 ± 0.008 Ga.

The U,Th–Pb system has proved to be a powerful tool to determine absolute ages. To obtain absolute ages, several methods have been developed for geochronology. In cosmochemistry, the Pb–Pb method provides the most accurate dates. It is based on the measurement of radiogenic lead generated from the two uranium isotopes and an assumed initial lead composition, measured in troilite of iron meteorites. This method works well for undisturbed early solar system samples with very low abundances of common lead, like CAIs. The current best measurement of a CAI yields a value of 4568.2 ± 0.5 Ma. This age is corroborated by other methods described in the next section. However, some additional uncertainty of the absolute age exists because of uncertainties in the decay rates of the uranium isotopes. CAIs are the oldest material so far dated and their age is taken as the age of the solar system.

Solidification ages for most meteoritic samples are "old", i.e. close to 4.56–4.57 Ga. A well studied example is the Shallowater aubrite with a crystallization age of 4563.3 ± 0.4 Ma. This age is also used as an "anchor" for precise dating of events in the early solar system by short-lived—now extinct—radionuclides.

While most meteorites have solidification ages around 4.56 Ga, there is clear evidence that all martian meteorites but one have "young" crystallization ages of $\leq$1.4 Ga

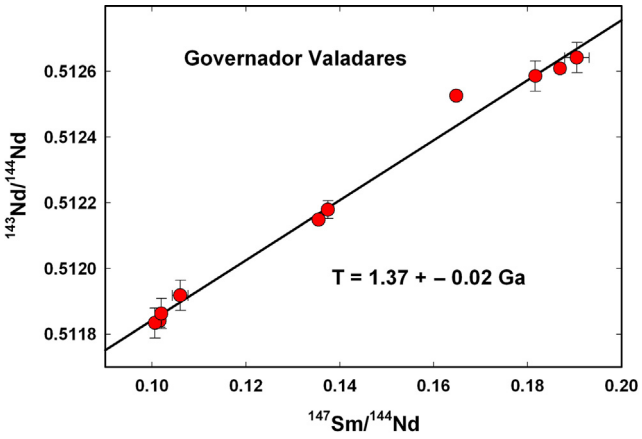

FIGURE 28.26 Samarium-neodymium isochron diagram for the martian meteorite Governador Valaderes. The regression line through the data of whole rock samples, mineral separates, and leachates defines a crystallization age of 1.37 ± 0.02 Ga. *Data from Shih et al. (1999).*

TABLE 28.7 Extinct Radionuclides Important as Early Solar System Chronometers

RadioNuclide	Half-Life (Ma)	Daughter	Initial Abundance
^{26}Al	0.73	^{26}Mg	$5 \times 10^{-5} \times {}^{27}$Al
^{10}Be	1.5	^{9}Be	$7 \times 10^{-4} \times {}^{9}$Be
^{53}Mn	3.74	^{53}Cr	$2\text{-}4 \times 10^{-5} \times {}^{55}$Mn
^{107}Pd	6.5	^{107}Ag	$5 \times 10^{-5} \times {}^{108}$Pd
^{182}Hf	9	^{182}W	$10^{-4} \times {}^{182}$Hf
^{129}I	15.7	^{129}Xe	$1.1 \times 10^{-4} \times {}^{127}$I
^{146}Sm	103	^{142}Nd	$8 \times 10^{-3} \times {}^{144}$Sm

(Figure 28.26). Most shergottites have crystallization ages between 165 and 475 Ma, while those of Nakhlites and Chassignites cluster around 1.3−1.4 Ga. The exception is ALH88001 (about 4.5 Ga), which may represent a sample from the ancient crust of Mars.

It is likely that the source craters of lunar meteorites are randomly distributed on the surface of the Moon. Some lunar meteorites are probably samples from the lunar farside, where no samples were collected by landing missions. Crystallization ages of lunar meteorites are similar to those of samples collected by Apollo or Luna missions. Ages of mare basalts cluster between 3.8 and 3.9 Ga, but the later impact bombardment of the Moon has reset the radiometric clocks to varying degrees. This crystallization-age cluster of lunar meteorites does not resolve the debate about whether the Moon experienced an increase in impact rates around 3.9 Ga ("lunar cataclysm") or the impact formation of the large Imbrium basin.

7.5. Extinct Radionuclides: Chronology of the Early Solar System

Short-lived, extinct radionuclides originally in the early solar system have been now completely decayed away. The decay products of these extinct nuclides, however, provide valuable information allowing determination of the order in which objects formed within the early solar system. This is based on the amount of radionuclides in objects that were present during their formation and are now detectable in their decay products. Short-lived radioisotopes used in cosmochronology are given in Table 28.7.

Measurements of decay products of an extinct radionuclide do not provide absolute dates in the sense discussed in the previous section, but do permit relative chronologies on timescales comparable with the half-life of the radionuclide. Often, relative ages are calculated from three-isotope plots involving decay products of the extinct radionuclide. For example, the "canonical" initial ratio in CAIs of the extinct nuclide ^{26}Al to the stable ^{27}Al is 5×10^{-5}. This value was determined from an excess of ^{26}Mg in several CAI samples, the oldest solar system material. Any material with lower $(^{26}\text{Al}/^{27}\text{Al})_0$ must have been formed later than the CAIs.

This relative chronologic information can be combined with absolute age data to establish small absolute time differences in the early solar system. The "anchor" is an object for which reliable measurements exist both for the Pb−Pb system and for the short-lived nuclide system. Such objects are CAIs, and individual meteorites like the Shallowater aubrite. Several isotope systems consistently indicate that the CAIs are the oldest objects formed in the early solar system over a time span of less than 1 Ma. Chondrules, the most abundant constituents of chondrites, followed a few million years later: for ordinary chondrites values are about 2 Ma while CO3 and CV3 chondrules formed 2−3 Ma after CAIs. Chondrules of metal-rich chondrites (CH, CB) formed significantly later, 5−6 Ma after CAIs.

Until recently, it was believed that differentiated meteorites formed from chondritic precursors and thus later than chondrules. Several isotope systems now indicate, however, that for the HED parent body, differentiation and crust formation began about 2.5−3 Ma after CAIs formed. The formation of the HED's parent body was probably very rapid, within about 1 Ma after formation of the solar system. The crystallization ages of individual eucrites are not very well known because of later shock overprinting. However, magmatic activity on Vesta, the proposed parent asteroid of these meteorites, seems to have continued over a longer time.

FIGURE 28.27 Representations of a French Southern and Antarctic Territories stamp illustrating a micrometeorite or cosmic dust particle (left) collected by melting Antarctic ice cores, the coring drill being at the meteor trails (of cometary origin) and a fireball are at the top.

For iron meteorites results from the $^{182}Hf-^{182}W$ system indicates that the parent bodies of magmatic iron meteorites differentiated within about 1 Ma after CAIs. For non-magmatic irons, however, the Hf–W systematics was modified by later impacts. The timing of these events is poorly constrained.

The thermal metamorphism and dates of aqueous alteration of chondrites have been studied by several isotopic systems. These processes continued for more than 30 Ma after CAI formation.

8. EPILOGUE

The most accessible source of extraterrestrial material are meteorites. The meteoritic record is read best in an interdisciplinary light. Results of one type of study give insight to another. Early experience gained from meteorite studies provided guidance for proper handling, preservation, and analysis of Apollo Lunar samples. Studies of these samples, in turn, led to the development of extremely sensitive techniques now being used to analyze meteorites and microgram-sized interplanetary dust particles collected by high-flying aircraft or found in Antarctic ice samples (Figure 28.27). The Stardust mission returned samples from a comet, the Genesis spacecraft collected particles of the solar wind, and Hayabusa brought to Earth samples from an asteroid. These samples have been analyzed with techniques developed for and tested with meteorite materials. Undoubtedly, this experience will prove invaluable as samples from other planets, their satellites, and small solar system bodies are brought to Earth for study.

Previous studies of meteorites have provided an enormous amount of knowledge about the solar system, and there is no indication that the scientific growth curve in this area is beginning to level off. Predictions about future developments are very hazardous but we can expect future surprises. New investigators, new ideas, and new techniques will contribute to the exploration of our solar system and—via presolar grains—study also the history of stars. Organic compounds present in carbonaceous chondrites, comets, and interplanetary dust particles may have contributed to the first prebiotic building blocks of life on Earth. Any new meteorite sample may reveal an unknown chapter in the history of the complete solar system.

3.2. Radiation Pressure and the Poynting–Robertson Effect 676
3.3. Collisions 677
3.4. Charging of Dust and Interaction with the Interplanetary Magnetic Field 677
3.5. Evolution of Dust in Interplanetary Space 678
4. Future Studies **678**
Bibliography **682**

Solar system dust is finely divided particulate matter that exists between the planets. These cosmic dust particles are also often called **micrometeoroids** and range in size from assemblages of a few molecules to tenth-millimeter-sized grains, above which size they are called **meteoroids**. Sources of this dust are larger **meteoroids**, comets, asteroids, the planets and their moons and rings; there is interstellar dust sweeping through the solar system. Because of their small sizes, forces additional to solar and planetary gravity affect their trajectories. Radiation pressure and the interactions with ubiquitous magnetic fields disperse dust particles in space away from their sources. In this way, **micrometeoroids** become messengers of their parent bodies in distant regions of the solar system. A tablespoon of finely dispersed micrometer-sized dust grains scatters about 10 million times more light than a single **meteoroid** of the same mass. Therefore, a tiny amount of dust becomes recognizable, while the parent body from which it derived may remain undetected.

1. INTRODUCTION

One of the earliest known phenomena caused by solar system dust is the **zodiacal light**. Zodiacal light is visible to the human eye in the morning and evening sky in non-polluted areas (Figure 29.1). Already in 1683, Giovanni Domenico Cassini presented the correct explanation for this phenomenon: It is sunlight scattered by dust particles orbiting the Sun. The relation to other "dusty" interplanetary phenomena, like comets, was soon suspected. Comets shed large amounts of dust, visible as dust tails, during their passage through the inner solar system. The genetic relation between **meteors** and comets was already known in the nineteenth century. It turned out that **meteoroids** are the link between interplanetary dust and the larger objects: **meteorites**, asteroids, and comets.

Cosmic dust can have different appearances in different regions of the solar system. It consists not only of **refractory** rocky or metallic material as in stony and iron meteorites, but also of **carbonaceous** material; dust in the outer solar system can even be ice particles.

Individual dust particles in interplanetary space have much shorter lifetimes than the age of the solar system. Several dynamic effects disperse the material in space and size (generally going from bigger to smaller particles). Therefore, interplanetary dust must have contemporary sources, namely, bigger objects like meteoroids, comets,

and asteroids in interplanetary space and also planetary moons and rings. In addition, there are dust particles immersed in the local interstellar cloud through which the solar system currently passes. Such interstellar dust particles penetrate the planetary system.

Dust is often a synonym for dirt, which is annoying and difficult to quantify. This is also true for interplanetary dust. Astronomers who want to observe extrasolar system objects have to struggle removing the foreground scattered light from the zodiacal light. Theoreticians who want to model interplanetary dust have the difficulty of representing these particles by simplified models, for example, a spherical particle of uniform composition and optical properties of a pure material. True interplanetary dust particles (IDPs) can be very different from these simple models (Figure 29.2).

Another practical aspect of dust is its danger to technical systems. A serious concern of the first spaceflights was the hazard from meteoroid impacts. Among the first instruments flown in space were simple dust detectors, many of which were unreliable devices that responded not only to impacts but also to mechanical, thermal, or

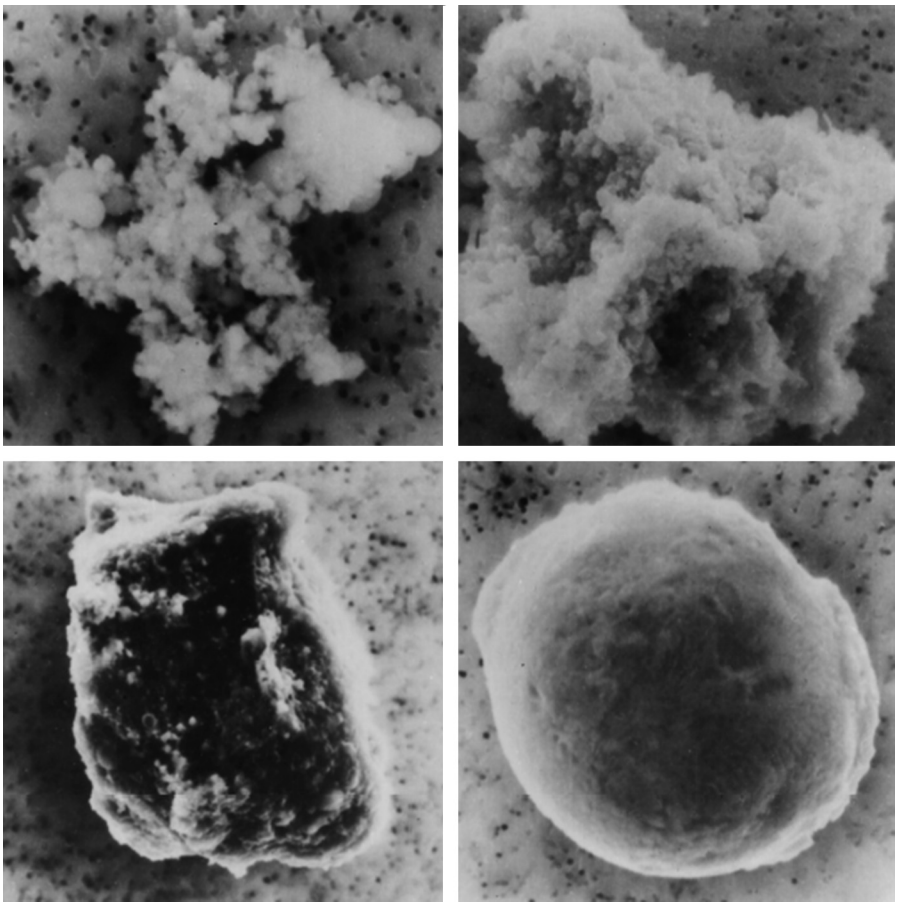

FIGURE 29.2 Interplanetary dust particles collected in the stratosphere by NASA's cosmic dust program. electrical interference. A dust belt around the Earth was initially suggested, which was dismissed only years later when instruments had developed enough to suppress this noise by several orders of magnitude. Modern dust detectors can reliably measure dust impact rates from a single impact per month up to a 1000 impacts per second.

In the early days of spaceflight, measures were taken to protect spacecraft against the suspected heavy bombardment by meteoroids. The bumper shield concept found its ultimate verification in the European Space Agency's *Giotto* mission to comet Halley. This spacecraft was designed to survive impacts of particles of up to 1 g mass at an impact speed of 70 km/s. These grains carry energies comparable to cannon balls that are 1000 times more massive. Heavy metal armor was not possible because spacecraft are required to be lightweight. The *Giotto* bumper shield combined a 1-mm-thick aluminum sheet positioned 23 cm in front of a 7-cm-thick lightweight composite rear shield. A dust particle that struck the thin front sheet was vaporized or disrupted. The cloud made of vapor and particle fragments then expanded into the empty space between the two sheets and penetrated the rear shield, where its energy was absorbed by being distributed over a large area. In this way, 2.7 m^2 front surface of the spacecraft was effectively protected by armor that weighed only 50 kg.

Only recently has the dust hazard become important again, because of man-made **space debris** in Earth orbit. Each piece of equipment carried into space becomes, after disruption by an explosion due to malfunctioning batteries or fuel systems or by an impact, the source of small projectiles, which endanger other satellites. Some estimates indicate that, in 50 years, the continuous increase in man-made space activity will lead to a runaway effect that will make the near-Earth space environment unhabitable to humans and equipment.

However, we are not concerned with this aspect of interplanetary dust; rather, the topic of this chapter is interplanetary dust as an exciting object of astrophysical research: through its wide distribution over the solar system, cosmic dust can tell stories about its parent bodies (comets, asteroids, moons, even interstellar matter) that are otherwise not easily accessible. This view, however, requires that dust particles be traced back to their origins. To do this, we must understand their dynamics. Dust particles not only follow the gravitational pull of the Sun and the planets but also feel the interplanetary magnetic field and the electromagnetic radiation that fills the solar system. In addition, they interact with the solar wind and with other dust particles that they encounter in space, generally at high speeds. These collisions lead to erosion or to disruption of both particles, thus generating many smaller particles. The dynamics of interplanetary dust cannot be described solely in terms of position and velocity; their size or mass must also be considered.

2. MANIFESTATIONS OF COSMIC DUST

Different methods are available to study cosmic dust (Figure 29.3). They are distinguished by the size or mass range of particles that can be studied. The earliest methods were ground-based zodiacal light and *meteor* observations. About 60 years ago, radar observations of meteor trails became available. With the advent of spaceflight, in situ detection by space instrumentation provided new information on small IDPs. Among the first reliable instruments were simple penetration detectors; modern impact ionization detectors allow not only the detection but also the chemical analysis of **micrometeoroids**. Deep space probes equipped with dust detectors identified micrometeoroids in interplanetary space from 0.3 AU out to 25 AU from the Sun. Natural (e.g. lunar samples) and artificial surfaces exposed to micrometeoroid impacts have been returned from space and analyzed. High-flying aircraft collected dust in the stratosphere that was identified as extraterrestrial material and was analyzed in the laboratory with the most advanced microanalytic tools. Modern space-based infrared observatories now allow the observation of the thermal emission from interplanetary dust in the outer solar system. Beyond our solar system, hundreds of so-called **debris disks** have been identified around other stars by their emission at infrared and longer wavelengths. They are naturally produced dust disks, forming the extrasolar counterparts of our own zodiacal dust cloud. Brightness asymmetries and other structures

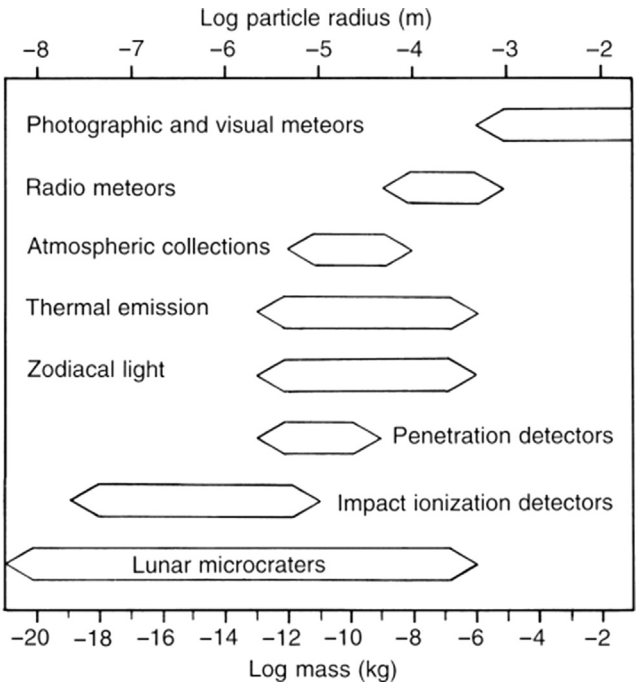

FIGURE 29.3 Comparison of meteoroid sizes and masses covered by different observational methods.

sometimes observed in these disks trace the presence of one or more planets orbiting their central star.

2.1. Meteors

Looking up at the clear night sky, one can record about 10 faint meteors (or shooting stars in colloquial language) per hour. Once in a while, a brighter streak or trail of light or "fireball" will appear. Around the year 1800, the extraterrestrial nature of meteors was established when triangulation was used to deduce their altitude and speed. This technique is still used in modern meteor research by employing specifically equipped cameras and telescopes. About 60 years ago, radar techniques were developed to observe faint meteor trails even during daylight.

Visible meteors result when centimeter-sized meteoroids enter the Earth's atmosphere at a speed greater than 10 km/s. At this speed, the energy of motion, which is converted to heat, is sufficient to totally vaporize the meteoroid. During its deceleration in the atmosphere at about 100 km altitude, the meteoroid heats up and atoms from its surface are ablated until it is completely evaporated. A luminous trail several kilometers in length follows the meteoroid. It is this ionized and luminous atmospheric gas and material from the meteoroid that is visible and that scatters radar signals. From triangulation of the meteor trail by ground stations (several cameras or a radar station), the interplanetary meteoroid orbit can be obtained with high accuracy.

During the atmospheric entry of objects larger than several tens of kilograms or about 10 cm in diameter, a surface layer several centimeters in thickness burns away, and the object gets decelerated. The surviving object which reaches Earth's surface is called a meteorite. Meteorites of 1 kg to several tons are sufficiently decelerated and fall on the Earth with their interior remaining mostly unaltered by atmospheric entry. These meteorites are the source of our earliest knowledge about extraterrestrial material (*see* Meteorites; Near-Earth Objects; Planetary Impacts).

Much of the material ablated from a meteoroid condenses into small droplets, which cool and form cosmic spherules that subsequently rain down to the Earth. These cosmic spherules can be found and identified in abundance in deep-sea sediments and on the large ice masses of Greenland, the Arctic, and Antarctica. An average of 40 tons of extraterrestrial material per day falls onto the surface of Earth in the form of fine dust.

At certain times, meteor showers can be observed at a rate that is a 100 (and more) times higher than the average sporadic meteor rate (Table 29.1). Figure 29.4 shows several meteors in a photograph of the night sky. The visible rate was about one meteor per second. Because all these meteoroids travel on parallel trajectories in space, to an observer on the Earth, they seem to arrive from a common point in the sky (the radiant), which in this case lies in the constellation Leo. Therefore, this meteor shower is called the Leonid shower.

The explanation for the yearly occurrence of meteor showers is that all meteoroids in one stream closely follow the elliptical orbit of their parent comet around the Sun but are spread out all around the orbit. Each year when the Earth crosses this orbit on the same day, some meteoroids of the stream hit the atmosphere and cause the shower.

Many meteor streams have orbits similar to those of known comets (cf. Table 29.1). It is generally accepted that meteor streams are derived from comets. Millimeter- to centimeter-sized particles that are emitted from comets at low speeds (meters per second) are not visible in the normal comet tail but form so-called **comet trails** along a short segment of the comet's orbit. Their different speeds slowly spread the particles out over the full orbit. Infrared observations by the *Infrared Astronomical Satellite* (*IRAS*) identified many such trails connected to short-period comets (Figure 29.5).

Gravitational interactions with planets and collisions with other cosmic dust particles scatter meteoroids out of their stream, and they eventually become part of the sporadic background cloud of meteoroids. The fact that some meteor showers display strong variations of their intensities indicates that they are young streams still concentrated in a small segment of their parent's orbit. The meteor streams of the Leonids and its parent, the periodic comet Tempel–Tuttle, have the same periodicity of 33.3 years. The parent object of one of the strongest yearly meteor showers, the Geminids, is 3200 Phaethon. It was classified as an asteroid because it shows no **cometary** activity. However, its association with a meteor stream indicates that it is an inactive, dead comet that at some time in the past emitted large quantities of meteoroids (*see* Physics and Chemistry of the Comets; Comet Populations and Cometary Dynamics; Near-Earth Objects).

Less than 1 of 10,000 radar meteors has been identified to be caused by interstellar meteoroids that pass through the solar system on hyperbolic orbits. Their heliocentric speed is significantly higher than the solar system escape speed, confirming that they are of truly interstellar origin. The radius of these interstellar meteoroids is about 20 μm. These particles generally arrive from southern ecliptic latitudes with enhanced fluxes from discrete sources.

2.2. Interplanetary Dust Particles Collected in the Stratosphere

There is another "window" through which extraterrestrial material reaches the Earth's surface in a more or less undisturbed state. Small **IDPs** of a few to 50 μm diameter are

Source: After Cook, A. F. (1973). In C. L. Hemenway, P. M. Millman, & A. F. Cook (Eds.), *Evolutionary and physical properties of meteoroids* (pp. 183–191). NASA SP-319.

decelerated in the tenuous atmosphere above 100 km. At this altitude, the deceleration is so gentle that the grains do not reach the temperature of substantial evaporation ($T \sim 800$ °C). The high surface area to mass ratio of these small particles enables them to effectively radiate away excess heat. These dust particles subsequently sediment through the atmosphere and become accessible to collection and scientific examination. The abbreviation IDP (or "Brownlee particle" after Don Brownlee, who first reliably identified their extraterrestrial nature) is often used for such extraterrestrial particles that are collected in Earth's atmosphere.

Early attempts to collect IDPs by rockets above about 60 km were not successful because of the very low influx of micrometeoroids into the atmosphere and the short residence times of IDPs at these altitudes. Airplane collections were more successful in the stratosphere at or above 20 km. At this altitude, the concentration of 10-μm-diameter particles is about 10^6 times higher than in space and terrestrial contamination is still low. Only micrometer- and submicrometer-sized terrestrial particles (e.g. from volcanic eruptions) can reach these altitudes in significant amounts. Another type of interference is caused by man-made contamination: About 90% of all collected particles in the 3 to 8 μm size range are aluminum oxide spheres, which are products of solid rocket fuel exhaust. Because of this overwhelming contamination problem for small particles, the lower size limit of IDPs collected by airplanes is a few micrometers in diameter.

Since 1981, IDP collection by airplanes has been routinely performed by National Aeronautics and Space Administration (NASA) using high-flying aircraft which can cruise at 20 km altitude for many hours. On their wings they carry dust collectors that sweep huge amounts

FIGURE 29.4 An unusually strong meteor shower (Leonids) was observed on November 17, 1966. The meteor trails seem to radiate from the constellation Leo.

FIGURE 29.5 Celestial structure mapped by IRAS. This false-color map plots the 12-μm fluxes as *blue* and 100-μm fluxes as *red*. The comet Temple 2 dust trail streaks across the bottom half of the image, while the diagonal broad *light blue bar* is the very bright midinfrared emission from the zodiacal dust along the ecliptic plane; the pronounced edges to this feature highlight the inner zodiacal dust bands. The more complex structure is the emission from interstellar dust, which is cool and, therefore, dominantly red away from the ecliptic plane.

of air. Dust particles stick to the collector surface that is coated with silicone oil. After several hours of exposure, the collector is retracted into a sealed storage container and returned to the laboratory. There, all particles are removed from the collector plate and the silicone oil is washed off. A wide variety of microanalytic tools are used to examine and analyze the IDPs. For example, scanning electron microscopes (SEMs) can image atomic lattice layer structures. Focused ion beams in combination with an SEM are used for sample preparation and secondary ion mass spectrometers can measure the distribution of individual elements and isotopes at submicrometer resolution, deriving important information on the composition of the samples.

According to their elemental composition, IDPs come in three major types: chondritic, 60% (cf. Table 29.2);

TABLE 29.2 Average Elemental Composition (All Major and Selected Minor and Trace Elements) of Several Chondritic Interplanetary Dust Particles (IDPs) is Compared with CI Chondrite Composition

Element	CI	IDP	Variation	T_c
Mg	1,191,000	0.9	0.6–1.1	1067

iron–sulfur–nickel, 30%; and mafic silicates (iron-magnesium-rich silicates, i.e. olivine and pyroxene), 10%. Most chondritic IDPs are porous aggregates, but some smooth chondritic particles are found as well. Chondritic aggregates may contain varying amounts of carbonaceous material of unspecified composition. Table 29.2 shows a significant enrichment of volatile (low-condensation-temperature) elements in IDPs when compared to CI chondrites. This observation is used to support the argument that these particles consist of some very primitive solar system material that had never seen temperatures above about 500 °C, as is the case for some cometary material. This and the compositional similarity with comets argue for a genetic relation between comets and chondritic IDPs.

A remarkable feature of IDPs is their large variability in isotopic composition. Extreme isotopic anomalies have been found in some IDPs, whereas under typical solar system conditions, isotopic variations of only fractions of percent can occur. These huge isotopic variations indicate that some grains were not homogenized with other solar system material but have preserved much of their presolar character. Submicrometer-sized grains known as GEMS (glass with embedded metal and sulfides) are major constituents of the chondritic porous class of IDPs. Several GEMS with nonsolar oxygen isotopic compositions were identified, confirming that at least some are indeed presolar grains. These **amorphous** interstellar silicates are considered one of the fundamental building blocks of the solar system.

2.3. Zodiacal Light

The wedge-shaped appearance of the zodiacal light (see Figure 29.1) demonstrates its concentration in the **ecliptic plane**. For an observer on the Earth, the zodiacal light extends along the ecliptic plane all the way around the sky to the antisolar direction, although at strongly reduced intensities. In the direction opposite to the Sun, this light forms a hazy area of a few degrees in dimension known as the gegenschein, or counterglow. If seen from the outside, the zodiacal dust cloud would have a flattened, lenticular shape that extends along the ecliptic plane about seven times farther from the Sun than perpendicular to the ecliptic plane.

The brightness of the zodiacal light is the result of light scattered by a huge number of particles in the direction of observation. The observed zodiacal brightness is a mean value, averaged over all sizes, compositions, and structures of particles along the line of sight. Zodiacal light brightness can be traced clearly into the solar corona. However, most of this dust is foreground dust close to the observer because of a favorable scattering function. Nevertheless, the vicinity of the Sun is of considerable interest for zodiacal light measurements because it is expected that close to the Sun the temperature of the dust rises, and the dust particles start to sublimate, first the more volatile components and closer to the Sun, even the refractory ones. Inside about four solar radii distance, dust should completely sublimate. Some observers indeed found a sharp edge of a dust-free zone at four solar radii, while others did not see such a sharp edge. Perhaps the inner edge of the zodiacal cloud changes with time.

The large-scale distribution of the zodiacal dust cloud is obtained from zodiacal light measurements on board interplanetary spacecraft spanning a distance ranging from 0.3 to approximately 3 AU from the Sun. Even though the intensity decreases over this distance by a factor of 150, the spatial density of dust needs to decrease by only a factor of 15. The radial dependence of the number density is slightly steeper than an inverse distance dependence. A slight **inclination** of about 3° of the symmetry plane of zodiacal light with respect to the ecliptic plane has been determined from zodiacal light measurements.

At visible wavelengths, the spectrum of the zodiacal light closely follows the spectrum of the Sun. A slight reddening (i.e. the ratio of red to blue intensities is larger for zodiacal light than for the Sun) indicates that the majority of particles are larger than the mean visible wavelength of 0.54 μm. In fact, most of the zodiacal light is scattered by 10- to 100-μm-sized particles. Therefore, the dust seen as zodiacal light is only a subset of the interplanetary dust cloud. Submicrometer- and micrometer-sized particles, as well as millimeter-sized and bigger particles, do not contribute much to the zodiacal light at optical wavelengths but they exist.

Above about 1 μm in wavelength, the intensities in the solar spectrum rapidly decrease. The zodiacal light spectrum follows this decrease up to about 5 μm, while at longer wavelengths the thermal emission of the dust particles prevails. Because of the low albedo (fraction of incident sunlight reflected and scattered in all directions is smaller than 10%) of IDPs, most visible radiation (>90%) is absorbed and emitted at infrared wavelengths. The maximum of the thermal infrared emission from the zodiacal dust cloud lies between 10 and 20 μm. From the thermal emission observed by the IRAS and Cosmic Background Explorer (*COBE*) satellites, an average dust temperature at 1 AU distance from the Sun between 0 and 20 °C has been derived. Some spatial structure has been observed at thermal infrared wavelengths. Asteroid bands mark several **asteroid families** as significant sources of solar system dust just as comet trails identify dust emitted from individual comets.

Optical and infrared observations of other extraterrestrial dusty phenomena have also provided important insights into the zodiacal dust complex. Cometary and **asteroidal** dust is considered to be an important source of the zodiacal cloud. The study of circumplanetary dust and rings has stimulated much research on the dynamics of dust clouds. Interstellar dust is believed to be the ultimate source of all refractory material in the solar system. Circumstellar

dust clouds like the one around β Pictoris are "zodiacal clouds" of their own right, the study of which may eventually give information on extrasolar planetary systems (*see* Infrared Views of the Solar System from Space; Planetary Rings; Extra-Solar Planets).

2.4. Lunar Microcraters and the Near-Earth Dust Environment

The size distribution of IDPs is represented by the lunar microcrater record. Microcraters on lunar rocks were found ranging from 0.02 μm to millimeters in diameter (Figure 29.6). Laboratory simulations of high-velocity impacts on lunarlike materials were performed to calibrate crater sizes with projectile sizes and impact speeds. Submicrometer- to centimeter-sized projectiles were used with speeds above several kilometers per second. The typical impact speed of interplanetary meteoroids on the Moon is about 20 km/s. For the low-mass particles, electrostatic dust accelerators were used that reach projectile speeds of up to 100 km/s. The high-mass projectiles were accelerated with light-gas guns, which reached speeds up to about 10 km/s. For the intermediate mass range, plasma drag accelerators reached impact speeds of 20 km/s. The crater diameter to projectile diameter ratio varies from 2 for the smallest microcraters to about 10 for centimeter-sized projectiles.

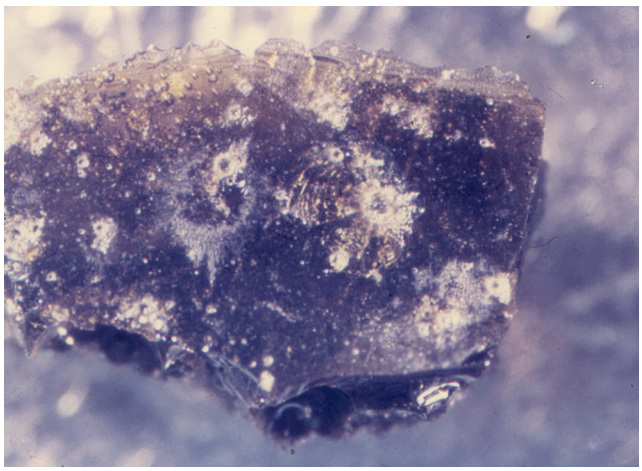

FIGURE 29.6 Microcraters on the glassy surface of a lunar sample. Bright spallation zones surround circular central pits.

The difficulty in deriving the impact rate from a crater count on the Moon is that the degree to which rocks shield other rocks and thus the exposure time of any surface is generally unknown. Therefore, the crater size or meteoroid distribution has to be normalized with the help of an impact rate or meteoroid flux measurement obtained by other means. In situ detectors or recent analyses of impact plates that were exposed to the meteoroid flux for several years on NASA's *Long Duration Exposure Facility* provided this flux calibration (Figure 29.7). The smallest particles dominate the flux, and the mass flux of meteoroids peaks at 10^{-5} g. The total mass density of interplanetary dust at 1 AU is 10^{-16} g/m^3 and the total mass of the zodiacal cloud inside Earth's orbit is between 10^{16} and 10^{17} kg, which corresponds to the mass of a single object (comet or asteroid) of about 20 km in diameter.

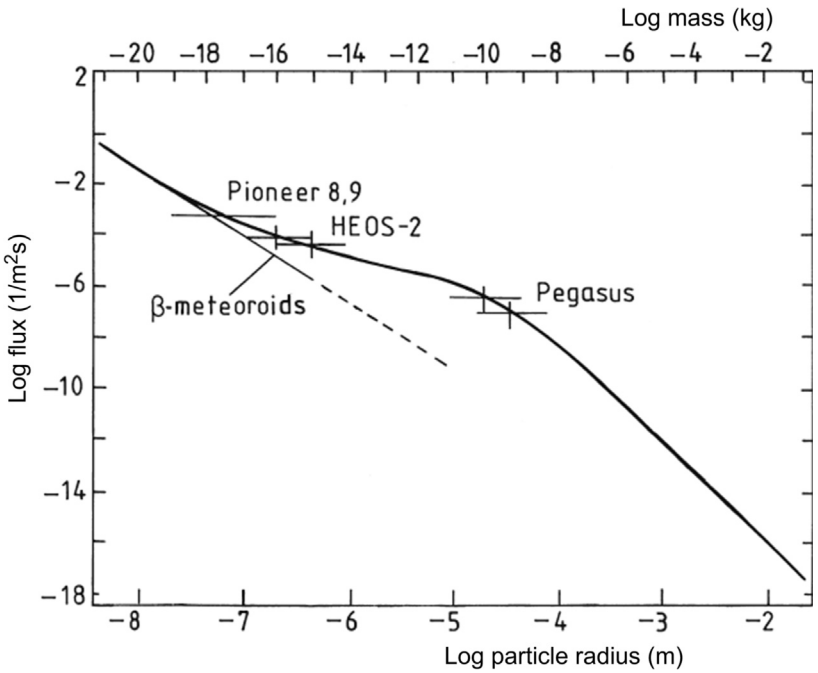

FIGURE 29.7 Cumulative flux of interplanetary meteoroids on a spinning flat plate at 1 AU distance from the Sun. The solid line has been derived from lunar microcrater statistics and it is compared with satellite and spaceprobe measurements.

In low Earth orbit the meteoroid flux is about a factor of two higher than in deep space because of the Earth's gravitational concentration. However, man-made space debris outnumbers micrometer-sized natural meteoroids (by a factor of three). Craters produced by space debris particle impacts are identified by chemical analyses of residues in the craters. Residues have been found from space materials and signs of human activities in space, such as paint flakes, plastics, aluminum, titanium, and human excretion.

2.5. Comet Dust

The inner **coma** of a comet (*see* Physics and Chemistry of Comets) is one of the most dust-rich environments in the solar system. Almost everything we see from a comet with the naked eye is dust. Both the coma and the tail are seen as sunlight scattered by micron-sized dust (cf. Figure 29.1). Particles ejected from a comet form different dust populations. Submicron-sized grains have high ejection velocity ($\sim$1 km/s), and on ejection from the comet they may rapidly assume hyperbolic orbits and escape from the solar system. Grains of size 1–100 μm are ejected at a speed of several hundred meters per second and under the action of solar radiation pressure they form the comet tail which disperses them far from the comet orbit within a short time period. Even bigger particles stay in a trail close to the comet's orbit. If the Earth crosses such a trail, it is observed as a meteor stream (Table 29.1).

One of the problems in characterizing the dust environment of a comet is that information on the nucleus, its dust, and gas release is very limited. Before 1986, observations of cometary dust were the domain of astronomers. High-resolution images of cometary comae revealed jets and other structures in the inner parts. Some of these structures formed spirals which rotated like water from a lawn sprinkler, indicating discrete dust emissions from localized active parts of the nucleus surface. A consequence of observing in visible light is that the results are biased by particle sizes in the range of 1–10 μm, because much smaller and much larger particles do not contribute significantly to the scattered light in the visible range. With the extension of the observable spectral range to infrared wavelengths using space-based telescopes, the thermal emission of dust also became accessible to astronomers. It revealed information on the abundance of larger grains and on the **mineralogical** composition of the dust.

A breakthrough in understanding cometary constituents came with space missions to several comets: Giotto and two VeGa spacecraft to comet 1P/Halley in 1986, Deep Space 1 to comet 19P/Borelly in 1999, Stardust to comet 81P/Wild 2 in 2004, Deep Impact to comets 9P/Tempel 1 in 2005 and 103P/Hartley 2 in 2010, and most recently Stardust to 9P/Tempel 1 in 2011. Water and CO were identified as the main species in the gas, and dust particles made of carbonaceous and silicate materials ranging from nanometer to millimeter sizes were detected. Active areas on resolved images of cometary nuclei and corresponding dust jets were identified for some of the visited comets.

The Stardust mission was the first space mission designed to return extraterrestrial material from interplanetary space. The primary goal of Stardust was to collect dust samples during its flyby of comet Wild 2. The spacecraft flew through the coma at a speed of 6.1 km/s within 236 km from the nucleus and comet particles were collected in **aerogel** of 50 and 20 kg/m^3 density. The collector consisted of 0.1 m^2 aerogel and of 0.015 m^2 aluminum foil. Micrometer-sized dust particles were decelerated gradually by the aerogel, forming several millimeter long tracks, and minimizing the damage to the dust grains. The collector was stored in a Sample Return Capsule which was released from the spacecraft just before reentry into Earth's atmosphere, for a landing on a parachute.

In January 2006, the Stardust sample capsule returned safely to the Earth with thousands of particles from comet 81P/Wild 2 for laboratory study. Impact tracks in aerogel created by particles ranging from dense **mineral** grains to loosely bound, polymineralic aggregates ranging from 0.01 to 100 μm in size displayed diverse impact features. Residues in impact craters on the structure supporting the aerogel were also analyzed.

The collected particles are chemically heterogeneous; however, the mean elemental composition of comet Wild 2 particles is consistent with CI meteorite composition (cf. chapter meteorites). The particles are weakly constructed mixtures of nanometer-scale grains with occasionally much larger Fe–Mg silicates, Fe–Ni sulfides, and Fe–Ni metal phases. A very wide range of olivine and low-Ca pyroxene compositions was also found.

The collected samples are dominated by high-temperature materials that closely resemble meteoritic components. These materials include chondrule and **calcium-aluminum-rich inclusion (CAI)**-like fragments (Figure 29.8). The abundance of high-temperature minerals such as forsterite and enstatite appears to have formed in the hot inner regions of the solar nebula. From there they were transported beyond the **orbit** of Neptune where they accreted together with ice and organic components to form comet Wild 2.

Hydrogen, carbon, nitrogen, and oxygen isotopic compositions are heterogeneous among particle fragments; however, extreme isotopic anomalies are rare, indicating that this comet is not a pristine aggregate of presolar materials. An extreme oxygen ratio $^{17}O/^{16}O = 10^{-3}$ was found which is a factor 2.6 higher than the Solar System value and is similar to that of some presolar grains found in meteorites. Only five presolar grains have been discovered in the Wild 2 samples so far. The presolar grain content appears to be lower than in chondrites and in most IDPs.

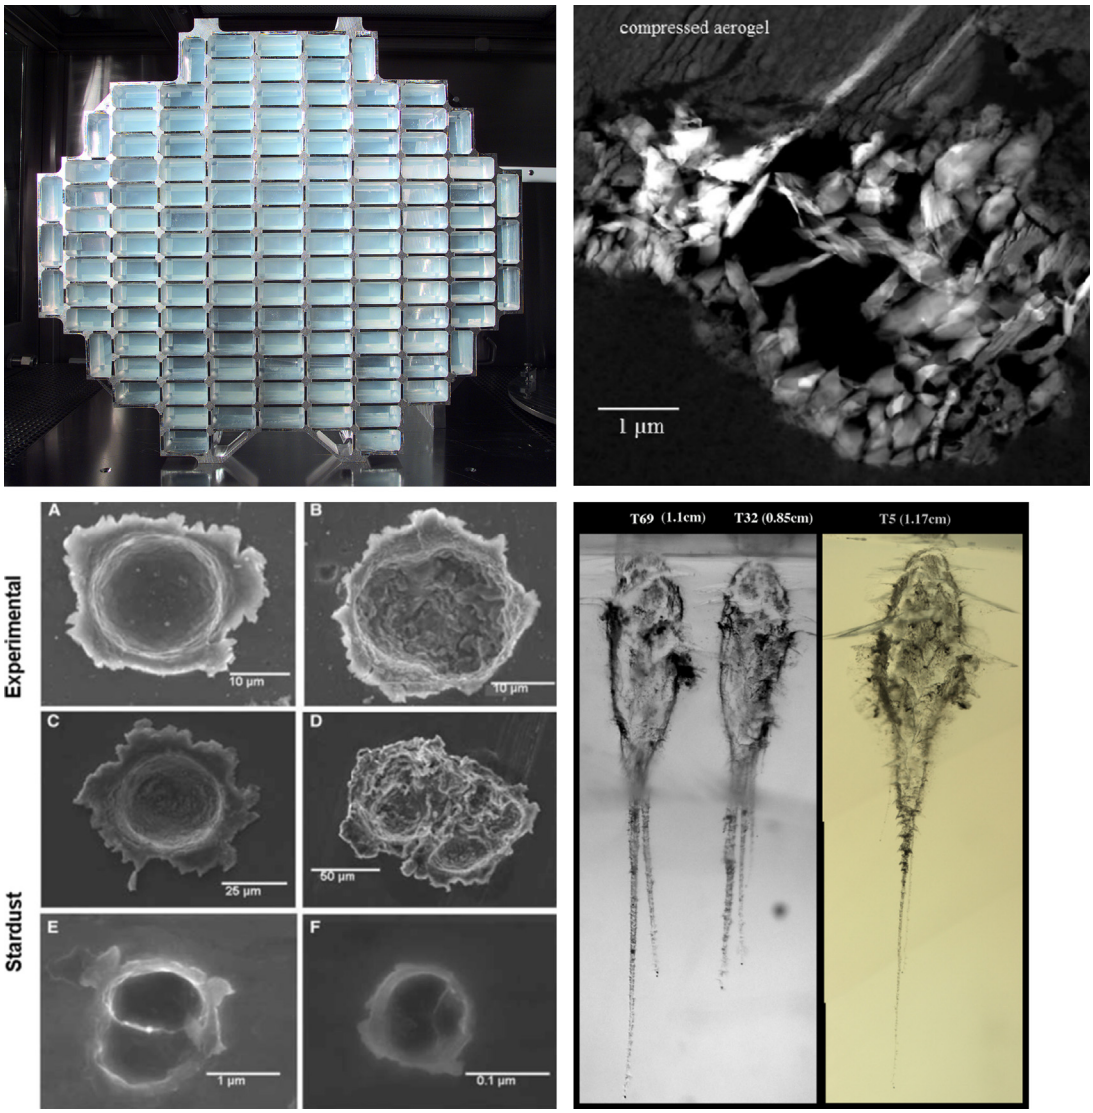

FIGURE 29.8 Top left: the Stardust aerogel dust collector that was returned to the Earth with dust particles from comet Wild 2 on one side of the collector and with interstellar dust particles on the other. Top right, a CAI particle found in the Stardust collection. Bottom left, comparison of experimental and Stardust impacts into the aluminum structure of the Stardust collectors. Bottom right, tracks of cometary particles in aerogel. The particles approached from the top. *Courtesy NASA, Science.*

The organics are rich in oxygen and nitrogen compared with **meteoritic** organics. Aromatic compounds are present but less abundant than in meteorites and IDPs. The organics found in comet Wild 2 shows a heterogeneous and unequilibrated distribution in abundance and composition. Even glycine, a fundamental building block of life, was found in samples of comet Wild 2 which supports the idea that these precursors of life are prevalent in space (*see* Physics and Chemistry of Comets; Meteorites).

Small bodies in the inner solar system were traditionally classified as either asteroids or comets. Comets are active objects, with activity showing up as a prominent coma and tail(s) when they approach the Sun. Cometary activity is largely driven by the sublimation of near-surface water ice. On the contrary, asteroids lack such signatures of activity. Recently, a small number of intermediate-type objects were discovered which are called "main belt comets" or "active asteroids". Dynamically their orbits resemble those of asteroids, while they show clear signs of activity similar to comets. The activity is usually evidenced by the light scattering off dust particles emitted from the object, forming a comalike structure and sometimes a tail. Their mass loss, however, is likely driven by a surprising diversity of mechanisms. Besides sublimation of water ice, impact ejection, rotational instability due to spin up, dehydration stresses and thermal fracture, as well as electrostatic repulsion and solar radiation pressure sweeping of dust particles from the surfaces of these objects have been

suggested. Even though no single mechanism can explain the varied examples of activity observed, coma and tail morphology as evidenced by the emitted dust particles can give valuable information about the dominant processes. Coma and tail structures may constrain the duration of activity, e.g. whether the emission event was impulsive due to an impact or long lasting or even repetitive. Astronomers may also be able to constrain particle sizes and ejection velocities from the coma and tail morphology (*see* Main-Belt Asteroids; Comet Populations and Cometary Dynamics).

2.6. Spacecraft Measurements

In situ measurements by dust impact detectors on board interplanetary spacecraft are complementary to ground-based and astronomical dust observations. In situ measurements have been performed in interplanetary space between 0.3 and 25 AU heliocentric distance (Table 29.3).

Two types of impact detectors were mainly used for interplanetary dust measurements: penetration detectors and impact ionization detectors. Penetration detectors record the mechanical destruction from a dust particle's impact, e.g. the penetration of a 25- or 50-μm-thick steel film has a detection threshold of 10^{-9} or 10^{-8} g (approximately 10 or 20 μm particle radius) at a typical impact speed of 20 km/s. At lower impact speeds the minimum detectable particle mass is bigger, and vice versa. A more sensitive penetration detector is the polyvinylidene fluoride (PVDF) film. PVDF is a polarized material (i.e. all dipolar molecules in the material are aligned so that they point in the same direction). When a dust particle impacts the film, it excavates some polarized material. This depolarization generates an electric signal which is then detected. The pulse height of the signal is a function of the mass and the speed of the dust particle. A typical measurement range is from 10^{-13} to 10^{-9} g (approximately 1−10 μm radius).

The most sensitive dust detectors are impact ionization detectors. Figure 29.9 shows a photograph of the dust detector flown on the *Cassini* spacecraft. The detector has an aperture of 0.1 m^2 and is based on the impact ionization effect: a dust particle that enters the detector and hits the hemispherical target in the back at speeds above 1 km/s produces an impact crater and part or all of the projectile's material is vaporized. Because of the high temperature at the impact site, some electrons are stripped off atoms and molecules and generate a vapor that is partially ionized. These ions and electrons are separated in an electric field within the detector and are collected by electrodes. Coincident electric pulses on these electrodes signal the impact of a high-velocity dust particle. The strength and the waveform of the signal are measures of the mass and speed of the impacting particle. The small central part of the Cassini detector is a time-of-flight mass spectrometer: a strong electric field between the target and a grid 3 mm in front of the target accelerates the ions to high speeds. During the flight between the grid and the ion collector, ions of different masses separate and arrive at different times at the multiplier. The lightest ions arrive first and heavier ones appear later. In this way, a mass spectrum is measured which represents the elemental composition of the dust grain. Entrance grids in front of the target pick up any electric charge of dust particles. Measurements of the electric charge carried by IDPs have been accomplished for the first time by the Cassini detector. Dust detectors incorporating a mass spectrometer were flown on the *Helios* spacecraft, the Giotto and VeGa missions to Comet Halley, the Stardust mission to Comet Wild 2, and the Cassini mission to Saturn. Electrostatic dust accelerators are used to calibrate these detectors with micrometer- and submicrometer-sized projectiles at impact speeds up to 100 km/s.

2.6.1. Interplanetary Dust

The radial profile of the dust flux in the inner solar system between 1 and 0.3 AU from the Sun was determined by the *Helios 1* and 2 space probes. Three dynamically different interplanetary dust populations were identified in the inner solar system. First, particles on low-eccentricity orbits about the Sun had already been detected by the *Pioneer 8* and *9* and *Highly Eccentric Orbit Satellite (HEOS) 2* dust experiments. They relate to particles originating in the asteroid belt that spiral toward the Sun under the **Poynting−Robertson** effect. Second, there are particles on highly eccentric orbits that have, in addition, large semimajor axes and that derive from short-period comets. Third, the *Pioneer 8* and *9* dust experiments detected a significant flux of small particles from approximately the solar direction which were called beta meteoroids. The existence of these particles was recently confirmed by measurements with the Japanese *Hiten* satellite.

Recently, the *Galileo* and *Ulysses* spacecraft carried dust detectors through interplanetary space between the orbits of Venus and Jupiter and above the ecliptic plane. In a swingby of Jupiter, the Ulysses spacecraft was brought into a heliocentric orbit almost perpendicular to the ecliptic plane that carried it under the South Pole, through the ecliptic plane, and over the North Pole of the Sun. The Galileo spacecraft always remained close to the ecliptic plane and became the first man-made satellite of Jupiter.

Interplanetary dust measurements were obtained by the Galileo spacecraft in the ecliptic plane between Venus orbit and the asteroid belt. The dust impact rate was generally higher closer to the Sun than farther away. After flybys at Earth and Venus, the spacecraft moved away from the Sun. At these times, the impact rate was more than an order of magnitude higher than before the flyby when the spacecraft moved toward the Sun. This observation is explained by the

fact that interplanetary dust inside the asteroid belt orbits the Sun on low-inclination (<30°) and in low-eccentricity **bound orbits**. Thus, the detector that looked away from the Sun all the time detected more dust impacts when the spacecraft moved in the same direction (outward) than in the opposite case when the spacecraft moved inward. The spatial dust density follows roughly an inverse radial distance dependence. Close passages of the asteroids Gaspra and Ida did not exhibit increased dust impact rates.

In the outer solar system, the dust detectors on board *Pioneers 10* and *11*, Galileo, Ulysses, Cassini, and *New Horizons* measured the flux of IDPs. The flux of micrometer-sized particles decreased from 1 AU going outward. No sign of a flux enhancement was detected in the asteroid belt. Outside Jupiter's orbit, *Pioneer 10* recorded a flat flux profile (Figure 29.10), which indicates a constant spatial density of micrometer-sized dust in the outer solar system. This observation has been interpreted to be due to the combined input of dust from the **Kuiper belt** and comets like Halley and Schwassmann−Wachmann 1.

2.6.2. Planetary Dust Streams

Inside a distance of about 3 AU from Jupiter, both the Ulysses and the Galileo spacecraft detected unexpected swarms of submicrometer-sized dust particles arriving from the direction of Jupiter. Figure 29.11 shows the strongly time-variable dust flux observed by Ulysses during its first flyby of Jupiter in 1992. About 1 month after closest approach to Jupiter, Ulysses encountered the most intense dust burst at a distance of about 40 million km from Jupiter. For about 10 h, the impact rate of submicrometer-sized particles increased by a factor of 1000 above the background rate. The measurements indicated that the particles in the burst were moving in collimated streams at speeds of several 100 km/s. Even stronger and longer lasting dust streams were observed in 1995 by the Galileo dust detector during its approach to Jupiter. Later, dust measurements inside the Jovian magnetosphere showed a modulation of the small particle impact rate with a period of 10 h, which is the rotation period of Jupiter and its magnetic field. Positively charged dust particles in the 10-nm-size range are coupled to the magnetic field and are thrown out of Jupiter's magnetosphere in the form of a warped dust sheet. Sources of these dust particles are the volcanoes on Jupiter's moon Io and, to a smaller extent, Jupiter's ring. During Cassini's flyby of Jupiter, this phenomenon was also observed, and mass spectra of the particles were obtained (Figure 29.12(a)). Both sodium chloride and sulfurous components were identified in the mass spectra, which is consistent with spectral measurements of Io's volcano-induced environment. In 2004 during its second flyby at Jupiter, Ulysses measured the dust streams even to a distance of 4 AU from Jupiter.

At Saturn, Cassini observed dust streams emanating from this system as well. Here, Saturn's dense A ring and the extended E ring were identified as sources. The ejection mechanism is very similar to that acting at Jupiter. Freshly generated nanometer-sized dust grains get charged and—if the charge is positive—thrown out by Saturn's magnetic

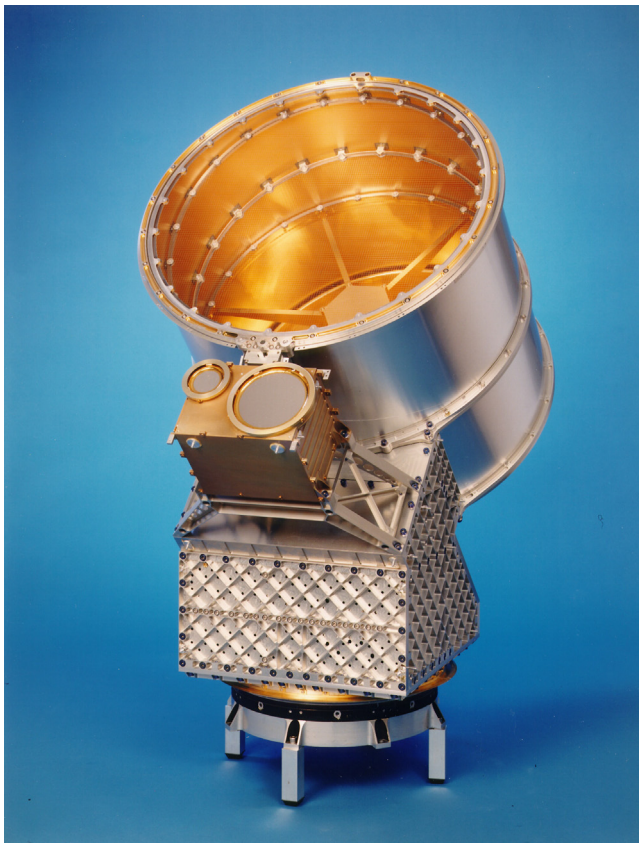

FIGURE 29.9 The Cassini Cosmic Dust Analyzer consists of two types of dust detectors, the High Rate Dust Detector, (HRD), and the Dust Analyzer, (DA). The cylindrical DA (upper center) has a diameter of 43 cm. The bottom of the sensor contains the hemispherical impact target; in the center are charge-collecting electrodes and the multiplier for the measurement of the impact mass spectrum. Two entrance grids sense the electric charge of incoming dust grains. The detector records impacts of sub-micron- and micron-sized dust particles above 1 km/s impact speed. HRD consist of two circular film detectors which record impacts of micron-sized dust particles at a rate of 10,000 per second. The detectors are carried by the electronics box which is mounted on top of a turntable bolted to the spacecraft.

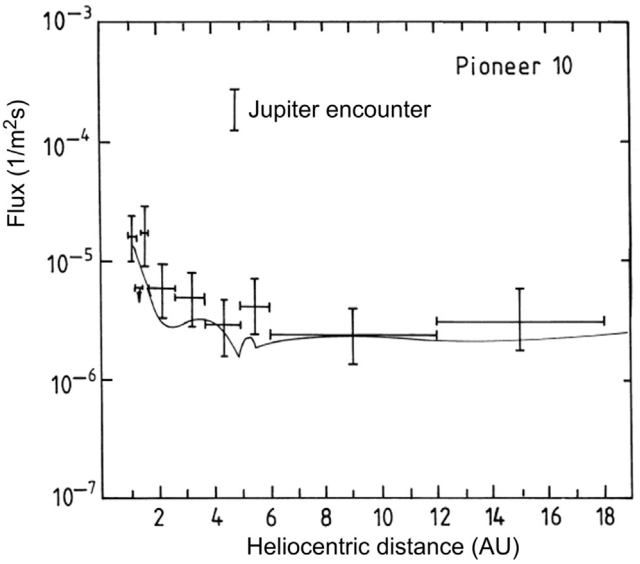

FIGURE 29.10 Flux of meteoroids with masses above 8×10^{-10} kg (about 10 μm in size) in the outer solar system measured by the Pioneer 10 penetration detector. At 18 AU distance from the Sun, the instrument quit operation. The measurements are in agreement with a model of constant spatial dust density in the outer planetary system. *From Humes (1980).*

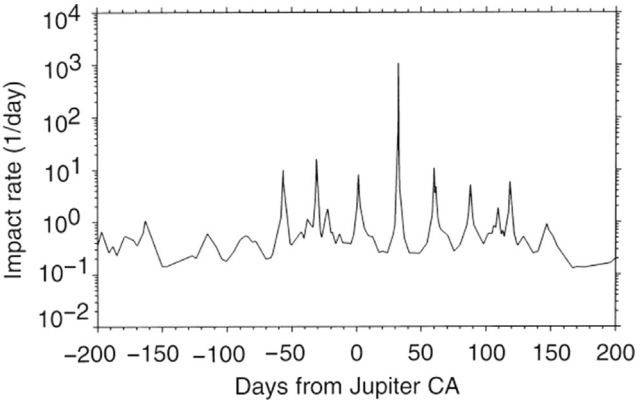

FIGURE 29.11 Dust impact rate observed by the Ulysses dust detector during 400 days around Jupiter closest approach (CA, February 8, 1992). At the beginning and end of the period shown, Ulysses was 240 million km (1.6 AU) from Jupiter, while at CA, the distance was only 450,000 km. Except for the flux peak at CA, when bigger particles were detected, the peaks at other times consisted of submicron-sized dust particles.

field. In some parts of the magnetosphere, dust particles become negatively charged; these particles remain bound to the magnetic field and stay in the vicinity of Saturn. The Saturnian stream particles primarily consist of silicate materials (Figure 29.12(b)) implying that the particles are the contaminations of icy ring material rather than the ice particles themselves (*see* Planetary Rings).

2.6.3. Tenuous Dusty Planetary Rings

All four giants planets have their own ring systems. Of these, Saturn's ring is by far the most prominent and most well known. In addition to its dense main ring system that is described in another chapter of this book (*see* Planetary Rings), Saturn also hosts a set of diffuse faint rings in and around its main rings. Similarly Jupiter, the largest of the giant planets, also has its own gossamer ring system. The dusty rings of both planets are composed primarily of particles smaller than 100 μm in radius. Interparticle collisions are rare in these tenuous rings, and the small sizes of the particles make them sensitive to nongravitational forces. Jupiter's and Saturn's dusty rings were studied in situ by dedicated dust detectors on board the Galileo and Cassini spacecraft and with Earth- and space-based imaging. This offered unique opportunities to combine in situ and remote imaging observations for the first time. The rings of Uranus and Neptune have not yet been studied with in situ dust detectors and are not covered in this chapter.

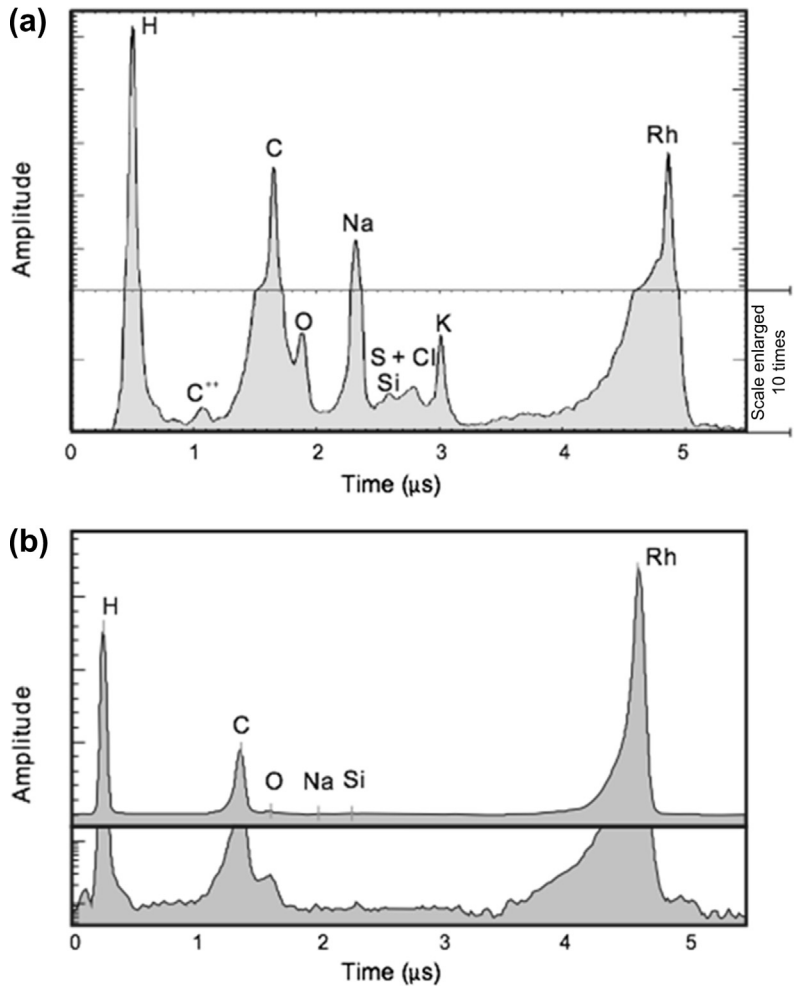

FIGURE 29.12 Cassini CDA mass spectra of (a) Jovian and (b) Saturnian stream particles. Due to the high impact velocity and small impactor mass, stream particle spectra are usually dominated by target and contaminant ions. (a) The mass spectrum is co-added from 30 Jovian stream particle spectra recorded upon Cassini's approach to Jupiter in 2000. The Na^+, K^+, S^+, Cl^+, and partly Si^+ and O^+ lines are particle constituents. (b) Saturnian stream particle mass spectrum recorded in 2004. The lower panel is on a logarithmic scale to show the weak lines. The major peaks in the spectrum are target (Rh^+) and target contamination ions (H^+, C^+). *From Postberg et al. (2009).*

2.6.3.1. Jupiter's Gossamer Rings

Jupiter's ring system consists of at least five distinct components: the main ring projecting inward from the orbits of the two moonlets Metis and Adrastea, the vertically extended halo interior to the main ring, two gossamer rings associated with the small moons Amalthea and Thebe, and a faint outward protrusion called the Thebe extension (Figure 29.13). The last of these is visible in edge-on ring images out to at least 270,000 km from the giant planet. During two passages of the ring system, the in situ dust detector on board the Galileo spacecraft measured dust impacts further away out to at least 360,000 km. The measured ring structure implies that the ring is maintained by dust particles released from the small moons embedded in the ring via impacts of micrometeoroids onto the surfaces of these moons and that evolve inward under Poynting–Robertson drag. The grain size distribution measured in situ ranges from 0.2 to 5 μm, with a steep increase of the particle number density toward smaller grains. In the ring region inside Amalthea's orbit, the grain size distribution was derived from in situ measurements and from imaging, and both agreed very well.

Observed ring structures, in particular gaps in the particle spatial density, large grain **orbit inclinations**, and the radial outward extension of the ring can be explained by electromagnetic forces having a strong influence on particle dynamics. Particles orbiting the giant planet attain variable electric charges on the day- and nightside of the planet. On the dayside of Jupiter, photoelectric charging by solar radiation dominates over charging from the ambient plasma in Jupiter's magnetosphere. When a dust grain enters Jupiter's shadow, photoelectric charging switches off, and the grain's

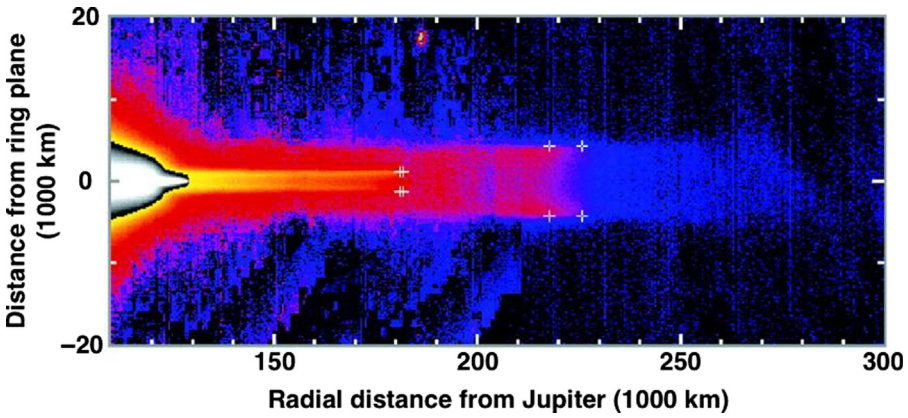

FIGURE 29.13 Jupiter's diffuse ring system seen edge-on. The main ring and the halo interior to the main ring are shown in white, the Amalthea gossamer ring is shown in yellow, and the Thebe ring in red. Crosses mark the extremes of the radial and vertical motions of the two small moons Amalthea and Thebe caused by their eccentric and inclined orbits. The Thebe extension is the material located outside Thebe's orbit (shown in blue). *False color; adapted from Burns et al. (1999).*

electric potential decreases. This leads to an oscillating particle charge due to the switch on and off of photoelectric charging on the day- and nightside of the planet (shadow resonance). It changes the electromagnetic force acting on the particle and results in coupled oscillations of the orbital eccentricity and semimajor axis of the particle's orbit. The oscillations cause the rings to extend significantly outward, but only slightly inward, of their source moons while preserving their vertical thicknesses. Electromagnetic forces seem to be crucial for determining the structure and dust transport in Jupiter's tenuous gossamer rings.

2.6.3.2. Saturn's Dusty Rings

Saturn's dusty rings are located in and around the planet's dense main rings. There are diffuse rings inside the main ring, dusty ringlets in various gaps in the main ring, B ring spokes, the narrow G ring, dusty ring arcs, and finally the very extended E ring. The last of these is maintained by particles ejected from Saturn's volcanically active moon Enceladus (Figure 29.14). Much farther from the planet, a dusty ring was recently discovered stretching along the orbit of the moon Phoebe that orbits Saturn on an eccentric orbit between 4 and 13 million km distance from Saturn. Only the B ring spokes and the E ring are discussed here.

2.6.3.2.1. B Ring Spokes Spokes are intermittent, approximately radial markings in Saturn's B ring. These perplexing features were first recognized in images taken by *Voyager 1* and *2*. Later, Hubble Space Telescope (HST) observations showed that spoke formation can be suspended for extended periods of time, implying that they are a seasonal phenomenon. Remote sensing observations from the early Cassini mission (2004−2008) showed spokes that were much fainter and less frequent than during the *Voyager* era, while by late 2008, spoke activity had recovered to values observed by the *Voyagers*.

Several spoke formation theories have been proposed, although there is still no generally accepted model for how they are triggered. The most widely accepted are those of meteoroid impacts onto the rings and field-aligned electron beams originating from the auroral regions of Saturn: both could transiently increase the plasma density above a critical threshold and trigger the formation of spokes. Seasonal variations in spoke activity may be a consequence of the variable plasma density near the ring as a function of the solar elevation angle above the ring plane. Other spoke formation scenarios include dusty plasma waves and impact-induced avalanches of small charged dust particles. The electrostatic charging of grains may also be linked to electrical storms in the atmosphere of Saturn itself.

2.6.3.2.2. E Ring The E ring stretches from about 180,000 km out to at least 700,000 km from Saturn. Already in the late 1970s it was recognized that in edge-on images the maximum brightness occurs near Enceladus' orbit, implying that this icy moon must be the dominant source of the ring particles. Since then the ring was extensively studied with ground- and space-based imaging and more

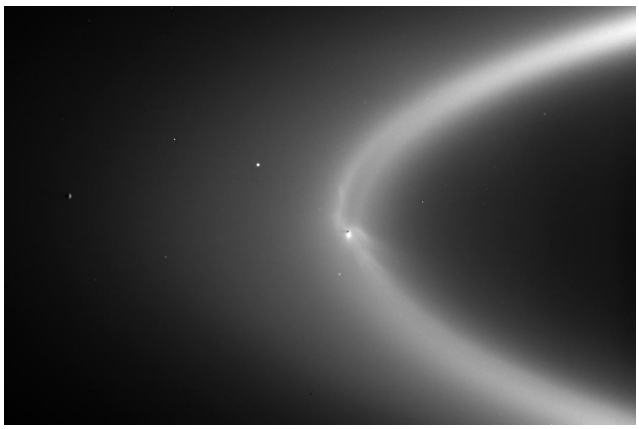

FIGURE 29.14 An arc of Saturn's E ring with the moon Enceladus (dark spot) ejecting dust particles into the ring. In this image the faint ring appears especially bright because the small particles that mostly populate the ring scatter light very efficiently in this observing geometry.

recently by the remote sensing instruments on board the Cassini spacecraft. In situ spacecraft measurements provide a complementary view by measuring dust impacts during passages through the ring. The first to identify dust impacts in the E ring were the radio and plasma wave instruments on board *Voyager*, as the spacecraft traversed the E ring in 1980. The Cosmic Dust Analyzer (CDA) on board Cassini was the first dedicated dust instrument to investigate the local properties of the E ring in situ. CDA measured the spatial and size distributions of the dust particles, their charge state, as well as their chemical composition.

The Cassini measurements revealed that Enceladus is a geologically active moon (*see* Enceladus). Plume particles launched from the vents at Enceladus' south pole are the likely primary source for most of the E ring (Figure 29.14). Plume particles condense from water vapor expanding inside fractures in the moon's surface, while wall collisions within the vents likely play a role in establishing the speed and size distribution of the escaping grains. The overall ring structure was derived from CDA measurements and can be described by a set of power laws. The vertical profiles are in good agreement with those derived from plasma wave measurements and edge-on ring images. Dust densities in the ring change by about a factor of two from one ring traversal to the next, reflecting time variability of the plumes, the plasma properties, and the magnetosphere configuration. In HST images, the ring blends with the background at about 450,000 km from the planet, while CDA measurements revealed that the ring extends much further away, reaching even Titan's orbit at 1.2 million km from the planet. CDA measured particle size distributions in the E ring for grains larger than 0.9 μm, in agreement with those inferred in the Enceladus plumes from remote imaging.

For the first time, the time-of-flight mass spectrometer of CDA allowed the composition of the ring particles to be determined in-situ (Figure 29.15). It turned out that water ice dominates the particle composition in the entire E ring. Besides a minor grain population which consist of pure minerals three major types of icy ring particles were identified. Type I spectra contain almost pure water ice and a tiny amount of sodium; Type II spectra exhibit impurities of organic compounds and/or silicate minerals within the ice particles. Type III particles contain a substantial amount (about 1−2%) of sodium salts, primarily sodium chloride (NaCl), sodium bicarbonate ($NaHCO_3$), sodium carbonate (Na_2CO_3) and a minor amount of potassium chloride (KCl). These are exactly the four most abundant species predicted for an oceanic composition on Enceladus. Therefore, salt-rich Type III grains suggest evaporation of salty liquid water from a reservoir below Enceladus' ice crust in contact with this moon's rocky core as the most plausible plume-producing process. All types of icy E ring grains almost entirely originate from Enceladus' ice geysers. The production of icy dust from these plumes seems to be sufficient to maintain the E ring and to fill the entire Saturnian magnetosphere with grains far beyond the optically visible boundary of the E ring.

2.6.4. Interstellar Dust in the Heliosphere

The solar system currently passes through a region of low-density weakly ionized interstellar medium of our galaxy. This material shows a larger abundance of heavy refractory elements in the gas phase such as iron, magnesium, and silicon than is found in cold dense interstellar clouds. Interstellar dust is part of the interstellar medium, although it was not directly observed by astronomical means in the tenuous local interstellar cloud. Interstellar dust is formed as stardust in the cool atmospheres of giant stars and in nova and supernova explosions.

In the 1990s, interstellar dust was positively identified inside the planetary system. At the distance of Jupiter, the dust detector on board the Ulysses spacecraft detected impacts predominantly from a direction that was opposite to the expected impact direction of interplanetary dust grains. The impact velocities exceeded the local solar system escape velocity, even if radiation pressure effects were considered. The motion of interstellar grains through the solar system turned out to be parallel to the flow of neutral interstellar hydrogen and helium gas, both traveling at a speed of 26 km/s with respect to the Sun. The interstellar dust flow persisted at higher latitudes above the ecliptic plane, even over the poles of the Sun, whereas interplanetary dust is strongly concentrated toward the ecliptic plane (Figure 29.16).

Since that time, Ulysses monitored the stream of interstellar dust grains through the solar system at higher latitudes. It was found that the flux of small interstellar grains varied with the period of the solar cycle, which indicates a coupling of the grains to the solar wind magnetic field. Interstellar dust was initially identified outside 3 AU out to Jupiter's distance. However, refined analyses showed that both Cassini and Galileo recorded interstellar grains in the region between 0.7 and 3 AU from the Sun as well. Even in the Helios dust data, interstellar grains were identified down to 0.3 AU distance from the Sun.

The radii of clearly identified interstellar grains range from 0.1 to above 1 μm with a maximum at about 0.3 μm. The deficiency of small grain masses (<0.3 μm) compared to astronomically observed interstellar dust indicates a depletion of small interstellar grains in the heliosphere. Interstellar particles even bigger than 1 μm were reliably identified by their hyperbolic speeds in radar meteor observations. The flow direction of these bigger particles varies over a much wider angular range than that of small (submicrometer-sized) grains observed by spacecraft.

There are significant differences in the particle sizes that were recorded at different heliocentric distances.

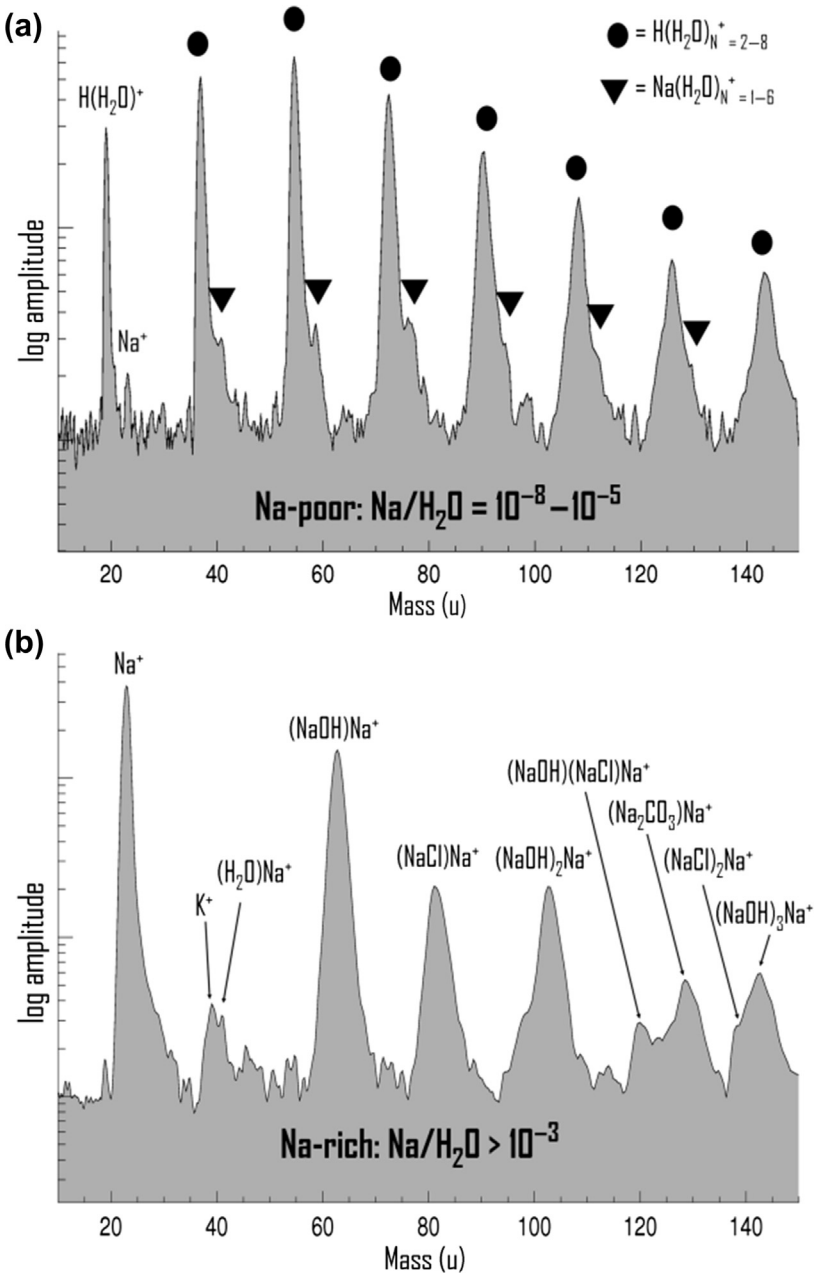

FIGURE 29.15 (a) Mass spectrum of a sodium-poor ice particle (Type I), dominated by a sequence of water cluster ions of the form $H(H_2O)_n^+$, ($n = 2–8$). A weak Na^+ mass line is also present. Within the water matrix, some of the Na ions immediately form hydrates $Na(H_2O)_n^+$. Since the sensitivity of the detector to Na is at least several hundred times higher than to water, the respective ice grains only contain traces of sodium. (b) Coadded mass spectra of sodium-rich water ice particles (Type III). These spectra typically show very few pure water and Na-hydrate clusters, if any. They are characterized by an abundant Na^+ mass line followed by a peak sequence of hydroxy-cluster ions $Na(NaOH)_n^+$. Ions with masses of $Na(NaCl)_n^+$, ($n = 1–3$), and $Na(Na_2CO_3)^+$ give evidence for NaCl followed by $NaHCO_3$ and/or Na_2CO_3 as the main Na-bearing compounds. *From Postberg et al. (2009).*

Measurements of the interstellar particle mass distribution revealed a lack of small grains inside 3 AU heliocentric distance. Measurements by Cassini and Galileo in the distance range between 0.7 and 3 AU showed that interstellar particles were bigger than 0.5 μm with average particle masses increasing closer to the Sun. The flux of these bigger particles did not exhibit temporal variations due to the solar wind magnetic field like the flux of smaller particles observed by Ulysses. The trend of increasing masses of particles continues as demonstrated by Helios measurements, which recorded particles of about 1 μm radius down to 0.3 AU. These facts support the idea that the interstellar dust stream is filtered by both radiation pressure and electromagnetic forces. It is concluded that interstellar particles with optical properties of grains consisting of astronomical silicates or organic refractory materials are consistent with the observed radiation pressure effect.

2.7. Extrasolar Debris Disks

Circumstellar disks play a fundamental role in the formation of stars and planets and the evolution of young planetary

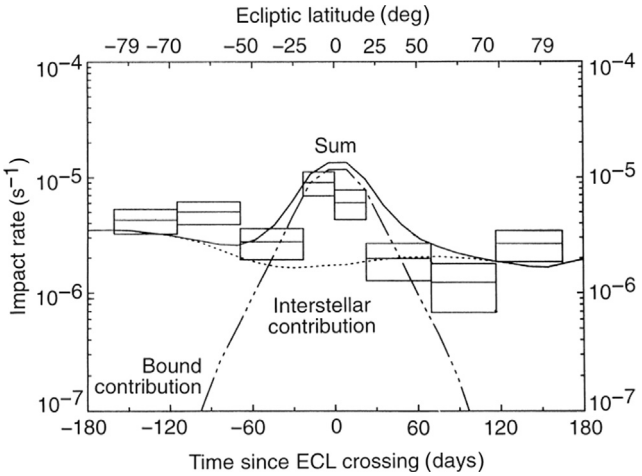

FIGURE 29.16 Ulysses dust impact rate observed around the time of its ecliptic plane crossing (ECL). ECL occurred on March 12, 1995, at a distance of 1.3 AU from the Sun. The boxes indicate the mean impact rates and their uncertainties. The top scale gives the spacecraft latitude. Model calculations of the impact rate during Ulysses' south−north traverse through the ecliptic plane are shown by the lines. Contributions from interplanetary dust on bound orbits and interstellar dust on hyperbolic trajectories and the sum of both are displayed. From these measurements, it is concluded that interstellar dust is not depleted to a distance of 1.3 AU from the Sun.

systems. Primordial disks form from the contraction and conservation of **angular momentum** of the densest regions of molecular clouds. A new star is born in the central condensation of the disk, and planet formation takes place by the accretion of gas and dust particles onto larger and larger bodies, resulting in a few massive planetary cores and a swarm of small objects, the so-called planetesimals. The formation of planets continues for approximately 10−100 million years until the thick prestellar disk is cleared and blown away by the strong wind of the newly formed young star.

Observations with the *Spitzer Space Telescope* show that at least 15% of solarlike stars show infrared emission in excess of that expected from the stellar photosphere. This excess is thought to arise from a circumstellar dust disk. However, given that typical lifetimes of dust grains are much shorter (0.01−1 million years) than the age of the star (10 million years−10 billion years), these disks cannot be leftovers from the primordial disks out of which the systems formed. Instead they must be of secondary origin, formed later after planet formation had ceased long ago. These disks are thought to result from ongoing dust production by planetesimals, like asteroids, comets, or the Kuiper Belt Objects in our solar system. This is why these dust disks are often called **debris disks**. This term must not be confused with man-made space debris described above!

The study of debris disks can give us information about the planetesimals' characteristics and about the planet populations in these disks. For example, the disks surrounding the stars β Pictoris, ε Eridani, or Fomalhaut show asymmetries and brightness enhancements that are thought to arise from one or more planets orbiting their central star within the disk. The structure of debris disks is sensitive to planets with a wide range of masses and semimajor axes. The study of debris disks and, hence, their source planetesimals can give us a more complete picture of the diversity of planetary systems, shedding light on their formation and dynamical histories. The study of debris disk structure can serve as a planet detection method, covering a parameter space complementary to that of the "classical" planet detection methods, and therefore may help us place our solar system in context with other planetary systems (*see* Extra-Solar Planets).

3. DYNAMICS AND EVOLUTION

3.1. Gravity and Keplerian Orbits

In the planetary system, solar gravity determines the orbits of all bodies larger than dust particles for which other forces become important. But even for dust, gravity is an important factor. Near planets, planetary gravity takes over. However, the basic orbital characteristics remain the same. Two types of orbits are possible: bound and unbound orbits around the central body. Circular and elliptical orbits are bound to the Sun; the planets exert only small disturbances to these orbits. Planets, asteroids, and comets move on such orbits. Objects on unbound orbits will eventually leave the solar system. Typically, interstellar dust particles move on unbound, hyperbolic orbits through the solar system. Similarly, interplanetary particles are unbound to any planetary system and traverse it on hyperbolic orbits with respect to the planet (*see* Solar System Dynamics).

A Keplerian orbit is a conic section that is characterized by its semimajor axis a, eccentricity e, and inclination i. The Sun (or a planet) is in one focus. The **perihelion** distance (closest to the Sun) is given by $q = a(1 - e)$. Circular orbits have eccentricity $e = 0$, elliptical orbits have $0 < e < 1$, and hyperbolic orbits have $e > 1$ and a is taken negative. The **aphelion distances** (furthest from the Sun) are finite only for circular and elliptical orbits. The inclination is the angle between the orbit plane and the ecliptic (i.e. the orbit plane of Earth).

Dust particles in interplanetary space move on very different orbits, and several classes of orbits have been identified. One class of meteoroids moves on orbits that are similar to those of asteroids, which peak in the asteroid belt. Another class of orbits that represents the majority of zodiacal light particles has a strong concentration toward the Sun. Both orbit populations have low to intermediate eccentricities ($0 < e < 0.6$) and low inclinations ($i < 40°$). These asteroidal and zodiacal core populations satisfactorily describe meteors, the lunar crater size distribution, and a major portion of zodiacal light observations. Also,

spacecraft measurements inside 2 AU are well represented by the core population. (*see* Main-Belt Asteroids).

3.2. Radiation Pressure and the Poynting–Robertson Effect

Electromagnetic radiation from the Sun (most intensity is in the visible wavelength range at $\lambda_{max} \approx 0.5$ μm) is absorbed, scattered, or diffracted by any particulate, exerting pressure on this particle. Because solar radiation is directed outward from the Sun, radiation pressure also points away from the Sun. Thus, the radiation pressure force reduces the gravitational attraction. Both radiation pressure and gravity have an inverse square dependence on the distance from the Sun. Radiation pressure depends on the cross-section of the particle and gravity on the mass; therefore, for the same particle, the ratio β of radiation pressure, F_R, over gravitational force, F_G, is constant everywhere in the solar system and depends only on particle properties: $\beta = F_R/F_G \sim Q_{pr}/s\rho$, where Q_{pr} is the efficiency factor for radiation pressure, s is the particle radius, and ρ is its density.

Figure 29.17 shows the dependence of β on the particle size for different shapes. For big particles ($s \gg \lambda_{max}$), the radiation pressure force is proportional to the geometric cross-section, giving rise to the $1/s$ dependence of β. For particle sizes comparable to the wavelength of sunlight ($s \sim \lambda_{max}$), β values peak, and they decline for smaller particles as their interaction with light decreases.

A consequence of the radiation pressure force is that particles with $\beta > 1$ are not attracted by the Sun but rather are repelled by it. If such particles are generated in planetary space either by a collision or by release from a comet, they are expelled from the solar system on hyperbolic orbits. But even particles with β values smaller than 1 eventually leave the solar system on hyperbolic orbits if their speed at formation is high enough so that the reduced solar attraction can no longer keep the particle on a bound orbit. A particle with $\beta > ½$ that is released from a parent body moving on a circular orbit will leave on a hyperbolic orbit. These particles are termed beta meteoroids.

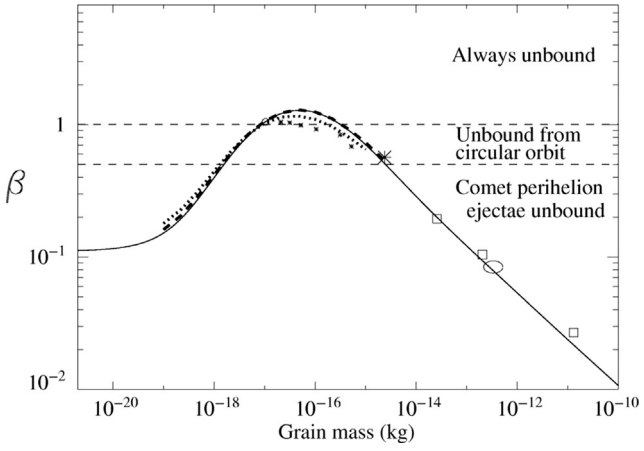

FIGURE 29.17 Ratio® of the radiation pressure force over solar gravity as a function of particle radius. Values are given for particles made of astronomical silicates (*from Gustafson et al., 2001*) with various shapes: sphere (solid curve), long cylinders (dashes), and flat plates (dots).

Because of the finite speed of light ($c \sim 300{,}000$ km/s) radiation pressure does not act perfectly radial but has an aberration in the direction of motion of the particle around the Sun. Thus, a small component (approximately proportional to v/c, where v is the speed of the particle) of the radiation pressure force always acts against the orbital motion, reducing its orbital energy. This effect is called Poynting–Robertson effect. As a consequence of this drag force, the particle is decelerated. This deceleration is largest at its perihelion distance where both the light pressure and the velocity peak. Consequently, the eccentricity (aphelion distance), is reduced, and the orbit is circularized. Subsequently, the particle spirals toward the Sun, where it finally sublimates.

The lifetime τ_{pr} of a particle on a circular orbit that spirals slowly to the Sun is given by $\tau_{pr} = 7 \times 10^5\ \rho s\ r^2/Q_{pr}$, where τ_{pr} is in years, r is given in astronomical units, and all other quantities are in SI units. Even a centimeter-sized ($s = 0.01$ m), stony ($\rho \sim 3000$ kg/m^3, $Q_{pr} \sim 1$) particle requires only 21 million years to spiral to the Sun if it is not destroyed earlier by a collision. This example shows that all interplanetary dust has to be recently generated; no dust particles remain from the times of the formation of the solar system. The dust we find today must originate from bigger objects (asteroids and comets) which have sufficient lifetimes.

The effect of solar wind impingement on particulates is similar to radiation pressure and Poynting–Robertson effect. Although direct particle pressure can be neglected with respect to radiation pressure, solar wind drag is about 30% of Poynting–Robertson drag. Particle orbits that evolve under Poynting–Robertson drag eventually cross the orbits of the inner planets and, thereby, are affected by planetary gravity. During the orbit evolution of particles, resonances with planetary orbits may occur even if the orbit periods of the particle and the planet are not the same but form a simple integer ratio. This effect is largest for big particles, the orbits of which evolve slower and which spend more time near the resonance position. Density enhancements of interplanetary dust have been found (i.e. the Earth-resonant ring was identified in IRAS data and later confirmed by COBE).

Dust near other stars also evolves under Poynting–Robertson drag and forms dust disks around these stars. Such disks were found around many stars (e.g. β Pictoris, ε Eridani, Fomalhaut). Brightness enhancements in these disks are indicative of resonances due to one or more planets in orbit around these stars (*see* Extra-Solar Planets).

3.3. Collisions

Mutual high-speed ($v > 1$ km/s) collisions among dust particles lead to grain destruction and generation of fragments. By these effects, dust grains are modified or destroyed, and many new fragment particles are generated in interplanetary space. From impact studies in stony material, we know that, at a typical collision speed of 10 km/s an impact crater is formed on the surface of the target particle if it is more than 50,000 times more massive than the projectile. This mass ratio is strongly speed and material dependent. A typical impact crater in brittle stony material (Figure 29.6) consists of a central hemispherical pit surrounded by a shallow spallation zone. The largest ejecta particle (from the spallation zone) can be many times bigger than the projectile; however, it is emitted at a very low speed on the order of meters per second. The total mass ejected from an impact crater at an impact speed of 10 km/s is about 500 times the projectile mass.

However, if the target particle is smaller than the stated limit, the target is catastrophically destroyed, and the material of both colliding particles is transformed into a huge number of fragment particles (Figure 29.18). Thus, catastrophic collisions are a very effective process for generating small particles in interplanetary space. Interplanetary particles bigger than about 0.1 mm in diameter are destroyed by a catastrophic collision rather than transported to the Sun by Poynting–Robertson drag.

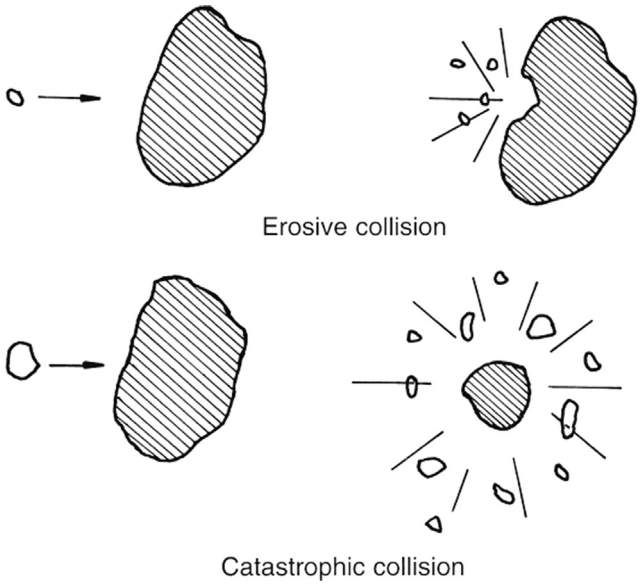

FIGURE 29.18 Schematics of meteoroid collisions in space. If the projectile is very small compared to the target particle, only a crater is formed in the bigger one. If the projectile exceeds a certain size limit, the bigger particle is shattered into many fragments. The transition from one type to the other is abrupt.

3.4. Charging of Dust and Interaction with the Interplanetary Magnetic Field

Any meteoroid in interplanetary space carries an electric charge, and several competing charging processes determine the actual charge of a meteoroid (Figure 29.19). Irradiation by solar ultraviolet light releases photoelectrons which leave the grain. The grains collect electrons and ions from the ambient solar wind plasma. Energetic ions and electrons then cause the emission of secondary electrons. Whether electrons or ions can reach or leave the grain depends on their energy and on the polarity and electrical potential of the grain. Because of the predominance of the photoelectric effect in interplanetary space, meteoroids are mostly charged positively to a potential of a few volts. Only at times of very high solar wind densities does the electron flux to the particle dominate and the particle gets negatively charged. The final charging state is reached when all currents to and from the meteoroid cancel. The timescale for charging is seconds to hours depending on the size of the particle; small particles charge slower. Electric charges on dust particles in interplanetary space were measured by the Cassini CDA. These measurements indicate a dust potential of +5 V. In the dense plasma of the inner Saturnian magnetosphere dust particles were found with a potential of −2 V.

The outward-streaming (away from the Sun) solar wind carries a magnetic field away from the Sun. Due to the rotation of the Sun (with a period of 25.7 days), magnetic field lines are drawn in a spiral, like water from a lawn sprinkler. The polarity of the magnetic field can be positive or negative, depending on the polarity at the base of the field line in the solar corona, which varies spatially and temporally. For an observer or a meteoroid in interplanetary space, the magnetic field sweeps outward with the speed of the solar wind (400–600 km/s) (*see* The Sun). In the magnetic reference frame, the meteoroid moves inward at about the same speed because its orbital speed is comparatively small. The *Lorentz* force on a charged dust particle

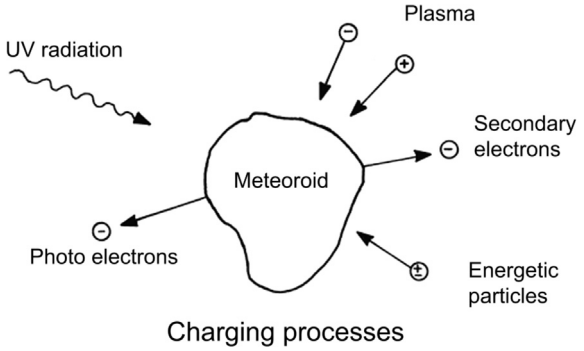

FIGURE 29.19 Charging processes of meteoroids in interplanetary space. UV radiation releases photoelectrons, electrons and ions are collected from the solar wind plasma; the impact of energetic particle radiation releases secondary electrons.

near the ecliptic plane points mostly either upward or downward, depending on the polarity of the magnetic field. Near the ecliptic plane, the polarity of the magnetic field changes with periods (days to weeks) that are much faster than the orbital period of an IDP, and the net effect of the Lorentz force on micrometer-sized particles is small. Only secular effects on the bigger zodiacal particles are expected to occur, which could have an effect on the symmetry plane of the zodiacal cloud close to the Sun. For nanometer-sized particles, like the ones that have been found in the dust streams, the Lorentz force dominates all other forces, and as a result the particles gyrate about the magnetic field lines and are eventually convected out of the solar system with the solar wind.

The overall polarity of the solar magnetic field changes with the solar cycle of 22 years. For one solar cycle, positive magnetic polarity prevails away from the ecliptic plane in the northern hemisphere and negative polarity in the southern hemisphere. Submicrometer-sized interstellar particles that enter the solar system are deflected either toward the ecliptic plane or away from it depending on the overall polarity of the magnetic field. Interstellar particles entering the heliosphere from one direction with a speed of 26 km/s need about 20 years (one solar cycle) to get close to the Sun. Therefore, trajectories of small interstellar grains (0.1 μm in radius) are strongly diverted: in some regions of space, their density is strongly increased; in others, they are depleted. At the time of the initial Ulysses and Galileo measurements (1992−1996), the overall solar magnetic field was in an unfavorable configuration; therefore, only big (micrometer-sized) interstellar particles reached the positions of Ulysses and Galileo. By 2003, the magnetic field had changed to the focusing configuration and the interstellar dust flux had recovered (*see* The Solar Wind).

3.5. Evolution of Dust in Interplanetary Space

Forces acting on interplanetary particles are compared in Table 29.4. The force from solar gravity depends on the mass of the particle; therefore, it depends on the size as $F_G \sim s^3$. Radiation pressure depends on the cross-section of the particle, hence, $F_R \sim s^2$. The electric charge on a dust grain depends on the size directly, as does the Lorentz force $F_L \sim s$. Therefore, these latter forces become more dominating at smaller dust sizes. At a size comparable to the wavelength of visible light ($s \sim 0.5$ μm), radiation pressure dominates over gravity, and below that size, the Lorentz force dominates the particles' dynamics. While gravity is attractive to the Sun, radiation pressure is repulsive. The net effect of solar wind interactions on small particles is that they are convected out of the solar system.

Besides energy-conserving forces, there are also dissipative forces: the Poynting−Robertson effect and the ion drag from the solar wind. They cause a loss of orbital energy and force particles to slowly spiral to the Sun, where they eventually evaporate. These atoms and molecules become ionized and are flushed out of the solar system by the solar wind.

Figure 29.20 shows the flow of meteoritic matter through the solar system as a function of the meteoroid size. There is a constant input of mass from comets and asteroids. From the intensity enhancement of zodiacal light toward the Sun it was deduced that, inside 1 AU, significant amounts of mass have to be injected into the zodiacal cloud by short-period comets. While comets shed their debris over a large range of heliocentric distances but preferentially close to the Sun, asteroid debris is mostly generated in the asteroid belt, between 2 and 4 AU from the Sun. Collisions dominate the fate of big particles and are a constant source of smaller fragments. Meteoroids in the range of 1−100 μm are dragged by the Poynting−Robertson drag to the Sun. Smaller fragments are driven out of the solar system by radiation pressure and Lorentz force.

Estimates of the mass loss from the zodiacal cloud inside 1 AU give the following numbers. About 10 tons per second are lost by collisions from the big (meteor-sized) particle population. A similar amount (on average) has to be replenished by cometary and asteroidal debris. About 9 tons per second of the collisional fragments are lost as small particles to interstellar space, and the remainder of 1 ton per second is carried by the Poynting−Robertson effect toward the Sun, evaporates, and eventually becomes part of the solar wind. Interstellar dust transiting the solar system becomes increasingly important farther away from the Sun. Already at 3 AU from the Sun, the interstellar dust flux seems to dominate the flux of submicrometer- and micrometer-sized interplanetary meteoroids. A summary of the various manifestations of cosmic dust presented in this chapter is given in Table 29.5.

4. FUTURE STUDIES

New techniques will generate new insights. These techniques will include innovative observational methods, new space missions to unexplored territory, and new experimental and theoretical methods to study the processes affecting solar system dust. Questions to be addressed are: the composition (elemental, molecular, and isotopic) and spatial distribution of interplanetary dust, the quantitative understanding of processes affecting dust in interplanetary space, and the quantitative determination of the contributions from different sources (asteroids, comets, planetary environments, and interstellar dust).

Analyses of brightness measurements at infrared wavelengths up to 200 μm by the COBE satellite result in refined models of the distribution of dust mostly outside

TABLE 29.4 Comparison of Various Forces (Dominating Forces in Bold) Acting on Dust Particles of Size s under Typical Interplanetary Conditions at 1 AU Distance from the Sun

s (μm)	F_G (N)	F_R (N)	F_L (N)	F_{PR} (N)	F_{ID} (N)
0.01	9×10^{-23}	1.4×10^{-21}	$\mathbf{1.5 \times 10^{-20}}$	1.4×10^{-25}	4×10^{-26}
0.1	9×10^{-20}	$\mathbf{1.4 \times 10^{-19}}$	$\mathbf{1.5 \times 10^{-19}}$	$\mathbf{1.4 \times 10^{-23}}$	4×10^{-24}
1	$\mathbf{9 \times 10^{-17}}$	1.4×10^{-17}	1.5×10^{-18}	1.4×10^{-21}	4×10^{-22}
10	$\mathbf{9 \times 10^{-14}}$	1.4×10^{-15}	1.5×10^{-17}	1.4×10^{-19}	4×10^{-20}
100	$\mathbf{9 \times 10^{-11}}$	1.4×10^{-13}	1.5×10^{-16}	1.4×10^{-17}	4×10^{-18}

Subscripts G, R, L, PR, and ID refer to gravity, radiation pressure, Lorentz force, Poynting–Robertson drag, and ion drag, respectively.

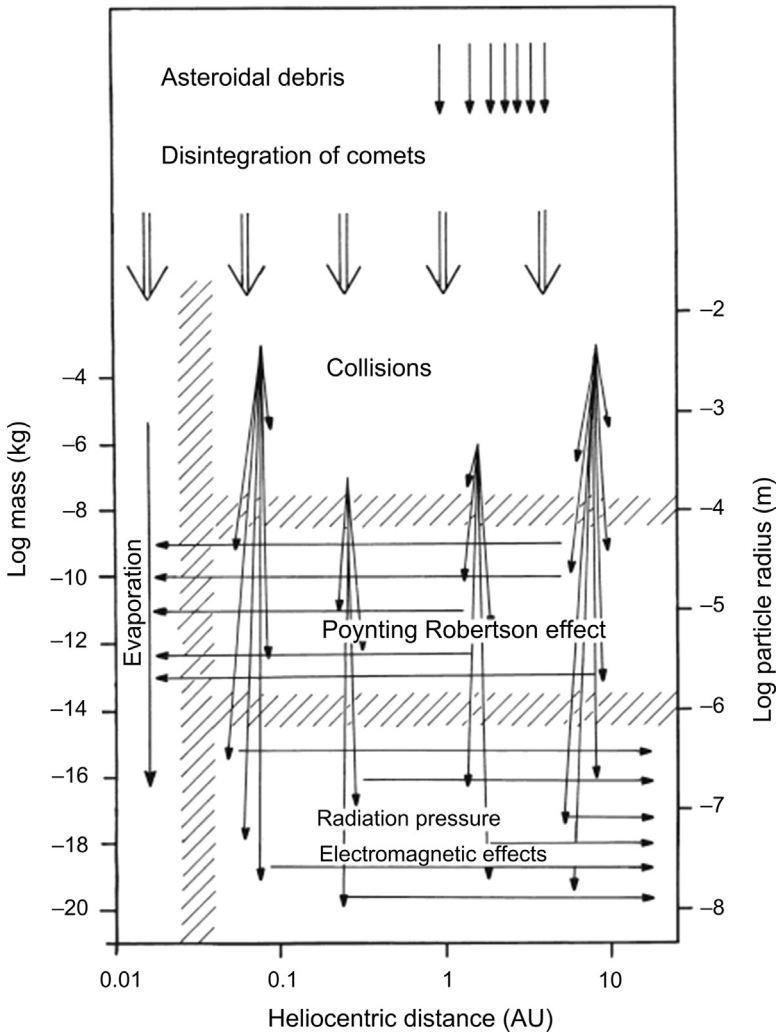

FIGURE 29.20 Mass flow of meteoritic matter through the solar system. Most of the interplanetary dust is produced by collisions of larger meteoroids, which represent a reservoir continually being replenished by disintegration of comets or asteroids. Most of it is blown out of the solar system as submicrometer-sized grains. The remainder is lost by evaporation after being driven close to the Sun by the Poynting–Robertson effect. In addition to the flow of interplanetary matter shown, there is a flow of interstellar grains through the planetary system.

TABLE 29.5 Manifestations of Cosmic Dust in Our Solar System Discussed in This Chapter

Dust Types	Details	Observations	Known Sources	Characteristics
Zodiacal dust	–	Visible and thermal IR observations, SC	Comets, asteroids	Dust mostly within Jupiter's orbit
Comet dust	Coma	Visible observations, SC	Comets	Within ~30,000 km from nucleus controlled by emission process
	Tail	Visible observations	Comets	Micron-sized particles. Several million kilometers; controlled by solar radiation pressure and gravity
	Trail	IR observations	Comets	Millimeter and bigger particles all along orbit
Asteroid dust	Bands	IR observations	Asteroids	Millimeter-sized grains created by asteroid collisions several million years ago
	Active asteroids	Visible observations	Asteroids	Currently ongoing emissions of micron-sized dust in contrast to old dust seen in dust bands
Meteoroids	–	SC, astronomical observations	Comets, asteroids	Any solid object in interplanetary space below the size of comets and asteroids
Meteors	Background	Visible, radar	Comets, asteroids	Meteoroids entering a planetary atmosphere and generating a visible or ionization trail at rates ~1/h
	Streams/storms	Visible	Comets	Meteors originating from a single object (comet or asteroid) at rates $\gg$1/h
Meteorites	–	Terrestrial collection	Comets, asteroids, Earth Moon, Mars	Residue of an extraterrestrial object found on the surface of the Earth
	IDPs, micrometeorites	Atmospheric collections, ice collections, deep-sea sediments	Comets, asteroids	Micrometeoroid of 5–50 μm size collected in the Earth stratosphere
Beta meteoroids	–	SC	Collisions of bigger meteoroids	Flux of submicron-sized dust arriving from the solar direction interacting with solar radiation and interplanetary magnetic field

Nanodust	—	SC	Unknown	High flux of potentially nanometer-sized dust observed by plasma wave instruments
Planetary rings	Dense rings	SC, astronomical observations	Planetary moons	Centimeter- to meter-sized objects orbiting gas planets within Roche zone
	Diffuse rings	SC, astronomical observations	Planetary moons	Micron-sized dust generated by planetary moons and interacting with the magnetosphere
Planetary moons	Volcanism: Io, Enceladus, Triton	SC	Planetary moons	Submicron-sized dust emitted by volcanic action energized by tidal effects
	Ejecta clouds	SC	Planetary moons	Micron-sized dust ejected by meteoroid impacts onto moons
Lunar dust	Electrostatically levitated dust	SC, manned missions	Lunar regolith	Electrostatic forces are believed to both mobilize lunar dust and to cause strong clinging to other surfaces
	Ejecta	Lunar samples, SC	Lunar regolith	Lunar soil consists of ejecta material generated in impacts
Kuiper belt dust	—	SC	Collisions of Kuiper-Belt (KB) objects	Dust generated by collisions in the Kuiper belt populates the outer planetary system
Interstellar dust	—	SC, astronomical observations	Stars, molecular clouds	The solar system currently passes through a tenuous cloud of interstellar dust and gas
Space debris	Aluminum oxide, slack	SC	Solid rocket motors	The dominant source of micron-sized space debris are reaction products of solid rocket motors
	Defunct and broken up satellites	SC, radar, optical	Man-made satellites, space vehicles	Material brought into space feeds a collisional cascade in which fragments are generated that become projectiles for more collisions

Abbreviations: IR, infrared; SC, spacecraft measurements.

1 AU. Spectrally resolved observations of asteroids, comets, and zodiacal dust by infrared space observatories (*Infrared Space Observatory (ISO), Spitzer*, and *Herschel*) show the genetic relation between these larger bodies and interplanetary dust. Improved observations of the inner zodiacal light and the edge of the dust-free zone around the Sun will provide some clues to the composition of zodiacal dust. Improved optical and infrared observations of extra-solar systems will bring new insights to zodiacal clouds around other stars.

The Cassini spacecraft has become the first man-made satellite of Saturn and will continue investigating the dust environment of the gas giant including its dusty ring system. The detailed study of cometary and interstellar dust was the goal of NASA's Stardust mission, which returned samples of dust from comet Wild 2. Similarly, the Japanese *Hyabusa* mission returned dust from asteroid Itokawa. The analyses of these cometary and asteroidal dust samples are ongoing. The European Space Agency's *Rosetta* mission will follow comet 67P/Churyumov–Gerasimenko through its perihelion and investigate its dust release to interplanetary space. The Rosetta lander Philae will make the first attempt ever to land on a cometary nucleus. New Horizons will pass by Pluto and its icy moons and head on to the Kuiper Belt. It is the first spacecraft investigating the dust environment in the outer solar system with a dedicated dust detector since *Pioneer 10* and *11* launched in the 1970s.

Dust particles, like photons, are born at remote sites in space and time, and carry from there information that may not be accessible to direct investigation. From knowledge of the dust particles' birthplace and the particles' bulk properties, we can learn about the remote environment out of which the particles were formed. This approach is called dust astronomy and is carried out by means of dust telescopes on dust observatories in space. Targets for dust telescopes are dust from the local interstellar medium, cometary and asteroidal dust, and space debris. Dust particles' trajectories are determined by the measurements of the electric charge signals that are induced when the charged grains fly through charge-sensitive grid systems. Modern in situ dust detectors are capable of providing mass, speed, and physical and chemical information of dust grains in space. A dust telescope can, therefore, be considered as a combination of detectors for dust particle trajectories along with detectors for physical and chemical analysis of dust particles. Both dust trajectory sensors and large-area dust analyzers have been developed recently and await their use in space.

In near-Earth space, ambitious new techniques will be applied to collect meteoritic material which is not accessible by other methods. High-speed meteoroid catchers which permit the determination of the trajectory as well as the recovery of material for analysis in ground laboratories have been developed and await deployment in space.

Laboratory studies are instrumental in improving our understanding of planetary and interplanetary processes in which dust plays a major role. The study of dust–plasma interactions is a new and expanding field that is attracting considerable attention. New phenomena are expected to occur when plasma is loaded with large amounts of dust. Processes of this type are suspected to play a significant role in cometary environments, in planetary rings, and in protoplanetary disks.

The spectacular sight of a bright comet with a tail stretching across the sky (Figure 30.1) prompts questions about the nature of the object and the physical processes at work. The current era is one of major comet research, with several space missions to comets producing pioneering results. The images and data that are becoming available often prompt new questions and challenge old ideas. A quarter century has passed since the first space missions to comets, and comet science has reached a level of maturity that was unimaginable not long ago.

1. SPACE MISSIONS TO COMETS

Many lines of evidence indicate that the source of all cometary phenomena is a rather small central body called the **nucleus**. Typical dimensions are in the range 1−10 km. Comets are typically observed when they are near the Earth. Thus, viewing an object, say, 3 km across from a distance of 0.2 AU (or 3×10^7 km) means that the object subtends an angle 1/50th of an arc second. Typical resolution from ground-based observatories is about 1.0 arc second and, for large telescopes, is determined by the effects of the Earth's atmosphere. Mountaintop observatories in good locations can do better, and the *Hubble Space Telescope* (HST) has a resolution of about 0.1 arc seconds. From Earth, except in extraordinary circumstances, the nucleus cannot be resolved, and no detail on the surface can be seen. The solution is to send spacecraft with imaging systems close to the cometary nuclei. In situ measurements of gas, dust, plasma, magnetic fields, and energetic particles can be obtained while the spacecraft is near the comet. The imaging and in situ data provide a major source of information on comets.

Table 30.1 summarizes completed missions to comets. Of course, analysis often continues for years. In this section, only the missions with imaging are discussed. The missions to comet Halley in 1986 were collectively called the Halley Armada, and three of them had imaging. Two *VEGA* spacecraft were sent by the Soviet Union. These spacecraft first went to Venus, and the name is a contraction of the Russian language words for Venus(VEnera) and Halley(GAllei). They passed within 8890 km (*VEGA 1*) and 8030 km (*VEGA 2*) of the comet. The images from the *VEGA*s are valuable, but they were somewhat noisy and were taken from larger distances than those taken by *Giotto*.

The European Space Agency (ESA) sent the *Giotto* spacecraft to pass the nucleus of Halley's comet within 596 km. The spacecraft carried the Halley Multicolor Camera (HMC), which obtained images of the nucleus until approximately the time of closest approach (CA) when it was damaged by the impacts of dust particles. Figure 30.2(a) is an overall view of the nucleus composed of 68 individual images. The nucleus was not spherical but was a potato-shaped object with a long axis of approximately 15 km and short axes of approximately 7 km. The nucleus showed features that appeared to be valleys, hills, and craters. The average albedo or reflectivity of the surface was only 0.04; the surface was very dark. The **jets** containing the dust and gas emission from the nucleus came from approximately 10% of the entire surface and were active when their location was in

sunlight. The direction of emission was generally sunward.

The National Aeronautics and Space Administration (NASA) sent the *Deep Space 1* spacecraft to within about 2171 km of the nucleus of comet Borrelly on September 22, 2001, (Figure 30.2(b) shows a close-up view of the nucleus). The long axis of the nucleus is approximately 8 km and the short axes are about 3.2 km. The surface showed features and was also very dark. The albedo varied between 0.01 and 0.03 over the surface. The jets with dust and gas emission, which were clearly seen, occupied 10% or less of the surface area.

NASA's *Stardust* spacecraft passed within approximately 236 km of comet Wild 2 on January 2, 2004. Excellent images were obtained, and an example, taken just after CA, is shown in Figure 30.2(c). The nucleus is roughly a rounded body with a diameter of 4 km. Jets of dust and gas emission were seen, and the albedo determined was 0.03 ± 0.015. Features with steep slopes have been identified, providing clues to the history of the surface. The main goal of the *Stardust* mission, which is to return to the Earth dust samples collected in the comet's **coma**, has been achieved with the return of samples that parachuted to the Utah desert on January 15, 2006 (see the discussion in Section 4).

The *Deep Impact* impactor spacecraft collided with comet Tempel 1 on July 4, 2005. The impactor spacecraft separated from the flyby spacecraft 24 h before impact, and the flyby spacecraft passed the nucleus at a distance of 500 km. An image of the nucleus taken from the impactor is shown in Figure 30.2(d). The average diameter of the nucleus is close to 6.0 km, the longest dimension is 7.6 km, and the shortest dimension is 4.9 km. The surface shows both smooth and rough terrain, scarps (a line of cliffs usually produced by faulting), and impact craters. The surface is generally homogeneous in color and albedo, which varied from 0.02 to 0.06, and the temperature of the surface indicates an equilibrium with sunlight. Observations on approach detected numerous short outbursts that can be associated with specific regions on the surface.

The impactor spacecraft delivered 19 GJ of kinetic energy to comet Tempel 1. The spectacular impact is shown in Figure 30.3, and a view of the ejecta plume containing $\sim 10^6$ kg of material is shown in Figure 30.4. In addition to observations from *Deep Impact,* the event was extensively observed by ground-based and space-based observatories. By 9 July the comet had returned to its preimpact state and the impact crater was not seen until the revisit in 2011 discussed below. The ejecta consisted of fine particles (1–100 μm) and individual species, including water, **water ice**, carbon, carbon dioxide, hydrocarbons, and crystalline silicates. The spectra of the ejecta are a good match to the spectra of material ejected from comet Hale–Bopp and to the dusty disk spectrum of a young stellar object.

The flyby spacecraft from the *Deep Impact* mission was retargeted to comet Hartley 2 as part of Extrasolar Planet Observation and Deep Impact Extended Investigation (EPOXI). Close approach to comet Hartley 2 took place on November 4, 2010, at a distance of 694 km. An image of this remarkable comet is shown in Figure 30.2(e). The nucleus is bilobed and small, with a length of 2.3 km. The average albedo is approximately 0.04. The surface has two principal types of terrain: (1) areas containing knobby features with typical dimensions in the range 50–100 m and (2) smooth areas on part of the larger lobe and the waist area. Comet Hartley is considered hyperactive in the sense that the gas production is much higher than expected from simple sublimation from a comet its size. Volatiles, primarily CO_2, drag chunks of ice out of the nucleus and these sublimate to enhance the gas production rate. Individual chunks were seen in many images during *EPOXI*'s CA.

The *Stardust* spacecraft was retargeted for a revisit of comet Tempel 1 as part of the *Stardust-NExT* mission. The

TABLE 30.1 Missions to Comets

Spacecraft	Comet	Encounter Date	Imaging
International Cometary Explorer (ICE)	Giacobini–Zinner	September 11, 1985	No
VEGA 1	Halley	March 6, 1986	Yes
Suisei	Halley	March 8, 1986	No
VEGA 2	Halley	March 9, 1986	Yes
Sakigake	Halley	March 11, 1986	No
Giotto	Halley	March 14, 1986	Yes
ICE	Halley	March 25, 1986	No
Giotto Extended Mission (GEM)	Grigg–Skjellerup	July 10, 1992	No
Deep Space 1	Borrelly	September 22, 2001	Yes
Stardust	Wild 2	January 2, 2004	Yes
Deep Impact	Tempel 1	July 4, 2005	Yes
EPOXI	Hartley 2	November 4, 2010	Yes
Stardust-NExT	Tempel 1	February 14, 2011	Yes

name NExT is derived from New Exploration of Temple 1. Close approach was on February 14, 2011, at a distance of 178 km. The revisit provided an opportunity to complete the *Deep Impact* experiment by reexamining the impact site and looking for changes in comet Tempel 1's complex surface after an interval of about 5.5 years. The *Stardust-NExT* imagery increased the coverage of the surface to 60%. With the new coverage the so-called smooth flow areas were found to cover some 30% of the surface. These appear to form from eruptions of ice-dust material that flows to areas of gravitational lows. The surface also shows thicker layers probably caused by impact events.

Comparison of images shows that most of the comet's surface was unchanged in 5.5 years. But, there was a major exception. A scarp, the edge of a smooth flow area (called S2), was 10–15 m high and receded by as much as 50 m as shown in Figure 30.5. This result is supported by the result that many jets appear to come from the edges of eroding scarps. Pitted terrain covers more than 50% of the surface. These are not produced by impacts, but are probably the result of CO-driven minioutbursts.

The *Deep Impact* impact site was imaged by *Stardust-NExT*; the before and after images are shown in Figure 30.6. The crater is about 50 m in diameter and is unremarkable. Possible changes during the 5.5 years since the impact, including filling in by ejecta falling back, are unknown. But, the crater size is consistent with an impact into lightly packed snow.

All these images confirm the basic view of the nucleus as a single, sublimating (direct phase transition from the solid to the gas state) body as proposed by F. L. Whipple. As the solid body approaches the Sun, energy supplied by solar radiation raises the temperature of the near-surface layers, sublimation of ices (mostly water ice) takes place, and the emission of gas and entrained dust produces the large features seen in the sky. The five comets with surfaces imaged in detail represent a currently unknown combination of intrinsic diversity and postformation evolution.

Before leaving space missions, it is important to note that ESA's *Rosetta* mission to comet Churyumov–Gerasimenko was launched on March 2, 2004, to begin its 10-year journey to the comet. The plan is for the main spacecraft to rendezvous with the comet in May 2014, to spend approximately 2 years in the vicinity of the comet, and to place the lander *Philae* on the surface in November 2014.

2. A BRIEF HISTORY OF COMET STUDIES

The realization that the nucleus of a comet was a single, sublimating body prior to the confirmation by direct imaging was the result of several lines of reasoning. In the seventeenth century, it was known that the part of a comet's orbit near the Sun could often be accurately represented by a parabola with the Sun at the focus. This idea was used by Isaac Newton to determine a parabolic orbit for the comet of 1680. Edmond Halley refined the calculation and showed

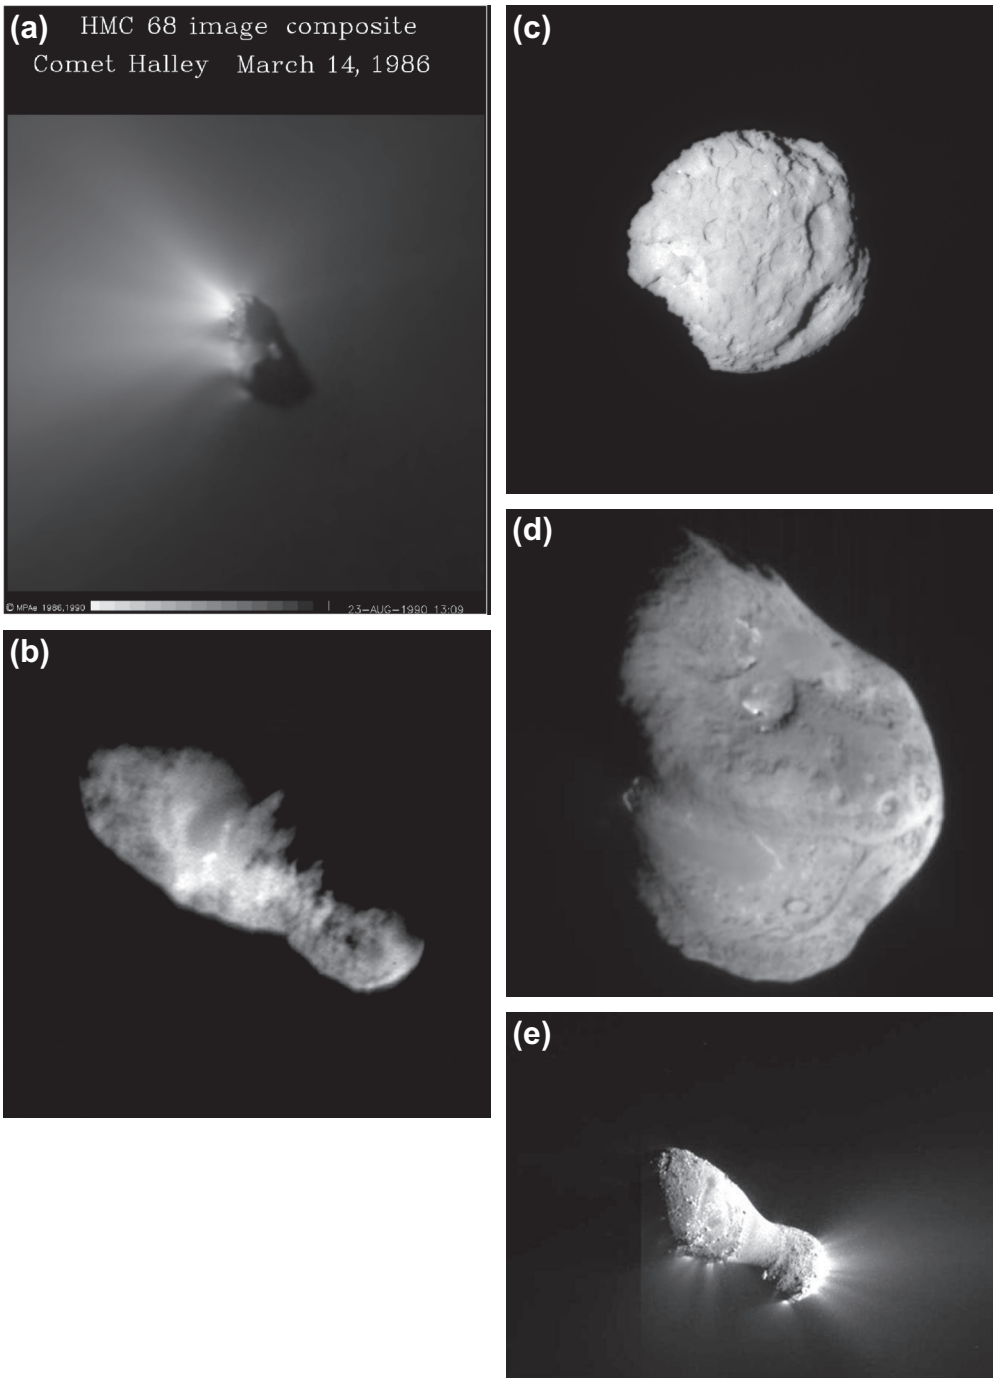

FIGURE 30.2 Images of comet nuclei. (a) Comet Halley nucleus composite. (*Courtesy of H. U. Keller, Max-Planck-Institut für Aeronomie, Katlenburg-Lindau, Germany © MPAE.*) (b) Comet Borrelly. that an ellipse of high eccentricity very accurately represented the comet's orbit. Comet orbits generally are ellipses with high eccentricities. Halley continued to determine the orbits of comets and found that the orbits of comets observed in 1531, 1607, and 1682 were quite similar and had periods of approximately 75−76 years. This was the basis of his famous prediction that the comet that now bears his name would return in 1758.

A complication in the detailed orbit calculations was that Jupiter and Saturn would perturb the orbit through their gravitational attraction. Halley's comet passed perihelion in early 1759. The successful prediction of the return of

FIGURE 30.3 Spectacular image of comet Tempel 1 taken from *Deep Impact's* flyby spacecraft 67 s after the impactor spacecraft's impact. The linear spokes of light radiate away from the impact site. Light from the collision site saturated the camera's detector. Compare with Figure 30.2(d). *Courtesy of NASA/JPL-Caltech/UMD.*

Halley's comet began the development of celestial mechanics and the positional astronomy of comets that flourished in the eighteenth and nineteenth centuries. But the orbit of comet Encke presented another problem. The comet had a very short period of 3.3 years. Many orbits were observed, and it would typically arrive at perihelion about 0.1 day early. The only explanation for this behavior was some sort of nongravitational force, and the only version that has stood the test of time is a "rocket effect" produced by the ejection of material in a preferential direction. Such an effect was suggested by F. W. Bessel based on his observations of a sunward plume of material in Halley's comet in 1835. But how would such a plume of material be produced?

Another problem was the persistence of comets after many passes through the inner solar system. Comets are rich in water ice (discussed later), and small icy clumps or a surface layer of ice on dust grains would not persist.

The Whipple model solves these problems by postulating that the nucleus is a single, rotating, icy body. Ices are poor conductors of heat, and only a relatively thin layer is lost during a perihelion passage. The rocket effect is produced by the reaction force on the nucleus due to the sublimating ices. Historically, the mass loss due to sublimation of ices was assumed to come preferentially from the afternoon side. Just as on the Earth, the warmer temperatures would occur in the afternoon, and the sublimation rate is higher. This type of mass loss would accelerate or retard the comet in its orbit. This basic type of nongravitational force model was used for decades and was successful in producing accurate ephemeris predictions. Nevertheless, the basic model is not realistic when complications are considered, such as the mass loss occurring in jets and precession of the rotation axis. Physically sound models require detailed models of the outgassing surface features and the nucleus rotation. The sublimation of the ices produces the gas molecules that form the gas coma and subsequently the **plasma tail**. When the ices sublimate, the embedded dust particles are released to form the dust coma and the **dust tail**. The dust particles that are not carried away or that fall back onto the nucleus form an insulating crust on the surface.

The bright coma and tails of comets are the features that distinguish them from other solar system objects. Their study was greatly facilitated during the twentieth century by the development of photography. Images and spectra of comets could be accurately recorded and analyzed. The gas and dust comas could extend to approximately 10^5–10^6 km. The nucleus and the coma surrounding it form the comet's head. Dust tails could achieve lengths of roughly 10^7 km, and plasma tails often could achieve lengths of tenths of astronomical units (or several times 1.5×10^7 km). In exceptional cases, plasma tails can exceed 1 AU (or 1.5×10^8 km) in length. Figure 30.7 shows a summary of comet features. Subsequent sections

present the physical processes that produce features with these large dimensions, all originating from the small icy bodies shown in Section 1.

Traditionally, comet orbits were classified as short period or long period with the dividing line at periods (P) of 200 years. This evolved to a system with three groups. The Jupiter family contains comets with periods $P \leq 20$ years. These orbits are direct (in the same sense as the Earth's revolution around the Sun) and generally have low inclinations with respect to the plane of the ecliptic. Halley-type comets (HTCs) have periods $20 < P \leq 200$ years. The long-period comets (LPCs) have $P > 200$ years, and their orbital inclinations to the plane of the ecliptic are approximately isotropic. A newer classification system, based on the ***Tisserand*** *parameter*, T, will be used (Section 7) in the discussion of cometary formation scenarios. The older

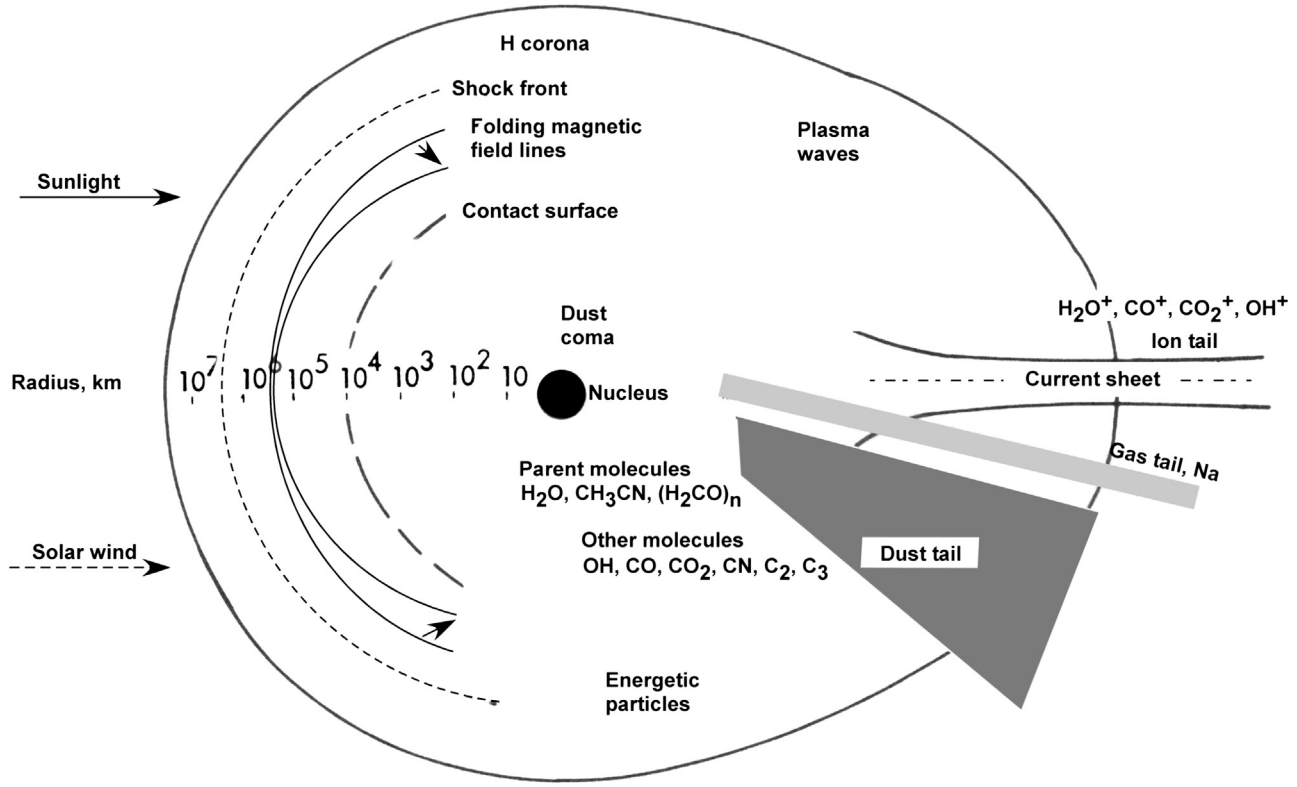

FIGURE 30.7 Summary schematic on a logarithmic scale of cometary features and phenomena. *Reprinted with permission from John C. Brandt and Robert D. Chapman. Copyright © Cambridge University Press, 2004.*

classification schemes were not based on physical parameters, but were mostly for convenience. The newer scheme of H. Levison uses a dividing line of $T = 2$ to neatly divide comets into two classes: ecliptic and nearly isotropic. For details, see Comet Populations and Cometary Dynamics. Basically, the ecliptic comets ($T > 2$) are mostly the Jupiter-family comets (JFCs). A small fraction have $T > 3$ and these cannot cross the orbit of Jupiter. In this case, Encke-type comets have orbits interior to Jupiter's and Chiron-type comets have orbits exterior to Jupiter's. The nearly isotropic comets ($T < 2$) include the HTCs and the LPCs. The latter are nearly isotropic. The HTCs have semimajor axes small enough to fall into a mean motion resonance with a major planet. Their orbital inclinations are not isotropic.

3. PHYSICS OF THE NUCLEUS

The basic physical process—the one that ultimately produces the cometary features (e.g. the tails)—is sublimation of ices. Sublimation is the phase transition that goes directly from the solid to the gaseous state without passing through the liquid state. The evidence for the ice composition of the nucleus—80–90% H_2O (water) ice, roughly 10% CO (carbon monoxide) ice, and small amounts of other ices—is presented in Section 6. The ice in a cometary interior is almost surely amorphous ice. This comes about because ices formed by condensation on a surface at low temperatures do not have energy available to change into the crystalline forms that minimize energy.

When the water ice or snow sublimates, water vapor is produced, and embedded dust particles are released. The energy sources for the sublimation are solar radiation, ice phase transitions, and radioactive decay. Solar radiation deposits energy on the surface or in the near-surface layers. This energy affects the deeper layers by producing a heat wave that moves inward. The transition from amorphous ice to crystalline ice releases energy. Amorphous ice undergoes a transition to cubic ice at approximately 137 K, and cubic ice undergoes a transition to hexagonal ice at approximately 160 K. Model calculations usually treat both transitions as a single energy release event. Radioactive decay is primarily from short-lived isotopes, such as ^{26}Al with a half-life of $\approx 7 \times 10^5$ years. These sources are most important in the deep interior and during approximately the first million years. Diffusion of volatiles could result.

In simple terms, the energy balance of the surface layers is as follows. When a comet is far from the Sun, the energy balance is achieved by the solar radiant energy being reradiated by blackbody (infrared) radiation. The temperature of the surface layers is not high enough to produce

significant sublimation. At intermediate distances, the surface temperature is high enough for sublimation, and the solar radiant energy input is balanced both by blackbody reradiation and by sublimation. At closer distances to the Sun, the surface temperature increases further, and essentially the entire solar radiation input is balanced by sublimation. Of course, blackbody reradiation takes place, but it is small in terms of the energy balance. For water ice, sublimation becomes important around 3 AU, and it dominates the energy balance near 1 AU. The sublimation rate is roughly proportional to an exponential containing the temperature, T. Thus, it is extremely sensitive to T. This copious production of material drives cometary activity and produces cometary features as described later.

Naturally, there are complications to this simple picture. When the surface layer ices are sublimated, not all the dust is liberated, and a porous dust mantle is formed. The mantle insulates the ices beneath the surface. This idea has been confirmed observationally. Infrared observations of the surface layers indicate temperatures reasonably close to values expected for a nonsublimating, low-albedo object bathed by sunlight. These temperatures are much higher than the temperatures for sublimating water ice. The ice sublimation probably takes place a few centimeters below the surface. Also, there is no reason to believe that sublimation takes place uniformly over the surface. Regions of enhanced sublimation are expected, a view consistent with the images of comet nuclei that show dust and gas emission predominantly in jets. These jets can produce some of the surface features on the nucleus, and, along with impact craters, they can produce an irregular shape for the nucleus.

Figure 30.8 shows how the surface layers of a comet can become stratified and illustrates the potential complexity of accurate modeling. These layers include many intermediate stages—from the pristine composition of the deep interior to the ejected gas and dust—and these must be modeled accurately. The details of the gas flow through the porous dust layers are important. In recent years, the trend has been to think of the nucleus as a fairly porous body. The porosity is defined as the fraction of the volume occupied by the pores, and values of roughly 0.5 are often discussed. At present, such values can apply to some, but probably not all, comet nuclei.

The rotation of comet nuclei provides an example of how complex some situations can become. Given the extensive ground-based observations of comet Halley and the close-up images taken by *VEGA 1*, *VEGA 2,* and *Giotto*, the determination of the rotation was expected to be straightforward. An initial complication was the reports of different periods of brightness variation. Sorting things out was a major effort. In short, the rotation was complex, and a model with five jets was needed to reproduce the observations. Figure 30.9 shows views of the rotating nucleus through an entire period. The solution was consistent with a constant internal density.

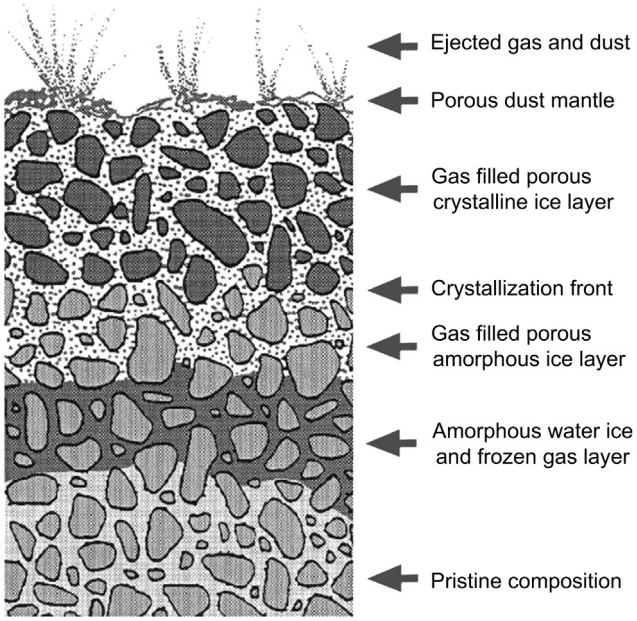

FIGURE 30.8 Schematic showing the layered structure of a cometary nucleus from the pristine composition up to the porous dust mantle. The vertical scale is arbitrary. *Courtesy of D. Prialnik 1997–1999, Modeling gas and dust release from comet Hale-Bopp. Earth, Moon, and Planets, 77:223–230, Figure 1. The rotation state determined for comet Halley is interesting because it is not in the lowest rotational energy state for a given angular momentum. This would be rotation only around the short axis. The excited rotational state is probably not primordial because estimates of the relaxation time due to frictional dissipation in the comet's interior (caused by flexing as the angular momentum vector moves through the interior) are in the range 10^6–10^8 years. It is probably due to jet activity or splitting of the nucleus.

The splitting of comet nuclei has been observed many times. A recent example is the case of comet LINEAR in early August 2000 (see Figure 30.10). LINEAR is the acronym for Lincoln Near-Earth Asteroid Research. The Lincoln Laboratory is run by the Massachusetts Institute of Technology. Large pieces and fragments of the nucleus are visible in the images. Most of the fragments have an estimated size of less than 500 m. This is an example of "spontaneous" splitting (i.e. there is no apparent correlation with orbital parameters or time in the orbit relative to perihelion). This type of splitting occurs for roughly 10% of dynamically new comets on the first perihelion passage. Splitting can also occur when the nucleus passes close enough to the Sun or a planet and is tidally disrupted. Comet Shoemaker–Levy 9 passed close to Jupiter in July 1992. The disruption produced about 20 fragments (see Figure 30.11). These crashed into Jupiter over several days in July 1994. The tide-induced splittings

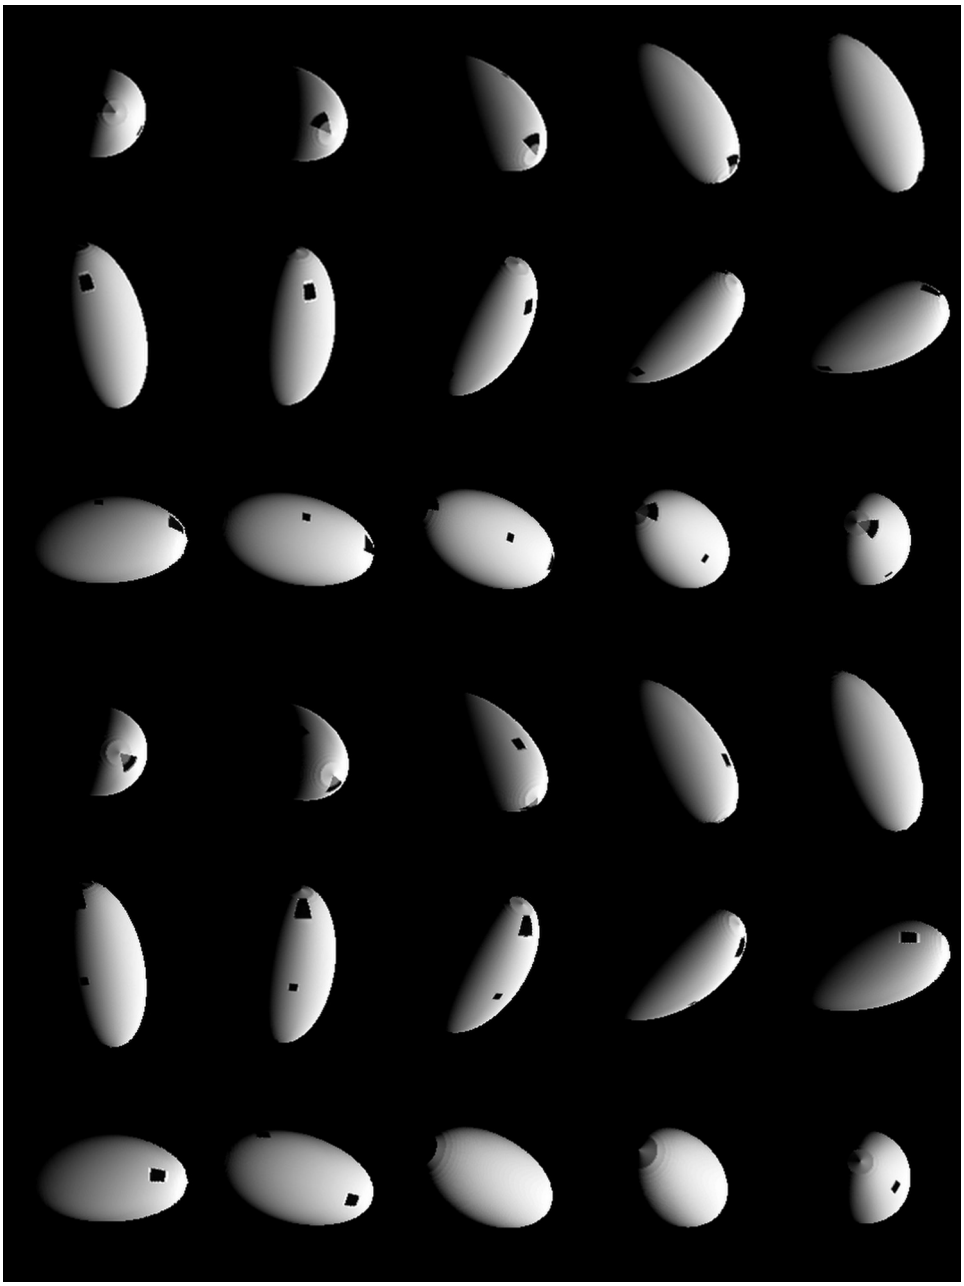

FIGURE 30.9 The complex rotation of comet Halley's nucleus through one full sequence. The images read left to right starting at top left. The time between images is 0.25 days and the sequence repeats after approximately 7.25 days. The five active areas (jets) are marked as low-albedo features. *Courtesy of M. J. S. Belton, Belton Space Initiatives.*

have been used to estimate the tensile strength of the nuclei, and very low values were found. The units of tensile strength are force per unit area (N/m^2) or the Pascal (Pa). The inferred values from splittings are in the range 10^2–10^4 Pa. For comparison, rocks have values $\sim 4 \times 10^6$ Pa, and the value for steel is $\sim 4 \times 10^8$ Pa.

The splittings are consistent with the view of the cometary interior as being porous, having a weak structure, and consisting of agglomerated building blocks called cometesimals. Available evidence indicates that the interior consists of volatile ices (mostly H_2O ices, probably amorphous) and dust. The interior does not appear to be differentiated, the compositions are surprisingly uniform, and the ratio of ice to dust does not vary with depth.

Some cometary outbursts may be related to splittings. In a major outburst, the brightness of a comet increases by a factor typically of 6–100, and the outburst lasts for weeks. The observational evidence indicates that the increase in

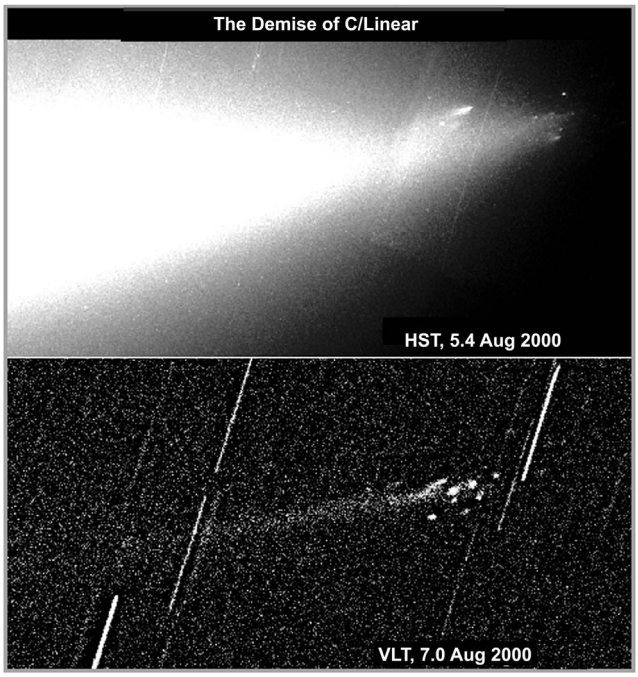

FIGURE 30.10 Splitting of comet LINEAR. (Top) The *HST* image on August 5.4, 2000, showing the dust tail (extending to the left) and several large remnants near the tip of the tail; July 22, 2000, is the estimated date of disintegration of the nucleus. (Bottom) The *Very Large Telescope (VLT)* image on August 7.0, 2000, showing fragments. Image processing was used to suppress light from the diffuse tail. The streaks are star trails. *Courtesy of H. Weaver, Johns Hopkins University; C. Delahodde, O. Hainaut, R. Hook, European Southern Observatory; Z. Levay, Space Telescope Science Institute; and the HST/VLT observing team; NASA/ESA, ESO.*

brightness is due to an increase in the number of dust particles that scatter sunlight. Comet Halley displayed an extraordinary outburst on February 12, 1991, when it was 14.3 AU from the Sun.

Splitting exposes fresh ice surfaces and hence produces enhanced loss of material. An impact from an interplanetary boulder would have much the same effect. A plausible mechanism not involving splitting or impacts uses the crystallization of amorphous ices as the energy source. On this picture, a heat wave propagates inward, triggering the energy release from the amorphous ice and producing pockets of gas that break through to the surface to produce the outburst. This mechanism is plausible for the outburst in comet Halley (mentioned earlier) and in comets that have repeated outbursts, such as comet Schwassmann–Wachmann 1.

Our knowledge of interiors is insecure, but there is general agreement that it is a loosely bound agglomeration of smaller, icy cometesimals with a bulk density less than 1 g/cm^3. Some hints about nucleus structure have come from the *Stardust* images of comet Wild 2. The nucleus shows a highly structured surface that can be described as pockmarked. Some of the features, possibly impact craters, have steep slopes, and the surface must have some cohesive strength. How did these sharp features persist if layers were peeled off by sublimation during every perihelion passage? For comet Wild 2, at least part of the answer lies in its orbital history. Comet Wild 2 was captured into its current (Jupiter-family) orbit by a close encounter with Jupiter only 30 years ago. With an orbital period of 6.4 years, this comet has probably made only a handful of passes through the inner solar system. By comparison, comet Halley has probably made hundreds or thousands of inner solar system passes and thus has a surface smoothed by many sublimation episodes. The surface of comet Wild 2 appears young in terms of sublimation exposure. The steep slopes, which imply some cohesive strength, mean that the surface does not resemble a pile of material held together by gravity. The results from *Deep Impact* have raised new questions and begun the process of understanding the

FIGURE 30.11 Comet Shoemaker–Levy 9 on May 17, 1994, as imaged by the *HST*. The fragments extended for over 1.1 million km. *Courtesy of H. A. Weaver and T. E. Smith, Space Telescope Science Institute/NASA.*

nucleus. The surface geology of comet Tempel 1 shows clearly distinct layers that seem to be discrete blocks like geologic strata. The surfaces of the three JFCs (Borrelly, Wild 2, and Tempel 1) are quite different, and the existence of the vastly different surface of the hyperactive come Hartley 2, challenge the notion of a typical comet. Analysis of the ejecta and its evolution yields the following results. The fine particles seen in the ejecta must be from a surface layer at least tens of meters deep. The tensile strength was estimated at 65 Pa or less. This is comparable to the strength of talcum powder or lightly packed snow. The density of the nucleus is about 0.6 g/cm^3 meaning that the interior must be porous with some 50–70% of the volume consisting of empty space.

4. COMA AND HYDROGEN CLOUD

The gas and dust liberated by the sublimation of the ice is the origin of comet features with large dimensions. The coma is the essentially spherical cloud around the nucleus of neutral molecules and dust particles. It is visible in images of comets with low gas production rates (Figure 30.12) or in short-exposure images of comets with high production rates. The size of comas can range up to 10^5–10^6 km. The dusty gas expands at speeds of $\approx$1 km/s, and the flow is transonic in that the flow begins subsonic and becomes supersonic. This is similar to the flow of the solar wind (see The Solar Wind). Because the gas is dragging the dust along, the gas flows faster than the dust. Images and in situ measurements show that the material emission from the nucleus is structured into jets in the near-nucleus region. On the mechanism proposed by M. J. S. Belton, pockets of volatile ices such as CO and CO_2 can be sublimated when the solar energy wave from the surface reaches them. The gases punch through the dust layer to form jets. Collimation is provided by the ambient coma and visibility is enhanced by the turbulent flow picking up additional dust particles from the edges of the jet on the surface. The image of comet Hartley 2 (Figure 30.2(e)) shows excellent examples of the jets. Well away from the nucleus, this structure is not usually important.

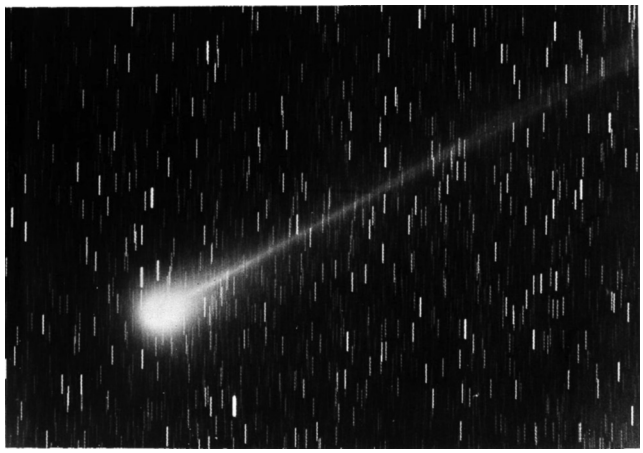

FIGURE 30.12 Comet Giacobini–Zinner on October 26, 1959, showing the coma and a plasma tail extending some 450,000 km. *Photograph by E. Roemer, University of Arizona: official U.S. Navy photograph.*

Most of our observations and measurements of composition in comets refer to the coma region. For some species, the variation with radial distance from the nucleus can be modeled by including creation and destruction mechanisms for parent and daughter molecules. For a molecular gas expanding radially at constant speed, the density falls off as r^{-2} (r is the distance from the nucleus), and the surface brightness (proportional to an integral along a line of sight through the coma) falls off as ρ^{-1} (ρ is the projected distance from the nucleus). The slope on a log$B$ (brightness) vs logρ plot would be -1. Shallower slopes indicate a creation process, and steeper slopes indicate a destruction process. This behavior is observed in molecules such as C_2. These results and results from more detailed modeling lead to an important conclusion.

The molecules measured and observed in the coma are not necessarily the molecules coming directly from the nucleus, but they are part of a chain of creation and destruction of species, presumably from complex molecules in the nucleus to progressively simpler molecules with increasing distance from the nucleus. Thus, the molecules observed are simply the ones that are caught at some specific distance from the nucleus or with the method of observation.

Calculations that include the various changes in composition with the goal of understanding the composition of the original material from the nucleus are very complex and must include gas-phase reactions and photolytic (involving photons) reactions as well as possible interactions between the gas and dust. While progress has been made, final resolution of this problem may require measurements obtained at a cometary surface. As discussed in Section 6, the knowledge of the bulk composition of comets seems secure and is consistent with condensation from a cloud that initially had solar abundances.

Table 30.2 lists chemical species observed spectroscopically and measured by mass spectrometry in comets. This table shows the variety of species in comets and the similarity to interstellar material. This relationship is discussed in Section 4.

The **hydrogen cloud** around comets is much larger than the coma but was not observed until the 1970s. Its existence was predicted in 1968 by L. Biermann. Observations above the Earth's atmosphere were needed because the hydrogen cloud is best seen in Lyman-α (121.6 nm), the resonance line of hydrogen. Figure 30.13 shows the hydrogen cloud of comet Hale–Bopp along with a visible light image. The huge size of the cloud is shown by the yellow disk at the

TABLE 30.2 Measured and Observed Species in Comets

right. This disk is the angular size of the Sun at the comet's distance. The hydrogen cloud has the largest size; however, smaller clouds of oxygen and carbon are also seen.

Modeling the outflow of hydrogen (the lifetime of the H atoms is determined primarily by the proton flux in the solar wind) to produce the observed cloud size shows that the required outflow speed is 8 km/s. This is much larger than the outflow speed in the coma, ≈ 1 km/s. An additional energy source is needed. If H_2O were photodissociated, a speed of 19 km/s would result, and this value is too high. The likely scenario is that OH is produced by photodissociation and then is further dissociated into H outside the thermalization region. These H atoms and the thermalized H atoms from H_2O photodissociation combine to give the deduced outflow speed of 8 km/s.

The outflow rate of hydrogen, Q_H, provides a good surrogate for the total gas production rate from a comet. For large comets, this rate can approach 10^{31} atoms/s, and the general range is $10^{27}-10^{30}$ atoms/s. The heliocentric variation is roughly $r_h^{-1.3}$ (r_h = the heliocentric distance). This expression follows the practice of basing variations on the value at 1 AU (where comets are most easily observed) and using a power law to give the heliocentric variation.

Early dust measurements were made in the coma of comet Halley by dust detectors on the *VEGA* spacecraft and on *Giotto*. Three basic types of dust composition were found. The CHON particles have only the light elements **C**arbon, **H**ydrogen, **O**xygen, and **N**itrogen. The silicate particles are rich in Silicon, *M*agnesium, and *I*ron. The third type is essentially a mixture of the CHON and silicate types. The differential size distribution can be represented by a power law in size, r^a, with $a \sim -3.5$, for grain sizes

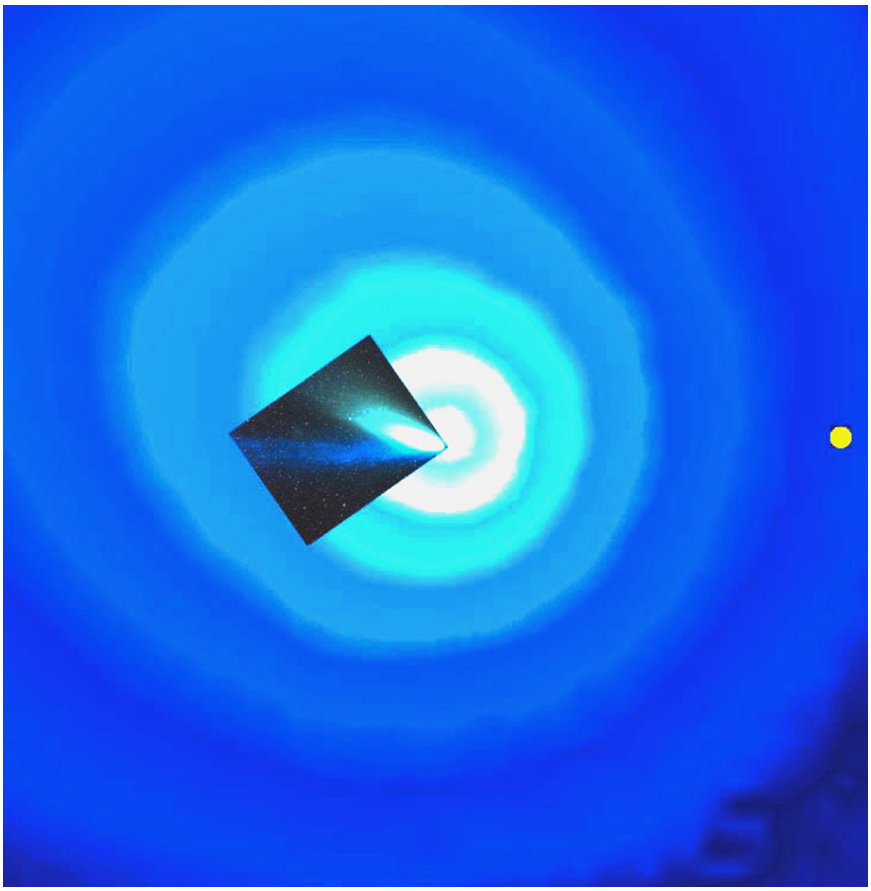

FIGURE 30.13 Hydrogen Lyman-α image taken on April 1, 1997, showing the hydrogen cloud of comet Hale–Bopp (contours in shades of blue) along with a visible image showing the plasma and dust tails. Combi, University of Michigan; visual photograph by Dennis di Cicco and Sky and Telescope.*

greater than 20 μm. This implies that most of the dust mass is emitted in large grains. There was also evidence for large numbers of small dust grains down to sizes of 0.01 μm. The results are compatible with the sizes needed in models of the dust tail.

Interest in the dust particles from the coma has increased with the return to the Earth of the dust collected by *Stardust.* Having particles collected in the coma and available for analysis in the laboratory opens a whole new era. The sample return portion of the *Stardust* mission to comet Wild 2 was accomplished by catching the particles in an ultralow density glasslike material called aerogel. The collection exceeded expectations with thousands of particles embedded in the aerogel. The mineral structure has been preserved for many of the grains. Some first results indicate the presence of high-temperature minerals such as olivine, one of the most common minerals in the universe. It certainly did not form inside the comet's cold body. It probably formed near the Sun or from hot regions around other stars. In any event, the discovery that cometary material contains substances formed in hot and cold environments adds a new constraint to formation scenarios.

5. TAILS

The dust and gas in the coma are the raw materials for the comet's tails. The prominent dust and gas (plasma) tails are the traditional identifying characteristic of comets. Dust tails are flat, curved structures and, compared to plasma tails, are relatively featureless. They can reach lengths $\sim 10^7$ km.

Dust particles, once they are decoupled from the coma gas, are in independent orbits around the Sun (see Solar System Dust). But the solar gravitational attraction is not the full value because the dust particles generally stream away from the Sun. An extra force, solar radiation pressure, is acting on the particles. Because both solar gravity and radiation pressure vary as r_h^{-2}, the orbit is determined by initial conditions and an effective gravity. The parameter μ is the ratio of the net force on the tail particle to the gravitational force. Or, the parameter $(1-\mu)$ gives the normalized nongravitational force.

For a constant emission rate of dust particles with a single size or a small range of sizes, the *syndyne* (or same force) from the Bessel–Bredichin theory is a good description. The tails are tangent to the radius vector (the prolonged Sun–comet line) at the head, and the curvature of the tail increases with decreasing $(1-\mu)$. An important concept is the fact that the shape of a particle's orbit is not the observed shape of the tail. The observed tail shape is the location of dust particles at a specific time of previously emitted particles.

Another case from the Bessel–Bredichin theory is the *synchrone* (or same time). It is produced by particles with many sizes [or values of $(1-\mu)$] being emitted at the same time. These features are rectilinear, and the angle with the radius vector increases with time. This type of feature is occasionally observed as synchronic bands.

In practice, comets emit dust particles with a range of sizes and at a rate that varies with time. Several computational approaches that accurately model observed dust tails with reasonable assumptions are available. The size distribution generally peaks at a diameter around 1 μm.

Besides the synchronic bands (mentioned earlier), fine structure in the form of *striae* occasionally appear in dust tails. They are a system of parallel, narrow bands found at large distances from the head. So far, striae appear at heliocentric distances greater than 1 AU and always after perihelion. Figure 30.14 shows a spectacular example in comet Hale–Bopp. Currently, there is no satisfactory explanation. Organization by the solar wind's magnetic field acting on electrically charged dust particles or dust particle fragmentation has been proposed.

Two other dust features are sometimes observed. Antitails or sunward spikes are produced by large dust particles in the plane of the comet's orbit. These particles do not experience the relatively large force that sends the smaller dust particles into the dust tail. They remain near the comet and, when seen in projection, appear to point in the sunward direction. If the Earth is close to the plane of the comet's orbit, a sunward spike is observed. If the Earth is away from the orbital plane but reasonably close, a sunward fan is observed.

The most famous sunward spike of the twentieth century was observed in comet Arend–Roland during April 1957 (Figure 30.15). Comets Kohoutek (December 1973/January 1974) and Halley (February 1986) also showed sunward spikes. Some of these are produced by large ejection speeds in the sunward direction, but most only appear to be sunward in projection.

The neck-line structure is a long, narrow dust feature observed when the comet is past perihelion and the Earth is close to the comet's orbital plane. Dust particles emitted from the comet at low speeds are, in fact, in orbit around the Sun. These orbits return to the orbital plane to produce a dust concentration. The neck-line structure has been observed in comets Bennett, Halley, and Hale–Bopp (Figure 30.16). The neck-line structure in comet Halley was stable and was a major feature for over a month in May and June 1986.

Although the existence of sodium gas tails was implied by spectroscopic observations of earlier comets, the definitive detection was comet Hale–Bopp's dramatic example. Figure 30.17 shows the long, narrow sodium tail. There is also a wide sodium tail superimposed on the dust tail. The source for the narrow tail is probably sodium-bearing

molecules in the inner coma that are dissociated. The source for the wide tail is probably the dust tail itself.

Sodium tails may well be a common feature of comets. Comet Hale–Bopp's nucleus was very large, with a diameter 60 ± 20 km. Estimates for the total gas production rate near perihelion are as high as 10^{31} molecules/s. Visibility of the sodium tail was enhanced by the sodium atom's high oscillator strength (one of the highest in nature), but the exceptional brightness of comet Hale–Bopp greatly increased the likelihood of observing the sodium tails.

Comet McNaught in January and February of 2007 was the brightest comet seen from the Earth in 40 years and the major visible structure was dust. Figure 30.18 shows an extraordinary image of the comet taken from an observatory in Chile overlooking the Pacific Ocean. Normally, the dust structures (the long streaks) point toward the nucleus. When they do not, the cause is larger particles breaking up and the smaller fragments moving on new orbits under the influence of solar radiation pressure. The size of the comet's nucleus must be quite large to produce this extraordinary dust tail. This view is supported by the large, downstream solar wind disturbance from this comet (discussed below). A curiosity is that the usual, blue plasma tail is not clearly visible in Figure 30.18.

The plasma tails of comets are long and generally straight and show a great deal of fine structure that constantly changes. They are typically 10^5–10^6 km wide, and the lengths recorded optically are routinely several tenths of astronomical units (or several times 1.5×10^7 km). The structure of the plasma tail may extend much farther. Measurements of magnetic fields and ions made on board

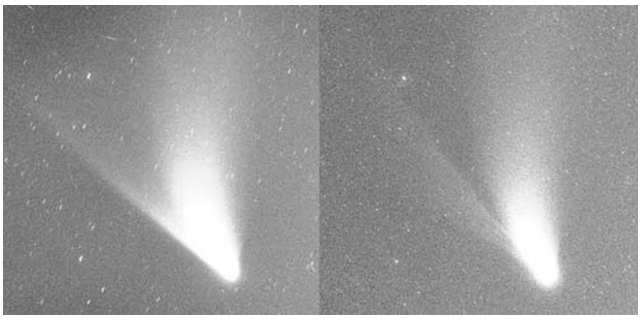

FIGURE 30.17 Images of comet Hale–Bopp in April 1997. The left-hand image records the fluorescence emission from sodium atoms and clearly shows the thin, straight sodium tail. the *Ulysses* spacecraft (when the Sun, the comet, and the spacecraft were radially aligned) have detected the signatures of comet Hyakutake's plasma tail 550 million km (or 3.7 AU) from the head and comet McNaught's plasma tail 225 million km (or 1.5 AU) from the head.

These tails are composed of electron-molecular ion plasmas. As the neutral molecules in the coma flow outward, they are ionized. Photoionization is the traditional process and easiest to include in models. Impact ionization by solar wind and cometary electrons and ionization by charge exchange also need to be considered. The result is to produce the molecular ions H_2O^+, OH^+, CO^+, CO_2^+, CH^+, and N_2^+. Images of plasma tails, particularly those taken with photographic emulsion, usually show the plasma tail to be bright blue because of strong bands of CO^+ (e.g. see Figure 30.1).

These molecular ions cannot continue their simple outward flow because they encounter the solar wind magnetic field. The **Larmor radius** gives the radius for an ion spiraling around the magnetic field lines, and a typical value is $\sim$100 km. Thus, the solar wind and the cometary ions are joined together. The magnetic field lines are said to be loaded with the addition of the pickup ions and their motion slows down. This effect is strong near the comet and weak well away from the comet. The effect causes the field lines loaded with ions to wrap around the comet like a folding umbrella. This behavior is observed. These bundles of field lines loaded with molecular ions form the plasma tail. The central, dense part of the plasma tail contains a current sheet separating the field lines of opposite magnetic polarity. Because the tail is formed by an interaction with the solar wind flow, the tail points approximately antisunward but makes an angle of a few degrees with the prolonged radius vector opposite to the comet's orbital motion. The flow direction is given by the **aberration angle** produced by the solar wind speed and the comet's motion perpendicular to the radius vector. This aberration effect was used by L. Biermann to discover the solar wind in 1951 and to estimate its speed. H. Alfvén introduced the magnetic field into the interaction and gave the basic view of plasma tails presented here. Spacecraft measurements have verified this view. Note that plasma tails usually should be considered as attached to the head of the comet. This contrasts with dust tails where the tail emanates from the head region but the dust particles are on independent orbits. Additional complications from the interaction with the solar wind are a bow shock and plasma waves, which are present over very large volumes of space (also see Planetary Magnetospheres).

The interaction between the solar wind and a comet is clearly shown in Figure 30.19, which is a plot of results from the ion analyzer on the *Deep Space 1* mission. The undisturbed solar wind flow is shown at approximately

FIGURE 30.18 Comet McNaught as imaged from the Paranal Observatory in Chile on January 21, 2007. The Pacific Ocean forms the horizon and the bright object at lower right is Venus. *Courtesy of Sebastian Deiries, European Southern Observatory.*

700 eV/Q, and it steadily decreases toward CA as the solar wind flow is loaded by the addition of cometary ions. The situation reverses as the spacecraft passes through the comet. The higher energy ions are the pickup molecules from the comet.

The exception to the picture of plasma tails usually being attached to the comet's head is when disconnection events (DEs) occur. Here, the entire plasma tail disconnects from the head and drifts away. The comet forms a new plasma tail. Many DEs have been observed over the past century, and Figure 30.20 shows a spectacular example in comet Hyakutake. DEs occur when a comet crosses the heliospheric current sheet (HCS). The HCS is an important feature in the solar wind. It separates "hemispheres" of opposite magnetic polarity and is, in essence, the magnetic equator of the heliosphere. When a comet crosses the HCS, the field lines being captured by the comet (as described earlier) are of opposite polarity. Thus, field lines of opposite polarity are pressed together in the comet causing the field lines to be severed by the process of magnetic reconnection. The old plasma is no longer attached to the head and moves away. Meanwhile, the comet develops a new plasma tail. The sequence is a regular process and repeats at each HCS crossing.

The HCS separates the heliosphere into regions of opposite magnetic polarity and defines the latitudinal structure of the solar wind. Well away from solar maximum, the solar wind is organized into a dense, gusty, slow equatorial region and a less dense, steady, fast polar region. These solar wind properties are clearly reflected in plasma tails. In the polar region, plasma tails have a smooth appearance, show aberration angles corresponding to a fast solar wind, and do not exhibit DEs. In the equatorial region, plasma tails have a disturbed appearance, show aberration angles corresponding to a slow solar wind, and exhibit DEs.

Although cometary X-rays properly belong in the coma discussion, they are included here because they are produced by a solar wind interaction. X-rays in the energy range 0.09–2.0 keV were unexpectedly discovered in comet Hyakutake; see Figure 30.21 for a false-color X-ray image of comet LINEAR. When databases were searched, several more comets were seen as X-ray sources. X-ray emission is an expected phenomenon of all comets.

The principal mechanism is charge exchange between heavy minor species in the solar wind and neutral molecules in the coma. The heavy species in the solar wind are multiply ionized. For example, six-time ionized oxygen can charge exchange with a neutral molecule to produce an ionized molecule and a five-time ionized oxygen in an excited state. X-ray lines are produced when the excited ions spontaneously decay. Spectroscopic X-ray observations have confirmed this mechanism. Some contribution to the total flux may come from electron-neutral thermal bremsstrahlung.

6. COMET CHEMISTRY

The overall chemical composition of comets seems to be rather uniform. Exceptions to this general statement are discussed later. Ultraviolet spectra of comets (see

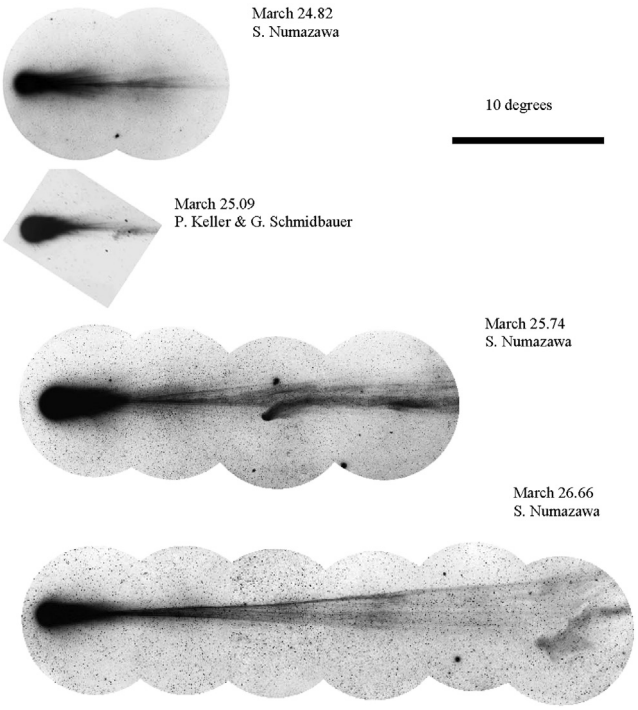

FIGURE 30.20 The spectacular 1996 disconnection event in comet Hyakutake. Figure 30.22) are dominated by the hydrogen (H) Lyman-α line at 121.6 nm and by the hydroxyl (OH) bands at 309.0 nm. This is certainly compatible with the conclusion that the nucleus is composed of roughly 80–90% water ice, 10% carbon monoxide (CO), and many minor constituents.

Table 30.2 lists species in comets that have been observed spectroscopically or measured in situ by mass spectrometers on spacecraft. The list is not exhaustive.

Providing a detailed explanation of the abundances of these species is a formidable task and is subject to many processes in the coma. But, as argued by W. F. Huebner, the situation is comprehensible if we assume a condensation process in the primordial solar nebula at a temperature of 30 K and solar abundances except for H and N. The abundance of hydrogen is determined by the capability to chemically bind to other species. Much is lost from the solar system. Some nitrogen is also lost; for example, when N_2 is formed, the nitrogen is in a form that is not chemically active. A gas mixture consisting of C, O, Mg, Si, S, and Fe in solar abundances with reduced amounts of H and N can condense into molecules at 30 K. The silicates Fe_2SiO_4 and Mg_2SiO_4 are formed from Fe, Mg, Si, and O. Then, the remainder of O goes into H_2O and into HCO and CO compounds. Finally, the remainder of the C, N, and S goes into HCNS compounds.

The result of this fairly straightforward condensation sequence is a material that, when formed into a substantial solid body, resembles comets. By mass, the relative abundance of H_2O:silicates:carbonaceous molecules plus hydrocarbons is approximately 1:1:1. Also, by mass, the abundances of ices:dust is about 1:1.

The temperature of 30 K used in the previous discussion is not only the approriate temperature for the condensation sequences but also consistent with direct determinations of the interior temperatures of cometary nuclei using the *ortho-* to *para*-hydrogen ratio (OPR). Hydrogen in water (and some other compounds) can have the spin of their nuclei in the same direction (*ortho*-water) or in the opposite direction (*para*-water). The OPR depends on the temperature of the water molecules at the time of formation, and the OPR can only be changed by chemical reactions. Thus, the ice can be sublimated in a comet's subsurface layers and flow through the crust into the coma while retaining its original OPR.

Infrared measurements of the OPR for comets Halley, Hale–Bopp, and LINEAR are all consistent with an interior temperature near 30 K. These results are important in discussing formation scenarios. The existence of S_2 in comets may require a formation temperature as low as

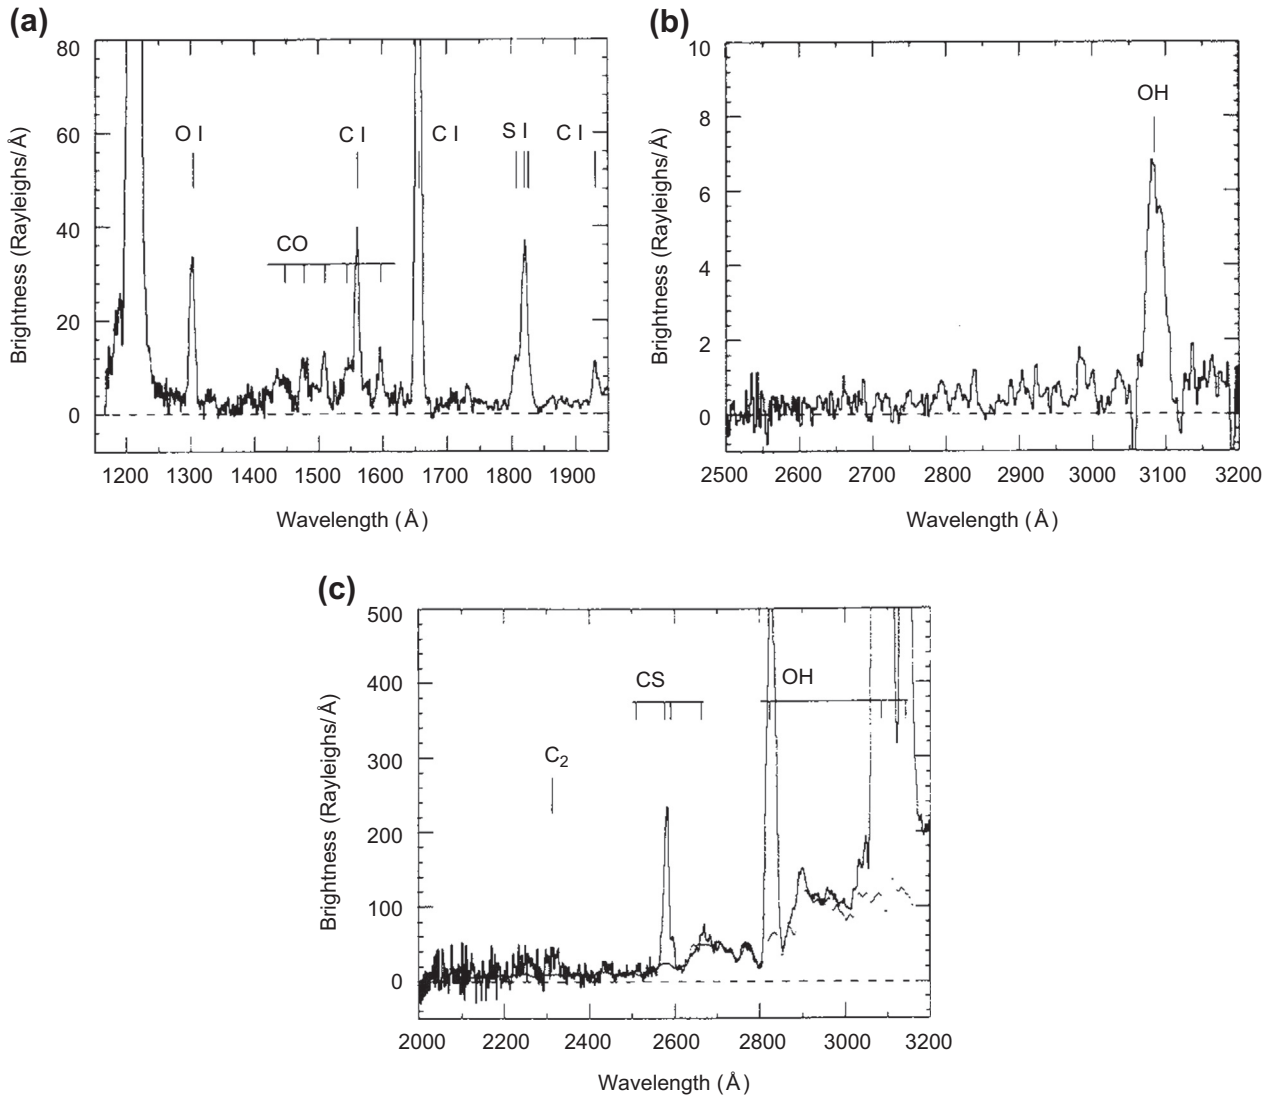

FIGURE 30.22 *International Ultraviolet Explorer* spectra of comet Halley. (a) Spectrum on March 9, 1986: the very strong line close to 1200 Å is the Lyman-α line of neutral hydrogen. 15 K. While there is some uncertainty in the exact temperature, cold temperatures are required.

A monumental study using narrow-band photometry with major results for the chemical compositions of comets was led by astronomer M. F. A'Hearn. Standardized techniques were used to characterize 85 comets with filters that covered emission bands from CN, C_2, C_3, OH, and NH as well as selected continuum regions. As with the ultraviolet results described previously, the compositions are surprisingly uniform. Barring some unusual event, a comet's production of gases and dust from orbit to orbit (and position in the orbit) is essentially the same. This implies a basically homogeneous interior. When the sample of comets was divided into old and new comets based on their orbital properties, no compositional differences were found.

The preponderance of evidence implies chemical homogeneity for comets. Still, there were some exceptions to the similarity in compositions. A class of comets shows depletions in the carbon chain molecules C_2 and C_3 relative to CN. Comet Giacobini–Zinner is the prototype for this class. Almost all the members of this class are JFCs, but not all JFCs are members of the class. And, there may be some differences in the deuterium-to-hydrogen ratios determined for comets.

7. FORMATION AND ULTIMATE FATE OF COMETS

The icy bodies of the solar system formed as part of the process that produced the Sun, the terrestrial planets, and

the giant planets. The icy bodies include some of the asteroids (including the Centaurs, which are bodies with eccentric orbits generally between Saturn and Neptune), comets, and Kuiper Belt Objects (KBOs) (see Kuiper Belt Objects: Physical Studies).

The solar system is thought to have formed from the collapse of an interstellar gas cloud. The collapse process produced a newly formed star with a circumstellar disk of gas and dust, the solar nebula (see The Origin of the Solar System). As discussed in Section 6, cometary material can condense at temperatures of roughly 30 K. Models of the early solar nebula have temperatures of approximately 30 K in the (current) Uranus–Neptune region, and it is reasonable to conclude that comets formed near there, meaning that the material condensed and agglomerated into comet-sized (most with radii in the range 1–10 km) bodies. Note, however, that the uncertainty in the temperatures for models of the presolar nebula may be as much as a factor of 2.

But the story does not end there because most comets are not in the Uranus–Neptune region today. The classical view is that dynamical processes dispersed the icy bodies. Gravitational perturbations by the giant planets sent some of the comets to large distances from the Sun and some into the inner solar system. The latter comets faded long ago. Many of the comets sent to large distances escaped from the solar system, but the ones that are barely bound form a roughly spherical cloud with dimensions of 10^4–10^5 AU. This is the cloud of comets, the Oort cloud, postulated by J. Oort many years ago. It is the source of the LPCs with $P > 200$ years. They are perturbed and sent into the inner solar system by passing stars, passing giant molecular clouds, and the tidal gravitational field of the Milky Way galaxy (see Cometary Dynamics). The HTCs were captured from the population of LPCs. Further study indicates that the Oort cloud probably has two components: the spherical outer cloud discussed previously and a more flattened inner cloud. The boundary between the inner and outer Oort cloud is at approximately 20,000 AU.

The JFCs with $P \leq 20$ years cannot come from the Oort cloud. Their origin requires a close-in, flattened source. The logical source is the Kuiper Belt. Most observed KBOs are much larger than observed JFCs, but this is almost surely due to observational selection. It is reasonable to assume that the size distribution of objects in the Kuiper Belt includes comets. Note that most KBOs are currently found with semimajor axes between 35 and 50 AU. They were not always there but were moved outward along with the outward migration of Uranus and Neptune early in the history of the solar system. The sharp outer boundary for the region of the KBOs was thought to originally be at about 30 AU; it is now at 50 AU.

A different view is evolving from the viewpoint of chemical composition advocated by M. F. A'Hearn and from the viewpoint of orbital dynamics advocated by H. Levison (recall the discussion of comet classification schemes in Section 2). While there are some differences in comet chemistry as discussed in Section 6, the overall differences are small. It is likely that all comets were formed in a region of limited extent with the same physical properties, such as the Uranus–Neptune region of the solar nebula. If the view of essentially all comets being chemically homogeneous is accepted, mechanisms are required to deliver the same comet bodies as ecliptic comets and as nearly isotropic comets. The required dynamical evolution can be done if comets formed in the present Uranus–Neptune region and were moved to the scattered disk population of the Kuiper Belt by Neptune's outward migration. The scattered disk population has perihelia around the orbit of Neptune (perihelion < 40 AU) and their eccentricities are high ($e \sim 0.5$). These objects are not in stable orbits and the scattered disk is said to be dynamically active. Objects scattered inward come from a flattened source area (as required to match the orbital inclinations) and produce the ecliptic comets. Objects scattered outward evolve with increasing semimajor axes until they are far enough out that galactic perturbations become important. Then, the comet joins the Oort cloud. Thus, scattering near perihelion by Neptune ejects objects from the scattered disk inward to produce ecliptic comets and outward to produce the source of the LPCs or the nearly isotropic comets, the Oort cloud. On this picture, the HTCs are considered part of the nearly isotopic comet population. This scenario is not yet established, but is very attractive. Final acceptance can occur when the dynamical histories and observed chemical compositions of comets converge with models of the solar nebula.

Several possible KBOs with semimajor axes greater than of 200 AU are known. The trans-Neptunian object Sedna has a semimajor axis of about 530 AU. If it is a KBO, it could indicate additional objects at large distances (see Kuiper Belt: Dynamics). And these objects could indicate complications in the basic scheme just outlined.

The dynamical processes that involve comets eject many of them from the solar system. Some estimates suggest that the number lost can be as high as 30–100 for every comet in the Oort cloud. There are many stars similar to the Sun in the solar neighborhood and throughout the galaxy, and if the formation of comets is an integral part of star and planetary system formation, there should be many interstellar comets. Some of these should pass through the solar system. They would reveal themselves by having clearly hyperbolic orbits. A quantitative calculation yields the result that six or more comets should have traveled through the solar system at distances within the orbit of Mars during the past 150 years. None has been observed so far. The newer view of populating the Oort cloud via the scattered disk may help to resolve this apparent discrepancy. J. A. Fernández has noted that the orbital evolution

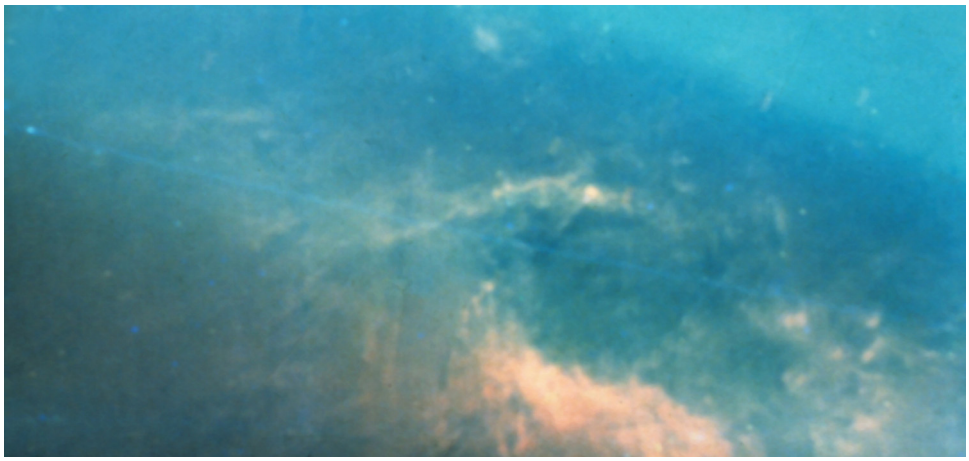

FIGURE 30.23 *Infrared Astronomical Satellite* false-color image constructed from infrared scans showing the long dust trail of comet Tempel 2. The trail appears as the thin blue line stretching from the comet's head at upper left to lower right. *Courtesy of Mark Sykes, Planetary Science Institute.*

from the scattered disk to the Oort cloud is quite smooth and the process produces a ratio of Oort cloud comets to ejected comets close to 2:1. In other words, most comets moving outward are trapped in the Oort cloud before they could be ejected.

Active comets have a limited life because the volatile materials sublimated away are not replenished. Eventually, the volatiles are gone and the body is inactive. Such objects would be classified as asteroids, and some "asteroids" are clearly dead comets because examples of the transition from comet to asteroid have been documented (see Near-Earth Objects; Main-Belt Asteroids).

Remnants of comets in the solar system include the dust particles on bound Keplerian orbits that, along with an asteroidal contribution, constitute the cloud that produces the zodiacal light from scattered sunlight. The remnants also include the meteoroid streams that produce meteor showers. These streams have long been known to be closely associated with the orbits of comets. Perturbations distribute the rocky or dusty pieces of the comet along its orbit. When the Earth encounters the stream, the pieces enter our upper atmosphere and are observed as meteor showers.

Infrared observations of comets show many long trails of dust, and several were associated with known comets. Figure 30.23 shows the long dust trail of comet Tempel 2. The false-color image from the *Infrared Astronomical Satellite* was constructed from 12-, 60-, and 100-μm scans. The dust trail is the thin blue line stretching from the comet's head at upper left to lower right. The particle sizes are estimated to be in the range 1 mm−1 cm. These dust trails appear to be meteoroid streams in the making (see Solar System Dust).

Comets can also be destroyed by collisions with the Sun, moon, planets, and satellites. The collision of the train of fragments from comet Shoemaker−Levy 9 (see Figure 30.11) with Jupiter in July 1994 is a spectacular example. Collisions of comets with the Earth have been invoked as a source of terrestrial water and possibly a source of complex organic molecules that could be important for the origin of life. At present, there is no consensus on these ideas.

8. SUMMARY

Comets are a diverse population of icy, sublimating bodies that display large-scale phenomena. The central body, the nucleus, has typical dimensions of 1−10 km. The bulk composition is mostly H_2O ice and dust, and the composition of comets is remarkable uniform. The physical processes involved—sublimation of ices in the interior, the flow of gases away from the nucleus, the dissociation and ionization of molecules, and the interaction with the solar wind—continue to provide challenges for scientists. Comets are important to our understanding of other solar system phenomena such as meteors and the zodiacal light. Many problems in comet physics can be solved only by sending spacecraft to the immediate vicinity for close-up imaging and in situ measurements. The past few years have seen several space missions to comets and an extraordinary increase in our knowledge of comets and their diversity. The interiors of comets are not well understood, but results from the *Deep Impact* and *EPOXI* missions provide an important first step. These missions showed that comet Tempel 1's nucleus is porous and that at least the outer layers have very low tensile strength. Ultimately, samples of cometary material must be returned to the Earth for analysis in the laboratory. This has begun with the return of dust particle samples from the *Stardust* mission in 2006. Although the *Rosetta* mission to comet Churyumov−Gerasimenko is expected to greatly

expand our knowledge of comets, with the main spacecraft spending an extended time period near the comet and the lander spacecraft landing on and anchoring itself to the nucleus, the return of icy materials to the Earth for analysis is probably well in the future. Comet Tempel 1 has been suggested as a good candidate for a sample return mission.

Chapter Outline

1. Basic Orbital Dynamics of Comets **706**
2. Taxonomy of Cometary Orbits **709**
2.1. Nearly Isotropic Comets 711
2.2. Ecliptic Comets 712
2.3. Orbital Distribution of Comets 712
3. Comet Reservoirs **713**
3.1. The Oort Cloud 713
3.2. The Scattered Disk 714
3.3. Formation of the Oort Cloud and Scattered Disk 717
4. Conclusions **719**
Bibliography **719**

The Solar System formed from a collapsing cloud of dust and gas. Most of this material fell into the Sun. However, since the primordial cloud had a little bit of angular momentum or spin, a flattened disk also formed around the Sun. This disk contained a small amount of mass, as compared with the Sun, but most of the cloud's original angular momentum. This disk, known as the **protoplanetary nebula**, contained the material from which the planets, satellites, asteroids, and comets formed.

The first step in the planet formation process was that the dust, which contained ice in the cooler, distant regions of the nebula, settled into a thin central layer within the nebula. Although the next step has not been fully explained (see *The Origin of the Solar System*), as the dust packed itself into an ever-decreasing volume of space, larger bodies started to form. First came the objects called **planetesimals** (meaning small planets), which probably ranged in size from roughly a kilometer across to tens of kilometers across. As these objects orbited the Sun, they would occasionally collide with one another and stick together. Thus, larger objects would slowly grow. This process continued until the planets or the cores of the gas giant planets formed. (See *Interiors of the Giant Planets*.)

Fortunately for us, planet formation was a messy process and was not 100% efficient. There are a large number of remnants floating around the Solar System. Today we call these small bodies comets and asteroids. These pieces of refuse of planet formation are interesting because they can tell us a lot about how the planets formed. For example, because comets and asteroids are the least chemically processed objects in the Solar System (there is a lot of chemistry that happens on planets), studying their composition tells us about the composition of the protoplanetary nebula.

From our perspective, however, comets and asteroids are most interesting because their orbits can tell us the story of how the planets came together. Just as blood spatters on the wall of a murder scene can tell as much, or more, about the event than the body itself, the orbits of asteroids and comets play a pivotal role in unraveling the planetary system's sordid past.

In this chapter we present the story of where comets originated, where they have spent most of their lives, and how they occasionally evolve through the planetary system and move close enough to the Sun to become the spectacular objects we sometimes see in the night sky.

However, to tell this story, we must work backward because the majority of observational information we have about these objects comes from the short phase when they are close to the Sun. The rest of the story is gleaned by combining this information with computer-generated dynamical models of the Solar System. Thus, in Section 1 we start with a discussion of the behavior of the orbits of comets. In Section 2 we present a classification scheme for comets.

This step is necessary because, as we will show, there are really two stories here. Comets can follow either one of

them, but we must discuss each of them separately. In Section 3, we describe the cometary reservoirs that are believed to exist in the Solar System today. In addition, we discuss our current understanding of how these reservoirs came to be. We conclude in Section 4.

1. BASIC ORBITAL DYNAMICS OF COMETS

For the most part, comets follow the basic laws of orbital mechanics first set down by Johannes Kepler and Isaac Newton. These are the same laws that govern the orbits of the planets. In this section, we present a brief overview of the orbits of small bodies in the Solar System. (For a more detailed discussion, see *Solar System Dynamics: Regular and Chaotic Motion*.)

In the Solar System there are eight major planets, many smaller dwarf planets, and vast numbers of smaller bodies, each acting to perturb gravitationally the orbits of the others. The major planets in the Solar System follow nearly circular orbits. They also all lie in nearly the same plane, and so it has been long assumed that the planets formed in a disk. The planets never get close to each other. So, the first-order gravitational effect of the planets on one another is that each applies a torque on the other's orbit, as if the planets were replaced by rings of material smoothly distributed along their orbits. These torques cause both the longitude of perihelion, $\overline{\omega}$, and longitude of the ascending node, Ω, to precess. In particular, $\dot{\overline{\omega}} > 0$ and $\dot{\overline{\Omega}} < 0$. The periods associated with these frequencies range from 47,000 to 2,000,000 years in the outer planetary system. Because the masses of the planets are much smaller than the Sun's mass, this is much longer than the orbital periods of the major planets, which are all less than 170 years.

There are four main differences between the orbits of the comets that we see and those of the planets. First, unlike planets, visible comets usually are on eccentric orbits, and so they tend to cross the orbits of the planets. So, they can suffer close encounters with the planets. While these encounters sometimes lead to direct collisions, like the impact of the comet D/Shoemaker-Levy 9 on Jupiter in 1994, more frequently the planet acts as a gravitational slingshot, scattering the comet from one orbit to another. The solid curve in Figure 31.1 shows the temporal evolution of comet 95P/Chiron's semimajor axis according to a numerical integration of the comet's orbit (black curve). This comet currently has $a = 14$ AU, which means it is between Saturn and Uranus, $e = 0.4$, and $i = 7°$. All the changes seen in the figure are because of gravitational encounters with the giant planets. Individual distant encounters lead to small changes, while close encounters lead to large changes. According to this integration, the comet will be ejected

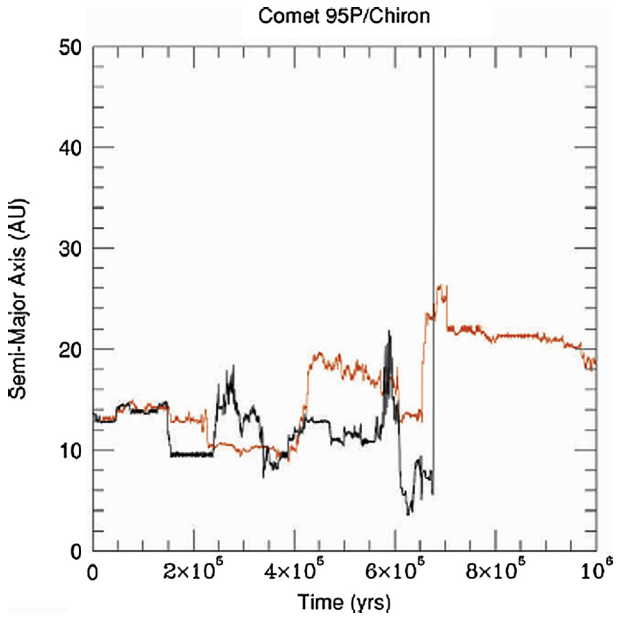

FIGURE 31.1 The long-term evolution of the semimajor axis of comet 95P/Chiron (black curve) and a *clone* of this comet (red curve). These trajectories were determined by numerically integrating the equations of motion of these comets, the Sun, and the four giant planets. The clone was an object with almost the exact same initial conditions as 95P/Chiron, but the position was offset by 1 cm. The fact that the two trajectories diverge shows that the orbit is chaotic.

from the Solar System by a close encounter with Jupiter in 675,000 years.

This calculation illustrates that the orbits of objects on planet-crossing orbits, and thus the comets that we see, are generally unstable. This means that, on timescales very short compared with the age of the Solar System, most of these objects will be ejected from the Solar System by a gravitational encounter with a planet, or hit the Sun or a planet. (Some comets appear to disintegrate spontaneously, for reasons that are not well understood.) So, the comets that we see could not have formed on the orbits that we see them on, because if they had, they would no longer be there. They must have formed, or at least been stored, for long periods of time in a reservoir or reservoirs where their orbits are long lived and they remain cold enough so that their volatiles are, for the most part, preserved. These reservoirs are mainly hidden from us because they are far from the Sun. We discuss cometary reservoirs in more detail in Section 3.

Figure 31.1 also shows that cometary orbits are formally **chaotic**. If the Solar System consisted of only the Sun and one planet, interacting through Newton's law of gravity, the planet's orbit would remain a Keplerian ellipse for all time. The distance between the planet and the Sun would vary periodically, akin to a pendulum. This is an example of **regular** motion. For regular motion, if there were two planetary systems that were exactly the same, except that the position of the planet was slightly offset in

one versus the other, this offset would increase linearly with time. However, if three or more bodies are present in the system, **chaos** is possible, meaning that any offset between two nearly identical systems would increase exponentially. In certain cases, such as if the orbit of a comet or asteroid crosses that of a planet, chaos leads to gross unpredictability. That is, in these cases it is impossible to foretell, even qualitatively, the orbit of a comet or asteroid very far into their future or past.

For example, in Figure 31.1, the black curve shows the predicted evolution of 95P/Chiron's semimajor axis, using its nominal orbit. The red curve shows the evolution of an object (the clone) that initially had exactly the same velocity as 95P/Chiron, and an initial position that differed by 1 cm! In less than a million years, a tiny fraction of the age of the Solar System, the orbits are totally different. One clone has been ejected from the Solar System, while the other continues to orbit within the planetary region. This **sensitivity to initial conditions** means that we can never predict where any object in the Solar System will be over long periods of time. By "long periods" we mean at most tens of millions of years for the planets, but for many comets less than a few hundred years. On timescales longer than this, we can only make statistical statements about the ultimate fate of small bodies on chaotic orbits.

The chaotic nature of cometary orbits has important implications for our study of cometary reservoirs. Once we determine the current orbit of a comet, it would be ideal if we could calculate how the orbit has changed with time and trace it backward to its source region. Thus, by studying the physical characteristics of these comets, we could determine what the cometary reservoirs are like. Unfortunately, the unpredictability of chaotic orbits affects orbital integrations that go backward in time as well as those that go forward in time. Thus, it is impossible to follow a particular comet backward to its source region. To illustrate this point, consider the analogy of an initially evacuated room with rough walls and a large open window into which molecules are injected through a narrow hose. Once the system has reached a steady state (i.e. the number of molecules entering through the hose is equal to the number leaving through the window), suppose that the position and velocity of all the particles in the room were recorded, but with less than perfect accuracy. If an attempt were made to integrate the system backward, the small errors in our initial positions and velocities would be amplified every time a molecule bounced off a wall. Eventually, the particles would have "forgotten" their initial state, and thus, in our backward simulation of the gas, more particles would leave through the window than through the hose, simply because the window is bigger. In our case, injection through the hose corresponds to a comet's leaving its reservoir, and leaving through the window corresponds to the many more avenues of escape available to a comet.

So, it is not possible to directly determine which comet comes from which reservoir. Therefore, the only way to use visible comets to study reservoirs is to dynamically model the behavior of comets after they leave the reservoir, and follow these hypothetical comets through the Solar System, keeping track of where they go and what kind of comets they become. By comparing the resulting orbital element distribution of the hypothetical comets to real comet types, we can determine, at least statistically, which type of comets come from which reservoir.

A second major difference between cometary and planetary orbits is that many comets are active. That is, since they are mainly made of dust (or rock) and water ice, and water ice only sublimates within $\sim$4 AU of the Sun, comets that get close to the Sun spew out large amounts of gas and dust. This activity is what makes comets so noticeable and beautiful in the night sky. However, outgassing also acts like a rocket engine that can push the comet around and change its orbit. The most obvious effect of these so-called **nongravitational forces** is to change the orbital period of the comet. For example, nongravitational forces increase the orbital period (ΔP) of comet 1P/Halley by roughly 4 days every orbit.

The magnitude, direction, and variation with time of nongravitational forces are functions of the details of an individual comet's activity. Most of the outflow is in the sunward direction; however, the thermal inertia of the spinning nucleus delays the maximum outgassing toward the afternoon hemisphere. Thus, there is a nonradial component of the force. This delay is a function of the angle between the equator of the cometary nucleus and its orbital plane and will vary with time because of seasonal effects. Also, localized jetting can also produce a nonradial force on the comet and will also change the spin state and orientation of the nucleus.

As a result, there is a huge variation of nongravitational forces from comet to comet. For example, for many comets there is no measurable nongravitational force because they are large and/or relatively inactive. Some active comets, like Halley, have nongravitational forces that behave similarly from orbit to orbit. For yet other comets, the magnitude of these forces has been observed to change over long periods of time. A good example of this type of behavior is comet 2P/Encke, which had $\Delta P = -0.13$ days in the early nineteenth century, but now has ΔP of -0.008 days.

In general it is possible to describe the nongravitational accelerations $\vec{a}_{\rm ng}$ that a comet experiences by:

$$\vec{a}_{\rm ng} = g(r)\,[A_1\hat{r} + A_2\hat{t} + A_3\hat{n}],$$

where the A's are constants fit to each comet's behavior, r is the instantaneous heliocentric distance, and $\hat{r}$, $\hat{n}$, and $\hat{t}$ are unit vectors in the radial direction, the direction normal to

the orbit of the comet, and the transverse direction, respectively. The value $g(r)$ is related to the gas production rate as a function of helocentric distance and is usually given as

$$g(r) = 0.111262\left(\frac{r}{r_0}\right)^{-2.15}\left[1+\left(\frac{r}{r_0}\right)^{5.093}\right]^{-4.6142}$$

where the parameter $r_0 = 2.808$ AU is the heliocentric distance at which most of the solar radiation goes into sublimating water ice.

A third difference between a planetary orbit and a cometary orbit arises because visible comets tend to be on eccentric (sometimes very eccentric) orbits and on orbits that are inclined with respect to the ecliptic (sometimes even **retrograde** orbits with inclinations greater than 90°). The rates at which the **apse** and **node** of a comet ($\overline{\omega}$ and Ω) precess depend upon the comet's eccentricity and inclination. Thus, although cometary orbits precess, like the orbits of the planets, their behavior can be very different from the subtle behavior of the planets. Of particular interest, if the inclination of a comet is large, it can find itself in a situation in which, on average ($\dot{\overline{\omega}} = \dot{\Omega}$), that is $\overline{\omega}$ and Ω are said to be in resonance with one another. Since these two frequencies are linked to changes in eccentricity and inclination, this resonance allows eccentricity and inclination to become coupled, and allows each to undergo huge changes at the expense of the other. And, since a comet's semimajor axes is preserved in this resonance, changes in inclination also lead to changes in perihelion distance.

An example of this so-called **Kozai resonance** can be seen in the behavior of comet 96P/Machholz 1 (Figure 31.2). 96P/Machholz 1 currently has an eccentricity of 0.96 and an inclination of 60°. Its perihelion distance, q, is currently 0.12 AU, well within the orbit of the planet Mercury. Figure 31.2 shows the evolution of the orbit of 96P/Machholz 1 over the next few thousand years. The Kozai resonance is responsible for the slow systematic oscillations in both inclination and eccentricity (or q, which equals $a \times (1-e)$). These oscillations are quite large; the inclination varies between roughly 10° and 80°, while the perihelion distance gets as large as 1 AU. According to these calculations, the Kozai resonance will drive this comet into the Sun ($e = 1$) in less than 12,000 years! Similarly, the Kozai resonance was important in driving comet D/Shoemaker-Levy 9 to collide with Jupiter. However, in that case, the comet had been captured into orbit around Jupiter, and the oscillations in i and e were with respect to the planet, not the Sun.

The final gravitational effect that we want to discuss in this section is the effect that the galactic environment has on cometary orbits. Up to this point, our discussion has assumed that the Solar System was isolated from the rest of

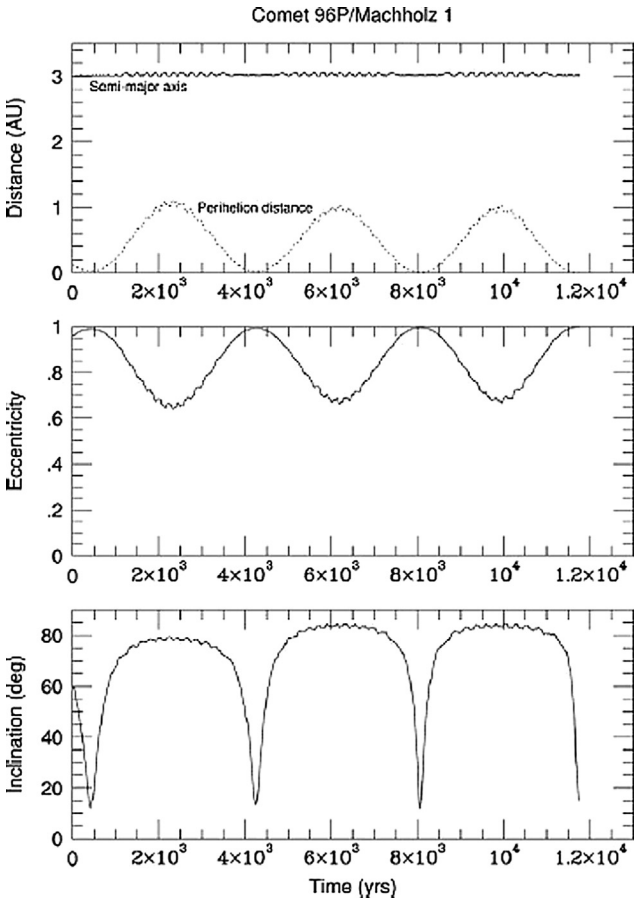

FIGURE 31.2 The long-term dynamical evolution of comet 96P/Machholz 1, which is currently in a Kozai resonance. Three panels are shown. The top presents the evolution of the comet's semimajor axis (solid curve) and perihelion distance (dotted curve). The middle and bottom panels show the eccentricity and inclination, respectively. Because of the Kozai resonance, the eccentricity and inclination oscillate with the same frequency, but are out of phase (i.e. eccentricity is large when inclination is small and vice versa). According to this calculation, this comet will hit the Sun in less than 12,000 years.

the Universe. This, of course, is not the case. The Sun, along with its planets, asteroids, and comets, is in orbit within the Milky Way Galaxy, which contains hundreds of billions of stars. Each of these stars is gravitationally interacting with the members of the Solar System. Luckily for the planets, the strength of the Galactic perturbations varies as a^2, so the effects of the Galaxy are not very important for objects that orbit close to the Sun. However, if a comet has a semimajor axis larger than a few thousand AU, as some do (see Section 2), the Galactic perturbations can have a major effect on its orbit.

For example, Figure 31.3 shows a computer simulation of the evolution through time of the orbit of a hypothetical comet with an initial semimajor axis of 20,000 AU, roughly 10% of the distance to the nearest star. (For scale remember that Neptune is at 30 AU.) For the sake of discussion, it is useful to

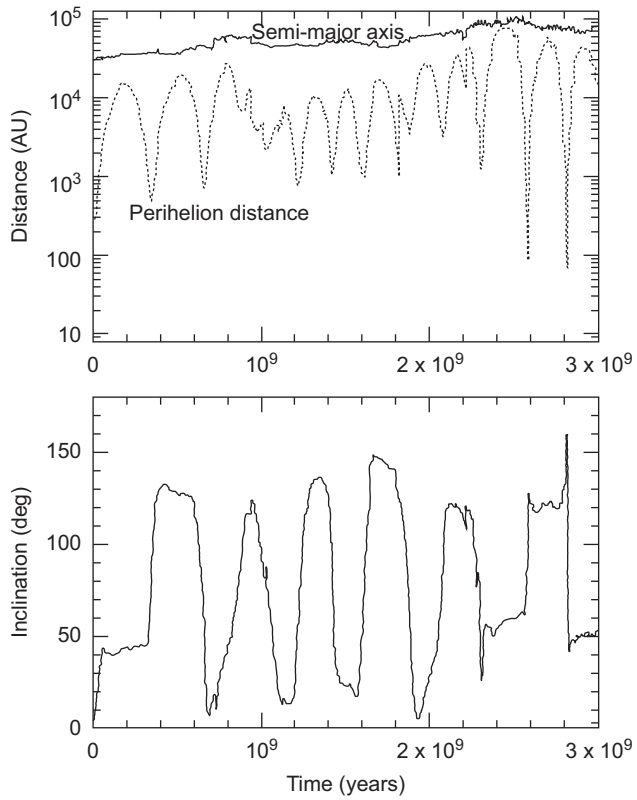

FIGURE 31.3 The long-term dynamical evolution of a fictitious object initially at 20,000 AU from the Sun under the gravitational perturbations of the Galaxy. Two panels are shown. The top presents the evolution of the comet's semimajor axis (solid curve) and perihelion distance (dotted curve; recall that $e = 1 - q/a$). The bottom panel shows the inclination.

divide the evolution into two superimposed parts: (1) a slow secular change in perihelion distance (i.e. eccentricity) and inclination, and (2) a large number of small, but distinct jumps leading to a **random walk** in the orbit.

The secular changes are because of the smooth background gravitational potential of the Galaxy as a whole. If we define a rectangular coordinate system $(\tilde{x}, \tilde{y}, \tilde{z})$ centered on the Sun, such that $\tilde{x}$ points away from the galactic center, $\tilde{y}$ points in the direction of the galactic rotation, and $\tilde{z}$ points toward the south, it can be shown that the acceleration of a comet with respect to the Sun is where $\Omega_0 = 27.2 \pm 0.9$ km/s/kpc is the Sun's angular speed about the Galactic center, $\delta \equiv -\frac{A+B}{A-B}$ and $A = 14.5 \pm 1.5$ km/s/kpc and $B = -12 \pm 3$ km/s/kpc are Oort's constants of Galactic rotation, $\rho_0 = 0.1\, M_\odot/\text{pc}^3$ is the density of the galactic disk in the solar neighborhood, and G is the gravitational constant. The value of δ is usually assumed to be zero.

Because of the nature of the above acceleration, it acts as a torque on the comet. As a result, the smooth part of the Galactic perturbations can change a comet's eccentricity and inclination, but not its semimajor axis. In addition, the eccentricity and inclination oscillate in a predictable way. In this example, in Figure 31.3 the oscillation period is approximately 300 million years (Myr). However, this period scales as $a^{-3/2}$, and thus the oscillations are faster for large semimajor axes. The small jumps are because of the effects of individual stars passing close to the Sun. Since these stars can come in from any direction, the kick that the comet feels can affect all the orbital elements, including the semimajor axis. The apparent random walk of the comet's semimajor axis seen in the figure is because of this effect.

2. TAXONOMY OF COMETARY ORBITS

The first step toward understanding a population is to construct a classification scheme that allows one to place like objects with like objects. This helps us begin to construct order from the chaos. However, before we talk about comet classification, we need to make the distinction between what we see and what is really out there. As we describe in much more detail below, most of the comets that we see are on orbits that cross the orbits of the planets. For example, the most famous comet, 1P/Halley (the "1P" stands for the first known *periodic* comet, see below), has $q = 0.6$ AU and an **aphelion distance** (farthest distance from the Sun) of 35 AU. Thus, it crosses the orbits of all the planets except Mercury. But planet-crossing comets represent only a very small fraction of the comets in the Solar System, because we can only easily see those comets that get close to the Sun.

Comets are very small compared with the planets. As a result, we cannot see comets very far away. For example, 1P/Halley, a relatively large comet, is a roughly (American) football-shaped object roughly 16 km long and 8 km wide. The farther away an object is, the fainter it is. The brightness (b) of a light-bulb decreases as the square of the distance d from the observer ($b \propto 1/d^2$). However, this is not true for objects in the Solar System that shine by reflected sunlight. To first approximation, the brightness of a solid sphere seen from the Earth is proportional to $1/(d_\odot^2 d_\oplus^2)$, where $d_\odot$ and $d_\oplus$ are the distance between the object and the Sun and Earth, respectively. As objects get farther from the Sun, they get less light from the Sun and so reflect less (that is the $1/d_\odot^2$ term). Also, the further they get from us, the fainter they appear (that is the $1/d_\oplus^2$ term). In the outer Solar System, $d_\oplus$ and $d_\odot$ are nearly equal and thus $b \sim 1/d^4$.

It is even worse for a comet since it is not simply a solid sphere. As described above, as a comet approaches the Sun, its ice begins to sublimate. The resulting gas entrains dust from the comet's surface, forming a halo known as the **coma**. Because the dust is made of small objects with a lot of surface area, it can reflect a lot of sunlight. So, this cometary activity makes the comet much brighter. Observational studies show that as a comet approaches the Sun, its brightness typically increases as $1/(d_\odot^4 d_\oplus^2)$. The result of

all this activity is that it can make an object that would normally be very difficult to see, even through a telescope, into a body visible with the naked eye. Thus, we know of only a very small fraction of comets in the Solar System and this sample is **biased** because it represents only those objects that get close to the Sun. However, before we can try to understand the population as a whole, we need to first try to understand the part that we see.

The practice of developing a classification scheme or taxonomy is widespread in astronomy, where it has been applied to everything from Solar System dust particles to clusters of galaxies. Classification schemes allow us to put the objects of study into a structure in which we can look for correlations between various physical parameters and begin to develop evolutionary models. In this way, classification schemes have played a crucial role in advancing our understanding of the universe. However, we must be careful not to confuse these schemes with reality. In many cases, we are forcing a classification scheme on a continuum of objects. Then we argue over where to draw the boundaries. The fact that we astronomers find cubbyholing objects convenient does not imply that the universe will necessarily cooperate. With this caveat in mind, in the remainder of this section we present a scheme for the classification of cometary orbits.

Historically, comets have been divided into two groups: long-period comets (with periods greater than 200 years) and short-period comets (with $P < 200$ years). This division was developed to help observers determine whether a newly discovered comet had been seen before. Since orbit determinations have been reliable for only about 200 years, it may be possible to link any comet with a period less than this length of time with previous apparitions. Conversely, it is very unlikely to be possible to do so for a comet with a period greater than 200 years, because even if it had been seen before, its orbit determination would not have been accurate enough to prove the linkage. Thus this division has no physical justification and is now of historical interest only. Unfortunately, there does not yet exist a physically meaningful classification scheme for comets that is universally accepted. Nonetheless, such schemes exist. Here we present a scheme developed by one of the authors roughly 10 years ago. A flowchart of this scheme is shown in Figure 31.4.

The first step is to divide the population of comets into two groups. Astronomers have found that the most physically reasonable way of doing this is to employ the so-called **Tisserand parameter**, which is defined as

$$T \equiv a_J/a + 2\sqrt{(1-e^2)a/a_J}\quad \cos i,$$

where a_J is Jupiter's semimajor axis. This parameter is an approximation to the **Jacobi constant**, which is an **integral of the motion** in the **circular restricted three-body problem**. The circular restricted three-body problem, in turn, is a well-understood dynamical problem consisting of two massive objects (mainly the Sun and Jupiter in this context) in circular orbits about one another, with a third,

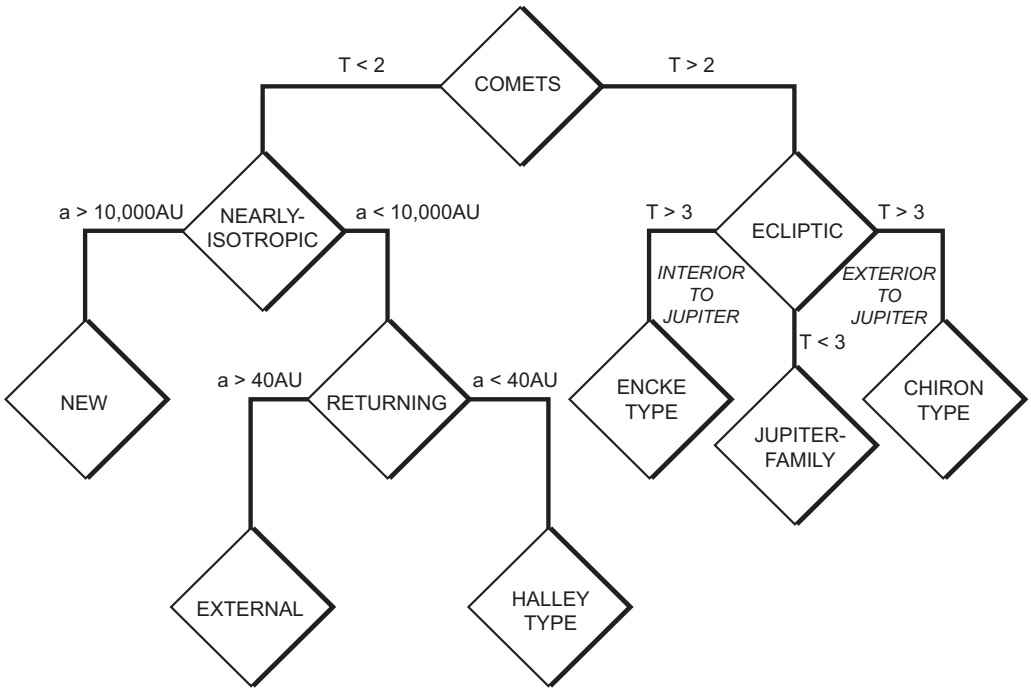

FIGURE 31.4 A flowchart showing the cometary classification scheme used in this chapter.

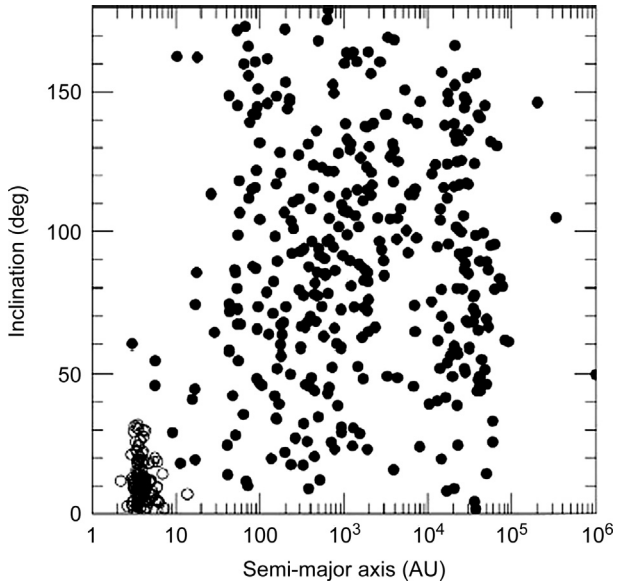

FIGURE 31.5 The inclination–semimajor axis distribution of all comets in the 2003 version of Marsden and Williams' *Catalogue of Cometary Orbits*. Comets with $T > 2$ are marked by the open circles, while comets with $T < 2$ are indicated by the filled circles.

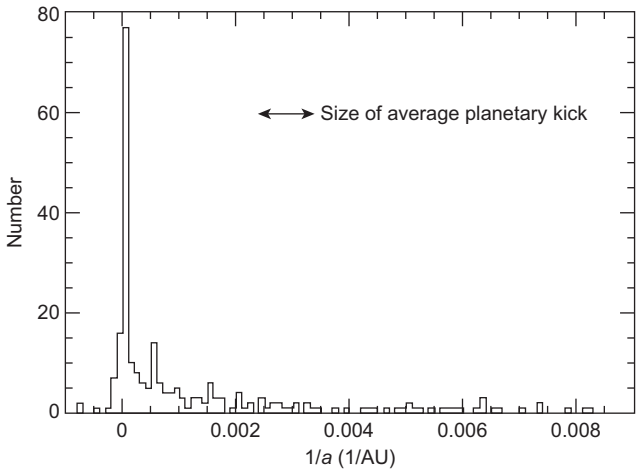

FIGURE 31.6 The distribution of inverse semimajor axis a, which measures the strength with which comets are gravitationally bound to the Solar System, for the known nearly-isotropic comets.

very small, body in orbit about the massive pair. If, to zeroth order, a comet's orbit is approximately a perturbed Kepler orbit about the Sun, then, to first order, it is better approximated as the small object in the circular restricted three-body problem with the Sun and Jupiter as the massive bodies. This means that as comets gravitationally scatter off Jupiter or evolve because of processes like the Kozai resonance, T is approximately conserved. The Tisserand parameter is also a measure of the relative velocity between a comet and Jupiter during close encounters, $v_{\rm rel} \sim v_{\rm J}\sqrt{3-T}$, where $v_{\rm J}$ is Jupiter's orbital speed around the Sun. Objects with $T > 3$ cannot cross Jupiter's orbit in the circular restricted case, being confined to orbits either totally interior or totally exterior to Jupiter's orbit.

Figure 31.5 shows a plot of inclination versus semimajor axis for known comets. Astronomers put the first division in our classification scheme at $T = 2$. Objects with $T > 2$ are shown as open circles in the figure, while those with $T < 2$ are the filled circles. The bodies with $T > 2$ are confined to low inclinations. Thus, we call these objects **ecliptic comets**. We call the $T < 2$ objects **nearly isotropic** comets to reflect their broad inclination distribution. We now discuss each of these in turn.

2.1. Nearly Isotropic Comets

Nearly isotropic comets (hereafter NICs) are divided into two groups: dynamically "new" comets and "returning" comets. This division is one that has its roots in the dynamics of these objects and is based on the distribution of their semimajor axes, a. Figure 31.6 shows a histogram of $1/a$, which is proportional to orbital binding energy $\overline{E} = -\frac{GM_\odot}{2a}$. These values of semimajor axes were determined by numerically integrating the observed trajectory of each comet backward in time to a point before it entered the planetary system. Taken at face value, a comet with $1/a < 0$ is unbound from the Sun, that is it follows a hyperbolic orbit. However, all of the negative values of $1/a$ are because of errors in orbit determination either due to poor astrometry or due to uncertainties in the estimates of the nongravitational forces. Thus, we have yet to discover a comet from interstellar space. The fraction of comets that suffer from this problem is small and we will ignore them for the remainder of this chapter.

The most striking feature of this plot is the peak at about $1/a \sim 0.00005$/AU, that is $a \sim 20{,}000$ AU. In 1950, this feature led Jan Oort to conclude that the Solar System is surrounded by a spherically symmetric cloud of comets, which we now call the Oort cloud. The peak in the $1/a$ distribution of NICs is fairly narrow. And yet, the typical kick that a comet receives when it passes through the planetary system is approximately ± 0.0005/AU, that is a factor of 10 larger than the energy of a comet initially in the peak (Figure 31.6). Thus it is unlikely that a comet that is in the peak when it first passes through the Solar System will remain there during successive passes. We conclude from this argument that comets in the peak are dynamically "new" in the sense that this is the first time that they have passed through the planetary system.

Comets not in the peak ($a \lesssim 10{,}000$ AU) are most likely objects that have been through the planetary system before. Comets with $a \ll 20{,}000$ AU that are penetrating the planetary system for the first time cannot make it into the inner Solar System where we see them as active comets without first encountering a planet (see Section 3.1 for a

more complete discussion). Therefore, we should expect to see few comets directly from the Oort cloud with semimajor axes smaller than this value. We can conclude that an NIC not in the peak is a comet that was initially in it but has evolved to smaller a during previous passes through the planetary system. These comets are called "returning" comets. The boundary between new and returning comets is usually placed at $a = 10{,}000$ AU.

Returning comets are, in turn, divided into two groups based on their dynamics. Long-term numerical integrations of the orbits of returning comets show that a significant fraction of those with semimajor axes less than about 40 AU are temporarily trapped in what are called **mean motion resonances** with one of the giant planets during a significant fraction of the time they spend in this region of the Solar System. Such a resonance is said to occur if the ratio of the orbital period of the comet to that of the planet is near the ratio of two small integers. For example, on average Pluto orbits the Sun twice every time Neptune orbits three times. So, Pluto is said to be in the 2:3 mean motion resonance with Neptune. Comet 109P/Swift–Tuttle, with a semimajor axis of 26 AU, is currently trapped in a 1:11 mean motion resonance with Jupiter. Mean motion resonances can have a large effect on the orbital evolution of comets because they can change eccentricities and inclinations, as well as protecting the comet from close encounters with the planet it is resonating with. This is true even if the comet is only temporarily trapped. In our classification scheme, comets that have a small enough semimajor axis to be able to be trapped in a mean motion resonance with a giant planet are designated as **Halley-type** comets, named for its most famous member comet 1P/Halley. Returning comets that have semimajor axes larger than this are known as **external** comets. Although it is not really clear exactly where the boundary between these two type of comets should be, we place the boundary at $a = 40$ AU.

2.2. Ecliptic Comets

Recall that ecliptic comets are those comets with $T > 2$. These comets are further divided into three groups. Comets with $2 < T < 3$ are generally on Jupiter-crossing orbits and are dynamically dominated by that planet. Thus, we call these **Jupiter-family** comets. This class contains most of the known ecliptic comets. As described above, comets with $T > 3$ cannot cross the orbit of Jupiter and thus should not be considered members of the Jupiter family. A comet that has $T > 3$ and whose orbit is interior to that of Jupiter is designated a *Encke type.* This class is named after its best-known member, 2P/Encke. 2P/Encke is a bright active comet that is decoupled from Jupiter. Its aphelion distance is only 4.2 AU.

A comet that has $T > 3$ and has a semimajor axis larger than that of Jupiter is known as a **Chiron type**, again named after its best-known member, 95P/Chiron. As we discussed in Section 2.2, Chiron has a semimajor axis of 14 AU and a perihelion distance of 8 AU, putting it well beyond the grasp of Jupiter. Indeed, 95P/Chiron is currently dynamically controlled by Saturn. Although 95P/Chiron has a weak coma and is designated as a comet by the International Astronomical Union (IAU), it is also considered to be part of a population of asteroids known as **Centaurs**, which are found on orbits beyond Jupiter and that cross the orbits of the giant planets. The IAU distinguishes between a comet and an asteroid based on whether an object is active or not. This distinction is therefore not dependent on an object's dynamical history or where it came from. Thus, Chiron is simply a member of the Centaurs, of which there are currently a few dozen known members. For the remainder of this chapter, we will not distinguish between the **Chiron-type** comets and the Centaur asteroids, and will call both Centaurs.

2.3. Orbital Distribution of Comets

Figure 31.7 shows the location of the comet classes described above as a function of their Tisserand parameter and semimajor axis. Also shown is the location of all comets in the 2003 version of Marsden and Williams' *Catalogue of Cometary Orbits.* The major classes of ecliptic and NICs are defined by T and are independent of a. The ranges of these two classes are thus shown with arrows only. The extent of the subclasses is shown by different

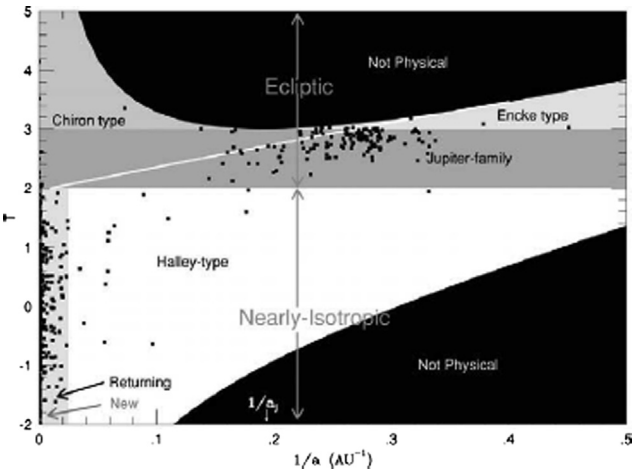

FIGURE 31.7 The location of the classes in our adopted comet taxonomy as a function of the Tisserand parameter (T) and semimajor axis (a). The major classes of ecliptic comets and NICs are defined by their values of T. The ranges of these two classes are thus shown with arrows only. The extent of each subclass is shown by different shadings. Also shown is the location of all the comets with $1/a > 0$ in the 2003 version of Marsden and Williams' *Catalogue of Cometary Orbits*. The white curve shows the relationship of T versus a for a comet with $q = 2.5$ AU and $i = 0$. Comets above and to the left of this line have $q > 2.5$ AU and thus are difficult to detect.

shadings. Also shown is the location of all the comets with $1/a > 0$ in the catalog. The white curve shows the relationship of T versus a for a comet with $q = 2.5$ AU and $i = 0$. Comets above and to the left of this line have $q > 2.5$ AU and thus are difficult to detect. By far, most comets in the plot are new or returning NICs. The second largest group consists of the Jupiter-family comets.

We end this section with a short discussion of the robustness of this classification scheme. Long-term orbital integrations show that comets rarely change their primary class (*ecliptic* versus *nearly isotropic*), but do frequently change their subclass (i.e. *new* versus *returning* or *Jupiter family* versus *Chiron type*). This result suggests that ecliptic comets and NICs come from different source reservoirs. In particular, as we will now describe, the NICs come from the Oort cloud, while the ecliptic comets are thought to originate in a structure that we call the **scattered disk**.

3. COMET RESERVOIRS

As we discussed above, the active comets that we see are on unstable short-lived orbits because they cross the orbits of the planets. For example, the median dynamical lifetime of a Jupiter-family comet (defined as the span of time measured from when a comet first evolves onto Jupiter-family comet-type orbit until it is ejected from the Solar System, usually by Jupiter) is only about 300,000 years. So, these comets must have been stored in one or more reservoirs, presumably outside the planetary region, for billions of years before being injected into the inner Solar System where they can be observed. These reservoirs are far from the Sun (and they would have to be to store an ice ball for 4 billion years), and thus much of what we know about them has been learned by studying the visible comets and linking them to their reservoirs through a theoretical investigation of the orbital evolution of comets. As we currently understand things, there are two main cometary reservoirs: the Oort cloud and the scattered disk. We discuss each of these separately.

3.1. The Oort Cloud

NICs originate in the Oort cloud, which is a nearly spherical distribution of comets (at least in the outer regions of the cloud), centered on the Sun. The position of its outer edge is defined by the Solar System's tidal truncation radius at about 100,000–200,000 AU from the Sun. At these distances, the gravitational effect of stars and other material in the Galaxy can strip a comet away from the Solar System. This edge can be seen in the distribution of NICs shown in Figure 31.6. For reasons described below, we have no direct information about the location of the Oort cloud's inner edge, but models of Oort cloud formation (see Section 3.3) predict that it should be between 2000 and 5000 AU.

The orbits of comets stored in the Oort cloud evolve because of the forces from the Galaxy. As shown in Figure 31.3, the primary role of the Galaxy is to change the angular momentum of the comet's orbit, causing large changes in the inclination and, more importantly, the perihelion distance of the comet. Occasionally, a comet will evolve so that its perihelion distance falls to within a few AU of the Sun, thus making it visible as a new NIC. As we discussed above, the new comets that we see have semi-major axes larger than 20,000 AU, as illustrated by the spike in Figure 31.6. This led Jan Oort to suggest that the inner edge of the Oort cloud was at this location. However, this turns out not to be the case. In order for us to see a new comet from the Oort cloud, it has to get close to the Sun, which generally means that its perihelion distance, q, must be less than 2 or 3 AU.[1] However, during the perihelion passage before the one on which we see a comet for the first time, its perihelion distance must have been outside the realm of the gas giants ($q > 15$ AU), because if the comet had q near either Jupiter or Saturn when it was near perihelion, it would have received a kick from the planets that would have knocked it out of the spike. Thus, new comets can only come from the region in the Oort cloud in which the Galactic tides are strong enough that the change in perihelion in one orbit (Δq) is greater than $\sim$10 AU. It can be shown that the timescale on which a comet's perihelion changes is

$$\tau_q = 6.6 \times 10^{14} \text{ year } a^{-2} \Delta q/\sqrt{q},$$

in the current galactic environment where a, Δq, and q are measured in AU. Thus, only those objects for which τ_q is larger than the orbital period can become a visible new comet. For $\Delta q = 10$ AU and $q = 15$ AU, this occurs when $a > 20{,}000$ AU.

The above result does not imply that Oort comets far inside of 20,000 AU do not contribute to the population of NICs. In fact, they do. It is simply that these objects do not become active comets until their orbits have been significantly modified by the giant planets.

Figure 31.8 shows the cumulative inclination distribution for a combination of new and external comets (solid curve) and Halley-type comets (dotted curve). The solid curve is what would be expected from an isotropic Oort cloud. The curve follows a roughly $\sin(i)$ distribution, which has a median inclination of 90° and thus has equal numbers of prograde and retrograde orbits. It is these data

1. Comets are sometimes discovered at larger perihelion distances because the comet is unusually active because of the sublimation of ices, such as carbon monoxide, that are more volatile than water ice. The current record holder, the new comet C/2003 A2 Gleason, had $q = 11$ AU. Some become returning comets. Indeed, from modeling the inclination distribution of the Halley-type comets, we think that some objects from the inner regions of the Oort cloud eventually become NICs.

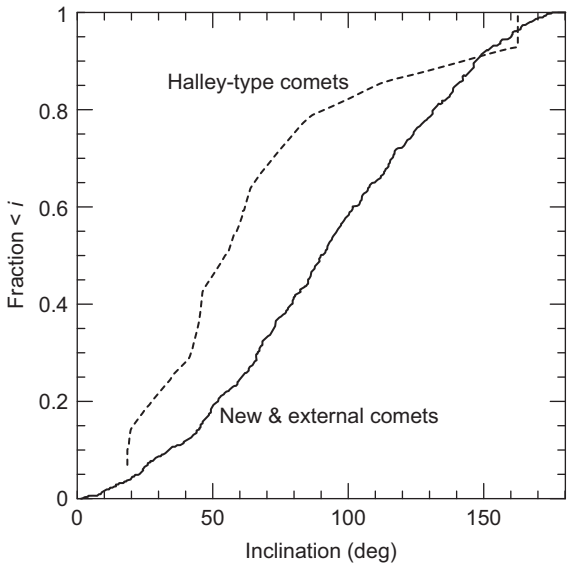

FIGURE 31.8 The cumulative inclination distribution of the NICs in Marsden and Williams' catalog. We divide the population into two groups: Halley types ($a < 40$ AU) and a combination of new and external comets.

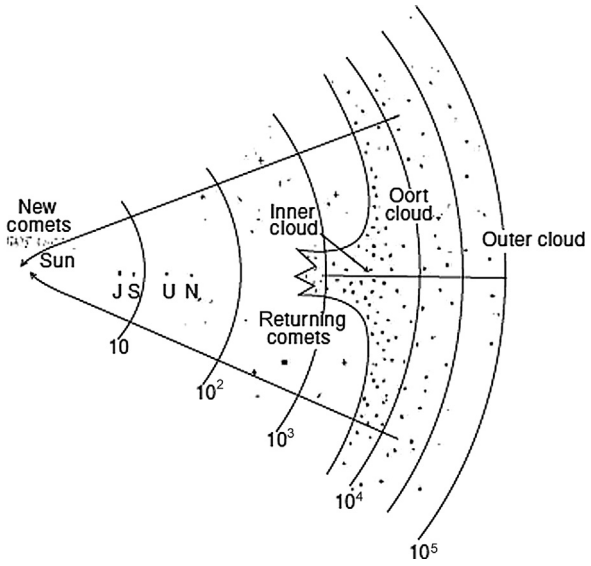

FIGURE 31.9 An artist's conception of the structure of the Oort cloud. In particular, the locations of the inner and outer edges of the Oort cloud, and where the cloud is flattened, are shown with respect to the location of the giant planets. Note that the radial distance from the Sun is spaced logarithmically. The location of the returning comets and the source for the new comets are also illustrated.

that astronomers use to argue that the outer Oort cloud is basically spherical.

The inclination distribution of the Halley-type comets is quite different from that of the rest of the NICs. Almost 80% of Halley-type comets are on prograde orbits ($i < 90°$); the median inclination is only 55°. Numerical simulations of the evolution of comets from the Oort cloud to Halley-type orbits show that the inclination distribution of the comets is approximately conserved during the capture process. This means that the source region for these comets should have the same inclinations, on average, as the dotted curve in Figure 31.8. The only way to reconcile this with the roughly spherical shape of the outer Oort cloud is if the inner regions of the Oort cloud are flattened into a disk-like structure. Indeed, simulations suggest that the inner Oort cloud must have a median inclination of between 10° and 50° for it to match the observed inclination distribution of Halley-type comets. Figure 31.9 shows an artist's conception of what the Oort cloud may look like in cross-section.

3.2. The Scattered Disk

To start the discussion of the scattered disk, we turn our attention back to Figure 31.5, which shows the semimajor axis—inclination distribution of the known comets. There is a clear concentration of comets on low-inclination orbits near $a \sim 4$ AU. Indeed, 27% of all the comets in the catalog lie within this concentration. As we described above, we call these objects ecliptic comets, and most are Jupiter-family comets.

Until the 1980s, the origin of these objects was a mystery. Even at that time it was recognized that the inclination distribution of comets does not change significantly as they evolve from long-period orbits inward. This is a problem for a model in which these comets originate in the Oort cloud, as most astronomers believed, because the median inclination of the Jupiter family is only 11°. So, dynamicists argued that Jupiter-family comets could not come from the Oort cloud, but must have originated in a flattened structure. Indeed, it was suggested that these objects originated in a disk of comets that extends outward from the orbit of Neptune. Spurred on by this argument, observers discovered the first trans-Neptunian object in 1992. Although this object is about a million times more massive then the typical ecliptic comet (it needs to be much larger than a typical comet, or we would not have seen it that far away), it was soon recognized that it was part of a population of objects both large and small—mainly small.

Since 1992, the trans-Neptunian region has been the focus of intense research, and over a 1000 objects are now known to reside there. The diversity (both physical and dynamical) of its objects make it one of the most puzzling and fascinating places in the Solar System. As such, a complete discussion is beyond the scope of this chapter and, indeed, chapters on the Kuiper Belt are dedicated to this topic (See *Kuiper Belt: Dynamics; Kuiper Belt Objects: Physical Studies*). For our purposes, it suffices to say that the trans-Neptunian region is inhabited by at least two populations of objects that roughly lie in the same region of physical space, but have very different dynamical properties.

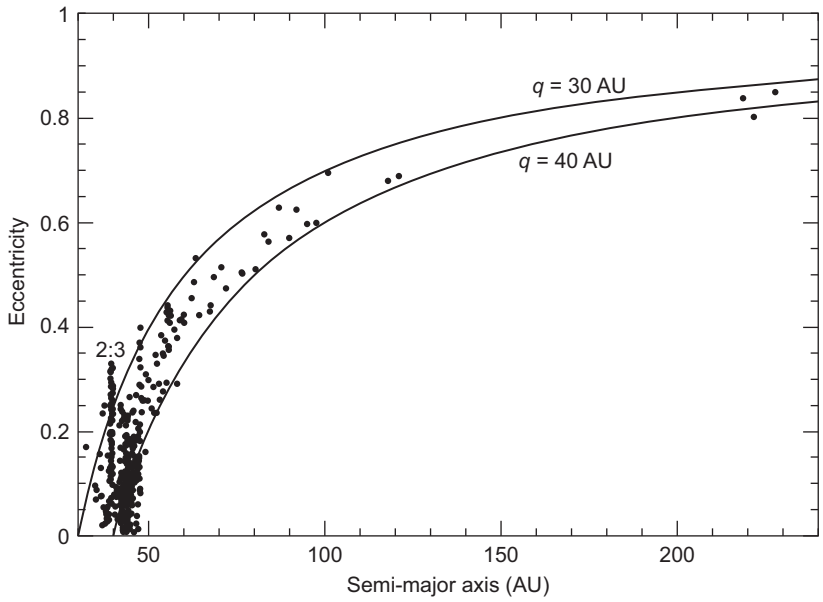

FIGURE 31.10 The eccentricity—semimajor axis distribution for the known trans-Neptunian objects with good orbits as of November 2005. We truncated the plot at 250 AU to resolve the inner regions better. Two curves of constant perihelion distance (q) are shown. In addition, the location of Neptune's 2:3 mean motion resonance is marked.

These are illustrated in Figure 31.10, which shows the semimajor axis and eccentricity of all known trans-Neptunian objects with good orbits as of November 2005.

The first population of interest consists of those objects which are on orbits that are stable for the age of the Solar System. These objects mostly have perihelion distances (q) larger than 40 AU, or are in mean motion resonances with Neptune. Of particular note are the bodies in Neptune's 2:3 mean motion resonance, which are marked in the figure. Pluto is a member of this group. Even though some objects in the resonances are on orbits that cross the orbit of Neptune, they are stable because the resonance protects them from close encounters with that planet. All in all, we call this population the **Kuiper Belt**.[2]

The second population is mainly made up of objects with small enough perihelion distances that Neptune can push them around as they go through perihelion. Because of this characteristic, we call this population the **scattered disk**. These are mainly nonresonant objects with $q < 40$ AU. (See *Kuiper Belt: Dynamics for a more detailed definition*.) Although most of the trans-Neptunian objects thus far discovered are members of the Kuiper Belt as defined here, it turns out that this is because of observational bias, and the Kuiper Belt and scattered disk contain roughly the same amount of material. In particular, the scattered disk contains about a billion objects that are comet sized (roughly kilometer sized) or larger.

Since the scattered disk is a dynamically active region, objects are slowly leaking out of it with time. Indeed, models of the evolution of scattered disk objects show that the scattered disk contained about 100 times more objects when it was formed roughly 4 billion years ago than it does today (see below). Objects can leave the scattered disk in two ways. First, they can slowly evolve outward in semimajor axis until they get far enough from the Sun that Galactic tides become important. These objects then become part of the Oort cloud. However, most of the objects evolve inward onto Neptune-crossing orbits. Close encounters with Neptune can then knock an object out of the scattered disk. Roughly one comet in three that becomes Neptune crossing, in turn, evolves through the outer planetary system to become a Jupiter-family comet for a small fraction of its lifetime.

Figure 31.11 shows what we believe to be the evolution of a typical scattered disk object as it follows its trek from the scattered disk to the Jupiter family and out again. The figure shows this evolution in the perihelion distance (q)—aphelion distance (Q) plane. The positions are joined by blue lines until the object first became "visible" (which we take to be $q < 2.5$ AU) and are linked in red thereafter. Initially, the object spent considerable time in the scattered disk, that is with perihelion near the orbit of Neptune (30 AU) and aphelion well beyond the planetary system. However, once an object evolves inward, it tends to be under the dynamical control of just one planet. That planet will scatter it inward and outward in a random walk, typically handing it off to the planet directly interior or exterior

2. There are two meanings of the phrase "Kuiper Belt" in the literature. There is the one employed above. In addition, some researchers use the phrase to describe the entire trans-Neptunian region. In this case the term "classical Kuiper Belt" is used to distinguish the stable regions. We prefer the former definition.

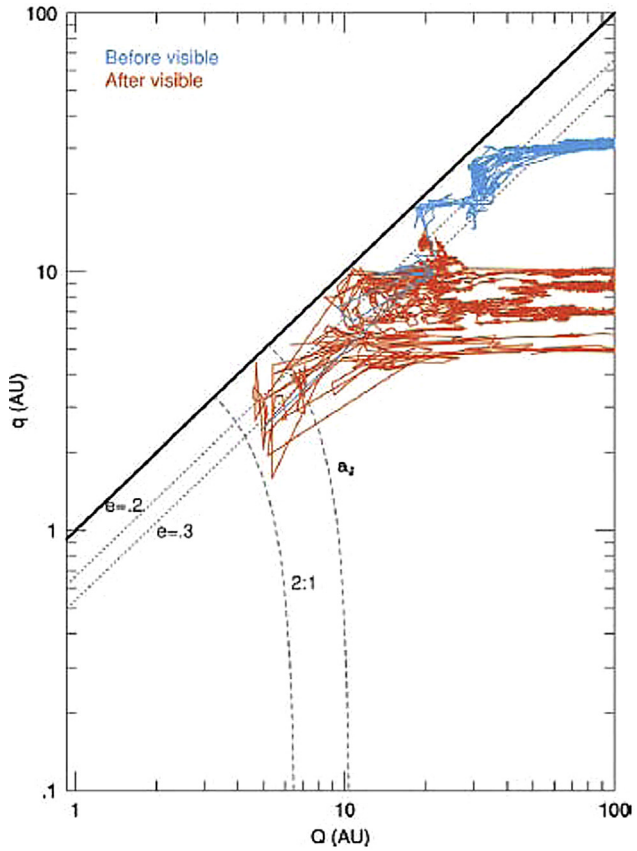

FIGURE 31.11 The orbital evolution of a representative object originating in the scattered disk. In particular, the locations of the object's orbit in the $q-Q$ (perihelion−aphelion) plane are joined by blue lines until the object became "visible" ($q < 2.5$ AU) and are linked in red thereafter. The sampling interval was every 10,000 years in the previsibility phase and every 1000 years thereafter. Also shown in the figure are three lines of constant eccentricity at $e = 0$, 0.2, and 0.3. In addition, we plot two dashed curves of constant semimajor axis, one at Jupiter's orbit and one at its 2:1 mean motion resonance. Note that it is impossible for an object to have $q > Q$, so objects cannot move into the region above and to the right of the solid diagonal line.

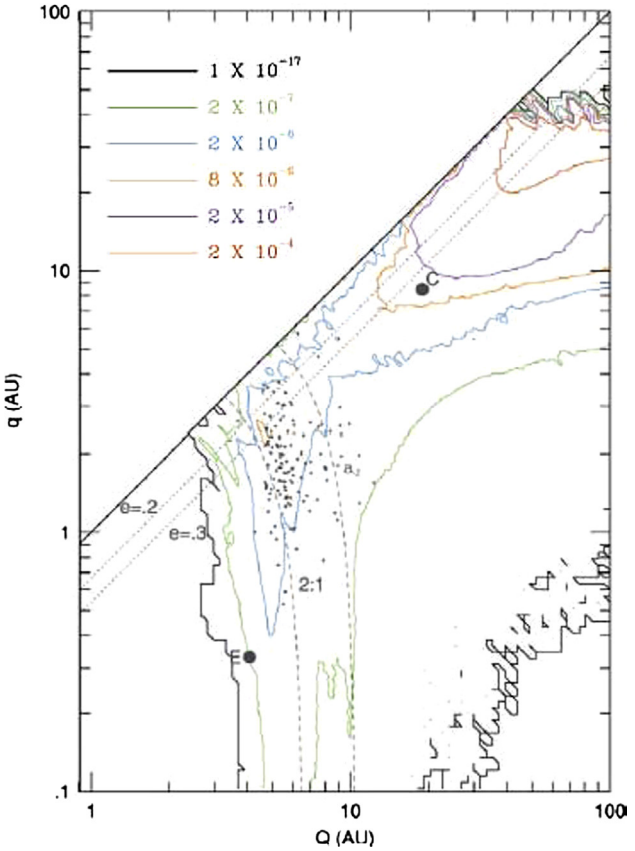

FIGURE 31.12 A contour plot of the relative distribution of ecliptic comets in the solar system as a function of aphelion (Q) and perihelion (q). The units are the fraction of comets per square AU in $q-Q$ space. Also shown in the figure are three lines of constant eccentricity at $e = 0$ (solid), 0.2, and 0.3 (both dotted). In addition, we plot two dashed curves of constant semimajor axis, one at Jupiter's orbit and one at its 2:1 mean motion resonance. They gray dots labeled "E" and "C" show the locations of comets 2P/Encke and 95P/Chiron. The small gray dots show the orbits of the Jupiter-family comets.

to it. Because of the roughly geometric spacing of the giant planets, comets tend to have eccentricities of about 25% between "handoffs" and spend a considerable amount of time with perihelion or aphelion near the semimajor axis of Saturn, Uranus, or Neptune.

However, once comets have been scattered into the inner Solar System by Jupiter, they can have much larger eccentricities as they evolve back outward. The post-visibility phase of the object in Figure 31.11 is reasonably typical of Jupiter-family comets, with much larger eccentricities than the previsibility comets and perihelion distances near Jupiter or Saturn. This object was eventually ejected from the Solar System by a close encounter with Saturn.

Numerical models, like the one used to create Figure 31.11, show that most of the ecliptic comets and Centaurs most likely originated in the scattered disk. Figure 31.12 shows the distribution of the ecliptic comets derived from these simulations. The figure is a contour plot of the relative number of comets per square AU in perihelion−aphelion ($q-Q$) space. Also shown are the locations of 95P/Chiron and 2P/Encke (big dots marked "C" and "E", respectively), and the known Jupiter-family comets (small gray dots).

There are two well-defined regions in Figure 31.12. Beyond approximately $Q = 7$ AU, there is a ridge of high density extending diagonally from the upper right to the center of the plot, near $e \approx 0.25$. The peak density in this ridge drops by almost a factor of 100 as it moves inward, having a minimum where the semimajor axes of the comets are the same as Jupiter's (shown by a dotted curve and marked with a_J). This region of the plot is inhabited mainly by the Centaurs. Inside of $Q \approx 7$ AU, the character of the distribution is quite different. Here there is a ridge of high

density extending vertically in the figure at $Q \sim 5-6$ AU that extends over a wide range of perihelion distances. Objects in this region are the Jupiter-family comets. This characteristic of a very narrow distribution in Q is seen in the real Jupiter-family comets and is a result of the narrow range in T which, in turn, comes from the low to moderate inclinations and eccentricities of bodies in the scattered disk.

Figure 31.12 shows the relationship between the Centaurs and the Jupiter-family comets and illustrates the distribution of objects throughout the outer Solar System. The simulations predict that the inclinations of this population should be small everywhere, which is consistent with observations.

3.3. Formation of the Oort Cloud and Scattered Disk

Let us take stock of where we have come thus far. Active comets can be divided into two groups based on the value of the Tisserand parameter, T. The NICs have $T < 2$ and originate in the Oort cloud. The ecliptic comets have $T > 2$ and originate in the scattered disk. The Oort cloud is a population of comets that lie very far from the Sun, with semimajor axes extending from tens of thousands of AU down to thousands of AU. It also is roughly spherical in shape. The scattered disk, on the other hand, lies mainly interior to ~ 1000 AU and is flattened. It may be surprising, therefore, that modern theories suggest that both of these structures formed as a result of the same process and therefore the objects in them formed in the same region of the Solar System.

First, we must address why we think that these structures did not form where they are. The answer has to do with the comets' eccentricities and inclinations. Although comets are much smaller than planets, they probably formed in a similar way. The Solar System formed from a huge cloud of gas and dust that initially collapsed to a protostar surrounded by a disk. The comets, asteroids, and planets formed in this disk. However, initially the disk only contained very small solid objects, similar in size to particles of smoke, and much smaller than comets. Although it is not clear how these objects grew to become comet sized, all the processes thus far suggested require that the relative velocity between the dust particles was small. This, in turn, requires the dust particles to be on nearly circular coplanar orbits. So, the eccentric and inclined orbits of bodies in the cometary reservoirs must have arisen because they were dynamically processed from the orbits in which they were formed to the orbits in which they are found today.

Astronomers generally agree that comets originally formed in the region of the Solar System now inhabited by the giant planets. Although comets formed in nearly circular orbits, their orbits were perturbed by the giant planets as the planets grew and/or the planets' orbits evolved. Figure 31.13 shows the behavior of a typical comet as it evolves into the Oort cloud. At first, the comet is handed off from planet to planet, remaining in a nearly circular orbit (Region 1 in the figure). However, eventually Neptune scatters the body outward. It then goes through a period of time when its semimajor axis is changing because of encounters with Neptune (Region 2). During this time its perihelion distance is near the orbit of Neptune, but its semimajor axis can become quite large. (If this reminds you of the scattered disk, it should.) When the object gets into the region beyond 10,000 AU, galactic perturbations lift its perihelion out of the planetary system, and it is then stored in the Oort cloud for billions of years (Region 3).

Figure 31.14 shows the result of a numerical model of the formation of the Oort cloud and scattered disk. The simulation followed the orbital evolution of a large number of comets initially placed on nearly circular low-inclination orbits between the giant planets, under the gravitational influence of the Sun, the four giant planets, and the Galaxy. The major steps of Oort cloud formation can be seen in this figure. Initially the giant planets start scattering objects to large semimajor axes. By 600,000 years, a massive scattered disk has formed, but only a few objects have evolved far enough outward that Galactic perturbations are important.

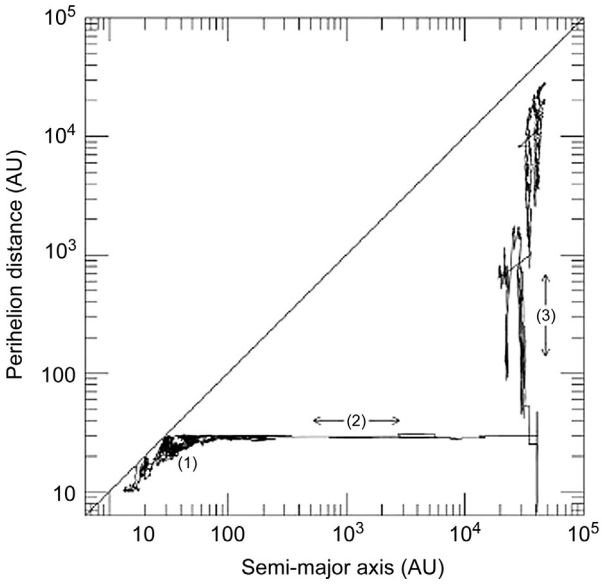

FIGURE 31.13 The dynamical evolution of an object as it evolves into the Oort cloud. The object was initially in a nearly circular orbit between the giant planets. Its evolution follows three distinct phases. During Phase 1 the object remains in a relatively low eccentricity orbit between the giant planets. Neptune eventually scatters it outward, after which the object undergoes a random walk in semimajor axis (Phase 2). When it reaches a large enough semimajor axis, galactic perturbations lift its perihelion distance to large values (Phase 3).

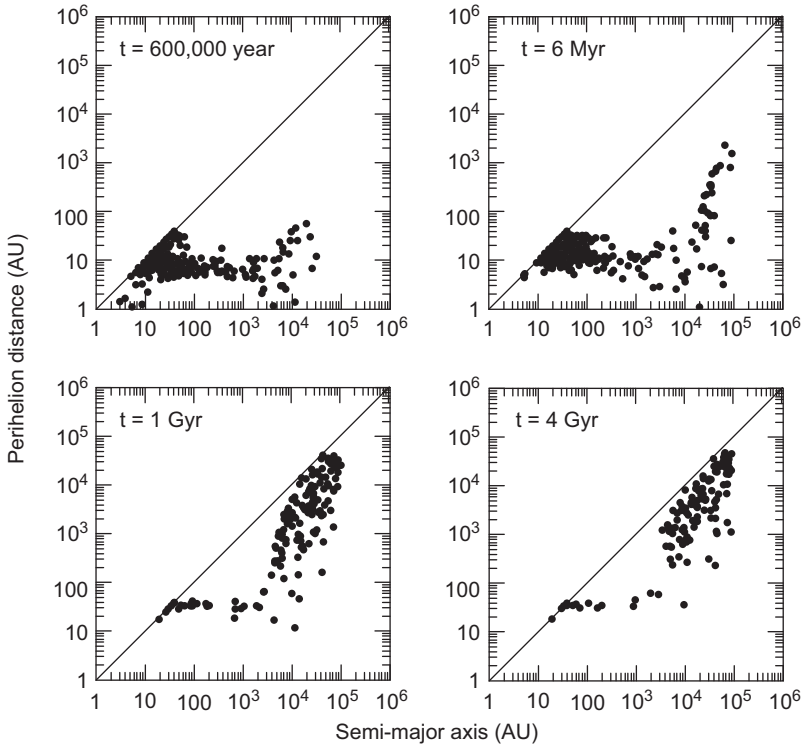

FIGURE 31.14 Four snapshots of comets in a simulation of the formation of the scattered disk and the Oort cloud.

At $t = 6$ Myr the Oort cloud is beginning to form. The Galactic perturbations have started to raise the perihelion distances of the most distant comets, but a complete cycle in q has yet to occur (see Figure 31.3). Note that the scattered disk is still massive. By 1 billion years, the Oort cloud beyond 10,000 AU is inhabited by objects on moderate-eccentricity orbits (i.e. where $a \sim q$). Note also that a scattered disk still exists. There is also a transition region between $\sim$2000 and $\sim$5000 AU, where objects are beginning to have their perihelia lifted by the Galaxy, but have not yet undergone a complete cycle in perihelion distance. By 4 billion years, the Oort cloud is fully formed and extends from 3000 to 100,000 AU. The scattered disk can easily be seen extending from Neptune's orbit outward. If our current understanding of comet reservoirs is correct, these are the two source reservoirs of all the known visible comets.

The above calculations assume that the Sun has always occupied its current Galactic environment, that is it is isolated and not a member of a star cluster. However, almost all stars form in dense clusters. The gravitational effects of such a star cluster on a growing Oort cloud is similar to that of the Galaxy except that the torques are much stronger. This would lead to an Oort cloud that is much more compact if the Sun had been in such an environment at the time that the cloud was forming. However, models of the dynamical evolution of star clusters show that the average star spends less than 5 Myr in such an environment and the giant planets might take that long to form. Additionally, even if the planets formed very quickly, Figure 31.14 shows that the Oort cloud is only partially formed after a few million years. In particular, only those objects that originated in the Jupiter–Saturn region have evolved much in semimajor axis. Therefore, the Oort cloud probably formed in two stages. Before $\sim$5 Myr a dense *first generation* Oort cloud formed from Jupiter–Saturn planetesimals at roughly $a \sim 1000$ AU because of the effects of the star cluster. After the Sun left the cluster, a normal Oort cloud formed at $a \sim 10{,}000$ AU from objects that originated beyond Saturn. Figure 31.15 shows an example of such an Oort cloud as determined from numerical experiments. There is some observational evidence that the Solar System contains a first-generation Oort cloud. In 2004, the object known as Sedna was discovered. Sedna has $a = 468$ AU and $q = 76$ AU, placing it well beyond the planetary region. Numerical experiments have shown that the most likely way to get objects with perihelion distances as large as Sedna is through external torques (as in Figure 31.15). And, since the current Galactic environment is too weak to place Sedna on its current orbit, Sedna's orbit probably formed when the Sun was in its birth star cluster. If true, Sedna's orbit represents the first observational constraint we have concerning the nature of this star cluster. If such a structure really exists, it does not contribute to the

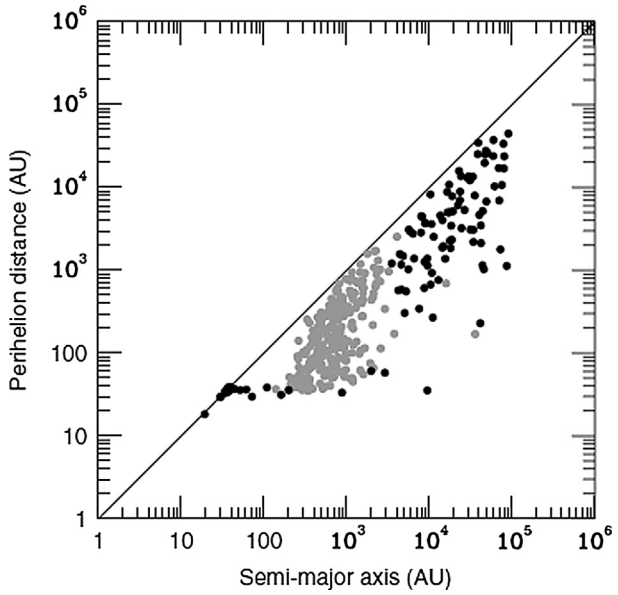

FIGURE 31.15 The final distribution of comets in the scattered disk and the Oort cloud according to a numerical experiment where the Sun spent 3 Myr in a star cluster. The gray and black dots refer to objects that formed interior to or exterior to 14 AU.

population of observed comets because it is in a part of the Solar System which is currently stable: objects in this region do not get close to the planets and the Galactic tides are too weak.

4. CONCLUSIONS

Comets are only active when they get close to the Sun. However, they must come from more distant regions of the Solar System where it is cold enough for them to survive the age of the Solar System without sublimating away. Dynamical simulations of cometary orbits argue that there are two main source regions in the Solar System. One, known as the Oort cloud, is a roughly spherical structure located at heliocentric distances of thousands to tens of thousands of AU. The NICs come from this reservoir. The scattered disk is the other important cometary reservoir. It is a disk-shaped structure that extends outward from the orbit of Neptune. The ecliptic comets come from the scattered disk.

However, there are substantial reasons to believe that these two cometary reservoirs are not primordial structures and that their constituent members formed elsewhere and were dynamically transported to their current locations. Indeed, current models suggest that objects in both the Oort cloud and scattered disk formed in the region between the giant planets and were delivered to their current locations by the action of the giant planets as these planets formed and evolved. Comets, therefore, represent the leftovers of planet formation and contain vital clues to the origin of the Solar System.

1. INTRODUCTION

To be an astronaut explorer in Jupiter's atmosphere would be strange and disorienting. There is no solid ground to stand on. The temperature would be comfortable at an altitude where the pressure is eight times that of the Earth's surface, but it would be perpetually hazy overhead, with variable conditions (dry or wet, cloudy or not) to the east, west, north, and south. One would need to carry oxygen as there is no free oxygen and wear special clothing to protect the skin against exposure to ammonia and hydrogen sulfide gases, which form clouds and haze layers higher in the atmosphere. A trip to high latitudes would offer an opportunity to watch the most powerful, vibrant, and continuous auroral displays in the solar system. On the way, one might pass through individual storm systems the size of Earth or larger and be buffeted by strong winds alternately from the east and west. One might be sucked into a dry downwelling sinkhole like the environment explored by the *Galileo* probe. The probe fell to depths where the temperature is hot enough to vaporize metal and rock. It is now a part of Jupiter's atmosphere.

Although the atmospheres of the giant planets share many common attributes, they are at the same time very diverse. The roots of this diversity can be traced to a set of basic properties, and ultimately to the origins of the planets. The most important properties that influence atmospheric behavior are listed in Table 32.1. The distance from the Sun determines how much sunlight is available to heat the upper atmosphere. The minimum temperature for all these atmospheres occurs near the 100-mbar level and ranges from 110 K at Jupiter to 50 K at Neptune. The distance from the Sun and the total mass of the planet are the primary influences on the bulk composition. All the giant planets are enriched in heavy elements, relative to their solar abundances, by factors ranging from about 3 for Jupiter to 1000 for Uranus and Neptune. The latter two planets are sometimes called the ice giants because they have a large fraction of elements (O, C, N, and S) that were the primary constituents of ices in the early solar nebula.

The orbital period, axial tilt, and distance from the Sun determine the magnitude of seasonal temperature variations in the high atmosphere. Jupiter has weak seasonal variations; those of Saturn are much stronger. Uranus is tipped such that its poles are nearly in the orbital plane, leading to more solar heating at the poles than at the equator when averaged over an orbit. The ratio of radiated thermal energy to absorbed solar energy is diagnostic of how rapidly convection is bringing internal heat to the surface, which in turn influences the abundance of trace constituents and the morphology of eddies in the upper atmosphere. Vigorous convection from the deeper interior is responsible for the unexpectedly high abundances of several trace species on Jupiter, Saturn, and Neptune, but convection on Uranus is sluggish. All these subjects are treated in more detail in the sections that follow.

[4] *Saturn's internal rotation rate is not accurately known. The value indicated is approximate.*

2. CHEMICAL COMPOSITION

This section is concerned with chemical abundances in the observable part of the atmosphere, a relatively thin layer of gas near the top (where pressures are between about 5 bar and a fraction of a microbar). To place the subject in context, some mention will be made of the chemical makeup of the interior (*see* Interiors of the Giant Planets).

The chemical constituents of the interior of a planet cannot be directly observed, but must be inferred from information on its mean density, its gravity field, and the abundances of constituents that are observed in the outer layers. The more massive planets were better able to retain the light elements during their formation, and so the chemical makeup of Jupiter resembles that of the Sun. When the giant planets formed, they incorporated relatively more rock and ice fractions than a pure solar elemental mix would allow, and the fractional amounts of rocky and icy materials increase from Jupiter through Neptune (*see* The Origin of the Solar System). Most of the mass of the heavy elements is sequestered in the deep interior. The principal effects of this layered structure on the observable outer layers can be summarized as follows.

On Jupiter, the gas layer (a fluid molecular envelope) extends down to about 40% of the planet's radius, where a phase transition to liquid metallic hydrogen occurs. Fluid motions that produce the alternating jets and vertically mix gas parcels may fill the molecular envelope but probably do not extend into the metallic region. Thus, the radius of the phase transition provides a natural boundary that may be manifest in the latitudinal extent of the zonal jets (see Section 4), whereas vertical mixing may extend to levels where the temperature is quite high. These same characteristics are found on Saturn, with the additional possibility that a separation of helium from hydrogen is occurring in the metallic hydrogen region, leading to enrichment of helium in the deep interior and depletion of helium in the upper atmosphere.

Uranus and Neptune contain much larger fractions of ice and rock-forming constituents than do Jupiter and Saturn. A large water ocean may be present in the interiors of these planets. Aqueous chemistry in the ocean can have a profound influence on the abundances of trace species observed in the high atmosphere.

In the observable upper layers, the main constituents are molecular hydrogen and atomic helium, which are well mixed, up to the **homopause** level, where the mean free path for collisions becomes large enough that the lighter constituents are able to diffuse upward more readily than heavier ones. Other constituents are significantly less abundant than hydrogen and helium, and many of them condense in the coldest regions of the atmosphere. Figure 32.1 shows how temperature varies with altitude and pressure, and the locations of the methane, ammonia, and water cloud layers.

The giant planets have retained much of the heat generated by their initial collapse from the solar nebula. They cool by emitting thermal infrared radiation to space. Thermal radiation is emitted near the top of the atmosphere, where the opacity is low enough to allow infrared photons to escape to space. In the deeper atmosphere, heat is

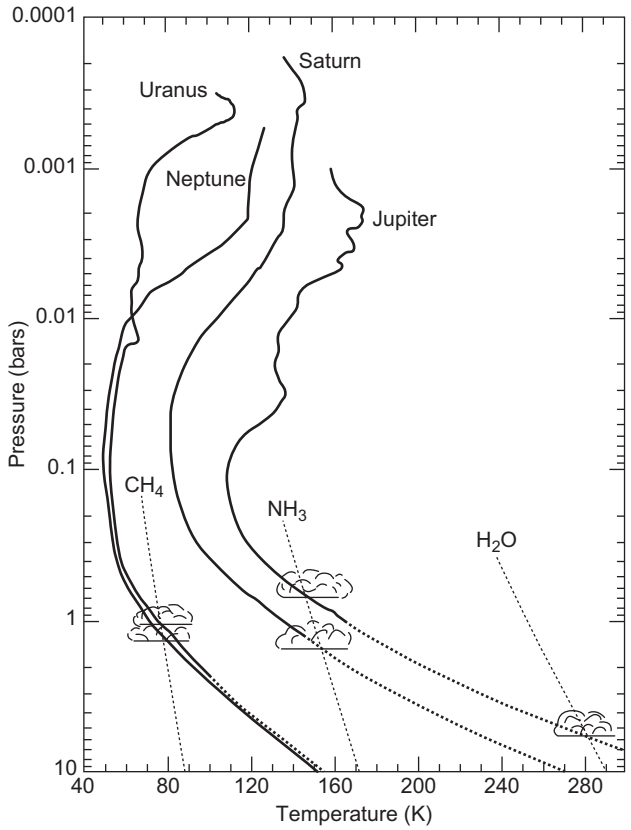

FIGURE 32.1 Profiles of temperature as a function of pressure in the outer planet atmospheres derived from measurements by the Voyager Radio Sciences experiment (solid curves). The dashed parts of the temperature profiles are extrapolations using the adiabatic lapse rate. At high altitudes (not shown), temperatures rise to about 1200 K for Jupiter, 800 K for Saturn and Uranus, and 300 K for Neptune. The dotted lines show vapor pressure curves divided by observed mixing ratios for water, ammonia, and methane. Condensate clouds are located where the solid and dotted curves cross. *From Gierasch, & Conrath, (1993). Copyright American Geophysical Union.*

transported by convective fluid motions from the deep, hot interior to the colder outer layers. In this region, upwelling gas parcels expand and subsiding parcels contract adiabatically (e.g. with negligible transport of heat through their boundaries by radiation or conduction). Therefore temperature depends on altitude according to the adiabatic law $T = T_0 + C(z - z_0)$, where T_0 is the temperature at some reference altitude z_0, C is a constant (the adiabatic lapse rate) that depends on the gas mixture, and z is the altitude. The adiabatic lapse rate for dry hydrogen andhelium on Jupiter is -2.2 K/km. On Uranus it is -0.8 K/km. The adiabatic lapse rate is different in regions where a gas is condensing or where heat is released as *ortho*-hydrogen and is converted to *para*-hydrogen. Both of these processes are important in the giant planet atmospheres at pressures between about 30 and 0.1 bar.

Hydrogen is the main constituent in the observable part of the giant planet atmospheres, but not until recently was it recognized as especially important for thermodynamics. The hydrogen molecule has two ground-state configurations for its two electrons. The electrons can have their spins either parallel or antiparallel, depending on whether the spins of the nuclei are parallel or antiparallel. These states are called the ortho and para states. Transitions between ortho and para states are slow because, unlike most molecules, the nuclear spin must change when the electron spin changes. At high temperature (about 270 K or higher), the ortho:para relative abundance is 3:1. At lower temperature, a larger fraction is converted to the para state. Heat release from conversion of *ortho*- to *para*-hydrogen can act in the same way as **latent heat** release from condensation. The relative fractions of *ortho*- and *para*-hydrogen are observed to be close to thermal equilibrium values in the giant planet atmospheres, leading to the question of how equilibrium is achieved. Catalytic reactions on the surfaces of **aerosol** particles are thought to be important in equilibrating the ortho and para states.

The competition between convective cooling and solar heating produces a temperature minimum near the 100 mbar level (the tropopause). At pressures between about 100 and 0.1 mbar, the temperature is determined primarily by equilibrium between thermal radiative cooling and solar heating. At even lower pressures, other processes, including auroral heating, dump energy into the atmosphere and produce higher temperatures. More will be said about this in Section 5.

The current inventory of observed gaseous species is listed in Table 32.2. Molecular hydrogen and helium are the most abundant. Helium is in its ground state in the **troposphere** and **stratosphere** and therefore does not produce spectral lines from which its abundance can be determined. The mixing ratio for Saturn, Uranus, and Neptune is inferred from its influence on the broad collision-induced hydrogen lines near the 45 μm wavelength and from a combined analysis of the infrared spectrum and refractivity profiles retrieved from spacecraft radio occultation measurements. Helium on Jupiter is accurately known from measurements made by the *Galileo* probe, which descended through the atmosphere. It is a little smaller than the mixing ratio inferred for the primitive solar nebula from which the planets formed. Helium is depleted in Saturn's upper atmosphere, consistent with the idea that helium is precipitating out in the metallic hydrogen region. For Uranus and Neptune, the helium mixing ratio is close to the mixing ratio (0.16) in the primitive solar nebula. There is still some uncertainty in the helium mixing ratio for Uranus, Neptune, and Saturn because additional factors, such as aerosol opacity and molecular nitrogen abundance, affect the shapes of the collision-induced spectral features, and we do not have a completely consistent set of values for all these parameters.

TABLE 32.2 Abundances of Observed Species in the Atmospheres of the Giant Planets

	Peak Mixing Ratio (by Number) or Upper Limit			
Constituent	**Jupiter**	**Saturn**	**Uranus**	**Neptune**
Species with Constant Mixing Ratio below the Homopause				
H_2	0.86	0.90	0.82	0.79
HD	4×10^{-5}	4×10^{-5}		
He	0.14	0.10	0.15	0.18
CH_4	2×10^{-3}	2×10^{-3}		
CH_3D	3.5×10^{-7}	2×10^{-7}		
^{20}Ne	2×10^{-5}			
^{36}Ar	1×10^{-5}			
Condensable Species (Estimated or Measured below the Condensation Region)				
NH_3	2.5×10^{-4}	2×10^{-4}		
H_2S	7×10^{-5}			
H_2O	6×10^{-4}			
CH_4			0.04	0.04
CH_3D			2×10^{-5}	2×10^{-5}
Disequilibrium Species in the Troposphere				
PH_3	5×10^{-7}	2×10^{-6}		
GeH_4	7×10^{-10}	4×10^{-10}		
AsH_3	2.4×10^{-9}	3×10^{-9}		
CO	2×10^{-9}	$1–25 \times 10^{-9}$	$<1 \times 10^{-8}$	1×10^{-6}
HCN			$<1 \times 10^{-10}$	1×10^{-9}
Photochemical Species (Peak Values)				
C_2H_2	1×10^{-7}	3×10^{-7}	1×10^{-8}	6×10^{-8}
C_2H_4	7×10^{-9}			
C_2H_6	7×10^{-6}	7×10^{-6}	$<1 \times 10^{-8}$	2×10^{-6}
C_3H_4	2.5×10^{-9}			
C_6H_6	2×10^{-9}			

Mixing ratios of **deuterated** hydrogen and methane (HD and CH_3D) also provide information on the formation of the planets. **Deuterium**, which once existed in the Sun, has been destroyed in the solar atmosphere, and the best information on its abundance in the primitive solar nebula comes from measurements of the giant planet atmospheres. On Jupiter, the deuterium mixing ratio is thought to be close to that of the primitive solar nebula. On Uranus and Neptune, it is enhanced because these planets incorporated relatively more condensed material on which deuterium preferentially accumulated through isotopic fractionation. Isotopic fractionation (the enhancement of the heavier isotope over the lighter isotope during condensation) occurs because the heavier isotope has a lower energy than the lighter isotope in the condensed phase.

The elements oxygen, carbon, nitrogen, and sulfur are the most abundant molecule-forming elements in the Sun (after hydrogen), and all are observed in the atmospheres of the giant planets, mostly as H_2O, CH_4, NH_3, and (for Jupiter) H_2S. Water condenses even in Jupiter's

atmosphere, at levels that are difficult to probe with infrared radiation (6 bars or deeper). A straightforward interpretation of Jupiter's spectrum indicated its abundance to be about a 100 times less than what is expected from a planet formed from the same material as the sun. The *Galileo* probe measurements indicated that water was depleted relative to solar abundance by roughly a factor of two at the deepest level measured (near 20 bars of pressure) and even more depleted at higher altitude. However, the probe descended in a relatively dry region of the atmosphere, analogous to a desert on the Earth, and the bulk water abundance on Jupiter may well be close to the solar abundance. Water is not observed on any of the other giant planets because of the optically thick overlying clouds and haze layers. It is thought to form a massive global ocean on Uranus and Neptune based on the densities and gravity fields of those planets, coupled with theories of their formation.

Methane is well mixed, up to the homopause level, in the atmospheres of Jupiter and Saturn, but it condenses as ice in the atmospheres of Uranus and Neptune. Its mixing ratio below the condensation level is enhanced over that expected for a solar-type atmosphere by factors of 2.6, 5.1, 35, and 40 for Jupiter, Saturn, Uranus, and Neptune, respectively. These enhancements are consistent with ideas about the amounts of icy materials that were incorporated into the planets as they formed. The stratospheres of Uranus and Neptune form a cold trap, where methane ice condenses into ice crystals that fall out, making it difficult for methane to mix to higher levels. Nevertheless, the methane abundance in Neptune's stratosphere appears to be significantly higher than its vapor pressure at the temperature that the tropopause would allow (and also higher than the abundance in the stratosphere of Uranus), suggesting some mechanism such as convective penetration of the cold trap by rapidly rising parcels of gas. This mechanism does not appear to be operating on Uranus, and this difference between Uranus and Neptune is symptomatic of the underlying difference in internal heat that is available to drive convection on Neptune but not on Uranus.

Ammonia is observed on Jupiter and Saturn, but not on Uranus or Neptune. Ammonia condenses as an ammonia ice cloud near 0.6 bar on Jupiter and at higher pressures on the colder outer planets. Ammonia and H_2S in solar abundance would combine to form a cloud of NH_4SH (ammonium hydrosulfide) near the 2-bar level in Jupiter's atmosphere and at deeper levels in the colder atmospheres of the other giant planets. Hydrogen sulfide was observed in Jupiter's atmosphere by the mass spectrometer instrument on the *Galileo* probe. Another instrument (the nephelometer) on the probe detected cloud particles in the vicinity of the 1.6-bar pressure level, which would be consistent with the predicted ammonium hydrosulfide cloud. Evidence from thermal emission at radio wavelengths has been used to infer that H_2S is abundant on Uranus and Neptune. Ammonia condenses at relatively deep levels in the atmospheres of Uranus and Neptune and has not been spectroscopically detected. A dense cloud is evident at the level expected for ammonia condensation (2−3 bar) in near-infrared spectroscopic observations, but the microwave spectra of those planets are more consistent with a strong depletion of ammonia at those levels. An enhancement of H_2S relative to NH_3 could act to deplete ammonia by the formation of ammonium hydrosulfide in the deeper atmosphere. In that case, H_2S ice is the most likely candidate for the cloud near 3 bars.

Water, methane, and ammonia are in thermochemical equilibrium in the upper troposphere. Their abundances at altitudes higher than (and temperatures colder than) their condensation level are determined by temperature (according to the vapor pressure law) and by meteorology, as is water in the Earth's atmosphere. Some species (PH_3, GeH_4, and CO) are not in thermochemical equilibrium in the upper troposphere. At temperatures less than 1000 K, PH_3 would react with H_2O to form P_4O_6 if allowed to proceed to thermochemical equilibrium. Apparently, the timescale for this reaction (about 3 years) is longer than the time to convect material from the 1000 K level to the tropopause. A similar process explains the detection of GeH_4. Yet another phenomenon (impact of a comet within the past 200 years) probably accounts for the detection of CO in the stratosphere.

Ammonia and phosphine are present in the stratospheres of Jupiter and Saturn, and methane is present in the stratospheres of all the giant planets. These species are destroyed at high altitudes by ultraviolet (UV) sunlight and by charged particles in auroras, producing N, P, and C, which can react to form other compounds. Ammonia photochemistry leads to formation of hydrazine (N_2H_4), and phosphine photochemistry leads to diphosphine (P_2H_4). These constituents condense in the cold tropospheres of Jupiter and Saturn and may be responsible for much of the UV-absorbing haze seen at low latitudes. Nitrogen gas and solid P are other by-products of ammonia and phosphine chemistry. Solid phosphorus is sometimes red and has been proposed as the constituent responsible for the red color of Jupiter's Great Red Spot (GRS). This suggestion (one of several) has not been confirmed, and neither N_2H_4 nor P_2H_4 has been observed spectroscopically.

Organic compounds derived from the dissociation of methane are present in the stratospheres of all the giant planets. The photochemical cycle leading to stable C_2H_2 (acetylene), C_2H_4 (ethylene), C_2H_6 (ethane), and C_4H_2 (diacetylene) is shown schematically in Figure 32.2. The chain may progress further to produce polyacetylenes ($C_{2n}H_2$). These species form condensate haze layers in the cold stratospheres of Uranus and Neptune. More complex

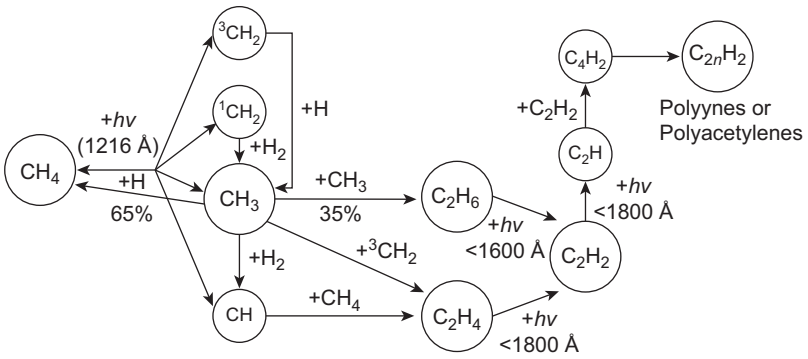

FIGURE 32.2 Summary of CH_4 (methane) photochemical processes in the stratospheres of the giant planets. Photodissociation by ultraviolet light is indicated by $+h\nu$ at the indicated wavelength. Methane photodissociation is the starting point in the production of a host of other hydrocarbons. *Revised by Atreya, S. K. from Figure 5.3 from Pollack, J. B., & Atreya, S. K. (1992).*

hydrocarbon species (C_3H_8, C_3H_4) are observed in Jupiter's atmosphere primarily in close proximity to high-latitude regions, where auroral heating is significant. The abundant polar aerosols in the atmospheres of Jupiter and Saturn may owe their existence to the ions created by auroras in the upper atmosphere.

As instruments become more sensitive, new species are detected. These include C_2H_4, C_3H_4, and C_6H_6 in the atmospheres of Jupiter and Saturn, and C_3H_8 for Saturn. The methyl radical CH_3 (an unstable transition molecule in the reaction chain) has been detected on Jupiter, Saturn, and Neptune.

Hydrogen cyanide (HCN) is observed in the stratospheres of Jupiter and Neptune. On Jupiter, HCN was emplaced high in the stratosphere as a result of the 1994 impacts of comet Shoemaker–Levy 9. During the 3 years after the impacts, it was observed to spread north of the impact latitude (near 45°S), eventually to be globally distributed. It is expected to dissipate over the span of a decade or so. Impact by cometary and interplanetary dust particles may also be responsible for HCN in Neptune's stratosphere.

Quantitative thermochemical and photochemical models are available for many of the observed constituents and provide predictions for many others that are not yet observed. These models solve a set of coupled equations that describe the balance between the abundances of species that interact and include important physical processes such as UV **photolysis**, condensation/sublimation, and vertical transport. Current models heuristically lump all the transport processes into an effective eddy mixing coefficient, and the value of that coefficient is derived as part of the solution of the set of equations. As we gain more detailed observations and more comprehensive laboratory measurements of reaction rates, we will be able to develop more sophisticated models. Some models are beginning to incorporate transport by vertical and horizontal winds. Figures 32.3 and 32.4 show vertical profiles calculated from models for a number of photochemically produced species.

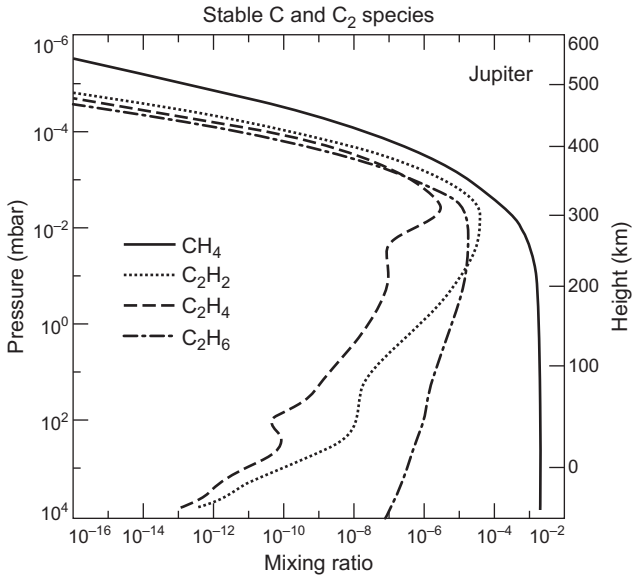

FIGURE 32.3 Vertical profiles of some photochemical species in Jupiter's stratosphere. The mixing ratios (horizontal axis) are plotted as a function of pressure. *From Gladstone, G. R., et al. (1996). Copyright Academic Press.*

3. CLOUDS AND AEROSOLS

The appearance of the giant planets is determined by the distribution and optical properties of cloud and aerosol haze particles in the upper troposphere and stratosphere. Cameras on the *Voyager* spacecraft provided detailed views of all the giant planets, whose general appearances can be compared in Figure 32.5. Their atmospheres show a banded structure (which is difficult to see on Uranus) of color and shading parallel to latitude lines. These were historically named belts and zones on Jupiter and Saturn, with belts being relatively dark and zones being relatively bright. Specific belts and zones were named in accordance with their approximate latitudinal location (Equatorial Belt, North and South Tropical Zones near latitudes ±20°, North

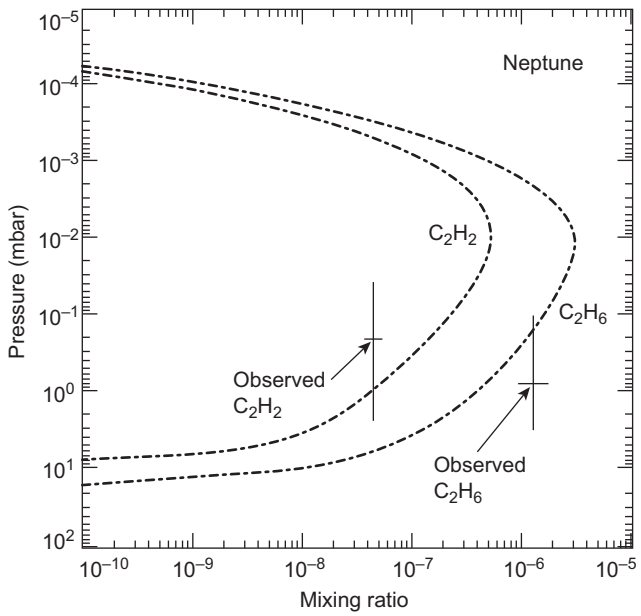

FIGURE 32.4 Vertical profiles of photochemical species in the Neptunian stratosphere. *From Romani, P., et al. (1993). Copyright by Academic Press.*

and South Temperate Zones and Belts near ±35°, and polar regions).

The nomenclature should not be construed to mean that low latitudes are relatively warmer than high latitudes, as they are on Earth and Mars. Nor is it true that the reflectivities of these features remain constant with time. Some features on Jupiter, such as the North and South Tropical Zones, are persistently bright, whereas others, like the South Equatorial Belt, are sometimes bright and sometimes dark. On Jupiter, there is a correlation between visible albedo and temperature, such that bright zones are usually cool regions and dark belts are usually warm near the tropopause. Cool temperatures are associated with cooling of upwelling gas, and the correlation of cool temperatures with bright clouds points to enhanced condensation of ice particles as condensable gases flow upward and cool. This correlation does not hold completely on Jupiter and almost not at all on the other giant planets. The mechanisms responsible for producing reflectivity contrasts and color remain largely mysterious, although a number of proposals have been advanced. These will be discussed in more detail.

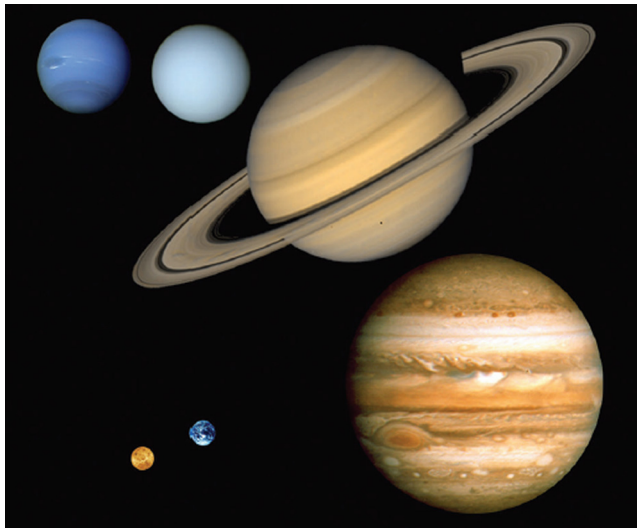

FIGURE 32.5 *Voyager* images of Jupiter, Saturn, Uranus, and Neptune, scaled to their relative sizes. Earth and Venus are also shown scaled to their relative sizes.

Our understanding of aerosols and clouds is rooted in thermochemical equilibrium models that predict the temperature (and hence pressure and altitude) of the bases of condensate clouds. The cloud base occurs where the vapor pressure of a condensable gas equals its partial pressure. Model predictions for the four giant planets are shown in Figure 32.6. The deepest cloud to form is a solution of water and ammonia on Jupiter and Saturn, with dissolved H_2S as well on Uranus and Neptune. At higher altitudes, an ammonium hydrosulfide cloud forms, and its mass depends on both the amounts of H_2S and NH_3 available and the ratio of S to N. At still higher altitudes, an ammonia or hydrogen sulfide cloud can form if the S/N ratio is less than or greater than 1, respectively. If the ratio is greater than 1, all the N will be taken up as NH_4SH, with the remaining sulfur available to condense at higher altitudes. This seems to be the situation on Uranus and Neptune, but the reverse is true for Jupiter and Saturn. Only the atmospheres of Uranus and Neptune are cold enough to condense methane, which occurs at 1.3 bar in Uranus and at about 2 bar in Neptune. It is predominantly the uppermost clouds that we see at visible wavelengths.

Observational evidence to support the cloud stratigraphy shown in Figure 32.6 is mixed. The *Galileo* probe detected cloud particles near 1.6-bar pressure and sensed cloud opacity at higher altitudes corresponding to the ammonia cloud. With data only from remote sensing experiments, it is difficult to probe to levels below the top cloud, and the evidence we have for deeper clouds comes from careful analyses of radio occultations and of gaseous absorption lines in the visible and near infrared, and from thermal emission at 5, 8.5, and 45 μm. Contrary to expectation, spectra of the planets show features due to ice in only a small fraction of the cloudy area. The *Voyager* radio occultation data showed strong refractivity gradients at locations predicted for methane ice clouds on Uranus and Neptune, essentially confirming their existence and providing accurate information on the altitude of the cloud base. Ammonia gas is observed spectroscopically in Jupiter's upper troposphere, and its abundance decreases with altitude above its cloud base in accordance with expectation. There is no doubt that ammonia ice is the major

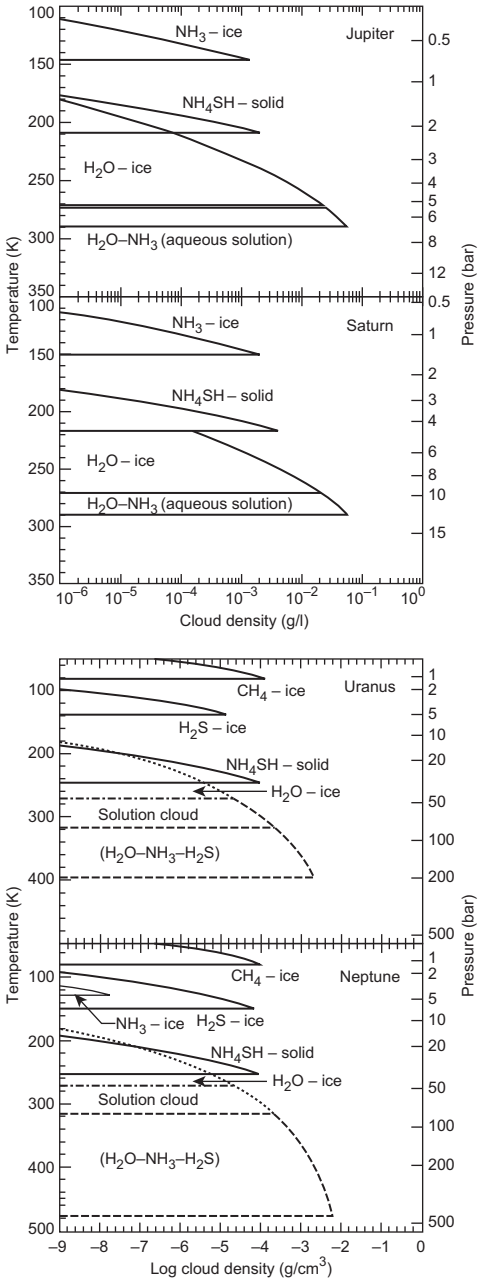

FIGURE 32.6 The diagrams in the four panels show the locations of condensate cloud layers on Jupiter, Saturn, Uranus, and Neptune. These figures indicate how much cloud material would condense at various temperatures (corresponding to altitude) if there were no advective motions in the atmosphere to move vapor and clouds. They are based on simple thermochemical equilibrium calculations, which assume, for Jupiter and Saturn, that the condensable species have mixing ratios equal to those for the sun. *Figures for Jupiter and Saturn were constructed from models by Atreya, S. K., & Wong, M. based on Atreya, S. K., & Romani, P. N. (1985). Those for Uranus and Neptune were first published by de Pater, I., et al. (1991). Copyright by Academic Press.*

component of the visible clouds on Jupiter and Saturn, but it cannot be the only component and is not responsible for the colors (pure ammonia ice is white). In fact, all the ices shown in Figure 32.6 are white at visible wavelengths. The colored material must be produced by some disequilibrium process like photochemistry or bombardment by energetic particles from the magnetosphere.

Colors on Jupiter are close to white in the brightest zones, gray yellow to light brown in the belts, and orange or red in some of the spots. The colors in Figure 32.5 are slightly and unintentionally exaggerated owing to the difficulty of achieving accurate color reproduction on the printed page. Colors on Saturn are more subdued. Uranus and Neptune are gray-green. Neptune has a number of dark spots and white patchy clouds. Part of the green tint on Uranus and Neptune is caused by strong methane gas absorption at red wavelengths, and part is due to aerosols that also absorb preferentially at wavelengths longer than 0.6 μm.

Candidate materials for the **chromophore** material in outer planet atmospheres are summarized in Table 32.3. All candidate materials are thought to form by some

TABLE 32.3 Candidate Chromophore Materials in the Atmospheres of the Giant Planets

Material	Formation Mechanism
Sulfur	Photochemical products of H_2S and NH_4SH. Red allotropes are unstable.
H_2S_x, $(NH_4)_2S_x$, $N_2H_4S_x$	Photochemical products of H_2S and NH_4SH.
N_2H_4	Hydrazine, a photochemical product of ammonia, a candidate for Jupiter's stratospheric haze.
Phosphorus (P_4)	Photochemical product of PH_3.
P_2H_4	Diphosphine, a photochemical product of phosphine, a candidate for Saturn's stratospheric haze.
Products of photodecomposition or charged particle decomposition of CH_4	Includes acetylene photopolymers (C_xH_2), proton-irradiated methane, and organics with some nitrogen and/or sulfur. Confined to stratospheric levels where ultraviolet photons and auroral protons or ions penetrate.

nonequilibrium process such as photolysis or decomposition by protons or ions in auroras, which acts on methane, ammonia, or ammonium hydrosulfide. Methane is present in the stratospheres of all the giant planets. Ammonia is present in the stratosphere of Jupiter. Ammonium hydrosulfide is thought to reside near the 2-bar level and deeper in Jupiter's atmosphere, which is too deep for UV photons to penetrate.

There are two major problems in understanding which, if any, of the proposed candidate chromophores are responsible for the observed colors. First, no features have been identified in spectra of the planets that uniquely identify a single candidate material. Spectra show broad slopes, with more absorption at blue wavelengths on Jupiter and Saturn and at red wavelengths on Uranus and Neptune. All the candidates listed in Table 32.3 produce broad blue absorption. None of them can account for the red and near-infrared absorption in the spectra of Uranus and Neptune. Second, our understanding of the detailed processes that lead to the formation of chromophores is inadequate. Gas-phase photochemical theory cannot account for the abundance of chromophore material. It is likely that UV photons or charged particle bombardment of solid, initially colorless particles like acetylene and ethane ice in the stratospheres of Uranus and Neptune or ammonium hydrosulfide in Jupiter's atmosphere breaks chemical bonds in the solid state, paving a path to the formation of more complex hydrocarbons or inorganic materials that seem to be required. Additional laboratory studies are needed to address these questions (*see* The Solar System at Ultraviolet Wavelengths).

Haze particles are present in the stratospheres of all the giant planets, but their chemical and physical properties and spatial distributions are quite different. Jupiter and Saturn have UV-absorbing aerosols abundant at high latitudes and high altitudes (corresponding to pressures ranging from a fraction of a millibar to a few tens of millibars). The stratospheric aerosols on Uranus and Neptune do not absorb much in the UV and are not concentrated at high latitude. The polar concentration of UV-absorbing aerosols on Jupiter and Saturn suggests that their formation may be due to chemistry in auroral regions, where protons and/or ions from the magnetosphere penetrate the upper atmosphere and deposit energy. Association with auroral processes may help explain why UV absorbers are abundant poleward of about 70° latitude on Saturn, extend to somewhat lower latitudes on Jupiter, and show a hemispheric asymmetry in Jupiter's atmosphere. Saturn's magnetic dipole is nearly centered and parallel to Saturn's spin axis, but Jupiter's magnetic dipole is both significantly offset and tilted with respect to its spin axis, producing asymmetric auroras at lower latitudes than on Saturn. Other processes, such as the **meridional circulation**, also influence the latitudinal distribution of aerosols, so more work needs to be done to establish the role of auroras in aerosol formation.

Photochemistry is responsible for the formation of diacetylene, acetylene, and ethane hazes in the stratospheres of Uranus and Neptune. The main steps in the life cycle of stratospheric aerosols are shown in Figure 32.7. Methane gas mixes upward to the high stratosphere, where it is photolyzed by UV light. Diacetylene, acetylene, and ethane form from gas-phase photochemistry and diffuse downward. Temperature decreases downward in the stratosphere, so ice particles form when the vapor pressure equals the partial pressure of the gas. On Uranus, diacetylene ice forms at 0.1 mbar, acetylene at 2.5 mbar, and ethane at 14 mbar. The ice particles sediment to deeper levels on a timescale of years and evaporate in the upper troposphere at 600 mbar and deeper. Polymers that form from solid-state photochemistry in the ice particles are probably responsible for the little UV absorption that does occur. They are less volatile than the pure ices and probably mix down to the methane cloud and below.

Photochemical models predict formation of hydrazine in Jupiter's stratosphere and diphosphine in Saturn's atmosphere. If these are the only stratospheric haze constituents, it is not apparent why the UV absorbers are concentrated at high latitude. As discussed earlier, auroral bombardment of methane provides an attractive candidate process for the abundant high-latitude aerosols on Jupiter and Saturn. However, we do not know enough to formulate a detailed chemical model of this process.

Thermochemical equilibrium theory serves as a guide to the location of the bases of tropospheric clouds, but meteorology and cloud microphysical processes determine the vertical and horizontal distribution of cloud material. These processes are too complex to let us predict to what altitudes clouds should extend, and so we must rely on observations. Several diagnostics are available to measure cloud and haze vertical locations. At short wavelengths, gas molecules limit the depth to which we can see. In the visible and near infrared are methane and hydrogen absorption bands, which can be used to probe a variety of depths depending on the absorption coefficient of the gas. There are a few window regions in the thermal infrared where cloud opacity determines the outgoing radiance. The deepest probing wavelength is 5 μm. At that wavelength, thermal emission from the water cloud region near the 5-bar pressure level provides sounding for all the main clouds in Jupiter's atmosphere (*see* Infrared Views of the Solar System from Space).

The results of cloud stratigraphy studies for Jupiter's atmosphere are summarized in Figure 32.8. There is spectroscopic evidence for the two highest tropospheric layers in Jupiter's atmosphere. There is also considerable controversy surrounding the existence of the water-ammonia cloud on Jupiter. The *Galileo* probe descended into a dry region of the atmosphere and did not find a water cloud, but water clouds may be present in moister regions of the atmosphere that are obscured by overlying clouds. There is evidence for a large range of particle sizes. Small particles (less than about 1 μm radius) provide most of the cloud opacity in the visible. They cover belts and zones, although their optical thickness in belts is sometimes less than in zones. Most of the contrast between belts and zones in the visible comes from enhanced abundance or greater visibility of chromophore material, which seems to be vertically, but not horizontally, well mixed in the ammonia cloud. The top of this small-particle layer extends up to about 200 mbar, depending on latitude. Jupiter's GRS is a location of relatively high-altitude aerosols, consistent with the idea that it is a region of upwelling gas.

Larger particles (mean radius near 6 μm) are also present, mostly in zones. This large-particle component appears to respond to rapid changes in the meteorology. It is highly variable in space and time and is responsible, together with the deeper clouds, for the richly textured appearance of the planet at 5 μm wavelength (Figure 32.9). Some of the brightest regions seen in Figure 32.9 are called 5-μm hot spots, not because they are warmer than their surroundings but because thermal radiation from the 5-bar region emerges with little attenuation from higher clouds. The *Galileo* probe sampled one of these regions. The dark regions in the image are caused by optically thick clouds in the NH_4SH and NH_3 cloud regions. The thickest clouds are generally associated with upwelling, bright (at visible wavelengths) zones, but many exceptions to this rule are observed. Until we understand the chemistry and physics of

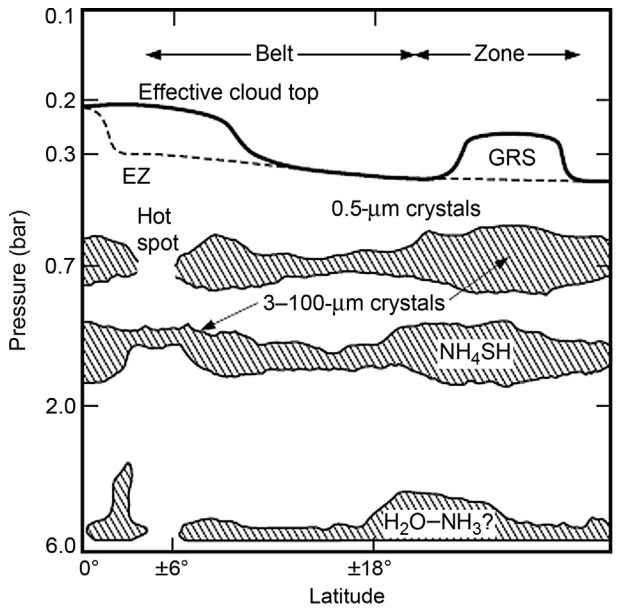

FIGURE 32.8 Observations of Jupiter at wavelengths that sense clouds lead to a picture of the Jovian cloud stratigraphy shown here. There has been no direct evidence for a water-ammonia cloud near the 6-bar pressure level, but it is likely that such a cloud exists from indirect evidence. The hot spots are named from their visual appearance at a wavelength of 5 μm. They are not physically much warmer than their surroundings, but they are deficient in cloudy material (see Figure 32.9). *From West, R., et al. (2004). Cambridge Univ. Press.*

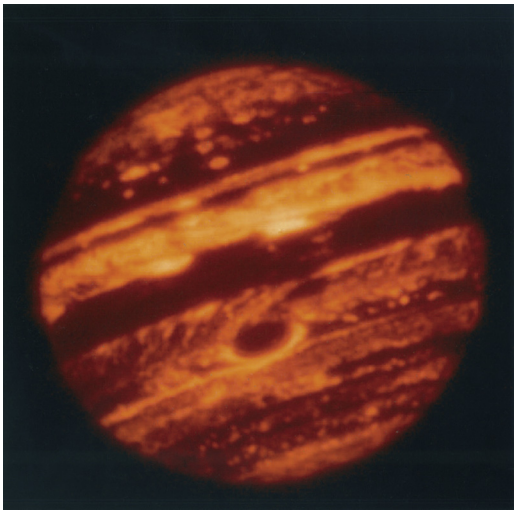

FIGURE 32.9 At a wavelength of 5 μm, most of the light from Jupiter is thermal radiation emitted near the 6-bar pressure level below the visible cloud. Places where the clouds are thin permit the deep radiation to escape to space, making these regions appear bright. Thicker clouds block the radiation and these appear dark. Jupiter's Great Red Spot is the dark oval just below the center. This image was taken with the NASA Infrared Telescope Facility. *Courtesy of J. Spencer.*

chromophores, we should not expect to understand why or how well albedo is correlated with other meteorological parameters.

Most of Jupiter's spots are at nearly the same altitude. Some notable exceptions are the GRS, the three white ovals just south of the GRS, and some smaller ovals at other latitudes. These anticyclonic features extend to higher altitudes, probably up to the 200 mbar level, compared to a pressure level of about 300 mbar for the surrounding clouds. Some of the anticyclonic spots have remarkably long lifetimes compared to the terrestrial norm. The GRS was recorded in drawings in 1879, and reports of red spots extend back to the seventeenth century. The three white ovals in a latitude band south of the GRS formed from a bright cloud band that split into three segments in 1939. The segments shrunk in longitude over the course of a year, until the region (the South Temperate Belt) was mostly dark except for three high-albedo spots that remain to the present. Anticyclonic ovals tend to be stable and long-lived, whereas cyclonic regions constantly change.

Similar features are observed in Saturn's atmosphere, although the color is much subdued compared to Jupiter, and Saturn has nothing that is as large or as long lived as the GRS. The reduced contrast may be related to Saturn's colder tropopause temperature. The distance between the base of the ammonia cloud and the top of the troposphere (where the atmosphere becomes stable against convection) is greater on Saturn than on Jupiter. The ammonia ice cloud on Saturn is both physically and optically thicker than it is on Jupiter. Occasionally (about two or three times each century), a large, bright cloud forms near Saturn's equator. One well-observed event occurred in 1990, but its cause is unknown. It appears to be a parcel of gas that erupts from deeper levels, bringing fresh condensate material to near the top of the troposphere. It becomes sheared out in the wind shear and dissipates over the course of a year.

Uranus as seen by *Voyager* was even more bland than Saturn, but recent images from the *Hubble Space Telescope* and from the ground show a much richer population of small clouds (see Figure 32.10). Midlatitude regions on Uranus and Neptune are cool near the tropopause, indicating upwelling. But cloud optical thickness may be lower there than at other latitudes. The relation between cloud optical thickness and vertical motion is more complicated than the simple condensation model would predict.

Neptune's clouds are unique among the outer planet atmospheres. *Voyager* observed four large cloud features that persisted for the duration of the *Voyager* observations (months). The largest of these is the Great Dark Spot (GDS) and its white companion. Because of its size and shape, the GDS might be similar to Jupiter's GRS, but the GDS had a short life compared to the GRS.

There is no explanation yet of what makes the dark spot dark. The deepest cloud (near the 3-bar level) is probably

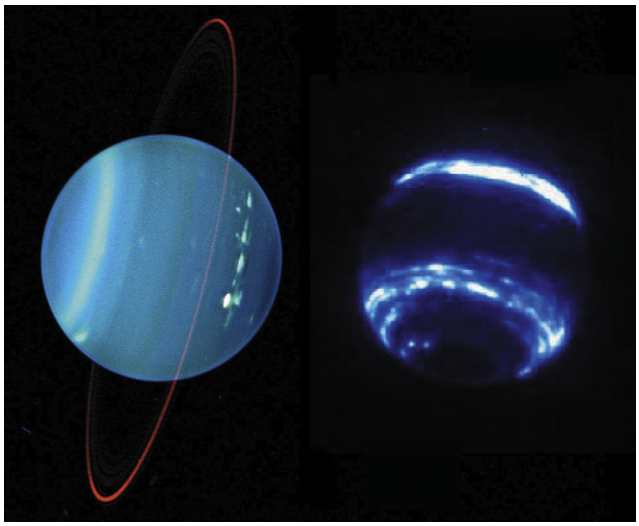

FIGURE 32.10 Images of Uranus (left) and Neptune (right) taken in 2004 and 2000, respectively. Both were obtained at the Keck telescope with filters in the near infrared. Many cloud features that were not seen during the *Voyager* flyby can be seen. The Uranus ring can also be seen (a red ellipse in this false-color representation). *The Uranus image appeared on the cover of* Icarus *(December 15, 2005, issue) and was provided by L. Sromovsky. The Neptune image is from de Pater, I., et al. (2005). Copyright Academic Press).*

H_2S ice, since ammonia is apparently depleted and NH_4SH would be sequestered at a deeper level. At higher altitudes there is an optically thin methane haze (near 2 bar) and stratospheric hazes of ethane, acetylene, and diacetylene. At high spatial resolution, the wispy white clouds associated with the companion to the GDS and found elsewhere on the planet form and dissipate in a matter of hours. It was difficult to estimate winds from these features because of their transitory nature. Individual wisps moved at a different speed than the GDS and its companion, suggesting that these features form and then evaporate high above the GDS as they pass through a local pressure anomaly, perhaps a standing wave caused by flow around the GDS. Cloud shadows were seen in some places, a surprise after none was seen on the other giant planets. The clouds casting the shadows are about 100 km higher than the lower cloud deck, suggesting that the lower cloud is near 3 bar and the shadowing clouds are near 1 bar, in the methane condensation region. More recent Hubble and ground-based images show clouds not seen in *Voyager* images (Figure 32.10).

4. DYNAMICAL METEOROLOGY OF THE TROPOSPHERE AND STRATOSPHERE

Our understanding of giant planet meteorology comes mostly from *Voyager* observations, with observations from *Galileo*, *Cassini*, the *Hubble Space Telescope*, and ground-

based data adding to the picture. Although we have theories and models for many of the dynamical features, the fundamental nature of the dynamical meteorology on the giant planets remains puzzling chiefly because of our inability to probe to depths greater than a few bars in atmospheres that go to kilobar pressures and because of limitations in spatial and time sampling, which may improve with future missions to the planets.

Thermodynamic properties of atmospheres are at the heart of a variety of meteorological phenomena. In the terrestrial atmosphere, condensation, evaporation, and transport of water redistribute energy in the form of latent heat. The same is true for the outer planet atmospheres, where condensation of water, ammonia, ammonium hydrosulfide, hydrogen sulfide, and methane takes place. Condensables also influence the dynamics through their effects on density gradients. In the terrestrial atmosphere, moist air is less dense than dry air at the same temperature because the molecular weight of water vapor is less than that of the dry air. Because of this fact, and also because moist air condenses and releases latent heat as it rises, there can be a growing instability leading to the formation of convective plumes, thunderstorms, and anvil clouds at high altitudes. On the giant planets, water vapor is significantly heavier than the dry atmosphere and so the same type of instability will not occur unless a strongly upwelling parcel is already present. Some researchers proposed that the Equatorial Plumes on Jupiter and the elongated clouds on Uranus are the outer planet analogs of terrestrial anvil clouds.

Terrestrial lightning occurs most frequently over tropical oceans and over a fraction of the land surface. Its distribution in latitude, longitude, and season is indicative of certain properties of the atmosphere, especially the availability of liquid water. Lightning has been observed on the giant planets as well, either from imaging on the night side (Jupiter) or from signals recorded by plasma wave instruments. A somewhat mysterious radio emission from Saturn (the so-called Saturn Electrostatic Discharge events) has been interpreted as a lightning signature. Combined imaging and plasma wave observations from *Cassini* in 2004 revealed a large cloud complex associated with this source. The intensity and size of the lightning spots in the images imply that they are much more energetic than the average lightning bolt in the terrestrial atmosphere and that they occur in the water-ammonia cloud region as expected. The *Galileo* probe did not detect lightning in Jupiter's atmosphere within a range of about 10,000 km from its location at latitude 6.5°N (*see* The Solar System at Radio Wavelengths).

The heat capacity of hydrogen, and therefore the dry lapse rate of the convective part of the atmosphere, depends on the degree to which the ortho/para states equilibrate. The lapse rate is steepest when equilibration is operative. The observed lapse rate for Uranus, as measured by the *Voyager* radio occultation experiment, is close to the "frozen" lapse rate—the rate when the relative fractions of ortho- and para-hydrogen are fixed. How can the observed relative fractions be near equilibrium when the lapse rate points to nonequilibrium? One suggestion is that the atmosphere is layered. Each layer is separated from the next by an interface that is stable and that is thin compared to the layer thickness. The air within each layer mixes rapidly compared to the time for equilibration, but the exchange rate between layers is slow or comparable to the timescale for conversion of ortho to para and back.

How can layers be maintained in a convective atmosphere? In the terrestrial ocean, two factors influence buoyancy: temperature and salinity. If the water is warmer at depth, or if the convective amplitude is large, the different timescales for diffusion of heat and salinity lead to layering. In the atmospheres of the outer planets, the higher molecular weight of condensables acts much as salinity in ocean water. Layering can be established even without molecular weight gradients. Layering in the terrestrial stratosphere and mesosphere has been observed. Layers of rapidly convecting gas occur where gravity waves break or where other types of wave instabilities dump energy. Between layers of rapid stirring are stably stratified layers with transport by diffusion rather than convection.

Some of the variety of the giant planet meteorology, as well as our difficulty to understand it, is nicely illustrated by observations of the wind field at the cloud tops. Wind vectors of all the giant planet atmospheres are predominantly in the east–west (zonal) direction (Figure 32.11). These are determined by tracking visible cloud features over hours, days, and months. Jupiter has an abundance of small features and the zonal winds are well mapped. Saturn has fewer features, and they are of less contrast than those on Jupiter, but there is still a large enough number to provide detail in the wind field. Only a few features were seen in *Voyager* images of the Uranus atmosphere, and all but one of these were between latitudes 20°S and 40°S. More recent images from the *Hubble Space Telescope* show new features at many other latitudes. The *Voyager 2* radio occultation provided an additional estimate for wind speed at the equator. Neptune has more visible features than Uranus, but most of them are transitory and difficult to follow long enough to gauge wind speed.

Figure 32.11 reveals a great diversity in the zonal flow among the giant planet atmospheres. Wind speed is relative to the rotation rate of the deep interior as revealed by the magnetic field and radio emissions. Jupiter has a series of jets that oscillate with latitude and are greatest in the prograde direction at latitude 23°N, and near ±10°. The pattern of east–west winds is approximately symmetric about the equator except at high latitude. Saturn has a very strong prograde jet at low latitudes (within the region

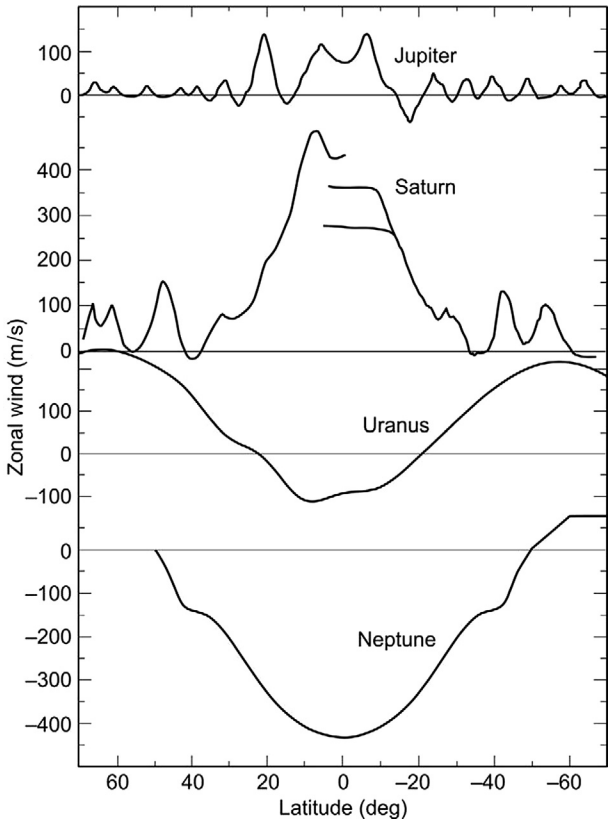

FIGURE 32.11 Zonal (east−west) wind velocity for the giant planets as a function of latitude. *For Jupiter, the data are from Porco et al. (2003). Copyright American Association for the Advancement of Science). For Saturn's northern hemisphere, the data are from Gierasch, P., & Conrath, B. (1993). Copyright American Geophysical Union). For Saturn's southern hemisphere, data are from Porco et al. (2005). Copyright American Association for the Advancement of Science). Two branches are shown for the southern low latitudes. Both are from* Cassini *observations, with similar values from* Hubble Space Telescope *images. The higher wind speeds were observed for deepest clouds, while the lower winds were observed for higher clouds. Both branches are moving more slowly than clouds at similar latitudes in the north observed by* Voyager. *This apparent change in the wind speed must have involved a large energy exchange. Data for Uranus and Neptune are mostly from analyses of Hubble and Keck data (Sromovsky, L., & Fry, P. (2005). Copyright Academic Press. Sromovsky, L., et al. (2001). Copyright Academic Press.).*

±15°). It also has alternating but mostly prograde jets at higher latitudes, with the scale of latitudinal variation being about 10°. Uranus appears to have a single prograde maximum near 60°S, and the equatorial region is retrograde. Neptune has an enormous differential rotation, mostly retrograde except at high latitude. Various theories have been advanced to explain the pattern of zonal jets. None of them can account for the great variety among the four planets.

The zonal jets are stable over long time periods (observations span many decades for Jupiter and Saturn), despite the many small-scale features that evolve with much shorter lifetimes. An interesting exception to this rule occurred at equatorial latitudes on Saturn between the time of the *Voyager* observations (around 1981) and observations in the 1990s and later by the *Hubble Space Telescope* and beginning in 2004 by the *Cassini* cameras. Current equatorial jet speeds are significantly less than those measured on Saturn by *Voyager*. It is difficult to understand how such a large change of momentum could occur, and another explanation has been sought. Possibly the equatorial atmosphere was clearer (less haze) during the *Voyager* epoch, permitting observations to deeper levels where the wind speed is higher. Detailed analyses of haze altitudes show that the haze is thicker and higher in more recent times than it was in 1981, but probably not enough to account for the difference in wind speed from this effect alone.

Some of the key observations that any dynamical theory must address include: (1) the magnitude, direction, and latitudinal scale of the jets; (2) the stability of the jets, at least for Jupiter and Saturn, where observations over long periods show little or no change except for Saturn's equatorial jet, which was mentioned earlier; (3) the magnitude and latitudinal gradients of heat flux; and (4) the interactions of the mean zonal flow with small spots and eddies. One of the controversies during the past two decades concerns how deep the flow extends into the atmosphere. It is possible to construct shallow-atmosphere models that have approximately correct jet scales and magnitudes. A shallow-atmosphere model is one in which the jets extend to relatively shallow levels (100 bar or less), and the deeper interior rotates as a solid body, or at least as one whose latitudinal wind shear is not correlated with the wind shear of the jets. The facts that the jets and some spots on Jupiter are very stable, that there is approximate hemispheric symmetry in the zonal wind pattern between latitudes ±60°, and that the Jovian interior has no density discontinuities down to kilobar levels suggested to some investigators that the jets extend deep into the atmosphere. A natural architecture for the flow in a rotating sphere with no density discontinuities is one in which the flow is organized on rotating cylinders (Figure 32.12).

Apart from the stability and symmetry noted here, there is little evidence to suggest that the zonal wind pattern really does extend to the deep interior. The conductivity of Jupiter's atmosphere at depth is probably too high to allow the type of structure depicted in Figure 32.12 to exist. The strength of the zonal jet at the location where the *Galileo* probe entered (6.5°N) increased with depth, consistent with the idea of a deeply rooted zonal wind field on Jupiter. One way to test that hypothesis is to make highly precise measurements of the gravity field close to the planet. There are density gradients associated with the winds, and these produce features in the gravity field close to the planet. The

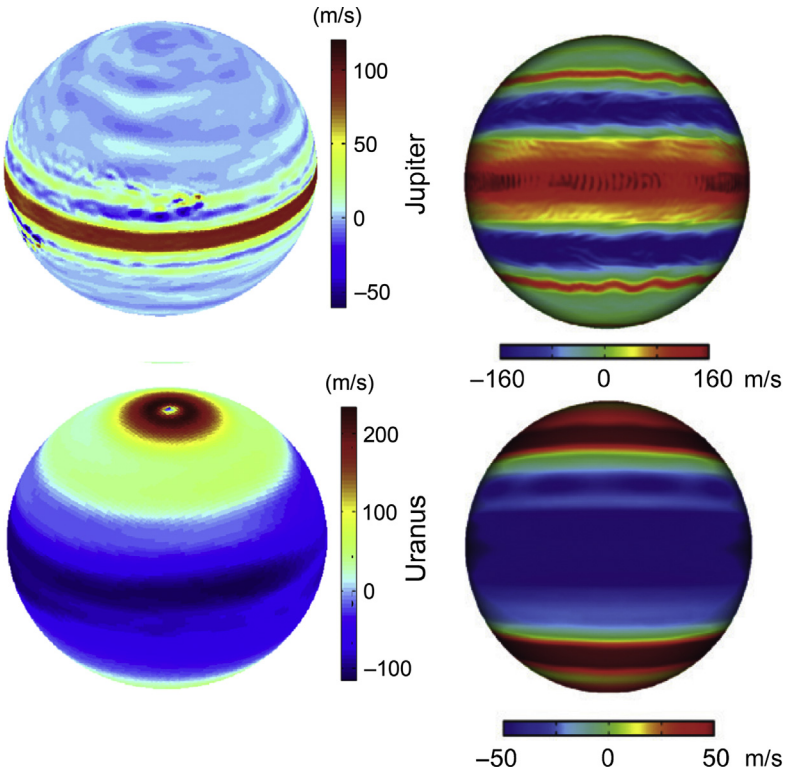

FIGURE 32.12 Models for the zonal wind fields of the giant planets attempt to explain the observed zonal wind profiles shown in Figure 32.11. *The left panels are from Lian, & Showman, (2010). (Copyright by Elsevier). Panels on the right are from Liu, & Schneider, (2010). (Copyright by the American Meteorological Society). Color bars indicate wind speeds.*

largest signature is produced by Neptune's remarkable differential rotation. The *Voyager 2* spacecraft flew just above Neptune's atmosphere and provided the first evidence that the differential rotation cannot extend deep into the atmosphere. Gravity-field tests of the deep-wind hypothesis for the other giant planets are more difficult because the differential rotation is much weaker. No spacecraft have come close enough to make the measurements but one (the Juno mission) will do so for Jupiter and another (the Cassini mission) will do so for Saturn.

What process maintains the zonal wind pattern? *Voyager* measurements shed some light on this question, but provided some puzzles as well. The ultimate energy source for maintaining atmospheric motions is the combination of internal thermal and solar energy absorbed by the atmosphere. Jupiter, Saturn, and Neptune all have significant internal energy sources, whereas Uranus has little or none. A measure of the amount of energy available for driving winds is the escaping radiative energy per square meter of surface area. Almost 20 times as much energy per unit area is radiated from Jupiter's atmosphere as from Neptune's, yet the wind speeds (measured relative to the interior as determined from the magnetic field rotation rate) on Neptune are about three times higher than those on Jupiter. Rather than driving zonal winds, the excess internal energy may go into driving smaller scale eddies, which are most abundant on Jupiter.

The widths and speeds of the zonal jets are very different for the different planets (see Figure 32.11). Is there a way to understand these differences in terms of fundamental atmospheric physical parameters, to achieve a unifying framework? Three hypotheses have emerged in recent years. One postulates that the important parameter is the ratio of convective heat flow to radiative heating (Figure 32.12 right panels). Another postulates that latent heat transfer associated with water condensation is key (Figure 32.12 left panels). A third proposes that the interaction of the Coriolis force with convective motions determines how the zonal bands are distributed and whether the equatorial flow is eastward or westward. It is possible that all these processes are important.

What role do eddies have in maintaining the flow? Measurements of the small spots on Jupiter and Saturn have provided an estimate of the energy flow between the mean zonal wind and the eddy motions. For Jupiter, the eddies at the cloud top appear to be pumping energy into the mean zonal flow. Recent measurements from cameras on the Cassini spacecraft show convincingly that eddies do pump energy into the zonal jets of Saturn. Ongoing studies try to understand why the jets are so stable when there is apparently enough energy in eddy motions to significantly modify the wind field. At the same time, other observations imply dissipation and decay of zonal winds at altitudes above the cloud tops.

The relationship known to atmospheric physicists as the thermal wind equation provides a means of estimating the rate of change of zonal wind with height (which is usually impossible to measure remotely) from observations of the latitudinal gradient of temperature (which is usually easy to measure). One of the common features of all the outer planet atmospheres is a decay of zonal wind with height in the stratosphere, tending toward solid-body rotation at high altitudes. The decay of wind velocity with height could be driven by eddy motions or by gravity wave breaking, which effectively acts as friction on the zonal flow.

Thermal contrasts on Jupiter are correlated with the horizontal shear and with cloud opacity as indicated by 5-μm images (see Figure 32.9). Cool temperatures at the tropopause level (near 100 mbar) are associated with upwelling and anticyclonic motion, and warmer temperatures are associated with subsidence. Jupiter's GRS is an anticyclonic oval with cool tropospheric temperatures, upwelling flow, and aerosols extending to relatively high altitudes. Enhanced cloud opacity and ammonia abundance in cooler anticyclonic latitudes (mostly the high-albedo zones on Jupiter) are predicted in upwelling regions. The correlation is best with cloud opacity in the 5-μm region. At shorter wavelengths (in the visible and near infrared), there is a weaker correlation between cloud opacity and **vorticity**. Perhaps the small aerosols near the top of the troposphere, sensed by the shorter wavelengths but not at 5 μm, are transported horizontally from zone to belt on a timescale that is short compared to their rainout time (several months).

The transport of heat may well be more complicated than the previous paragraph implies. There may be at least two regions, an upper troposphere where heat transport is determined by slow, large-scale motions as previously depicted, and a lower troposphere at pressures between 2 and 10 bar, where heat is transported upward mostly in the belts, by small convective storms which are seen in the belts. There is evidence from the *Galileo* and *Cassini* observations that this is the case.

The upwelling/subsidence pattern at the jet scale in the upper troposphere penetrates into the lower stratosphere. We have relatively little information on the stratospheric circulation for the giant planets. Most of it is based on the observed thermal contrasts and the idea that friction is a dominant driver for stratospheric dynamics. We are beginning to appreciate the role of forcing by gravity or other dissipative waves. A model for the Uranus stratospheric circulation is based on the frictional damping and the observed thermal contrast as a function of latitude. The coldest temperatures in the lower stratosphere are at midlatitudes, indicating upwelling there and subsidence at the equator and poles. A different pattern is expected if the deposition of solar energy controlled the circulation. Momentum forcing by vertically propagating waves from the deeper atmosphere is apparently more important than solar energy deposition.

The mean meridional circulation in Jupiter's stratosphere differs from that predicted by the frictional damping model at pressure levels less than about 80 mbar. The zonal pattern of upwelling/sinking extends to about 100 mbar, giving way at higher altitude to a two-cell structure with cross-equatorial flow. There is also a hemispheric asymmetry. The high latitudes (poleward of 60°S and 40°N) are regions of sinking motion at the tropopause. Images from the *Hubble Space Telescope* indicate that the optical depth of the ammonia cloud decreases rapidly with latitude poleward of 60°S and 40°N and is well correlated with the estimated downward velocity. The descending dry air inhibits cloud formation. To produce that circulation, there must be momentum forcing in the latitude range 40°S to 80°S and 30°N to 80°N at pressures between 2 and 8 mbar. Dissipation of gravity waves propagating from the deep interior is the most likely source of momentum forcing.

Superimposed on the long-term mean are much faster processes such as horizontal eddy mixing, which can transport material in the north–south direction in days or weeks. The impacts of comet Shoemaker–Levy 9 on Jupiter in 1994 provided a rare opportunity to see the effects of eddy transport on small dust particles and trace chemical constituents deposited in the stratosphere immediately after impact. Particles spread rapidly from the impact latitude (45°S) to latitude 20°S, but there has been almost no transport farther toward the equator. Trace constituents at higher altitude such as HCN were observed to move across the equator into the northern hemisphere (*see* Physics and Chemistry of Comets).

Long-term monitoring of the Jovian stratosphere has yielded some interesting observations of an oscillating temperature cycle at low latitudes. At pressures between 10 and 20 mbar, the equator and latitudes ±20° cool and warm alternately on timescales of 2–4 years. The equator was relatively (1–2 K above the average 147 K) warm and latitudes ±20° were relatively (1–2 K below average) cool in 1984 and 1990. The reverse was true in 1986 and 1987. Changes in temperature must be accompanied by changes in the wind field, and these must be generated by stresses induced by wave forcing or convection. The similarities of the Jovian temperature oscillations to low-latitude temperature oscillations in the terrestrial atmosphere led some researchers to propose that the responsible mechanism is similar to that driving the quasi-biennial oscillation on Earth: forcing by vertically propagating waves. The period of the oscillation is about 4 (Earth) years and so the phenomenon has been called the quasi-quadrennial oscillation. Recent measurements from the ground and from the Cassini spacecraft have identified the same kind of wave structure on Saturn.

The *Voyager* cameras and more recently *Hubble* and ground-based images provided much information about the shapes, motions, colors, and lifetimes of small features in the atmospheres of the giant planets. In terms of the number of features and their contrast, a progression is evident from Jupiter, with thousands of visible spots, to Uranus, with only a few. Neptune has a few large spots that were seen for weeks and an abundance of small ephemeral white patches at a few latitudes. We do not have a good explanation for the contrasts and color because the thermochemical equilibrium ices that form these clouds (NH_3, NH_4SH, H_2O, CH_4, and H_2S) are colorless. We need to know more about the chemical nature, origin, and location of the colored material before we can understand how the contrasts are produced.

Fortunately, it is not necessary to understand how the contrasts are produced to study the meteorology of these features. One of the striking attributes of some of the clouds is their longevity. Jupiter's GRS has been observed since 1879 and may have existed much earlier. A little to the south of the GRS are three white ovals, each about one-third the diameter of the GRS. These formed in 1939−1940, beginning as three very elongated clouds (extending 90° in longitude) and rapidly shrinking in longitude. They survived as three distinct ovals until 1998 when two of them merged. In 2000, the remaining two merged, leaving one. There are many smaller, stable ovals at some other Jovian latitudes. All these ovals are anticyclonic and reside in anticyclonic shear zones. Because they are anticyclonic features, there is upwelling and associated high and thick clouds, and cool temperatures at the tropopause. Sinking motion takes place in a thin boundary region at the periphery of the clouds. The boundary regions are bright at 5 μm wavelength, consistent with relatively cloud-free regions of sinking. The GRS as revealed by *Galileo* instruments is actually much more complex, with cyclonic flow and small regions of enhanced 5-μm emission (indicating reduced cloudiness) in its interior.

Another attribute of many of the ovals is the oscillatory nature of their positions and sometimes shape. The most striking example is Neptune's GDS, whose aspect ratio (ratio of shortest to longest dimension) varied by more than 20% with a period of about 200 h, with a corresponding oscillation in orientation angle. Neptune's Dark Spot 2 drifted in latitude and longitude, following a sinusoidal law with amplitude 5° in latitude (between 50°S and 55°S) and 90° (peak to peak) in longitude. Other spots on Neptune and Jupiter, including the GRS, show sinusoidal oscillations in position. The Jovian spots largely remain at a fixed mean latitude, but the mean latitude of the GDS on Neptune drifted from 26°S to 17°S during the 5000 h of observations by the *Voyager 2* camera. Ground-based observations in 1993 did not show a bright region at methane absorption wavelengths in the southern hemisphere, unlike the period during the *Voyager* encounter when the high-altitude white companion clouds were visible from the Earth. The GDS may have drifted to the northern hemisphere and/or may have disappeared. *Hubble Space Telescope* images and ground-based images since the *Voyager* encounter show new spots at new latitudes.

Jupiter's GRS is often and incorrectly said to be the Jovian analog of a terrestrial hurricane. Hurricanes are cyclonic vortices. The GRS and other stable ovals are anticyclones. Hurricanes owe their (relatively brief) stability to energy generated from latent heating (condensation) over a warm ocean surface, where water vapor is abundant. Upwelling occurs in a broad circular region, and subsidence is confined to a narrow core (the eye). The opposite is true for anticyclonic spots in the giant planet atmospheres, where subsidence takes pace in a narrow ring on the perimeter of the oval. The key to their stability is the long-lived, deep-seated background latitudinal shear of the jets. The stable shear in the jets provides an environment that is able to support the local vortices. Latent heat, so important for a terrestrial hurricane, seems to play no role. However, the ephemeral bright small clouds seen in some locations may be places where strong upwelling is reinforced by release of latent heat analogous to a terrestrial thunderstorm.

5. ENERGETIC PROCESSES IN THE HIGH ATMOSPHERE

At low pressure (less than about 50 μbar), the mean free path for collisions becomes sufficiently large that lighter molecules diffusively separate from heavier ones. The level where this occurs is called the homopause. The outer planet atmospheres are predominantly composed of H_2 and He, with molecular hydrogen dissociating to atomic hydrogen, which becomes the dominant constituent at the exobase (the level where the hottest atoms can escape to space). This is also the region where solar extreme ultraviolet (EUV) radiation can dissociate molecules and ionize molecules and atoms. Ion chemistry becomes increasingly important at high altitudes. Some reactions can proceed at a rapid rate compared to neutral chemistry. Ion chemistry may be responsible for the abundant UV-absorbing haze particles (probably hydrocarbons) in the polar stratospheres of Jupiter and Saturn.

The high atmospheres of the giant planets are hot (400−800 K for Jupiter to 300 K for Uranus and Neptune), much hotter than predicted on the assumption that EUV radiation is the primary energy source. Estimates prior to the *Voyager* observations predicted high-altitude temperatures closer to 250 K or less. One of the challenges of the post-*Voyager* era is to account for the energy balance of the high atmosphere. Possible sources of energy in addition to EUV radiation include (1) Joule heating, (2) currents

induced by a planetary dynamo mechanism, (3) electron precipitation from the magnetosphere (and also proton and S and O ion precipitation in the Jovian auroral region), and (4) breaking inertia-gravity waves.

Joule heating requires electric currents in the ionosphere that accelerate electrons and protons. It is a major source of heating in the terrestrial thermosphere. We do not have enough information on the magnetosphere to know how important this process or the others mentioned are for the giant planet atmospheres. The planetary dynamo current theory postulates that currents are established when electrons and ions embedded in the neutral atmosphere move through the magnetic field, forced by the neutral wind tied to the deeper atmosphere. Electric fields aligned with the magnetic field are generated by this motion and accelerate high-energy photoelectrons that collide with neutrals or induce plasma instabilities and dissipate energy. Similar mechanisms are believed to be important in the terrestrial atmosphere.

Electron precipitation in the high atmosphere was one of the first mechanisms proposed to account for bright molecular hydrogen UV emissions. There is recent evidence for supersonic pole-to-equator winds in the very high atmosphere on Jupiter driven by auroral energy. These winds collide at low latitudes, producing supersonic turbulence and heating. Electron and ion precipitation outside the auroral regions undoubtedly contributes to the heating, but the details remain unclear. The possible contribution from breaking planetary waves is difficult to estimate, but *Galileo* probe measurements, details of the radio occultation profiles, and less direct lines of evidence point to a significant energy density in the form of inertia-gravity waves in the stratosphere and higher. How much of that is dissipated at pressures less than 50 μbar is unknown but could be significant to the energy budget of the high atmosphere.

The giant planets have extensive ionospheres. Like the neutral high atmospheres, they are hotter than predicted prior to the *Voyager* encounters. As for Earth, the ionospheres are highly structured, having a number of high-density layers. Layering in the terrestrial ionosphere is partially due to the deposition of metals from meteor ablation. The same mechanism is thought to be operative in the giant planet ionospheres. The Jupiter and Saturn ionospheres are dominated by the H_3^+ ion, whereas those of Uranus and Neptune are dominated by H^+.

Auroras are present on all the giant planets. Auroras on the Earth (the only other planet in the solar system known to have auroras) are caused by energetic charged particles streaming down the high-latitude magnetic field lines. The most intense auroras on Earth occur when a solar flare disturbs the solar wind, producing a transient in the flow that acts on Earth's magnetosphere through ram pressure. As the magnetosphere responds to the solar wind forcing, plasma instabilities in the tail region accelerate particles along the high-latitude field lines.

The configuration of the magnetic field is one of the key parameters that determines the location of auroras. Jupiter's magnetosphere is enormous compared to the Earth's. If its magnetosphere could be seen by the naked eye from the Earth, it would appear to be the size of the Moon (about 30 arc minutes), whereas Jupiter's diameter is less than 1 arc minute. To a first approximation, the magnetic fields of the Earth and the giant planets can be described as tilted dipoles, offset from the planet center. Table 32.4 lists the strength, tilt, and radial offsets for each of these planets. Earth and Jupiter have relatively modest tilts and offsets, Saturn has virtually no tilt and almost no offset, whereas Uranus and Neptune have very large tilts and offsets. Such diversity presents a challenge to planetary dynamo modelers (*see* Planetary Magnetospheres).

The mapping of the magnetic fields onto the upper atmosphere determines where auroral particles intercept the atmosphere. Maps for Jupiter, Uranus, and Neptune are shown in Figure 32.13, along with locations of field lines connected to the orbits of some satellites that may be important for auroral formation. The configuration for Saturn is not shown because contours of constant magnetic field magnitude are concentric with latitude circles owing to the field symmetry. Because of the large tilts and offsets for Uranus and Neptune, auroras on these planets occur far from the poles.

The Jovian aurora is the most intense and has received the most scrutiny. The remainder of this section will focus on what is known about it. It has been observed over a remarkable range of wavelengths, from X-rays to the infrared, and possibly in the radio spectrum as well. Energetic electrons from the magnetosphere dominate the energy input, but protons and S and O ions contribute as well. Sulfur and oxygen k-shell emission seems to be the most plausible explanation for the X-rays. Models of energetic electrons impacting on molecular hydrogen provide a good fit to the observed molecular hydrogen emission spectra. Secondary electrons as well as UV photons are emitted when the primary impacting electrons dissociate the molecules, and these secondaries also contribute to the

TABLE 32.4 Magnetic Field Parameters (Offset Tilted Dipole Approximation)

	Earth	Jupiter	Saturn	Uranus	Neptune
Tilt (degrees)	11.2	9.4	0.0	58.6	46.9
Offset (planetary radius)	0.076	0.119	0.038	0.352	0.485

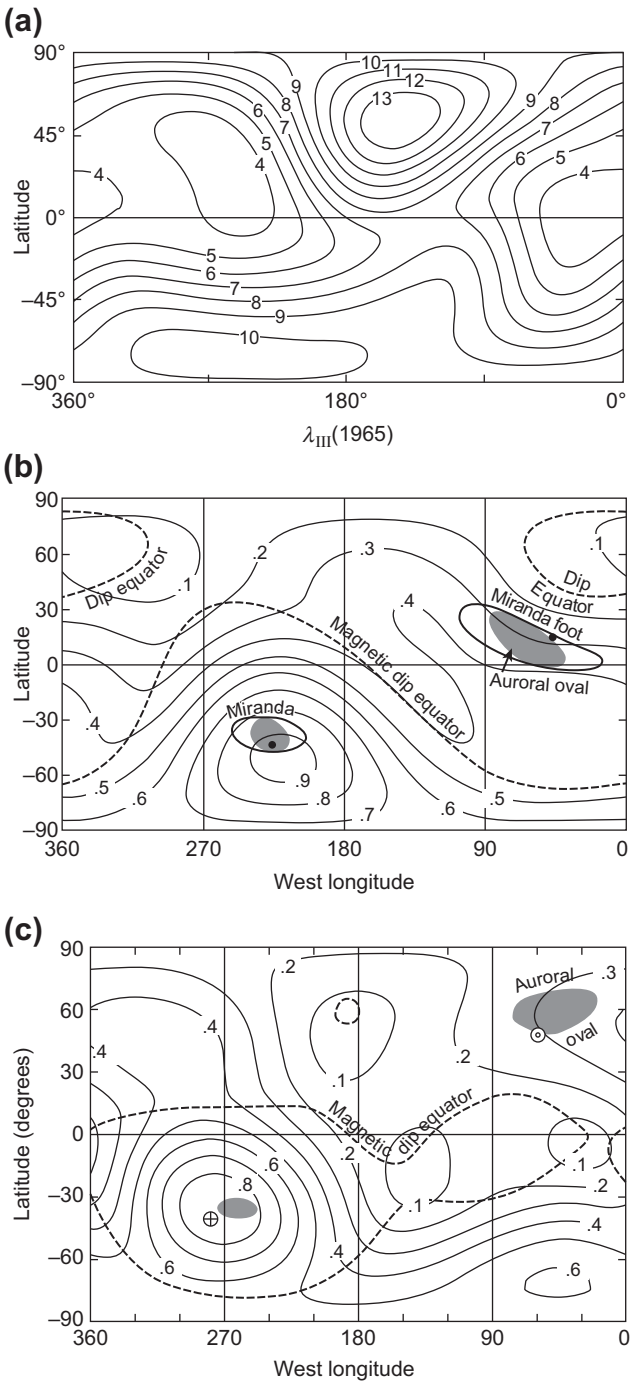

FIGURE 32.13 (a) Contours of magnetic field magnitude (gauss) on the surface of Jupiter (using the Goddard Spaceflight Center (GSFC) Model D_4). (b) Contours of constant magnetic field on the upper atmosphere of Uranus, along with the location of the auroral oval and the lines connected to the orbit of the satellite Miranda (Model Q_3). UV emissions. Some of the UV-emitted radiation is reabsorbed by other hydrogen molecules, and some is absorbed by methane molecules near the top of the homopause. From the detailed shape of the spectrum, it is possible to infer the depth of penetration of electrons into the upper atmosphere. In the near infrared (2–4 μm), emissions from the H_3^+ ion are prominent. Attempts to account for all the observations call for more than one type of precipitating particle and more than one type of aurora.

UV auroras from atomic and molecular hydrogen emissions are brightest within an oval that is approximately bounded by the closed field lines connected to the middle magnetosphere (corresponding to a region some 10–30 Jupiter radii from the planet) rather than the orbit of Io or open field lines connected to the tail. Weaker, diffuse, and highly variable UV emissions appear closer to the pole. They are produced by precipitation of energetic particles originating from more distant regions in the magnetosphere. There is also an auroral hot spot at the location where magnetic field lines passing through Io enter the atmosphere (the Io flux tube footprint). All these features are evident in Figure 32.14.

Io is a significant source of sulfur and oxygen, which come off its surface. The satellite and magnetosphere produce hot and cold plasma regions near the Io orbit, which may stimulate plasma instabilities. High-spatial-resolution, near-infrared H_3^+ images show emission from a region that maps to the last closed field lines far out in the magnetosphere (Figure 32.15). This and evidence for auroral response to fluctuations in solar wind ram pressure indicate that at least some of the emission is caused by processes that are familiar to modelers of the terrestrial aurora (*see* Io: The Volcanic Moon).

Auroral emission is strongest over a small range of longitudes. In the north, longitudes near 180°, System III coordinates (which rotate with the magnetic field) show enhanced emission in the UV and also in the thermal infrared. The spectrum of the aurora in the UV resembles electron impact on molecular hydrogen, except that the shortest wavelengths are deficient. This deficit can be accounted for if the emission is occurring at some depth in the atmosphere (near 10 μbar) below the region where methane and acetylene absorb UV photons. By contrast, the Uranian high atmosphere is depleted in hydrocarbons and does not produce an emission deficit.

Energy deposition at depth is also required to explain the warm stratospheric temperatures seen in the 7.8-μm methane band. At 10 μbar of pressure, the hot spot region near longitude 180° appears to be 60–140 K warmer than the surrounding region, which is near 160 K. Undoubtedly such temperature contrasts drive the circulation of the high atmosphere. Auroral energy also contributes to anomalous chemistry. An enhancement is seen in acetylene emission in the hot spot region, whereas ethane emission decreases

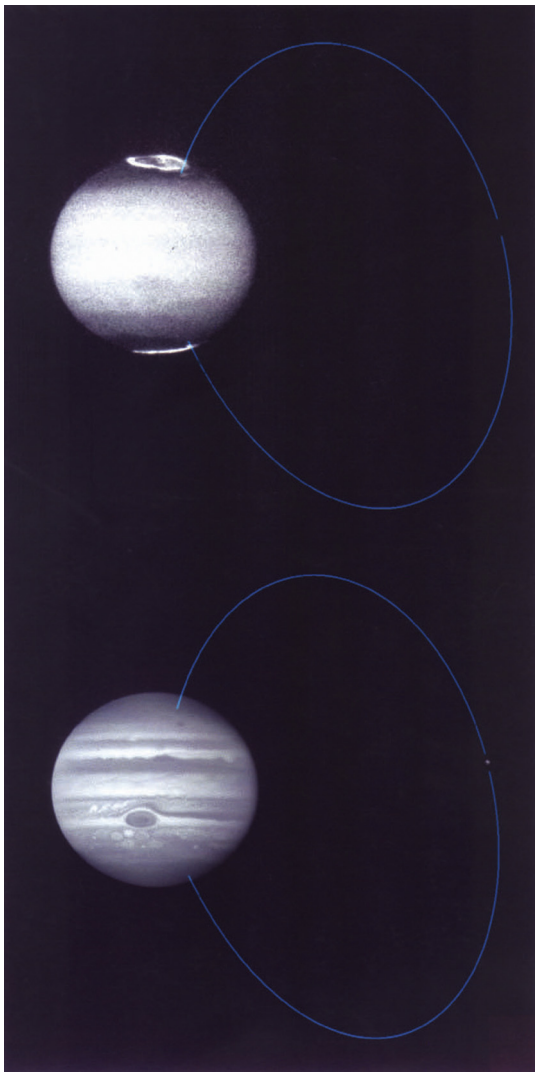

FIGURE 32.14 (Top) Image of Jupiter at ultraviolet wavelengths taken with the Wide Field and Planetary Camera 2 on the *Hubble Space Telescope*. Bright auroral ovals can be seen against the dark UV-absorbing haze and in the polar regions. Jupiter's north magnetic pole is tilted toward the Earth, making it easier to see the northern auroral oval as well as some diffuse emission inside the oval. Small bright spots just outside the oval in both hemispheres are at the location of the magnetic field lines connecting to Io, depicted by a blue curve. Io is dark at UV wavelengths. (Bottom) Image taken a few minutes after the one above in a filter that samples the violet part of the spectrum just within the range that the human eye can detect. The Great Red Spot appears dark at this wavelength and can just be seen in the top image as well. Io's small disk appears here along the blue curve, which traces the magnetic field lines in which it is embedded. *Courtesy of J. Trauger and J. Clarke.*

there. A significant part of the acetylene enhancement could be due simply to the higher emission from a warmer stratosphere, but a decrease in ethane requires a smaller ethane mole fraction.

Future work on the auroras of Jupiter and the other giant planets will focus on which types of particles are responsible for the emissions, the regions of the magnetosphere or

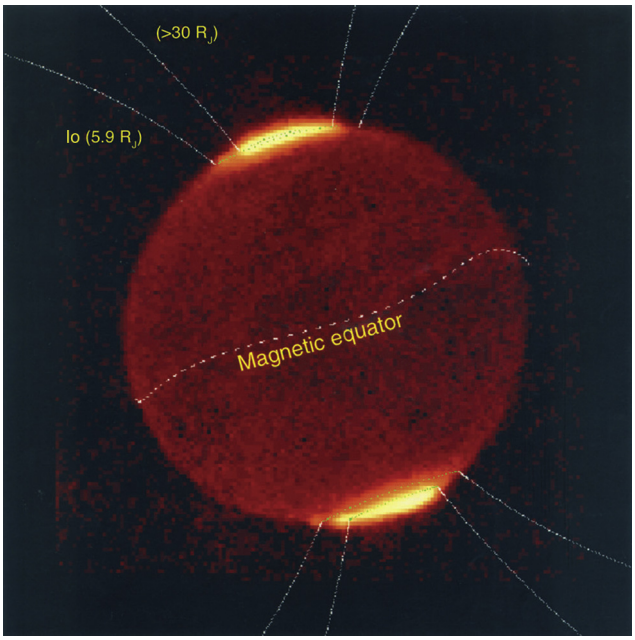

FIGURE 32.15 Auroral regions are bright in this image at wavelength 3.4 μm, where the H_3^+ ion emits light. Magnetic field lines connecting to Io and to the 30-Jupiter-radius equator crossing are shown. The brightest emissions are poleward of the 30R, field line, which means the precipitating particles responsible for this emission come from more distant regions on the magnetosphere. *Reprinted with permission from Connerney, J., et al. (1993). Copyright 1993 American Association for the Advancement of Science.*

torus from which they originate, the acceleration mechanisms, and how the deposited energy drives circulation and chemistry in the high atmosphere.

6. A WORD ABOUT EXTRASOLAR PLANETS

The discovery and study of planets in orbit around other stars (extrasolar planets) is an exploding field, with a rapidly increasing inventory of new planets, with new information from observations and theory. This field is likely to continue to blossom in the near future. So far most of the discoveries are in the category of the giant planets, and Neptune-size planets seem to be abundant. How can knowledge of the giant planets in our solar system inform about the properties of newly discovered giant planets?

What we know about the giant planets of our solar system provides a framework from which to extend our understanding of the atmospheres of planets around other stars. We have learned that two very different processes (rapid convection from the deep interior and photochemistry in the high atmosphere) produce molecular species unexpected from local chemical equilibrium. We have learned that the colors of clouds and hazes are influenced by similar disequilibrium processes. We have learned that

large vortices can be stable over long time periods and that the wind pattern is dominated by east–west jets. We have learned that energetic processes in the high atmosphere produce temperatures higher than expected from the deposition of solar energy.

In short, we have learned that the atmospheres of the giant planets are more complicated than we once thought. Dealing with these issues has forced us out of our comfort zone with respect to our understanding of how atmospheres work built on familiarity with the Earth's atmosphere.

Complexity will surely become even more evident for the atmospheres of giant planets orbiting other stars. A large fraction of those discovered so far are orbiting very close to their central star. These planets have hotter atmospheres, so the clouds in the upper atmospheres would be composed of rocky minerals instead of ices of water, ammonia, hydrogen sulfide, and methane. Photochemistry for the close planets will proceed at a much more vigorous rate than for the planets in our solar system. These planets will have some peculiar flow patterns due to tidal forcing and intense local heating at the substellar point. Some systems are far richer in carbon than ours is. Chemical composition and the appearance of planets in such systems will be strikingly different. This is all good because it forces us even farther out of our comfort zone and will stimulate yet a deeper understanding of how atmospheres work.

Bibliography **758**

The giant, or Jovian planets—Jupiter, Saturn, Uranus, and Neptune—account for 99.5% of all the planetary mass in the solar system. The internal composition and structure of all these planets thus provide important clues about the conditions in the solar nebula during the time of planet formation. But such information does not come easily. The familiar faces of these planets, such as the cloud-streaked disk of Jupiter, tell relatively little about what lies beneath. Knowledge of these planetary interiors must instead be gained from analysis of the mass, radius, shape, and gravitational fields of the planets. For the majority of giant planets around other stars, at best only the mass and radius can be discerned. Thus for both solar and **extrasolar planets**, theoretical models of the planetary interiors must be compared to the available data in order to infer what lies within the planets. The study of the behavior of planetary materials at high densities and pressures provides additional constraints for connecting mass, radius, and internal composition. Once constructed, interior models provide a window into the internal structure of these planets and shed light on processes that led to planet formation in our solar system and others.

1. GENERAL OVERVIEW

Several lines of observational evidence provide information on the composition and structure of the giant planets. The first and most easily obtained quantities are mass (known from the orbits of natural satellites), radius (polar and equatorial radii), and rotation period (obtained originally from telescopic observations, now derived from remote and in situ observations of planetary magnetic fields). By the 1940s, these fundamental observations, coupled with the advances in understanding the high-pressure behavior of matter in the 1920s and 1930s, constrained the composition of Jupiter and Saturn to be predominantly hydrogen. Direct measurement of the planets' high-order gravity fields, interior rotation states, and heat flow, along with spacecraft and ground-based spectroscopic detection of atmospheric elemental composition, has since allowed the construction of progressively more refined models of the interior structure of these planets.

These models divide the giant planets into two broad categories. Jupiter and Saturn are predominantly hydrogen–helium gas giants with a somewhat enhanced abundance of

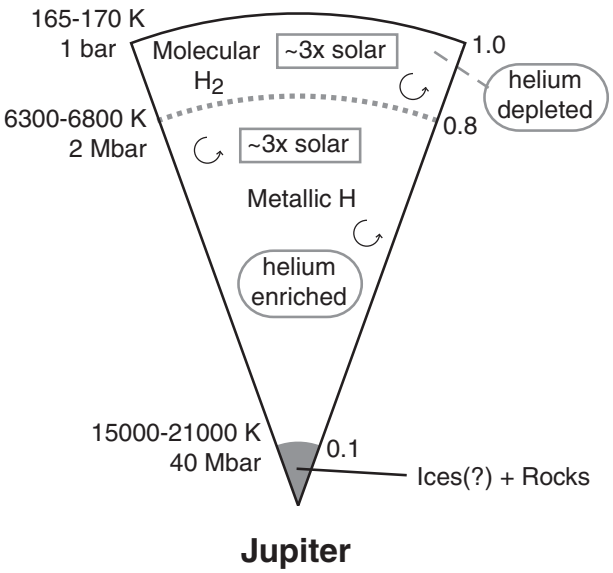

FIGURE 33.1 Highly schematic, idealized cross section of the interior structure of Jupiter. The numbers to the right refer to the relative radius *(r/R)* of the core and the molecular-to-metallic hydrogen phase transition. On the left are listed the approximate temperatures and pressures at which these interfaces occur. Arrows indicate convection. Boxes denote approximate enhancement of elements other than H and He over the abundance found in the Sun. The core mass is uncertain, but likely has a mass between 0 and 10 Earth masses. The real Jupiter is undoubtedly more complex. It is likely that interfaces are gradual and the composition of the various regions is inhomogeneous.

heavier elements and dense **cores**. Uranus and Neptune are **ice** giants with hydrogen–helium envelopes and dense cores. The following description of Jupiter's interior, as illustrated schematically in Figure 33.1, is qualitatively valid for Saturn and serves as a point of departure for understanding the interiors of Uranus, Neptune, and the extrasolar giant planets. Individual planetary interior structures are discussed in Section 5.

The interior begins at the base of the outermost atmospheric envelope that we can see directly. The Jovian atmospheres consist of a gaseous mixture of molecular hydrogen, helium, methane, ammonia, and water. At 1 **bar** pressure (the pressure at sea level on Earth), the temperature in Jupiter's atmosphere is 165 K. Near this level, the ammonia condenses into clouds; the water condensation level is even deeper. In the colder atmospheres of Uranus and Neptune, methane also condenses into clouds. Deeper into the planet the pressure of the overlying atmosphere compresses the gas, increasing its temperature and density. This process, **adiabatic compression**, is the same one responsible for the increase in temperature with decreasing altitude on Earth. About 100 km beneath the cloud tops, the temperature has reached 350 K.

As pressures and temperatures increase, the gas begins to take on the characteristics of a liquid. Since the **critical point** of the dominant constituent, molecular hydrogen, lies at 13 bars and 33 K, there is not a distinct gas–liquid phase boundary. By several hundred thousand bars the envelope closely resembles a hot liquid. This characteristic of the giant planets—they exist in the supercritical regime of their primary constituent—leads to their most fundamental property: these planets have essentially bottomless atmospheres.

Deeper into the planet the temperature and pressure continue to steadily increase. By 15,000 km beneath the cloud tops the temperature reaches 6,500 K and the pressure is 2 Mbar. Experiments and theory suggest that by this point hydrogen, previously present as molecules of H_2, has begun to undergo a phase transition to a liquid, metallic state. Most of the mass of Jupiter consists of this **metallic hydrogen**: protons embedded in a sea of electrons. Helium and other constituents exist as impurities in the hydrogen soup. For the remaining 50,000 km to Jupiter's core, the pressure and temperature continue to rise, reaching 40 Mbar and nearly 20,000 K in the deep interior. Near the center of the planet the composition changes, perhaps gradually, from a predominantly hydrogen/helium mixture to a combination of **rock** and **ice**. The density of this rock and ice core is 10,000–20,000 kg/m^3, higher than the metallic hydrogen density of about 1000 kg/m^3 (uncompressed water, like the one that comes out of a tap, also has a density of 1000 kg/m^3).

The interiors of giant planets are hot, thousands to tens of thousands of degrees Kelvin, while their observable atmospheres are cold, 100 K or so and cooler. To understand the evolution of a giant planet through time, one has to understand how the energy from the hot interior is transported out to the much cooler atmosphere. The three possible choices would be by radiation, conduction, and **convection**. Throughout most of the interior, the transport of energy by radiation is severely hampered by the high **opacity** of dense hydrogen. Other constituents such as methane and water effectively block energy transport by radiation in those regions of the spectrum where the hydrogen is a less powerful absorber. Since conduction of heat by the thermal motion of molecules is also inefficient, convection is the dominant energy transport mechanism throughout the interior. The rising and sinking convective cells in the interior move slowly, at velocities of just centimeters per second or less.

Convective transport of heat may be responsible for the banded appearance of the planets. Because of the rapid rotation of these planets, it is easier for convective cells to rise parallel to the rotation axes, from the center toward the poles, than in the perpendicular direction, out toward the equator. This tendency combined with the continuous nature of the atmosphere connects the atmosphere to the deep interior. The wind patterns seen in the belts and zones of Jupiter and Saturn may thus have roots that reach into the deep, convective interior of the planet. Indeed, the winds measured by Galileo spacecraft's atmosphere probe

continued to blow steadily at the deepest levels reached by the probe, about 20 bars.

The interior of Saturn may be similar to that of Jupiter, and that of Uranus similar to that of Neptune, although in both cases the different heat flows would allow for dissimilar interiors. Saturn's lower mass and consequently lower pressures produce a smaller metallic hydrogen region than Jupiter's. It is likely that Uranus and Neptune lack a metallic hydrogen region; instead, at about 80% of their radius the abundance of methane, ammonia, and water increases markedly. In this region, temperatures of over 2500−10,000 K produce an ocean of electrically charged fluid water, ammonia, methane molecules, and molecular fragments, along with more complex compounds. Most of the mass of Uranus and Neptune exists in such a state. Deep in their interiors, all the planets likely have cores of primarily rocky material.

This picture of the interiors of the Jovian planets has been painstakingly pieced together since the 1930s. This chapter discusses the components of observation, experiment, and theory that are combined to reach these conclusions.

2. CONSTRAINTS ON PLANETARY INTERIORS

2.1. Gravitational Field

A variety of observations yield information about the makeup and interior structure of the Jovian planets. The mass of each of the four Jovian planets (Table 33.1) has been known with some precision since the discovery of their natural satellites. The masses range from 318 times the Earth's mass ($M_\oplus$) for Jupiter to 14.5 $M_\oplus$ for Uranus. A second fundamental observable property is the radius of each planet measured at a specified pressure, typically the 1-bar pressure level. Radii are most accurately measured by the occultation technique, in which the attenuation of the radio signal from a spacecraft is measured as the spacecraft passes behind the planet. Jovian planet radii range from 11 times the Earth's radius ($R_\oplus$) for Jupiter to 3.9 $R_\oplus$ for Neptune. The combination of mass and radius allows calculation of mean planetary density, ρ. Although a surprising amount can be learned about the bulk composition of a planet from just ρ (as we will later see for extrasolar giant planets), more subtle observations are required to probe the detailed variation of composition and density with radius.

If the Jovian planets did not rotate, they would assume a spherical shape and their external gravitational field would be the same as that of a point of the same mass. No information about the variation in density with radius could be extracted. Fortunately, the planets do rotate and their response to their own rotation provides a great deal more information. This response is observed in their external gravitational field.

For a uniformly rotating body in hydrostatic equilibrium, the external gravitational potential, Φ, is

$$\Phi = -\frac{GM}{\mathbf{r}}\left(1 - \sum_{n=1}^{\infty}\left(\frac{a}{\mathbf{r}}\right)^{2n} J_{2n} P_{2n}(\cos\theta)\right)$$

Here G is the gravitational constant, M is the planetary mass, a is the planet's equatorial radius, θ is the colatitude (the angle between the rotation axis and the radial vector $\mathbf{r}$), P_{2n} are the Legendre polynomials, and the dimensionless numbers J_{2n} are known as the gravitational moments. The assumption of hydrostatic equilibrium means that the

TABLE 33.1 Observed Properties of Jovian Planets

Quantity	Jupiter	Saturn	Uranus	Neptune
M(kg)	1.8981×10^{27}	5.6833×10^{26}	8.683×10^{25}	1.024×10^{26}

$J_6 \times 10^6$	31 ± 20	86 ± 10	–	–
q	0.0892	0.151	0.0295	0.026
Λ_2	0.1647	0.108	0.1191	0.136
$\bar{\rho}$ (g cm^{-3})	1.328	0.687	1.27	1.64
Y	0.238 ± 0.007	0.18 − 0.25	0.26 ± 0.05	0.26 ± 0.05
T_1 (K)	165	135	76	74

planet is in a fluid state, responding only to its rotation, and there are no permanent, nonaxisymmetric lumps (e.g. mountains) in the interior. This assumption is believed to be quite good for the Jovian planets.

The gravitational harmonics are found from observations of the orbital motion of natural satellites, **precession** rates of elliptical rings, and perturbations to the trajectories of spacecraft. As a spacecraft flies by a planet, it samples the gravitational field at a variety of radii. Careful tracking of the spacecraft's radio signal reveals the Doppler shift due to its acceleration in the gravitational field of the planet. Inversion of these data yields an accurate determination of the planet's mass and gravitational harmonics (see Table 33.1). In practice, it is difficult to measure terms of order higher than J_4, and the value of J_6 is generally quite uncertain. Progressively higher order gravitational harmonics reflect the distribution of mass in layers progressively closer to the surface of the planet. Thus, even if they could be measured accurately, terms such as J_8 would not contribute greatly to understanding the deep interior.

A planet's response to its own rotation is characterized by how much a surface of constant total potential (including the effects of both gravity and rotation) is distorted. The amount of distortion on such a surface of constant potential, known as a level surface, depends on the distribution of mass inside the planet, the mean radius of the level surface, and the rotation rate. The distortion, or oblateness, of the outermost level surface is measured from direct observations of the planet and is given by $\varepsilon = (a - b)/a$, where b is the polar radius. The equatorial and polar radii can be found from direct telescopic measurement or, more accurately, from observations of spacecraft or stellar occultations. Distortion of level surfaces cannot be described simply by ellipses. Instead, the distortion is more complex and must be described by a power series of shapes, as illustrated in Figure 33.2. The most obvious distortion of a spherical planet (n = 0) is elliptical (n = 2). More subtle distortions are described by harmonic coefficients of ever increasing degree, as illustrated up to $n = 10$ in Figures 33.2.

A nonrotating, fluid planet would have no J_{2n} terms in its gravitational potential. Thus the gravitational harmonics provide information on how the shape of a planet responds to rotating-frame forces arising from its own spin. Since the gravitational harmonics depend on the distribution of mass of a particular planet, they cannot be easily compared between planets. Instead, a dimensionless linear response coefficient, Λ_2, is used to compare the response of each Jovian planet to rotation. To lowest order in the square of the angular planetary rotation rate, ω^2, $\Lambda_2 \approx J_2/q$, where $q = \omega^2 a^3/GM$. Table 33.1 lists the Λ_2 calculated for each planet. The Jovian planets rotate rapidly enough that the nonlinear response of the planet to rotation is also important and must be considered by computer models.

Since the gravitational harmonics provide information about the planet's response to rotation, interpretation of the harmonics requires accurate knowledge of the rotation rate of the planet. Before the space age, observations of atmospheric features as they rotated around the planet provided rotation periods. This method, however, is subject to errors introduced by winds and weather patterns in the planet's atmosphere. Instead, rotation rates are now found from the rotation rate of the magnetic field of each planet, generally as measured by the Voyager spacecraft (radio emissions arising from charged particles in Jupiter's **magnetosphere** can be detected by radio telescopes on Earth). This approach assumes that the magnetic field is generated by convective motions deep in the electrically conducting interior of the planet and that the field's rotation consequently follows the rotation of the bulk of the interior. This assumption is not certain and the measurement of the magnetic rotation period itself can also be challenging. As a result, in recent years there have been several suggestions that traditional rotation periods are in error by as much as several tens of minutes. This controversy has not yet been fully resolved and we quote here in Table 33.1 the generally accepted rotation periods.

2.2. Atmosphere

The observable atmospheres of the Jovian planets provide further constraints on planetary interiors. First, the atmospheric temperature at 1 bar pressure, or T_1, constrains the

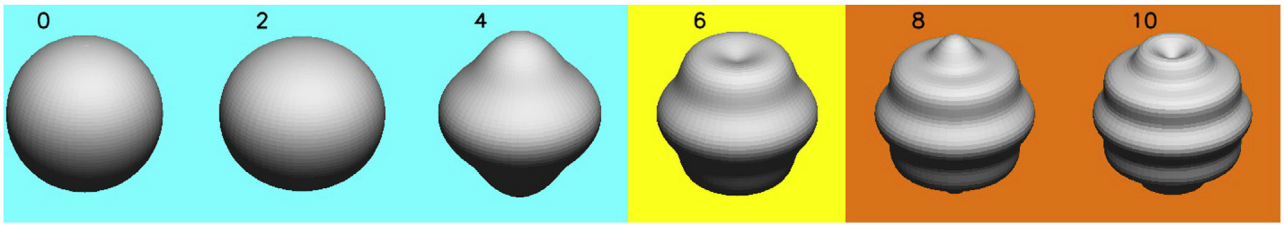

FIGURE 33.2 Illustration of the ways that a planet changes shape owing to its own rotation. A nonrotating planet is purely spherical (leftmost). The distortions due to second through tenth order in the gravitational harmonics J_n are also shown (for $n = 2$ through 10). The first three gravitational harmonics (mass, J_2 and J_4, cyan background) are well constrained. J_6 (yellow) is known with a larger uncertainty, while the values of J_8 and J_{10} are currently unknown but will be measured by the *Juno* spacecraft. Figure courtesy William Hubbard (Univ. Ariz.).

temperature of the deep interior. The interior temperature distribution of the Jovian planets is believed to follow a specified pressure–temperature path known as an **adiabat**. For an adiabat, knowledge of the temperature and pressure at a single point uniquely specifies the temperature as a function of pressure at all other points along the adiabat. Thus T_1 gives information about the temperature structure throughout the convective interior of the planet. Both the amount of sunlight that the atmosphere absorbs and the amount of heat carried by convection up from the interior of the planet to the atmosphere control T_1. For each planet, save Uranus, T_1 is higher than expected if the atmosphere were simply in equilibrium with sunlight. Thus each Jovian planet, save Uranus, exhibits a significant internal heat flow, ranging from 0.3 W/m^2 at Neptune, to 2.0 W/m^2 at Saturn, to 5.4 W/m^2 at Jupiter. For Uranus, only an upper limit to the heat flow, 0.08 W/m^2, has been measured.

Second, the composition of the observable atmosphere also holds clues to the internal composition. This is because of the supercritical nature of the Jovian atmospheres. The principal component of the Jovian atmosphere, hydrogen, does not undergo a vapor–liquid phase change above 33 K. Since the planets are everywhere warmer than this temperature, the observed atmosphere is directly connected to the deep interior. Knowledge of the composition of the top of the atmospheres therefore provides some insight into the composition at depth. (See Atmospheres of the Giant Planets.)

The Galileo spacecraft atmosphere probe returned direct measurements of the composition of Jupiter's atmosphere. The composition of the remaining planetary atmospheres is inferred from spectroscopy. In planetary science, compositions are often stated relative to "solar" abundances. Solar abundances are the relative quantities of elements present in the solar nebular at the time of planetary formation. The solar abundances of hydrogen and helium are about 70% and 28% by mass, respectively. Oxygen, carbon, nitrogen, and the other elements make up the remainder. These elements are collectively called the "heavy elements" to distinguish them from hydrogen and helium. Measurements of the rate at which the atmospheric pressure decreases with height in these atmospheres require that hydrogen and helium must be the dominant components of the atmospheres of all four Jovian planets. Spectroscopy supports this conclusion and gives the relative abundance of hydrogen and helium. The helium mass fraction of each atmosphere, Y, is listed in Table 33.1. The heavier elements are generally enriched in the Jovian atmospheres over their solar abundances, which must be explained by any formation scenario for these planets.

2.3. Magnetic Field

All four Jovian planets possess a magnetic field. Jupiter's is large and complex; Saturn's is less complex and weaker. The magnetic fields of both Uranus and Neptune are very complex: they deviate substantially from a dipole and their field axes are tilted strongly with respect to their rotation axes. The only known mechanism for producing global planetary magnetic fields, the hydromagnetic **dynamo** process, requires nonuniform motion of a large electrically conductive region. Convection in the highly conductive interior of the Jovian planets is presumed to be responsible for the formation of their fields. In Jupiter and Saturn, this is the liquid metallic hydrogen region. In Uranus and Neptune, this is the ionized fluid predominantly "icy" region. The level of complexity of each field plausibly relates to the depth of the electrically conducting region. Magnetic fields formed by relatively small, deep sources may be simpler and smaller than fields formed by large, shallow dynamos, albeit simple fields may require complex explanations. (See Planetary Magnetospheres.)

3. EQUATIONS OF STATE

3.1. Overview

Beyond observations of the planets themselves, a second major ingredient in interior models is an **equation of state** (EOS). An EOS is a group of equations, derived from laboratory observations and theory, that relate the pressure (P) of a mixture of materials to its temperature (T), composition (x), and density (ρ). Any attempt to model the interior structure of a giant planet must rely on an EOS. The construction of accurate EOSs is a primary activity in planetary interior modeling.

For an ideal gas, the well-known EOS is $P = nkT$. Here k is the Boltzmann's constant and n is the number density of the gas. The composition of an ideal gas does not affect the pressure; only the number of molecules and atoms in a given volume, n, enters the equation. Under the conditions of high temperature and pressure found in the interiors of the giant planets, atoms and molecules interact strongly with one another, thus violating the conditions under which the ideal gas EOS holds. Additionally, the typical pressures reached in the interiors of the giant planets (tens to hundreds of megabars) are also amply sufficient to modify the electronic structure of individual atoms and molecules. This further adds to the challenge of understanding the EOS. In short, the properties of planetary materials at high pressures will differ substantially from those encountered in their low-pressure, and more familiar, forms. In practice, the behavior of planetary materials must be understood from both experiments and theory.

For pressures less than about 3 Mbar, depending on the material, shock wave experiments provide guidance in the construction of EOSs. Gas guns, powerful lasers, explosives, or magnetic pressure can produce shock waves that produce both high temperatures and high pressures in the

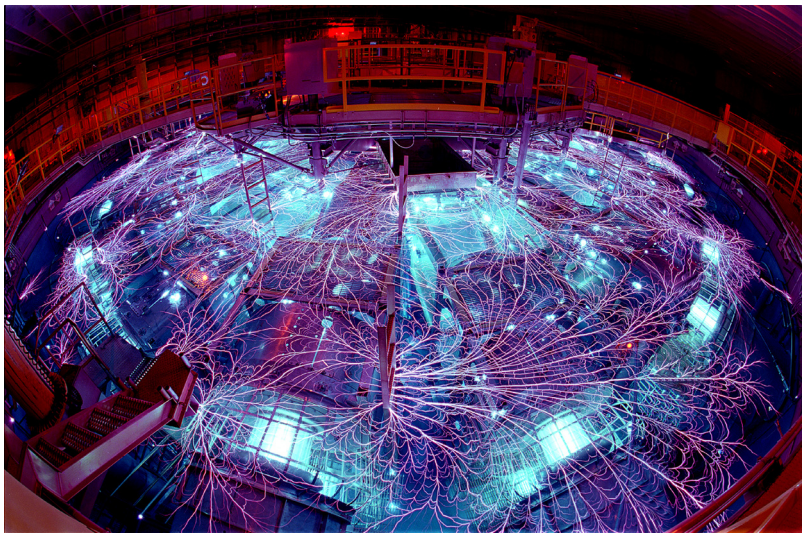

FIGURE 33.3 The Z Machine at the Sandia National Laboratory in Albuquerque, Mexico. The facility uses intense magnetic pressure to launch flyer plates at ~20 km/s into samples of hydrogen, deuterium, water, and other materials. The shocked samples are monitored during the collision so that pressure, density, and sometimes temperature can be determined. *Photo courtesy: Sandia National Laboratory.*

sample. High-speed measuring devices record the temperatures, pressures, and densities achieved during the brief experiments. A photograph of the "Z Machine" at Sandia National Laboratory, which employs magnetic pressure and has measured the EOS of many planetary materials under extreme pressure and temperature conditions, is shown in Figure 33.3.

The temperatures and pressures reached in these experiments are the closest that terrestrial laboratories can come to reliably duplicating the conditions in the interiors of the Jovian planets. Hydrogen experiments model conditions about 80–90% of the way out from the Jupiter's center and 60–70% for Saturn. An important recent advance has been the exploration of the EOS of water up to 7 Mbar at Sandia, which is similar to the central pressure of Uranus and Neptune.

Diamond anvils are used in another type of experiment to squeeze microscopically small samples of planetary materials to very high pressure. Although these experiments can reach higher pressures than the shock experiments, they have historically only been conducted at room temperature, making them less applicable to Jovian planets. Very recently, however, teams have begun dynamically shocking samples that have been precompressed by anvils, to allow a much wider range of final pressure and temperature states to be reached for shocked samples.

The EOSs that are used to model giant planets are becoming ever more sophisticated in the era of abundant computing power. Theoretical physicists are now able to directly simulate the quantum mechanical interactions of hydrogen atoms, helium atoms, their mixtures, and water and rock. When these direct computer simulations can be compared to laboratory work, excellent agreement has been found. This lends some confidence when these calculated EOSs are accurate when applied to deep planetary interiors, beyond the realm of current experiment. As we will see later, our understanding of the structure of Jupiter, in particular, is only as good as our understanding of the hydrogen EOS.

3.2. Hydrogen

For pressures less than about 1 Mbar, the behavior of molecular hydrogen, H_2, is understood fairly well from theory and the shock experiments. At higher pressures such as those encountered deeper in the interiors of Jupiter and Saturn, the hydrogen molecules are squeezed so closely together that they begin to lose their individual identities, as adjacent hydrogen molecules become as closely spaced as the two atoms within a given molecule. The electrons become free to move between atoms and are unbound. This "pressure-ionized" phase of hydrogen is termed metallic hydrogen. In giant planets, this metallic hydrogen is always fluid, not solid. A shock wave experiment suggests that this transition occurs gradually near 1.4 Mbar at 3000 K, however, more work is needed to fully understand this phase transition. All recent theoretical calculations show that the transition is continuous under planetary interior conditions and may not be complete until a pressure of 10 Mbar. Liquid metallic hydrogen in Jupiter and Saturn consists of a dense mixture of ionized protons and electrons at temperatures over about 6000 K. The EOS of liquid metallic hydrogen is understood well theoretically for pressures above about 10 Mbar, but the EOS is not well constrained from 0.5 to 10 Mbar, the transition region. A hydrogen phase diagram and temperature/pressure profiles for each giant planet are shown in Figure 33.4. The detailed

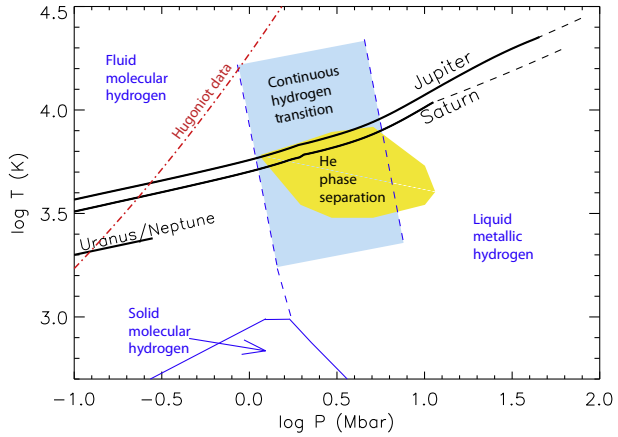

FIGURE 33.4 Phase diagram for hydrogen, the main constituent of Jupiter and Saturn. The approximate domains of liquid metallic hydrogen and molecular hydrogen are shown along with approximate interior temperature profiles for the Jovian planets. The light blue shaded region shows the approximate molecular to metallic transition region for hydrogen. The yellow shaded area indicates the approximate region in the interior of Saturn and, possibly, Jupiter where helium begins to separate out from liquid metallic hydrogen. The locations of phase boundaries are highly uncertain except for the liquid to solid transition of H_2. "Hugoniot data" shows the pressure−temperature curve where single shock experiments reach. High-pressure regions at lower temperatures can be probed by multiply shocking a sample. Most of the interior of Jupiter and Saturn exists at pressures greater than can currently be probed in laboratory experiments.

behavior of hydrogen near the phase transition is not fully known. Thus in the past various simplifying assumptions had to be made when considering these regions of giant planets. It is only recently that detailed computer calculations can simulate this important region in giant planets, although more data is nevertheless sorely needed.

3.3. Helium

Helium has not been as well studied as hydrogen, but shock wave data do provide information to around 1 Mbar. Above this pressure, theory must guide models of the behavior of this element. Helium is thought to be entirely neutral in Saturn but may become ionized in the deeper interior, just above the core, in Jupiter. Although the EOSs of hydrogen and helium individually are reasonably understood, the behavior of mixtures of these two constituents is less well constrained. This is a serious theoretical void because the hydrogen—helium mixture composes most of the mass of Jupiter and Saturn and is an important component in Uranus and Neptune.

Current calculations of the behavior of hydrogen and helium mixtures show that helium is not soluble in liquid metallic hydrogen at all mass fractions and temperatures. At the temperatures predicted in the interior of Saturn (and perhaps also in Jupiter), hydrogen and helium do not mix. According to this model, droplets of helium-rich material are constantly forming in the molecular to metallic transition region of the planet. Because they are denser than their surroundings, the drops fall to deeper, warmer levels of the envelope, where temperatures may be high enough to again allow mixing, and the droplets dissolve. Thus at certain depths in Saturn's interior, it is always raining helium. This remarkable conclusion is discussed in Section 5.3 in the context of the Saturn interior models.

3.4. Ices

The term "ices" is applied to mixtures of volatile elements in the form of water (H_2O), methane (CH_4), and ammonia (NH_3) in solar proportions, not necessarily present as intact molecules. Ices are the primary constituent of Uranus and Neptune, but are less abundant in Jupiter and Saturn. As the planetary interior temperatures are over several thousand degrees Kelvin, they are present as liquids.

EOS data are more sparse for these compounds, although shock wave experiments conducted on a mixture of water, isopropanol, and ammonia (dubbed "synthetic Uranus") have helped establish the EOS of such a mixture at pressures less than about 2 Mbar and temperatures less than about 4000 K, and water alone has been probed to 7 Mbar. These experiments helped confirm that ices are the primary constituent of Uranus and Neptune. The shock wave data on this mixture show that at pressures exceeding ~200 kbar, the planetary ice constituents ionize to form an electrically conductive fluid. At pressures $\geq$1 Mbar, the ice constituents dissociate and the EOS becomes quite "stiff", meaning the density is not particularly sensitive to the pressure. Modern computational work on icy mixtures is focusing on high-pressure chemistry, meaning that they investigate how mixtures of the ices behave differently than the pure phases. The rainout of pure carbon from the icy mixture in Uranus and Neptune has been suggested.

3.5. Rock

The remaining planetary constituents are lumped into the category "rock". Rock is presumed to consist of a solar mixture of silicon, magnesium, and iron, with uncertain additions of oxygen and the remaining elements. Although the rock EOS is not well known, it is also expected to be quite "stiff". The lack of a detailed rock EOS is not a serious limitation for planetary interior models, as the rock component is not believed to be a major fraction of the mass, at least for Jupiter and Saturn.

3.6. Mixtures

Since all the planetary components, including gas, ice, and rock, are likely mixed throughout the interiors, EOSs of such mixtures are required for interior modeling.

Hydrogen–helium mixtures, considered earlier, may not exist at all temperatures, pressures, and concentrations. The solubility of other mixtures, for example, rock or oxygen in metallic hydrogen, is less well known. From the limited data, it appears that the planetary constituents other than hydrogen and helium do mix well under the temperature and pressure conditions typically found in planetary interiors. This is because delocalization of electrons at high pressure diminishes the well-defined intermolecular bonds present at lower pressures. Thus the separation of planetary materials into distinct layers of "pure" rock or ice is highly unlikely. If correct, such considerations also have important cosmogonic implications. For example, the dense cores of the planets likely did not "settle" from an initially well-mixed planet, but instead the gaseous components likely collapsed onto a preexisting rocky nucleus that formed in the protosolar nebula. The water/rock cores of the planets may also slowly become dredged up and dissolve into the overlying H/He mixture, although the timescale for this process is not yet well constrained.

Since the EOS of all possible mixtures has not been studied, either experimentally or theoretically, approximations must be employed. One approximation, the additive volume law, weights the volumes of individual components in a mixture by their mass fraction. An implication of such approximations is that the computed densities of mixtures of rock, ice, and gas can be similar to that of pure ice. Thus it is not currently possible to differentiate between models of Uranus and Neptune with mantles of pure ice and models with mantles of a mixture of rock, ice, and gas.

4. PLANETARY INTERIOR MODELING

In addition to an EOS for the material in the interior of a planet, two more components are required to produce an interior model. The temperature and composition in the interior as a function of pressure, $T(P)$ and $x(P)$, respectively, must also be known. (These quantities are described as functions of pressure since the pressure increases monotonically toward the center of the planet.) The first of these ingredients, $T(P)$, is not difficult to find. If the Jovian planets are fully convective in their interiors, transporting internal heat to the surface by means of convection, the relation between temperature and pressure in their interiors is known as an adiabat. An adiabat has the property that knowledge of a single temperature and pressure at any point allows specification of T as a function of P at any other point (assuming the material's EOS is known). Since the temperature and pressure in the convecting region of each Jovian atmosphere have been measured, a unique $T(P)$ relation for each planet can be found. If there is indeed a large nonconvective region in the giant planets (see below) significant corrections may be required.

More difficult to specify is the variation in composition through each planet, $x(P)$. The composition of each planet's atmosphere is known, but there is no guarantee that this composition is constant throughout the planet. Earth's core, for example, has a very different composition from the crust. For the Jovian planets, an $x(P)$ relation is typically guessed at, an interior model computed, and the results compared to the observational constraints. With multiple iterations, a variation in composition with pressure that is compatible with the observations is eventually found. Modern theoretical work is also now addressing how composition gradients (due to He settling or core erosion) may lead to interior temperature profiles that significantly deviate from an adiabat.

The combination of these three ingredients, an EOS $P = P(T, x, \rho)$; a temperature–pressure relation, $T = T(P)$; and a composition–pressure relation, $x = x(P)$; completely specifies pressure as only a function of density, $P = P(\rho)$. Since the Jovian planets are believed to be fluid to their centers, the pressure and density are also related by the equation of hydrostatic equilibrium for a spherical rotating planet:

$$\frac{\partial P}{\partial r} = -\rho(r)g(r) + \frac{2}{3}r\omega^2\rho(r)$$

where g is the gravitational acceleration at radius r and ω is the angular rotation rate. This relation simply says that, at equilibrium, the pressure gradient force at each point inside the planet must support the weight of the material at that location. Combining the equation of hydrostatic equilibrium with the $P(\rho)$ relation finally allows determinations of the variation of density with radius in a given planetary model, $\rho = \rho(r)$.

The computed model must then satisfy all the observational constraints discussed in Section 2. Total mass and radius of the model are easily tested. The response of the model planet to rotation and the resulting gravitational harmonics must be calculated and compared with observations. Figure 33.5, showing the relative contribution versus the depth from the center of the planet, illustrates the regions of a Saturn model that contribute to the calculation of the gravitational harmonics J_2, J_4, and J_6. Higher degree modes provide information about layers of the planet progressively closer to the surface.

The construction of computer models that meet all the observational constraints and use realistic EOSs requires several iterations, but the calculation does not strain modern computers. The current state of the art is to calculate dozens of interior models, while varying the many parameters within theoretically or experimentally determined boundaries. The EOSs of hydrogen and helium both have uncertainties due to differences in experimental data and theory. In addition, the size and composition of the heavy element core, as well as the heavy element enrichment in

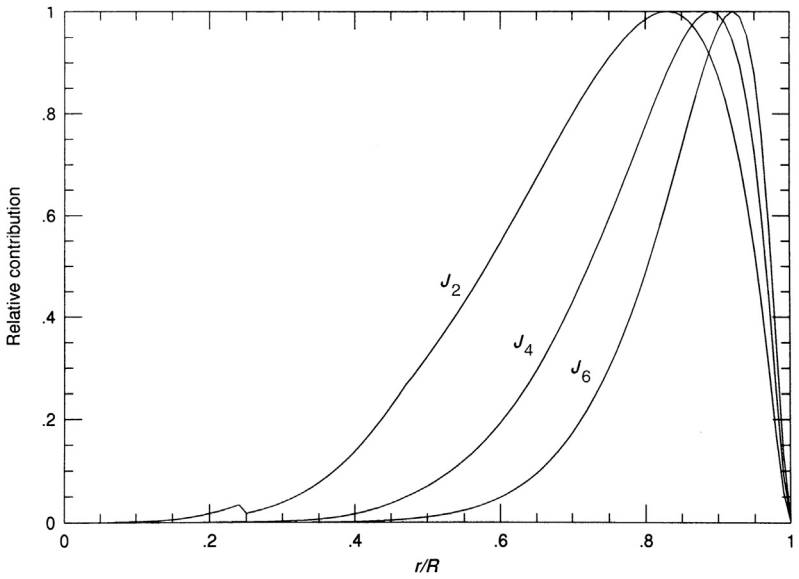

FIGURE 33.5 Gravitational harmonics are computed from integrals over density and powers of radius of a rotating planet. The curves illustrate the integrands for the harmonics J_2, J_4, and J_6 of a Saturn interior model. Higher-degree terms are proportional to the interior structure in regions progressively closer to the surface. All curves have been normalized to unity at their maximum value. The bump in the J_2 curve near 0.2 is due to the presence of the core.

the envelope, is varied with different EOSs for ices and rocks. A subset of these possible models fits all available planetary constraints. By necessity, each modeler begins with an ad hoc set of assumptions that limit the range of models that can be calculated. This inherent limitation of models should always be borne in mind when considering their results. The consensus for the structure of Jovian planet interior models is presented in the next section.

5. PLANETARY INTERIOR MODELS

5.1. General Overview

Even early "cosmographers" recognized that the giant planets of the solar system were distinct from the inner **terrestrial planets**. The terrestrial planets have mean densities of 4000−5000 kg/m^3, intermediate between the density of rocks and iron, whereas the giant planets have mean densities closer to that of water (1000 kg/m^3), between 700 and 1700 kg/m^3. From this single piece of information, it is clear that the bulk composition of the giant planets must be substantially different from that of the terrestrial planets.

It has been known since the 1940s that if the interiors of Jupiter and Saturn are "cold", the primary component of these planets must be hydrogen. In this context, "cold" means that the densities throughout the interior must not deviate significantly from the values they would assume at the same pressures if the temperature was 0 K. The approximation is relevant because the behavior of substances at 0 K and high pressure can be calculated analytically. Hydrogen is then a likely dominant constituent because at the high pressures prevalent in the interiors of Jupiter and Saturn it would be a metallic fluid with a density of about 1000 kg/m^3, not the more familiar molecular gas. Since the density of "cold" metallic hydrogen is close to the bulk densities of Jupiter and Saturn, it was recognized as a plausible major constituent of these planets.

Mass−radius calculations provide a more compelling demonstration of the dominance of hydrogen in the interiors of Jupiter and Saturn. For a given composition, there is a unique relation between the radius of a spherical body in hydrostatic equilibrium and its mass. These relations can be calculated analytically for all elements at high pressure and zero temperature. Although the interiors of Jovian planets are not at zero temperature, they are cool when measured on an atomic temperature scale. This is adequate for a qualitative calculation, but zero-temperature EOSs are insufficiently accurate for the calculation of detailed interior models.

Mass−radius curves for several likely planetary constituents are shown in Figure 33.6. For low masses, the interior pressures are small compared to intermolecular forces and the volume of an object is just proportional to its mass, thus $R \propto M^{1/3}$. This is a realm with which we are familiar in daily life. At larger masses, the greater interior pressures ionize the material, liberating many electrons. In this regime, $R \propto M^{-1/3}$: when mass is added to an object, it shrinks. For intermediate masses where the curves meet, there is a region where the radius is not highly sensitive to the mass. At sufficiently high masses, the hydrogen in the core of the object will undergo fusion, the temperature will rise, and the zero-temperature relations shown in Figure 33.6 are no longer applicable. However, for planets and white dwarf stars, Figure 33.6 is applicable. An important consequence of these considerations is that for

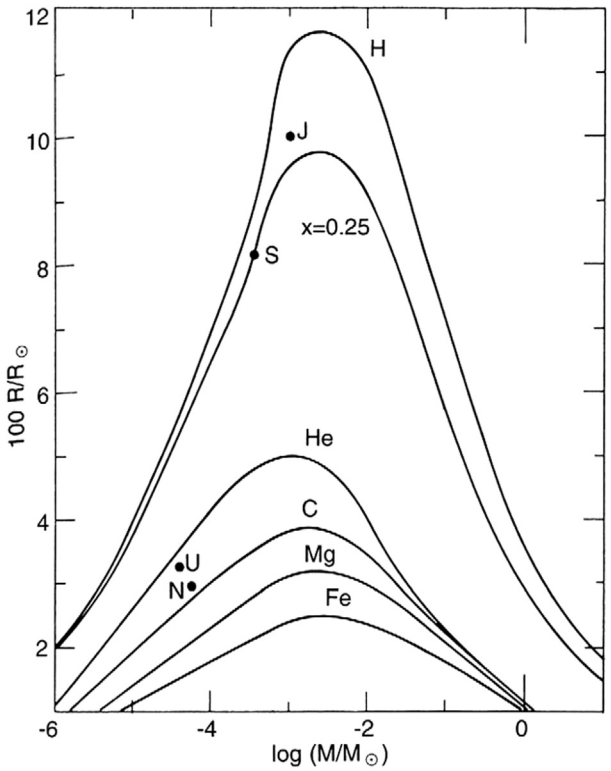

FIGURE 33.6 Mass-radius curves for objects of various compositions at zero temperature. Curve labeled $x = 0.25$ is for an approximately solar mixture of hydrogen and helium. Points J, S, U, and N represent Jupiter, Saturn, Uranus, and Neptune, respectively. Radius is in units of hundredths of a solar radius and mass is in units of solar masses ($1R_\odot = 6.96 \times 10^5$ km and $1\ M_\odot = 1.99 \times 10^{33}$ g). Jupiter and Saturn are clearly composed predominantly of hydrogen and helium; Uranus and Neptune must have a large complement of heavier elements. Figure from Zapolsky and Salpeter (1969).

any given composition, there is a maximum radius that a planet lacking a significant internal heat source can have. For solar composition, the maximum radius is about 80,000 km for a planet with about four times Jupiter's mass. Very young giant planets, which are still hot from their formation, can be larger. As we discuss below, some extrasolar planets also have unexpectedly large radii.

The total mass and radius of each Jovian planet are plotted on Figure 33.6 as well. This figure immediately proves that Jupiter must be composed primarily of hydrogen and helium. The maximum radii of planets composed of heavier, cosmically abundant elements are all much smaller. For example, only if Jupiter were very hot and very thermally expanded could carbon be a dominant constituent. But Jupiter's observed heat flux rules out a very hot ($>10^7$ K) internal state. Thus, Jupiter must primarily consist of a mixture of hydrogen and helium. Saturn's position on the graph implies a greater abundance of elements heavier than hydrogen, but still a primarily hydrogen bulk composition. Uranus and Neptune lie well below the mass–radius curve for hydrogen, thus revealing an appreciable component of heavier elements in their interiors. In Section 5, we will discuss giant planets around other stars, for which the only properties we can determine are radii and masses. For these planets, we can get a good estimate of the percentage of their mass that is made of hydrogen and helium, compared to the **heavy elements**.

Although the mass–radius relations clearly reveal the bulk composition of Jupiter and Saturn, they do not reveal information about the distribution of material inside the planet. It is here that the shape and gravitational harmonics enter the calculation. The response coefficient Λ_2 measures the response of the planet to its own rotation. For a uniform, hydrogen-rich material, $\Lambda_2 = 0.17$. Values smaller than 0.17 indicate a reduced gravitational response to rotation compared with that of the uniform composition hydrogen-rich planet. Such a reduced response results when more mass is concentrated toward the center of the planet. Thus, the smaller the Λ_2, the greater the degree of central condensation.

Λ_2 Varies (see Table 33.1) from 0.16 for Jupiter to 0.11 for Saturn. The mass–radius relations show that the Jovian planets are not pure hydrogen and their Λ_2 values suggest that they are centrally condensed. Hence the heavier constituents are not uniformly distributed in radius but are concentrated toward the center of each planet. Jupiter exhibits the least central condensation; Saturn and Uranus are most centrally condensed. Thus we begin to construct an elementary interior model.

Finally, the gravitational harmonics, J_2, J_4, and J_6, probe the detailed variation of the various planetary constituents. To simplify the interpretation of these harmonics, early interior models for Jupiter and Saturn tended to employ three distinct compositional zones: an inner rocky core, an icy core surrounding the rock one, and a hydrogen/helium envelope. More modern models allow the composition of various zones to vary gradually between layers and allow the outer envelopes to be enriched over solar abundance. The primary unknowns to be found from interior modeling are the mass of the rocky/icy core and the abundance of helium and other heavy elements in the envelope.

5.2. Jupiter

Jupiter contains more mass than all the other planets combined. Since its gravitational harmonics are also well measured, Jupiter serves as a test bed for theoretical understanding of Jovian interiors. The observed physical characteristics of Jupiter are listed in Table 33.1. From *Galileo Entry Probe* data, abundance of methane in Jupiter's atmosphere is about 3.5 times the solar abundance and the abundance of ammonia is about five times the solar abundance. Water does not show such enrichment, but it

has been argued that the *Galileo Entry Probe* fell into an anomalously dry region of Jupiter's atmosphere.

The general structure of Jupiter's interior was briefly described in Section 1. Modern interior models attempt to specifically determine the degree of enrichment of heavy elements in the hydrogen/helium envelope of the planet. The atmospheric enrichment of methane and ammonia provides some indication that heavy element enrichment in the deeper interior may be expected. Jupiter's Λ_2 implies that Jupiter is not homogeneous but is slightly centrally condensed. Indeed, detailed modeling has shown that Jupiter's current core is less than 15 Earth masses and there may not be a core at all. The size and composition of Jovian planet cores and the amount of heavy element enrichment in the envelopes have a bearing on the scenarios by which they are supposed to have formed.

The variation of density with radius for two typical Jupiter models is shown in Figure 33.7. It should be emphasized that these are two Jupiter models that are consistent with all available constraints. Other equally valid interior models exist. Figure 33.8 shows the mass of heavy elements in the core vs heavy elements in the hydrogen–helium envelope for a large number of Jupiter (and Saturn) models. Any model within the hatched region is a valid interior model for each planet, given the current model uncertainties. For Saturn, models with a homogeneous H/He envelope and distinct core are shown, which match the planet's gravity field. For both Jupiter and Saturn, modelers have recently applied state-of-the-art first principles H/He EOS. A feature of Jupiter modeling over the past 30 years is that as we have gained better knowledge of the EOS of hydrogen, the calculated mass of the core has shrunk.

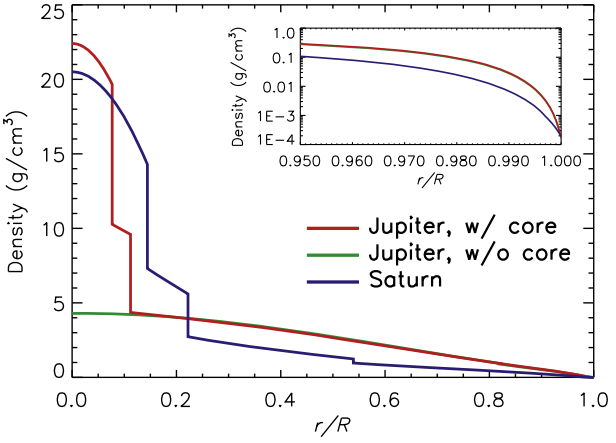

FIGURE 33.7 Density as a function of normalized radius for Jupiter and Saturn models. A helium deficit in molecular hydrogen regions and corresponding helium enrichment in metallic regions is responsible for the small density change near 0.55 *r/R* is Saturn. For Jupiter, a model with and without a core is shown. For the models with a core, the core is assumed to be ices overlying rock.

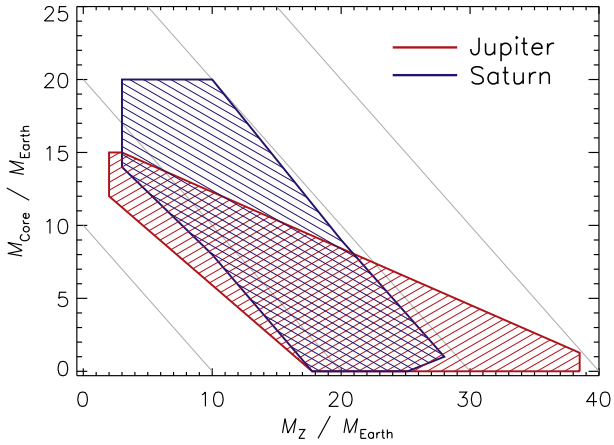

FIGURE 33.8 Earth masses of heavy elements in the hydrogen–helium envelope vs Earth masses of heavy elements in the core for Jupiter and Saturn. Models for Saturn include an H/He envelope that is uniform in its heavy element enrichment. Models for Jupiter include similar uniform models (models with large cores) and those where the H/He envelope is broken up into two layers, with an inner layer more enriched in heavy elements. These models have smaller cores and better fit the gravity field.

Surrounding the core is an envelope of hydrogen and helium. The temperature and pressure at the bottom of the hydrogen–helium envelope are near 15,000–20,000 K and 40 Mbar, respectively, for typical models. The gravitational harmonics require the envelope to be denser at each pressure level than a model that has only a solar mixture of elements. Thus the envelope must be enriched in heavy elements compared to a purely solar composition. The total mass of heavy elements is constrained between 10 and 40 Earth masses. If Jupiter had only a solar abundance of heavy elements, this value would be six Earth masses. This means that, averaged throughout the planet, Jupiter is enriched in heavy elements over solar abundances by a factor of 1.5–6.

Jupiter's atmospheric mass fraction of helium, $Y = 0.238 \pm 0.007$, is less than the solar abundance of about 0.28. This depletion is likely an indication that the process of helium differentiation, described more fully in Section 6, may have recently begun on Jupiter. The interior models do not provide a sufficiently clear view into the interior structure to determine if this is the case. The inferred interior structure is, however, compatible with limited helium differentiation.

Hydrogen and helium compose about 90% of Jupiter's mass. Most of the hydrogen exists in the form of metallic hydrogen. Jupiter is the largest reservoir of this material in the solar system. Convection in the metallic hydrogen interior is likely responsible for the generation of Jupiter's magnetic field. The transition from molecular to metallic hydrogen takes place about 10,000 km beneath the cloud tops, compared to about 30,000 km at Saturn. The exceptionally large volume of metallic hydrogen is likely responsible for the great strength of Jupiter's magnetic field.

5.3. Saturn

The observational constraints for Saturn are listed in Table 33.1. Although Saturn has less than one-third of Jupiter's mass, it has almost the same radius. This is a consequence of the relative insensitivity of radius to mass for hydrogen planets in Jupiter and Saturn's mass range (see Figure 33.6). Saturn's atmosphere, like Jupiter's, is enriched in methane and ammonia. The atmosphere's carbon enrichment (in the form of methane) was recently determined to be seven times the solar abundance. There are some indications that Saturn's atmosphere has less helium than Jupiter's but the error bars are large, since there has never been a Saturn entry probe. Since there is no known process by which Saturn could have accreted less helium than Jupiter, another process must be at work.

Saturn's interior is grossly similar to Jupiter's. The biggest difference is that Saturn's core may be as large as 20 Earth masses. A sample Saturn model is shown in Figure 33.7. Temperatures inside Saturn are also cooler. In the model shown in Figure 33.7, the temperature and pressure at the base of the metallic hydrogen envelope are 9000 K and 10 Mbar. Like Jupiter, there is strong evidence that Saturn's envelope is enriched in heavy elements over solar abundance. The mass of the core and the heavy elements in the hydrogen–helium envelope are also shown in Figure 33.8. The total mass fraction of heavy elements in Saturn is about 2½ times greater than in Jupiter. On the whole, Saturn is enhanced in heavy elements by a factor of 6–14, relative to the Sun. This may be an indication that more condensed icy material was available to be incorporated into Saturn at its location in the solar nebula. Nevertheless, as at Jupiter, hydrogen and helium are the dominant component of Saturn's mass ($\sim$75%).

Saturn's somewhat low atmospheric helium abundance implies that the process of helium differentiation (see Section 6) has begun inside the planet. This process results in removal of helium from the outer molecular hydrogen envelope of the planet and enhancement of helium in the deep interior. Thus the helium fraction should increase with depth in Saturn's interior. The inferred density structure is consistent with this widely accepted explanation for Saturn's low atmospheric helium abundance. If helium is presumed to be uniformly depleted from the outer molecular envelope of the planet, it can be self-consistently accounted for in the deeper interior. The unmixed helium may have actually been removed from molecular *and* metallic regions of the planet and settled down on top of the core. The models lack the sensitivity to confirm that this is definitely the case, however.

The inferred interior structure of Saturn is most consistent with the giant planet formation scenario known as nucleated collapse. In this scenario, a nucleus of rock and ice first forms in the solar nebula. When the nucleus has grown to about ten Earth masses, the gas of the nebula collapses down on the core, thus forming a massive hydrogen/helium envelope surrounding a rock/ice core. Planetesimals that accrete later in time cannot pass through the thick atmosphere surrounding the core. Instead, they break up and dissolve into the hydrogen/helium envelope. This scenario accounts for both the core of the planet and the enrichment of heavy elements in the envelope. It is possible that Jupiter formed via a different mechanism, such as the direct gravitational collapse of nebular gas. It is perhaps more likely that both Jupiter and Saturn had larger cores in the past, but have been dredged up by convective plumes over the past 4.5 Gyr. This mechanism could plausibly be more efficient in the hotter interior of Jupiter, where convection is more vigorous.

5.4. Uranus and Neptune

Before the *Voyager* encounters, Uranus and Neptune were assumed to have similar interior structures. This assumption was well justified given their similar radii, masses, atmospheric compositions, and location in the outer solar system. Uranus and Neptune were modeled as having three distinct layers: an inner rocky core, a large icy mantle, and a methane-rich, hydrogen–helium atmosphere. Little more could be said with precision since their atmospheric oblateness and interior rotation rates were not accurately known.

Upon its arrival at Uranus in 1986 and Neptune in 1989, *Voyager 2* provided the measurements needed to constrain interior models and provide individual identities for each planet. *Voyager* observed the structure of the magnetic field of both planets and measured their rotation rates. In both cases, the fields were off-center, tilted dipoles of similar strengths. *Voyager* also measured the higher order components of the gravitational fields of both planets. The abundance of carbon in both atmospheres is about 50 times the solar value. Although Uranus and Neptune have similar radii and masses, the differences are such that the mean density of Neptune is 24% higher than that of Uranus.

Voyager data revealed that, although similar, the interior structures of the two planets are not identical. As with Jupiter and Saturn, Λ_2 provides information on the distribution of mass inside each planet. If Uranus and Neptune had a similar distribution of mass in their interiors, their Λ_2 parameters would be similar. As Table 33.1 shows, for Uranus $\Lambda_2 = 0.119$, whereas for Neptune $\Lambda_2 = 0.136$. The larger value of Λ_2 for Neptune implies that Neptune is less centrally condensed than Uranus. Models show that this difference can be understood in terms of equal relative amounts of ice, rock, and gas that are simply distributed differently within the two planets. The two planets also

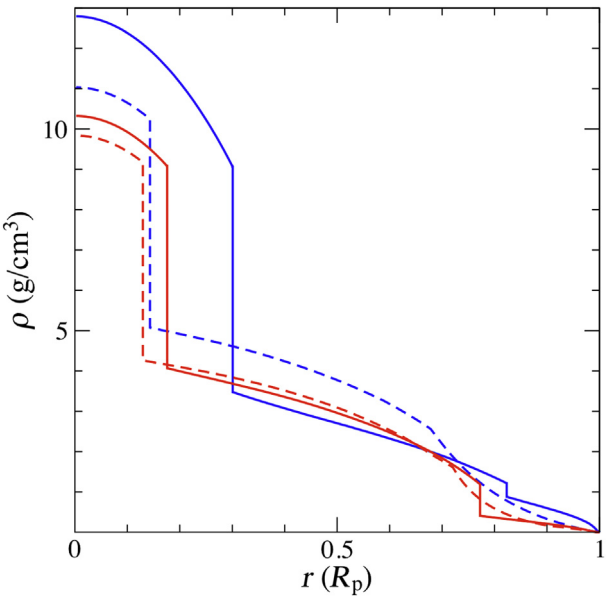

FIGURE 33.9 Density as a function of normalized radius for two Neptune models (blue) and two Uranus models (red). Solid curves use three distinct homogeneous layers, including a rocky core, a water-rich middle layer (but which includes some H/He), and an H/He-rich outer layer (but which includes some water). Dashed curves are four-layer models where the additional layer includes a gradient in the water abundance. A much wider variety of models are possible than can be shown here, including those with small or nonexistent rocky cores. Figure courtesy Nadine Nettelmann.

follow virtually the same pressure—density law, another indication that they have similar composition.

Models (Figure 33.9) of Uranus and Neptune's interior begin with a hydrogen-rich atmosphere that extends from the observable cloud tops to about 85% of Neptune's radius and 80% of Uranus' radius. The composition in this region does not vary significantly from the hydrogen-rich atmospheric composition. Near 0.3 Mbar and 3000 K ($0.85R_{\text{Neptune}}$ and $0.80R_{\text{Uranus}}$), the density rises rapidly to over 1000 kg/m^3. The density then increases steadily into the deep interior of both planets, where the pressure reaches 6 Mbar at 7000 K. The variation of density with pressure in this region is very similar to that found in the laboratory shock wave experiments on the artificial "icy" mixture known as "synthetic Uranus". The composition of this region is likely predominantly "icy", although models less dense then 100% icy composition are preferred. This may indicate that H/He may be mixed into the middle icy layer, or that the notion of a simple three-layer model is too simple. Since the density of rock/ice/gas mixtures can mimic the density of pure ice, the exact composition cannot be known with precision. Any hydrogen present in the deep interior would be in the metallic phase.

Interestingly, Uranus and Neptune models can be constructed that do not have rock cores. Other models with cores as large as 1 $M_\oplus$ are also consistent with the available data.

The total mass of hydrogen and helium in Uranus and Neptune is about 2 $M_\oplus$, compared to about 300 $M_\oplus$ at Jupiter. Given the relatively small amounts of gas compared to ices in Uranus and Neptune, these planets are aptly termed "ice giants", whereas Jupiter and Saturn are indeed "gas giants".

Shock compression measurements show that the fluids of the hot, ice-rich region of Uranus and Neptune are expected to be substantially ionized and dissociated. The large electrical conductivities of such fluids, coupled with the modest convective velocities predicted for the interiors of Uranus and Neptune, can generate and sustain the observed magnetic fields of the planets. One possible explanation for the complexity of their magnetic fields is that the electrically conductive region of these planets is comparatively close (within about 4000 km) to the cloud tops, a consequence of the ionization behavior of water, ammonia, and methane. This is consistent with the trend in field complexity seen at Jupiter and Saturn.

Uranus and Neptune likely represent failed gas giant planets. The time to accrete solid objects onto the growing ice and rock planetary cores was much longer in the outer solar nebula than at the orbital distances of Jupiter and Saturn. Thus Uranus and Neptune took longer to grow. By the time the nebular gas was swept away, these planets had not yet grown massive enough to capture substantial amounts of hydrogen and helium gas from the nebula. Perhaps if the nebular gas had persisted for a longer time, Uranus and Neptune would have grown large enough to complete the capture of a hydrogen/helium envelope. In that case, these planets might now more closely resemble the current Jupiter and Saturn.

5.5. Extrasolar Giant Planets

With current technology, we can learn very little of the physical state of most of the thousands of planets of planets that have been detected around other stars. The minimum masses of planets are obtained by observing the wobble induced on the parent star's orbit by the gravitational tug of the planet. But just knowing the minimum mass (since orbital inclinations are unknown) does not tell us much about the structure of a planet. However, there are hundreds of planets in orbit around other stars for which we have derived accurate masses *and* radii. The radii can be measured if the extrasolar planetary system has a favorable alignment, and the planet passes in front of its parent star (a transit), blocking a small fraction of the star's light. The planet's orbital inclination is then constrained to be essentially edge-on, so then the mass is also known. As was shown in Figure 33.6, with a determination of only the mass and radius of a planet, we can get to a reasonable understanding of its interior composition.

Since planets that orbit close to their parent stars are more likely to transit, as seen from the Earth, most discovered transiting planets are highly irradiated. New theoretical procedures have had to be developed to understand the structure of giant planets that are 100 times closer to their stars than Jupiter is to the Sun and hence receive intense stellar irradiation. This irradiation slows the cooling of the planet and hence slows the contraction of a giant planet with time. Our understanding of giant planets at small orbital distances is progressing, but the results are very surprising. Figure 33.10 shows the radius and mass of nearly 200 transiting planets, as compared to our solar system's planets. The density of these planets can be read from the dotted curves.

It is clear that there is *tremendous* diversity among the sample of detected planets. Two planets with the same mass can have radii that differ by a factor of two. There are two immediate implications. Many of the hottest transiting gas giants have been affected by some mechanism that has dramatically slowed, or even halted, planetary contraction. In addition, since some planets are smaller than Jupiter and Saturn, some of these planets are even more strongly enhanced in heavy elements than our Jovian planets.

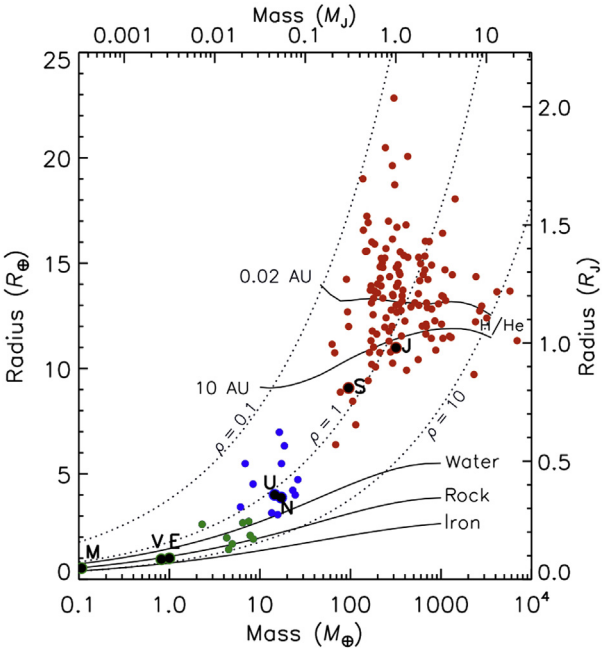

FIGURE 33.10 Mass vs radius for nearly 200 transiting planets. Jupiter, Saturn, Uranus, Neptune, Earth, Venus, and Mars are shown by black capital letters. Gas giants are shown in red, planets that may have thinner H/He envelopes (like Uranus and Neptune) are shown in blue, and low-mass, relatively dense planets are shown in green. Models for pure iron, rock, and water planets are shown as black curves. Models for 4.5-Gyr-old pure H/He gas giants at 10 AU and 0.02 AU from the Sun are shown as black curves as well. Dotted curves of constant density (in g/cm^3) are overplotted.

The "radius anomaly" question has not yet been solved, but it is now reasonably clear that the most strongly irradiated planets have the largest radii, and that the relatively cool planets below 1000 K do not appear inflated. The most promising postulated radius inflation mechanisms invoke ways to transport a small fraction of the large amount of absorbed stellar flux into the deep interior. These transport mechanisms generally involve the absorbed stellar flux driving fast winds in the atmosphere, with a small fraction of this wind kinetic energy dissipated in the deep atmosphere or the top of the convective interior. Studies of cooler, noninflated planets show that Jupiter- and Saturn-like enrichments of heavy elements, over parent star abundances, are extremely common. At the extreme enrichment end, the relatively small radii of some planets that are several Jupiter masses imply several hundred Earth masses of heavy elements within their interiors.

6. JOVIAN PLANET EVOLUTION

The amount of energy radiated by each of the Jovian planets, except possibly for Uranus, is greater than the amount of energy that they receive from the Sun (see Table 33.1). This internal heat source is far too large to be explained by decay of radioactive elements in the rock cores of the planets. Temperatures, even in the deep interior, are far below the 10,000,000 K required for thermonuclear fusion. The source of the excess energy is gravitational potential energy that was converted to heat during the planets' formation and stored in their interiors. (See The Origin of the Solar System.)

The potential energy of gas and solids in the solar nebula was converted to thermal energy when they were accreted onto the forming planet. Over time, the planets radiated energy into space and cooled, slowly losing their primordial energy content. Thus all four Jovian planets were initially warmer than they are now. During the early evolutionary stages the planets contracted as they cooled, thereby releasing even more gravitational potential energy. Today, the planets all cool at essentially constant radius because the internal pressures depend only slightly on temperature. The coupled contraction and cooling is known as Kelvin–Helmholtz cooling.

Evolutionary models test whether Kelvin–Helmholtz cooling can account for the current observed heat flows of the Jovian planets. In these calculations, a series of sequentially cooler planetary interior models is created with the last model representing the present-day planet. The time elapsed between each static model is calculated and thus the evolutionary age of the planet is found.

Models predict that Jupiter should have cooled from an initially hot state (accompanied by an atmospheric temperature greater than about 700 K) to its current temperature in about 4.5 billion years. Since this is about the age of

the solar system, the Kelvin–Helmholtz model is judged a success for Jupiter. For Saturn, however, the model is less successful. The models suggest that Saturn, with its current heat flow, should be about 2 billion years old. Since there is no reason to believe that Saturn formed 2.5 billion years later than Jupiter, another heat source must be adding to Saturn's Kelvin–Helmholtz luminosity. This leads to the hypothesis that differentiation of helium in the interior provides additional thermal energy to the planet.

The helium depletion hypothesis holds that as Saturn has cooled from an initially warmer state with the solar abundance of helium throughout, its interior reached the point (near 2 Mbar and 8000 K) at which hydrogen and helium no longer mix in all proportions. Like oil and vinegar in salad dressing, the hydrogen and helium are separating into different phases.

As the helium-rich drops form in Saturn's envelope and fall to deeper, warmer layers of its interior, the helium eventually again mixes with hydrogen. Over time, this rainfall is depleting the supply of helium in the outer envelope and visible atmosphere and enriching the helium content deeper in the interior, close to the core. The overall planetary inventory of helium remains constant. This model is compatible with the observed depletion at Saturn. Jupiter, with a warmer interior and smaller helium depletion, has apparently only recently begun this process.

This process of helium differentiation liberates gravitational potential energy as the drops fall. The helium abundance in a giant planet's atmosphere is difficult to determine without an entry probe. If the value for Saturn's atmosphere is correct, then the helium droplets in Saturn must be raining down very far into the planet, possibly all the way down the planet's core. No other process can simultaneously explain Saturn's anomalously high heat flow and the observed atmospheric depletion of helium. Observations from the *Cassini* spacecraft will allow for a better determination of the helium abundance (and the abundances of many other compounds) in Saturn's atmosphere.

The problem for Uranus and Neptune is somewhat different. The Kelvin–Helmholtz hypothesis predicts a correct age for Neptune, but an age that is too large for Uranus. In other words, the model predicts that Uranus should have a higher heat flow at the current time than it is observed to have. The problem is quite severe, since Uranus has no detectable heat flow. There are several possible resolutions to this contradiction.

One possibility is that gradients in the composition of Uranus with radius have served to impede convection in the deep interior. Composition gradients, for example, a gradual increase in the rock abundance with depth, can severely limit heat flow from the planet. In such a case, only the outermost layers could transport energy by convection to the atmosphere and cool effectively to space, thus producing a lower than expected heat flow. More of Neptune's interior than that of Uranus might be convective, thus explaining its higher current heat flow. Of course if this hypothesis were correct, then the existing interior models of these planets would have to be revised, since an initial assumption that the planets are fully convective would have been violated. Inhibition of convection in the deep interior by this mechanism has been proposed as one explanation for the strong nondipole component of both planets' magnetic fields.

The strongly irradiated extrasolar gas giants, in the absence of an additional energy source, are thought to evolve much like Jupiter, except that their interiors cool, and the planets contract, more slowly. The incident stellar flux leads to a radiative zone with a shallow temperature gradient to pressure of up to $\sim$1 kbar, 1000 times deeper than in Jupiter. This limits how quickly the interior heat flux can escape from the planet. However, this simple picture should limit giant planet radii to values 20% larger than Jupiter, whereas planets twice the radius of Jupiter have been found. Clearly there is missing physics. Finding more transiting planets, with a variety of radii, masses, and orbital separations will allow for a better understanding of how stellar irradiation effects the cooling of giant planets.

7. FUTURE DIRECTIONS

Models of Jovian planetary interiors have constrained the mass of each planet's core and the approximate composition of their envelopes. These results have provided important constraints on the processes by which these planets form. In turn, formation models place limits on the mass, composition, and evolution of the solar nebula. Further progress, however, requires even tighter limits on the interior structure of these planets. Sufficiently detailed interior models may even provide constraints on the EOS of hydrogen. Since Jupiter is the largest reservoir of metallic hydrogen in the solar system, it may potentially resolve issues such as the exact pressure of the transition between molecular and metallic hydrogen.

One might expect that in the future, more accurate measurements of each planet's gravitational harmonics would help to address questions such as these. The higher order moments, however, are most sensitive to the density distribution in the outer 10 or 20% of the planetary radius. Thus, little additional information about the deep interior is likely to be forthcoming from such observational improvements. The higher order harmonics do, however, provide some information about the state of rotation of the outer layers and may help address questions regarding the degree of differential rotation in the Jovian planets. For example, it is unknown if Jupiter rotates completely as a solid body, or if different cylindrical regions of its interior rotate at different rates.

The NASA spacecraft Juno, now heading toward a 2016 arrival at Jupiter, will answer this and other questions. Juno will be placed into a low polar orbit such that the spacecraft will readily be able to measure additional higher order harmonics up to J_{12}, which will allow for a determination of planet's interior rotation. Juno may measure Jupiter's **moment of inertia** which would help to constrain the core size. In addition, the spacecraft will observe microwave emission from below the "weather layer" of the planet's atmosphere (100 bars) to determine the deep abundance of water and ammonia. The planet's magnetic field will also be mapped in unprecedented detail. Together, these new measurements should shed new light on the interior structure of the planet.

Further improvements in delineating the EOSs of Jovian planetary components will help to clarify their interior structures. Better knowledge of the behavior of planetary constituents and their mixtures at high pressure will enable more accurate interior models to be constructed. Yet any possible dramatic changes in understanding are unlikely to result from such improvements. Only significantly new and different sources of information offer the potential of providing fundamentally new insights into the interior structure of these planets.

Jovian seismology is one particularly promising new avenue of research into these planetary interiors. Much of our knowledge of the interior structure of the Earth arises from study of seismic waves that propagate through the interior of the planet. The speed and trajectory of these waves carry information about the composition and structure of the Earth's interior. During the collisions of the fragments of **comet** Shoemaker-Levy 9 with Jupiter, several experiments attempted to detect seismic waves launched by the impacts. If these waves had been detected, they would have provided a direct probe into the interior structure of Jupiter.

Another avenue for Jovian seismology is to detect resonant acoustic modes trapped inside Jupiter. The frequency of a given Jovian oscillation mode depends on the interior structure of the planet within the region in which the mode propagates. Thus measurement of the frequencies of a variety of modes would provide information on the overall interior structure of the planet. Indeed, the study of such modes on the Sun, a science known as helioseismology, has revolutionized our knowledge of the solar interior. A number of attempts have been made to detect the Jovian oscillations with various techniques. Such observations and data analysis are difficult and interpretation of the available data has been limited by the restricted number of observing nights on large telescopes. Nevertheless, an analysis of the available data strongly suggests that Jupiter's oscillations have indeed been detected. There is also emerging evidence that certain wavelike features in Saturn's C-ring are created by periodic perturbations to the gravitational field of the planet induced by seismic oscillations of Saturn. The exact locations of these ring features depend upon the seismic mode frequencies and thus the internal structure of Saturn.

Definitive detection of oscillations of any Jovian planet would first serve to accurately determine the core size and rotation profile of the planet. Since such determinations would remove two important sources of uncertainty surrounding the interior structure, more information could then be gleaned from the traditional interior model constraints. Seismology might also help to constrain more accurately the location of the transition from molecular to metallic hydrogen in Jupiter's interior. If so, seismology may ultimately provide the tightest constraints on the hydrogen EOS and interior structure of Jovian planets.

Together with a refined understanding of the interiors of our solar system's giant planets, additional understanding of giant planet interiors will come from extrasolar planets. Determinations of the radii of transiting extrasolar planets will allow us to build up a statistical sample to learn how the radius of planets change as a function of mass, age, the amount of heavy elements available in the system (which can be estimated from spectra of the parent star), and the amount of irradiation the planet receives from its parent star. The interiors of giant planets will likely yield many additional surprises as more extrasolar planets are found. (See Extra-Solar Planets.)

4.5.2. The Outer Irregular Moons 777
Acknowledgment **777**
Bibliography **777**

A planetary satellite is any one of the celestial bodies in orbit around a planet, which is known as the **primary body**. They range from large, planetlike, geologically active worlds with significant atmospheres, such as Neptune's satellite Triton and Saturn's satellite Titan, to tiny irregular objects tens of kilometers in diameter. The satellites in the inner solar system—the two moons of Mars and the Earth's Moon—are composed primarily of rocky material. The satellites of the outer solar system, with the exception of Io, all have as major components some type of frozen volatile, primarily water ice, and also methane, ammonia, nitrogen, carbon monoxide, carbon dioxide, or sulfur dioxide existing alone or in combination with other volatiles. As of the end of 2013, the planets have among them a total of 173 known satellites (compare the list of satellites in the appendix). There undoubtedly exist many more undiscovered small satellites in the outer solar system. The relative sizes of the main satellites are illustrated in Figure 34.1. Table 34.1 is a summary of their characteristics. This chapter covers the satellites of Mars, Jupiter, Saturn, Uranus, and Neptune, except the Galilean satellites (the four largest moons of Jupiter), Triton, Titan, and Enceladus (*see* The volcanic Moon; Galilean Satellites; Titan; Enceladus; Triton; Pluto and Charon).

1. SUMMARY OF CHARACTERISTICS

1.1. Discovery

None of the satellites of the outer planets was known before the invention of the telescope. When Galileo turned his telescope to Jupiter in 1610, he discovered the four large satellites in the Jovian system. His observations of their orbital motion around Jupiter in a manner analogous to the motion of the planets around the Sun provided important evidence for the acceptance of the heliocentric (Sun-centered) model of the solar system. These four moons—Io, Europa, Ganymede, and Callisto—are sometimes called the Galilean satellites.

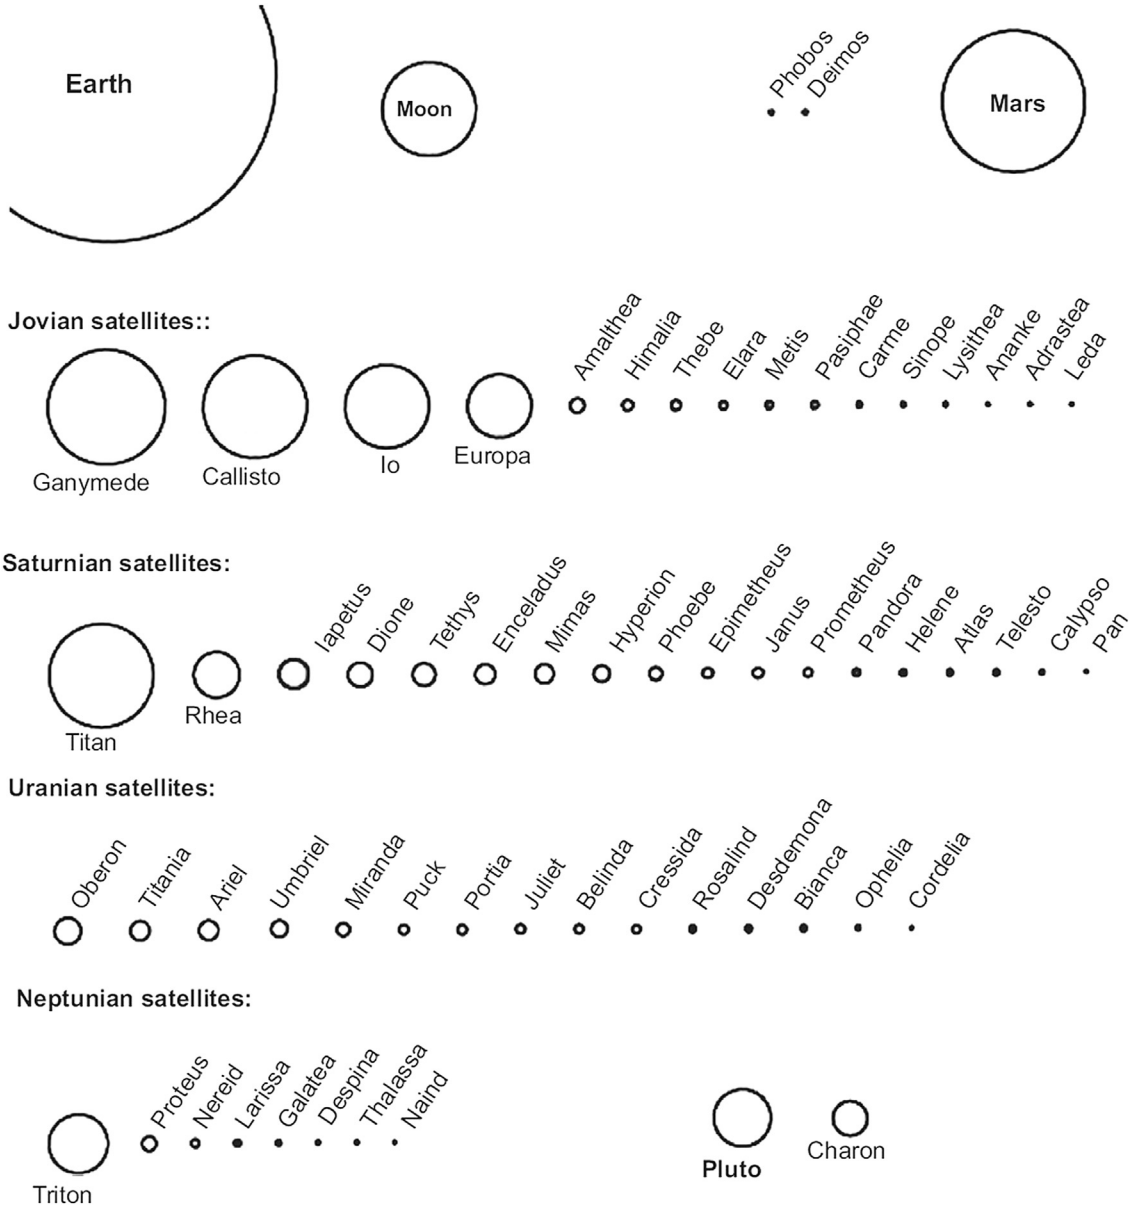

FIGURE 34.1 The relative sizes of the main planetary satellites.

In 1655, Christian Huygens discovered Titan, the giant satellite of Saturn. Later in the seventeenth century, Giovanni Cassini discovered the four next largest satellites of Saturn. More than 100 years would pass before the next satellite discoveries were made: the Uranian satellites Titania and Oberon and two smaller moons of Saturn. As telescopes acquired more resolving power in the nineteenth century, the family of satellites grew (see Table 34.1 and Figure 34.1). The smallest satellites of Jupiter and Saturn, and all the small satellites of Uranus and Neptune (except Nereid), were discovered during flybys of the *Pioneer* and *Voyager* spacecraft (see Table 34.2). Many small satellites have been recently discovered by sensitive charge-coupled device (CCD) cameras attached to large ground-based telescopes, the *Galileo*, *Voyager*, and Cassini spacecraft, and the Hubble Space Telescope.

The natural planetary satellites are generally named after figures in world mythologies that were associated with the namesakes of their primaries. They are also designated by the first letter of their **primary** and an Arabic numeral assigned in order of discovery: Io is J1, Europa is J2, and so on. When satellites are first discovered but not yet confirmed or officially named, they are known by the year in which they were discovered, the initial of the primary, and a number assigned consecutively for all solar system discoveries, for example,

TABLE 34.1 Properties of the Main Planetary Satellites (Compare the list of satellites and their properties in the appendix)

Satellite	Distance from Primary (10^3 km)	Revolution Period (days) R = Retrograde	Orbital Eccentricity	Orbital Inclination (Degrees)	Radius (km)	Density (g/cm^3)	Visual Geometric Albedo	Discoverer	Year Discovered

Cassini-Huygens	Saturnian satellites	2004–2017 (planned)
Mars Reconnaissance Orbiter	Phobos and Deimos from Mars orbit	2006–present

1980 J27. Official names for all satellites are assigned by the International Astronomical Union (IAU).

After planetary scientists were able to map geologic formations of the satellites from spacecraft images, they named many of the features after characters or locations from Western and Eastern mythologies. These names are also approved by the IAU.

1.2. Physical and Dynamical Properties

The motion of a satellite around its center of mass and its primary defines an ellipse with the primary at one of the foci. The orbit is defined by three primary orbital elements: (1) the semimajor axis, (2) the eccentricity, and (3) the angle made by the intersection of the plane of the orbit and the plane of the primary's spin equator (the angle of inclination). The orbits are said to be regular if they are in the same sense of direction (the prograde sense) as that determined by the rotation of the primary, and if their eccentricities and inclinations are low. The orbit of a satellite is irregular if its motion is in the opposite (or retrograde) sense of motion, if its orbit is highly eccentric (greater than ~5% of circular), or if it has a high angle of inclination (greater than ~5°). The majority of the outer planets' main satellites move in regular, prograde orbits. Many of the smaller satellites that move in irregular orbits are thought to be captured objects.

Except for the small, outer irregular moons, most of the planetary satellites present the same hemisphere toward their primaries, a state that is the result of tidal evolution. When two celestial bodies orbit each other, the gravitational force exerted on the nearside is greater than that exerted on the far side. The result is an elongation of each body to form tidal bulges, which can consist of solid, liquid, or gaseous (atmospheric) material. The primary tugs on the satellite's tidal bulge to lock its longest axis onto the primary–satellite line. The satellite, which is said to be in a state of **synchronous rotation**, keeps the same face toward the primary. Since this despun state occurs rapidly (usually within a few million years) and more easily at shorter distances from the primary, most of the inner natural satellites are in synchronous rotation. Satellites that are far away from the primary often maintain their original rotational period. One satellite of Saturn, Hyperion, rotates chaotically. Satellites that are in synchronous rotation generally exhibit an oscillating motion with respect to their primary to reveal more than half of their surfaces (for example, 59% of the Moon is visible from the Earth at some point). This motion, known as libration, is caused by differences between the satellite's average spin and the changing orbital velocity in elliptical orbits. Tidal forces can also induce pendulumlike swings away from an average rotation (forced libration).

The satellites of the outer solar system are unique worlds, each representing a vast panorama of physical processes. The two satellites of Mars and the small satellites of Jupiter and Saturn are irregular chunks of rock, ice, or mixtures of the two. They are perhaps captured asteroids or even objects from the Kuiper Belt that have been subjected to intensive meteoritic bombardment. Several of the satellites, including the Saturnian satellite Phoebe and areas of the Uranian satellites, are covered with **C-type** material, the dark, unprocessed, carbon-rich material found on the C **(carbonaceous)** class of asteroids. The surfaces of other satellites such as Hyperion and the dark side of Iapetus contain primitive matter that is spectrally red and is thought to be rich in organic compounds. Because these materials, which are common in the outer solar system, represent the material from which the solar system formed, understanding their occurrence and origin will yield clues on the state and early evolution of the solar system. In addition, the transport of organic matter from the outer solar system to the inner solar system, perhaps by comets, is generally concluded to be an essential step in the formation of life. Iapetus historically presented a particular enigma: one hemisphere is 10 times more reflective than the other (*see* Asteroids; Kuiper Belt).

Before the advent of spacecraft exploration, planetary scientists expected satellites to be geologically dead worlds. They assumed that heat sources were not sufficient to have melted their mantles to provide a source of liquid or semi-liquid ice or ice–silicate slurries. Reconnaissance of the icy satellite systems of the four outer giant planets by the two *Voyager* spacecraft uncovered a wide range of geologic processes, including currently active volcanism on Io and Triton. *Cassini* discovered active tectonic processes on Enceladus, a small satellite of Saturn. At least one additional satellite (Europa) may have current activity. The medium-sized satellites of Saturn and Uranus are large enough to have undergone internal melting with subsequent **differentiation** and resurfacing. Among the Galilean satellites, only Callisto lacks evidence for periods of such activity after formation.

Recent work on the importance of tidal interactions and subsequent heating has provided the theoretical foundation to explain the existence of widespread activity in the outer solar system. Another factor is the presence of nonice components, such as ammonia hydrate or methanol, which lower the melting point of near-surface materials. Partial melts of water ice and various contaminants—each with its own melting point and viscosity—provide material for a wide range of geologic activity. The realization that such partial melts are important to understanding the geologic history of the satellites has spawned interest in the rheology (viscous properties and resulting flow behavior) of various ice mixtures and exotic phases of ices that exist at extreme temperatures or pressures. Conversely, the types of features observed on the surfaces provide clues to the likely composition of the satellites' interiors. One key observable regarding the bulk composition of satellites is the density: lower densities imply higher ice content and lower rock content.

Because the surfaces of so many outer planet satellites exhibit evidence of geologic activity, planetary scientists have begun to think in terms of unified geologic processes that function throughout the solar system. For example, partial melts of water ice with various contaminants could provide flows of liquid or partially molten slurries that in many ways mimic terrestrial or lunar lava flows formed by the partial melting of mixtures of silicate rocks. The ridged and grooved terrains on satellites such as Ganymede, Enceladus, Tethys, and Miranda may all have resulted from similar tectonic activities. Finally, explosive volcanic eruptions occurring on Io, Triton, Earth, and possibly Enceladus may all result from the escape of volatiles released as the pressure in upward-moving liquids decreases (*see* Planetary Volcanism.).

2. FORMATION OF SATELLITES

2.1. Theoretical Models

Because the planets and their associated moons condensed from the same cloud of gas and dust at about the same time, the formation of the natural planetary satellites must be addressed within the context of the formation of the planets. The solar system formed 4.6 Ga. This age is derived primarily from radiometric dating of meteorites, which are thought to consist of primordial, unaltered matter (*see* The Origin of the Solar System).

The Sun and planets formed from a disk-shaped rotating cloud of gas and dust known as the protosolar nebula. When the temperature in the nebula cooled sufficiently, small grains began to condense. The difference in solidification temperatures of the constituents of the protosolar nebular accounts for the major compositional differences of the satellites. Since there was a temperature gradient as a function of distance from the center of the nebula, only those materials with high melting temperatures (e.g. silicates, iron, aluminum, titanium, and calcium) solidified in the central (hotter) portion of the nebula. Earth's Moon consists primarily of these materials. Beyond the orbit of Mars, carbon, in combination with silicates and organic molecules, condensed to form the **carbonaceous** material found on C-type asteroids. Similar carbonaceous material is found on the surfaces of the Martian moon Phobos, several of the Jovian and Saturnian satellites, regions of the Uranian satellites, and possibly Triton. In the outer regions of the asteroid belt, formation temperatures were sufficiently cold to allow water ice to condense and remain stable. Thus, the Jovian satellites are primarily ice–silicate admixtures (except for Io, which has apparently outgassed all its water). On Saturn and Uranus, these materials are predicted to be joined by methane and ammonia, and their hydrated forms. For the satellites of Neptune and Pluto, formation temperatures were low enough for other volatiles, such as nitrogen, carbon monoxide, and carbon dioxide, to exist in solid form. In general, the satellites that formed in the inner regions of the solar system are denser than the outer planets' satellites, because they retained a lower fraction of volatile materials.

After small grains of material condensed from the protosolar nebula, electrostatic forces caused them to stick together. Collisions between these larger aggregates caused meter-sized particles, or planetesimals, to be accreted. Finally, gravitational collapse occurred to form larger, kilometer-sized planetesimals. The largest of these bodies swept up much of the remaining material to create the protoplanets and their companion satellite systems. One important concept of planetary satellite formation is that a satellite cannot accrete within the **Roche limit**, the distance at which the tidal forces of the primary become greater than the self-gravity of the satellite.

The formation of the regular satellite systems of Jupiter, Saturn, and Uranus is sometimes thought to be a smaller scale version of the formation of the solar system. A density gradient as a function of distance from the primary does exist for the regular system of small, inner Neptunian

satellites and for the Galilean satellites (see Table 34.1). This implies that more volatiles (primarily ice) are included in the bulk composition as the distance increases. However, this simple scenario cannot be applied to Saturn or Uranus because their regular satellites do not follow this pattern.

The retrograde satellites are probably captured asteroids, Kuiper Belt Objects, or large planetesimals left over from the major episode of planetary formation. Except for Titan and Triton, the satellites are too small to possess gravitational fields sufficiently strong to retain an appreciable atmosphere against thermal escape. At least one satellite (Ganymede) has a magnetic field.

2.2. Evolution

Soon after the satellites accreted, they began to heat up from the release of gravitational potential energy. An additional heat source was provided by the release of mechanical energy during the heavy bombardment of their surfaces by remaining debris. The satellites Phobos, Mimas, and Tethys all have impact craters caused by bodies that were nearly large enough to break them apart; probably such catastrophes did occur. The decay of radioactive elements found in silicate materials provided another major source of heat. The heat produced in the larger satellites was sufficient to cause melting and chemical fractionation; the dense material, such as silicates and iron, went to the center of the satellite to form a core, while ice and other volatiles remained in the crust. A fourth source of heat is provided by tidal interactions. When a satellite is being tidally despun, the resulting frictional energy is dissipated as heat. Because this process happens very quickly for most satellites ($\sim$10 Million years), another mechanism involving orbital resonances among satellites is probably required to produce the heat for more recent resurfacing events. Gravitational interactions tend to evolve the orbital periods of the satellites within a system into multiples of each other. If two neighboring moons have orbital periods that are close to a ratio of small integers, a periodic extragravitational tug exerted by the moons when they are close will cause the periods of the orbits to evolve to exactly that ratio, a dynamical state known as a mean-motion resonance. In the Galilean system, for example, Io and Europa complete four and two orbits, respectively, for each orbit completed by Ganymede. The result is that the satellites meet each other at the same point in their orbits. The resulting flexing of the tidal bulge induced on these bodies by their mutual gravitational attraction causes significant heat production in some cases; this heating is related to an orbital eccentricity that is maintained by the resonance (*see* Planetary Impacts; Solar System Dynamics).

Some satellites, such as the Earth's Moon, Ganymede, and several of the Saturnian satellites, underwent periods of melting and active geology within a billion years of their formation and then became quiescent. Others, such as Io, Triton, Enceladus, and possibly Europa, are currently geologically active. For nearly a billion years after their formation, the satellites all underwent intense bombardment and cratering. The bombardment tapered off to a slower rate and presently continues. By counting the number of craters on a satellite's surface and making certain assumptions about the flux of impacting material, geologists are able to estimate when a specific portion of a satellite's surface was formed. Continual bombardment of satellites causes the pulverization of both rocky and icy surfaces to form a covering of fine material known as a **regolith**.

Many scientists expected that most of the craters formed on the outer planets' satellites would have disappeared owing to viscous relaxation. The two *Voyager* spacecraft revealed surfaces covered with craters that in many cases had morphological similarities to those found in the inner solar system, including central peaks, large ejecta blankets, and well-formed outer walls. Recent research has shown that the elastic properties of very cold ice provide enough strength to offset viscous relaxation. Silicate mineral contaminants or other impurities in the ice may also provide extra strength to sustain surface topography.

Planetary scientists classify the erosional processes affecting satellites into two major categories: endogenic, which includes all internally produced geologic activity, and exogenic, which encompasses the changes brought by outside agents. The latter category includes the following processes: (1) meteoritic bombardment and resulting gardening and impact volatilization; (2) magnetospheric interactions, including sputtering and implantation of energetic particles; (3) alteration by high-energy ultraviolet (UV) photons; and (4) accretion of particles from sources such as planetary rings.

Meteoritic bombardment acts in two major ways to alter the optical characteristics of the surface. First, the impacts excavate and expose fresh material (cf. the bright ray craters on the Moon, Ganymede, and the Uranian satellites). Second, impact volatilization and subsequent escape of volatiles result in a lag deposit enriched in opaque, dark materials. The relative importance of the two processes depends on the flux, size distribution, and composition of the impacting particles, and on the composition, surface temperature, and mass of the satellite. For the Galilean satellites, older geologic regions tend to be darker and redder, but both the Galilean and Saturnian satellites tend to be brighter on the hemispheres that lead in the direction of orbital motion (the so-called "leading" side, as opposed to the "trailing" side); this effect is thought to be due to preferential micrometeoritic gardening on the leading side due to systematic differences in impact velocities caused by the orbital motion of the satellite. The Uranian satellites show no similar dichotomy in albedo, but their leading

sides do tend to be redder, possibly due to more accretion of reddish meteoritic material on that hemisphere.

For satellites that are embedded in planetary **magnetospheres**, their surfaces are affected by magnetospheric interactions in three ways: (1) chemical alterations; (2) selective erosion, or sputtering; and (3) deposition of magnetospheric ions. In general, volatile components are more susceptible to sputter erosion than refractory ones. The overall effect of magnetospheric erosion is thus to enrich surfaces in darker, redder opaque materials. A similar effect is probably caused by the bombardment of UV photons, although much fundamental laboratory work remains to be done to determine the quantitative effects of this process (*see* Planetary Magnetospheres).

Sublimation and redeposition of frosts has also altered the surfaces of satellites. Triton, which has a thin atmosphere, undergoes seasonal transport of nitrogen on its surface. Thermal segregation, which is the tendency of frosts to collect in brighter, colder regions of the surface and accentuate existing albedo differences, is a significant effect for Iapetus and perhaps other moons.

3. OBSERVATIONS OF SATELLITES

3.1. Telescopic Observations

3.1.1. Spectroscopy

Before the development of interplanetary spacecraft, all observations from the Earth of objects in the solar system were obtained by naked eye observers and telescopes. One particularly useful tool of planetary astronomy is spectroscopy, or the acquisition of spectra from a celestial body.

Each component of the surface or atmosphere of a satellite has a characteristic pattern of absorption and emission bands. Comparison of the astronomical spectrum with laboratory spectra of materials that are possible components of the surface yields information on the composition of the satellite. For example, water ice has a series of absorption features between 1 and 4 μm. The detection of these bands on three of the Galilean satellites and several satellites of Saturn and Uranus demonstrated that water ice is a major constituent of their surfaces. Other examples are the detections of SO_2 frost on the surface of Io, methane in the atmosphere of Titan, nitrogen and carbon dioxide on Triton, and carbon monoxide on Pluto.

3.1.2. Photometry

Photometry of planetary satellites is the accurate measurement of radiation from their surfaces or atmospheres. These measurements can be compared to light-scattering models that depend on physical parameters, such as the porosity of the optically active upper surface layer, the albedo of the material, and the degree of topographic roughness. These models predict brightness variations as a function of solar **phase angle** (the angle between the observer, the Sun, and the satellite). Like the Earth's Moon, the planetary satellites present changing phases to an observer on the Earth. As the face of the satellite becomes fully illuminated to the observer, the integrated brightness exhibits a nonlinear surge in brightness that most likely results from the disappearance of mutual shadowing among surface particles. The magnitude of this surge, known as the "**opposition effect**", is greater for a more porous surface.

One measure of how much radiation a satellite reflects is the **geometric albedo**, p, which is the disk-integrated brightness at "full moon" (or a phase angle of 0°) compared to a perfectly reflecting, diffuse disk of the same size. The **phase integral**, q, defines the angular distribution of radiation over the sky:

$$q = 2\int_0^{\pi} \Phi(\alpha)\sin\alpha \, d\alpha$$

where $\Phi(\alpha)$ is the disk-integrated brightness and α is the phase angle.

The **Bond albedo**, which is given by $A = p \times q$, is the ratio of the integrated flux reflected by the satellite to the integrated flux received. The geometric albedo and phase integral are wavelength dependent, whereas a true (or bolometric) Bond albedo is the total power obtained by integrating energy at all wavelengths. Thus, it is the fraction of the incident power reflected, and $(1 - A)$ is the fraction absorbed.

Another ground-based photometric measurement that has yielded important information on satellites' surfaces is the integrated brightness of a satellite as a function of orbital angle. For a satellite in synchronous rotation with its primary, the subobserver geographical longitude on the satellite is equal to the longitude of the satellite in its orbit. Observations showing significant albedo and color variegations for Io, Europa, Rhea, Dione, and especially Iapetus suggest that diverse geologic terrains coexist on these satellites. This view was confirmed by images obtained by the *Voyager* spacecraft.

Another important photometric technique is the measurement of radiation as one celestial body occults, or blocks, another body. Time-resolved observations of occultations yield the flux emitted from successive regions of the eclipsed body. This technique has been used to map albedo variations on Pluto and its satellite Charon and to map the distribution of infrared emission—and thus volcanic activity—on Io.

3.1.3. Radiometry

Satellite radiometry is the measurement of radiation that is absorbed and reemitted at thermal wavelengths. The

distance of each satellite from the Sun determines the mean temperature for the equilibrium condition that the power of the absorbed radiation is equal to the power of the emitted radiation:

$$\pi R^2 \left(F/r^2\right)(1-A) = 4\pi R^2 \varepsilon \sigma T^4$$

$$T = \left(\frac{(1-A)F}{4\sigma\varepsilon r^2}\right)^{1/4}$$

where R is the radius of the satellite, r is the Sun–satellite distance, ε is the emissivity, σ is Stefan–Boltzmann's constant, A is the Bond albedo, and F is the incident solar flux (this equation assumes rotation sufficiently rapid to produce a constant surface temperature; for more slowly rotating bodies it is assumed that only the surface facing the sun is heated and thus radiates over $2\pi R^2$). Typical mean temperatures in Kelvin for the satellites are as follows: the Earth's Moon, 280; Europa, 103; Iapetus, 89; the Uranian satellites, 60; and the Neptunian satellites, 45. For thermal equilibrium, measurements as a function of wavelength yield a blackbody curve characteristic of T: in general, the temperatures of the satellites closely follow the blackbody emission values. Some discrepancies are caused by a weak **greenhouse** effect (in the case of Titan), or the existence of volcanic activity (in the case of Io).

Another possible use of radiometric techniques, when combined with photometric measurements of the reflected portion of the radiation, is the estimate of the diameter of a satellite. A more accurate method of measuring the diameter of a satellite from Earth involves measuring the light from a star as it is occulted by the satellite. The time the starlight is dimmed is proportional to the satellite's diameter.

A third radiometric technique is the measurement of the thermal response of a satellite's surface as it is being eclipsed by its **primary**. The rapid loss of heat from a satellite's surface indicates a thermal conductivity consistent with a porous surface. Eclipse radiometry of Phobos, Callisto, and Ganymede suggests that these objects all lose heat rapidly. The measurement of the thermal conductivity of the Saturnian satellites, particularly Mimas and Tethys, by the *Cassini* spacecraft suggests that parts of their surfaces may have been annealed by high-energy elections in Saturn's magnetosphere.

3.1.4. Polarimetry

Polarimetry is the measurement of the degree of polarization of radiation reflected from a satellite's surface. The polarization characteristics depend on the shape, size, and optical properties of the surface particles. Generally, the radiation is linearly polarized and is said to be negatively polarized if it lies in the scattering plane and positively polarized if it is perpendicular to the scattering plane. Polarization measurements as a function of solar phase angle for atmosphereless bodies are negative at small phase angles; comparisons with laboratory measurements indicate that this is characteristic of complex, porous surfaces consisting of multisized particles. In 1970, ground-based polarimetry of Titan that showed it lacked a region of negative polarization led to the correct conclusion that it has a thick atmosphere.

3.1.5. Radar

Planetary radar is a set of techniques that involve the transmission of radio waves to a remote surface and the analysis of the echoed signal. Among the outer planets' satellites, the Galilean satellites, Titan, and Iapetus have been observed with radar (*see* Planetary Radar).

3.2. Spacecraft Exploration

Interplanetary missions to the planets and their moons have enabled scientists to increase their understanding of the solar system more in the past 35 years than in all of previous scientific history. Analysis of data returned from spacecraft has led to the development of whole new fields of scientific endeavor, such as planetary geology. From the earliest successes of planetary imaging, which included the flight of a Soviet *Luna* spacecraft to the far side of the Earth's Moon to reveal a surface unlike that of the visible side, devoid of smooth lunar plains, and the crash landing of a United States *Ranger* spacecraft, which sent back pictures showing that the Earth's Moon was cratered down to meter scales, it was evident that interplanetary imaging experiments had immense capabilities. Table 34.2 summarizes the successful spacecraft missions to the planetary satellites, not including the Moon.

The return of images from space is very similar to the transmission of television images. A camera records the level of intensity of radiation incident on its focal plane, which holds an array of detectors. A computer onboard the spacecraft records these numbers and sends them by means of a radio transmitter to the Earth, where another computer reconstructs the image.

Although images are the most spectacular data returned by spacecraft, a whole array of equally valuable experiments are included in each scientific mission. For example, a gamma-ray spectrometer aboard the lunar orbiters was able to map the abundance of iron and titanium on the Moon's surface. The *Voyager* spacecraft included an infrared spectrometer capable of mapping temperatures; an UV spectrometer; a photopolarimeter, which simultaneously measured the color, intensity, and polarization of light; and a radio science experiment that was able to measure the pressure of Titan's atmosphere by observing

how radio waves passing through it were attenuated. The *Cassini* spacecraft includes sensitive spectrometers covering wavelengths from the UV to the far infrared.

The *Pioneer* spacecraft, which were launched in 1972 and 1973 toward an encounter with Jupiter and Saturn, returned the first disk-resolved images of the Galilean satellites. But even greater scientific advancements were made by the *Voyager* spacecraft, which returned thousands of images of the satellite systems of all four outer planets, some of which are shown in Section 4. Color information for the objects was obtained by means of six broadband filters attached to the camera. The return of large numbers of images with resolution down to a kilometer has enabled geologists to construct geologic maps, to make detailed crater counts, and to develop realistic scenarios for the structure and evolution of the satellites.

Further advances were made by the *Galileo* spacecraft, which was launched in 1990 and began obtaining data at Jupiter in 1996. The mission consisted of a probe that explored the Jovian atmosphere and an orbiter designed to make several close flybys of the Galilean satellites. The orbiter contained both visual and infrared imaging devices, a UV spectrometer, and a photopolarimeter. The visual camera was capable of obtaining images with better than 20-m resolution. The spacecraft was intentionally crashed into Jupiter in September 2003 to avoid possible contamination with Europa in the future. (Europa is thought to have a subsurface ocean that may be an appropriate habitat for primitive life.) The *Cassini/Huygens* mission to Saturn was launched in 1997 and entered into orbit around Saturn in 2004 for at a 4-year in-depth study of the planet, its rings, satellites and magnetosphere. Its instruments include a camera, an imaging spectrometer, infrared and UV spectrometers, a radar system, and a suite of fields and particles experiments. In January 2005, the spacecraft jettisoned its *Huygens* probe into Titan's atmosphere where it parachuted to the surface; valuable data on the **ionosphere**, atmosphere, and surface of this unique world were obtained. The prime mission was followed by a 2-year extended mission, and then by a 7-year solstice mission, during which scientists planned to continue a study of seasonal changes in the system as well as changes in activity on Enceladus (*see* Planetary Exploration Missions).

4. INDIVIDUAL SATELLITES

4.1. The Satellites of Mars: Deimos and Phobos

Mars has two small satellites, Phobos and Deimos (fear and terror), which were discovered by the American astronomer Asaph Hall in 1877. They were named after the attendants of Mars in Greek mythology. The two bodies are barely visible in the scattered light from Mars in Earth-based telescopes. Most of what is known about Phobos and Deimos was obtained from the *Mariner 9*, *Viking 1* and *2, and Mars Express* missions (see Table 34.2). Their physical and orbital properties are listed in Table 34.1. Both satellites are shaped approximately like ellipsoids, and they are in **synchronous rotation**. Phobos, and possibly Deimos, has a **regolith** of dark material similar to that found on D or CM-type **(carbonaceous)** asteroids common in the outer asteroid belt. This similarity poses problems for theories of the satellites' origin, as their regular orbits suggest a formation around Mars rather than capture from asteroidal orbits. Late-stage addition of more primitive materials from an impact of one or more objects originating beyond the orbit of Mars, for example, from the asteroid belt or even the Kuiper Belt, might alleviate this problem.

Both satellites are heavily cratered, which indicates that their surfaces are at least 3 Billion years old (Figure 34.2). Deimos is distinctively smooth, possibly because of ejecta from its large, southern crater, possibly in combination with different regolith mechanical properties from Phobos. The surface of Phobos is extensively scored by linear grooves that define several planes parallel to the intermediate axis of Phobos (the leading—trailing direction) and also cut the huge impact crater Stickney (named after the Asaph Hall's wife, Angeline Stickney Hall, who collaborated with him in many of his astronomical observations). The groove origins

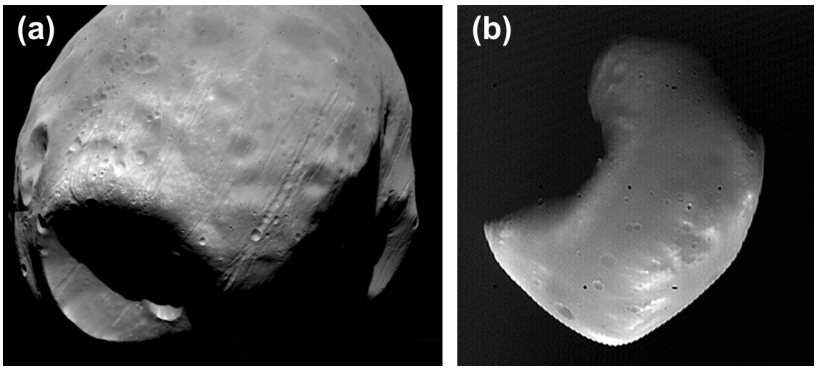

FIGURE 34.2 The two moons of Mars. (a) Phobos and (b) Deimos. Both pictures were obtained by the *Viking* Spacecraft.

remain controversial, possibly involving fractures or effects of secondary debris on Phobos' regolith. Tidal action is shrinking Phobos' orbit; the satellite will either disintegrate (perhaps to form a ring) or crash into Mars in about 100 Million years.

4.2. The Small Satellites of Jupiter

As late as 1979, Jupiter had only a dozen known small satellites (in addition to the Galilean satellites), including three discovered by the *Voyager* mission. As of November 2012, the planet had 67 known satellites; most of the new small satellites were discovered by sensitive CCD cameras and large telescopes. The small satellites are irregular in shape, and many may be captured objects.

Within the orbit of Io are at least four satellites: Thebe, Amalthea, Adrastea, and Metis (see Figure 34.3). Amalthea is a dark, reddish, heavily cratered object reflecting less than 5% of the visible radiation it receives; the red color is probably due to contamination by sulfur particles from Io. Little else is known about its composition except that the dark material may be carbonaceous. In addition to two large craters, Pan (100 km wide) and Gaea (80 km wide), Amalthea has mountains that are about 20 km high. In 2002, the *Galileo* spacecraft swooped to within 150 km of the moon's surface to find that its density is anomalously low, about that of water ice (1.0 g/cm^2). This result suggests that Amalthea has much internal void space and may be a "rubble pile" composed of an agglomeration of debris reaccreted from a collision long ago.

Adrastea and Metis, both discovered by *Voyager,* are the closest known satellites to Jupiter and move in nearly identical orbits just outside the outer edge of the thin Jovian ring, for which they may be a source of material. Between Amalthea and Io lies the orbit of Thebe, also discovered by *Voyager.* Little is known about the composition of these satellites, but they are most likely primarily rock—ice mixtures. The three inner satellites sweep out particles in the Jovian **magnetosphere** to form voids at their orbital positions.

Exterior to the Galilean satellites, there is a class of four satellites moving in highly inclined orbits (Lysithea, Elara, Himalia, and Leda). They are dark objects, reflecting only 2% or 3% of incident light, and may be similar to C- and **D-type** asteroids. Another family of objects is the outermost four satellites, which also have highly inclined orbits, except that they move in the retrograde direction around Jupiter. They are Sinope, Pasiphae, Carme, and Ananke, and they may be captured asteroids.

The 47 additional satellites discovered since 2000 are all small outer satellites less than about 10 km in diameter, the majority of which have retrograde orbits, indicating they are probably captured objects. These objects suggest a large reservoir of additional undiscovered satellites.

4.3. The Saturnian System

4.3.1. The Medium-Sized Icy Satellites of Saturn (Other than Enceladus): Rhea, Dione, Tethys, Mimas, and Iapetus

The Saturnian system contains 62 known satellites. Excluding the giant Titan, the six largest satellites of Saturn are smaller than the Galilean satellites but still sizable—as such they represent a unique class of icy satellite. Earth-based telescopic measurements showed the spectral signature of ice for all six satellites. The satellites' low densities and high albedos (see Table 34.1) imply that their bulk composition is largely water ice, possibly combined with ammonia or other volatiles. They have smaller amounts of rocky silicates than the Galilean satellites. Resurfacing has occurred on several of the satellites. Most of what is presently known of the Saturnian system was obtained from the *Voyager* flybys in 1980 and 1981 and the *Cassini—Huygens* exploration of Saturn's satellites. *Cassini* images of the main satellites of Saturn are shown in Figure 34.4.

The innermost medium-sized satellite Mimas is covered with craters, including one (named Herschel) with a size nearly one-third of the satellite's diameter, or about 130 km, and 10 km deep (see upper left of Figure 34.5). The craters on Mimas tend to be high-rimmed, bowl-shaped pits; apparently, surface gravity is not sufficient to have caused slumping. No components other than water ice have been detected on Mimas. Through orbital resonances, Mimas is responsible for many of the gaps in Saturn's ring, including the Cassini Division. Mimas is also in a mean-

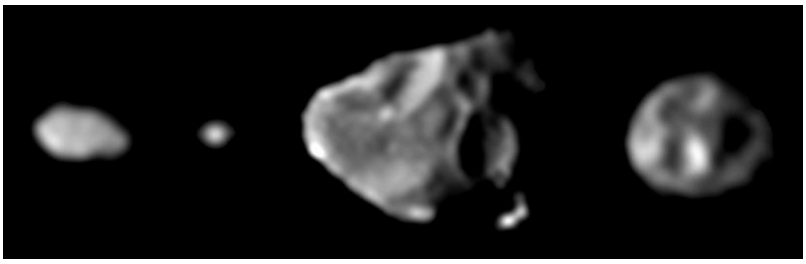

FIGURE 34.3 Four small satellites of Jupiter: Metis, Adrastea, Amalthea, and Thebe, shown to their correct relative sizes. All four satellites orbit between Jupiter's ring and the Galilean satellites.

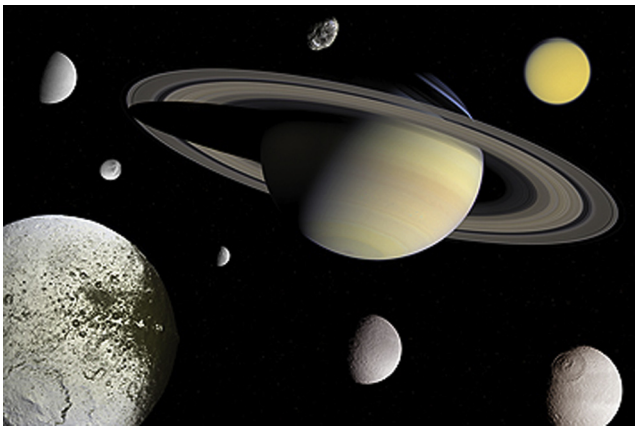

FIGURE 34.4 The major satellites of Saturn as imaged by the *Cassini* spacecraft. They are, from the upper left corner clockwise around Saturn: Enceladus, Hyperion, Titan, Tethys, Rhea, Mimas, Dione, and at the lower left corner, Iapetus.

motion resonance of 3:2 with Pandora, and a 2:1 resonance with Tethys. The infrared instrument on *Cassini* discovered a global, arcuate-shaped thermal anomaly that is thought to be due to increased thermal inertia, possibly from annealing by high-energy electrons.

Tethys is covered with impact craters, including Odysseus, which is shown in the upper left of Figure 34.6. The craters tend to be flatter than those on Mimas or the Moon, probably because of viscous relaxation and flow over the eons under the stronger gravitational field of Tethys. Evidence for resurfacing episodes is seen in regions that have fewer craters and higher albedos and in the huge trench formation, the Ithaca Chasma. This chasm is about 2000 km in length, 100 km in width, and 3 km deep. It may have formed during a global freezing and subsequent expansion of Tethys. The density of Tethys is lower than that of the other main Saturnian moons—only 0.98 g/cc—which implies a very small fraction of nonice material and possibly some internal void space. It is not known whether Tethys is differentiated, and no surface components other than water ice have been identified. A thermal anomaly similar to the one on Mimas appears on its surface, but it is less distinct.

Dione, which is about the same size as Tethys, exhibits a wide diversity of surface morphology. Most of the surface is heavily cratered (Figure 34.7), but gradations in crater density indicate that several periods of resurfacing occurred during the first billion years of its existence. The leading side of the satellite is about 25% brighter than the trailing side, possibly due to more intensive micrometeoritic bombardment on this hemisphere, in addition to the accretion of E-ring particles. Bright wispy streaks seen by the *Voyager* spacecraft were revealed by *Cassini* to be deep and extensive tectonic faults, or chasmata. Dione modulates the radio emission from Saturn, but the mechanism for this phenomenon is unknown. There is some evidence that Dione has been recently active, including geologic features that appear to be cryovolcanic and that are surrounded by smooth plains. The detection of an anomaly in Saturn's magnetic field can be explained by an outflow of material from Dione equal to 0.6% of the atmospheric loading by material from Enceladus.

Rhea is superficially very similar to Dione. Bright wispy streaks cover one hemisphere: as on Dione, *Cassini*

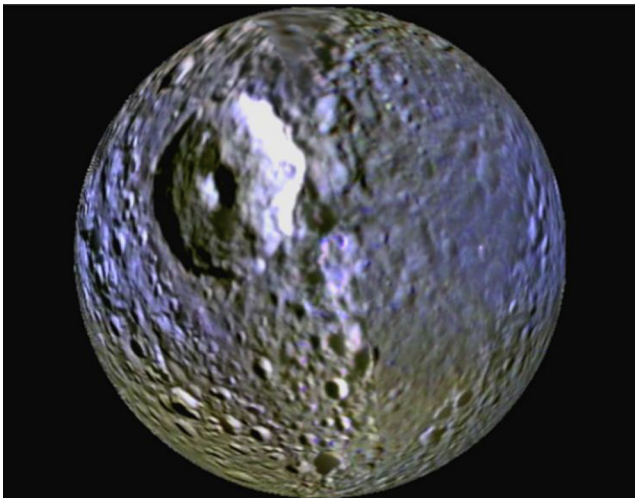

FIGURE 34.5 *Cassini* photomosaic of Mimas, showing its heavily cratered surface and the Herschel crater, which is 139 km in diameter. The bluish tinge occurs in the region of unusual thermal properties, which may be due to the impact of high-energy electrons on the moon's surface.

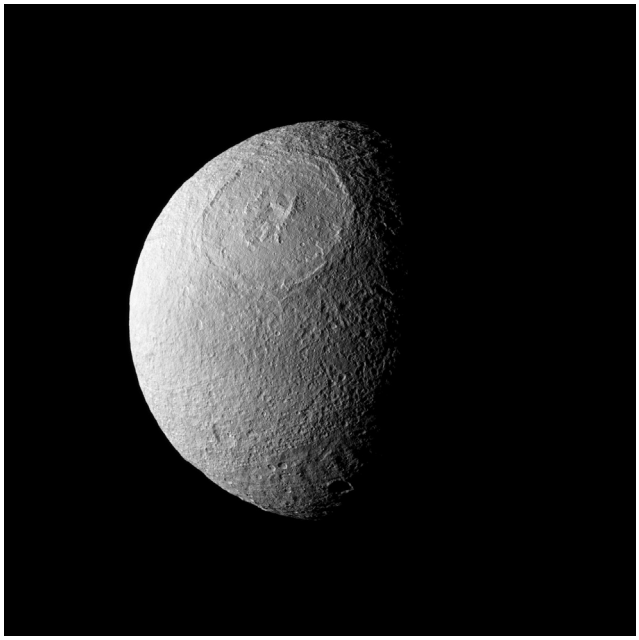

FIGURE 34.6 The best Cassini spacecraft view of the Odysseus impact crater on Tethys, which is about 450 km in diameter.

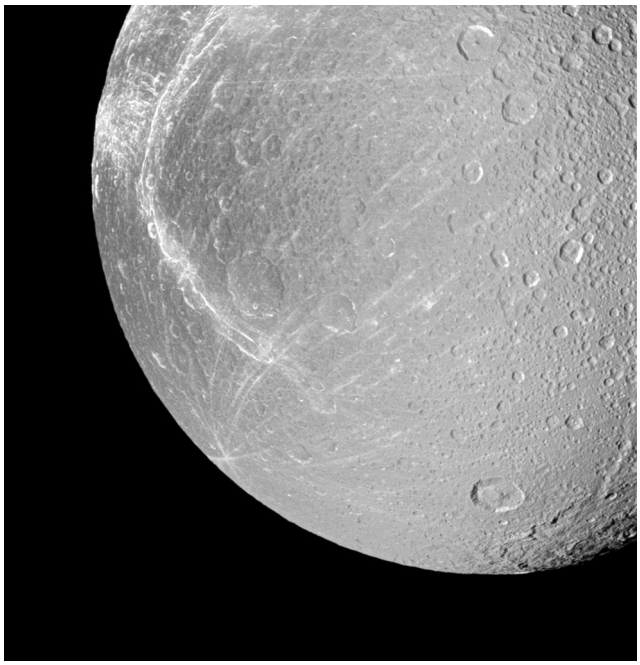

FIGURE 34.7 A *Cassini* image of Dione, showing both heavily cratered terrain and the bright wispy streaks, which are raised tectonic features up to several hundred meters in height.

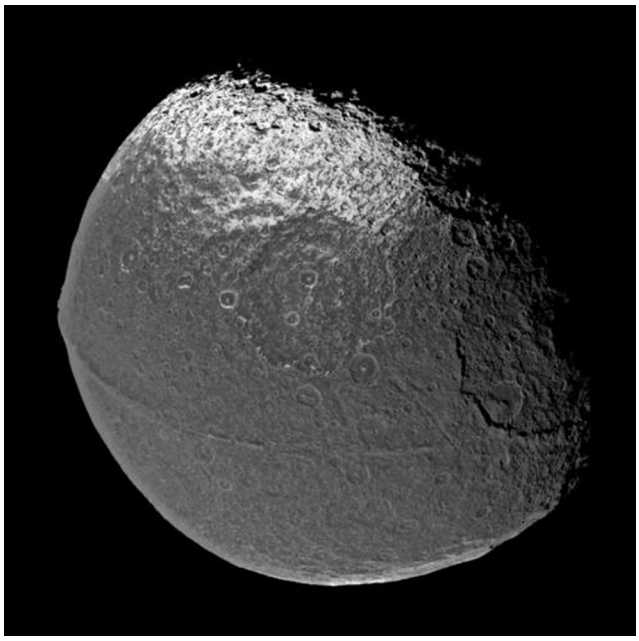

FIGURE 34.8 *Cassini* image of Iapetus, showing both bright and dark terrains. The image was obtained at a distance of 173,000 km, with a resolution of about 2 km.

showed they are tectonic features formed by extensional forces. There is a dichotomy between crater sizes on Rhea's surface, with some regions lacking craters larger than 40 km in diameter, while other regions have craters only larger than that. The larger craters may be due to a population of larger debris more prevalent during an earlier episode of collisions. A subsequent resurfacing may have covered up these features on a portion of the moon.

The most recent evidence from the *Cassini* spacecraft is that Rhea is an almost undifferentiated body in hydrostatic equilibrium. The spacecraft also detected a thin atmosphere with a surface pressure only a few trillionths that of the Earth and composed of oxygen and carbon dioxide. The discovery in 2008 of possible rings around Rhea has not been confirmed by later observations.

When G. D. Cassini discovered Iapetus in 1672, he noticed that at one point in its orbit around Saturn it was very bright, but on the opposite side of the orbit it nearly disappeared from view. He correctly deduced that one hemisphere is composed of highly reflective material and that the other side is much darker. *Voyager* images show that the bright side, which reflects about 60% of the incident visible sunlight from its brightest regions, is fairly typical of a heavily cratered icy satellite. The other side, which is centered on the direction of motion, is coated with a material with a reflectivity of about 3–4% (Figure 34.8). Other aspects of Iapetus are notable. It is the only large Saturnian satellite in a highly inclined orbit, and its density is only slighter higher than that of water ice, implying that very small amounts of rock exist in its interior.

Historically, two models were proposed for the origin of the dark material: that it was derived from an exogenic (external) source or that it was endogenically (internally) created. The discovery of a large dust ring around Saturn, consisting of material ejected from Phoebe due to meteoritic impacts, provided a plausible source for exogenous particles. The redder color of Iapetus implies that some nonvolatile thermal native lag deposit and perhaps material from other sources is mixed with the low-albedo material from the Phoebe ring. The pattern of the low-albedo side is consistent with material being swept up in the orbit of Iapetus and subsequently altered by thermal migration, The *Cassini* visual and infrared spectrometer detected carbon dioxide and organics in the dark material.

The surface of Iapetus is heavily cratered, implying an age >4 Ga, with at least five large-impact basins between 300 and ~800 km in diameter—the largest in the Saturnian system—and associated with landslides. The shape is less spherical than would be expected from its current rotation period of 79 days: it is more in agreement with an original rotation period of 10 h, which may have been its spin period as the crust cooled. The moon also has a unique equatorial ridge up to 20 km in height that extends nearly the entire circumference of the body; in the bright regions, the ridge breaks up into scattered mountains (see Figure 34.8). No completely satisfactory theory for the origin of this ridge exists.

4.3.2. The Small Satellites of Saturn

The Saturnian system has many unique small satellites. Telescopic observations showed that the surface of Hyperion, which lies between the orbits of Iapetus and Titan, is covered with ice. Because Hyperion has a visual **geometric albedo** of 0.30, this ice must be mixed with a significant amount of darker material rich in rocky or carbonaceous substances. Hyperion's highly irregular shape (see Table 34.1) suggests, along with the satellite's battered appearance, that it has been subjected to intense bombardment and fragmentation. Hyperion is the only satellite known to be in chaotic rotation—perhaps a collision within the last few million years knocked it out of a tidally locked orbit (*see* Chaotic Motion in the Solar System).

Saturn's outermost satellite, Phoebe, a dark object (see Table 34.1) with a surface composition similar to that of **C-type** asteroids (but apparently with more organic material), moves in a highly inclined, retrograde orbit, strongly suggesting that it is a captured object. The spectral signature of water ice was detected by ground-based telescopes. Although it is smaller than Hyperion, Phoebe has a more nearly spherical shape that could indicate very early heating and relaxation. Figure 34.9 shows an image of the satellite obtained by *Cassini–Huygens* in July 2004. The heavily battered surface has a number of unusual conical craters, and the largest crater reveals ice cliffs on its rims. Carbon dioxide and organic material was detected by *Cassini*, suggesting that the satellite formed in the outer solar system, perhaps as far out as the Kuiper Belt.

Saturnian small satellites occur in several dynamic niches: the shepherding satellites, the co-orbitals, the **Lagrangians**, and satellites that orbit in ring gaps. All these objects are irregularly shaped (see Figure 34.10) and probably consist primarily of ice. Those whose masses have been measured are less dense than water ice, suggesting substantial porosity. The three shepherds, Atlas, Pandora, and Prometheus, help define the edges of Saturn's A- and F-rings, but recent work shows that resonances among satellites also define the sharp edges of the rings. The orbit of Atlas lies several hundred kilometers from the outer edge of the A-ring. The other two shepherds, which orbit on either side of the F-ring, not only constrain the width of this narrow ring but also may cause its kinky appearance. *Cassini* discovered two new small satellites that are associated with the F-ring.

The co-orbital satellites Janus and Epimetheus, which were discovered in 1966 and 1978, exist in an unusual dynamical situation. They move in almost identical orbits at about 2.5 Saturn radii. Every 4 years the inner satellite (which orbits slightly faster than the outer one) overtakes its companion. Instead of colliding, the satellites exchange orbits. The 4-year cycle then begins over again. Perhaps these two satellites were once part of a larger body that disintegrated after a major collision.

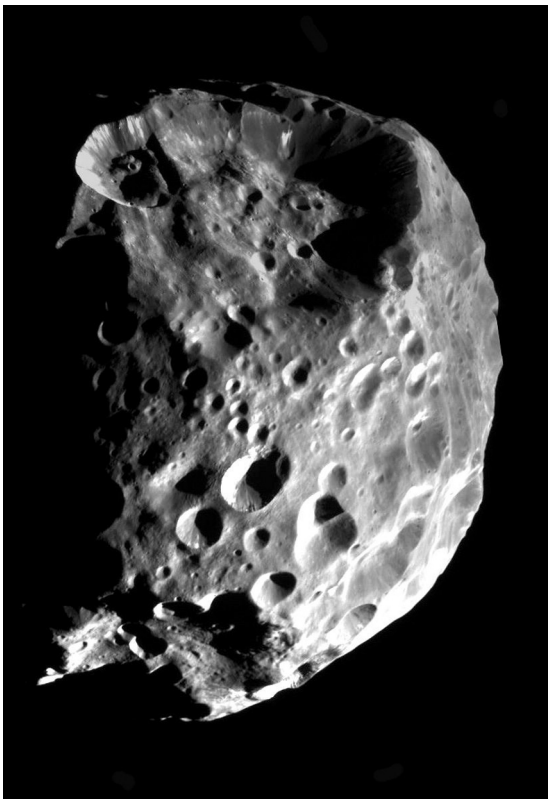

FIGURE 34.9 *Cassini* image of Phoebe, obtained at a distance of 32,500 km, with a corresponding resolution of about 300 m. The heavily cratered surface shows no hint of geological resurfacing. Icy cliffs are evident in the large crater at the top of the image, and the large crater near the center shows evidence for layering near its rim.

Four other small satellites of Saturn orbit in the **Lagrangian points** of larger satellites: two are associated with Dione (including Polydeuces, which was discovered by *Cassini* in October 2004) and two with Tethys. The Lagrangian points are locations along an object's orbit in which a less massive body can move in an identical, stable orbit. They lie about 60° in front of and at the back of the larger body. Although no other known satellites in the solar system are Lagrangians, the Trojan asteroids orbit in two of the Lagrangian points of Jupiter.

The final class of unusual Saturnian satellite is the one that dwells in ring gaps and sweeps and clears particles from the gaps. Pan, which was discovered in 1990 from *Voyager* images, sits in the Encke Gap. The *Cassini* spacecraft discovered Daphnis, a small satellite in the Keeler Gap, in May 2005.

Like Jupiter, Saturn has a large family of outer irregular satellites, most of which have been recently discovered with large telescopes. The 25 known outer small satellites move in eccentric inclined orbits, and most of their orbits

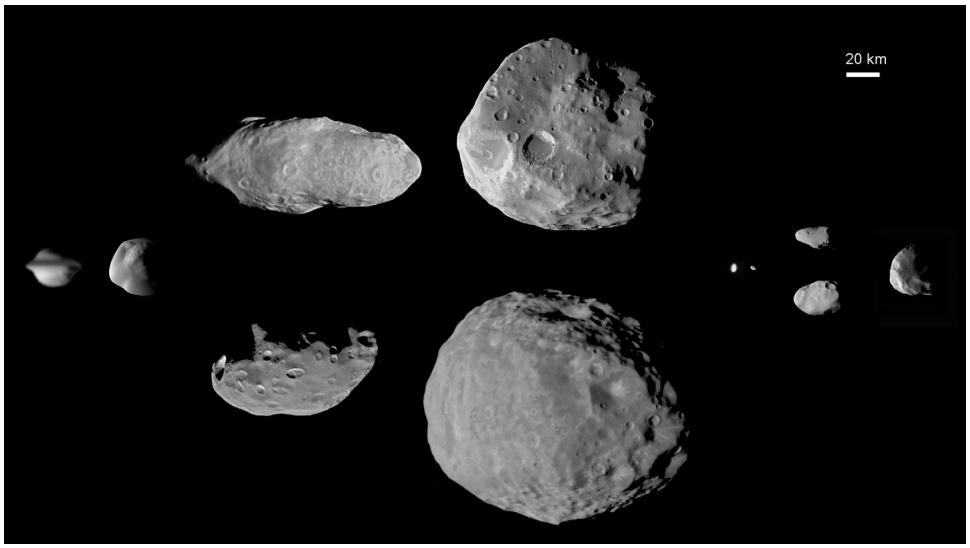

FIGURE 34.10 Some of the small satellites of Saturn. From the left they are: Pan, Atlas, Prometheus (top), Pandora (bottom), Epimetheus (top), Janus (bottom), Pallene, Methone, Calypso (top), Telesto (bottom), and Helene.

are retrograde, implying that they are captured objects. The farthest satellites orbit more than 20 million km from Saturn.

4.4. The Satellites of Uranus

4.4.1. The Medium-Sized Satellites of Uranus: Miranda, Ariel, Umbriel, Titania, and Oberon

Uranus has a total of 27 known satellites that can be grouped into three types: small inner moons, small outer irregular moons, and a main satellite system composed of medium-sized bodies that orbit the planet at distances from 130,000 to 583,000 km. The orbits of Ariel, Umbriel, Titania, and Oberon are regular, whereas Miranda's orbit is slightly inclined. Figure 34.11 is a telescopic image of the satellites typical of the quality attainable before the advent of spacecraft missions.

Theoretical models suggest that the satellites are composed of water ice, possibly in the form of methane clathrates or ammonia hydrates, and silicate rock. Water ice has been detected spectroscopically on all five satellites. Carbon dioxide has been detected on Ariel, Umbriel, and Titania. The relatively dark visual albedos of the satellites, ranging from 0.13 for Umbriel to 0.33 for Ariel (see Table 34.1), and gray spectra indicate that their surfaces contain a dark component such as graphite or carbonaceous material. Another darkening mechanism that may be important is bombardment of the surface by UV radiation. The higher density of Umbriel implies that it has a larger fraction of rocky material than the other four satellites. Heating and **differentiation** have occurred on Miranda and Ariel and possibly on some of the other satellites. Models indicate that tidal interactions may provide an important heat source in the case of Ariel.

Miranda, Ariel, Oberon, and Titania all exhibit large opposition surges, indicating surfaces composed of very porous material, perhaps resulting from eons of micrometeoritic "gardening". Umbriel lacks a significant surge, which

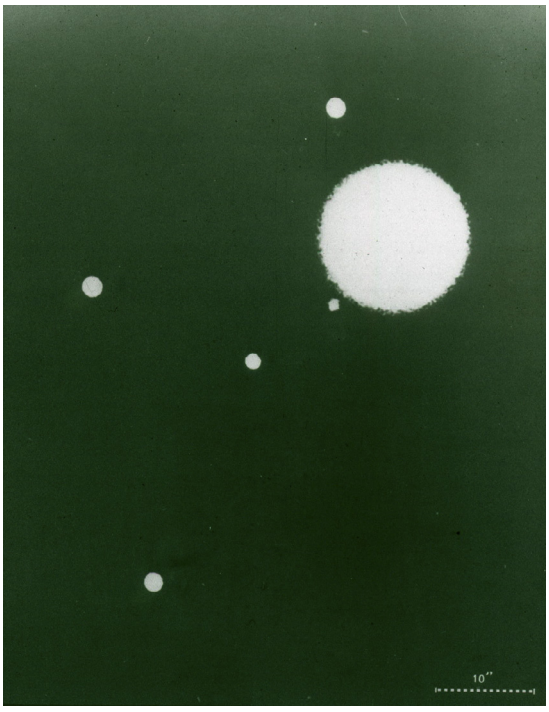

FIGURE 34.11 Telescopic view of Uranus and its five satellites obtained by Ch. Veillet on the 154-cm Danish-ESO telescope. Outward from Uranus they are: Miranda, Ariel, Ubriel, Titania, and Oberon. *Photograph courtesy of Ch. Veillet.*

FIGURE 34.12 The five major satellites of Uranus, shown to relative size based on *Voyager 2* images. They are, from the left, Miranda, Ariel, Umbriel, Titania, and Oberon.

suggests that its surface properties are in some way unusual. Perhaps its **regolith** is very compacted, or it is covered by a fine dust that scatters optical radiation in the forward direction.

The *Voyager 2* spacecraft encountered Uranus in January 1986 to reveal satellites that have undergone melting and resurfacing (Figure 34.12). Three features on Miranda, known as "coronae", consist of a series of ridges and valleys ranging from 0.5 to 5 km in height (Figure 34.13). Their origin is uncertain: some geologists favor a compressional folding interpretation, whereas others invoke a volcanic origin or a faulting origin. Both Ariel, which is the geologically youngest of the five satellites, and Titania are covered with cratered terrain transected by grabens, which are fault-bounded valleys. Umbriel is heavily cratered and it is the darkest of the satellites: both these observations suggest that its surface is very old, although the moderate-resolution images obtained by *Voyager 2* cannot rule out geologic activity on a smaller scale. Some scientists have in fact interpreted small albedo variegations on its surface as evidence for melting events early in its history. Oberon is similarly covered with craters, some of which have very dark deposits on their floors. On its surface are situated faults or rifts, suggesting resurfacing events (*Voyager 2* provided ambiguous, medium-resolution views of the satellite). In general, the Uranian satellites appear to have exhibited more geologic activity than the Saturnian satellites (except Enceladus) and Callisto, possibly because of the presence of methane, ammonia, nitrogen, or additional volatiles, as well as more rocky material that provided heat from radioactive decay.

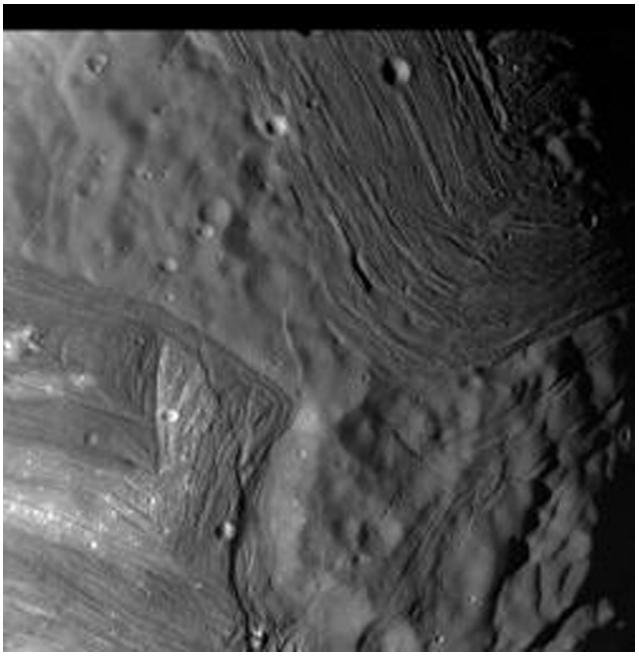

FIGURE 34.13 Image of Miranda obtained by the *Voyager 2* spacecraft at 30,000–40,000 km from the Moon. Resolution is 560–740 m. Older, cratered terrain is transected by ridges and valleys, indicating more recent geologic activity.

There is some evidence that Umbriel and Oberon, as well as certain regions of the other satellites contain the organic-rich primordial constituents that seem to be ubiquitous in the outer solar system. This material is found on primitive asteroids, and may contain some of the same molecules that are seen on the dark side of Iapetus, on Hyperion, and on specific areas of the larger satellites.

4.4.2. The Small Satellites of Uranus

Voyager 2 discovered 10 new small satellites of Uranus, including two that act as shepherding satellites for the outer (epsilon) ring of Uranus (see Table 34.1). All these satellites lie inside the orbit of Miranda. Images of two satellites, Puck and Cordelia, provided sufficient resolution to directly determine their radii (see Table 34.1). The sizes of the other bodies were estimated by assuming that their values of surface brightness are equal to those of the other inner satellites and calculating the projected area required to yield their observed integral brightness. Puck is slightly nonspherical in shape. It is likely that the other small satellites are irregularly shaped. The satellites' visual **geometric albedos** range from 0.04 to 0.09, which is slightly higher than that of Uranus's dark ring system. No reliable color information was obtained by *Voyager 2* for any of the small satellites,

although their low albedo suggests that they are **C-type** objects. Ground-based observers have discovered another 12 outer irregular satellites to bring the total of known Uranian satellites to 27.

4.5. The Satellites of Neptune

4.5.1. The Inner Moons

Neptune has 14 known satellites: one is the large moon Triton and the remaining 13 are small, irregularly shaped bodies (see Table 34.1). The small satellites can be divided into two categories: the seven inner bodies, which move in highly regular, circular orbits close to Neptune (<5 planetary radii), and the irregular outer satellites. Triton has an appreciable atmosphere, seasons, and currently active geologic processes (*see* Triton).

Six of the seven small inner satellites were all discovered within a few days during the *Voyager 2* encounter with Neptune in August 1989. They were given names of mythical nautical figures by the IAU. For four of these satellites (Proteus, Larissa, Galatea, and Despina), as well as Nereid, *Voyager 2* images provided sufficient resolution to determine their dimensions (see Table 34.1). All five bodies are irregularly shaped. The sizes of Thalassa and Naiad were derived by assuming that their albedos are equal to those of the other inner satellites. The size of the six satellites discovered by *Voyager 2* increases with the distance from Neptune. Proteus is the largest known satellite with an irregular shape. The seventh inner moon, S/2004 N 1, was discovered on archived *Hubble Space Telescope* Images in 2013.

Spacecraft tracking of the six inner satellites observed by *Voyager 2*, ground-based observations of Nereid, and *Hubble* observations of the seventh inner moon provided accurate orbit determinations, which are listed in Table 34.1. All the small inner satellites except Proteus orbit inside the so-called synchronous distance, which is the distance from Neptune at which the rotational spin period equals the Keplerian orbital period. However, Proteus has been tidally despun so that its rotational period equals its orbital period.

The masses of the satellites were not measured directly by *Voyager 2*. Limits may be obtained by assuming reasonable values for their bulk densities. These values range from 0.7 g/cm^3, corresponding to water ice with a bulk porosity of about 30%, to 2 g/cm^3, corresponding to water ice with a significant fraction of rocky material. If the satellites were formed from captured material, the higher density is more reasonable. In any case, the small satellites have less than 1% of the mass of Triton. The ring system of Neptune contains only a very small amount of mass, possibly one-millionth of the small satellites' combined masses.

Figure 34.14 depicts the best *Voyager 2* images obtained for Proteus, with a resolution of 1.3 km/pixel. The large feature—possibly an impact basin—has a diameter of about 250 km. Close scrutiny of this image reveals a concentric structure within the impact basin. Possible ridgelike features appear to divide the surface. The regions of Proteus outside of the impact basin show signs of being heavily cratered. The best image of Larissa was obtained at a resolution of 4.2 km/pixel, insufficient to depict surface features.

Analysis of calibrated, integral *Voyager 2* measurements of the four inner satellites reveals that their geometric albedos are about 0.06, in the *Voyager 2* clear filter with an effective wavelength of about 480 nm. The limited spectral data obtained by *Voyager 2* suggest that Proteus and Larissa are gray objects. The dark albedos and spectrally neutral character of the inner satellites suggest that they are carbonaceous objects, similar to the primitive **C-type** asteroids, possibly the Uranian satellite Puck, the satellites of Mars, and several other small satellites. The evolution of the inner satellites was likely punctuated by the capture of Triton. Initially, the inclinations and eccentricities of the satellites would have been increased by the capture, and subsequent collisions would have occurred. The resulting debris would then have reaccreted to form the present satellites. Models of the collisional history of the satellites suggest that the reaccreted satellites are much younger than the age of the solar system, with the exception of Proteus. The heavily cratered surface that appears in the one resolvable *Voyager 2* image of these bodies (see

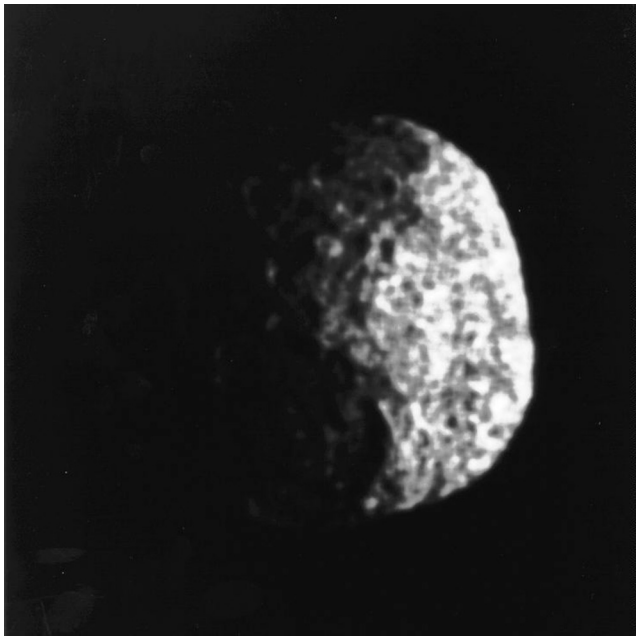

FIGURE 34.14 The best Voyager image of Proteus, obtained at 1.3 km/pixel.

Figure 34.14) does suggest that they have undergone vigorous bombardment.

The only satellite that has been shown to have a dynamical relationship with the rings of Neptune is Galatea, which confines the ring arcs. The orbits of the satellites have probably evolved under the influence of tidal evolution and resonances. For example, the inclination of Naiad is possibly due to its escape from an inclination resonance state with Despina. Larissa was probably detected in 1981 when it blocked a star that astronomers were measuring for possible occultations by planetary rings. Because it was not subsequently observed or tracked, it was not classified as a satellite until its existence was confirmed by *Voyager 2* observations.

4.5.2. The Outer Irregular Moons

The small outer moon Nereid was discovered in 1949 by Gerard P. Kuiper at the McDonald Observatory in Texas. In keeping with the theme of water and oceans for the Neptunian system, the satellite was named after the sea nymphs known in Greek mythology as Nereids. At the time of the *Voyager 2* encounter in 1989, Nereid, which moves in an eccentric orbit bringing it from 57 to 385 planetary radii from Neptune, was the only known small outer satellite of Neptune. Reliable ground-based observations of Nereid were limited to estimates of its visual magnitude. The integral brightness of Nereid is almost three times that of Proteus, which is slightly smaller; its geometric albedo is therefore $\sim$0.20. This markedly higher albedo, coupled with its gray color, implies a surface of water frost contaminated by a dark, spectrally neutral material. It is more similar to the differentiated satellites of Uranus than to the dark C-type objects. It is also similar in albedo, size, and color to Phoebe, the outer satellite of Saturn, which moves in an inclined, retrograde orbit, suggesting that it is a captured object.

Voyager 2 images of Nereid attained 43 km/pixel, not sufficient to clearly depict surface features. In 1988, 1989, and 1991, several ground-based observers reported large light curve amplitudes (up to factors of four), which they interpreted as significant albedo variegations on Nereid. Although there is some uncertainty (a factor of two at most) in comparing *Voyager 2* to ground-based observations because the orientation of Nereid's spin axis is unknown, a light curve for Nereid from *Voyager 2* images over a 12-day period shows an amplitude of less than 15%. No rotation period has yet been derived for this moon, although the *Voyager 2* observations suggest that it is not in **synchronous rotation**. Nereid has the largest eccentricity of any known satellite (0.75).

In 2003, five more moons were discovered, including one with a period of over 25 years, which corresponds to a distance of 48 million km from Neptune. Three of the five outer satellites discovered in 2003 have retrograde orbits, and may thus be captured objects. Jupiter, Saturn, and Neptune all appear to have families of outer, captured satellites.

ACKNOWLEDGMENT

Portions of this work were performed at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. P. Smith provided technical assistance.

Io, the innermost of Jupiter's four Galilean satellites, is the only body outside the Earth so far known to have large-scale active volcanism. Io's heat flow is much higher than that of the Earth's and its interior is thought to contain a magma ocean. Io's lavas may be hotter than any that erupt on the Earth's surface today.

1. INTRODUCTION

Io (Figure 35.1) was discovered by the Italian scientist and astronomer Galileo Galilei on January 8, 1610, and was named after one of the ancient Roman god Jupiter's illicit lovers. The discovery of active volcanism was made by the Voyager 1 spacecraft, which flew close to Io in 1979. Images showed volcanic plumes up to 300 km in height and a vividly colored surface dominated by large **caldera**-like and flowlike features. The study of Io's remarkable volcanism has continued since then using observations by telescopes on the Earth, by the Hubble Space Telescope, and the Galileo, Cassini, and New Horizons spacecraft.

Io's unusual spectroscopic characteristics, due to its volcanic activity and widespread covering of sulfur dioxide, were recognized in the 1970s. In 1979, just prior to the two Voyager flybys, Io's 4:2:1 orbital resonance with Europa and Ganymede was predicted to induce severe tidal heating and subsequent active volcanism on Io. The two Voyager spacecraft confirmed the prediction that Io is volcanically active.

Io's size (Table 35.1) is similar to that of the Earth's Moon but its density is higher, indicating that there is more iron in Io's interior than in the Moon's. Io's mantle composition is thought to be predominantly **silicates**. However, sulfur compounds are abundant on the surface. After the discovery of volcanism in 1979, a major question was the composition of the erupting material: silicates or sulfur? Ground-based observations and, later, Galileo's

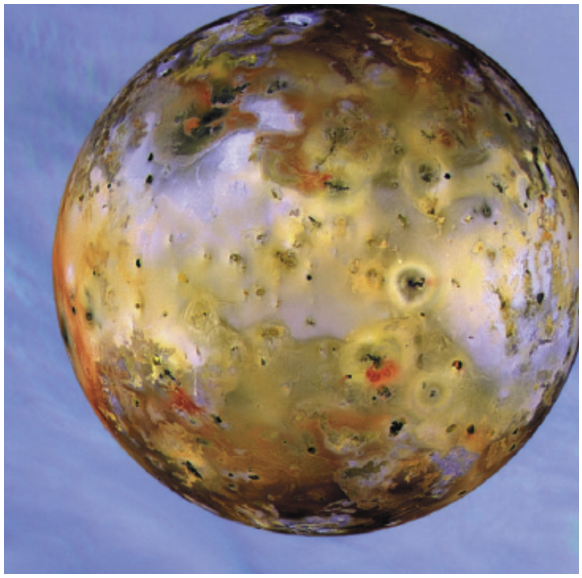

FIGURE 35.1 Io imaged by Galileo's Solid State Imaging System on September 7, 1996, at a range of about 487,000 km. The image is centered on the side of Io that always faces away from Jupiter. The black and bright red materials correspond to the most recent volcanic deposits. The near-infrared filter makes Jupiter's atmosphere (in the background) look blue. The active volcano Prometheus is seen as a dark sinuous feature near the right-center of the disk.

TABLE 35.1 Io's Basic Orbital and Physical Properties

Mean radius: 1821.6 ± 0.5 km
Bulk density: 3528 ± 3 kg/m^3
Orbital period: 1.769 days
Orbital eccentricity: 0.0041
Orbital inclination: 0.037
Orbital distance a: 421,800 km
Rotational period: synchronous with orbit
Maximum moment of inertia: 0.3769 ± 0.0004
Potential love number k^2: 1.292 ± 0.003
Mass: $(8.9320 \pm 0.0013) \times 10^{22}$ kg
Surface gravity: 1.80 m/s^2
Global average heat flow:>2.5 W/m^2
Radius of core: 656 km (if pure iron) and 947 km (iron and iron sulfide mixture)
Surface equatorial magnetic field strength:<50 nT
Geometric albedo: 0.62
Local topographic relief: up to ~17 km
Active volcanic centers: at least 166
Typical surface temperature (away from hot spots): 85 K (night) to 140 K (day)
Atmospheric pressure:$<10^{-9}$ bar, higher at locations of plumes
Escape velocity: 2.56 km/s
Crustal thickness (estimated): 30–50 km
Atmospheric composition: SO_2 (main), SO, S_2, Na

results showed that eruption temperatures were too high to be sulfur and were consistent with silicates, but some sulfur flows may exist.

Sulfur dioxide is ubiquitous on Io's surface, and sulfur and sulfur dioxide are known to be present in Io's volcanic plumes.

Io's **heat flow** (Table 35.1) is very large compared with that of the Earth and other planets. Io's heat flow is about 200 times what could be expected from heating due to the decay of radioactive elements, illustrating how crucial tidal heating is to driving Io's active volcanism. The effect of Io's volcanic eruptions extends well beyond the surface, and there is considerable interaction of Io with the Jovian magnetic field. Io has both a patchy, very low density atmosphere and an ionosphere. Sulfur dioxide is the main constituent of the atmosphere, and it is thought to be supplied largely by volcanic plumes, with a lesser amount coming from sublimation of frost deposits on the surface. An important discovery made during the Galileo mission was Io's aurora, caused by collisions between Io's atmospheric gases and energetic charged particles trapped in Jupiter's magnetic field.

Materials escaping from Io form a cloud of neutrals along Io's orbital path. Escaping materials also populate the Io torus, a donut-shaped region along Io's path, held by Jupiter's powerful magnetic field. Materials escaping from Io include sulfur, sulfur dioxide, sodium, potassium, and dust particles. Io is therefore a wonderful natural laboratory for the study of geological and geophysical processes, and its location within Jupiter's magnetic field makes it a rich source for studies of the fields and particle environment in space.

2. Io EXPLORATION

Since its discovery in 1610, Io has been important to our understanding of the solar system, along with the other Galilean satellites, Europa, Ganymede, and Callisto. After a few observations, Galileo Galilei concluded that the four objects were not stars as he originally thought, but satellites in orbit around Jupiter. Galileo's studies of the motion of the newly discovered satellites had a profound effect on human history becoming, along with Galileo's discovery of the phases of Venus, key evidence in favor of the Copernican theory of the universe. Another major step for science came in 1675, when Danish astronomer Olaus Roemer noted that the times of the eclipses and occultations of the four moons by Jupiter showed a phase shift with a periodicity of about 6.5 months. He concluded that, when Jupiter is at opposition (when Jupiter and Earth are closest, on the same side as the Sun), light from the Jovian system must travel a distance of approximately 4 astronomical units (AU) to reach the Earth. However, when Jupiter is at conjunction (when the Earth and Jupiter are farthest apart, on opposite sides of the Sun), light traveled about 6 AU on its journey to the Earth. Roemer concluded that this phase shift in the arrival time of jovicentric events meant that light has a finite velocity, and he used the motions of the Galilean satellites to determine the speed of light.

In 1805, Laplace demonstrated that the Galilean satellites have an orbital configuration (known as the Laplace resonance), which suggested a special dynamical relationship among Io, Europa, and Ganymede. For each time that Ganymede orbits Jupiter, Europa orbits almost exactly twice and Io orbits four times. Later studies would reveal that this resonance plays a key role in the existence of active volcanism on Io.

Even before the first close-up images of Io were returned by Voyager in 1979, there were indications that Io was a remarkably different world from our Moon and other moons in the solar system. Telescopic observations showed that Io's brightness varied according to its position in its

orbit, suggesting that the moon always keeps one face toward Jupiter (now referred to as the sub-Jovian hemisphere). During the mid-twentieth century, photometric and color data showed that Io is the reddest object in the solar system and has a marked color variation with orbital phase angle. These observations also showed Io to be very different from the other Galilean satellites (and most other satellites in the outer solar system) because of the absence of water bands in its spectra.

The peculiar nature of Io's surface became more evident in 1964, when astronomers A. P. Binder and D. P. Cruikshank reported an anomalous brightening of Io's surface as it emerged from eclipse. This first report of "posteclipse brightening" and the suggestion of a possible atmosphere spurred more telescopic observations but, even though the presence of an atmosphere was confirmed, posteclipse brightening has remained controversial and has not been confirmed to this day.

The first evidence of an electromagnetic link between Io and the Jovian magnetosphere was put forward in 1964 by E. K. Bigg, who found that bursts of decametric radio emission by Jupiter were apparently controlled by Io's orbital position. Models of electrodynamic interaction between Jupiter and Io addressed the coupling mechanism between Io and Jupiter's inner magnetosphere.

The first spacecraft to fly by the Jupiter system was Pioneer 10 in 1973. These observations revealed that Io has an ionosphere and thin atmosphere. Pioneer measurements also showed a cloud of neutrals along Io's orbital path. Ground-based measurements in the mid-1970s revealed ionized sulfur emission in the inner Jovian magnetosphere, but on the opposite side of Jupiter from the position of Io at the time. Subsequent studies revealed this to be a plasma torus. The Io torus is a donut-shaped trail along Io's orbital path, made up almost exclusively of various charged states of sulfur and oxygen, thought to be derived from the break up of volcanic sulfurous compounds (SO_2 and S_2). The ionized particles are held within the torus by Jupiter's magnetic field, in a similar way to the mechanism that holds charged particles in the Van Allen radiation belts around the Earth.

The first clues to Io's bulk composition came from measurements of Io's mean radius using a stellar occultation and from mass derived from the Pioneer flyby in 1973. The bulk composition of 3.54 g/cm^3 indicated that silicates were dominant on Io, but the surface's high albedo and cold temperatures indicated frosts. Telescopic observations using improved spectral reflectance techniques were used to attempt to determine Io's surface composition, and polysulfides were suggested as a possible coloring agent for the surface. The idea of sulfur on Io was strongly supported by laboratory experiments by W. Wamsteker, which showed that sulfur and its compounds matched the strong UV absorption and reflectance spectrum of Io, suggesting that these compounds might be abundant on Io's surface. However, the discovery of a strong absorption band near 4 μm could not be explained by sulfur. It was later found to be due to sulfur dioxide (SO_2), which is now known to be the dominant compound covering Io's surface. Other key discoveries during the 1970s were those of the Io sodium cloud in 1973 by R. Brown and in 1975 of a potassium cloud by L. Trafton.

The first indications of volcanic activity were given by infrared photometry and radiometry that showed higher brightness temperatures at 10 μm than at 20 μm, but the thinking at the time was that Io was a cold and dead world, and these observations remained puzzling. However, shortly before Voyager 1 arrived at the Jupiter system in March 1979, several scientists published results that, in retrospect, suggested active volcanism. In 1978, R. Nelson and B. Hapke reported a spectral edge at 0.33 μm and proposed that sulfur was the major contributor to this spectral feature. They suggested that the presence of allotropes of sulfur could explain this and several other spectral features and that these allotropes could be produced by melting yellow sulfur and subsequently quenching it, possibly "in the vicinity of a volcanic fumarole or hot spring". Astronomers F. Witteborn and colleagues reported a telescopic observation of an intense temporary brightening of Io in the infrared wavelengths from 2 to 5 μm. They explained it, although with some skepticism, as thermal emission caused by part of Io's surface being at a temperature of about 600 K, much hotter than the average expected daytime temperature of about 130 K. A few days before the Voyager 1 flyby of Io, a seminal theoretical paper by Stan Peale and colleagues was published. They had studied the tidal stresses generated within Io as a result of the gravitational "tugs" from Jupiter and Europa. Their calculations showed that the possible heat generated by tidal stresses was on the order of 10^{13} W, much greater than heat that could be released from normal radioactive decay. Their prediction—that Io might have "widespread and recurrent volcanism"—was spectacularly confirmed by Voyager 1.

Io's tidal heat comes from the orbital energy of the Io–Jupiter system (resulting in orbital acceleration), whereas dissipation of energy in Jupiter causes Io's orbital motion to decelerate. If Europa and Ganymede were not interacting with Io, its orbit would be circular and tidal deformation would not occur. Due to Laplace resonance between the satellites, Io's orbit is elliptical and Jupiter's differential gravitational pull causes Io to continuously and repeatedly deform as it orbits Jupiter. It is estimated that Io's surface moves up and down by as much as 100 m over one orbit around Jupiter. If Laplace resonance is ever broken, as some studies by V. Lainey and colleagues indicate, then Io will, in the distant future, become dormant.

Active volcanoes were not immediately obvious in the first images returned by Voyager 1. The most striking aspect of Io shown in the first images was its colorful surface, with yellows, oranges, reds, and blacks. Scientists on the imaging team nicknamed Io the "pizza moon" and suggested the colors were likely due to large quantities of sulfur on the surface. Another surprising aspect was the absence of impact craters. The obvious conclusion was that Io's surface was very young and the craters must have been obliterated—but how? The answer came soon after, when a navigation engineer at the Jet Propulsion Laboratory, Linda Morabito, noticed a peculiar umbrella-shaped feature emanating from Io's limb in one of the images that was taken to aid navigation of the spacecraft (Figure 35.2). The pattern turned out to be an eruption plume rising about 260 km above the surface. A second plume was found on the same image, and more plumes were seen on close examination of various other images. Additional evidence for active volcanism came from another of Voyager's instruments, the infrared interferometer spectrometer (IRIS), which detected enhanced thermal emission from parts of Io's surface—some areas had temperatures of about 400 K, much higher than the rest of the surface, which has noontime equatorial temperatures of about 107−124 K. When one of the hot areas was found to coincide with one of the plumes, there was no doubt that active volcanism was taking place.

About 18 weeks after Voyager 1's dramatic discovery, the companion spacecraft, Voyager 2, flew close to Io.

FIGURE 35.2 Io's active volcanoes were discovered from this image, taken by Voyager 1 on March 8, 1979, looking back 4.5 million km. The Pele plume is seen on the lower right, rising nearly 300 km above the surface. The bright spot near the terminator (shadow between day and night) is the top of the Loki plume, illuminated by the Sun.

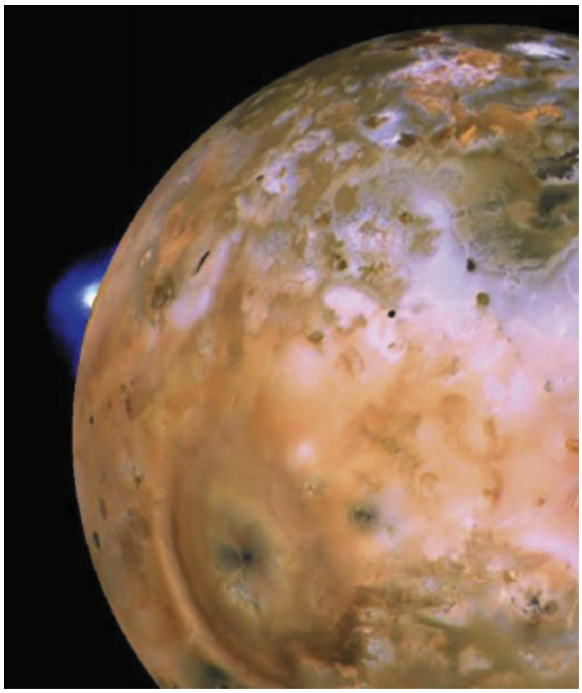

FIGURE 35.3 Voyager 1 image showing the Loki plume on the limb and the heart-shaped Pele plume deposit in the lower part of the image. When Voyager 2 arrived 18 weeks later, the "heart" had become an oval, as material from the plume had filled out the area.

Intense activity was still taking place, but significant changes had occurred between the two flybys, including the cessation of the largest plume, Pele, and the altered shape of the deposits associated with this plume (Figure 35.3). An area of about 10,000 km^2 had been filled in, presumably by fresh material falling down from the plume. It became evident that dramatic changes of Io's surface could occur over short timescales.

Initial analysis of the Voyager observations showed nine plumes and nine hot spots (active volcanoes), although not all plumes coincided with hot spots, and vice versa. "Hot spot" is a term used by Io researchers to define a region of enhanced thermal emission, a sign of active volcanism. The Voyager IRIS experiment did not observe the whole surface, so it was suspected that other hot spots existed. The surface showed many features with morphologies similar to volcanic landforms on other planets, such as calderas (volcanic craters) and flows.

After the two Voyager spacecraft left the Jupiter system on their way to Saturn and beyond, the study of Io's volcanism was continued from the Earth by astronomers using infrared detectors mounted on telescopes. These observations showed that brightenings and fadings of hot spots occur, indicating variations in the level of volcanic activity. Telescopic observations were also used to analyze the reflected light from Io's surface to determine surface composition, confirming that it was dominated by sulfur

dioxide (SO_2). Io was also observed by the International Ultraviolet Explorer satellite and by the Hubble Space Telescope.

The first spacecraft to orbit Jupiter was Galileo, which was able to image Io and monitor its volcanic activity from 1996 through early 2002. Galileo was designed to orbit the planet Jupiter for 2 years (1996−1997) and collect data on the planet's atmosphere, its moons, rings, and magnetic field. However, the failure of Galileo's high-gain antenna to deploy (a problem discovered while the spacecraft was on its way to Jupiter) drastically reduced the quantity of images and data that could be returned to the Earth. The mission still accomplished its objectives, thanks to the successful reconfiguration of the spacecraft's software to utilize a lower gain antenna and perform data compression on board. These measures, along with changes made in the Deep Space Network, maximized the amount of data that could be returned. Galileo observations were so successful and spectacular that two mission extensions to gather additional data were approved. The Galileo Europa Mission lasted from 1998 to 1999 and the Galileo Millennium Mission from 2000 to 2002. These extensions were particularly important for Io because all the high-resolution remote sensing observations obtained by Galileo were collected during these mission extensions. The close Io flybys during which high-spatial-resolution remote sensing observations were collected happened in October and November 1999, February 2000, and August and October 2001. The main remote sensing instruments observing Io were the solid-state imaging system (SSI), the near-infrared mapping spectrometer (NIMS), and the photopolarimeter radiometer (PPR).

Io was observed by the Cassini spacecraft on its way to Saturn in 2000 and in 2007 by the New Horizons spacecraft on its way to Pluto. Both spacecraft detected large plumes and New Horizons detected a previously unknown hot spot. Continued monitoring from ground-based telescopes continued to find variations in the level of activity, including those of Io's most powerful hot spot, Loki, which exhibits brightenings that switch on in 1 month or less and last several months before fading.

3. Io'S SURFACE

Io's phenomenal volcanic activity makes it the most geologically active object in the solar system. Remote sensing observations from Galileo revealed its surface in unprecedented detail and substantially changed our understanding of Io's geology and geophysics. Galileo's remote sensing instruments (visible and infrared) were used to study the surface features and volcanic activity, while the tracking of the spacecraft itself provided new constraints on the interior. Gravity measurements from tracking indicated that Io has a large iron/iron sulfide core and a silicate mantle. Galileo's close flybys of Io failed to reveal an intrinsic magnetic field, suggesting that little core convection is taking place.

The surface of Io contains three primary types of features (Figure 35.4): (1) broad, flat, layered plains, which are partially covered with visible, diffuse **pyroclastic materials**; (2) volcanic structures including **paterae** (caldera-like depressions), **flucti** (lava flow fields), and **tholi** (shield volcanoes and other positive-relief structures); and (3) mountains of volcano−tectonic origin. The complementary imaging coverage of Galileo and Voyager has allowed these features to be mapped in a global scale, thus giving us a window into not only local but also global processes.

Between the paterae, mountains, and other major geologic features, Io's surface appears smooth except for scarps that cut across the plains. Some scarps are linear and occur in parallel groups, which suggests a tectonic origin. Other scarps, however, are irregular and appear to be erosional, sometimes forming a series of mesas or large plateaus. The presence of these features on Io is somewhat puzzling because of the lack of a significant atmosphere or flow of liquid water. Sulfur and sulfur dioxide, possibly escaping explosively from a subterranean "aquifer", have been suggested as the main eroding agent on Io's surface.

Volcanic features dominate Io's surface, and the volcanoes cover a wide range of sizes and present varying characteristics such as power output, persistency of activity, and association with plumes. Interestingly, most of Io's volcanoes manifest themselves as caldera-like depressions, referred to as paterae. Unlike terrestrial volcanoes, those on Io rarely build large topographic structures such as tall shields (like Mauna Loa) or stratovolcanoes (like Mount St Helens). There are only a few tholi scattered across Io.

Io's surface shows a few remarkably large flucti. The lava flow field from the Amirani volcano is ∼300 km long, the largest active flow field known in the solar system. Io's large lava flows are possibly analogs of the continental flood basalt lavas on the Earth, such as the Columbia River Basalts in the United States. These ancient terrestrial flows were never directly observed, but they are suspected of producing major climatic effects.

A major question about Ionian volcanism after Voyager was the nature of volcanism—whether sulfur or silicates were predominant. Although temperature measurements from Galileo clearly showed that many hot spots have temperatures far too high for sulfur, the possibility that some sulfur flows occur on the surface cannot be ruled out. At the time of the Voyager flybys, Carl Sagan argued that the colorful flows around Io's Ra Patera volcano were sulfur (Figure 35.5). Unfortunately, the flows could not be studied by Galileo as the area had been covered over by new eruptions before Galileo's first observations in 1996. However, other locations may have sulfur flows. Most Ionian flows appear dark, but a few locations show pale

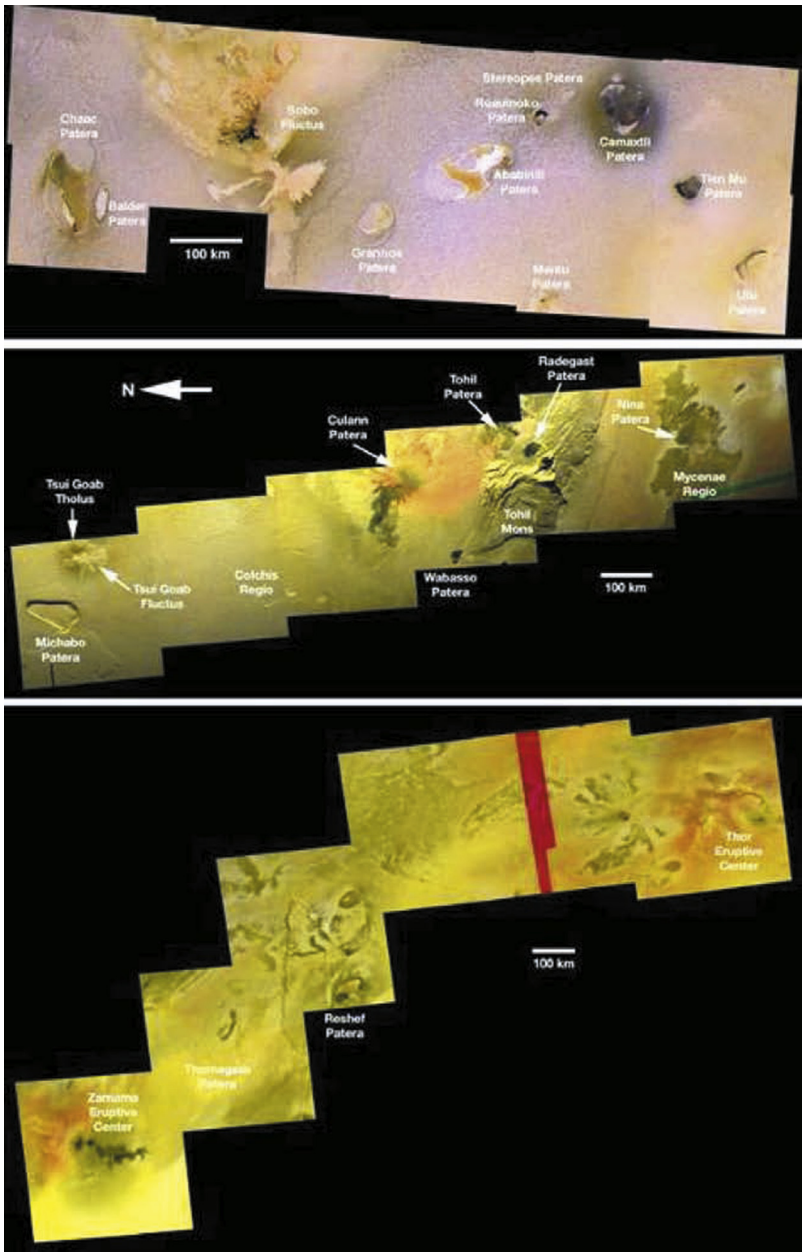

FIGURE 35.4 Mosaics of images acquired by Galileo's camera of three regions that accentuate the different types of geologic materials and terrains on Io. (Top) The Chaac-Camaxtli region shows paterae in various sizes, shapes, and colors, indicating varying volcanic and tectonic influences on their formation *(from Williams et al., 2002)*. (Middle) The Culann−Tohil region, which contains paterae, fluctii (lava flow fields), a mountain (Tohil Mons), and a volcanic construct (Tsui Goab Tholus) *(from Williams et al., 2004)*. (Bottom) The Zamama−Thor region, dominated by two eruptive centers, Zamama and Thor. Zamama has a long lava flow field and Thor was the site of the tallest eruptive plume seen on Io. *From Williams et al., 2005 (Figure courtesy of David Williams, Alfred McEwen, and Moses Milazzo).*

yellow or white flows that may well be sulfur. D. Williams and colleagues proposed that flows radiating from Emakong Patera may be sulfur and that low-temperature liquid sulfur (∼450 K) could explain many of the morphological features seen around Emakong Patera, such as a meandering channel 105 km in length that appears to feed a gray−white flow some 270 km in length. Infrared measurements using Galileo NIMS indicated temperatures less than 400 K inside Emakong caldera, and much cooler conditions (below the instrument's detection capabilities) over the flows. However, Galileo's instruments could not distinguish between sulfur flows and cooled silicates coated by bright sulfurous materials after erupting. One possibility, suggested by R. Greeley and colleagues, based on studies of a sulfur flow at Mauna Loa in 1984, is that rising silicate magma may melt sulfur-rich country rock as it

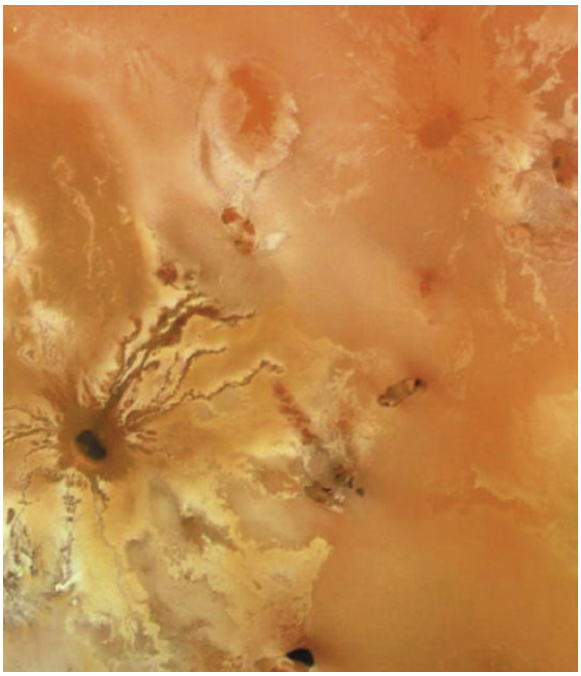

FIGURE 35.5 This image of Ra Patera volcano was taken by Voyager 1 at a range of 128,500 km (77,100 miles). The width of the picture is about 1000 km. Ra Patera is the dark spot with the irregular radiating pattern of flows, which were interpreted as being sulfur.

nears the surface, producing "secondary" sulfur flows (as opposed to "primary" flows that originate from molten magmas at depth). Sulfur dioxide is ubiquitous on Io, and the colorful surface is thought to be the result of **sulfur allotrope** deposits, making the possibility of secondary sulfur flows likely. Galileo data of the volcanoes Balder and Tohil Paterae suggest that sulfur dioxide could be mobilized as "flows" in very cold regions. However, the presence of sulfur and SO_2 flows on Io has not been confirmed and whether these flows exist on Io remains an open question.

The most common type of volcanic feature on Io is the patera. Although the origin of paterae is still somewhat uncertain, they are thought to be similar to terrestrial volcanic calderas, formed by collapse over shallow magma chambers following partial removal of magma. Some paterae show angular shapes that suggest some structural control, indicating that they may be structural depressions that were later used by magma to travel to the surface. At least 400 Ionian paterae have been mapped. Their average diameter is ~40 km, but Loki, the largest patera known in the solar system, is over 200 km in diameter. In contrast, the largest caldera on Earth, Yellowstone, is ~80 km by 50 km in size. The larger sizes of the Ionian features probably reflect the much larger sizes of magma chambers.

Mountains are the major structural landforms on Io and tower over the surrounding plains. Ionian mountains are defined as steep-sided landforms rising more than ~1 km over the plains. At least 115 mountains have now been identified and mapped. Io's mountains rise, on an average, about 6 km high, with the highest rising 17 km above the surrounding plains. Galileo images revealed that many mountains are partly or completely surrounded by debris aprons, plateaus, and layered plains. Mountains appear to be unstable and are thought to be relatively short-lived features. They are not active volcanoes, but their origin is still uncertain. Various models have been proposed to explain the origin of the mountains. Their asymmetrical shapes suggest the uplift and rotation of crustal blocks, implying that compressional uplift is probably the dominant mechanism.

Neither the volcanic features nor the mountains appear to follow a distinct global pattern such as seen on the Earth, suggesting that, on Io, surface expressions of internal dynamics are subtle. However, the distribution of mountains and paterae is not totally random; both features are concentrated toward lower latitudes and follow a bimodal distribution with longitude. According to P. Schenk and colleagues, the greatest frequency of mountains occurs in two large antipodal regions near the equator at about 65° and 265°. In contrast, J. Radebaugh and colleagues studied the distribution of Ionian patera, and although they found the paterae to follow a similar bimodal distribution, the highest concentrations are 90° out of phase with that of the mountains. When only the hot spots known to be currently or recently active are studied, their distribution appears random, although no active (or inactive) volcanic center has been detected at latitudes greater than 78°. The distribution pattern for volcanic centers is consistent with the pattern of heat flow from tidal heating in Io's asthenosphere predicted from simulations. The anticorrelation in the distribution of mountains and volcanic centers is further evidence that the two are not related, but the reasons for the anticorrelation are still unknown.

Because of the dynamic nature of Io's volcanism, its surface appearance can change in dramatic ways over time. Detectable changes occurred in the years between the Voyager and Galileo observations (1979−1995); however, many surface changes at the timescale of months have also been detected. One example is the change in the Pele plume deposit between the two Voyager flybys, which were spaced about 4 months apart. Surface changes are mostly due to new volcanic eruptions, particularly sulfur and sulfur dioxide from volcanic plumes and pyroclastic (ash and **tephra**) deposits. Other changes include new lava flows, increases in the area of flows, and changes in surface color. Volcanic materials have been observed to fade or disappear due to burial, alteration, radiation exposure, or erosion. Most surface changes have been detected at visible wavelengths; however, within individual volcanic centers, changes in temperature and sulfur dioxide coverage have been detected at infrared wavelengths. Most surface changes are localized and take place inside dark volcanic

paterae that cover only 1.4% of Io's surface, or are ephemeral volcanic plume deposits that fade or change color on timescales of a few months to years. One surprise from the first Galileo observations was that Io's surface appearance remained largely the same since the last Voyager flyby. Based on the changes observed between the two Voyager flybys (4 months apart), major changes were expected in the years between Voyager and Galileo. Instead, more than 90% of Io's surface remained unchanged between Voyager (1979) and the end of the prime Galileo mission (1999). New Horizons imaged almost all of Io in 2007, at conditions suitable for comparison with previous surface maps, and detected only one-fourth of the number of surface changes detected by Galileo. Although this is partly due to the limited spatial resolution of the images, it is consistent with previous results indicating that Io's surface remains largely unchanged.

Localized changes from major eruptions, however, can be dramatic. Some of these were particularly useful in the study of surface changes from Galileo. The eruption of the Pillan volcanic center in 1997 left a conspicuous "black eye" on Io's surface (Figure 35.6), covering an area of about 200,000 km^2 and reaching distances up to 260 km from the source (Figure 35.6). Later observations from Galileo's SSI showed a spectral absorption at 0.9 μm in these and other dark materials on Io, suggesting silicate composition (possibly magnesium-rich orthopyroxene). The dark deposit at Pillan slowly faded between 1997 and 1999 as it was covered by red sulfurous deposits from nearby Pele.

Surface colors are the most easily observed manifestations of surface change. Galileo results brought new insights into the intriguing question of what causes the vivid colors of Io's surface. The global distribution of the different color deposits gives some clues to their origin and Galileo's repeated flybys allowed observations at different illumination angles, which affect how colors appear in images. Io's surface has four primary color units: most of the surface is yellow (about 40%), white–gray (about 27%), or red–orange (about 30%), while black deposits are localized around volcanic centers. Red and orange materials are interpreted as deposits of short-chain sulfur molecules (S_3, S_4). These are concentrated at latitudes higher than 30° north and south and, where they are thought to result from the breakdown of sulfur (cyclo-S_8), by charged particle irradiation. These red deposits at high latitudes appear to last longer than those at equatorial regions. At lower latitudes, patches of red materials are associated with hot spots and plumes and are thought to be formed by condensation from sulfur-rich plumes. These red plume deposits are ephemeral, lasting perhaps a few years if the deposit is not replenished.

The yellow materials that cover a lot of the surface are interpreted to be sulfur (cyclo-S_8), with or without a covering of sulfur dioxide (SO_2) frosts deposited by plumes, or alternatively polysulfur oxide and sulfur dioxide without large quantities of elemental sulfur. White–gray materials are interpreted to be composed of coarse- to moderate-grained sulfur dioxide that condensed from plumes and later recrystallized. Black areas (<2% of

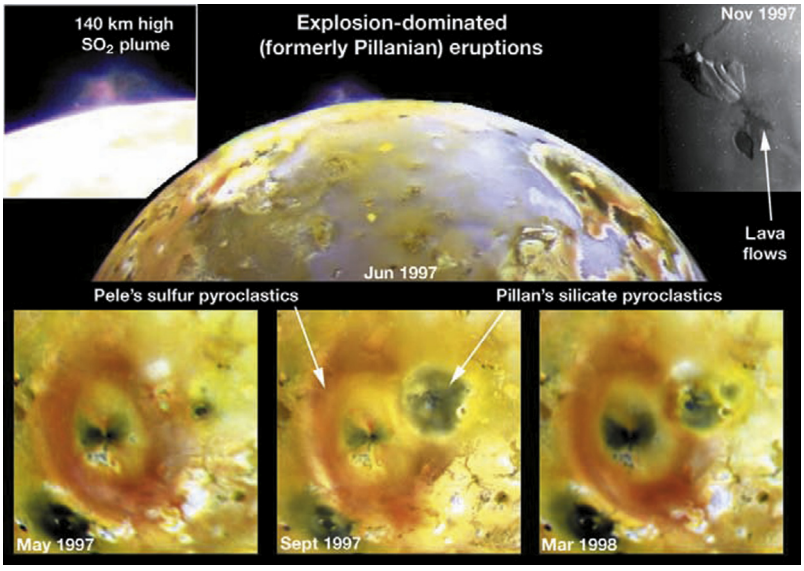

FIGURE 35.6 Explosion-dominated or Pillanian eruptions on Io occur in relatively brief (few months or less), intense outbursts that produce very high (possibly ultramafic) temperatures, plumes (top left), and rapidly emplaced lava flows (top right). Plumes can reach great heights (several hundred kilometers), and their deposits have produced black (Pillan), red (Pele, Tvashtar), and white (Thor) rings. These compositions are thought to be associated with silicate, sulfur, and SO_2 pyroclastic materials, respectively. *Figure courtesy of David Williams.*

surface) mostly correlate with active hot spots and occur as patera floors, as lava flow fields, or as dark diffuse materials near or surrounding active vents. These materials are consistent with magnesium-rich orthopyroxene, indicative of silicate lava flows or lava lakes (within paterae) or diffuse silicate pyroclastic deposits near paterae. Perhaps the most intriguing materials on Io's surface are the small greenish yellow deposits seen in a few isolated patches in or near active vents, which are thought to be composed of either sulfur compounds contaminated by iron or silicates such as olivine or pyroxene with or without sulfur-bearing contaminants.

Detection of other substances on Io's surface has been difficult because sulfur dioxide condensed from volcanic plumes blankets most of the surface and hinders detection of other species. Galileo NIMS detected a broad absorption at about 1 μm, which had been seen from telescopic observations. However, it is still not known what substance this spectral absorption is due to, although NIMS observations showed that it is anticorrelated with recently emplaced lavas. NIMS also detected local patches of almost pure SO_2, in one case, in Balder Patera, topographically confined, raising the possibility that it was emplaced as a fluid.

4. Io'S VOLCANIC ERUPTIONS

Shortly after the Voyager mission, the major controversy about Io's volcanic activity concerned the nature of the volcanism: sulfur or silicates? Io's surface colors were interpreted as sulfur deposits and this, among other factors, made the sulfur volcanism hypothesis attractive. One way to distinguish between sulfur and silicate volcanism is to measure the temperature of the molten material because sulfur has a lower melting temperature than silicate lavas. Sulfur volcanism would not produce temperatures exceeding ~700 K (427 °C), whereas basaltic lavas on the Earth range from 1300 to 1450 K (1027−1177 °C). The temperatures of the hot spots measured by the Voyager IRIS instrument were relatively low (below ~650 K) and could be consistent with either molten sulfur or silicates. However, Voyager instruments lacked the sensitivity and wavelength coverage needed to detect small areas at higher temperatures; hence, Voyager was "seeing" only the cooler areas, perhaps cooling silicate lava flows. Between the Voyager observations in 1979 and the Galileo observations that started in 1996, several of Io's hot spots were detected by ground-based telescopes. Temperature measurements using infrared detectors mounted on telescopes showed higher temperatures than had been measured by IRIS—such as 900 K reported by T. Johnson and colleagues in 1988, and 1225 and 1500 K reported by G. Veeder and colleagues in 1991. These measurements are consistent with silicate magmas but not with sulfur volcanism.

Galileo included much more sensitive instruments than Voyager, such as the SSI sensitive from ~400 to 1000 nm wavelengths and the NIMS sensitive from 700 to 5200 nm, but both had limitations. SSI was able to detect only spots hotter than ~700 K and only when Io was in eclipse (in Jupiter's shadow) to eliminate reflected and scattered light. NIMS had the ideal spectral coverage for detecting both the temperatures and spectral reflectances expected from silicate lavas, but it had limited spatial resolution (120 km or more) except during the close Io flybys. However, Galileo's instruments soon showed the hot spot temperatures to be indeed consistent with silicate rather than sulfur volcanism. The greatest surprise was the detection of very high temperature volcanism on Io when Galileo's NIMS and SSI instruments observed a vigorous eruption at Pillan in 1997 (Figure 35.6). The results, reported by A. McEwen and colleagues in 1998, provided evidence of temperatures exceeding 1500 K at several hot spots and, in the case of the Pillan eruption, temperatures of about 1800 K. The Pillan eruption temperatures are higher than any seen on lavas erupting on Earth now or in recent times and suggested compositions similar to those of ancient lavas on Earth. More recent analysis of the same data for the Pillan eruption suggests lower temperatures, about 1600 K, which could be due to unusually hot (superheated) basalts. Magma can be superheated by rapid ascent from a deep, high-pressure source. Melting temperatures of dry silicate rocks increase with pressure; therefore, the erupted lava can be significantly hotter than its melting temperature at surface pressure. Rapid ascent of basaltic magmas resulting in ~100 K of superheating should be possible. However, no record of such an eruption is known on the Earth.

Io eruption temperatures measured from observations of other hot spots by Cassini and New Horizons have been in the temperature range of basalts. The composition of Io's lavas remains questionable, as the temperatures measured could be consistent either with unusually hot basalts or with ultramafic (komatiite-like) lavas that had cooled by a couple of hundred degrees Celsius at the time the measurements were made. Komatiites and komatiitic basalts are ultramafic volcanic rocks on Earth that are rich in magnesium and dominated by olivine or pyroxene. These lavas have very rarely erupted on the Earth since the Proterozoic, about 1.8 billion years ago. Therefore, if Io's lavas are indeed ultramafic, studying Io's current volcanism may lead to a better understanding of the emplacement of lavas on the ancient Earth.

It is important to note that at present there are no direct measurements of the composition of Io's lavas. The most critical question about Io's volcanism—the composition of the erupting magma and crust—remains open.

Not all Ionian eruptions are vigorous like Pillan. On Earth, volcanic eruptions are often classified depending on their character—effusive, explosive, very explosive—and

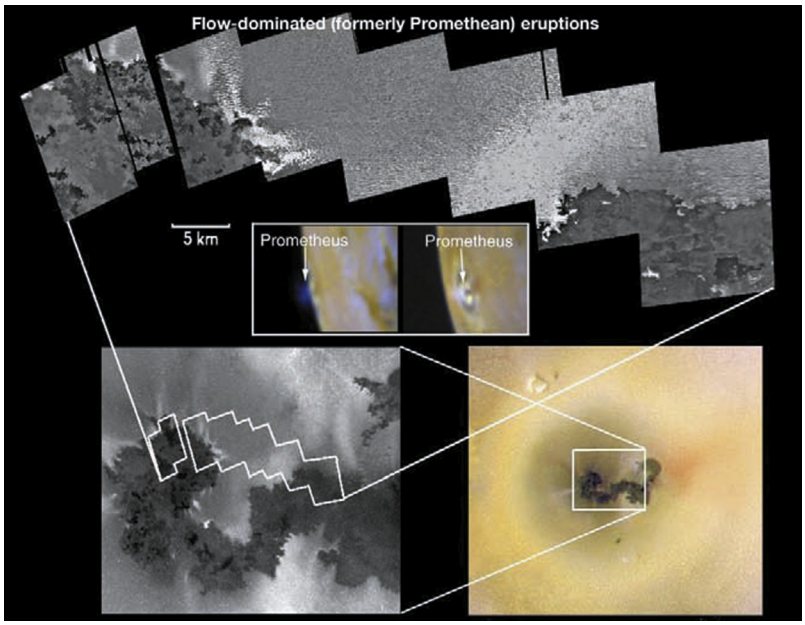

FIGURE 35.7 Flow-dominated or Promethean eruptions are relatively long lived (months to years) and are associated with long-lived plumes and flow fields. In this montage, Galileo SSI views of the Prometheus plume (center) are surrounded by increasingly higher resolution views of the Prometheus flow field. Note also the bright plume deposit forming an annulus in the lower right image.

these eruptions are often named after volcanoes or locations where they have been studied (e.g. Hawaiian, Icelandic, Strombolian, Pelean). High-resolution observations and temporal data on Io's hot spots showed that some broad generalizations can also be made for Ionian eruptions. The majority of Ionian eruptions can be placed in three classes initially designated "Promethean", "Pillanian", and "Lokian", although a single hot spot can exhibit more than one eruption style over time. Explosion-dominated ("Pillanian") eruptions (Figure 35.6) have an intense, short-lived phase that may correspond to the outbursts detected from the Earth. These eruptions originate from either paterae or fissures and produce extensive dark lava flow fields and dark pyroclastic deposits through short-lived, high-effusion-rate, vigorous activity. These events may or may not include eruption episodes with large (>200 km high) explosive plumes, which can produce large plume deposits such as that around the Pillan itself.

Less intense but more persistent flow-dominated eruptions ("Promethean") are named after the Prometheus hot spot (Figure 35.7), which has a persistent plume about 100 km high, active during both Voyager encounters in 1979, throughout the Galileo mission, and spacecraft observations since then. Surprisingly, distant images obtained by Galileo in 1996 showed that the Prometheus plume site had moved about 80 km west since 1979 but that its size and appearance had not changed. A new lava flow linked the old and new plume sites. Images and infrared observations obtained in 1999 showed that the main vent of this volcano was near the Voyager plume site and that the plume, not the volcano, had moved west. The plume's movement was modeled in terms of the interaction between the advancing hot lava and the underlying sulfur dioxide snowfield by Susan Kieffer and colleagues. The movement of lava flows on Earth over marshy ground can give rise to small, short-lived explosive activity, but nothing on the scale of the Prometheus plume has ever been observed. This type of eruption may be common on Io and, once the flow stops moving, the plume eventually shuts off, as has been observed at the Amirani volcano. The lava flows associated with these eruptions can be quite extensive and are thought to be emplaced through repeated small breakouts of lava, similar to the slowly emplaced flow fields at Kilauea in Hawaii.

Intrapatera ("Lokian") eruptions (Figure 35.8) are confined within the caldera-like paterae. These eruptions are thought to be lava lakes, some of which are possibly overturning. Observations from Galileo flybys showed that lava lakes are abundant on Io, and they may be a significant mechanism for heat loss from the interior. Io's most powerful hot spot, Loki, is thought to be a giant lava lake that perhaps undergoes periodic overturning, leading to brightenings that have been observed from the Earth for decades. Many other hot spots on Io appear to be persistent lava lakes.

5. HEAT FLOW AND INTERIOR

Observations of Io have also provided knowledge about the satellite's interior, where the tidal heat is being dissipated, driving the volcanic eruptions. Observations from the Earth and spacecraft have shown that the heat that comes

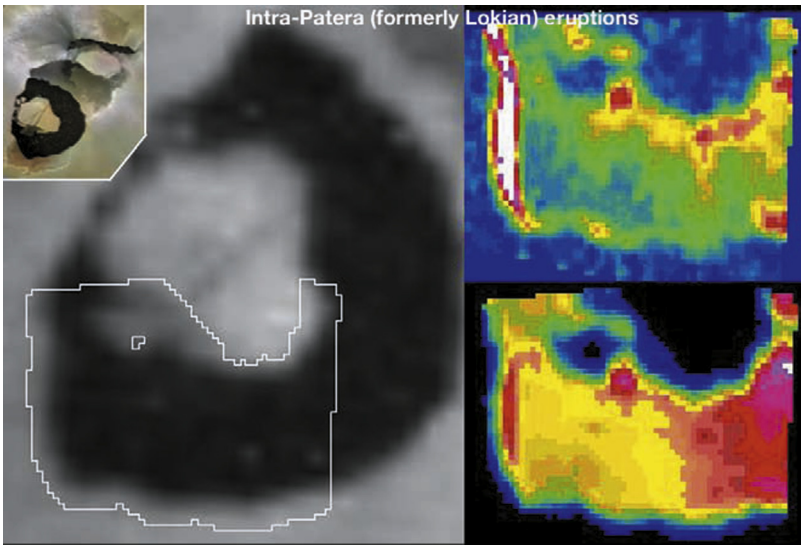

FIGURE 35.8 Intrapatera or Lokian eruptions are confined to paterae (caldera-like depressions) and are thought to represent the resurfacing of paterae floors by lava flows or overturning lava lakes. The style of eruption is exemplified by Loki (inset upper left, Voyager image). In this montage, Galileo NIMS images track the temperature changes across the floor of Loki. The top right image is at 2 μm, showing the hottest areas, while the bottom image, at 4 μm, shows the distribution of cooler areas. Note that the center of Loki (which appears white in the SSI image) is cold at infrared wavelengths.

out of Io and is radiated into space, called the heat flow, is very large compared with that of the Earth and other planets. The heat flow is measured at infrared wavelengths and the portion due to reflected sunlight is calculated and subtracted, taking into account Io's surface albedo. The difference is the heat flow due to volcanism and originates in Io's interior.

The first estimate of Io's heat flow was done by D. Matson and colleagues in 1981, who reported a value of 2 ± 1 W/m^2. In 1991, G. Veeder and colleagues reported measurements of Io's heat flow compiled from 10 years of ground-based photometric observations in the range 5−20 μm and estimated a minimum average heat flow of 2.5 W/m^2. The latest estimates of Io's heat flow are from J. Spencer and colleagues in 2002, using Galileo PPR measurements. They reported 2.2 ± 0.9 W/m^2, which is in close agreement with the first estimate by Matson. This range of values is very high even compared to geothermal and volcanic areas on the Earth such as Yellowstone. Io's heat flow is about 200 times what could be expected from heating due to the decay of radioactive elements and illustrates how crucial tidal heating is to drive Io's active volcanism. The heat flow is not uniform over the surface; in fact, it is dominated by the Loki hot spot.

An unresolved problem for Io is that there is a discrepancy between observed values of heat flow and theoretical estimates expected from steady-state tidal heating models over the course of Io's history. The current estimates of heat flow from observations are about twice the predicted value. If the theoretical estimates are correct, then Io's heat flow must have varied over time due to its orbital evolution. Other studies also suggest that Io's current heat flow and tidal heating rate are higher than the long-term equilibrium value. One suggestion is that Io is spiraling slowly inward, losing more energy from internal dissipation than it gains from Jupiter's tidal torque. The resolution of the apparent discrepancy between the observed and theoretical heat flow will have important implications for understanding not only the evolution of Io but also that of Europa and Ganymede.

What is happening deep within Io? Studies of Io's interior, including the lithosphere and mantle, are still in their early stages, but the Galileo spacecraft made some significant contributions. The properties of Io's interior determine how tidal forces deform the body. Therefore, one can use measurements of the deformation (variations in shape) of Io to get information on internal structure. Data obtained from images and radio tracking of the spacecraft as it came close to Io during several flybys provided this information. Variations in the spacecraft's motion revealed distortions in Io's gravitational field, which provided evidence that Io is differentiated.

Io is about the same size as the Earth's Moon, but it has a higher density. On the basis of density alone, it can be inferred that Io has a large metallic core. The size of this core can be inferred from the density and spacecraft measurements of Io's shape, assuming Io is in hydrostatic equilibrium. Work by M. Segatz and colleagues using Voyager observations revealed the basic structure of the interior, Galileo measurements have been used to refine this knowledge. Io is thought to be a two-layer body, consisting of a large metallic core of iron and sulfur and a silicate mantle. Galileo's magnetometer instrument measurements were complex to analyze because of the influence of Jupiter's strong magnetic field and the question of whether

Io had a magnetic field. However, more recent reexamination of the data by K Khurana and colleagues showed that Io has an induced magnetic field. Induced magnetic fields are created when a time-variable magnetic field sweeps through an electrically conducting material, which Khurana and colleagues suggest is a global magma ocean about 50 km beneath Io's surface. A model for Io's interior of a completely molten core and a crystal-rich ("mushy") magma ocean had been suggested by L. Kezthelyi and colleagues a few years earlier in 2004.

Other key measurements made by Galileo, including the discovery of widespread, high-temperature, silicate volcanism and tall mountains have contributed to a model of Io's interior. If the mountains are formed as thrust blocks, then Io's lithosphere must be at least as thick as the tallest mountains ($\sim$15 km).

The possibility that ultramafic volcanism exists on Io has strong implications for the interior. The idea that Io's crust is ultramafic (magnesium-rich) seems inconsistent with the well-understood process of magmatic **differentiation**. Heat flow on Io is sufficiently high that Io was expected to have undergone partial melting and differentiation hundreds of times, producing a low-density crust, depleted of heavy elements like magnesium (as mantle rocks begin to melt, the first component to melt has a lower density and segregates and rises toward the surface, while the heavier components sink). The "mushy" magma ocean model of Kezthelyi and colleagues suggested that widespread ultramafic volcanism would be present on Io, as the upper mantle would consist of orthopyroxene-rich magma with about the same density as the overlying crust. As lavas are deposited, the crustal layers sink and are eventually mixed back into the magma ocean, so a low-density crust cannot form. However, this model may not allow for sufficient tidal heat generation to occur and thus may be inconsistent with the heat flow observed. Another possibility, suggested by W. Moore and colleagues in 2005, is that local processes such as tidal forcing through cracks may account for the very high temperatures (>1400 K) observed at some hot spots on Io.

6. ATMOSPHERE, TORUS, AND THE JUPITER ENVIRONMENT

Io orbits Jupiter at a distance of about 421,800 km, which is deep within the Jovian magnetopause. Io has both a patchy but relatively large atmosphere and an ionosphere, and there is considerable interaction of Io with the Jovian magnetic field. Io's atmospheric density is low (about 10^{-9} bar), equivalent to good laboratory vacuums on the Earth, but the density is greater at the locations of active volcanic plumes. The main constituent of the atmosphere is SO_2, which is supplied largely by volcanic plumes, with a lesser amount coming from evaporation of the SO_2 frost deposits on the surface. Io's low gravity allows some of the atmosphere to escape, but it is continuously replenished by volcanic outgassing.

Since the time of the Voyager flybys, Io has been known to produce volcanic plumes hundreds of kilometers high, which serve as an efficient delivery mechanism for gas and dust particles into the magnetosphere and the space surrounding Io, although only a relatively minor amount of atmospheric gas is lost to space. The dynamics of Io's plumes are very complex, particularly because models of plume emplacement have to take into account the very low atmospheric pressure on Io.

Large plumes were detected by Galileo, Cassini, and New Horizons. The largest plume known on Io (500 km high) was detected from images obtained in August 2001, shortly after the Galileo spacecraft had flown through it. Observations by the plasma science experiment indicated the presence of SO_2 molecules in the plume. This in situ measurement is consistent with others that show the presence of SO_2 in plumes and SO_2 frost in plume deposits. Sulfur (S_3 and S_4), in addition to SO_2, was detected in the Pele plume from measurements made from the Hubble Space Telescope by J. Spencer and colleagues.

The temperatures of the frost deposits on Io's surface are sufficiently low that cold trapping of SO_2 by condensation is a very important process. Some material does escape Io, forming a corona and neutral clouds, and the Io torus. The corona refers to the region within Io's gravitational pull, where bound and escaping atoms and molecules populate a low-density shell. The neutral clouds of sodium, oxygen, and sulfur extend from the corona to distances of many times the radius of Jupiter.

An important discovery made during the Galileo mission was Io's aurora. The aurora (Figure 35.9) was detected through color eclipse imaging with the camera while Io was in Jupiter's shadow. The vivid colors detected (red, green, and blue) are caused by collisions between Io's atmospheric gases and energetic charged particles trapped in Jupiter's magnetic field. The green and red emissions are probably produced by mechanisms similar to those in the Earth's polar regions that produce terrestrial aurorae. The green (actually yellow) glow comes from emission from sodium ions, whereas the red glow is associated with oxygen ions. The bright blue glows mark the sites of dense plumes of volcanic vapor and may represent the locations where Io is electrically connected to Jupiter via a flux tube. Subsequent observations of Io's aurora by the New Horizons spacecraft as Io went in and out of eclipse by Jupiter showed variations in auroral brightness and morphology.

Observations from the Pioneer spacecraft were the first to reveal a cloud of neutrals along Io's orbital path. The most easily observed of these neutral clouds around Io is

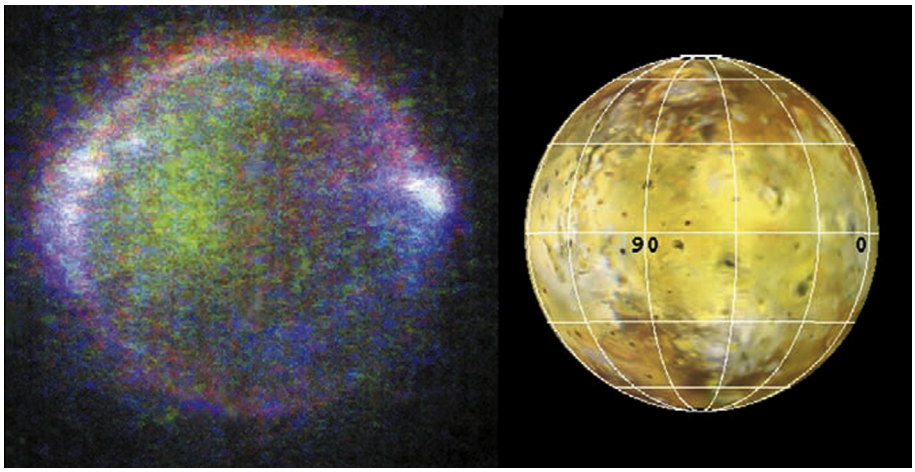

FIGURE 35.9 Io aurora. Bright blue glows represent sulfur dioxide excited by electrical currents flowing between Io and Jupiter in the flux tube. The blue glow on the right is over the Acala hot spot, which is thought to be the site of a "stealth plume" (composed of mostly gas and therefore hard to detect from images). Red and green (actually yellow) glows represent atomic oxygen and sodium, respectively.

the sodium cloud. The cloud is populated by sodium atoms escaping Io at about 2.6 km/s. It appears as a diffuse yellowish emission produced by scattered light from volcanic plumes and Io's lit crescent. This emission comes from neutral sodium atoms within Io's extensive material halo that scatter sunlight at the yellow wavelength of about 589 nm. Although neutral sodium atoms are most easily detectable by spectroscopy, it has been determined through extensive Earth-based telescopic studies that sodium is a minor component of the neutral material escaping from Io. The primary neutral elements in the cloud are oxygen and sulfur, which are thought to have dissociated from sulfur dioxide gas (SO_2) expelled from many of Io's active volcanoes at a rate of $\sim$1 t/s. So far, sodium has not been detected on Io's surface or plumes, but its existence is inferred because of its detection in the cloud.

The Io torus is a donut-shaped trail about 143,000 km wide along Io's orbital path. The torus is made up almost exclusively of various charged states of sulfur and oxygen, thought to be derived from the breakup of volcanic SO_2 and S_2. The ionized particles are held within the torus by Jupiter's magnetic field, in much the same way that charged particles are held in the Van Allen radiation belts around the Earth. Measurements made by the Galileo spacecraft during its close flybys showed that the plasma in the torus is slowed by Io's ionosphere, redirected around Io, and then reaccelerated in Io's wake. Other Galileo measurements showed that Io strongly perturbs Jupiter's magnetic field. These perturbations vary with time, suggesting that Io's variable volcanic activity influences the density of the plasma torus and the strength of its interactions with the Jovian magnetic field. (See Planetary Magnetospheres.)

7. OUTSTANDING QUESTIONS AND FUTURE EXPLORATION

The Galileo mission significantly advanced our knowledge of Io, but the failure of the high-gain antenna to open (and subsequent low data rates) prevented all but a very small part of Io's surface to be imaged at high resolution. The last spacecraft to date to fly by Io was New Horizons, which provided a valuable data set but limited in temporal coverage. Future exploration by spacecraft is needed to reveal Io's surface in detail at a variety of different wavelengths and to answer many outstanding questions. The geometry of Galileo's orbit around Jupiter resulted in lack of coverage at high resolution of Io's Jupiter-facing side, which should be a priority for future missions to observe. However, even parts of the surface previously imaged by Galileo and New Horizons are likely to change because of the dynamic nature of Io, so new missions will always reveal new features.

One of the most significant questions raised by Galileo which is still outstanding concerns the nature of Io's high-temperature volcanism. If ultramafic compositions are involved, it is difficult to explain how the magma composition would have stayed ultramafic throughout Io's history because differentiation would have been expected, leading to evolved types of magmas such as those that we find in present-day Earth. It is possible that the current style of volcanic activity is a geologically recent phenomenon (i.e. Io has only recently attained its resonant orbit with resulting tidal heating) or that the response of Io's lithosphere mantle to tidal heating has prevented extreme differentiation. Perhaps the magmas are not ultramafic, but are basaltic, possibly superheated during ascent. Compositional measurements of Io's fresh magmas would be invaluable for

future missions to obtain. Another intriguing question considers what the **volatiles** in the magma are dissolved in. The presence of explosive volcanism on Io is evident from the plumes and dark deposits that are thought to be ash and magma fragments. On Earth, the most common volatile is water; on Io, sulfur and sulfur dioxide have been detected in the plumes. But are there other compounds?

Other aspects of Io's geology are also intriguing. How are the mountains formed? Nearly half of Io's mountains are located adjacent to volcanic centers (paterae), but they do not appear to be part of the volcanic system. What can that relationship tell us about Io's crust? Questions also abound about Io's atmosphere and the interaction between Io and the Jovian magnetosphere, particularly the interaction of the flux tube that allows the transfer of charged particles between the two bodies. What are the sources of the atoms, neutrals, and ions that are released into the plasma torus and magnetosphere, and what physical processes allow them to escape? These are just some of the key questions that have developed about Io after Galileo and New Horizons and that require further analysis of existing data sets, and likely new data obtained by future missions. At the time of this writing, there are no missions to Io planned, but the European Jupiter Icy Moons Explorer is expected to observe Io and make significant contributions to outstanding questions. Advances are possible from ground-based and space telescope-based programs. Ground-based observations using Adaptive Optics have been a major step forward in the study of Io because the spatial resolution of these observations can now rival some of those obtained from Galileo. Io has been successfully observed by the Hubble Space Telescope and can potentially be observed from future orbiting telescopes.

1. INTRODUCTION AND EXPLORATION HISTORY

Europa and her sibling satellites (See also chapters on Io, Ganymede and Callisto, and Planetary Satellites) were famously discovered by Galileo in 1610, and more controversially by Simon Marius at essentially the same time, but it took almost four centuries before any detailed views of their surfaces were seen and the grandeur of the **Galilean satellites** was revealed. In the 1960s, ground-based telescopic observations determined that Europa's surface composition is dominated by water ice, as are most other solid bodies in the far reaches of the solar system.

The Pioneer 10 and 11 spacecraft flew by Jupiter in the 1970s, but the first spacecraft to image the surfaces of Jupiter's moons in detail were the Voyager twins. Voyager 1's closest approach to Jupiter occurred in March 1979, and Voyager 2's, in July of the same year.

Both Voyagers passed farther from Europa than from any of the other Galilean satellites, with the best imaging resolution limited to 2 km per **pixel**. These images revealed a surface brighter than that of most other moons, crossed with numerous bands, ridges, cracks, and a surprising lack of large impact craters or high-standing topography (see Galileo spacecraft image in Figure 36.1). Despite the distance from which the images were acquired, they were of sufficiently high resolution that researchers noted some of the dark bands had opposite sides that matched each other extremely well, like pieces of a jigsaw puzzle. These cracks appeared to have separated, and **ductile** icy material

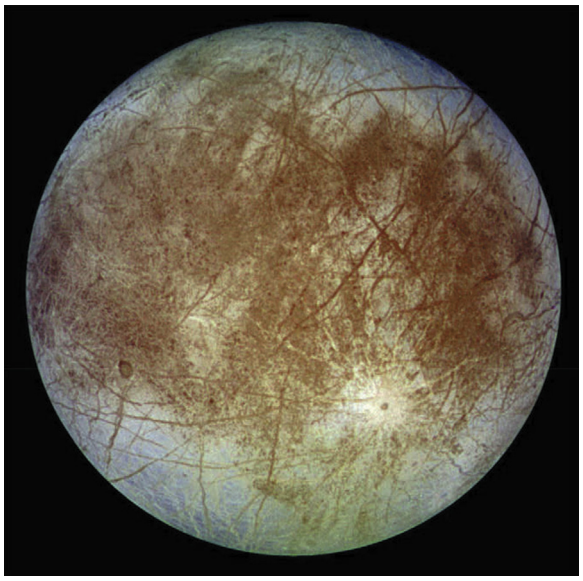

FIGURE 36.1 Global view of Europa's trailing hemisphere, acquired early in the Galileo spacecraft's tour of the Jovian system. The colors in this image have been enhanced to emphasize detail. This image shows the extent of the reddish-brown material that mottles Europa's surface, along with numerous linear features, many over 1000 km long. Two large impact features are also visible: Pwyll crater, surrounded by bright rays, is thought to be the youngest large crater on Europa, and the Callanish multiringed structure is the large circular feature toward the west (left).

TABLE 36.1 Properties of Europa

Discovered	**1610**
Discoverers	Galileo Galilei, Simon Marius
Mean distance from Jupiter	671,100 km
Radius	1560.8 km
Mass	4.79955×10^{22} kg
Density	3.013 g/cm^3
Orbital period (sidereal)	85.224 h (3.551 Earth days)
Rotational period	85.224 h (3.551 Earth days)
Synodic period	11.23 h (0.4649 Earth days)
Orbital eccentricity	0.0094
Orbital inclination	0.466°
Visual geometric albedo	0.67
Escape velocity	2.026 km/s
Spacecraft visitors	Voyager 1 (March 1979)
	Voyager 2 (July 1979)
	Galileo (July 1996 to 2000)
Predicted average surface temperature	~50 K (poles) to ~110 K (equator)

appeared to have flowed into the opened gaps. This suggested that the surface could have once been mobile. The relative youth of Europa's surface is demonstrated by the lack of large impact structures—Voyager images suggested only a handful. These are expected to build up over time as a planetary surface is constantly bombarded by asteroidal and cometary debris over billions of years, until the surface is covered in craters. A lack of craters implies that something has erased them—such as volcanic (or in Europa's case, **cryovolcanic**) flows or tectonic features, or perhaps **viscous relaxation** of the icy crust. Researchers studying the Voyager data also noted that the patterns of some of the longest linear features on the surface did not fit with predicted simple models of global stresses that might arise from tidal interactions with Jupiter. However, if the shell was rotated backward a few tens of degrees, the patterns fit well to a model of **nonsynchronous rotation**, by which the icy surface had slowly migrated eastward with respect to the satellite's tidal axes. This mechanism requires a ductile or liquid layer between the surface ice and the deeper interior. Combined with the observations of dark bands, these were tantalizing hints that Europa had a warm interior at some time in the past, and perhaps still today. Increasingly sophisticated theoretical models of **tidal heating** of Europa, discussed later in more detail, suggested that a global subsurface ocean might yet persist within Europa.

Such intriguing findings meant there was much anticipation for the Galileo mission, which launched from the space shuttle Atlantis in 1989 and entered orbit around Jupiter in 1995. The primary mission included dropping a probe into Jupiter's atmosphere, as well as observing all its large satellites, its atmosphere, and the local environment. Despite severe data rate limitations during the mission (because the spacecraft's main antenna failed to open), the data from Galileo were so intriguing that the mission was extended in 1997 for a further 3 years, to enable eight further close flybys of Europa, and to study its volcanically active neighbor, Io. Data from the extended Galileo Europa Mission afforded many more high-resolution images of Europa, as well as magnetic data that strongly imply the presence of a briny water layer beneath the surface today. After running low on fuel, the Galileo spacecraft was intentionally commanded to crash into Jupiter in 2003, ending its successful mission. The physical and orbital properties of Europa are summarized in Table 36.1.

2. FORMATIONAL AND COMPOSITIONAL MODELS

During the formation of our solar system, the growing gas giant planet Jupiter pulled material from the solar nebula. It is now understood that, in contrast to early models of

satellite **accretion**, the solids of the Jovian circumplanetary disk were probably grabbed from the **solar nebula** in nearly **primordial** form, and that the circumplanetary disk may have been gas-poor. Thus, the material incorporated into the Galilean satellites was probably similar in composition to the asteroids of the outer asteroid belt, containing ice, **anhydrous silicates, carbonaceous** material, and nickel–iron metal alloy.

The Galilean satellites formed by aggregation of these solids, with the proportion of ice varying with distance from the warm protoplanet Jupiter. Io formed relatively close to Jupiter, so it was not able to accrete and retain significant amounts of water ice. As the next moon outward, Europa formed as a mostly rocky satellite, able to accrete sufficient volatiles to form a $\sim$100 km thick outer layer of H_2O. In the colder reaches of the Jovian circumplanetary disk, Ganymede and Callisto formed with near-equal amounts of rock and ice. If the Jovian subnebula were cold enough, some lower temperature condensates such as CO_2 could have been incorporated as Europa and the other Galilean satellites formed.

Europa's early heat of **accretion** combined with heat from radioactive decay in the silicate component would have warmed the satellite's interior and could have formed a primordial ocean, which was likely reduced and sulfidic. Thermal and geochemical evolution would have caused some oxidation of the ocean through time, forming sulfates. Refined models of Europa's accretion and chemical evolution are bringing improved understanding of the satellite's initial conditions.

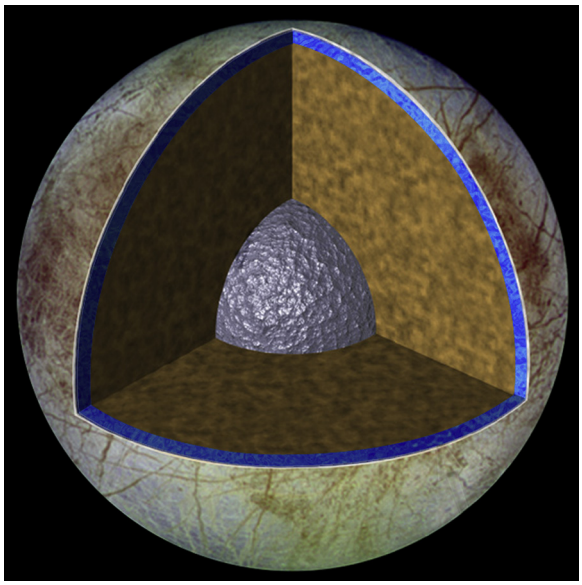

FIGURE 36.2 Interior structure of Europa. Rocky mantle (brown) and iron-rich core (gray) are synchronously locked in position with respect to Jupiter, but the ice shell (white) may rotate nonsynchronously—slightly faster than the interior—if decoupled by the water layer (blue). Layer thicknesses are approximately to scale.

3. INTERNAL STRUCTURE, TIDES, AND GLOBAL TECTONICS

3.1. Europa's Internal Structure

Measurements of Europa's gravity field from the Galileo spacecraft constrain Europa's axial **moment of inertia** to 0.346 ± 0.005 (a value 0.4 represents a constant density body), indicating significant concentration of mass toward its center. Further assumptions of likely composition and density of its internal layers suggest that Europa probably has a $\sim$100 km thick layer of H_2O overlying a rocky **mantle**, which surrounds an iron-rich **core** (Figure 36.2). The gravity data do not constrain the nature of the water-rich layer, i.e. whether it is solid or liquid.

The most definitive evidence that there is a liquid water ocean within Europa at the present time comes from the Galileo spacecraft's magnetometer, combined with theoretical analyses. Because Jupiter's powerful magnetic field is tilted by 10° relative to the planet's equatorial plane in which the satellites revolve, the satellites experience Jupiter's magnetic field as time-varying. For Europa, each 5.6 h (half the synodic period) the satellite finds itself alternately above and below the magnetic equator of Jupiter. Surprisingly, the Galileo magnetometer measured a magnetic signature in the vicinity of Europa that alternately flips to oppose the external Jovian magnetic field. This implies that Europa is behaving as a conductor, generating an induced magnetic field in response to the external Jovian field. Modeling of the Galileo observations suggests that there is a conductive layer—probably a briny ocean—within the outer portion of Europa.

The thickness of the ice shell overlying the ocean is significant for models of Europa's thermal evolution, geological processes, and astrobiology. With future missions we will want to sample material from the ocean to understand Europa's potential for life, but accomplishing this task is dependent upon the ease of accessing material from the ocean, and the ways this material may have been processed. To estimate Europa's ice shell thickness, we must search for clues in the geophysical history and geological record preserved in the icy surface.

3.2. Tidal Evolution

The principal energy source that heats Europa's interior and drives its tectonics today comes from its orbital interaction with Jupiter. An **orbital resonance** can occur when two satellites have orbital periods that are related by integer relationships, allowing them to exert a gravitational influence over each other and affecting the eccentricity of their orbits. The three Galilean satellites are locked in the

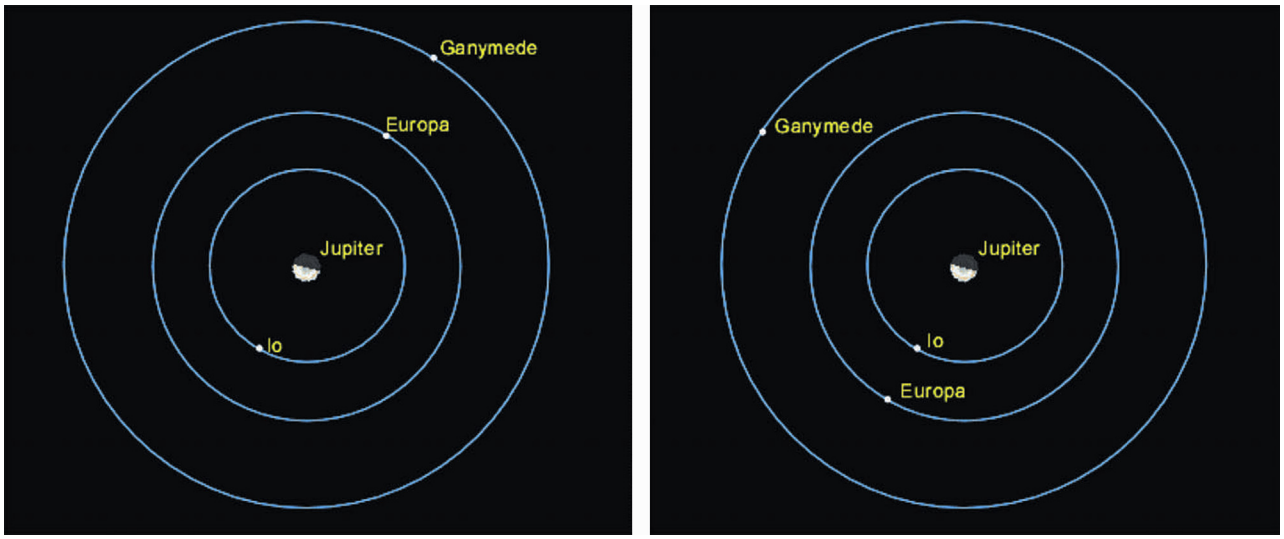

FIGURE 36.3 Mutual conjunctions resulting from the Laplace resonance of Io, Europa, and Ganymede. Io completes approximately four orbits to every two of Europa's, while Ganymede orbits approximately once during the same time. (Left) Mutual conjunction of the Europa–Ganymede pair. (Right) Io and Europa experience a mutual conjunction one Io day later, while Europa has moved along half an orbit, and Ganymede has progressed through one-quarter of its orbit. The resonance forces Europa's eccentricity to be nonzero, causing tidal heating and geological consequences.

Laplace resonance, in which the orbital periods of Ganymede:Europa:Io are in a near 1:2:4 ratio (Figure 36.3), but more important, the mutual **conjunctions** of the Io–Europa pair and of the Europa–Ganymede pair **precess** around Jupiter at precisely the same rate. Like a child on a swing pushed at the optimal moment, the recurring mutual conjunctions force and maintain eccentricities in their orbits (Figure 36.3). Although it is not known exactly when or how the moons came to form the precise clock that is the Laplace resonance, one model suggests this resonance was progressively achieved after Io moved outward into a near 2:1 resonance with Europa, and then the Io–Europa pair moved outward until Ganymede was captured into its own near 2:1 resonance with Europa. An alternative model suggests early (primordial) formation of the resonance closely connected to formation scenarios of the Galilean satellite system. Europa's forced eccentricity is key to its youthful and complex surface, as will be described in the following sections.

3.3. Tidal Heating

Europa's resonance with siblings Io and Ganymede causes it to have a slightly **eccentric** orbit ($e = 0.0094$). This eccentricity causes Europa to move closer to and farther from Jupiter (at **perijove** and **apojove**, respectively) as it moves along its 85 h orbit, causing the satellite to undergo increasing and decreasing gravitational pull from Jupiter. At the same time, Europa undergoes **libration**, its tidal bulge rocking from side to side as Europa orbits Jupiter. If an ocean is present decoupling the shell (as described below), Europa could deform by up to ~30 m over each orbital period, and the dissipation of **strain** energy resulting from this deformation would cause the interior to warm. Dissipation of tidal energy can occur in several ways, such as by friction along **faults**, turbulence at liquid/solid boundaries, and **viscoelastic heating** at the scale of individual ice or mineral grains. It is likely that a great degree of tidal energy is currently dissipated near the base of Europa's icy shell, just above the interface between the ice and the underlying liquid ocean, where the ice is warmest and most deformable on the timescale of the satellite's orbit. Combined with radiogenic heating from the deep interior, this regular input of energy is believed to be sufficient to keep Europa's ocean liquid; additional heating might result if there is also tidal dissipation in the rocky mantle.

3.4. Diurnal Stressing

In addition to heating, the tides induced by Europa's eccentric orbit are believed to be responsible for many of its tectonic processes, including formation of cracks on its surface. As Europa orbits Jupiter, its radial and librational deformation results in **diurnal stresses** (so named because Europa's day is equal to its orbital period). These stresses are relatively small (<0.1 MPa), but they are apparently sufficient to crack Europa's ice shell, producing regions of extensional and compressional stresses that migrate across the surface, changing in direction and magnitude as Europa moves through its eccentric orbit. The magnitude of distortion, and thus stress, due to tidal flexing depends on a satellite's interior structure. If Europa's ice shell were frozen to the rocky mantle, there would be very little tidal

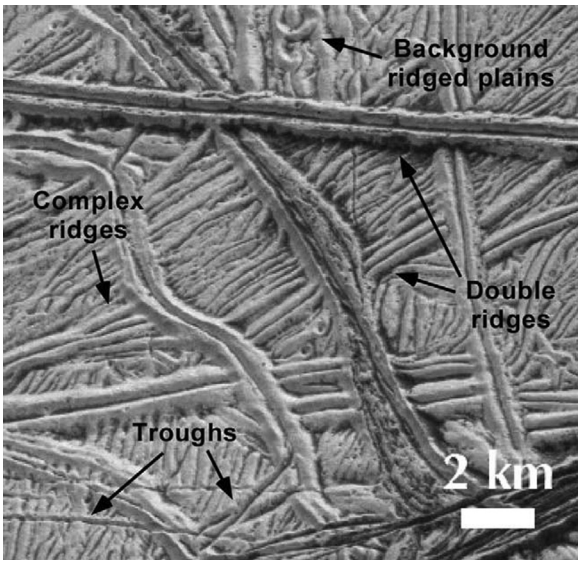

FIGURE 36.4 Galileo image of a typical portion of Europa's ridged plains, showing ridges and troughs crisscrossing and overprinting each other. Double ridges are most common, but ridge complexes (also known as "complex ridges") with more than two crests also occur, along with simple troughs (cracks). The background terrain is so heavily overprinted that it is difficult to distinguish individual features.

distortion overall, with a tidal amplitude of about 1 m; however, if there is a liquid water ocean beneath the ice shell, the surface is predicted to distort by up to 30 m during an orbit. (In comparison, the Earth's rocky moon, which has a relatively cold interior and high eccentricity of 0.055, deforms by just ~10 cm over each orbit due to tides raised by the Earth.)

Diurnal stresses have been invoked to explain some of Europa's unusual surface features, including cracks and ridges (Figure 36.4), and likely contribute to the relatively youthful surface age. Most dramatically, diurnal stresses have been invoked to explain the unusual **cycloidal** shapes of some ridges and other structures on Europa, due to the changing direction and magnitude of stresses, as described further in Section 4.1.3. Moreover, diurnal stresses tend to rotate anticlockwise in the northern hemisphere, and clockwise in the southern. These stress rotations may be responsible for the observed preponderance of left-lateral **strike-slip** faults observed in Europa's northern hemisphere and right-lateral strike-slip faults in the southern.

3.5. Nonsynchronous Rotation

If a satellite is in a perfectly circular orbit around its primary, it keeps the same face toward its parent planet, and this tidal bulge remains fixed relative to the planet. Most of the solar system's large satellites, including the Earth's moon, rotate synchronously, keeping the same hemisphere always facing the parent planet. Because of Europa's combination of eccentricity and a decoupling global ocean, a net torque results due to eccentricity, causing Europa's decoupled ice shell to rotate slightly faster than synchronously. Europa's rocky interior is expected to maintain a permanent mass asymmetry to counter this effect, so beneath the icy shell, Europa is probably synchronously locked (as is the Earth's moon). The rate of this predicted "nonsynchronous rotation" is not known, and it might not be constant through time, but a lower limit time for one complete rotation of the shell is ~10,000 years, based on nondetection from comparisons of Voyager and Galileo images. Nonsynchronous stresses are expected to be large—perhaps an order of magnitude larger than the diurnal stresses and potentially sufficient to open deep (kilometer-scale) cracks in the ice shell. The orientations of Europa's major lineaments do not correspond to the current patterns expected from tidal stresses alone, but if the shell is backrotated by moving it "back in time" by ~30° westward in longitude, there is an overall good fit of lineaments to the predicted stresses. Mapping of crosscutting relationships among lineaments in some areas of Europa suggest that the ice shell may have completed one or many rotations. Some geological features, including several arcuate troughs, suggest that the icy shell probably has also undergone some degree of **polar wander**, i.e. a tilt of the ice shell relative to the spin axis.

4. LANDFORMS ON EUROPA

Europa exhibits two primary types of terrain: (1) the bright-ridged plains, which are crisscrossed by bright and dark linear features, and (2) mottled terrain, which shows evidence for **endogenic** disruption and modification of the surface. Each type of terrain and the **morphologies** of their constituent **landforms** are discussed in this section.

4.1. Ridges, Troughs, and Bands

Europa's linear features are ubiquitous, covering most of the satellite's surface. These landforms exist at a variety of sizes and scales, and exhibit several morphologies, some of which are unique to Europa. Many linear features have overprinted and offset one another, sometimes by several kilometers, making it difficult to piece together the history of the surface. Some ridges have shallow topographic depressions and/or fine-scale fractures alongside them, suggestive of loading of the **lithosphere** by the weight of the ridge material from above and/or from withdrawal of material from below. Understanding how ridged plains form and evolve is important to the question of where liquid water exists within Europa, whether and how water is involved in the formation of surface landforms, and possible niches for life.

4.1.1. Troughs

The simplest of Europa's landforms, troughs (commonly called "cracks"), may be several hundred kilometers long and less than a few hundred meters wide (Figure 36.4). They can have subtle rims or none, and are generally V shaped, suggesting an origin as **tension fractures**. Some have undergone **mass wasting** along their sides, and some troughs have elevated flanks and appear to be transitional forms between troughs and double ridges. As discussed previously, Europa's troughs probably originate by tensile cracking due to diurnal and/or nonsynchronous rotation stresses.

4.1.2. Double Ridges and Ridge Complexes

The most ubiquitous landform on Europa, ridges are most commonly found in a "double ridge" form, with two parallel ridges separated by an axial valley (Figure 36.4). Double ridges can be from ~0.5 to ~2 km wide, and some span thousands of kilometers in length. Slopes of these ridges tend to be near the **angle of repose** (~30°), and at some, preexisting topography can be traced up the flank, suggesting that they may have formed by upwarping of the surface. Most ridges tend to be linear or only gently curved, and mass wasting is prevalent along ridge flanks. The cycloidal ridges discussed below (Section 4.1.3) have notably arcuate shapes, but are otherwise morphologically identical to other double ridges on Europa. "Ridge complexes" have three or more subparallel ridge crests (Figure 36.4). Some ridge complexes appear to be sets of several double ridges, running parallel to, or in some cases intertwined with, each other, while others seem to be composed of bundles of ridge crests separated by intervening troughs.

Ridge formation on Europa is not yet fully understood, and several models have been suggested. Europa's troughs are probably modified by additional processes to form double ridges with distinct and uniform crests. In one model, ridges form through the buildup of cryovolcanic material erupted from fissures. A major drawback with this model is that it is hard to explain the remarkable uniformity of ridge crests, and the distinct V-shaped trough along their axes. An alternative model suggests that double ridges form in response to cracking and subsequent rise of warm or compositionally buoyant ice. Possibly aided by tidal heating, the buoyant ice intrudes and lifts the surface to form ridges. However, this model does not explain how multiple ridges might form within ridge complexes.

Another model proposes that the ridges form in a manner similar to pressure ridges in Arctic sea ice. In this model, cracks created by diurnal tidal stresses allow water to seep up from the ocean below, filling the crack and partially freezing into a slurry. It is envisioned that diurnally varying tidal stresses would then push the crack margins back together, and this partially frozen ice is easily smashed up, forming a jumbled pile of ice that squeezes out of the crack. Although pressure ridge formation is well understood in the Earth's sea ice, where the ice is thin and ocean currents cause movement of the ice, it is unknown whether Europa's ice is sufficiently thin to pull apart atop the liquid layer. Even if so, it is not clear that this model can explain the morphology of Europa's ridges, including distinct V-shaped troughs along double ridges, their uniform parallel ridge crests, and the apparently upwarped features along some ridge flanks.

Alternative models have suggested that water-filled cracks instead penetrate upward from the ocean into the ice shell and upwarp the surface. This model might explain the general morphology of ridges, but it has difficulty explaining the uniformity of the crests and the morphologies of ridge complexes.

Another model is one in which a fracture forms along the surface and then undergoes **shear stresses** and strike-slip motion as a result of Europa's diurnal tides. This strike-slip motion along the crack produces frictional heating as the walls of the crack rub past each other, warming the subsurface ice (Figure 36.5). This shear heating may trigger warm ice to well up beneath the crack, forming ridges, and perhaps inducing partial melting beneath the ridge axis at the same time. This model predicts that a ridge a few hundred meters high could be built by upwelling warm ice in only a decade or so, and because both sides of the crack are subject to the heating, the ridges would be expected to be of uniform width and height, as is observed. If shear heating were sufficient to induce partial melting below the ridge, the melt would tend to drain downward, perhaps forming the V-shaped axial trough above as material is removed. This model predicts softened ice along the ridge, perhaps enabling contractional deformation to occur in response to compressional stress. A model in which contraction occurs across some ridges is viable based on reconstruction of preexisting features and kinematic arguments. If ridges do hide contraction along initially extensional structures, then ridges could help to balance the abundant extension on Europa that is represented by its pull-apart bands (see Section 4.1.5). Ultimately it may be found that ridge formation is a combination of several processes, but currently these features remain an enigma.

4.1.3. Cycloidal Structures

While most double ridges are linear in overall planform, cycloidal ridges are shaped like a chain of distinct arcs (Figure 36.6). Cycloidal fractures, ridges, and some other structures on Europa's surface are likely explained by the action of diurnal stresses. If a fracture propagates slowly enough—at about walking speed—the rotation of **tensile**

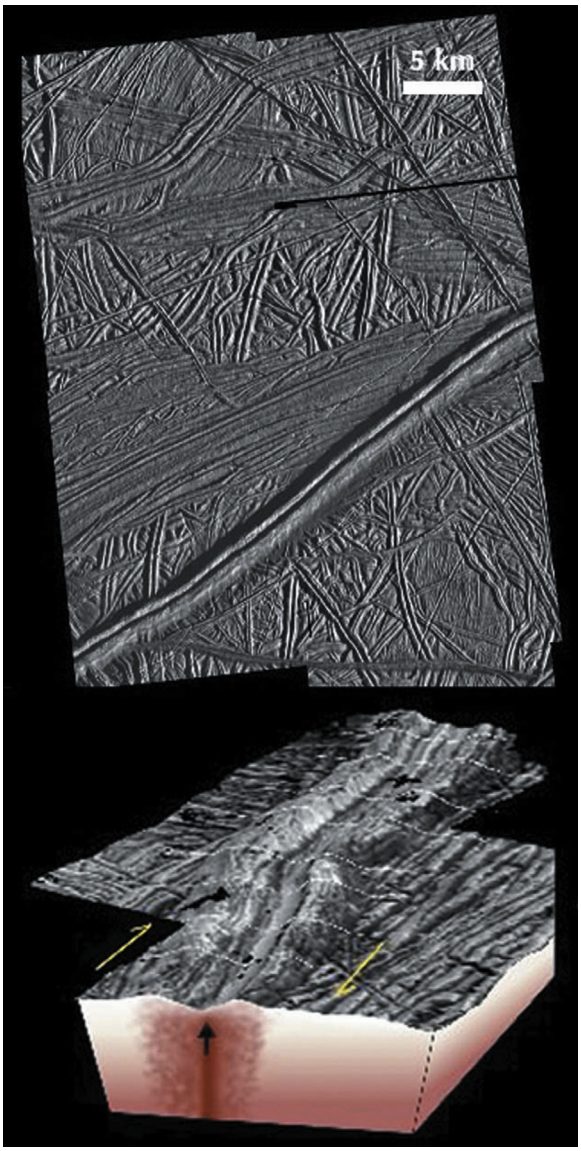

FIGURE 36.5 Double ridges such as Androgeous Linea (top) are ubiquitous on Europa, but their origin is not well understood. In the shear heating model (bottom), strike-slip, or shear, motion along a fracture results from diurnal tidal stresses. Friction between the fracture walls warms the ice, softening or partially melting it. Warm ice close to the fracture rises buoyantly, upwarping the ridge crests. Downward drainage of melt may aid formation of the axial depression. *Image: NASA/JPL. Diagram: Topography courtesy B. Giese, DLR.*

stresses over a Europan day occurs on a timescale such that the propagating fracture can be affected by these changing stresses, tracing out an arc instead of a straight path. As Europa moves in its orbit, the tensile diurnal stresses will drop below a critical value needed for fracture propagation, until the next orbit, when tensile diurnal stresses again increase above the critical value for fracture propagation, generating the next cycloidal arc. In this model, the diurnal stresses that crack the ice to create cycloidal fractures are relatively small, just a few tens of kilopascals. Cycloidal ridges would evolve from cycloidal fractures in a manner similar to the formation of other ridges. Some pull-apart bands (Section 4.1.5) with arcuate and scalloped margins may have opened along preexisting cycloidal ridges. Tides imparted by Jupiter's gravitational pull would be insufficient to crack the surface into cycloidal patterns if Europa had no ocean, so the presence of cycloid structures is strong argument for the existence of an underlying ocean at the time these structures formed.

4.1.4. Triple Bands

One specific type of lineament consists of a bright central ridge, flanked by patchy, diffuse, low-albedo margins, hence the term "triple band" (Figure 36.7). These are most commonly larger, more prominent ridges. It has been suggested that the dark flanks were created by the eruption of icy cryovolcanic material (similar to some explosive volcanoes on Earth), which either seeped out along the ridge flanks or rained dark **pyroclastic** material onto the surface alongside the ridge. Another possibility is that **intrusions** of ice that is warmer than its surroundings might result in local **sublimation** of icy surface materials, leaving a layer of more **refractory** dark deposits.

4.1.5. Pull-Apart Bands

Polygonal dark and gray bands on Europa's surface have margins that can be closed together almost perfectly, reconstructing structures that were apparently laterally displaced when the bands formed along fractures. Many such bands are bounded along each of their margins by an individual ridge, suggesting that a double ridge was split along its axis during band formation (Figure 36.8). These structures have been termed "pull-apart" bands, or dilational bands, and they are a clear indication of movement of a brittle surface layer atop a mobile subsurface. Where the bands pulled apart, dark, probably low-**viscosity** subsurface material moved up to fill the gap. Limited topographic data across bands suggest that many stand somewhat higher than the surrounding terrain, consistent with formation atop buoyant ice, rather than liquid water. Bands have been shown to have brightened over time, possibly because of frost deposition or radiation damage. This has led to a wide range of band brightnesses, ranging from relatively dark, through gray, to as bright as the brightest background plains on the surface.

Many bands exhibit bilateral symmetry, with V-shaped central troughs and hummocky textures, and some have zones of ridges and troughs parallel to the central axis, which may include normal faults (Figure 36.9). Morphological comparisons between bands and terrestrial mid-ocean ridges suggest that band formation may have been analogous to seafloor spreading centers on the Earth, where

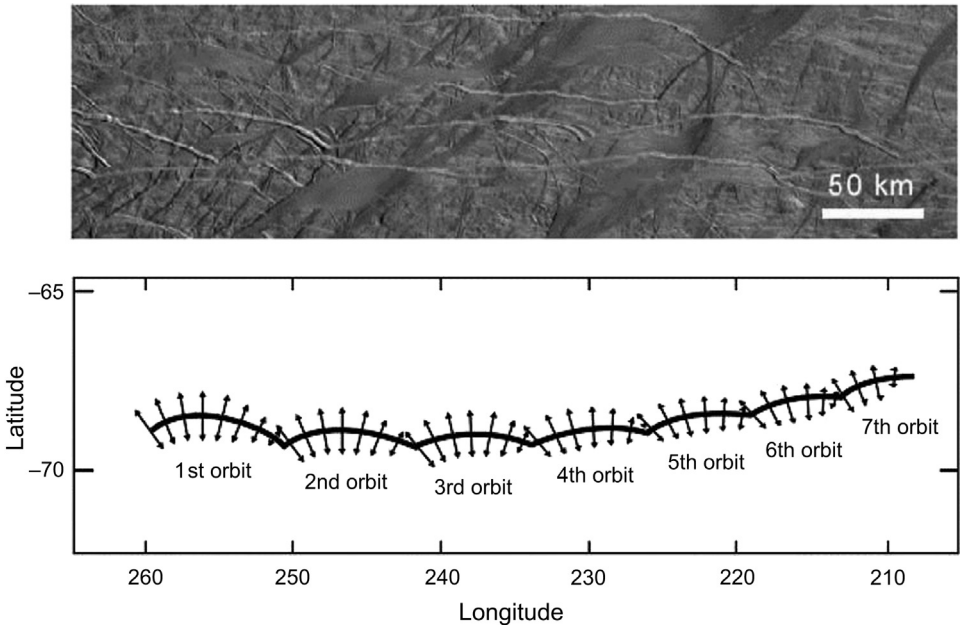

FIGURE 36.6 (Top) Cycloidal ridges on Europa. (Bottom) Model for cycloidal ridge formation, in which each arc forms during one orbital cycle. A crack initiates when stresses reach a critical value and propagates slowly enough that the changing diurnal stress field affects its orientation, causing it to follow a curved path. When the stress drops below a critical level, the crack ceases propagation until the stresses are once again sufficiently large to reinitiate cracking. When the crack reinitiates, Europa has moved along in its orbit, and the stresses are now in a different orientation, leading to a sharp cusp as the next arc begins to propagate. *Top: NASA/JPL. Bottom: After Hoppa et al. (1999).*

plates are pulled apart and new volcanic material erupts along the spreading axis. Features on both planets exhibit central troughs and subparallel ridges where volcanic (in Europa's case, cryovolcanic) material has apparently erupted intermittently throughout the spreading process. Newly formed terrain at terrestrial midocean ridges undergoes normal faulting as it cools and moves away from the ridge crest. On Europa, normal faults parallel to the central axis may have similarly formed as new band material cooled sufficiently for faulting to take place (Figure 36.9).

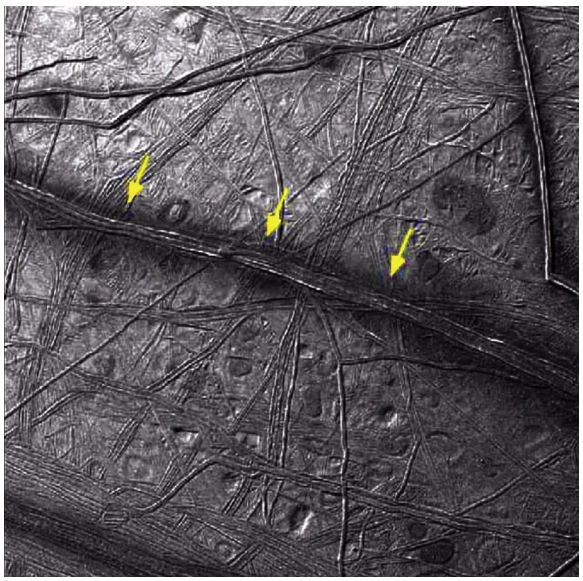

FIGURE 36.7 An example of a triple band, consisting of a central ridge about 5 km wide that is flanked on each side by diffuse, dark material (arrows). This flanking material can be patchy and discontinuous, and may be related to cryovolcanic eruptions during formation of the band, although the exact mechanism is not yet understood.

A major difference between terrestrial plate tectonics and Europan band formation is the lack of subduction zones on Europa. Thus, because band formation has clearly resulted in a large amount of extension (many tens of percent in some areas), there must be some mechanism for balancing this extension elsewhere on Europa's surface. Some fraction of Europa's extension could be related to net global expansion, as would be the case if the ocean were freezing and the ice shell were thickening with time.

4.1.6. Folds

Analysis of high-resolution images of Europa has identified regional-scale contractual folds in a handful of regions on Europa. The most apparent are in the band Astypalaea Linea, where they appear as subtle hills and valleys; several have warped the band at a wavelength of ~25 km, with fine-scale fractures along the crests of the hills and small contractional ridges within the valleys (Figure 36.10). It is unclear whether such folds can represent the primary mechanism by which the icy satellite's considerable surface

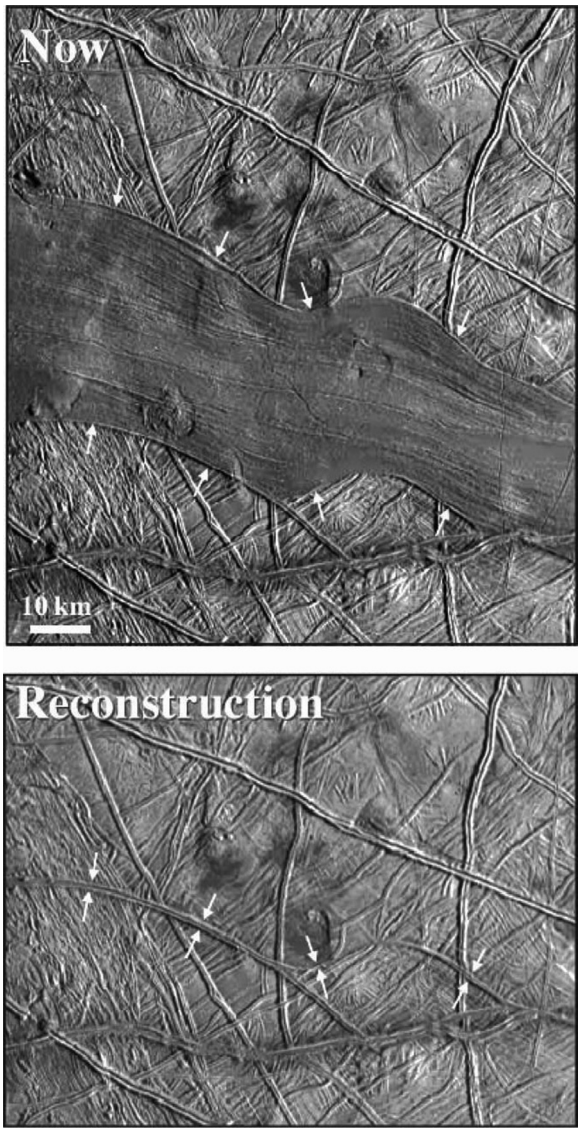

FIGURE 36.8 Points along a prominent gray band (arrows, top) can be reconstructed if the band is removed (arrows, bottom), with the preexisting terrain matching up perfectly along the margins. The band appears to have exploited two existing double ridges during its formation. Reconstructions like this show that a completely new surface has been created by band formation, suggesting that bands represent a considerable amount of extension of Europa's surface. *After Prockter et al. (2002).*

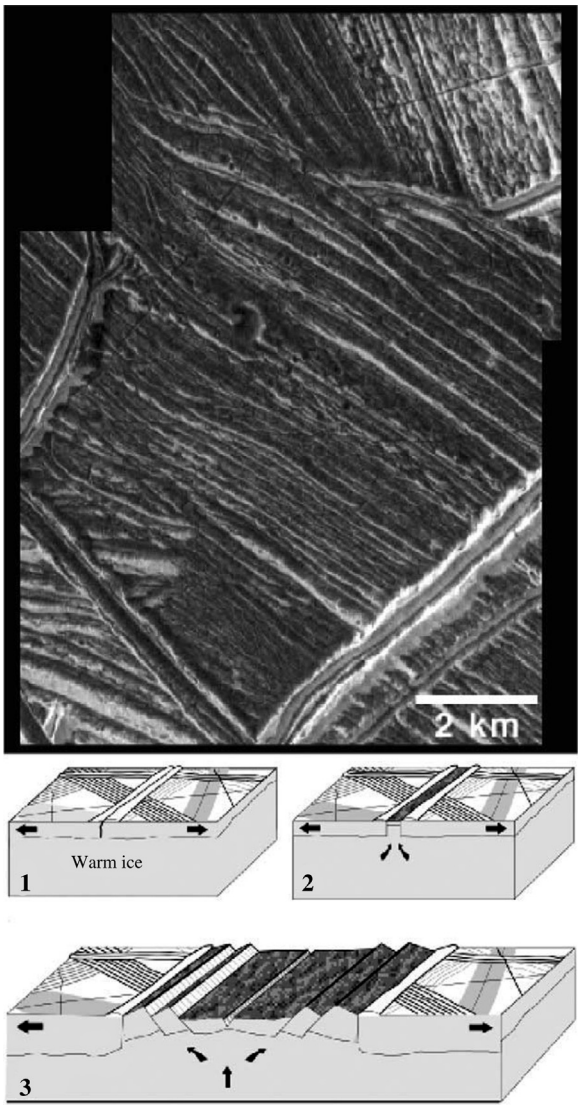

FIGURE 36.9 Model for band formation suggests they are analogous to midocean ridges on Earth. (Top) Distinct morphological zones are mirrored on either side of the central axis of this band. Closest to a central trough, the terrain is hummocky and relatively fine-textured. Further away from the axis, the terrain breaks into normal faults. These types of terrains are also found at spreading centers on midocean ridges on Earth, leading to the suggestion that Europa's bands form in a similar way (cracking followed by extension), allowing new, warmer ice to well up to fill the gap. As this new material cools and moves away from the central axis, it thickens sufficiently that it can form normal faults. This process is analogous to the way new seafloor crust forms on Earth. *After Prockter et al. (2002).*

extension has been accommodated. Other features (such as ridges), along with net global expansion (from freezing of its ice shell), may play roles in explaining how Europa's surface extension is balanced.

4.2. Lenticulae and Chaos

Much of Europa's surface is covered with dark terrain with a mottled appearance, termed "mottled terrain" from Voyager images. High-resolution Galileo images show that in these areas the surface has been endogenically disrupted at small and large scales.

4.2.1. Lenticulae

Portions of Europa's surface are disrupted by subcircular to elliptical pits, spots, and domes, and microchaos regions (collectively termed "lenticulae"), with size a distribution

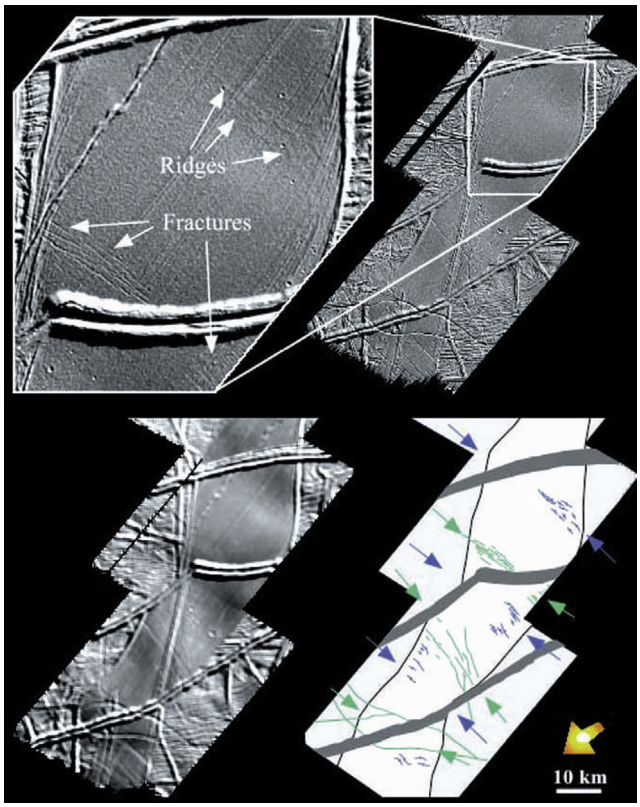

FIGURE 36.10 The best example of folds on Europa, within the gray band Astypalaea Linea. (Top) Close examination of the band reveals fine-scale ridges and fractures. (Bottom left) If a low-pass filter is applied to the image, the 25 km wavelength folds can be distinguished. (Bottom right) Map showing sets of small-scale ridges (blue arrows) within the fold valleys, and fractures (green arrows) that mark the fold crests. *Prockter and Pappalardo, 2000.*

that peaks at ~7 km in diameter, and with a variety of specific morphologies (Figure 36.11). Domes can be convex with upwarped and faulted or unbroken margins against the plains. Pits are topographically low areas where the surface has downwarped while preserving the preexisting terrain. Many pits are associated with dark plains material that **embays** surrounding valleys in the ridged terrain, so it was probably relatively fluid when emplaced. Spots were apparently flooded with dark plains material. Lenticulae known as "microchaos" typically consist of a fine-scale hummocky material, including embedded small plates of preexisting material, commonly with some associated dark plains material. These microchaos regions resemble the larger chaos terrains described in Section 4.2.2.

Although a range of dome, pit, and spot sizes exists, there is a preferred diameter of ~7 km. This consistency in size and the range in their morphologies suggests that they are genetically related; the size and range are consistent with an origin from convective upwelling of buoyant ice **diapirs** within Europa's icy shell (Figure 36.12). Convection is predicted within a tidally heated ice shell greater than about 20 km thick overlying a liquid water ocean. The ice may be thermally buoyant (commonly referred to by the counterintuitive term "warm" ice) and/or compositionally buoyant, where the rising diapiric ice is "clean" relative to its surroundings. Compositional buoyancy of diapirs is possible if they are cleaned out of low melting temperature substances, specifically salts (see Section 5), allowing the clean ice to be more buoyant than the surroundings. In this model, domes form by buoyant diapirs that would reach and break through the surface, and pits may form when a

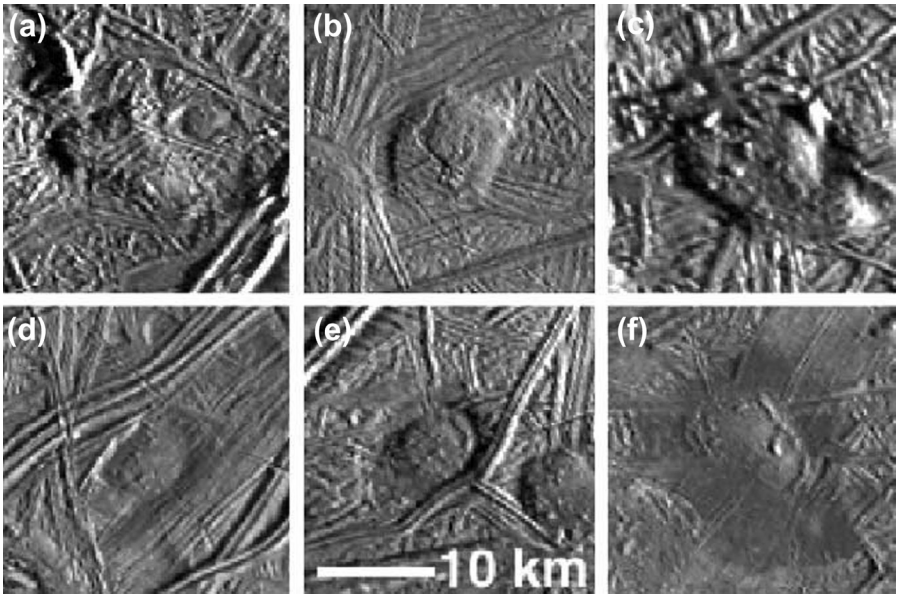

FIGURE 36.11 Lenticulae are found in a range of morphologies, including domes (a, b), microchaos (c), pits (d), and combinations of these morphologies (e), which may or may not have dark plains material associated with them (f). *After Pappalardo et al. (1998).*

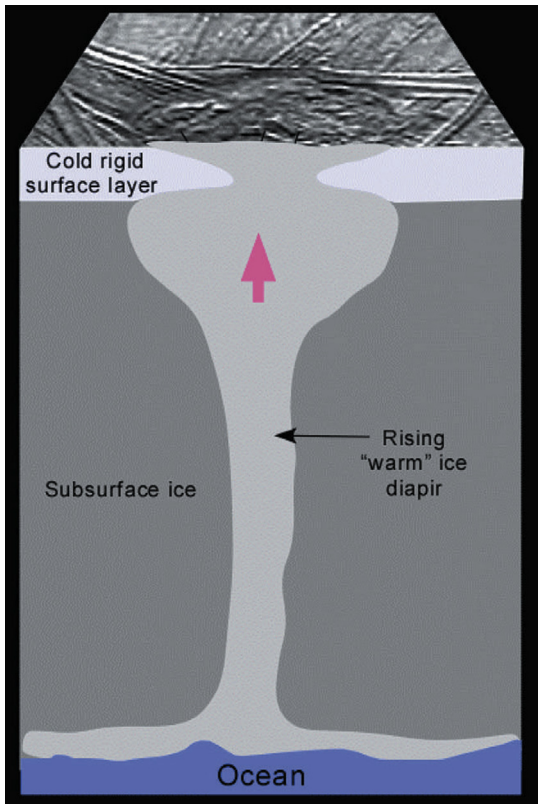

FIGURE 36.12 Model for the formation of lenticulae through diapiric upwelling of buoyant warm ice.

diapir does not quite make it to the surface but melts out impurities from the ice above it, allowing the surface to sag downward.

The range of morphologies and levels of degradation observed in microchaos regions supports the suggestion that upwelling diapirs may partially melt pockets of briny ice as they rise to the surface, causing disaggregation into matrix material and local flooding by dark low-viscosity melt.

4.2.2. Chaos

Chaos regions are areas in which kilometer-scale blocks of existing ridged plains material have translated and rotated with respect to one another within a matrix of hummocky material (Figure 36.13). The matrix material can be low-lying or high-standing relative to the surrounding plains. In one chaos area, Conamara Chaos, at least 60% of the preexisting terrain has been replaced with or converted into matrix material, and the matrix in part stands above the surroundings. Some of the broken plates have been rotated and/or moved horizontally by as much as several kilometers. These plates can be reassembled like a jigsaw puzzle, reconstructing portions of preexisting ridges and troughs (Figure 36.14), although much of the original surface has been destroyed.

Chaos regions have been interpreted as places where Europa's heat flow has been enhanced. One model suggests that local melt-through of ocean water to the surface may have occurred, in which case the blocks are analogous to icebergs floating buoyantly on top of the watery matrix. This model requires that Europa has a very thin shell, less than ~6 km; otherwise, the warm base of the ice shell would flow to maintain its thickness faster than the ice shell could melt from below. Moreover, this model requires that the ocean is only weakly **stratified** in temperature and salinity because strong stratification would prevent heat from being transferred from the ocean floor to the base of the ice shell. In addition, a large, concentrated mantle heat source would need to be stable for hundreds of years to melt the overlying ice.

A proposed alternative model for chaos formation is analogous to that for lenticulae, where ice diapirs have risen buoyantly through the ice crust, breaking or otherwise interacting with the surface (Figure 36.15). This mechanism would explain why some chaos areas stand several hundred meters above the surrounding plains, something that is hard to explain if they formed atop liquid water, but

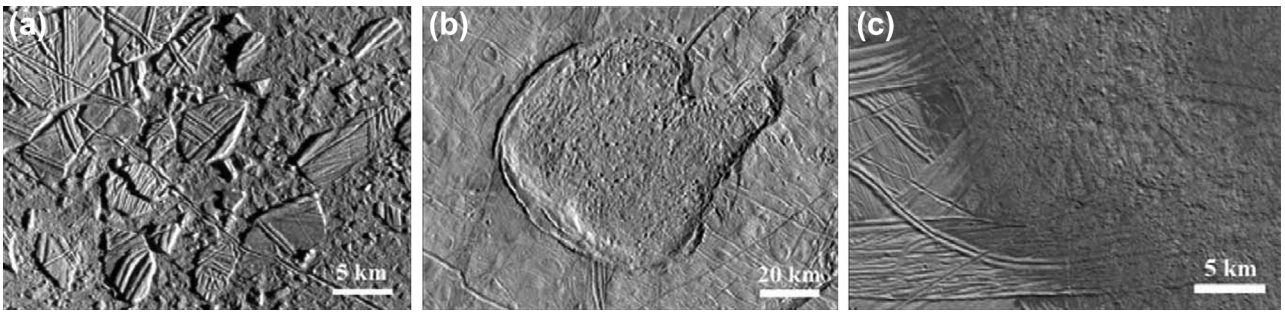

FIGURE 36.13 Examples of chaos on Europa. (a) Conamara Chaos exhibits distinct plates of preexisting terrain (see also Figure 36.14). (b) Murias Chaos, a region of fine-textured chaos that has apparently overflowed its margins on one side, depressing the surrounding plains. (c) The edge of Thrace Macula, showing fine-textured material and a hint of preexisting ridged terrain within, suggesting that the preexisting plains material has disaggregated in place. Dark plains material from Thrace has embayed the surrounding ridged plains, indicating that it was relatively fluid when emplaced. *After Prockter et al. (2004).*

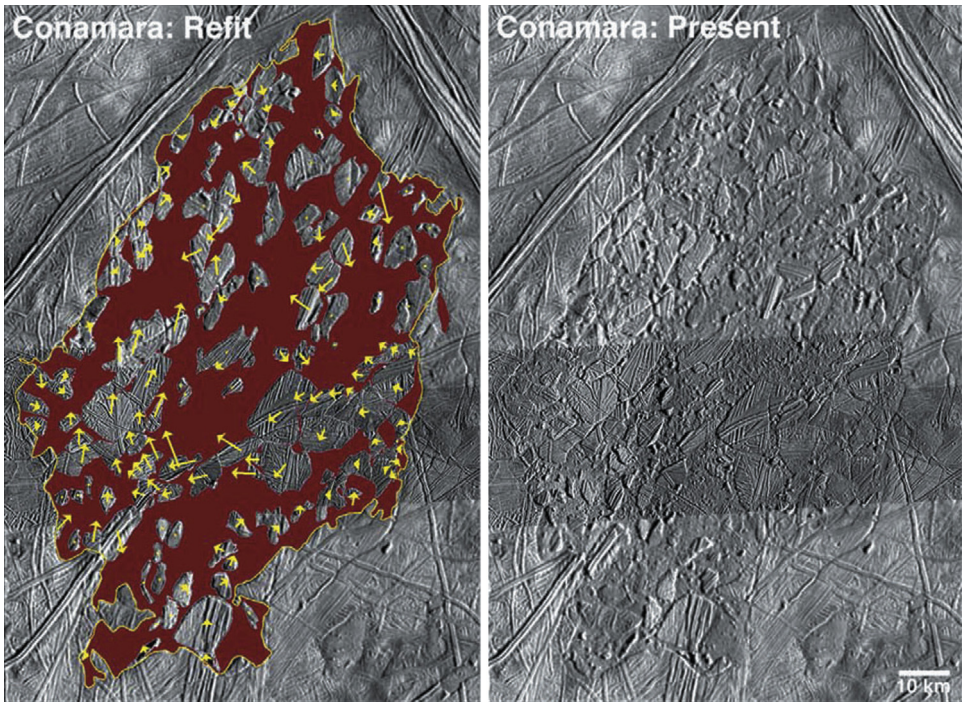

FIGURE 36.14 Broken plates of material within the hummocky matrix of Conamara Chaos (right) can be reconstructed into their original positions like a jigsaw puzzle (left), by matching up older lineaments. This exercise shows that the plates may have moved by several kilometers (arrows show approximate amount of displacement), indicating that the matrix material was originally mobile. Most of the original terrain is missing, however, and may have been subsumed or disaggregated during formation of the chaos. *After Spaun et al. (1998).*

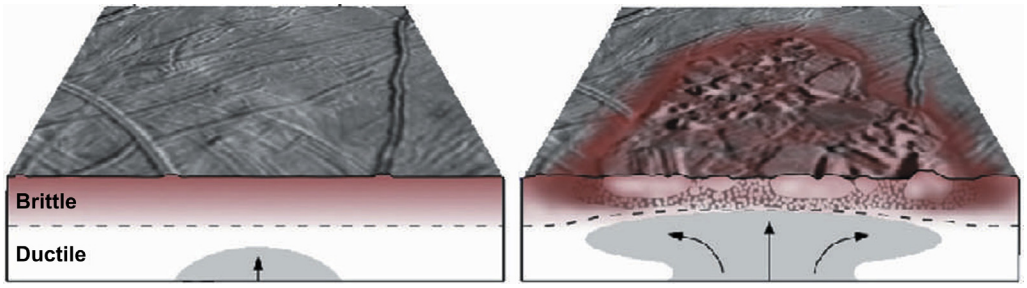

FIGURE 36.15 Model showing how a rising diapir may impinge upon brine-rich ice (reddish material), which lowers the melting temperature, thereby thermally disaggregating the surface (right). *See Collins, Head, Pappalardo, and Spaun (2000).*

feasible if buoyant diapirs rose to their level of neutral buoyancy. Given the morphological similarities between lenticulae and chaos, it seems entirely plausible that they have similar origins through diapiric upwelling. In such a model, chaos terrains may form from a number of separate lenticulae that link together by fractures, forming distinct plates that then separate and mobilize. The diapiric model for chaos formation, however, has difficulty explaining partial melting of the matrix because initially warm ice diapirs would be expected to cool significantly as they approach the surface, before being able to rotate and translate surface crustal blocks.

A recent hybrid model suggests that chaos formation occurs above lakes that have melted out within Europa's icy shell, potentially due to diapirism in briny ice. Disaggregation and collapse of ice above such a lake is envisioned as analogous to the rapid collapse observed of some terrestrial ice shelves, initiated by hydrofracture due to water-filled cracks. This lake model predicts that chaos topography should be sunken relative to the surroundings while a subsurface water lens exists; later freezing would cause the topography to rise upward above the surroundings. Thus, low-lying Thera Macula (Figure 36.16) may signal the presence of a lake the size of Lake Superior within Europa's ice shell today. How a lake could melt out within Europa's ice shell remains uncertain. It is possible that tidal heating would concentrate in the warm ice of a rising diapir, potentially countering its cooling, and melting salty ice.

FIGURE 36.16 Thera Macula is a chaos region that lies below the level of the surrounding terrain, suggesting a huge lake lies beneath it within Europa's icy shell today. *ASU/Univ. Arizona/JPL.*

If so, chaos would represent yet another manifestation of the tidal effects imposed by Jupiter and the Laplace resonance.

4.2.3. Impact Structures

Although formed in ice, rather than silicate rock, Europa's craters have a similar range of morphological features as craters on other planetary bodies, including bowl shapes, central peaks, bright ray systems, and **secondary crater** fields. Europa's craters are shallower than those formed on silicate bodies, however, probably because of viscous behavior of the ice in which they form. Another difference is the size at which the transition from simple, bowl-shaped craters to more complex craters with central peaks occurs. On the Moon, a rocky body with similar gravity, this transition occurs at ~15–20 km in diameter, while on Europa it occurs at only 5–6 km, presumably because the ice crust is relatively weak compared to rock. Simple or bowl-shaped craters are too small to undergo gravity-driven collapse or other significant modifications during formation.

The 24-km-diameter crater Pwyll (Figure 36.17) is thought to be the youngest large impact crater on Europa because it exhibits a bright ray system that extends for over 1000 km and can be seen in global views of the satellite. These rays overlie everything in their path, and their brightness suggests they are so young that they have not been darkened or significantly eroded by charged particle irradiation or micrometeorite bombardment. Pwyll's relaxed topography and the presence of a central peak imply that it formed in warm but solid ice.

One of Europa's largest impact structures is Tyre (Figure 36.18), with a diameter of ~44 km. Tyre and one other known feature named Callanish (Figure 36.1) are multiringed structures, somewhat analogous to impact basins on the terrestrial worlds. While Tyre's rim crest is difficult to identify, the structure exhibits a complex interior with a smooth, bright central patch interpreted to be impact

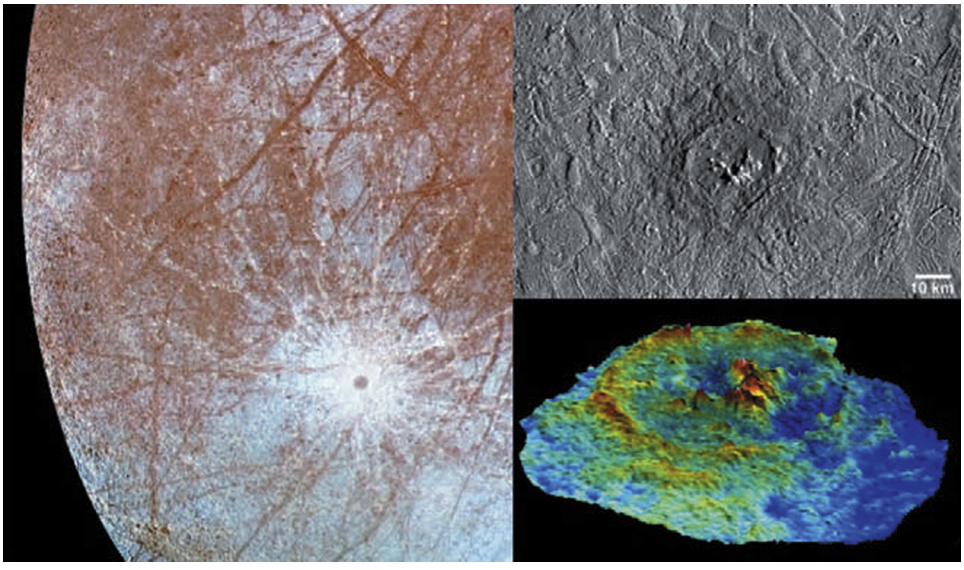

FIGURE 36.17 Several views of the impact crater Pwyll. (Left) Global color-enhanced view showing bright ejecta and rays from material thrown over 1000 km by the impact, the white color indicating exposure of fresh, icy material. (Top right) Higher resolution image of Pwyll, showing distinct rim and central peak, along with a blanket of proximal ejecta around the impact. (Bottom right) Topographic model of Pwyll, created from stereo imaging. This shows the fresh but shallow topography of the crater. *NASA/JPL/DLR.*

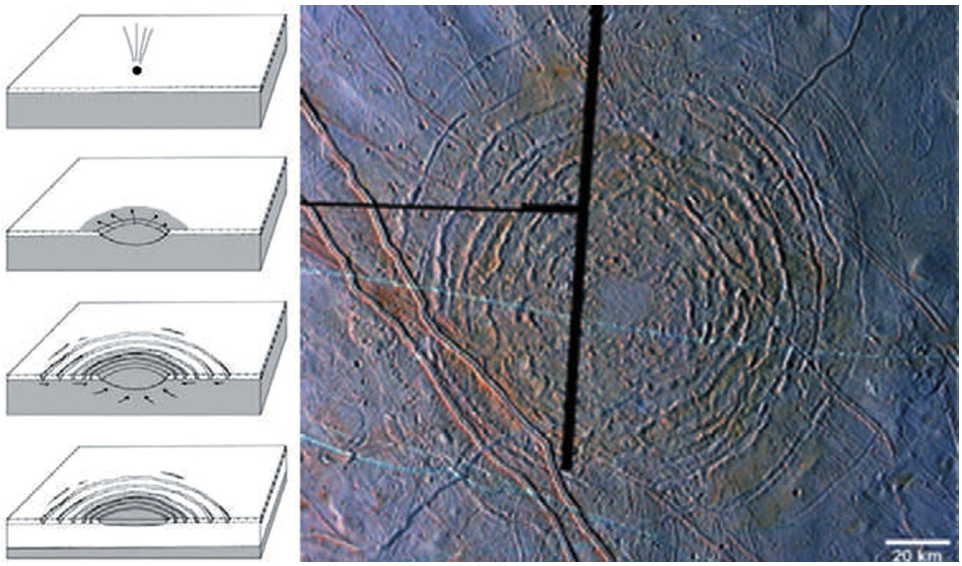

FIGURE 36.18 (Right) The Tyre impact structure has numerous concentric rings around a smoother central region. Outside the rings are many small craters, which are secondary craters caused by ejecta from the impact. This false-color image highlights the reddish material associated with the Tyre rings. (Left) Model for formation of multiring impact structures on the icy Galilean satellites. This model may be applicable to structures such as Tyre, which are inferred to have formed in a relatively thin, brittle layer (white) over a fluid (potentially liquid) layer (gray). *Image: NASA/JPL; Sketch: after McKinnon and Melosh (1980).*

melt or frozen remnants of fluid material that may have been emplaced from below during the impact event. Tyre's most striking characteristic is its concentric troughs, tectonic features resulting from the impact process. These structures are thought to originate when an impact occurs through a brittle layer into relatively fluid material, allowing for rapid collapse and infill of the **transient crater**, and dragging the cold and brittle overlying crust inward to break along concentric faults (Figure 36.18). Galileo near-infrared mapping spectrometer (NIMS) observations of Tyre show that dark material associated with the troughs is similar to the reddish material observed elsewhere on the surface.

Europa's simple and complex craters have morphologies consistent with impact into a solid (although warm and weak) ice target. In contrast, the larger ($\sim$40 km) impacts inferred to have formed Tyre and Callanish, with their distinctive rough topography and concentric ring systems, imply penetration of the transient crater to a fluid layer at a depth of $\sim$20 km. These observations are consistent with Europa's solid ice shell being $\sim$20 km thick, overlying Europa's liquid water ocean.

5. SURFACE COMPOSITION AND THERMAL STATE

It has long been known from Earth-based telescopic observations that Europa's surface is predominantly water ice, as amply confirmed by Galileo's NIMS instrument. However, Europa's darker regions show a distinctly different composition, associated with many landforms such as ridges and chaos (Figure 36.19). This material is thought to contain impurities including **hydrated** salts, along with a reddish component.

Spectra from the NIMS instrument show highly distorted water bands in the dark regions, indicative of one or more hydrated minerals (Figure 36.20). Some thermal evolution models of Europa predict large quantities of

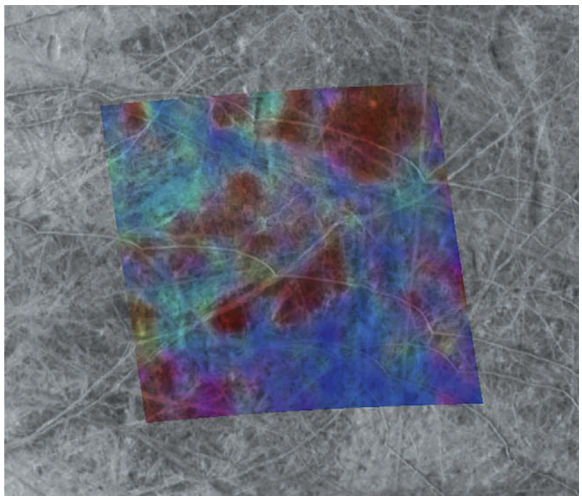

FIGURE 36.19 Composite image of a false-color NIMS infrared image overlain on a monochrome camera image. Blue areas represent relatively clean, icy surfaces, while redder areas have high concentrations of dark, nonice materials, which may originate in a subsurface ocean. The infrared image is about 400 km across.

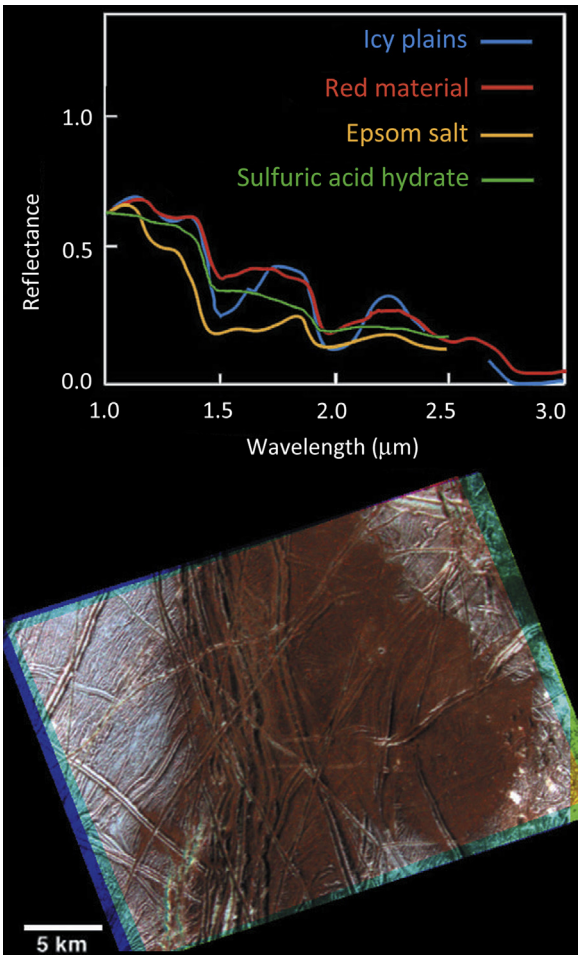

FIGURE 36.20 Infrared spectrum (top after Pappalardo, Head, & Greeley, 1999; Scientific American) of material such as found in Castalia Macula (bottom), one of the reddest, darkest spots on Europa. The spectrum of the icy plains material is distinct from the red material of the spot, which is more similar to something like Epsom salt or hydrated sulfuric acid.

magnesium sulfate hydrate (such as Epsom salt) within the ocean, and mixtures of this and sodium hydrate are predicted at Europa. Another candidate for the surface material is hydrated sulfuric acid (H_2SO_4), more commonly known as battery acid. Although these candidate compounds are colorless, irradiation of the surface by charged particles may be why Europa's dark areas appear reddish. Because of its proximity to Jupiter, Europa's surface is constantly irradiated by high-energy ions and electrons. This irradiation is sufficient to rip apart molecules of water ice and other compounds, allowing them to recombine in a process known as **radiolysis**. This could allow sulfur ions (at least some of which likely originate at Io) and sulfur-containing compounds such as sulfuric acid to synthesize long molecular chains that are ochre in color. These sulfur chains may be responsible for the reddish color of materials that have been emplaced on the surface relatively recently. Sulfuric acid itself could result from the breakdown and recombination of ice and sulfur dioxide frost, which has also been detected on Europa.

Generally the stratigraphically youngest features on Europa are the darkest, implying that the darkening and reddening process is rapid relative to the age of observable surface features. Also, the fact that Europa's older features are relatively bright implies that some other process brightens features over time, as discussed in Section 6. (The exception to this is young craters, such as Pwyll, which have bright crater rays, probably as a result of depositing fresh materials onto and stirring the preexisting surface upon secondary impact.) Whatever their specific origin, the close association of these hydrated minerals with areas of presumed surface disruption suggests they are related to endogenic processes and may have originated, at least in part, in the subsurface ocean.

Strong absorptions in the infrared region of the spectrum by Europa's H_2O-bearing minerals easily mask the signatures of minor constituents; however, hydrogen peroxide (H_2O_2) is observed and is probably a radiolysis product of water ice. An ultraviolet absorber identified on the trailing side of Europa has been attributed to sulfur from Io, delivered to Europa's surface via the Jovian magnetosphere.

The Galileo spacecraft carried a photopolarimeter radiometer (PPR) instrument that showed that temperatures at low latitudes are in the range 86−132 K, with higher temperatures where the surface is dark, and colder temperatures where it is bright. This correlation between brightness and temperature holds on a global scale, but significant local temperature variations are inferred beyond the spatial resolution of the PPR instrument. These may be due to local-scale variations in surface physical properties. A distinct anomaly around the crater Pwyll may imply a relatively warm (blocky) ejecta blanket. Other thermal variations such as lower than expected temperatures along the equator at dusk are harder to explain. These may be due to variations in grain sizes and structures of ice, but endogenic heat fluxes indicative of interior activity cannot be ruled out.

6. SURFACE PHYSICAL PROCESSES

Processes affecting Europa's surface materials are dominated by thermal processing and radiation bombardment, with meteorite bombardment playing a lesser role.

Jupiter's magnetosphere sweeps up and traps particles including electrons, protons, and heavy ions such as S and O. Because of its close proximity to Jupiter, these particles result in a high-energy (<10 MeV) radiation flux at the surface of Europa. The heavy ions in particular are responsible for **sputtering**, where molecules are physically blasted from the surface, creating an **exosphere** of sputtered products, including sodium and low-energy electrons.

There is much still to be learned about the effects of irradiation of ices and the stability of hydrated salt minerals at Europa's surface temperatures.

Europa's water ice exhibits a variety of grain sizes and is particularly abundant and fine grained (<100 μm diameter) between ±60° latitude on the **leading hemisphere**, but it is less abundant with coarser grains (>400 μm) on the trailing hemisphere. The polar regions have a mixture of particles with a range of grain sizes. Bright regions of Europa's surface are topped with a 1 μm layer of **amorphous** ice, which is probably the result of radiolytic disruption of the regular crystalline structure. This disruption can be counteracted by thermal annealing and recrystallization, but these processes are impeded by Europa's cold surface temperatures.

Sputtering and **thermal desorption** act to remove water from water ice and hydrated minerals. These water molecules may either escape to space, but more typically, recondense elsewhere on the satellite as frost. This deposition will vary depending on temperature and surface albedo, so the frost will be more likely to be deposited at high latitudes and on bright surfaces than at the warmer equatorial latitudes on darker materials. Frost deposition may be responsible for the brightening and whitening of Europa's dark reddish surface features over time. In addition, radiolysis itself may cause chemical changes that brighten the surface.

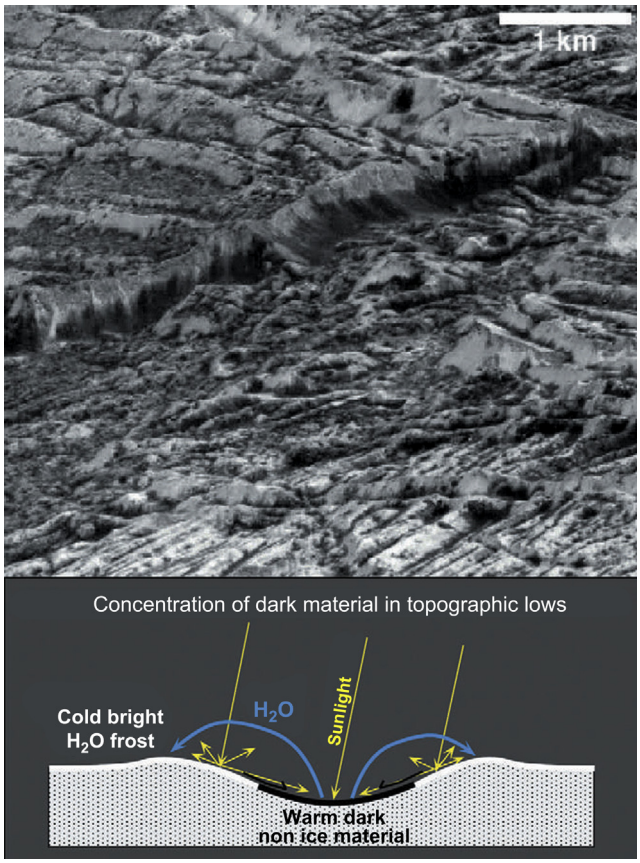

FIGURE 36.21 Sublimation of water molecules by sunlight results in a dark lag deposit, which can move down slopes to collect at their bases. This process appears to have occurred at the cliff in the center of this high-resolution Galileo image. The water molecules may be "cold-trapped" on brighter, icier surfaces, forming frost deposits.

Mass wasting, which is movement of material downslope under the influence of gravity, is less significant on Europa than on the other Galilean satellites because the surface is so young. Mass-wasted material is commonly dark and is likely the nonice debris that remains after the surrounding ice has been removed by sputtering and sublimation. This lag material may be salts and impactor contaminants.

Sublimation (Figure 36.21) has played a significant role in shaping and muting the topography of Callisto and, to a lesser extent, of Ganymede, and has occurred only in darker warmer regions on Europa, potentially including where warm material has been in close proximity to the surface. Sublimation lags have been suggested to result as water molecules are driven off by the intrusion of warm water or ice along ridges and chaos regions. This process has been suggested as the origin of low-albedo spots along triple bands and of dark material along the flanks of ridges. Some craters have dark material in their floors, which is consistent with a thermal lag produced during the impact cratering process, when very hot material from the impact would have rapidly sublimated any water ice off the surface, and by the downslope movement of dark lag material onto the crater floor.

7. SURFACE AGE AND EVOLUTION

7.1. Surface Age

Europa's surface age can be estimated from the number of recent large impact craters on its surface, if accurate estimates of the impactor flux can be made. Modeling of the dynamics of small solar system bodies suggests that the impactor population at Jupiter's orbit is dominated by **Jupiter-family comets**. From the paucity of large (>10 km diameter) craters on Europa, this model implies a surface age of ~60 Ma (million years), with uncertainties of about a factor of 3.

Another way to estimate Europa's age is to use estimates of ice sputtering, which occurs when high-energy particles swept along with Jupiter's magnetic field impact Europa's surface, causing ice particles to be dislodged, most of which then escape to space. This process has a number of uncertainties, but measurements from Galileo's energetic particle detector have lead to estimates that a couple of centimeters to over half a meter of ice may be removed every million years. High-resolution imaging has

shown numerous examples of topography on vertical scales of tens of meters; this observation is consistent with an age similar to that predicted by the comet impactor model.

The dearth of impact craters on Europa makes it an excellent place to study the ratio of primary to secondary craters, something that is very difficult to accomplish on heavily cratered bodies like the Moon or Mercury. Although high-resolution imaging of Europa's surface is limited, studies suggest that most of the small (<1 km diameter) craters on Europa are secondaries.

Comparisons of images from Voyager and Galileo, acquired 20 years apart, show no definitive evidence for current activity on Europa's surface, although such comparisons are hampered by a lack of overlapping high-resolution image data taken at similar lighting geometries. Similarly, searches for plumes such as those observed on Io and Enceladus have so far proved unsuccessful. Nevertheless, if the surface is only ~60 Ma old, it seems very likely that Europa is still geologically active today.

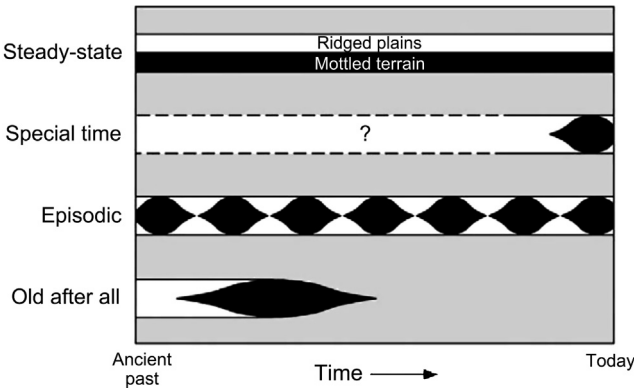

FIGURE 36.22 Possible schematic evolutionary models for Europa's surface. White represents epochs dominated by ridged plains formation, and black represents mottled terrain formation. Current analyses suggest that Europa is either at a special time in its history or, more likely, that it undergoes episodic resurfacing. *After Pappalardo, Belton, et al., 1999.*

7.2. Surface History and Geological Evolution

Mapping of Europa's landforms and their interactions with each other yields a rough time history, or **stratigraphy**, of surface evolution and can reveal whether the **resurfacing** style has changed over time. Several areas across Europa's surface have been mapped at a variety of scales, and most researchers infer that there has been a change in geological activity and style through the decipherable time history of the surface. The oldest type of terrain is the "ridged plains", a mélange of ridges and linear structures that are uniformly bright overall, where it is difficult to distinguish distinct feature types. Bands are intermediate in the stratigraphic column, while chaos and lenticulae are among the youngest surface features, commonly disrupting bands and ridged plains. Troughs and double ridges have formed throughout Europa's surface history and crosscut bands and are younger than some lenticulae and chaos. There appears to have been more activity in the earlier surface record, with a waning in the number and width of features in the later stratigraphy.

Stratigraphic mapping therefore suggests that Europa's geological style has generally changed over time, from ridged plains formation, to band formation, to chaos and lenticulae formation, with the activity level simultaneously waning. The mechanism for this change is uncertain, but one plausible model that fits the observations is one in which Europa and its ocean have been slowly cooling, such that the ice shell has thickened as the ice shell reached a critical thickness, **solid-state convection** may have initiated, allowing ice diapirs to rise toward the surface. Thus, a thickening ice shell could be related to a waning intensity of geological activity, and with a transition from a predominance of ridged plains to formation of chaos and lenticulae.

Because Europa's surface is probably relatively young, such a fundamental change in style might seem unlikely over the last ~1% of the satellite's history, and we must speculate on Europa's activity over the rest of its ~4.5 billion year existence. Four possible scenarios have been proposed (Figure 36.22): (1) Europa resurfaces itself in a steady state and relatively constant, but patchy style; (2) Europa is at a unique time in its history, having undergone a recent major resurfacing event; (3) global resurfacing is episodic or sporadic; or (4) the satellite's surface is actually much older than our cratering models suggest.

From the standpoint of the dynamical evolution of the Galilean satellite system, there is good reason to believe that Europa's surface evolution could be cyclical (i.e. scenario (3) above). As participants in the Laplace resonance, the orbital characteristics of Io, Europa, and Ganymede are inherently linked to one another, and also to their interior thermal characteristics. Io experiences the greatest amount of tidal heating and largely drives the predicted cycling. The eccentric orbit of Io can cause a great amount of tidal heating in that satellite, which tends to drive its orbit toward circularity, and in turn decreases its tidal heating. The decreased tidal heating causes Io to cool, but it also allows its eccentricity and internal heating to increase again, thereby completing the cycle. This cyclical evolution of Io's tidal heating and orbital characteristics pulls Europa (and Ganymede) along for the ride via the Laplace resonance. In this way, Europa can experience cyclical variations in its orbital characteristics and tidal heating on timescales of perhaps 100 Ma. Thus, Europa may undergo changes in its activity level and perhaps its resurfacing style on approximately these timescales. In this scenario, Io and

Europa are currently in a diminishing phase of activity. The observed surface characteristics of Europa may represent the latest, waning stage of a long cyclical thermal and geological history.

8. ASTROBIOLOGICAL POTENTIAL

Based on our terrestrial view, the primary ingredients for life are water (See also chapter on Astrobiology), the elements to build organic compounds, and energy. Europa may have all three: water of the ocean, organic compounds that have been delivered to the satellite, and chemical energy from the products of radiolysis at the surface and possibly hydrothermal activity at the ocean floor. The evidence for liquid water within Europa is strong, as discussed in the sections above, and Europa's subice ocean may have a volume twice that of all Earth's surface water. Cometary and asteroidal impactors have rained onto the surfaces of the Galilean satellites throughout solar system history. Just as Ganymede and Callisto have been darkened by impactor material through time, similar material must have been delivered to Europa, where its young and bright surface implies that much of this material is now incorporated into the ice shell and ocean. Moreover, the original accretion of Europa may have delivered carbon in the form of CO and CO_2.

Metabolic reactions within living cells depend upon chemical reactions between **oxidants** and **reductants**. For animals, this depends on taking in oxygen, which is combined with sugars to produce CO_2 and water. For plants, CO_2 is combined with water to form sugars and oxygen. In extreme environments on Earth, and possibly within Europa, more exotic materials such as hydrogen sulfide (H_2S), formaldehyde (HCOH), methane (CH_4), or even sulfuric acid (H_2SO_4) can be key molecules of metabolism. If chemical disequilibrium exists, then organisms may be able to exploit chemical reactions to create and store the energy needed for metabolism.

Whether Europa has sufficient chemical energy to support life is the most significant unknown in understanding Europa's potential for life. Irradiation of surface ice can create free oxygen and hydrogen, with most of the hydrogen floating off but much of the oxygen and other oxidants remaining behind, like a condensed atmosphere frozen into the uppermost centimeters of ice. If these oxidants can be delivered to the ice shell and ocean, they may be able to power the chemical reactions necessary for life. Geological processes such as chaos formation may be able to deliver near-surface materials to the deep ice shell and ultimately the ocean, but the means of surface–ocean communication remain poorly understood.

At Europa's ocean floor, reaction between rock and water should result in serpentinization, a weathering reaction that produces hydrogen as a by-product. Furthermore, if Europa's rocky mantle is tidally heated, then hydrothermal systems could exist on Europa's ocean floor. On Earth, hot chemical-laden water pours into the oceans, delivering organic materials and reductants into the water. If reductants are produced at the bottom of Europa's ocean, and if oxidants are delivered from the ice shell above, then the necessary chemical disequilibrium to support life could exist.

Another important consideration is whether Europa's interior environment is stable enough through time, such that if life ever developed it would still exist today. Europa's ocean may have persisted for eons thanks to internal radioactive heating and the tidal dissipation resulting from Jupiter's gravitational tug. However, the internal heating induced by the Laplace resonance is not necessarily ancient, and (as discussed in Section 7.2) the intensity of tidal heating may have varied (perhaps cyclically) through time. It is an open question whether chemical energy sources for life exist within Europa and have been sufficiently stable to permit life to persist through time.

9. FUTURE EXPLORATION

The harsh radiation environment near Jupiter makes exploration of the satellite technically and financially challenging. Nevertheless, the possibilities for life on this icy moon are sufficiently intriguing and significant that such a mission has a very high priority. Key scientific issues remain to be addressed, including confirmation that there is indeed a liquid water ocean, the characteristics and composition of the ocean, the nature of surface–ice ocean material exchange, and whether Europa has the chemical energy to support life.

Possible means to explore Europa are with a spacecraft in Europa orbit, or from a spacecraft in Jupiter orbit that makes many close flybys of Europa. A spacecraft in orbit around Europa could make continuous gravimetric and topographic measurements of the fluctuating tidal bulge and magnetic measurements of the conductive layer below the ice shell. Either from orbit or from flybys, an ice-sounding radar would be able to sense shallow water deposits and brines and may be able to probe to the bottom of the ice if the ice is relatively cold and thin.

The composition of Europa's surface is not well known, so high-resolution spectral and spatial compositional measurements are also needed to understand Europa's evolution and surface processes. Using a mass spectrometer, it is also possible to determine surface composition by "sniffing" the particles of Europa's very tenuous atmosphere, which are sputtered off the surface by radiation.

Experiments designed to determine Europa's potential for life are ultimately best made with a lander on the surface, which could directly sample and analyze material from beneath the upper $\sim$10 cm of the surface, which is most strongly affected by irradiation. Moreover, the only

way to acquire an unambiguous measurement of the thickness of Europa's ice shell is to make seismic measurements, by landing a seismometer on the surface. Spacecraft data has yielded tantalizing insights into Europa's history and evolution, but there is still much we do not know. Further exploration is the only way by which we will learn Europa's deepest and most intriguing secrets.

1. INTRODUCTION

Ganymede and Callisto (Figure 37.1) are the largest and outermost of Jupiter's four Galilean satellites. Similar in size to Mercury, and with surfaces dominated by dirty water ice, they are prime examples of planet-sized icy bodies. Although Ganymede and Callisto are neighbors and they share many bulk characteristics such as size and density, they have followed divergent evolutionary paths. The striking differences in their interior structure and surface geology provide insight into which processes are common and which processes are unique in the development of a large icy world.

2. EXPLORATION

2.1. Discovery

Ganymede and Callisto were discovered by Galileo Galilei in 1610, when he first trained his telescope on Jupiter and shortly thereafter published his results in the *Siderius Nuncius*. Along with Io and Europa, they became the first natural satellites, other than the Moon, known to science. Galileo immediately recognized the significance of the "new stars" traveling with Jupiter and changing their positions every night. The orbits of what are now known as the Galilean satellites were rapidly calculated and found to be essentially circular and in the same plane as Jupiter's equator. Because Galileo made these observations centuries ago, his records of satellite eclipses provide a long time line to compare with modern measurements, and they are still used to constrain calculations of the dynamical evolution of Jupiter's satellite system under the influences of tidal dissipation and the satellites' mutual gravitational interactions.

2.2. Astronomical Observations

The Galilean satellites are large enough to exhibit distinct disks (on the order of $\sim$1 arcsec in angular diameter) when

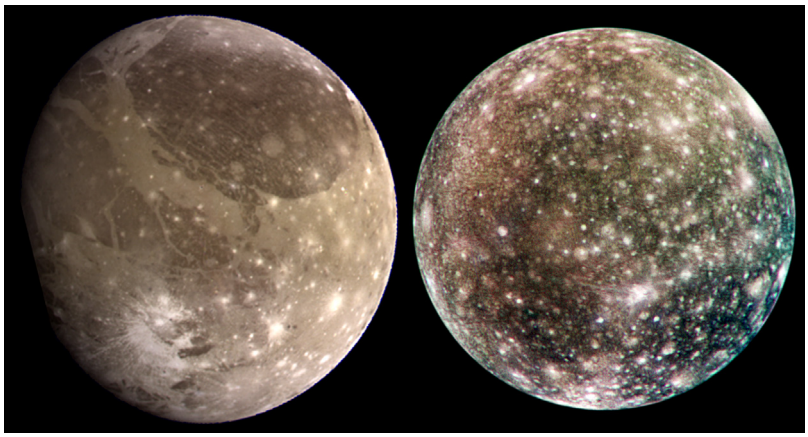

FIGURE 37.1 Global views of Ganymede (left) and Callisto (right), obtained by the camera on the Galileo spacecraft.

viewed through even moderate power telescopes, and it was thus known from simple geometry that they must be bodies comparable in size to the Moon. Precise measurements of their sizes proved difficult with conventional astronomical techniques, with published estimates from different observers disagreeing significantly. Even these relatively uncertain size estimates were sufficient, when combined with the satellites' brightness, to indicate that their surfaces are highly reflective compared with the Moon.

In the two decades leading up to the first spacecraft exploration of the Jupiter system, astronomical techniques advanced rapidly, particularly in the area of sensors in the visible and near-infrared spectral range (~0.3–2.5 μm). The pioneering planetary astronomer Gerard Kuiper used early infrared detectors to show that Ganymede's reflectance at 2 μm was much lower than that in the visible range and suggested that water ice might be responsible. Vassily Moroz, a planetary scientist working at the Crimea Observatory in the Soviet Union, made even more detailed infrared color measurements and concluded that water ice was the best explanation for Ganymede's spectrum.

At the spectral resolution and signal-to-noise ratio of these pioneering measurements, however, a conclusive identification of the surface composition could not be made, since several other candidate materials, including ices of carbon dioxide and ammonia, were known to have **spectral absorptions** in the same part of the infrared spectrum. The issue was settled conclusively for Ganymede and Europa by a team led by Carl Pilcher, then at MIT, who published the first high-resolution infrared reflection spectra for these satellites in 1972 and compared them in detail with laboratory spectra of ices at low temperature. All the significant absorption features in the 1- to 2.5-μm region matched spectra of water ice and ruled out any major contribution from other ices. Callisto's spectrum also displays water ice and hydrated silicate features, although the water signature is subdued compared with Ganymede's strong water ice spectral absorptions, due to the larger amount of dark material mixed with the ice on Callisto's surface.

Figure 37.2 shows a compilation of the best telescopic spectra of Ganymede and Callisto compared with Io and Europa. The dominant features in all the spectra except Io's are the deep absorptions at wavelengths longer than 1 μm due to the presence of hydrated minerals and water ice. Laboratory studies of water ice reflectance and theoretical simulations of spectra from mixtures of material have demonstrated that the observed spectra can be explained by water ice/frost, mixed with varying amounts of a spectrally neutral darker component with a reddish color in the visible portion of the spectrum (that is, increasingly absorptive at shorter wavelengths). The nature of the non–water ice component in the satellites' surfaces is still under investigation, but spectra of different regions on both satellites

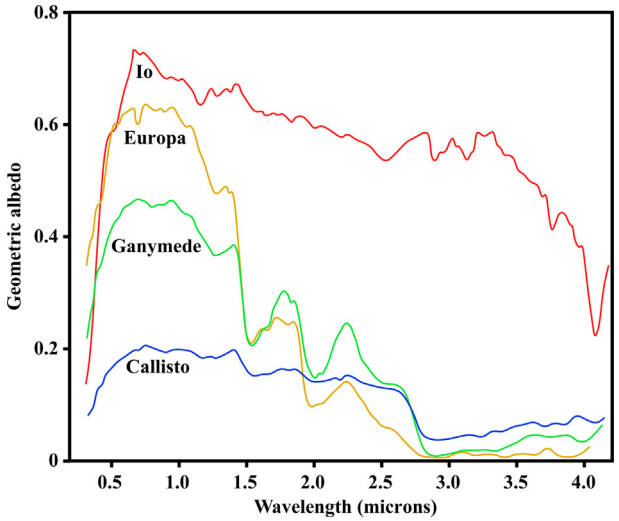

FIGURE 37.2 Compilation of telescopic spectra of Ganymede (green) and Callisto (blue) compared with Io (red) and Europa (yellow). All the satellites except for Io show absorptions on infrared light due to water ice and hydrated minerals, notably near 1.5 and 2 μm. *Modified from R. Clark & T. McCord, (1980).*

taken by the near-infrared mapping spectrometer (NIMS) instrument on the Galileo mission are providing clues to the identification of this material (see Section 3).

2.2.1. Masses and Densities

The mass of a distant planetary object is normally impossible to determine from remote astronomical observations alone, unless it happens to have a companion whose orbit can be determined, as is the case for the giant planets with their satellite systems, Mars, numerous asteroids, and several trans-Neptunian objects including Pluto. The Galilean satellites represent a more difficult case. They do not themselves have satellites, but the mutual gravitational attraction among these large satellites produces significant and measurable changes in their orbits about Jupiter. The mathematician Pierre Laplace studied these interactions in the late nineteenth century, and subsequent developments in this new branch of dynamical astronomy permitted reasonable estimates of the satellites' masses to be made in the early twentieth century. When combined with the still uncertain size estimates, the best estimates of masses prior to 1970 suggested that the inner satellites, Io and Europa, had rocklike densities, similar to the Moon's, while Ganymede and Callisto appeared to be less dense, suggesting the possible presence of large amounts of ice in their constituent materials.

In 1972, observations from two stations on the Earth of a stellar occultation by Ganymede provided the first high-precision measurement of its diameter. This was closely followed by the first spacecraft exploration of Jupiter by the Pioneer 10 and 11 missions in 1973 and 1974, which greatly improved the mass estimates of the satellites from tracking the gravitational perturbations in the spacecraft trajectories caused by the satellites. This led to the first accurate determination of Ganymede's density of about 1900 kg/m^3, adding more evidence to the hypothesis that its bulk composition is a mixture of rock and ice. The Voyager 1 and 2 Jupiter encounters in 1979 provided even more data on satellites' masses and accurate determination of their shapes and volumes. These data showed that Callisto is very similar to Ganymede in its bulk properties, with a density of about 1800 kg/m^3. Interior structure models estimate that the average bulk composition for both satellites is 50–60% (by mass) dry silicate rock, mixed with 40–50% water, which exists as normal water ice at the surface, but transforms into higher density phases at high pressures deeper in the interior (see Section 2).

2.3. Spacecraft Exploration

Eight spacecraft have visited the Jupiter system to date: Pioneer 10 and 11, Voyager 1 and 2, Galileo, Ulysses, Cassini, and New Horizons. Ulysses, a joint European Space Agency/National Aeronautics and Space Administration (NASA) mission to study the sun's environment at high latitudes, made measurements of Jupiter's magnetic field, radiation belts, and dust environment, but did not study the satellites directly. Cassini, on its way to its rendezvous with Saturn, flew by Jupiter in 2000 and returned spectacular observations of its atmosphere and **magnetosphere**, but its trajectory was too far from the Galilean satellite system to provide high-resolution views of the satellites. New Horizons also flew through the Jupiter system on its way to Pluto, but Ganymede and Callisto were on the far side of Jupiter during the flyby, so only very low resolution images were obtained, as well as infrared spectra of a portion of Ganymede's Jupiter-facing hemisphere.

The first Jupiter-focused missions, Pioneer 10 and 11, were designed to provide an initial reconnaissance of the system and to establish the intensity of the radiation belts. The Pioneer program's major contribution to knowledge of Ganymede and Callisto was improving the mass estimates of the satellites (as mentioned earlier), leading to the first precision bulk density measurements.

In 1979, Voyager 1 and 2, with powerful remote sensing payloads and close targeted flybys of each Galilean satellite, provided the first in-depth reconnaissance of the satellites and set the stage for the geological and geophysical exploration of these worlds. Voyager's cameras showed that Ganymede and Callisto, alike in many large-scale properties, have divergent geological histories. Callisto's surface is heavily cratered at all scales, from large-impact scars over 1000 km in diameter down to craters a few kilometers in diameter, the smallest scale resolvable on Callisto by the Voyager cameras. This battered, uniform surface stands in stark contrast to Ganymede's varied landscape. Ganymede's surface can be divided into two distinct types of terrain, based on a sharp **albedo** contrast. The darker areas (named "dark terrain") are heavily cratered and exhibit **palimpsests**, much like the surface of Callisto. The brighter parts of Ganymede's surface (named "bright terrain") form wide lanes through the dark terrain and are less heavily cratered, implying a younger surface. Voyager images showed the bright terrain to have some areas that appeared to be smooth, while other areas exhibit sets of parallel ridges and troughs.

One of the major objectives of the Galileo mission was to perform detailed observations of the Galilean satellites. The mission design allowed multiple close flybys at ranges 100–1000 times closer than the Voyager encounters, enabling high-resolution studies of their surfaces and detailed measurements of their gravity fields and interactions with Jupiter's magnetospheric environment. High-resolution images of the different terrains first identified by Voyager have illuminated their origins, described in detail in subsequent sections of this chapter. The close flybys also enabled more detailed spectroscopic observations, which identified some of the non–water ice

components on the satellite surfaces, including carbon dioxide embedded in the surface and evidence for carbon compounds.

Repeated close flybys of Ganymede and Callisto enabled Galileo to make precise gravity and magnetic measurements, resulting in several major discoveries. First, Ganymede has a strongly layered internal structure, with heavier rock and metal concentrated in the center, while Callisto has a more homogenous structure. Second, Ganymede was found to have a relatively strong internal magnetic field, creating its own "mini-magnetosphere" embedded within Jupiter's vast magnetosphere. Finally, the interactions of Ganymede and Callisto with Jupiter's rotating, tilted magnetic field show that both satellites exhibit an induced magnetic field interpreted as evidence for an electrically conducting liquid water ocean beneath their icy crusts.

3. INTERIORS

3.1. Interior Structures

The ice/rock bulk composition inferred for Ganymede and Callisto from their densities naturally led to the suggestion that even modest heating from **accretion** and the decay of radioactive elements in the rocks would melt the ice in the interior and allow the rocks to sink, leading to differentiated interiors—that is, a layered structure with the denser rock and metal constituents concentrated closer to the center of the satellite and the ice in the outer layers. Most analyses following the Voyager mission operated on the assumption that Ganymede and Callisto had similar differentiated interior structures, but the data to test this assumption would not come until the Galileo mission.

Determining the interior structure of a planetary object is intrinsically difficult, particularly from remote observations alone. Most of the information about the interior of our Earth, for instance, comes from over a century of study of seismic data, where waves created by earthquakes travel deep through the Earth and provide clues to the density and composition throughout the interior [see *Earth Surface and Interior*]. So far the only other world for which we have seismic data is the Moon, acquired with seismometers left by the Apollo astronauts (see *The Moon*).

An extremely important quantity that can be used to assess the distribution of mass inside an object is a dimensionless number known as the moment of inertia; a sphere with uniform density throughout has a moment of inertia of 0.4, with lower values indicating increasing degrees of mass concentration near the center. The moments of inertia for Ganymede and Callisto were measured indirectly by the radio experiment on Galileo, which measured the perturbations of the spacecraft's trajectory as it flew by the satellites on multiple occasions at low altitudes and different latitudes. Although perfect spheres with different moments of inertia have identical external gravity fields, the key to this experiment is that the distribution of mass in the interior of a satellite does affect the way its shape is perturbed from a perfect sphere by rotation and tides. The rotation rates of Ganymede and Callisto, although slow by terrestrial standards (a little over a week for Ganymede, and over 2 weeks for Callisto), are still sufficient to cause a slight equatorial bulge and polar flattening, while Jupiter's strong gravity raises tidal bulges on the sub- and anti-Jupiter hemispheres. The combination of these two effects leads to distinctly nonspherical components to the external gravity field (in mathematical terms, the description of the satellites' gravity in a spherical harmonic expansion contains significant J_2 and C_{22} terms). The magnitude of these nonspherical terms depends on the degree of internal mass **differentiation**, and they are related directly to the moment of inertia as long as the object responds as a fluid to spin and tidal distortion (i.e. hydrostatically).

The surprising results of the Galileo tracking experiment showed that Ganymede and Callisto have distinctly different interiors. The derived moments of inertia for both satellites were lower than they would be for bodies of uniform density, as expected. Ganymede's measured value of 0.31 is so low that it implies essentially complete separation of its water ice from the heavier rock and metal. However, Callisto has a significantly larger moment of inertia, 0.35. This is small enough to imply some differentiation, but too large to be compatible with full separation of light and heavy components. Callisto probably has some significant portion of its interior composed of a rock—ice mixture.

The measured moments of inertia can be combined with the values for the total mass, size, and properties of ice and rock under pressure to construct models of the satellite's interiors that match all the known quantities. As there are several unknown parameters regarding interior chemistry, the exact compositions and thicknesses of layers in such models are inherently uncertain, but reasonable assumptions can be made to construct a general model. Figure 37.3 shows the best current estimates of their internal structures. Ganymede is shown with a three-layer structure: a metallic core, a rock mantle, and a deep water-rich upper layer; Callisto is shown with a two-layer structure: a large rock-ice core, with the fraction of dense material increasing toward the center, and an upper water-rich layer. Note that the water-rich layers on both satellites are shown with liquid water oceans trapped below thick layers of surface ice, as discussed in the next section.

3.2. Internal Oceans

A major question regarding these icy worlds is whether they possess subsurface oceans of liquid water. This intriguing possibility was first raised in the early 1970s by planetary geochemist John Lewis, who pointed out that radioactive

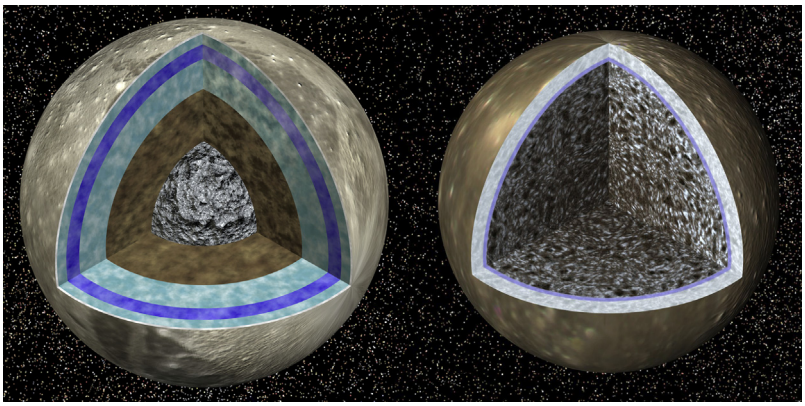

FIGURE 37.3 Cutaway diagrams showing current models for the interior structures of Ganymede and Callisto based on Galileo gravity data. Ganymede (left) is highly differentiated, with a molten iron core surrounded by a rocky mantle, in turn surrounded by a thick outer layer of ice. An interior ocean of liquid water may exist sandwiched between the surface layer of Ice-I and the higher pressure phases of ice below. Callisto (right) has an interior composed of a mixture or rock and ice, slowly increasing in density toward the center. The outermost layer is relatively clean water ice, with a liquid water ocean at its base. *Zareh Gorjian and Eric De Jong, NASA/Jet Propulsion Laboratory.*

heating of satellites' interiors might result in their internal temperatures reaching the water ice melting point at some depth below their surfaces. With the satellites' densities known, a relatively simple calculation of internal temperature from the heating produced by the decay of radioactive nuclides in the rock fraction (primarily U, Th, and K) shows that indeed the ice melting point should be reached about 75−100 km below the surface. More detailed calculations are complicated by several additional factors.

The behavior of water as a function of temperature and pressure is complex. At the surface of the Earth, only normal low-density ice, known as Ice-I, exists. It floats in liquid water and melts at 273 K (0 °C, 32 °F). Increased pressure decreases the melting temperature, but under terrestrial conditions the solid form remains as low-density Ice-I. Laboratory studies show that at the high pressures reached deep in the interiors of icy satellites the size of Ganymede and Callisto, ice transforms to various high-density forms over a wide range of temperatures (Figure 37.4). These phases of ice, as they are known, are denser than liquid water and would sink in a liquid ocean. Calculations of the temperature and pressure as a function of depth within the satellites show that if temperatures reach the required melting point the resulting subsurface oceans are strange indeed—a liquid layer sandwiched between low-density Ice-I on the top and higher density ice phases on the bottom (or possibly a mixture of high-density ice and rock in the case of Callisto).

The other major complication is whether the interior will ever actually warm up to the ice melting point. Simple calculations that reach the melting temperature are based on the heat produced by radioactive decay, escaping the interior by thermal conduction through the ice crust. However, as the temperature of ice approaches the melting point within the satellite, another heat transfer process comes into play, convection. Ice near its melting point is not stiff and brittle, but can flow and deform under pressure, particularly over long periods of time. In geophysical

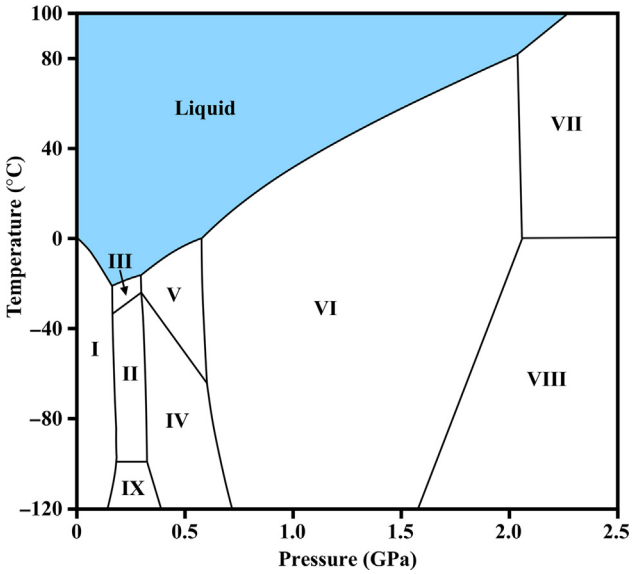

FIGURE 37.4 Phase diagram of water ice. At low pressures near the surface, Ice-I is less dense than liquid water. At higher pressures, ice converts to denser phases, with higher melting points.

terms, the solid ice may be considered as a low-viscosity fluid. Low-viscosity ice under some conditions can begin to convect, with warmer lower density ice rising toward the surface, exchanging with cooler higher density ice sinking into the interior. This glacially slow solid ice circulation is similar to what occurs in the Earth's rock mantle. The important point is that convection is much more efficient at transporting heat than conduction alone. In simple terms, as the ice heats up from the radioactive energy from below, it will begin to convect, taking heat to the surface, but never allowing the temperature within the ice to rise above the melting point. Under these conditions, even if an ocean formed early in the satellite's history, the convection process in the ice crust could rapidly freeze it solid.

On Ganymede, the low-viscosity ice may also play an alternative role as a source of thermal energy due to tidal

interactions with Europa and Io (see Section 2.4). Tidal heating is currently a minor source of energy on Ganymede compared to the large role it plays on Europa and Io, but it may have been more significant in the past. This additional heating process does not affect Callisto.

A final complication is the issue of ammonia, NH_3. In many formation models, ammonia is a possible minor constituent of the icy satellites. If present, it has a major effect on the melting point of a water–ammonia mixture, depressing the temperature of the solid–liquid transition to about 173 K, 100° below the point at which pure water melts. Although ammonia has not been detected on the surfaces of the satellites, even small amounts can affect the results of theoretical thermal and convection calculations, and most discussions of the satellites' interiors include both ammonia and nonammonia cases.

Whether convective cooling "wins" over heating determines whether a liquid ocean can exist at the present time. The calculations for interior models including convection are quite complex and depend on some properties of ice that are poorly known. Current models for Ganymede and Callisto show that liquid layers are possible under some conditions, but these models cannot definitively demonstrate their existence. Measurements pointing strongly to the presence of liquid oceans in both satellites came from an unexpected source—magnetic field measurements made by the Galileo mission, which is the subject of the next section.

3.3. Magnetic Fields

The Galileo magnetometer experiment had two major objectives for studying Ganymede and Callisto: (1) to determine whether they possess intrinsic magnetic fields of their own and (2) to study the interactions of the satellites with Jupiter's huge and powerful magnetosphere. These two objectives are closely coupled because the satellites orbit deep within the region of space controlled by Jupiter's magnetic field and its associated trapped radiation and **plasma**. Measurements of magnetic fields in the vicinity of the large satellites thus have to take into account the large background field from Jupiter, which is continually changing due to Jupiter's fast rotation sweeping the field past the satellites and magnetic perturbations from large-scale electrical currents flowing within the magnetosphere. Once these effects are measured and understood, the experimenters can search for the smaller perturbations in the local magnetic field produced by any intrinsic field and from local currents set up by the interactions of the satellites and their tenuous atmospheres with the magnetosphere.

3.3.1. Intrinsic Fields

On the very first Galileo close encounter with Ganymede, the space physics instruments detected strong evidence for both an intrinsic field and complex interactions with Jupiter's environment. As the spacecraft flew by the satellite, the magnetometer recorded a marked change in both the magnitude and direction of the magnetic field. At the same time the plasma wave spectrometer (which receives natural radio "noise" produced by the interactions of charged particles and magnetic fields) showed sharp changes in the nature of the radio signals they received, coinciding closely in time with the observed magnetic deflections. To the investigators on these experiments, these observations were familiar, a "fingerprint" indicating that the spacecraft had passed though a planetary magnetosphere. Due to the complexities discussed earlier, it took observations on subsequent flybys to confirm the discovery, but it soon became clear that Ganymede possesses a relatively strong intrinsic magnetic field, oriented in the opposite sense to Jupiter's field, which produces a "mini-magnetosphere" embedded within Jupiter's magnetosphere. This nested magnetosphere arrangement is a unique situation in our solar system.

An intrinsic field at Ganymede was not totally unexpected. UCLA space physicist Margaret Kivelson, the head of the Galileo magnetometer team, had suggested prior to the Galileo mission that the big satellites might be able to generate their own internal fields. Nevertheless, the discovery of an intrinsic field at Ganymede raises a number of issues for our understanding of planetary magnetic field generation (see *Planetary Magnetospheres*).

How planetary fields, including the Earth's, are generated and maintained is an active area of research. It is believed that some form of what is called a "geodynamo" is responsible for producing a magnetic field within a planetary core. The exact requirements for generating a field by this dynamo process in a given planet are the subject of debate. Ganymede's internal field is consistent with its high degree of differentiation and favors a three-layer model with a metallic iron/iron sulfide core. However, merely having a metallic iron core is not sufficient to produce a planetary magnetic field. Although the Earth's field and other planetary fields are frequently described in textbooks as "bar magnet" fields, this only describes the field's mathematical description (having a dipolar—N and S—configuration with field lines connecting the poles). The solid iron bar magnet analogy is misleading in terms of the source of the field, since it has long been known that iron will lose its magnetization at the temperatures typical of planetary cores (temperatures above the Curie point, at which a magnetic material loses its magnetism).

Current theories of planetary dynamos suggest that the basic requirement for generating a field is continual convective motion of an electrically conducting fluid. Theoretical models of Ganymede's thermal evolution suggest that it could have a fluid, electrically conducting, iron or iron sulfide core at the present time. However, the

same models show that although there could have been convective motion in the fluid core early in Ganymede's history, at present the core should be stable against thermal convection, thus explaining the source of Ganymede's magnetic field requires additional factors. Possibilities discussed in the literature include some event, such as tidal heating, stirring up the core in recent geological history, or that Ganymede has heated over a longer timescale than earlier models suggest, reaching the required conditions for core convection and planetary dynamo formation only recently. Another possible explanation is due to a change in the phase behavior of iron sulfide at the lower pressures experienced in Ganymede's core, solid iron snow may form at the top of the liquid outer core and stir up convective motions as it falls through the liquid.

3.3.2. Induction Fields and Oceans

Callisto shows no evidence for an intrinsic dipole field like the one observed at Ganymede. When Galileo flew close to Callisto, the magnetometer recorded perturbations to the background field, but comparisons of data from several encounters showed there was no pattern consistent with single dipole field. However, when the investigators correlated the data with Callisto's position with respect to Jupiter's field, they found another intriguing pattern. Since Jupiter's dipole field is tilted about 10° to its rotation axis, the background field seen by a satellite orbiting in the equatorial plane exhibits a periodic rocking motion as Jupiter rotates. The observed magnetic perturbations correlated with times when this tilt was at different angles.

The key to understanding this type of perturbation lies in the basic theory of electromagnetism—moving magnetic fields can produce electrical currents and electrical currents can produce magnetic fields (electromagnets and electric motors are among the practical applications of this principle). A classic laboratory physics experiment demonstrates that placing an electrically conducting sphere (such as a copper ball) in an oscillating magnetic field will set up electrical currents in the surface of the sphere that produce an induced magnetic field, countering the imposed field. The magnetometer investigators found that the Callisto perturbations closely matched those expected for an induced field in response to the changing Jupiter field. In other words, Callisto was acting as if it had an electrically conducting layer at or under its surface.

What is the conducting layer on Callisto? The electrical conductivity required to produce the observed perturbations is much larger than the known conductivities of ice or rock, the major surface constituents. Going back to the theoretical possibility of a subsurface ocean, the investigators found a possible explanation for Callisto's behavior. The electrical conductivity of salty ocean water is in the right range to produce the required induction field. Although the argument is indirect, these magnetic results are the best evidence to date that the hypothesized ocean exists under Callisto's icy crust. After this discovery, investigators looked closely at the Ganymede magnetic data and found that there are small deviations from the best-fit intrinsic dipole model, which indicate the presence of an induced field from a conducting ocean layer on Ganymede as well. This same type of induced magnetic field evidence was used to infer a liquid water ocean under the ice on Europa, but ironically, the evidence for a conducting ocean layer on Callisto is stronger than on Europa, because the background field is smaller at Callisto.

3.4. Formation and Evolution

The Galilean satellites have been viewed as a sort of "miniature solar system" since the time of Galileo. Their coplanar, nearly circular orbits strongly suggest that they formed as part of the same process that formed Jupiter. The water-rich, low-density composition of the outer satellites, Ganymede and Callisto, compared with the rock-rich, high-density inner satellites, Io and Europa, suggest that there was a gradient in the conditions within the circumplanetary gas and dust nebula from which the satellites formed, much like the gradient in the solar system as a whole that produced rocky inner planets and volatile-rich outer planets.

The mixed rock/ice composition of Ganymede and Callisto is very similar to that expected from condensation from a nebula with solar composition. Early models for the formation of the satellites envisioned a circumplanetary nebula of gas and dust, which was heated by the growing Jupiter at the center. In this scenario, Ganymede and Callisto formed in the cooler outer portion of the system, under conditions similar to the surrounding solar nebula, which permitted the condensation of water ice. Io and Europa, on the other hand, formed further inside the nebula, under warmer conditions with little to no condensation of water.

This relatively simple Jovian subnebular theory explains the major characteristics of the system in the context of the formation of Jupiter itself. However, there are problems with the details of the model when the evolution of the forming satellites is considered. One problem is that as the satellites form they are subjected to drag from remaining gas and dust in the subnebula. This drag can quickly cause a protosatellite to spiral inward and be swallowed up by the growing proto-Jupiter. Current calculations show that this is a serious problem with early forms of the subnebular models since the timescale for the accretion of the satellites is much shorter than the times for dissipation of the nebula and decay of the satellite orbits. Another issue is the differences between Ganymede and Callisto. In the simple subnebula accretion models, they should have similar histories. However, Voyager and

Galileo observations show major differences in their interior structures and geologic histories. The most difficult point to reconcile is that Callisto's incompletely differentiated interior implies a longer accretion time to prevent melting and differentiation triggered by accretional heating.

The latest formation models attempt to address these issues in a number of ways. Current models for Jupiter's formation suggest that the Jovian subnebula interacts strongly with the surrounding solar nebula as the growing giant planet opens a "gap" in the solar nebula and material is continually fed from the solar nebula surroundings to the outer parts of the subnebula. This class of models can account for longer satellite accretion times and allows them to form without being dragged into the proto-Jupiter. Another type of formation model proposes that the inner satellites formed in a hot dense subnebula, but avoided destruction by opening gaps themselves in the subnebula, slowing their orbital decay. In this type of model, Callisto forms more slowly in a thinner outer nebula environment, accounting for some of its differences.

A final factor which may have affected the apparently different histories of Ganymede and Callisto is the existence of what is known as the **Laplace resonance**. This is a dynamical relationship between the orbital periods of the inner three satellites, first studied by the French mathematician Laplace in the nineteenth century. Io, Europa, and Ganymede currently exhibit a simple numerical relationship (1:2:4) in their orbital periods, causing them to always encounter each other at the same points in their orbits. The gravitational tugs from this repeating encounter pattern continually perturb their orbits, resulting in significantly noncircular orbits. The noncircular orbits cause tidal heating in each of these satellites, resulting most notably in the violent volcanic activity on Io, which has the largest dose of tidal heating due to its proximity to Jupiter (*see* Io). Callisto does not participate in this celestial dance and apparently has never experienced tidal heating.

Despite its participation in the Laplace resonance, Ganymede does not currently experience significant tidal heating because of its distance from Jupiter and the relatively small degree of noncircularity of its orbit. However, calculations of the dynamical evolution of the satellite system suggest that Ganymede's orbit may have been more **eccentric** during its capture into the resonance, possibly resulting in a pulse of tidal heating, which could have triggered differentiation and/or stirred up the core and started magnetic field generation. While the question of why Ganymede and Callisto have experienced such different interior and geological evolution has not been conclusively solved, it seems likely that the key to the solution lies in some combination of differences in their formation conditions and subsequent orbital evolution.

4. SURFACE MATERIALS

4.1. Composition of Surfaces

As noted in the discussion of astronomical discoveries (Section 1.2), water ice was identified as a primary surface constituent on the surface of Ganymede and Callisto (and Europa as well) in the 1970s by obtaining infrared spectra of these bodies. Seen with the eye, the surfaces are darker and redder than pure water ice, so there must be some other material mixed with the ice, but the composition of this material has been difficult to determine. Based on analogy to meteorite and asteroid spectra as well as cosmochemical arguments, most researchers have assumed that the nonwater component of the surface is similar to the material found in primitive, carbon-rich meteorites—a mixture of hydrated silicates (clays) and dark, complex organic compounds (dubbed "tholins" by the astronomer Carl Sagan, who studied the production of organic material in laboratory simulations of planetary environments). Laboratory studies of ice and mineral mixtures show that even small amounts of dark material will disproportionately lower the reflectance (albedo) of the mixture and weaken the spectral signature of water ice, producing reflectances consistent with the observed spectra of the satellites. Unfortunately, the more subtle spectral signatures of the dark minerals are themselves obscured in the mixed spectra by the much stronger water features, making identification of the dark constituents difficult.

The **Near Infrared Mapping Spectrometer (NIMS)** on Galileo provided new insights into the composition of the nonwater constituents. This instrument not only covered the spectral range accessible to Earth-based telescopes but also returned spectra in the 3−5 μm spectral region. This part of the infrared spectrum is inaccessible from the surface of the Earth due to strong absorptions in the Earth's atmosphere by water vapor and carbon dioxide. It is also a key part of the spectrum for studying non−water ice components mixed into the satellite surfaces, since water ice is essentially black at these wavelengths and whatever signal is seen arises primarily from the non−-water ice component of the surface mixture.

NIMS spectra of Ganymede and Callisto indeed proved their value in the 3−5 μm range, exhibiting a number of detectable absorption features (see Figure 37.5). The strongest feature is a relatively sharp absorption of infrared light centered at about 4.25 μm wavelength, with weaker, but still easily detectable, absorptions at 3.88, 4.05, and 4.57 μm. There is also a weak absorption seen centered near 3.4 μm. These absorptions are seen in the spectra from both satellites, but are most easily seen in the Callisto spectra, where there is more of the dark material exposed on the surface.

The 4.25-μm feature has been identified as being caused by the presence of CO_2 on the surface. The location of the

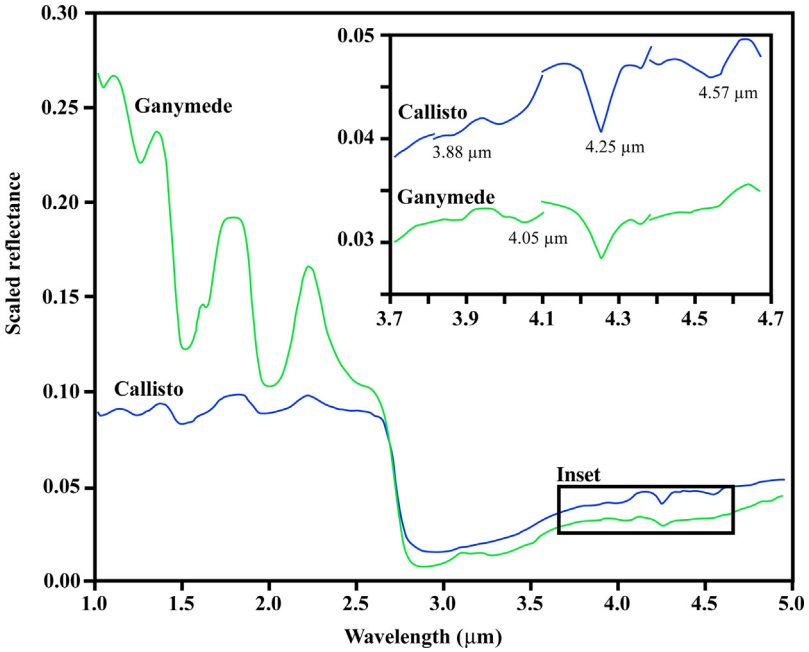

FIGURE 37.5 Galileo NIMS spectra of Ganymede and Callisto, showing absorption of infrared light by various surface materials. The lower reflectance of Callisto at wavelengths shorter than 2.7 μm and the higher reflectance of Callisto at longer wavelengths are both indicative of the lower fraction of water ice exposed on Callisto's surface as compared to Ganymede. Several absorptions at other wavelengths indicative of minor chemical species are highlighted in the inset, including CO_2, SO_2, C−H bonds, and C≡N bonds. See text for details. *Modified from T. McCord et al., (1998).*

center of the absorption indicates that the CO_2 is not in the form of either solid ice or liquid, but rather occurs in microdeposits, bonded to some other material in the soil. The 4.57-μm absorption is believed to be due to a carbon−nitrogen compound based on its frequency, which corresponds to that expected for C≡N (a triple bond of carbon and nitrogen). The weaker features near 3.4 μm are also believed to be due to carbon bonds with hydrogen (C−H hydrocarbons). These features have also been identified in spectra of interstellar ice grains obtained by the European Space Agency's Infrared Space Observatory (ISO) mission. Observations of the satellites of Saturn by a similar instrument on the Cassini spacecraft show nearly identical CO_2 absorption and similar C≡N and C−H features (*see* Planetary Satellites). The other two absorption features (3.88 and 4.05 μm) seen on Ganymede and Callisto appear to be unique to the Jupiter system and are thought to be due to S−H bonds and sulfur dioxide, respectively.

4.2. Surface and Atmosphere Interactions with Local Environment

The environment around Jupiter is awash in radiation from charged particles trapped in Jupiter's intense magnetic field. Since they are trapped in the field, which rotates rapidly with Jupiter's spin, the particles sweep past the satellites in their comparatively slow orbits. Thus, the side of a satellite facing away from the direction of orbital motion (the trailing hemisphere) is exposed to a much higher dose of radiation than the leading hemisphere. When the charged particles strike the surfaces of the satellites, they can send surface molecules flying (a process called sputtering), and they can break molecular bonds in the surface material, causing new chemical reactions to occur and creating new compounds.

Laboratory studies suggest that the CO_2, C≡N, and C−H features seen in the spectra of Ganymede, Callisto, and other icy satellites in the solar system may have a common origin due to charged particle irradiation of minerals containing potassium cyanide and possibly other cyanogens (carbon-nitrogen-bearing compounds). Irradiation of these compounds by energetic particles in the presence of water ice is believed to be an important source of the CO_2 found embedded in the mineral/ice matrix on the surfaces of Ganymede and Callisto. On Callisto, the distribution of CO_2 mapped by NIMS shows a marked concentration on the trailing hemisphere of the satellite, as would be expected from radiation-induced CO_2 production. Ganymede shows no such enhancement of CO_2 on the trailing hemisphere, but instead shows an enhancement in the ancient regions of dark terrain.

Sulfur is an important ion in the Jupiter system, continually supplied to space by the escape of sulfur and sulfur dioxide gases from volcanic Io. The sulfur becomes ionized and joins the low-energy plasma streaming through Jupiter's magnetosphere, which then washes up on the other satellite surfaces. Implantation of sulfur into the surfaces of the icy Galilean satellites has been suggested in the past as the likely reason for the low reflectance of the satellites in the ultraviolet part of the spectrum. The sulfur-induced infrared absorption features are also plausible

results of bombarding the icy surfaces with sulfur-rich plasma. However, the distribution of SO_2 on the surfaces of Ganymede and Callisto do not show a strong leading–trailing hemisphere asymmetry as one would expect from an external source trapped in Jupiter's magnetosphere, indicating that perhaps there is also sulfur in the ice bedrock.

Both Ganymede and Callisto exhibit other effects from their continual bombardment by charged particles in Jupiter's magnetosphere. Both molecular oxygen, O_2, and ozone, O_3, have been detected in telescopic spectra of their surfaces. These oxygen compounds appear to exist as microscopic bubbles trapped in the matrix of the icy surface material and have also been attributed to irradiation by charged particles.

In addition to the frozen and trapped gases in their surfaces, Ganymede and Callisto have very tenuous atmospheres. The ices on the surfaces of Ganymede and Callisto are weakly warmed by the sun, and exposed to near-vacuum conditions. Even at the cold temperatures in the Jupiter system, ice will slowly sublime and escape as a gas. On Ganymede, Hubble Space Telescope spectra have identified molecular oxygen, and the Galileo ultraviolet instrument detected a thin veil of hydrogen in the surrounding space. Callisto's atmosphere is similarly of very low density, and the only detectable gas so far has been CO_2 identified in NIMS spectra.

A combination of thermal segregation and sputtering has also been invoked to explain the distribution of water frost on Ganymede, where the high-latitude regions appear to be coated with polar caps of frost which may have migrated there from the equatorial areas and been retained there due to lower temperatures. The edges of Ganymede's polar caps (the northern cap is visible in Figure 37.1) closely follow the region where Ganymede's magnetosphere becomes connected with the external Jupiter magnetosphere, indicating that charged particles play an important role in creating the caps. The magnetosphere also plays a role in creating aurora displays on Ganymede, as charged particles funneled into Ganymede's polar regions from Jupiter's magnetosphere impact atomic oxygen in Ganymede's tenuous atmosphere.

Another interaction with the external environment of the satellites is micrometeoroid bombardment. All airless bodies are exposed to the flux of tiny grains from interplanetary space striking their surfaces. In the case of Ganymede and Callisto, the interplanetary particle fluxes are enhanced due to Jupiter's gravity. Galileo carried a sensitive detector that measured the surrounding dust environment as the spacecraft orbited Jupiter, and sampled the population of dust particles near the satellites. The dust investigators found that both satellites have a population of small (micron-sized) particles loosely bound by gravity in the space surrounding the satellites. These measurements are consistent with icy dust grains that have been blasted off the satellite surfaces by the impact of interplanetary micrometeorites.

The **sublimation** of surface ices into the thin atmospheres of Ganymede and Callisto and escape into space or redeposition as frost elsewhere appears to play a crucial role in shaping and redistributing the material seen at their surfaces. At typical temperatures in the Jupiter system, water ice could sublimate at a rate of meters per million years if directly exposed to a vacuum, but on Ganymede and Callisto, sublimation of dirty ice is soon choked off by a blanket of nonice dust left behind as the ice sublimates. A few centimeters of dust cover can slow the process by over a million times and preserve the ice beneath. Sublimation will occur millions of times faster for SO_2 ice than for water ice, and CO_2 ice will sublimate thousands of times faster than SO_2, so incorporation of these compounds into the ice bedrock will drive the sublimation erosion process much faster.

4.3. Regolith

Bright ice crystals and dark nonice dust both exist on the surfaces of Ganymede and Callisto, but they are largely segregated from each other. If one were to pick up a sample of the loose surface material (the regolith), it would probably be composed of mostly ice or mostly dust, and not a mixture of the two. High-resolution images show very high albedo contrasts over small spatial scales, with relatively pure icy material outcropping in patches surrounded by blankets of dark nonice material. This effect is most pronounced on Callisto (Figure 37.6). It appears that the ice

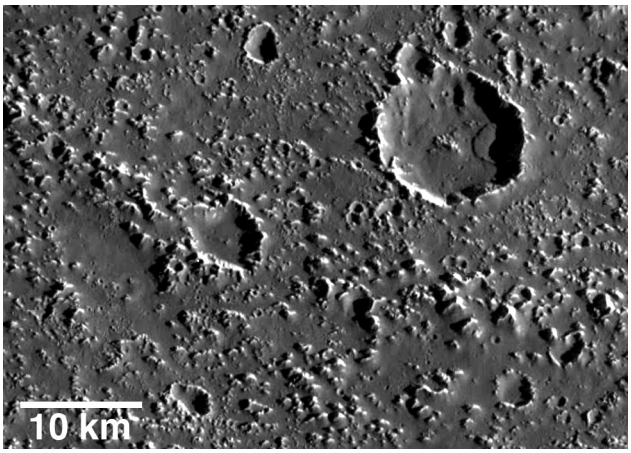

FIGURE 37.6 Callisto's surface is characterized by bright icy hills and impact crater rims surrounded by blankets of dark dust. This surface is thought to result from sublimation of an ice/dust mixture, leaving a lag deposit of loose dust in the low areas and depositing bright frost on steep slopes and hilltops. Note the prominent crater in the upper right section of the image displaying the raised tongue of a landslide deposit consisting of loose dark material originating from the shadowed crater wall. This area is located within the Asgard impact basin.

bedrock is composed of a mixture of ice and nonice dust. When a fresh outcrop of bedrock is exposed at the surface, the ice will begin to sublimate into the near-vacuum atmosphere. Enhanced solar heating of dark material drives faster sublimation of ice from that material, further darkening the material, while any reflective surface will serve as a cold trap, building up a layer of frost and further brightening the surface. These positive feedbacks lead to the effective segregation of ice and nonice materials in the surface regolith.

This process also operates on Ganymede, but it has not modified the surface to the same extent seen on Callisto. Perhaps there is more dark material mixed in with the surface ice on Callisto, or perhaps the ice on Callisto includes a higher proportion of volatile SO_2 and CO_2 ices that enhance the rate of sublimation. Patches of frost are often seen on steep slopes facing away from the sun on many parts of Ganymede's surface. Bright terrain on Ganymede has a higher **thermal inertia** than the dark terrain, indicating that much of the bright ice exposed in this terrain must be more solid or compacted than the loose dust that covers dark terrain.

On both Ganymede and Callisto, the dark material is found filling the topographic lows, while bright material covers the slopes and hilltops. Part of the reason for this is that reflection and emission of light from surrounding terrain tends to make topographic lows slightly warmer, but much of this effect appears to be due to the loose, dusty nature of the dark material. Buildup of loose dark material on steep slopes due to sublimation leads to avalanches of the material into topographic lows. The large crater in the northeastern corner of Figure 37.6 exhibits a thick tongue of dark material that has flowed over the floor; this appears to be a deposit of regolith that has slid from the steep eastern wall of the crater, and its shape indicates that it slid downhill as a dry avalanche of loose debris. Images of dark terrain on Ganymede also show chutes on steep slopes where material has slid downhill, with dark material piled along the bottoms of the slopes. Bright terrain on Ganymede shows the same effect, with dark material filling in the valleys of the grooved terrain, between bright steep icy slopes. The dark dust often appears to form a thick, smooth blanket on Callisto and Ganymede dark terrain, but there are many small craters that penetrate through the dark material, indicating that the layer of loose dark dust may only be meters deep before a solid layer of ice/dust mixture is reached.

5. IMPACT CRATERS

5.1. Crater Structures

Ganymede and Callisto exhibit a wide variety of impact features, including some types unique to these large icy satellites. The smallest craters imaged on the two moons have a classic bowl-shaped morphology, as is the case for small craters on any planet. At a diameter of 2−3 km, central peaks begin to appear (Figure 37.7(a)), again following the normal morphological progression for most planets. However, as crater diameter increases beyond 35 km, instead of the transition to larger central peaks or peak rings seen on the inner planets, large craters on Ganymede and Callisto exhibit central pits (Figure 37.7(b)). Young craters undergo another transition at about 60 km diameter, where the central pits begin to exhibit round domes of material in their centers (Figure 37.7(c)). These central domes have fractured surfaces reminiscent of lava domes, and they may be formed by rapid extrusion of warm, viscous ice into the center of the crater just after its formation. Most large craters on Ganymede and Callisto are very shallow, especially older craters, indicating that warm subsurface ice has flowed in toward the crater depressions and bowed their floors back up to the topographic level of their surroundings (a process known as viscous relaxation). Some central dome craters have been so flattened that they do not exhibit any obvious rim structure; the central dome and surrounding pit wall are the only obvious structures remaining (Figure 37.7(d)). A few large craters, known as penepalimpsests, exhibit only subdued topographic rings, with a smooth patch in the middle (Figure 37.7(e)). Where these occur on Callisto and the dark terrain of Ganymede, they show up as a distinct circular patch of bright material against the dark background. Still other bright circular patches are found within Ganymede's dark terrain and on Callisto that are almost completely flat, except for a subtle outward-facing scarp around the outside and a depressed smooth area in the center (Figure 37.7(f)). These features are called palimpsests, a word for an ancient piece of parchment where the writing has been erased. In a similar way, these large ancient craters have almost been erased by the process of viscous relaxation.

On the Moon, the largest craters form multiring basins (*see* The Moon). On Ganymede, one large basin called Gilgamesh shares similar characteristics with the lunar basins: a smooth central region surrounded by large irregular massifs, in turn surrounded by a few large concentric mountain ranges. However, most large impact basins on Ganymede and Callisto exhibit a distinctly different morphology, with a large palimpsest in the middle surrounded by many evenly spaced concentric rings. The best example of such an impact basin is Valhalla on Callisto, which is about 1000 km across and exhibits about 20 concentric rings around its central bright palimpsest (Figure 37.8). Most basin rings on Callisto are troughs that appear to have formed by extension of the surface material. These multiring structures are thought to form as subsurface material rapidly flows in from the sides to fill the

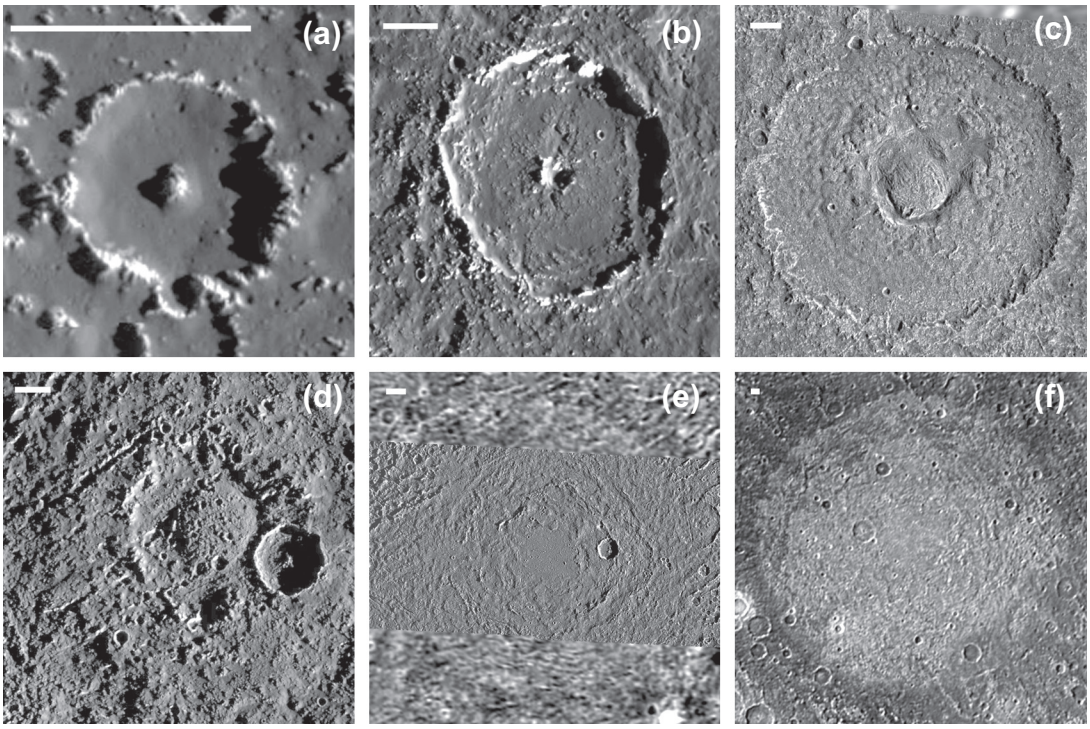

FIGURE 37.7 Diversity of impact crater morphologies on Ganymede and Callisto. All scale bars are 10 km long, and illumination is from the right. FIGURE 37.8 View from the Voyager 1 spacecraft of the Valhalla multiring basin on Callisto. The extensive system of concentric troughs surrounding the impact site is over 3000 km across.

center of the impact basin, pulling a thin brittle veneer of surface material inward.

The viscous relaxation and modification of craters can inform us about the nature of the subsurface ice during and after crater formation. Older craters are distinctly shallower, showing the action of viscous relaxation through time. However, there is not a continuum of viscously relaxed craters as one might expect if this process was ongoing at a constant rate. Instead, it appears that early craters relaxed quickly, while more recent craters are being preserved in a stiff material. This implies that heat flow was higher in the past, allowing warm ice to flow just below the surface early in solar system history, while more recently the subsurface ice has become colder and stiffer. There is overlap in size between central dome craters, penepalimpsests, and palimpsests, implying that impacts of similar energy formed all these morphologies at different times. Palimpsests are found only in the most ancient terrains, while central dome craters appear to be relatively young. Again, it appears that palimpsests formed early when the subsurface was warm and flowed easily, penepalimpsests record a time when the ice was cooling, and dome craters have formed more recently in a thicker layer of cold stiff ice. On Ganymede, the formation of the bright terrain appears to mark an important transition in crater morphology, with no palimpsests or Valhalla-type multiring basins formed after the formation of bright terrain. Thus, it appears that heat flow was higher on Ganymede in the past, and Ganymede's subsurface became colder and stiffer after the formation of bright terrain.

5.2. Distribution of Craters and Surface Ages

Variations in the aerial density of impact craters are observed on Ganymede and Callisto, giving us information about the population of impactors and the relative ages of

different surfaces. In general, the highest crater densities are found on the dark terrain of Ganymede and the plains of Callisto. Bright terrain on Ganymede has a distinctly lower density of craters than the dark terrain, supporting the view that it formed substantially later. The only areas on Callisto with lower crater densities are the interiors of impact craters and large multiring basins, where the surface age has been reset by the impact event.

Translating the spatial density of impact craters into absolute ages of different surfaces on Ganymede and Callisto is a tricky proposition. On the Moon, this has been accomplished by correlating areas of varying crater density on the lunar surface with physical samples of those surface materials that have been returned to the Earth to be precisely dated in the laboratory using radioisotope techniques. Since we have no surface samples from the Galilean satellites, we cannot directly date them. In addition, we cannot be sure that the same population of debris that impacted the Moon also impacted the Galilean satellites, so it is dangerous to directly compare crater densities between these two different parts of the solar system. In general, it is agreed that the surface of Callisto and the dark terrain on Ganymede represent primordial surfaces, formed shortly after the formation of the planets, 4.5 Bya. Bright terrain on Ganymede could have formed shortly after that, or it could have formed only a billion years ago. The current best guess from crater statistics is that bright terrain most likely formed at some time during the middle half of solar system history, but obtaining an exact age is likely to remain elusive for a long time.

Since Ganymede and Callisto are tidally locked and always have the same side facing Jupiter, it is expected that they should gather more of the debris coming from outside the Jupiter system on the sides facing forward in their orbital motion (the bug on the windshield effect), and thus there should be more craters on their leading hemispheres than on their trailing hemispheres. Callisto does exhibit such an asymmetry in crater density, but the asymmetry on Ganymede is much weaker. One hypothesis to explain this is that Ganymede's outer ice shell has rotated with respect to Jupiter in the past and has become locked to Jupiter more recently, while Callisto's surface has always been locked with respect to Jupiter. Another piece of evidence to support this view comes from the study of split comets. In 1994, the comet Shoemaker–Levy 9 impacted into Jupiter, after having been tidally disrupted into a string of fragments by its previous close encounter with Jupiter. If such a string of comet fragments hits one of the satellites on its way out of the Jupiter system, it would form a line of closely spaced, simultaneously formed impact craters called a catena. These catenae are in fact observed on the surfaces on Ganymede and Callisto, recording previous tidally disrupted objects like Shoemaker–Levy 9. On Callisto, all the catenae are found on the Jupiter-facing hemisphere, as one would expect from the impact of a comet on its way out of the system after a close brush with Jupiter. On Ganymede, one-third of the catenae are found on the hemisphere facing away from Jupiter, which would be impossible unless Ganymede's ice shell has rotated in the past.

6. TECTONISM AND VOLCANISM

Like rocky planets, icy worlds also respond to intense surface stresses by cracking and faulting, forming rift valleys and ridges through tectonics. Ice is weaker than rock, but at the cold temperatures in the Jupiter system it is stronger and stiffer than the comparatively warm glacial ice found on the Earth. If liquid water is able to make its way to the cold surface of an icy world, a type of volcanism known as **cryovolcanism** may form lava flows of ice across the surface.

The observed surface record of past tectonic and volcanic activity is the most obvious difference between Ganymede and Callisto. Most of Ganymede's surface has been reworked by some combination of these processes, while Callisto's surface appears to be untouched by internally driven geological activity. Below, we separately consider the roles of tectonism and volcanism in the extensively resurfaced bright terrain of Ganymede, the marginally resurfaced dark terrain of Ganymede, and the relatively pristine surface of Callisto.

6.1. Bright Terrain

Bright terrain covers two-thirds of Ganymede's surface and is composed of a dense network of intersecting and overlapping areas of parallel ridges and troughs, termed "grooved terrain", and other areas with more subdued topography, termed "smooth terrain".

Smooth terrain may occur either as patches bounded by grooved terrain on all sides or as lanes of smooth material tens of kilometers wide cutting across bright and dark terrain. In either case, the terrain appears to be smooth in kilometer-resolution regional images (Figure 37.9(a)), leading to the hypothesis that it formed by low-viscosity cryovolcanic flows flooding the underlying terrain. At higher resolution, it becomes apparent that the smooth terrain is not so smooth after all. In some areas, it appears to be a flat plain crossed by ridges or sets of aligned hills (Figure 37.9(b)). In other areas, especially where the smooth terrain occurs as narrow lanes, it appears to be a flat or gently undulating surface crossed by parallel dark lineations, which may be narrow valleys formed by tensile fracturing of the ice (Figure 37.9(c)). The presence of parallel sets of ridges and valleys in smooth terrain suggests that tectonism plays an important role in shaping this terrain, in addition to possible cryovolcanism.

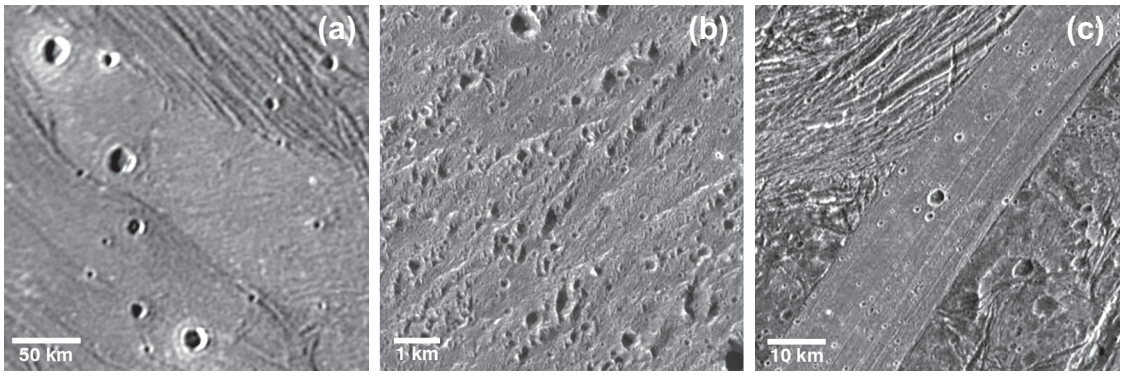

FIGURE 37.9 Views of smooth bright terrain on Ganymede. (a) Voyager 1 image of smooth bright terrain in Harpagia Sulcus; (b) Galileo high-resolution image of smooth terrain from the center of (a), showing ridges and hills not visible in regional-scale views; and (c) Galileo image of Arbela Sulcus, a narrow lane of smooth terrain cutting through the dark terrain of Nicholson Regio.

Although cryovolcanism is an attractive explanation for the smooth, flat areas found within smooth terrain, its role had not been conclusively demonstrated. No obvious volcanic constructs or flows have been observed, although it is unclear if we know what an ice volcano is really supposed to look like. A few features that may possibly be volcanic calderas have been observed (Figure 37.10), but most areas of smooth terrain exhibit no such features. While the smooth regions shown in Figure 37.10 are topographic lows, as one would expect if they were troughs filled by low-viscosity volcanic flows, the smooth regions shown in Figure 37.9 have been found to lie locally higher than parts of their immediate surroundings. Another possible interpretation for the linear bands of smooth terrain is that they formed through separation and spreading of the crust in a manner analogous to Europa's gray bands (see Europa). In either case, the formation of smooth terrain appears to involve the extrusion of liquid water or warm ice from Ganymede's subsurface.

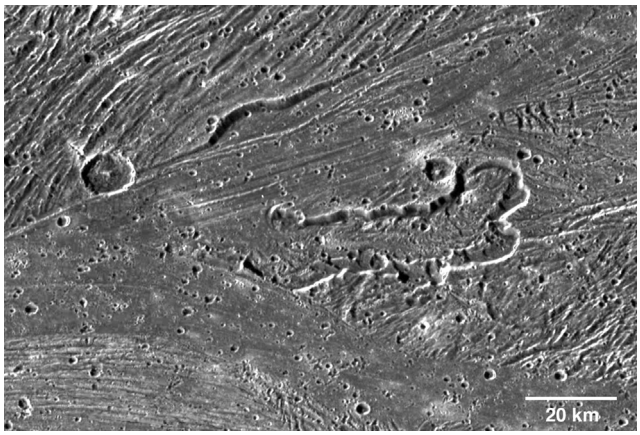

FIGURE 37.10 This irregular pit is one of several found along the edges of smooth terrain in Sippar Sulcus on Ganymede. Faint curved ridges within the pit suggest flow folding in the surface of a cryovolcanic flow emanating from the closed end of the pit and flowing out the open end, into the surrounding smooth terrain.

Tectonism plays a more obvious role in the formation of grooved terrain. In kilometer-resolution images, grooved terrain is characterized by parallel valleys and ridges spaced about 5−10 km apart (Figure 37.11(a)). At higher resolution, each ridge and valley is itself composed of many smaller ridges and valleys (Figure 37.11(b)). Each of these smaller ridges is thought to be a fault block, a piece of the icy crust which has been separated from its surroundings by faults and then moved and tilted as it slid along those faults. The shapes and intersections of the faults are indicative of a style of faulting known as tilt-block normal faulting, in which many parallel faults slice the upper portion of the crust into roughly rectangular blocks which then tilt over and slide against each other as the crust extends, much like books sliding over on a bookshelf when a bookend is removed. This style of faulting creates parallel ridges with a sawtooth topographic profile, matching the triangular ridges on Ganymede with their sharp crests, frosty upper slopes, and dark V-shaped valleys between them.

In a few places on Ganymede, large impact craters have been cut by these networks of faults (Figure 37.12). Since almost all craters are formed in a roughly circular shape, these cut craters offer an opportunity to directly measure how the crust has deformed as their shape becomes progressively distorted by motion along the faults. Measurements of these craters confirm that the development of grooved terrain on Ganymede is dominated by extensional tectonics. At the extreme end of the spectrum, some small parts of the crust appear to have been pulled apart to more than twice their original width, but in most cases, the extension appears to be more moderate. Circumstantial evidence exists for contractional deformation in a few areas, but it is not widespread.

These observations force us to ask how the crust of Ganymede could have undergone a large amount of extension with very little evidence for contraction to balance it out. There are a few possible solutions to this conundrum. One solution is that Ganymede actually expanded during the

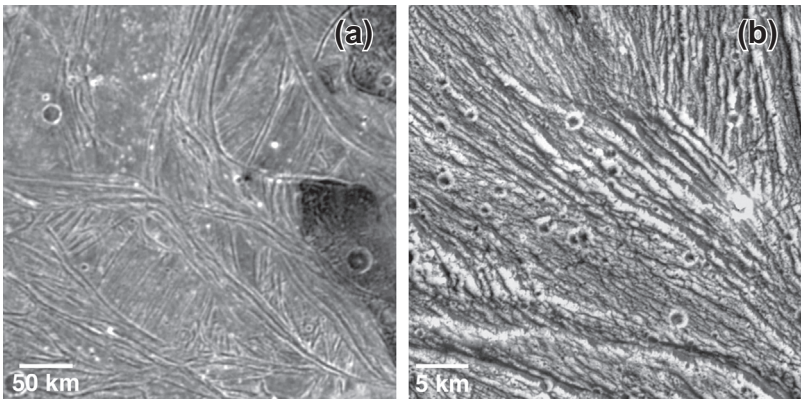

FIGURE 37.11 Views of bright grooved terrain on Ganymede. (a) Voyager 2 imaged this region of grooved terrain in Uruk Sulcus and (b) Galileo image of grooves in the central part of (a), shown at 10 times the scale.

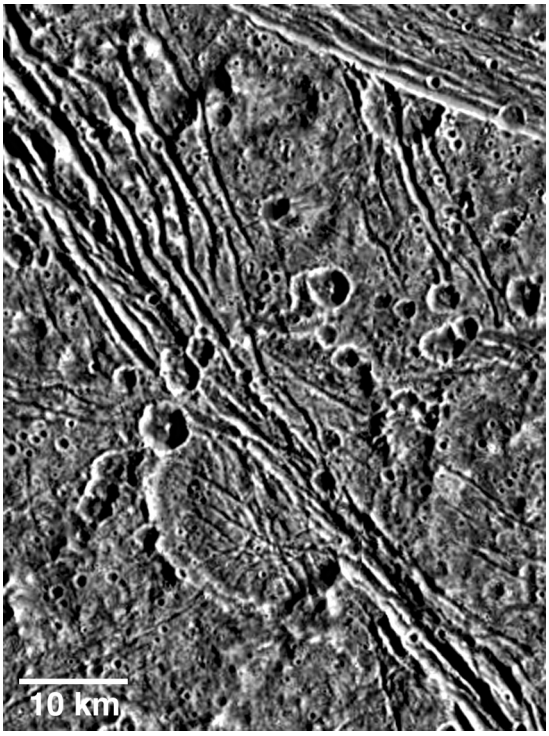

FIGURE 37.12 This crater in the dark terrain of Marius Regio on Ganymede has been cut by faults extending from a nearby region of grooved terrain. Measurement of the postdeformation shape of the crater demonstrates that the faults have extended the terrain and also horizontally translated the eastern part northward relative to the western part.

formation of grooved terrain. Differentiation of Ganymede's interior or melting of high-pressure ices can serve to increase the volume of the satellite, leading to an increase in surface area and thus stretching of the crust. Alternatively, we may have missed seeing the contractional features on Ganymede either because the crust shortened mostly in a ductile fashion, leaving few obvious surface features, or because we simply do not recognize the morphology of contractional features formed in ice.

In places where narrow lanes of grooved terrain cut across dark terrain, it is clear that bright grooved terrain can form simply by extension of the dark terrain, without the cryovolcanism that may have taken place in smooth terrain. Faulting may serve to erase the impact craters on the dark terrain by slicing them up and making their rims unrecognizable. Brightening of the terrain can occur by breaking through the dark regolith layer and exposing bright subsurface ice along the fault scarps.

In larger regions of grooved terrain, tectonism and cryovolcanism may have acted together to shape Ganymede's surface. Small deviations in the trajectory of the Galileo spacecraft as it flew past Ganymede appear to be due to gravity anomalies, which are areas where the local density of the subsurface material is higher or lower than the average for the rest of the satellite. These gravity anomalies can be interpreted to show that bright terrain has anomalously low density, while dark terrain has anomalously high density. This could mean that the icy brightness of bright terrain and the rocky darkness of dark terrain are more than skin-deep.

6.2. Dark Terrain

Dark terrain on Ganymede is dominated by impact craters. Aside from the swaths of bright grooved terrain that cut across the dark terrain, and small peripheral fractures adjacent to the grooved terrain, tectonic features in dark terrain are primarily systems of arcuate to linear features known as furrows. Furrows are usually composed of two bright ridges spaced 10–20 km apart, with a dark trough in between them. Most furrows are arranged in concentric sets of arcs (Figure 37.13), indicating that they are probably ancient multiring basins that originally resembled Valhalla on Callisto, but are now sliced up into fragments by the formation of bright terrain. This interpretation is supported by some small furrow systems that appear to have an impact basin in the center. Some sparse systems of linear

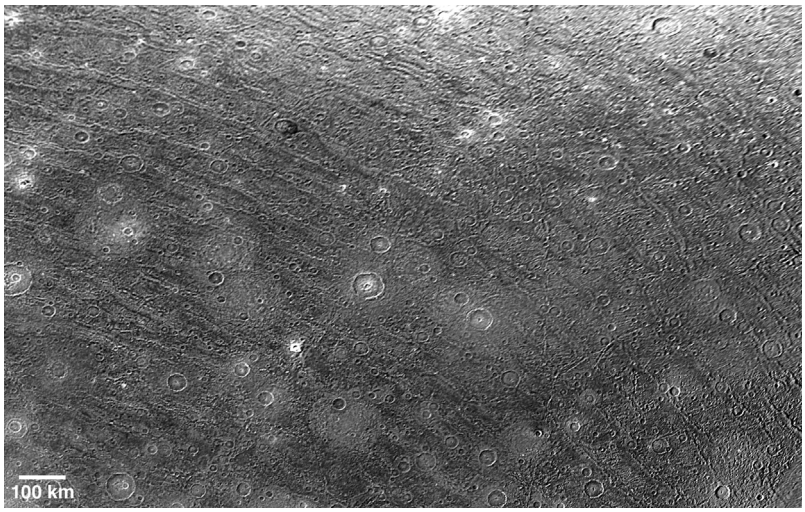

FIGURE 37.13 Furrows in Galileo Regio on Ganymede arc gently from northwest to southeast. Furrows are thought to be the Ganymede equivalent of the concentric rings found around impact basins such as Valhalla on Callisto (see Figure 37.8).

furrows appear to radiate out from a point rather than being concentric arcs. The origin of these radial systems is unclear.

There was speculation based on Voyager images that some areas of dark terrain had a splotchy appearance due to patches of dark cryovolcanic material oozing onto the surface. At higher resolution, however, these splotchy areas were revealed to be plains of dark regolith interrupted by networks of bright fractures.

6.3. Callisto

The story of tectonism and volcanism on Callisto is reminiscent of Ganymede's dark terrain. All the obvious tectonic features are arranged in concentric rings and surround large impact basins. The rings are high scarps or deep troughs with sharp boundaries (Figure 37.14). The scarps and troughs are formed by faults that have extended the crust by a small amount during the formation of the impact basin (see Section 4). Multiring basins on Callisto provide the type examples for the ancient impact basins that formed the furrow systems on Ganymede before they were broken apart. There is also a system of troughs near Callisto's north pole that appears to radiate out from a central point. Unfortunately, the center of this system on Callisto was never imaged at high resolution, so the origin of these features remains mysterious, as does the origin of similar radial furrow systems on Ganymede. Early speculation that smooth dark patches on Callisto might be cryovolcanic in origin has been largely dispelled by evidence that Callisto has a loose regolith that smoothes over the underlying terrain like a thick dark blanket.

7. UNANSWERED QUESTIONS AND FUTURE EXPLORATION

Several interesting unanswered questions remain about Ganymede and Callisto. Since the general properties of these satellites appear to be so similar, understanding the processes and events that have driven their interior

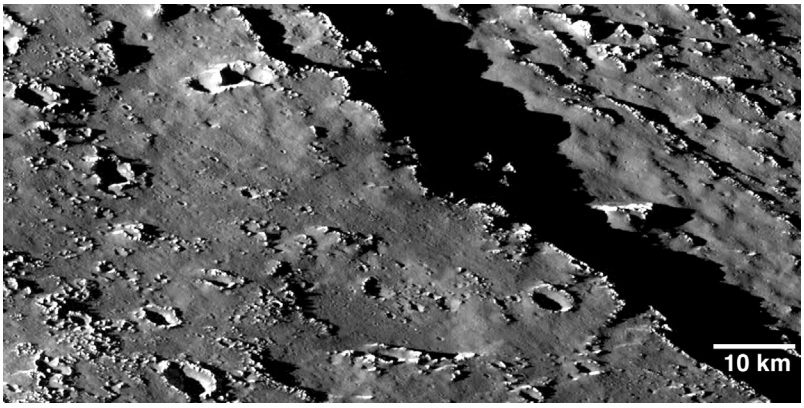

FIGURE 37.14 Oblique view over the surface of Callisto, looking over the edge of one of the concentric ring scarps of the Valhalla impact basin.

evolution and geological records to different states is an important problem in comparative planetology. In the interiors of the satellites, making Ganymede hot enough to generate a **magnetic dynamo** and keeping Callisto cold enough to remain undifferentiated are both challenging problems for our understanding of planetary geophysics. The oceans of liquid water that exist within these bodies, sandwiched between different phases of ice, are interesting phenomena in themselves. On the surfaces of Ganymede and Callisto, we still do not have a clear idea of the composition of some of the materials that are mixed in with the water ice, and which of those materials come from the interiors of the satellites, which ones come from their external environments, and which ones are the products of chemical reactions and radiation processing at the surface.

The unfortunate failure of the main antenna on the Galileo spacecraft left us without a complete global reconnaissance of these bodies at a level of detail sufficient to resolve features at the scale of a kilometer or less. The small target areas that Galileo imaged at high resolution revolutionized our understanding of these bodies, but much of their surfaces will remain relatively unknown for the near future. The Juno mission will arrive to study Jupiter in 2016, but it will not be making significant observations of the satellites.

Our knowledge of Ganymede and Callisto will be revolutionized in the early 2030s when the European Space Agency's Jupiter Icy Moons Explorer (JUICE) spacecraft is scheduled to arrive at the Jupiter system, making several close flybys of Callisto and parking in orbit around Ganymede. The JUICE payload will include instruments for understanding the magnetosphere and plasma environments around the moons, their thin atmospheres, and the detailed spectra of their surface materials. In addition, several instruments will be able to map the surfaces of these bodies in much greater detail, measure the global topography of Ganymede's surface, and use radar to probe the subsurface structure of the regolith and underlying ice. By the end of the JUICE mission, we will have a much more complete survey of the geology and geophysics of Ganymede as a prototypical icy world, and we will have a clearer understanding of its subsurface ocean and its prospects for habitability. In addition to JUICE, a mission to explore Europa is still ranked as a high priority for NASA, and any future mission to Europa would use close flybys of Ganymede and Callisto for gravitational assistance into Europa's orbit. Such a mission would also provide several opportunities to gather more information about these mysterious twin moons of Jupiter.

1. INTRODUCTION

1.1. Titan's Discovery, First Observations, and Models

Titan, Saturn's biggest satellite (second in size among the satellites in our solar system), has attracted the eye of astronomers preferentially ever since its discovery by Dutch astronomer Christiaan Huygens on March 25, 1655. Titan orbits around Saturn at a distance of 1,222,000 km (759,478 mi) in a synchronous rotation, taking 15.9 days to complete. As Titan follows Saturn on its trek around the Sun, one Titanian year equals about 30 Earth years. The sunlight that reaches such distances is only 1/100th of that received by the Earth. Titan is therefore a cold and dark place, but a fascinating one.

It has been known for a long time that Titan possesses a substantial atmosphere: Catalan astronomer Jose Comas i Solá claimed in 1908 to have observed **limb darkening** on Titan. Due to its thick atmosphere, Titan subtends 0.8 **arcsec** in the sky, and it was thought to be the largest of the satellites in the solar system. This explains the name it was given (following a proposition by Herschel, who suggested names of gods associated with Saturn for naming its satellites), until the advent of the **Voyager** missions that showed Ganymede to be a few kilometers larger. Today, we know that this massive atmosphere is the one most similar to the Earth's among the other objects of our solar system, as N_2 is its major constituent and it hosts a complex organic chemistry.

In 1925, Sir James Jeans showed that Titan could have indeed kept an atmosphere, in spite of its small size and weak gravity, because some of the constituents which could have been present in the protosolar nebula (ammonia, argon, neon, molecular nitrogen and methane) would not escape. It was realized later that although ammonia (NH_3) is in solid phase at the current Titan temperatures and could not in principle contribute to its present atmosphere, it could have evaporated in the early atmosphere and been converted into N_2 at the end of the accretion period when the environment was warmer.

On the other hand, methane (CH_4), the second most abundant constituent on Titan, is gaseous at the present Titan's atmospheric temperature range and, unlike molecular nitrogen, exhibits strong absorption bands in the infrared. These bands were first detected in 1944 by Gerard Kuiper of Chicago University. Ethane (C_2H_6),

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00038-4

monodeuterated methane (CH_3D), ethylene (C_2H_4), and acetylene (C_2H_2) were also discovered later.

Prior to spacecraft observations, two models were popular: (1) a "thin methane" atmosphere model, which favored methane as the main component (about 90%) and predicted surface conditions of $T = 86$ K for 20 mbar as well as a temperature inversion in the higher atmospheric levels, illustrated by the presence of emission features of hydrocarbon gases in the infrared spectrum of Titan, and (2) a "thick nitrogen" atmosphere model, which was based on the assumption that ammonia dissociation should produce molecular nitrogen (transparent in the visible and infrared spectrum) in large quantities and held that the surface temperature and pressure could be quite high (200 K for 20 bars). The second model was found to be closer to the truth for the atmospheric composition. Independent of these two models, an explanation of the high observed ground temperatures was advanced: a pronounced greenhouse effect, thought to result from H_2—H_2 pressure-induced **opacity** at **wavelengths** higher than 15 μm. Later, climate modeling showed that nitrogen and methane also contributed significantly to this greenhouse effect, while the haze caused an antigreenhouse effect (see Section 2.2).

1.2. Titan's Exploration

Titan has since then been extensively studied from the ground and from space. In the latter case, Titan was "blessed" by several space mission encounters in the course of the planetary exploration in our solar system. (See also Planetary Exploration Missions.)

The Pioneer 11 spacecraft was the first to take a close look at the giant planets Jupiter and Saturn, but it flew by Titan at a considerable distance of 363,000 km on September 2, 1979. The Voyager missions that followed were also dedicated to an extended study of the outer solar system. The Voyager 1 (V1) spacecraft (launched in 1977) arrived in the Saturnian system and made its closest approach of Titan on November 12, 1980, at a distance of only 6969 km (4394 miles) to the satellite's center. Voyager 2 flew by Titan 9 months later but at a distance a 100 times greater (663,385 km).

Titan's visible appearance at the time was unexciting—an orange ball, completely covered by thick haze, which allowed no visibility of the surface (Figure 38.1(a)). The most obvious feature seen by Voyager was a difference in the brightness of the two hemispheres. This difference is of the order of 25% at blue wavelengths and falls to a few percent in the ultraviolet (UV) and at red wavelengths. This so-called north—south asymmetry (NSA) is probably related to circulation in the atmosphere pushing haze from one hemisphere to the other. The altitude of unity vertical optical depth is of the order of 100 km. Also noticeable was a dark ring above the north

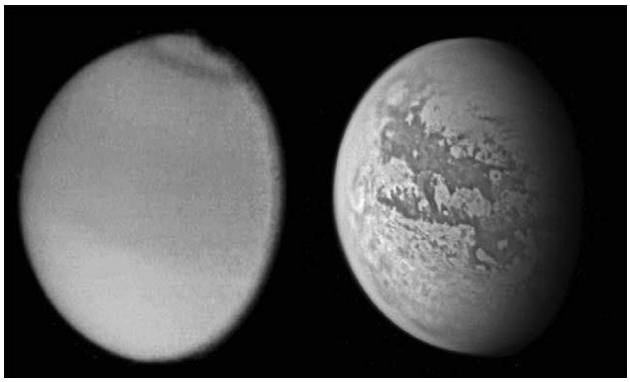

FIGURE 38.1 Titan observed in 1980 with the cameras of Voyager 1 in the visible region (left) and in 2004 with the Cassini Imaging Science Subsystem (ISS) camera at 0.94 μm (right). In the first case, the bland appearance of the satellite belies a complex world. The only features apparent in the images taken by Voyager were the detached haze layers, the dark polar hood, and generally a difference in brightness between the two hemispheres. In contrast, the recent images by Cassini show Titan's surface features.

(winter) pole. This feature, called polar hood, extending from 70° to 90° N, was most prominent at blue and violet wavelengths, and has since then been associated with the lack of illumination in the polar regions during the winter (since the subsolar latitude goes up to 26.7°) and/or subsidence in global circulation.

Besides the images, the Voyager **radio-occultation** experiment obtained by the Radio Science Subsystem (RSS) provided the basic parameters for Titan (Table 38.1) and the Infrared Radiometer Spectrometer (IRIS) determined the chemical composition and temperature structure in parts of the atmosphere (Table 38.2). Titan's surface radius was found to be 2575 ± 2 km, with a surface temperature of 94 ± 2 K and a pressure of about 1.44 bar,

TABLE 38.1 Titan's Orbital and Body Parameters and Atmospheric Properties

Surface radius	2575 km
Mass	1.35×10^{23} kg (=0.022 × Earth)
Mean density	1.88 g/cm^3
Distance from Saturn	1.23×10^9 m (=20 Saturn radii)
Distance from Sun	9.546 AU
Orbital period	15.95 days
Revolution around Sun	29.5 years
Obliquity	26.7°
Surface temperature	93.6 K
Surface pressure	1.467 bar

values that were later confirmed by the in situ measurements.

After Voyager, scientists had to wait for about 25 years before getting another close look at Titan. In the meantime, ground-based and Earth-bound observatories (like the Canada France Hawaii Telescope (CFHT), the Keck, the Very Large Telescope (VLT) or the Hubble Space Telescope (HST), and the Infrared Space Observatory (ISO)) were used to extract complementary information on Titan's inhomogeneous surface and exciting organic chemistry. Cassini–Huygens is a very ambitious mission and an extremely successful collaboration between the European Space Agency (ESA) and National Aeronautics and Space Administration (NASA) (with contributions from 17 countries). It is composed of an orbiter (Cassini) and a probe (Huygens). Although the mission's objectives span the entire Saturnian system, Titan is a privileged target (as for Voyager before it), and the mission is designed to address our principal questions about this satellite and more during its 13-year duration from 2004 onward. The spacecraft is equipped with 18 science instruments (12 on the orbiter and six carried by the probe), gathering both remote sensing and in situ data. It communicates through one high-gain and two low-gain antennas. Power is provided through three radioisotope thermoelectric generators.

The 5650-kg (6 ton) Cassini–Huygens spacecraft was launched successfully on October 15, 1997, from the Kennedy Space Center at Cape Canaveral at 4:43 a.m. EDT. Because of its massive weight, Cassini could not be sent directly to Saturn but used the "gravity assist" technique to gain the energy required by looping twice around the Sun. It also performed flybys of Venus (April 26, 1998, and June 24, 1999), Earth (August 18, 1999), and Jupiter (December 30, 2000). Cassini–Huygens reached Saturn in July 2004 and achieved a flawless Saturn Orbit Insertion, becoming trapped in orbit, like one of Saturn's moons. This situation will last at least until 2017 when it is foreseen to "crash" Cassini into the giant planet.

The Cassini instruments have since then returned a great amount of data concerning the Saturnian system. During its mission so far, the Cassini orbiter has made more than 100 flybys of Titan (up to 2014), some as close as 1000 km (Voyager 1 flew by at 4400 km) from the surface. Cassini performs direct measurements with the visible, infrared, and radar instruments designed to perform remote and in situ (on-site) studies of elements of Saturn, its atmosphere, moons, rings, and magnetosphere. One set of instruments studies the temperatures in various locations, the plasma levels, the neutral and charged particles, the surface composition, the atmospheres and rings, the solar wind, and even the dust grains in the Saturn system, while another performs spectral mapping for high-quality images of the ringed planet, its moons, and its rings.

Additionally, the mission saw the deployment of the European-built Huygens probe. After release from the Cassini orbiter, on December 25, 2004, this 300-kg probe plunged into Titan's atmosphere on January 14, 2005, at

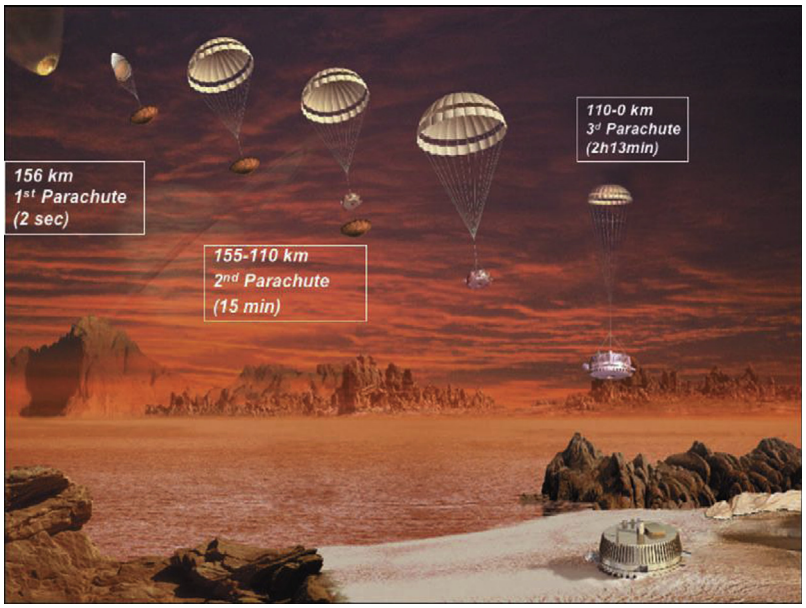

FIGURE 38.2 Artistic view of the descent of the Huygens probe in Titan's atmosphere and its landing (the real landing site is different from that depicted here). The three parachutes that helped brake the descent and reduce the speed to about 5 m/s on the surface are shown. The total descent lasted 2 h 28 min. The probe spent 1 h 12 min on the surface. The signal from Huygens received on Earth also via radio-telescopes was for a total of 5 h 42 min including 3 h 14 min on the surface.

11:04 UTC and through it descended to the ground. The heat shield decelerated the probe from supersonic speeds down to about 0.5 km/s, followed by several parachute brakes (Figure 38.2), which further slowed the probe to 0.005 km/s at impact. The five batteries onboard the probe lasted much longer than expected, allowing Huygens to collect atmospheric data for 2 h 27 min and surface data for 1 h 12 min. During its descent, Huygens' camera returned more than 750 images, while the probe's other instruments sampled Titan's atmosphere to help determine its composition and structure. The telemetry data from Huygens was stored onboard Cassini's Solid State Recorders at the rate of 8 kbits/s, while the spacecraft was at an altitude of 60,000 km from Titan. Although some measurements (in particular for the wind and the telemetry) from Huygens were lost during its transmission to Cassini, in the end the wind profile was recovered thanks to the fact that Titan's weak signal was captured by Earth-based radio telescopes!

Apart from measuring the atmosphere and surface properties, the probe took samples of the haze and gases. These in situ measurements complement the remote sensing data recorded from the orbiter.

The Cassini–Huygens mission has already provided a wealth of data. Although there are only a few years left until its foreseen termination in 2017, the Cassini orbiter promises to unveil yet more of Titan's secrets in the years to come. In this it is complemented by observations from the large telescopes on the ground and from Earth-orbiting satellites. What follows is an attempt to provide the reader with a brief account of our current understanding of Titan's environment from all such available means of investigation.

2. THE ATMOSPHERE OF TITAN

One of the most interesting features of Titan is its unique atmosphere, a close analog to the Earth's, but more extended and dense and located almost 10 times further away from the Sun.

2.1. Thermal Structure

The first definitive measurement of the atmospheric temperature structure was made by Voyager. The V1 radio-occultation experiment provided density and temperature profiles in Titan's atmosphere from refractivity measurements. Titan's temperature profile was also measured in situ on January, 14, 2005, by the Huygens Atmospheric Structure Instrument (HASI) at the probe's landing site (10° S, 192° W) from 1400 km in altitude down to the surface, where 93.65 ± 0.25 K was measured for a surface pressure of 1467 ± 1 mbar. As Voyager had shown before, Cassini/HASI also found Titan's atmosphere to exhibit the features that characterize the Earth's thermal structure: the atmospheric layers include a thermosphere, a mesosphere, a stratosphere and a troposphere, with two major temperature inversions at 40 and 250 km, corresponding to the tropopause and stratopause, associated with temperatures of 70.43 K (min) and 186 K (max), respectively (Figure 38.3). In addition, HASI recorded several temperature fluctuations due to dynamical (gravity and tidal) phenomena at higher levels of the atmosphere. Indeed, gravity waves signatures of 10–20 K in amplitude were recorded above 500 km around an average temperature of 170 K. Moreover, HASI found a lower ionospheric layer between 140

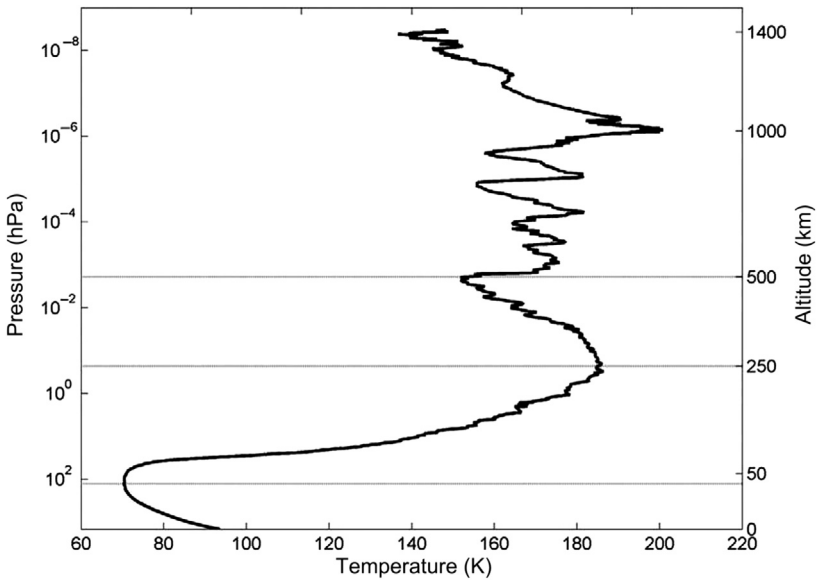

FIGURE 38.3 Titan's temperature profile as derived from Huygens/HASI measurements. The several large inversion layers in the upper atmosphere correspond to gravity waves. The inflection at around 40 km marks the tropopause, whereas the one at around 250 km is due to the stratopause. *Adapted from Fulchignoni et al. (2005).*

and 40 km, with electrical conductivity peaking near 60 km. At the same time, the Composite Infrared Radiometer Spectrometer (CIRS) on the orbiter took spectra that confirmed the presence of a stratopause around 310 km of altitude for a maximum temperature of 186 K. Another inversion region, less contrasted than the previous ones and corresponding to the mesopause, was found at 490 km (for 152 K) in the early years but has gradually disappeared in the recent years.

Besides the Huygens measurements, Titan's higher atmosphere was also explored by the V1 Ultraviolet Spectrometer (UVS) experiment which recorded a temperature of 186 ± 20 K at 1265 km during a solar occultation for a methane mixing ratio of $8 \pm 3\%$ toward 1125 km, placing the homopause level at around 925 ± 70 km. A value of 183 ± 11 K near 450 km was derived from the July 3, 1989, stellar occultation of Titan. The occultation of star 28 Sgr by Titan was observed from places as widely dispersed as Israel, the Vatican, and Paris. This rare event provided information in the 250−500 km altitude range. A mean scale height of 48 km at 450 km altitude ($\sim$5 μbar level) was inferred. This allowed the mean temperature to be constrained to between 149 and 178 K at that level.

From 1980 V1 infrared disk-resolved measurements, latitudinal variations in temperature were already demonstrated to exist in Titan's stratosphere. At that time, a maximal temperature decrease of 17 K at the 0.4-mbar level (225 km in altitude) was observed between 5° S (the warmest region in the Voyager data) and 70° N, whereas the temperature dropped by only 3 K from 5° S to 53° S. The coldest temperatures, found at high northern latitudes, were associated with enhanced gas concentration and haze opacity (as this may be caused by more efficient cooling) or/and **dynamical inertia**. CIRS has been mapping stratospheric temperatures over much of Titan's disk from the later half of 2004, when it was early southern summer on Titan (solstice was in October 2002) to well after the northern spring equinox (in August 2009). In mid-2010, the epoch on Titan was the same as during the V1 encounter, almost 30 years before (1 Titan year). Temperatures are found to have returned to their 1980 values, with the coldest ones in the north (by 10−20 K with respect to the equatorial ones below 300 km), where the season has been winter moving into spring after mid-2009.

2.2. Chemical Composition

Molecular nitrogen (N_2, detected in the UV) is by far the major component of the atmosphere (average of $\sim$95%). The presence of methane (the next most abundant molecule with a mixing ratio of about 1.5% in the stratosphere and 5% at the surface) and of traces of hydrogen give rise to a host of organic gases whose presence in the stratosphere had been established since the twentieth century.

About 90% of the energy at the surface of Titan is held in by a greenhouse effect due to nitrogen, methane, and hydrogen, symmetrical molecules which normally do not have a greenhouse effect on the Earth but have the effect on Titan, due to the dense atmosphere. This opacity blocks the thermal emission reflected by the surface, thus heating up the lower part of the atmosphere, as found on the Earth, where water is the major player. The increase in temperature from the tropopause to the surface of Titan due to this greenhouse effect is of 21 K. Even more interestingly, Titan is the only world in the solar system that has an anti-greenhouse effect that lets light in and stops infrared,

caused by the haze layers in the atmosphere. The antigreenhouse effect on Titan is half as strong as the greenhouse effect. The troposphere emission temperature (near the tropopause) is determined by the antigreenhouse effect and is 9 K cooler than the effective temperature.

A big leap in understanding Titan's chemical structure came from Cassini and measurements by its Ion and Neutral Mass Spectrometer (INMS) in the ionosphere. Titan was found to have a quite extended ionosphere, due to the lack of a strong intrinsic global magnetic field. High-energy photons (Extreme Ultra Violet and X-rays) and energetic particles from Saturn's magnetosphere are the main energy sources in Titan's upper atmosphere that create an extended ionosphere between 700 and 2700 km. At lower altitudes, galactic cosmic rays are responsible for the production of another ion layer in the atmosphere (between 40 and 140 km), while the neutral atmospheric photochemistry is mainly driven by Far Ultraviolet solar photons.

As Cassini flew through the upper parts of the ionosphere it discovered a multitude of complex positive and negative ions with masses reaching about a few hundreds of atomic mass units for positive and thousands of atomic mass units for negative ions. These molecules are increasing size hydrocarbons and nitrogen-containing species, which diffuse downward. These species are continuously quantified and monitored with precision since 2004 in INMS spectra (with mass detections ranging up to 100 amu and a resolution of 1 amu).

In parallel, the stratospheric chemical composition is revealed from the thermal emission bands of the different molecules observed in the infrared spectrometer CIRS spectra, which cover the 200−1500 cm^{-1} spectral region with a spectral resolution of up to 0.5 cm^{-1} (Table 38.2). In particular, following up on disk-averaged determinations of the chemical abundances on Titan in 1997 by the ISO Short Wavelength Spectrometer, Cassini has recently provided accurate spatial (latitudinal and vertical) distributions of the trace gases (Figure 38.4). The vertical distributions generally increase with altitude, confirming the prediction of photochemical models that these species form in the upper atmosphere and then diffuse downward in the stratosphere. Below the condensation level of each gas, the distributions are assumed to decrease following the respective vapor saturation law. In particular, the ISO spectra had provided the first detection of water vapor in Titan's atmosphere from two emission lines around 40 μm, for an associated

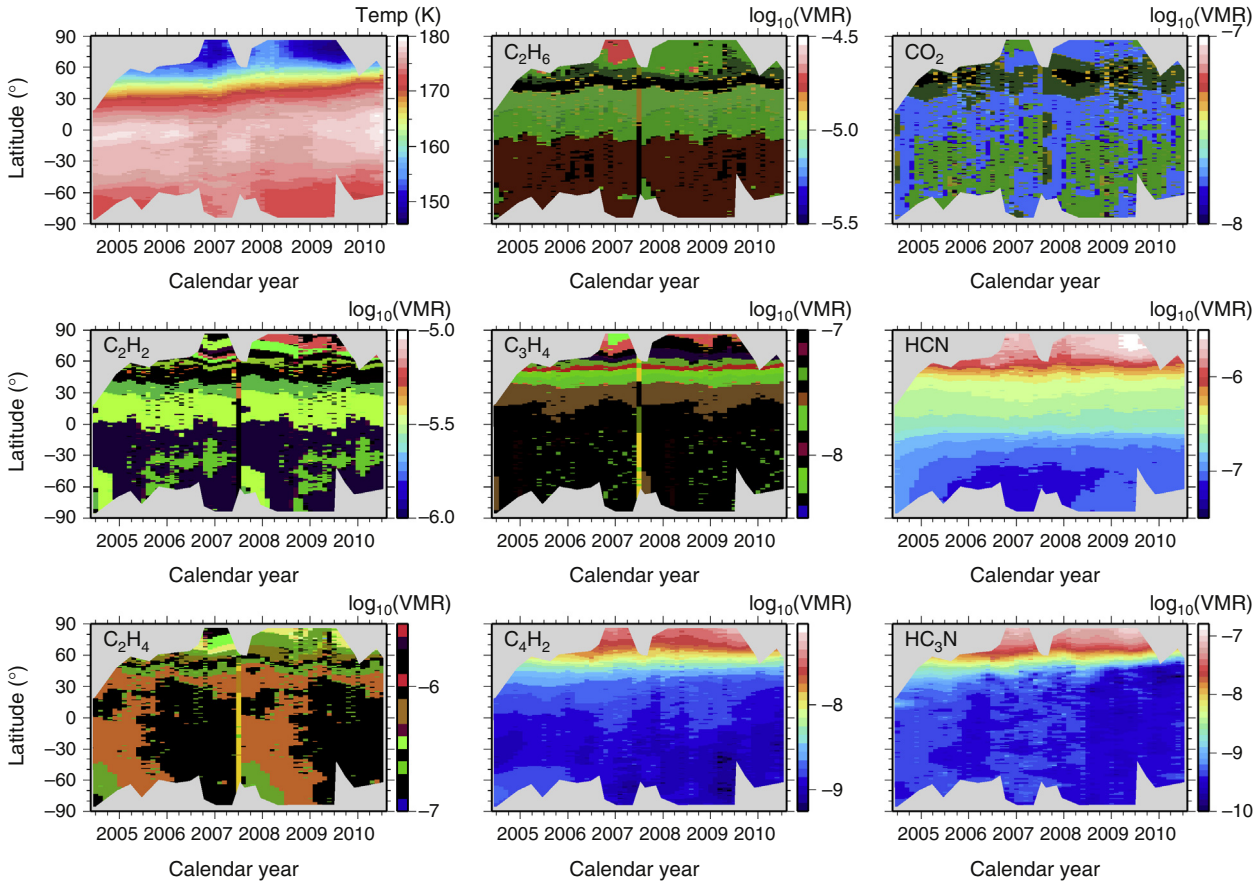

FIGURE 38.4 Titan's chemical composition and variations during the Cassini mission. Note the high values around northern spring equinox (August, 2009) at Titan's northern latitudes. VMR stands for "vertical mixing ratio". *Adapted from Teanby et al. (2010).*

mole fraction derived at 400 km of altitude of about 10^{-8}. ISO had also hinted at the presence of benzene (C_6H_6) at 674 cm^{-1} for a mole fraction on the order of a few 10^{-10}. Since then, benzene detection has been confirmed by Cassini/CIRS and INMS. The water vapor abundance was more precisely inferred by CIRS at stratospheric altitudes (a few 10^{-10} in the 100–200 km range), with strong implications on the whole oxygen chemistry on Titan, which remains yet to be accurately reproduced by photochemical models.

Ground-based high-resolution heterodyne millimeter observations of Titan offered the opportunity to determine vertical profiles and partial mapping in some cases of HCN, CO, HC_3N, and CH_3CN, which showed that the nitrile abundances increase with altitude. Subsidence causes the abundance of these species to decrease in the lower atmosphere.

Closer to the ground, Cassini–Huygens finally allowed for firm determinations of the major components: consistent with CIRS measurements in the stratosphere, the Huygens Gas Chromatograph Mass Spectrometer (GCMS) found a methane mole fraction of $(1.48 \pm 0.1) \times 10^{-2}$ in the stratosphere, increasing below the tropopause and reaching 5.65×10^{-2} near the surface in agreement with the CIRS stratospheric values and the surface estimate given by the Huygens Descent Imager Spectral Radiometer (DISR) spectra (also roughly 5%). The GCMS also saw a rapid increase of the methane signal after landing, which suggests that liquid methane exists on the surface, together with other trace organic species, including cyanogen, benzene, ethane, and carbon dioxide.

2.3. Dynamical Processes

2.3.1. Zonal Circulation

At the time of the Voyager encounter, Titan's northern hemisphere was coming out of winter. During the Cassini observations, so far, Titan's northern hemisphere has moved from winter to spring.

The general faintly banded appearance of Titan's haze suggests rapid zonal motions (i.e. winds parallel to the equator). This impression is reinforced by the infrared temperature maps of the stratosphere, which show very small contrasts in the longitudinal direction and rather large ones (of around 20 K) between the equator and the winter pole. The mean zonal winds inferred from this temperature field are weakest at high southern latitudes and increase toward the north, with maximum values at midnorthern latitudes (20–40° N) of about 160 m/s. On Titan, pressure gradients are in **cyclostrophic balance** with centrifugal forces. The stratospheric zonal winds and temperatures in both hemispheres of Titan are symmetric about a pole that is offset from the surface pole by ~4°.

Stellar occultations are another indirect means to obtain the zonal winds. The atmospheric oblateness due to the zonal winds can be constrained from the analysis of the central flash, the increase of the signal at the center of the shadow (when the star is behind Titan) due to the focusing of the atmospheric rays at the limb. On July 3, 1989, Titan occulted the bright K-type star 28 Sgr, and fast zonal winds were derived close to 180 m/s at high southern latitudes and close to 100 m/s at low latitudes. Other occultations occurred on December, 20, 2001, and November, 14, 2003. They seem to suggest a seasonal variation with respect to 1989. In 2001, a strong 220 m/s jet was located at 60° N, with lower winds extending between 20° S and 60° S and a much slower motion at midlatitudes. The CIRS data suggest that the strongest northern winds have migrated closer to the equator with respect to previous measurements, while the southern winds have weakened.

Space and occultation wind measurements could not provide the wind direction, a crucial factor for the Huygens probe mission, so different teams of ground-based observers tried to measure the zonal winds directly using alternative methods. The first measurement of prograde winds (in the sense of the rotation of the surface) was performed using infrared heterodyne spectroscopy of Doppler-shifted ethane emission lines. The measured winds were on the order of 210 ± 150 m/s between 7 and 0.1 mbar, a result that has since been refined. Other Doppler studies probing somewhat different stratospheric levels also found prograde winds, using millimeter-wavelength interferometry of nitrile lines or high-resolution spectroscopy of Fraunhofer solar absorption lines in the visible. The recent advances in **adaptive optics** also allowed for the first detections of tropospheric clouds from the ground, mainly at circumpolar southern latitudes, but so far, Titan winds remain poorly constrained due to the sparse data set of cloud positions. Better spatially resolved Cassini ISS observations only indicate slow eastward motions, which, extrapolated to the equator under the assumption of solid-body rotation, yield 19 ± 15 m/s at around 25 km altitude. Finally, in 2005, the Huygens probe provided ground truth measurements of the wind magnitude and direction in the lower stratosphere and troposphere. The Doppler wind experiment shows a marked decrease of winds with decreasing altitude, from 100 m/s at 140 km down to about nil at 80 km, then an increase up to 40 m/s at 60 km before decreasing again to null zonal velocity at the surface, noting also a reversal in the wind direction.

2.3.2. Latitudinal and Temporal Variations in the Atmosphere of Titan as Evidence of Meridional Circulation

Periodic change of Titan's disk-integrated brightness has been monitored from Earth-based observations since the

1970s. Spatially resolved observations, starting with Voyager, have provided an interpretation of the periodic changes of the disk-integrated brightness as the combined action of the high inclination of the rotation axis and the seasonally varying NSA. The NSA that Voyager 1 observed in 1980, with a darker northern hemisphere in visible light, has since been observed to reverse, as Titan's season shifted from northern spring to northern winter. When the HST first observed Titan in 1994, a little over a quarter of a Titan year after the Voyager encounters, the northern hemisphere was found to be brighter than the southern hemisphere. The turnover was later also found to occur gradually, starting at higher altitudes in the atmosphere.

A change in the vertical structure of the photochemical haze has been reported with a detached layer dropping in altitude from 500 km to 350 km from 2007 to 2010. Modeling with a two-dimensional general circulation model provided a qualitative description of the seasonal variations of the haze, where both the gradual inversion of the asymmetry and the detached haze layer can be explained by a seasonally varying **Hadley circulation**. The meridional wind in the upper branch of the Hadley cell is stronger close to the production zone (at 450 km) than below, and particles there are more rapidly transported toward the pole, where they sink. The asymmetry thus reverses first at higher altitudes. But this is not the only effect. As the season changes, shortly after equinox, the circulation reverses and an ascending motion sets in where the particles were previously descending. At the time of the transition, the polar haze, which was previously descending, is then redistributed about a scale height below the production zone, becoming physically separated from the freshly created particles aloft.

Meridional variations were also established for the gases in Titan's stratosphere, and these are also tightly coupled with the circulation. The molecular abundances found by Cassini at this era (1 Titan year after the V1 encounter) indicate an enhancement for most species in the northern stratosphere at high latitudes, with values similar to those observed 30 years ago, with a few exceptions (Figure 38.4). Since 2012, a clear indication of a reversal of the enhancement and the appearance of several gases at southern latitudes is observed.

Such latitudinal contrasts observed in the chemical trace species may be explained by invoking photochemical and dynamical reasons. The UV radiation from the Sun acts on methane and nitrogen to form radicals that combine into nitriles and the higher hydrocarbons. This production occurs in the mesosphere at high altitudes (above 300 km or 0.1 mbar). Eddy mixing transports these molecules into the lower stratosphere and troposphere where most of them condense. Photodissociation by UV radiation occurs on timescales ranging from days to thousands of years. The combination of these processes leads to a vertical variation in the mixing ratio, which usually increases with height toward the production zone. Three-dimensional computation of **actinic fluxes** suggests that this mechanism alone cannot explain the latitudinal contrasts and that circulation must intervene. Simulations coupling photochemistry and atmospheric dynamics provide a consistent view: competition between rapid sinking of air from the upper stratosphere in the winter polar vortex and latitudinal mixing controls the vertical distribution profiles of most species. The magnitude of the polar enrichment is controlled by downwelling over the winter pole, which brings enriched air from the production zone to the stratosphere, and by the level of condensation. Short-lived species are more sensitive to the downwelling due to steeper vertical composition gradients and exhibit higher contrasts.

In the stratosphere, the calculated radiative relaxation time is longer than the Titan season, so the temperature contrasts should be symmetric about the equator. That they are not indicates that the Hadley circulation must be connected with the lower atmosphere, where the time constant is much longer. This is consistent with the small thermal contrasts of 2−3 K in the troposphere, which suggest an efficient heat redistribution. Since Titan's slow rotation and small radius rule out nonaxisymmetric processes, such as **baroclinic** eddies, as a preferred mechanism for heat transport, considerable meridional motions must be inferred. Latitudinal contrasts would be much larger if heat were not being transported poleward by Hadley advection.

Another phenomenon was first reported in 2001 from adaptive optics data taken in 1998 and since then confirmed in Keck observations, among others. A diurnal change was found, manifested in an east−west asymmetry, with a brighter morning limb observed on Titan on several occasions. This dawn haze enhancement could be due to an accumulation of condensates during the Titan night (8 Earth days, although the superrotation of Titan's atmosphere would lead to shorter nights for stratospheric clouds).

2.3.3. A Three-Dimensional View and Waves

Meridional contrasts are apparent in Titan's atmospheric distributions of composition, haze, and temperature, and their seasonal variability is proof for a strong coupling with an underlying meridional circulation that has never been directly detected.

The superrotation observed in the stratosphere, a dynamical state in which the averaged angular momentum is much greater than that corresponding to corotation with the surface, is difficult to explain and has defied our understanding in the much better documented Venus case, the paradigm of a slowly rotating body with an atmosphere in rapid rotation. In recent studies, such a process has been identified under the form of planetary waves, forced by

instabilities in the equatorward flank of the high-latitude jet. Two factors play a key role in facilitating the acceleration process. On the one hand, high-altitude absorption processes decouple upper atmosphere dynamics from dissipation occurring at the surface layer, while on the other hand the slow rotation allows the Hadley cell to reach high latitudes by reducing the Coriolis force in the poleward branch. A strong seasonal cycle due to Titan's obliquity of 26.7° was also established: During most of the Titan year, the meridional motion is dominated by a large Hadley cell extending from the winter to the summer pole, with the symmetric two-cell configuration typical of equinoxes occurring only in a limited transition period. In models, the jet is located close to 60° in the winter hemisphere, while the summer zonal circulation is close to solid-body rotation.

The radiative time constant is long in the troposphere, but the surface has a smaller thermal inertia, so the surface temperature does respond to seasonal forcing, albeit by only a few Kelvin. This surface temperature variation is sufficient to reverse the circulation pattern of the Hadley circulation after the equinox when the Sun moves to the opposite hemisphere. Also, the development of convective methane clouds is partly ascribed to seasonal surface heating. The reversal of the Hadley circulation may play an important role in the methane "hydrological" cycle because the vertical and horizontal transport of methane would vary seasonally.

Direct evidence for wave processes in Titan's atmosphere remains scarce, despite their importance in the maintenance of superrotation. Because baroclinic processes are excluded, waves essentially **barotropic** in nature should be expected as the principal carrier of momentum from high to low latitudes. Modeling predicts **wavenumber-2** waves with amplitude of the zonal component about 10% of the mean wind speed, and in principle, they can be inferred from horizontal maps of temperature and trace species exhibiting strong latitudinal contrasts. The first Cassini/CIRS temperature maps at 1.8 mbar do show spatial inhomogeneity, but long time series and better spatial coverage are needed to constrain spatial and temporal variations.

Another relevant nonaxisymmetric phenomenon in Titan's troposphere is the gravitational tide exerted by Saturn. The eccentric orbit of Titan around Saturn gives rise to a tidal force, resulting in periodical oscillation in the atmospheric pressure and wind with a period of a Titan day (16 days), among which the most notable effect is the periodical reversal of the north–south component of the wind. In the lower atmosphere, the effect of this tide is modest, with a maximum temperature amplitude about 0.3 K and winds of 2 m/s.

Temperature inversions have been detected in both the HASI measurements and in stellar occultation data. Inversion layers were present close to 510 km altitude in HASI and 2003 occultation data and at 425 and 455 km in 1989 occultation light curves. Vertical wavelengths were on the order of 100 km.

2.4. Haze and Clouds on Titan

It was recognized quite early on that another important aspect of Titan's atmosphere was the presence of aerosols. Pre-Cassini models treated the dissociation of methane molecules by solar actinic radiation, followed by chemical combination to heavier hydrocarbons that condense into particles. The cloud physics models with sedimentation and coagulation predicted a strong increase in haze opacity with decreasing altitude.

2.4.1. Titan's Haze

The analysis of high-phase Voyager images indicated aerosol radii between 0.2 and 0.5 μm. These "smog" particles form a layer that enshrouds the entire globe of Titan and stretches from the surface to an altitude of about 200 km. A detached haze layer at 340–360 km altitude with large, compact, irregular dark particles was also found. The small haze particles required by Voyager measurements (radii less than or equal to 0.1 μm) produce a strong increase in optical depth with decreasing wavelength shortward of 1 μm. To fit the observations in the methane bands, it was necessary to remove the haze permitted by the cloud physics calculations at altitudes below about 70–90 km (called cutoff altitude) by invoking condensation of organic gases produced at high altitudes as they diffused down to colder levels. The condensation of many organic gases produced by photochemistry at high altitudes on Titan seemed consistent with this view. The next step in the development of Titan haze models included the use of fractal aggregate particles composed of several tens of small (0.06 μm in radius) monomers to produce strong linear polarization. Monomers composed of 45 aggregates with an effective radius of about 0.35 μm matched the Voyager observations.

Starting from the upper atmosphere, the complex chemical composition observed in the thermosphere along with the detection of large mass ions hinted at the formation of aerosols in the ionosphere. This argument was further supported by observations from the Ultraviolet Imaging Spectrometer that detected aerosols up to ∼900 km of altitude, as well as by the detection of large-mass negative ions in the ionosphere by the Cassini Plasma Spectrometer.

In the mesosphere, the Cassini ISS camera showed a faint thin haze layer that encircles the denser stratospheric haze (Figure 38.1(b)) and could be the equivalent of the "detached haze layer" observed by Voyager 25 years ago, except for the difference in altitudes: The thin current haze layer is indeed located 150–200 km higher than the one seen by Voyager. In subsequent observations, right after the vernal equinox, this layer appeared to drop in altitude, reaching the altitude levels of the detached layer observed by Voyager. Current models are still unable to render the

complexity of seasonal phenomena or circulation patterns on Titan, which could be responsible for such variability in the aerosol distribution.

Cassini images also show a multilayer structure in the north polar hood region and, in some cases, at lower latitudes. These features could be due to gravity waves that have been detected on Titan at lower latitudes. Some of these layers may be related to the two global inversion layers observed in stellar occultations of Titan above 400 km in altitude.

The nature of the haze aerosols measured by Huygens/DISR during the descent through Titan's lower atmosphere came as a surprise to scientists recalling the results from Pioneer and Voyager, as well as predictions by cloud physics models with sedimentation and coagulation. The new observations estimate the monomer radius to be 0.05 μm, in good agreement with previous values. However, contrary to previous assumptions, the DISR data seem to show that the size of the aggregate particles is several times as large as previously supposed.

In addition, measurements by the DISR violet photometer extend the optical measurements of the haze to wavelengths as short as the band from 350 to 480 nm, also helping to constrain the size of the haze particles. The number density of the haze particles does not increase with depth nearly as dramatically as predicted by the older cloud physics models. In fact, the number density increases by only a small factor over the altitude range from 150 km to the surface. This implies that vertical mixing is much less than had been assumed in the older models where the particles were distributed approximately as the gas is with altitude. In any event, the clear space at low altitudes, which was suggested earlier, was not observed.

The methane mole fraction of 1.5−1.6% measured in the stratosphere by the CIRS and the GCMS, is consistent with the DISR spectral measurements. At very low altitudes (20 m), DISR and the GCMS measured $5 \pm 1\%$ for the methane mole fraction.

2.4.2. Titan's Clouds

Cassini−Huygens has provided new information on the role of methane and the methane cycle in Titan's atmosphere. The relative humidity of methane (about 50%) at the surface found by DISR and the evaporation witnessed by the GCMS show that fluid flows have existed and will probably again exist on the surface, implying precipitation of methane through the atmosphere.

Although some discussion took place as to whether Titan's lower atmosphere could support convection and as to whether methane was supersaturated, there is clear evidence today that clouds exist in Titan's troposphere. Methane clouds in Titan's troposphere were first suspected from variability in the methane spectrum observed from the ground. Direct imaging of clouds on Titan has been achieved from Earth-based observatories since the turn of the century.

Most of the clouds detected in the past years are located in Titan's southern hemisphere, as expected given the season on Titan that has been essentially probed (summer in the south), which means that solar heating is concentrated there as are rising motions. In recent years, they have been found to be building up now in the north as the season on Titan changes. Other than the large, bright South Pole system observed for the past 5 years or so, transient, discrete clouds have been detected at midlatitudes (Cassini Visual and Infrared Mapping Spectrometer (VIMS) observations tend to indicate that they rise quickly to the upper troposphere and dissipate through rain within an hour). Keck and Gemini data indicate that they tend to cluster near 350° W and 40° S. They may be related to some surface−atmosphere exchange (such as geysering or **cryovolcanism**) because they do not seem to be easily explained by a shift in global circulation. A dozen or so large-scale zonal streaks have also been observed by Cassini preferentially at low southern latitudes and mostly between 50 and 200° W.

The large south polar system has been visible consistently essentially in the near infrared (at 2.12 μm for instance) since 1999 from ground-based observations, while no previous indication of it was ever reported. It was extremely bright in 2001−2002, and recent Cassini images have shown that it is disappearing (indeed it was visible only during the few first Titan flybys and not afterward, see Figure 38.5). Its shape is irregular and changing with time, recently more resembling a cluster of smaller-scale clouds than a large compact field. Should it prove that this system's life was indeed on the order of 5−6 years (fairly close to a Titan season), stringent constraints can be retrieved on

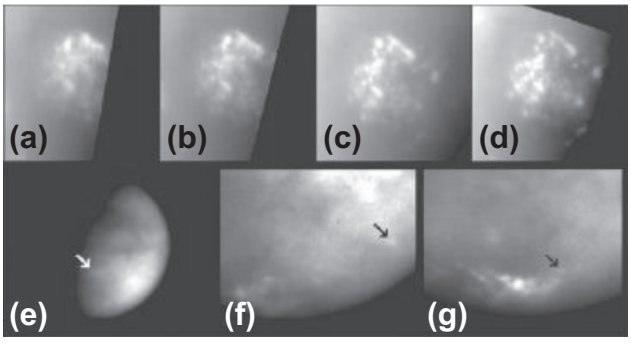

FIGURE 38.5 Titan's meteorology observed with Cassini ISS. (a−d) A sequence of four methane continuum (IRP0-IR3, 928 nm) images showing the temporal evolution over the period 05:05−09:38 of the Titan south polar cloud field on July 2, 2004. (e−g) Three examples of discrete midlatitude clouds (arrows) for which motions have been tracked in CB3 images. (e) 38° S, 81° W (29 May 2004); this image was also viewed through an infrared polarizing filter. (f) 43° S, 67° W (23 October 2004). (g) 65° S, 110° W (October 25, 2004). *From Porco et al. (2005).*

seasonal and circulation patterns on Titan. The cloud made a strong reappearance in 2006, but has been fading again since, although Titan's southern hemisphere still shows a very active meteorology with more than 200 clouds observed in three-and-a-half years.

Note that DISR reported no definite detection of clouds during its descent through Titan's atmosphere. However, the data are compatible with a thin haze layer at an altitude of 21 km, which could be due to methane condensation.

2.5. Origin and Evolution

The only noble gas detected on Titan to date is argon, seen by GCMS in the form of primordial ^{36}Ar (2.1×10^{-7}) and its radiogenic isotope ^{40}Ar (3.4×10^{-5}). The low abundance of primordial noble gases on Titan implies that nitrogen was originally captured as NH_3 rather than N_2. Subsequent photolysis may have created the N_2 atmosphere we see today. The absence of Kr and Xe also has implications on the evolution of the atmosphere, as discussed hereafter. In addition, the detection of neon (^{22}Ne) in Titan's atmosphere requires further investigation.

Isotopic ratios for Titan were determined from Cassini and Huygens instruments: $^{12}C/^{13}C$ (roughly 90, close to the solar and terrestrial value), $^{14}N/^{15}N$ (about 170, which is roughly 1.5 times less than on Earth possibly implying large nitrogen escape during Titan's evolution), and D/H (measured in situ in H_2, $1.35 \pm 0.3 \times 10^{-4}$, from the GCMS, and 1.2×10^{-4} in CH_4, from remote sensing of infrared spectra recorded aboard the Cassini orbiter with CIRS). The D/H ratio is very important for Titan's cosmogonical models and the value on Titan tends to suggest a deuterium enrichment in the atmosphere with respect to the protosolar value as well as in the giant planets (D/H $\sim 2-3.4 \times 10^{-5}$). The interpretation of this enrichment is related both to the origin of CH_4 (is this species older than Titan itself or was it produced in the satellite's interior?) and to its evolution in the satellite's atmosphere. In particular, CH_4 is continuously photodissociated so that, in the absence of a substantial reservoir, it would entirely vanish from the atmosphere in 10–50 Myr. This implies that some delivery mechanism needs to be invoked in order to maintain the methane abundance against photolytic depletion throughout Titan's history. A possibility is to have a continuous supply from the interior or by buffering by a surface or near-surface reservoir. Imaging, infrared, and visible observations from the orbiter rule out the presence of a global ocean containing a large amount of CH_4 on the surface of Titan, but lakes and seas (of which the largest are named Kraken Mare, Ligeia Mare, Punga Mare, etc.) have been detected on Titan's surface. However, the composition of these lakes is dominated by ethane and heavier hydrocarbons and the fraction of dissolved methane is too small to account for its atmospheric abundance. Alternatively, some models suggest that methane can outgas from time to time from the interior of the satellite. Two scenarios for the origin of the internal CH_4 have been proposed. One scenario advocates that CH_4 was produced from hydrothermal reactions in the interior of Titan but the D/H value predicted via this mechanism does not match the measured one. The formation of methane from carbon monoxide in an initially warm Saturn's subnebula is also ruled out because the produced CH_4 would harbor a much lower D/H ratio than the one observed in Titan. A more plausible scenario argues that CH_4 originates from the solar nebula. In this scenario, CH_4 would have come from the interstellar medium and was initially highly enriched in deuterium by ion–molecule reactions in the presolar cloud. Once vaporized in the solar nebula, methane would have continuously exchanged deuterium with protosolar hydrogen as long as it remained in the gas phase. After the solar nebula cooled down to about 50–60 K, methane became trapped in the form of clathrates in the feeding zone of Saturn and these ices were incorporated in the forming of planetesimals. The D/H value measured in Titan's atmosphere would then reflect the one acquired by methane in the gas phase of the solar nebula at the time of its trapping in clathrates. Ice incorporated in planetesimals is composed of pure condensates that formed at extremely low temperatures (about 20 K) and clathrates that resulted from the trapping of some volatiles in crystalline water-based solids at slightly higher temperatures (about 50–60 K) in the nebula. Once embedded within the Saturnian subnebula, planetesimals accreted by proto-Titan would have suffered from partial devolatilization during the processes of migration and accretion that led to the satellite's formation. This scenario is consistent with the fact that Titan's atmosphere is strongly impoverished in carbon monoxide and heavy noble gases but harbors primordial methane and nitrogen derived from primordial ammonia.

3. THE SURFACE OF TITAN

To the eyes of the public and many scientists, the most exciting features revealed by the Cassini–Huygens mission were those found on Titan's surface, finally observed in close-up mode by the Orbiter in 2004 and then in in situ conditions by the Huygens probe instruments on January 14, 2005. The spaceship has offered detailed views of Titan's surface in the visible and the near-infrared regions with its camera, the mapping spectrometer, and the radar. Descending through the atmosphere, the Huygens probe returned extraordinary images of a first-seen domain, the farthest location a human-made vessel has ever landed upon. Although we still have not exactly determined the nature or the composition of the surface, a combined analysis of all the continuously arriving data should eventually force Titan to uncover the nature of its mysterious

soil. Undoubtedly, the signs of dried lakes, volcanoes, dunes and channels on Titan's surface, in addition to signs of a possibly active interior, were unexpected. They offer an even more amazing view of a land much fantasized on.

3.1. Pre-Cassini Glimpses of an Exotic Ground

To the Voyager optical cameras, the surface of Titan was obscured by the dense haze in the atmosphere. Glimpses of what lay below were revealed afterward by ground-based radar and infrared images from HST and ground-based observatories.

Theory argued that unless methane supersaturation conditions prevailed on Titan, the organics present in the atmosphere should condense at some level in the lower stratosphere and precipitate out, ending up on Titan's surface and coating the ground in large proportions. Based on the surface conditions believed to prevail on Titan, liquid methane—and its principal by-product, ethane—is expected to exist and could even form an ocean, and in the troposphere, methane clouds (formed by saturation of methane gas) might cause rains. The degree of saturation in the lower atmosphere, however, was unknown, so the methane abundance was difficult to determine.

On the other hand, much of the outer part of the solid body of the satellite must, to be consistent with the observed mean density, consist of a thick layer of ice. The ethane ocean model, developed in 1983, was aesthetically appealing and compatible with all the Voyager-era data. It has since then long been abandoned in view of the spectroscopic and imaging evidence for a heterogeneous surface and the radar echoes indicating the presence of solid material.

Indeed, a shallow, global ocean was shown to be inconsistent with the constraints imposed by Titan's orbital characteristics. The tidal action on an ocean less than 100 m deep would have dissipated Titan's **orbital eccentricity** of 0.03 (where 0 is circular and 1 is parabolic) long ago. Furthermore, the first remote sensing technique to be used for sounding Titan's surface, radar, indicated that the surface should be nonuniform but mostly solid with at most small lakes. Indeed, the radar echoes obtained in 1990 using the National Radio Astronomy Observatory's Very Large Array in New Mexico combined as a receiver of the signal transmitted to Titan by the NASA Goldstone Apple Valley Radio Telescope in California were among the first evidence against the global ocean model of the surface. Radar measurements from Arecibo Observatory in Puerto Rico in 2003, however, revealed a specular component at 75% (12 of 16) of the regions observed (globally distributed in longitude at about 26° S), which was interpreted as indicative of the existence of dark, liquid hydrocarbon somewhere on Titan's surface. The idea of a widespread surface liquid was challenged from more observations from the ground, in particular from spectroscopic data in the near-infrared region (0.8−5 μm). This part of Titan's spectrum, like that of the giant planets, is dominated by the methane absorption bands. At short (blue) wavelengths, light is strongly absorbed by the reddish haze particles. At red wavelengths, light is scattered by the haze, although the column optical depth is still high. In the near-infrared region, the haze becomes increasingly more transparent (since the haze particles are smaller than the wavelength), although absorption by methane in a number of bands is very strong. Where the methane absorption is weak, clear regions or "**windows**", situated near 4.8, 2.9, 2.0, 1.6, 1.28, 1.07, 0.94 and 0.83 μm, permit the sounding of the deep atmosphere and of the surface (Figure 38.6). In between these windows, contrary to the giant planets, solar flux is not totally absorbed but scattered back through the atmosphere by stratospheric aerosols, especially at short wavelengths. The near-infrared spectrum is thus potentially extremely rich in information on the atmosphere and surface of Titan.

The observations all agreed: the **geometric albedo** of Titan, measured over one orbit (16 days), showed significant variations indicative of a brighter leading hemisphere and a darker trailing one and inconsistent with a global ocean. The leading side corresponds to Titan's Greatest Eastern Elongation at about 90° Longitude of the Central Meridian (LCM—as opposed to geographical longitude, which is about 210°), when Titan rotates synchronously with Saturn; the trailing side is near 270° LCM or Greatest Western Elongation. As a consequence, Titan's surface had then to be heterogeneous and rather "dry" and it was proposed that a hydrocarbon reservoir could be stored in the porous, uppermost few kilometers of **methane clathrate** or water ice "bed rock."

The heterogeneity of Titan's surface, indicated in the near-infrared region and with radar light curves (Figure 38.6), was further graphically revealed by images of Titan's surface using the HST and adaptive optics techniques at the CFHT on top of Mauna Kea and its twin at the VLT in Chile. From such images, maps were produced of the surface in several near-infrared wavelengths, showing in some detail the bright leading and dark trailing sides, with notably a large (2500 × 4000 km) bright region, at 114° E and 10° S (nowadays known as Xanadu), as well as at a number of distinct darker regions known today for hosting hydrocarbon liquids or organic deposits.

Although it was thus already essentially demonstrated that Titan's surface was much more complex than initially thought, the arrival of the Cassini−Huygens mission revolutionized our perception of Titan with a particular focus on its mysterious surface, as described hereafter.

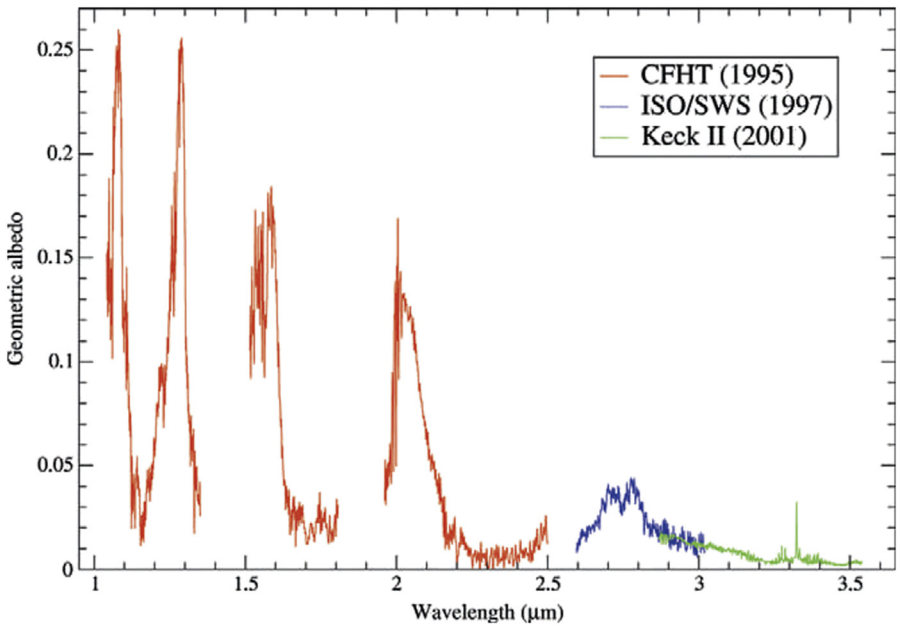

FIGURE 38.6 Titan's albedo observed from ground-based observatories such as the VLT in Chile and the Keck Telescope in Hawaii, as well as with the satellite ISO (in the 2.75-μm window, where the terrestrial turbulence does not allow us to observe Titan from the ground). The spectrum exhibits several strong methane absorption bands, but also "windows" where the methane absorption is weak enough to allow for the lower atmosphere and surface to be probed. *Adapted from Negrao et al. (2006) and Coustenis et al. (2006).*

3.2. The View from the Orbiter

The Cassini ISS and the VIMS cameras first pierced Titan's thick atmosphere and confirmed essentially the results from the ground-based observations showing that the borders of the bright and dark regions were linear but not smooth and that dramatic changes in surface albedo could be noticed. The best resolution achieved by ISS was of a few kilometers on Titan's surface. The large bright area around the equator first observed by the HST and the adaptive optics in 1994 was resolved and finely observed by Cassini instruments. It is centered at 10° S and 100° W and officially named Xanadu Regio (Figure 38.7). The midlatitude regions around the equator on Titan were found to be rather uniformly dark with some extensive bright regions (mostly elevated structures like mountains and ridges), while the poles are relatively bright and also filled with large dark areas now recognized as hydrocarbon "lakes" (mostly in the North Pole) formed possibly by precipitation through the atmosphere. In terms of hypsometry, Titan is considered flat with a range up to 2 km when compared to other planetary bodies such as the Earth (10−30 km). Furthermore, the polar regions were found to be substantially lower in topography than the equator (Figure 38.7).

What exactly is causing the albedo variations is still uncertain but they are more readily attributed to the presence on the surface of constituents with different albedos and possibly a combination with topography. The reason is that the Cassini cameras observing at short wavelengths cannot see shadows and provide information regarding the altitudes, the contours, and in general, the shape of the surface and that Titan's icy bulk does not plead for high topographic structures on the surface (mountains should not exceed 2 km or so).

For the brighter regions, the task of interpreting the data is more difficult. It has been hypothesized that they could be associated with some topography and more exposed ice content, and this tends to be in agreement with findings of the Huygens DISR instrument whose stereoscopic imaging revealed that the brighter terrain was also more elevated than the darker, smoother, and lower ice regions. Alternative interpretation seems to be needed for a number of other areas such as Xanadu, which is low but particularly bright. The exact ice constituent that can satisfy the constraints imposed by all the observations is not easy to determine, but water ice, tholin, CO_2 ice, and hydrocarbon ices have been suggested by various investigators.

Tortola Facula (8.5° N, 143° W), a bright circular structure (about 30 km in diameter) found in the VIMS hyperspectral images is interpreted as a cryovolcanic dome in an area dominated by extension. The VIMS team hypothesized that the dry channels observed on Titan are likely controlled by tectonic processes and related to upwelling "hot ice" and contaminated by hydrocarbons that vaporize as they get close to the surface (to account for the methane gas in the atmosphere), which are similar to the mechanisms operating for silicate volcanism on Earth (using tidal heating as an energy source) and which may lead to flows of non-H_2O ices on Titan's surface. Following such eruptions and the formation of a tectonic pattern on the surface, methane rain could form the dendritic dark structures seen by Cassini−Huygens. Such features could also form solely from heavy localized rainfall, as has been

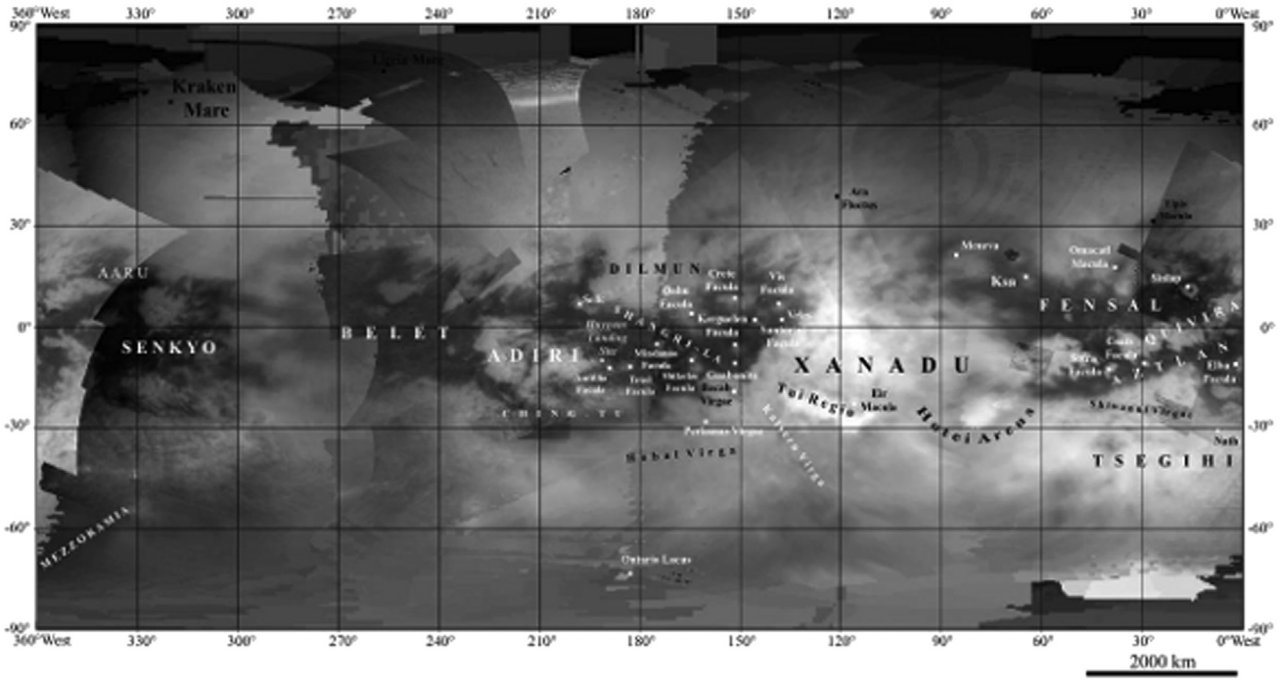

FIGURE 38.7 Global map of Titan's surface at a wavelength of 2 μm produced from Cassini VIMS observations including Titan's recent nomenclature. The map is displayed in a simple cylindrical projection centered at 0° N and 180° W. *From Stephan et al. (2009).*

observed directly through darkening and subsequent rebrightening reported from ISS images of some of Titan's equatorial terrain in the wake of a large low-latitude cloud system early in Titan's northern spring. The changes are interpreted as seasonal methane rainfall that can explain the channels observed at Titan's low latitudes. If these structures are indeed channels, they could have dried out due to climatological phenomena such as evaporation during a dry season at these latitudes. Studying volcanism on Titan (if Cassini definitely yields evidence for it) is important to understand not only the thermal history of Titan (which must surely have evolved differently because it differs in its incorporation of volatiles from the Galilean satellites) but also how volatiles—in particular, methane—were delivered to the surface.

The Cassini instruments have found no obvious evidence for a heavy craterization on the bright or the dark areas of Titan so far (Figure 38.7). A few features interpreted as impact craters have been announced to date: Cassini's RADAR and VIMS saw a 440-km-diameter impact crater on Titan during two separate flybys in early 2005. The coloring of the feature indicates that its terrain is rough, with different material for the crater floor and the ejecta, and tilted toward the radar during the observations. The multiringed impact basin was named Circus Maximus by the science team and later received its official name, "Menrva". A smaller crater of about 40 km was also observed, exhibiting a parabola-shaped ejecta blanket. In spite of the detection of more craterlike features, such formations, identified by the RADAR, VIMS, or the ISS are rare. This may mean that the surface of Titan is young (less than a billion years) or highly eroded/modified.

Other features observed by the Cassini orbiter include areas covered with analogs to terrestrial dunes in a set of linear dark features visible across a large part of the RADAR swath to the west of the large crater. These formations are aligned west to east covering hundreds of kilometers and rising to about 100 m. They are expected to have formed by a process similar to that on the Earth, but the nature of this "sand" is quite different, consisting of fine grains of ice and/or organic material, rather than of silicates (Figure 38.8). These structures and their orientation (west-east) were originally attributed to the influence of Saturn, through tidal forces 400 times greater than on the Earth which could have moved the Titanian "sand" in this world of low gravity, but it is thought now that more likely winds higher than 1 m/s on the surface are needed which points to a more important role of the Hadley circulation for the dune formation.

Additionally, and quite importantly for the hypothesized missing liquid methane or ethane surface reservoir, the RADAR instrument onboard Cassini has discovered lakes sprinkled over the high northern altitudes of Titan (Figure 38.9). In the data recorded since then by several instruments, a variety of dark patches is observed, some of which extended outward (or inward) by means of channels, seemingly carved by liquid. In 2010, specular reflections of the Sun off Titan's northern lakes ("sunglints") were

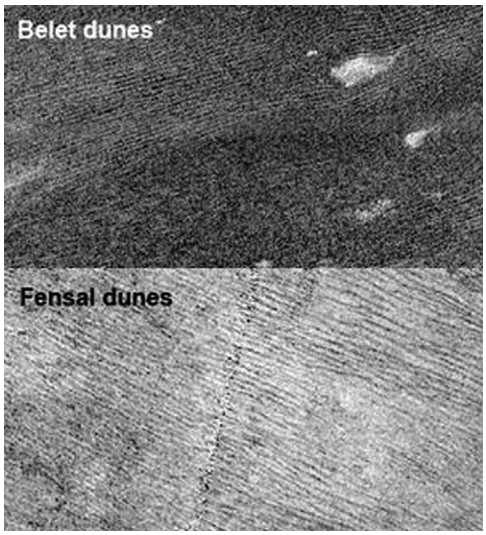

FIGURE 38.8 Dune fields on Titan as captured from Cassini RADAR in the Belet area (upper) and Fensal region (lower). In these images, the dunes are the dark streaks that are 1−2 km wide and the areas between dunes (bright streaks) are 1−4 km wide. Two different types of dune fields are shown: Fensal is at a higher latitude and elevation than Belet and clearly shows thinner dunes with brighter and wider areas in between, suggesting less dune material in this region. *Image Credit: NASA/JPL-Caltech/ASI/ESA and USGS/ESA.*

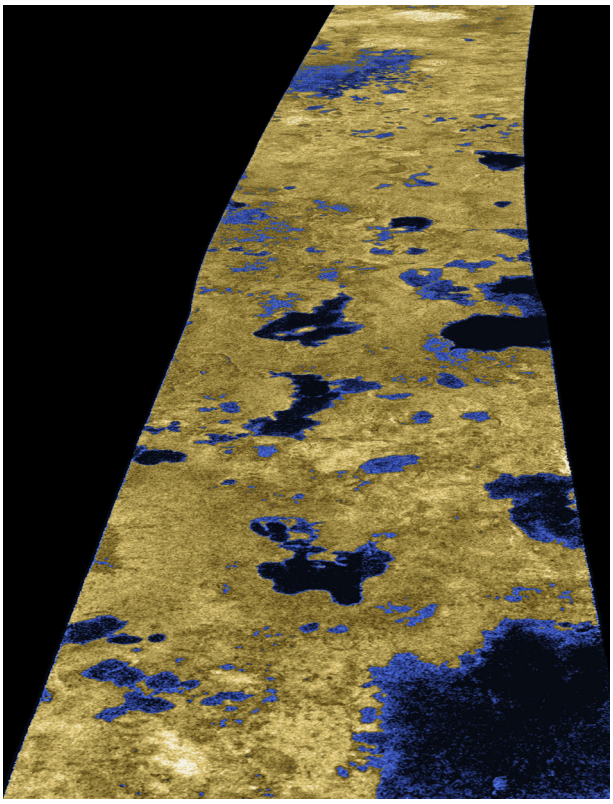

FIGURE 38.9 Cassini RADAR image of Titan's surface in synthetic aperture mode taken in 2006 and showing the highly contrasted terrain with a variety of geological features like the dark areas which are most probably hydrocarbon lakes. Bolsena Lacus is at the lower right, with Sotonera Lacus just above and to its left. Koitere Lacus and Neagh Lacus are in the middle distance, left of the center and on the right margin, respectively. Mackay Lacus is at the upper left. *Image Credit: Cassini Radar Mapper, JPL, ESA, NASA.*

reported, while Cassini looked back toward a crescent Titan at high phase angle. The data were used to set some constraints on possible surface waves on a north polar lake (Jingpo Lacus), and since then the observed specular reflections have been quite useful, along with spectroscopic detections of liquid ethane in Ontario Lacus by the VIMS instrument, in corroborating the presence of large extents of liquid hydrocarbons on Titan's surface. The major seas on Titan, which are very extended in size and discovered in 2007, are Kraken Mare (surface area of at least 400,000 km^2 centered at 68° N, 310° W), Ligeia Mare (79° N, 248° W), and Punga Mare (85° N, 339° W). Although some of these "seas", or "lakes", or even "oases", are found at midlatitudes, most are located in the northern hemisphere at Titan's current season, but they are expected to build up in the South, following the atmospheric evolution, as the season changes.

3.3. In Situ Data: the Ground Truth

On January 14, 2005, the Huygens probe manufactured by ESA landed at 10° S and 192° W on Titan (Figure 38.7), providing the "ground truth" for the orbital measurements in terms of composition, structure, and geomorphology. The probe flew over an icy surface and then floated down and drifted eastward for about 160 km. Several of the instruments on board contributed to our knowledge of Titan's surface conditions.

At the Huygens landing site, the fact that the surface is solid but unconsolidated was verified by all the data. The first part of the probe to touch the surface was the Surface Science Package (SSP) penetrometer whose data are now interpreted as indicative of the probe first hitting one of the icy pebbles littering the landing area before sinking into the softer, darker ground material. The SSP detected the ground from 88 m in altitude by acoustic sounding, revealing a relatively smooth, but not flat, surface for which our best current hypothesis is gravel, wet sand, wet clay, or lightly packed fine icy particles. With a landing speed of about 5 m/s, the front of the probe followed and penetrated the surface and then slid slightly before settling to allow the DISR camera to take several pictures of a Mars-like landscape, complete with a dark riverbed and brighter pebbles.

No evidence for standing liquid was found at the Huygens landing site, but the surface is expected to be very humid because methane evaporation (a 40% increase of the abundance) was measured by the GCMS after landing. In addition to the GCMS thermal data, the SSP penetrometer,

the GCMS composition measurements, and the detection of a likely dewdrop by DISR support the suggestion of the presence of humidity at the place where and at the time when Huygens landed. Thus, either the methane liquid reservoir may not be so far below the surface, but located instead in niches close to the exposed ground, or perhaps Huygens landed on Titan in a "dry" season when the rivers and lakes that may exist near the equator were empty but that could be flowing with hydrocarbons at a different era. Also, the presence of hydrocarbon lakes close to the North Pole may also imply that there are seasonal phenomena that distribute the liquid on the ground. Nevertheless, Huygens landed on an organic-rich surface, with trace organic species such as cyanogens and ethane detected on the ground.

The DISR imager and spectrometer gathered a precious set of data. Starting from the first surface image at 49 km, down to the unprecedented-quality snapshots of the Huygens landing site, and through the lamp-on data recorded below 700 m in altitude, this instrument played a decisive part in untangling the enigma of Titan's surface morphology and lower atmospheric content. Panoramic mosaics constructed from a set of images taken at different altitudes show brighter regions separated by lanes or lineaments of darker material, interpreted as channels, which come in short stubby features or more complex ones with many branches (Figure 38.10). This latter dendritic network can be caused by rainfall creating drainage channels, implying a liquid source somewhere or at some time on Titan's surface. The former stubby channels are wider and rectilinear. They often start or end in dark circular areas suggesting dried lakes or pits.

Stereoscopic analysis was performed on the DISR images indicating that the bright area cut with the dendritic systems is 50−200 m higher than the large darker plane to the south. If the latter feature is a dried lakebed, it seems too large by Earth standards to have been created by the creeks and channels seen on the images and could be due to larger rivers or a catastrophic event in the past. The dark channels visible in Figure 38.10 could be due to liquid methane irrigating the bright elevated terrains before being carried through the channels to the region offshore in southeasterly flows. This migration toward the lower regions probably leads to water ice being exposed along the upstream faces of the ridges. The slopes are generally on the order of 30°. Some of the bright linear streaks seen on the images could be due to icy flows from the interior of Titan emerging through fissures.

The images taken after the probe had landed on Titan's surface show a dark riverbed strewn with brighter round rocks. These "stones", which are 15 cm in diameter at most, could possibly be hydrocarbon-coated water ice pebbles (Figure 38.11).

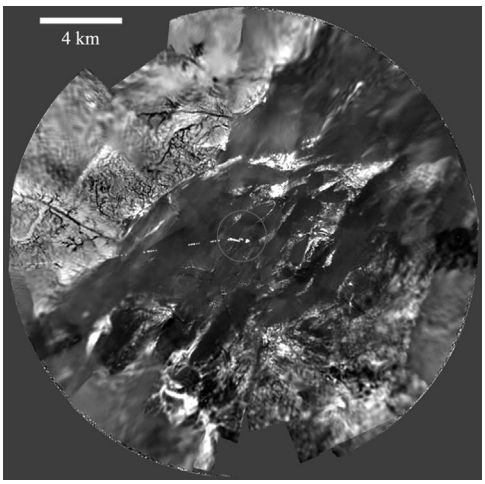

FIGURE 38.10 Titan's surface as viewed by the Huygens/DISR cameras from an altitude of 8 km. *Tomasko et al. (2005). Image Credit: ESA/JPL/University of Arizona.*

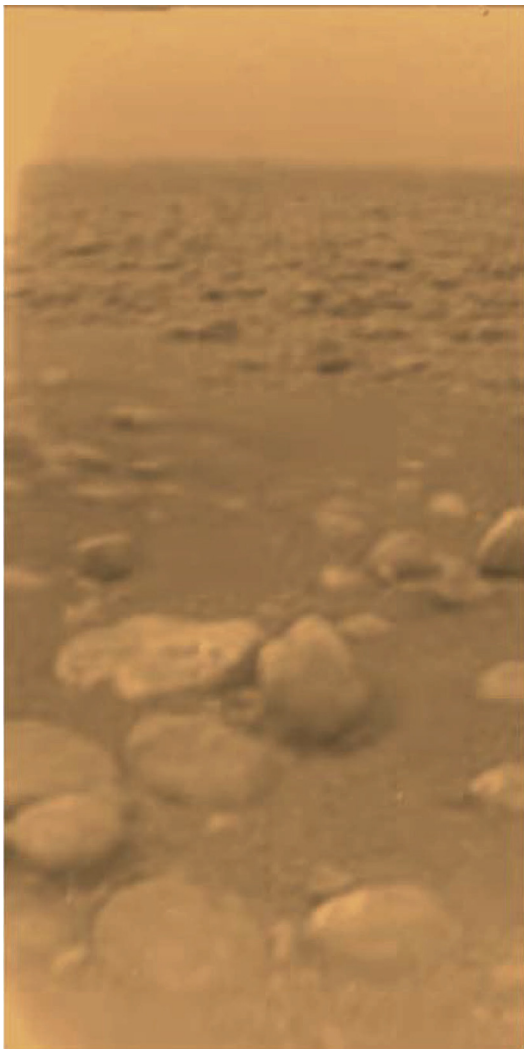

FIGURE 38.11 Titan's surface after the landing of the Huygens probe. The icy pebbles are at most 15 cm in diameter, and the darker riverbed is thought to be methane-wet sand. *Tomasko et al. (2005). Image Credit: ESA/JPL/University of Arizona.*

The spectra acquired during the descent gave information on the atmospheric (Table 38.2) and surface properties. Indeed, it was shown from spectral reflectance data of the region seen from the probe that the differences in albedo were related to differences in topography, which in turn can be connected to the spectral behavior of the ground constituents. Thus, the higher brighter regions were also found to be redder than the lowland lakebeds. The regions near the mouths of the rivers are also redder than the lake regions. The spectra taken by DISR are compatible with the presence of water ice on Titan's surface, something that had already been suggested from ground-based observations. The most intriguing feature found in the spectra was, however, the featureless quasi-linear unidentified blue slope observed between 830 and 1420 nm. No combination of any ice and organic material from laboratory measurements has been adequate in reproducing this characteristic. The jury is still out on the constituent(s) that create(s) this signature.

Although many questions still remain about the sequence of flooding and the formation of all the complex structures observed by DISR, these data tend to clear the picture we have of Titan today and at the same time enhance the impression that by studying this satellite of Saturn we are looking at an environment resembling the Earth more closely than any other place in our solar system.

The reality pictured by the Cassini–Huygens instruments went beyond anything that has been speculated about Titan's environment. The diversity of the terrain includes impact craters, dark plains with some brighter flows, mysterious linear black features possibly related to winds, sand dunes, and a host of possible actors (solids, winds, liquids, ices, volcanism, tectonism, etc.). Titan has been proved to be a much more complex world than originally thought and much tougher to unveil.

4. THE INTERIOR AND EXCHANGE PROCESSES

Titan possesses a complex and dynamic geology as witnessed by its varied surface morphology resulting from aeolian, fluvial, and possibly tectonic and endogenous cryovolcanic processes. Linear features and possible cryovolcanic spots are located close to the equator. In general, even with limited data, Titan's topography seems to be similar to that of Ganymede and Europa. The equatorial regions are considered to be higher in terms of hypsometry than the polar regions.

In particular, elevated as well as fractured crustal features are observed, and the fact that these features are locally regrouped (equator) indicates a morphotectonic pattern. Their shapes, sizes, and morphologies suggest that they are tectonic in origin, although it may be a different form of tectonism than the terrestrial one, originating from internal compressional and/or extensional activities. The triggering mechanism that leads to such dynamic movements is possibly Saturn's tide, whose effects concentrate around the equator.

In addition, the presence of an internal liquid water ocean for Titan is supported by models, radar and gravity Cassini measurements, and the HASI experiment. The extremely low-frequency electric signal recorded by HASI was interpreted as Schumann resonance between the ionosphere and a modestly conducting ocean roughly 50 km below the surface. Current thermal evolution models suggest that Titan may have an icy crust 50–150 km thick, lying atop a liquid water ocean a couple of hundred kilometers deep, with some amount (perhaps $\sim$10%) of ammonia dissolved in it, acting as an antifreeze. A layer of high-pressure ice could exist underneath (Figure 38.12). The presence of ammonia, from which Titan's nitrogen atmosphere was presumably derived, distinguishes Titan's thermal evolution from that of Ganymede and Callisto. Cassini's measurement of a small but significant asynchronicity in Titan's rotation is most straightforwardly interpreted as a result of decoupling of the crust from the deeper interior by a liquid layer. The recent detection of periodic tidal stresses on Titan requires that its interior be deformable over timescales of the orbital period in a way that is consistent with a global ocean at depth.

Cryovolcanism has also been suggested on Titan, although it has not been proven to this day. This activity can be described as ice-rich volcanism, due to the satellite's conditions (internal and external) which are quite different from the terrestrial ones, while the cryovolcanic ejecta are referred to as cryomagma. The cryomagma could appear in the form of icy cold liquid and, in some cases, as partially crystallized slurry, but still with unknown precise composition. There are currently some cryovolcanic candidate regions on Titan, all of which are located close to the equator, and include Tui Regio, Hotei Regio, and Sotra Patera for instance (Figure 38.7). Indeed, radiative transfer modeling of Cassini/VIMS data taken from these regions from several flybys indicates possible albedo variations with time, suggesting possible fluctuating deposition of material with endogenic origin (i.e. cryovolcanism). On the other hand, an alternative hypothesis, based on spectral similarities between Tui Regio and dry lakebeds at the poles, is that the features at Tui Regio are evaporitic deposits with no interior connection. Other studies focusing on Tui Regio and Hotei Regio describe the areas as paleolake clusters and fluvial or lacustrine deposits indicating an exogenic origin. In particular, some investigators have pointed out the resemblance between Hotei's radar-bright materials and channels with Earth's sediment-filled valleys, thus arguing in favor of the fluvial origin of the observed features.

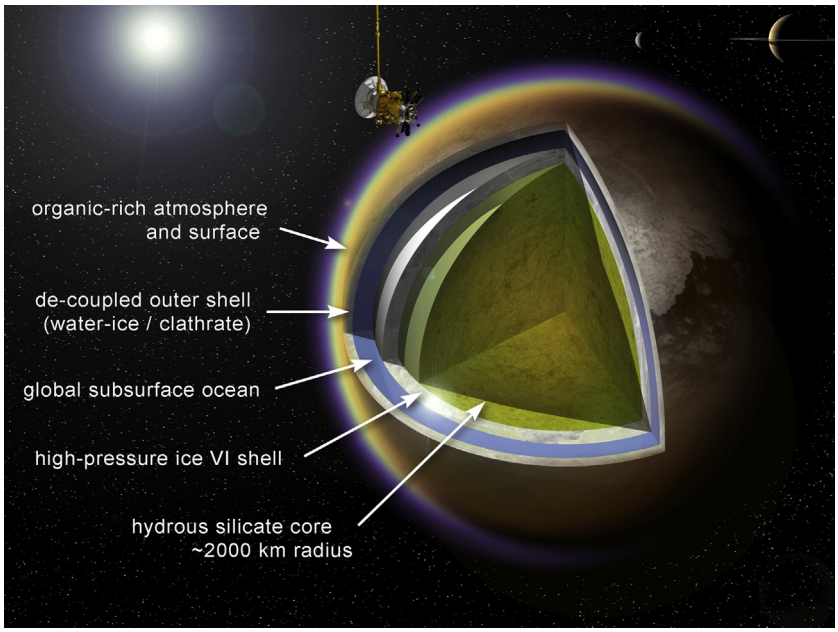

FIGURE 38.12 Artist's concept of a possible Titan internal structure according to Cassini data. *From Fortes, A. D (2012).*

Cryovolcanism may be considered as one of the processes that replenishes methane in the atmosphere and reshapes and changes the surface. However, alternative interpretations of the regions of interest and theories for methane ejection in the atmosphere exist. Among others, one can cite mountain formation by thermal contraction of the interior, isostasy and impacts. In the occasion of such "violent" events, clathrate hydrate in the high-pressure ice of Titan's interior can be destabilized and methane could be released in the atmosphere. Other theories, suggesting the lakes as a source of methane replenishment, are now less in favor since estimates show that only 1% of methane can be provided by that source.

5. LOOKING AHEAD

On Titan we are observing an active hydrologic cycle subjected to seasonal and longer term changes, as on the Earth, and by investigating such a close Earth analog in terms of processes, but with sufficient differences in working fluids and timescales, we can rigorously test the depth of our understanding of planetary climate.

The Cassini data since 2004 show that seasonal variations are quite prominent in Titan's atmosphere with a buildup of trace gases over the south pole approximately 2 years after observing the 2009 postequinox circulation reversal, indicating that middle-atmosphere circulation must extend up to at least 600 km. The primary drivers of this circulation are found to be summer-hemisphere heating of haze by absorption of solar radiation and winter-hemisphere cooling through infrared emission by haze and trace gases.

Furthermore, comparisons made with earlier ground-based and Voyager observations indicate that, although the thermal and chemical structure of Titan's atmosphere is stable after 1 Titanian year, consistent with the solar input being the major energy source on Titan as on the Earth, some interannual variations may exist for a few of the most complex molecules.

The lakes seen by Cassini are signposts of climate change at the Titan poles—with a period of tens of thousands of years— and the cycling of methane and ethane between Titan's poles leads to an active geologic surface modification in the polar latitudes. Seasonal transport of methane from pole to pole may replenish the polar lakes during the wintertime in the North and deplete them in the summer, but more permanent deposits of ethane appear to remain behind.

Indeed, it has been shown that Titan's pole precesses over tens of thousands of years and this (with the eccentric orbit of Saturn around the Sun) leads to an asymmetry in the seasons that biases hydrocarbon lakes toward the north, where we see them. The effect is modulated by, and reverses with, dynamical variations in the orbit of Saturn around the Sun. Much akin to the famous Croll–Milankovitch cycles on the Earth (which are likely also responsible for the Mars polar layered deposits), the resulting cycling of methane and ethane between Titan's poles—with a period of tens of thousands of years—leads to active geologic surface modification in the polar latitudes, but with two interacting fluids, ethane and methane,

rather than one as on the Earth. This phenomenon needs to be studied further on longer timescales and with in situ access.

Methane is an essential constituent on Titan, causing a greenhouse effect, much like on Earth, which has important consequences on the surface temperature. As discussed in Section 2.2, methane is normally photolyzed in Titan's atmosphere, and unless it can be replenished by a large reservoir on or beneath the surface, it is bound to disappear in a few million years. What would then be the fate of Titan's atmosphere? In such a case, the surface temperature would drop below the condensation point for nitrogen, and Titan's atmosphere would collapse. Should the absorptivity of the surface increase subsequently (e.g. due to the accumulation of organics), the surface temperature might once again rise and cause the reevaporation of methane and nitrogen, thus rebuilding the atmosphere. Such cycles have been hypothesized to occur on Titan.

Furthermore, should the methane supply become abundant in the future, a small perturbation in the solar flux received on Titan (such as is expected when the Sun becomes a red giant and then a dwarf) would produce a dramatic warming of the climate, raising the temperature on the surface and the pressure to values as high as 180 K (twice what we have today) for several bars. It is not inconceivable to imagine that some day in the distant future, conditions on Titan one day may very closely resemble those found on our own planet today.

But Titan can also be viewed as an analog, albeit with different working materials, of a future state of the Earth when surface conditions, due to the increasing solar luminosity, shall preclude stable equatorial/mid-latitude oceans and the liquid water will be limited to the poles. Thus by studying the evolution of Titan and how the various geologic and meteorological processes interact, we have a glimpse into the Earth's past and future "simulated" on a planetary scale by different materials.

These aspects of Titan, as the fragility and changeability of the climate of our own home world, and the habitable potential of the moon, need to be studied more thoroughly.

In the meantime, the Cassini mission has demonstrated the complexity of this world and our need to further investigate it in order to better comprehend our solar system. Beyond the extended Cassini mission (2017), discussions of future missions to Titan are already underway.

Such concepts are currently in study (even if Cassini is still on the spot, we need in the future a dedicated orbiter, more in situ exploration, and more adapted instrumentation, among others). The use of aerial explorers such as an airplane or balloons and dune and lake landers has been suggested and studied by space agencies (Figure 38.13).

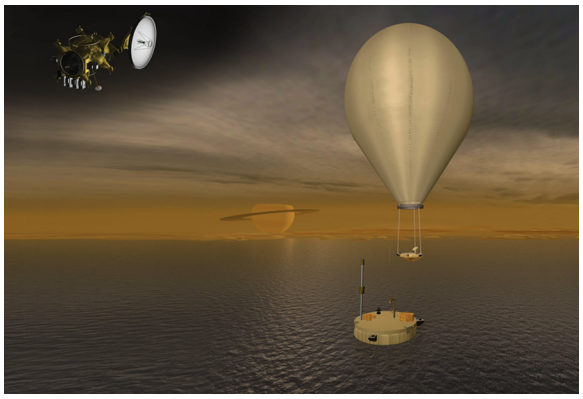

FIGURE 38.13 Artist's concept of a future Titan mission including several concepts studied by space agencies (such as a dedicated orbiter, a lander or a balloon) *ESA/NASA TSSM mission study, 2009. Image credit: C. Waste, NASA/JPL.*

Such missions would allow us to thoroughly explore the unique and complex Titan environment which may have many more surprises in store for us.

1. INTRODUCTION AND HISTORY

Enceladus, a small icy satellite of Saturn (Figure 39.1), is one of the very few solar system bodies that is geologically active at the present day. The discovery, in early 2005, of erupting jets of water vapor, organic compounds, and ice grains, as well as an anomalously large heat flux, from the moon's south polar region represents arguably the most important finding of the Cassini mission.

Voyager, the last spacecraft to encounter Saturn before Cassini, revealed a surface characterized by extensive smooth, crater-free terrains, a clear sign of past internally driven geologic activity; it did not image the south polar region. The persistence of the tenuous E-ring centered on Enceladus had been tentatively ascribed to resupply by geysers, but this idea (now known to be correct) was not generally accepted prior to 2005.

Enceladus is in a 2:1 mean motion eccentricity-type **resonance** with its larger sibling moon, Dione, and thus has a forced nonzero eccentricity (Table 39.1). Tidal heating and flexing arising from the eccentric orbit is the most plausible explanation for the observed activity, but the details and history are unclear (see below).

2. SHAPE, GRAVITY, TOPOGRAPHY

Enceladus' bulk density of 1609 kg/m^3 (the second largest in the Saturnian satellite system after Titan) suggests a compositional mix of ice and silicates. The bright surface material is pure crystalline ice, so Enceladus has generally been presumed to be a differentiated object containing a silicate core beneath an H_2O layer.

As with all synchronously rotating bodies—where the rotation period is equal to the orbital period and hence the moon always presents the same face to the host planet—Enceladus is distorted by tides and centrifugal forces into a triaxial ellipsoid. However, its shape is not that expected for a strengthless (hydrostatic) body. A slowly rotating hydrostatic body has a ratio $(b - c)/(a - c)$ of 0.25, where a, b, and c are the ellipsoidal axis lengths. For Enceladus, the value of this quantity is 0.37 ± 0.04; its shape is clearly not hydrostatic. The equivalent gravity coefficients are also not in the hydrostatic ratio, although in this case the deviation is smaller. The nonhydrostatic shape and gravity make it harder to determine the polar moment of inertia C and internal structure of Enceladus. Although interpretations are nonunique, preliminary analyses yield a dimensionless moment of inertia factor of $C/MR^2 = 0.33–0.34$. Assuming a differentiated, two-layer structure with a surface (H_2O) layer density of 900–950 kg/m^3, the implied H_2O layer thickness is 47–61 km and the silicate core density is 2225–2472 kg/m^3. The latter density range is more consistent with porous or hydrated silicates or silicates containing ~10% ice, than with anhydrous, pore-free silicates.

The moment of inertia determination is incapable of distinguishing between liquid and solid H_2O, although gravity and topography data have been used together to infer the presence of a subsurface liquid sea beneath the SPT or a global ocean that is thicker under the SPT than elsewhere. A regional sea, at the minimum, can be inferred from other lines of evidence (Section 5.2). It is generally assumed that the majority of the H_2O layer is solid ice rather than liquid water, but direct constraints on the ice shell thickness are currently lacking. A global ocean could potentially be detected from its effect on Enceladus' obliquity or the amplitude of the moon's physical **librations**, but neither has yet been measured.

Limb profiles and stereo imaging have quantified Enceladus' regional topography (Figure 39.2(b)). This is dominated by a south polar depression of about 0.5 km in amplitude. This observation strongly suggests (together with the gravity results and other data) the existence of a regional sea beneath the south polar terrain (SPT), in essence making the depression a sink hole. Shallower, 100-km-scale depressions are present elsewhere on the moon, but show no obvious relationship to the surface geology (Figure 39.2(b)) and are not associated with anomalous heat (see Section 5.4). They are therefore not likely to be associated with subsurface liquid water at present but instead may be due merely to shell thickness variations or lateral variations in shell density (e.g. due to differential compaction of porosity).

Despite the fact that parts of Enceladus are heavily cratered, at wavelengths shorter than 100 km the topography is much smoother than all other airless satellites except Europa. This is presumably due to resurfacing and/or relaxation caused by past internal heating. Locally high heat fluxes sometime in the past have been deduced based on the **flexural response** of individual features, and the shallow (relaxed) nature of some large impact craters; the gravity observations are also consistent with a highly compensated (weak) shell, again suggesting past high heat fluxes.

3. SURFACE COMPOSITION

Enceladus' surface is dominated by crystalline water ice with surface grain sizes ~10–100 μm. Local variations in inferred grain size correlate with geology; for instance, the tiger stripes exhibit larger grain sizes than the surrounding terrain, perhaps as a result of sintering or the fallout of larger grains. Minor amounts of CO_2 ice have also been detected.

4. SURFACE GEOLOGY AND TECTONICS

Enceladus, like Gaul, is divided into three parts (Figure 39.2). Heavily cratered terrain forms a north–south girdle around the moon, encompassing the Saturn-facing,

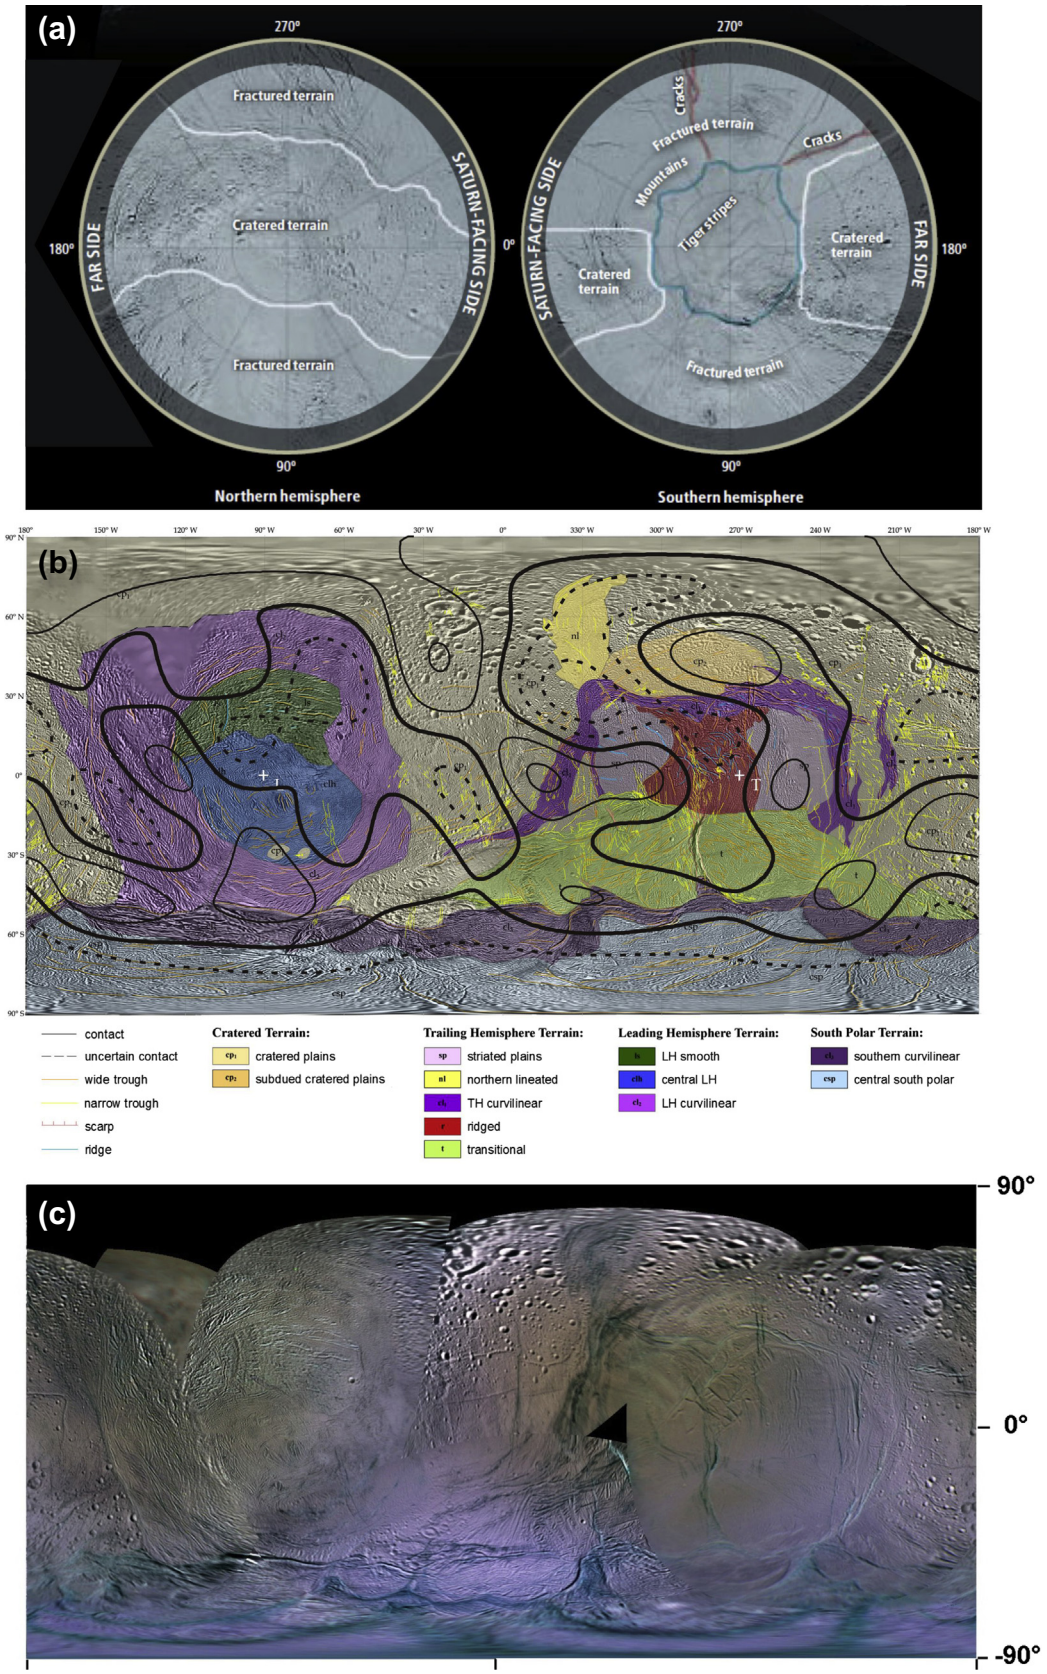

FIGURE 39.2 (a) Regional views of the north and south poles showing the three-part nature of the surface. *(From Porco (2008). Scientific American.)* (b) Global geological map, from Crow-Willard and Pappalardo (submitted). Black contours are spherical harmonic topography from $l = 3$ to $l = 8$. *(From Nimmo et al. (2011))*; bold line is zero contour, solid and dashed lines are positive and negative, and contour interval is 0.5 km (c) Global color (IR-green-UV) map, simple cylindrical projection. *From Schenk et al. (2011).*

north polar, and anti-Saturnian regions, but interrupted by the SPT. The SPT region is tectonically deformed, geologically active, and is described in more detail in Section 5. The leading and trailing hemispheres, in contrast, both consist of tectonically resurfaced, relatively crater-free terrains, although in detail they differ. All the latter regions—leading and trailing hemispheres and the SPT—show a similar overall architecture, consisting of a central tectonized region wrapped by a circumferential belt of mountains. It is currently unclear whether this similarity implies a commonality in origin, but the pronounced symmetry of the terrains about the present-day tidal axis suggests that tidal processes have been important.

The cratered terrain has a nominal age range of 0.6−4.6 Gyr, depending on which model of impact flux is used. The corresponding age ranges from the trailing hemisphere and SPT are 0.04−2 Gyr and 1−100 Myr, respectively. Almost all the large impact craters show signs of viscous relaxation, indicative of ancient elevated heat fluxes in regions other than the SPT.

The surface color of Enceladus shows pronounced spatial variations (Figure 39.2(c)) quite different from the hemispheric asymmetries seen on other Saturnian moons. Two antipodal swaths of blue-pink material protrude northward from the SPT, becoming less pronounced as they do so. This behavior is very similar to modeled patterns of fallout from the south polar jets, and suggests that SPT activity controls the global color distribution. Models of the jet eruptions also show that most of the solid material falls back down to the surface, with some very small percentage—∼9% or less—escaping the moon to supply the E-ring (Section 5.2). The extreme brightness overall of Enceladus (**Bond albedo** 0.8) is almost certainly due to this process. Plume fallout has also been inferred at a local scale from the apparent mantling or softening of topography along the tiger stripe fractures seen in high-resolution images (Section 5.2).

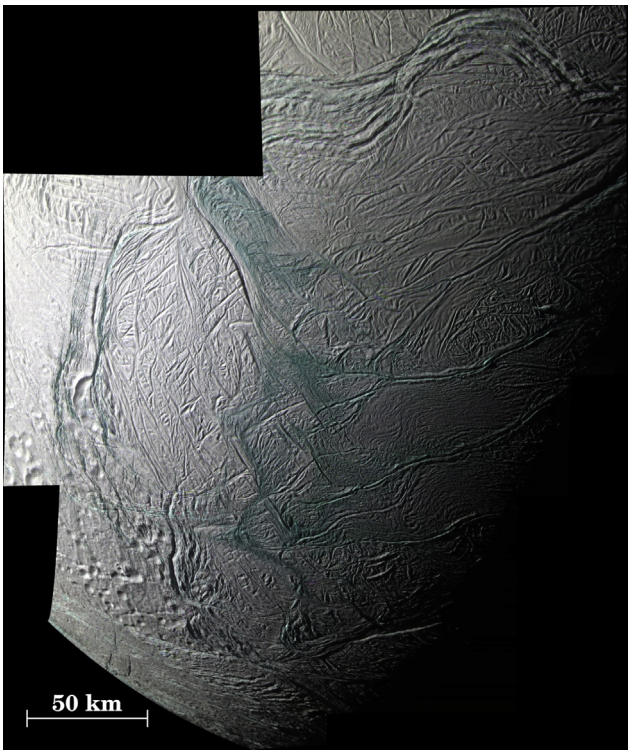

FIGURE 39.3 A false color Cassini mosaic of the SPT taken in August 2008, a year before southern autumnal equinox. The four major tiger stripe fractures, and the belt of mountains circumscribing the entire SPT, are clearly visible.

5. THE SOUTH POLAR REGION

Because of its importance, we treat the south polar region separately. In discussing this region, it is important to distinguish between "jets" or "geysers"—individual eruption features (Figure 39.1(b))—and the "plume"—the combined, regional envelope of vapor and ice grains.

5.1. Regional Geology

The outermost region of the SPT, at about 55°S, is bounded by arcuate mountain belts, perhaps reflective of compressional relative motion there (Figure 39.3). At several locations along this arcuate boundary, prominent fractures extend northward for hundreds of kilometers. These fractures cross-cut all other features and are thus young. In the center of the SPT are the so-called tiger stripes, prominent linear depressions ∼0.3 km deep, 135 km long, and about 2 km wide and separated by ∼35 km. These fractures are the source of all the observed jets and the hottest thermal anomalies (see below). In between the tiger stripes are a dense array of cross-cutting fractures, some of which may represent the remnants of earlier tiger stripe-like features.

5.2. Jets

Cassini images show ∼100 distinct, prominent jets emanating from the south pole (Figure 39.1(b); Figure 39.4). The jet locations (dots in Figure 39.4(b)) and tilts (Figure 39.4(a)) can be determined by triangulation. In all cases, jets lie along the main trunks of the four major tiger stripes or their split ends and erupt roughly in a plane defined by the perpendicular to the surface, with some exceptions. Individual jets in some cases turn on and off, but there appears to be no systematic relationship to the orbital phase, as would be expected if tidal stresses alone controlled the individual jets.

The jets consist of vapor (Section 5.3) as well as ice grains having a range of sizes; the grains that escape and supply the E-ring are ∼1 μm in diameter but larger grains

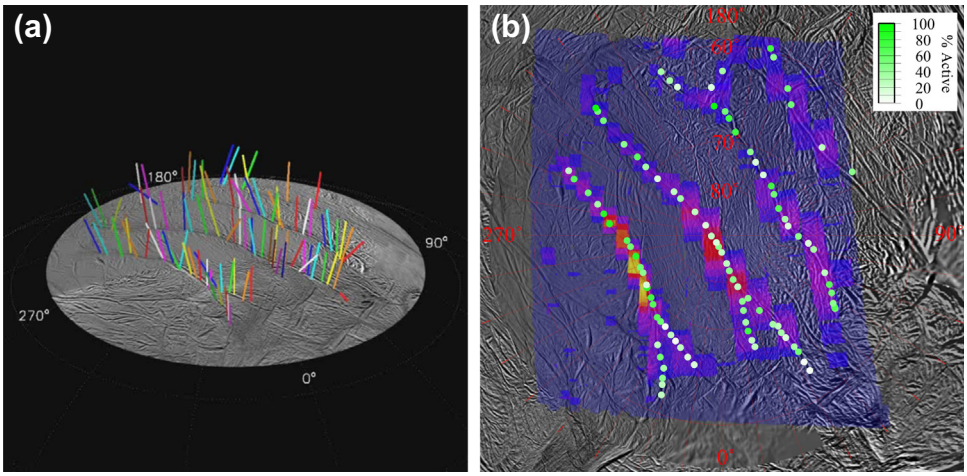

FIGURE 39.4 Tiger stripe region showing the location (b) and (a) tilts of all identified jets, or geysers, and the correlation of low resolution thermal emission with geysering activity (Porco et al. 2013). In part (b), the background is a Cassini ISS mosaic. Colors indicate CIRS temperature map. (*From Howett et al. (2011)*) Dots are individual jet locations derived from triangulation of images, and green color scale indicates the frequency with which each jet is observed to be active. At much higher resolution, individual geysers have been found to be coincident with small-scale thermal hot spots. *Porco et al. (2013)*.

are present and fall back to the surface. The characteristic velocity of the grains exiting the vent is a few tens of meters per second, slow compared to the escaping vapor. Their mass flux is $\sim 30-70$ kg/s, comparable to or slightly smaller than the total vapor mass flux: the ratio of solids to vapor is $\sim 0.4-0.7$. This value is too large for the solids to be explained by the adiabatic expansion and condensation of vapor alone. Instead, the most plausible explanation is the flash freezing of liquid droplets. Only a small fraction of this mass is required to resupply grains in the E-ring, which have a lifetime against sputtering measured in decades. The velocity of the escaping grains is obviously much higher than typical and greater than the escape velocity from Enceladus.

Moreover, a small fraction of the ice grains are rich in NaCl, with a salinity comparable to the Earth's oceans. The generally accepted explanation for both observations is that the grains form by direct, flash freezing of salty water droplets as they reach the vacuum of space, presumably from a subsurface liquid reservoir that has been in contact with a silicate core. The Na-rich grains and the comparatively large solids/vapor ratio thus represent strong direct evidence for subsurface liquid water. The obvious implication is that the jets are in fact geysers erupting from a liquid water reservoir.

Although individual geysers do not appear to respond in a systematic way to the orbital position of Enceladus, the spatially integrated plume brightness (a reasonable proxy for total mass in solids) does show a correlation with orbital position in both Cassini Visual and Infrared Mapping Spectrometer (VIMS) and Imaging Science Subsystem (ISS) data. The brightness peaks near when Enceladus is at **apoapse**, which is broadly consistent with models in which the tiger stripes open and close in response to tidal stresses.

Geysering activity across the SPT is spatially correlated with the hottest locations in the region as seen at low resolution (Figure 39.4). Individual geysers have also been shown to be spatially coincident with the few, very small-scale (approximately tens of metres) hot spots that have so far been reported. In general, where there are

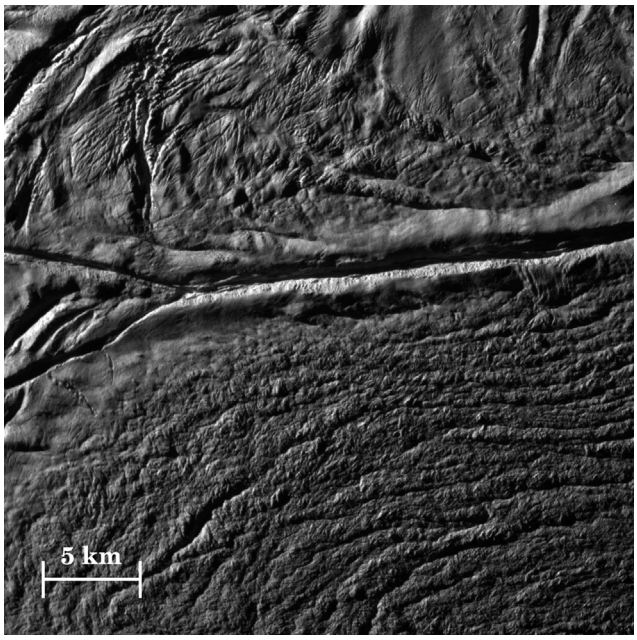

FIGURE 39.5 The region on the tiger stripe fractures that is hottest as seen in low resolution CIRS data (Figure 39.4), and the site of the most geysering activity, is the portion of Damascus fracture captured in this ISS image, with a spatial scale of 32 m/pixel. The ramparts of the fracture are smooth in appearance but eventually give way, at some distance from the fracture, to typical deformed interstripe terrain.

geysers, there is heat and vice versa. The ramparts of jet-active regions on the SPT are smooth in appearance (Figure 39.5), likely caused by local plume fallout.

5.3. Vapor Component of the Plume

Detailed compositional measurements of the plume were obtained by the Cassini Ion and Neutral Spectrometer instrument during multiple fly-throughs of the plume. Preliminary analysis of the results revealed a host of short-chain hydrocarbons, among them acetylene, propane, and benzene. Whether more sophisticated analyses will confirm that these light hydrocarbons are the result of the breakup of larger organic molecules is not yet clear. What is clear is the presence of water vapor at a volume mixing ratio of $\sim$90%, and the presence of carbon dioxide, ammonia, and methane. The detection of NH_3 is important because of its potential role as an antifreeze in a subsurface ocean, its effect on ice **rheology**, and as a carrier of **biologically available nitrogen**. The measured D/H ratio is similar to the cometary value and twice the terrestrial value.

The presence of organic materials and biologically available nitrogen in the vapor composing the geysers, and the inference of a water reservoir in contact with a silicate core, make for the very exciting suggestion that the geysers of Enceladus are directly connected to a subsurface habitable zone. (See Section 9.)

Occultation data constrain the upward velocity of the molecules in the vapor component of the plume to be about 300–500 m/s, greater than the escape speed of Enceladus (239 m/s). The vapor mass production rate appears to have held steady to within a factor of two over the course of the Cassini observations.

5.4. Thermal Signature

Because of its high albedo, the surface temperature of Enceladus is about 80 K at the equator, and lower toward the poles. Measurements made by the Cassini Composite Infrared Spectrometer (CIRS) instrument indicate that the tiger stripes are much hotter than their surroundings (Figure 39.4), with the excess power totaling about 5 GW ($1\ \text{GW} = 1 \times 10^9$ W). It is possible that a comparable amount of heat, in total, arises from the entire area of the SPT but with sufficiently low flux to escape detection by CIRS. High-resolution infra-red measurements suggest that the hottest heat flow anomalies along the fractures are confined to very small regions, tens of meters in size. The heat flux emerging from these local hot spots is many times greater than the average heat flux arising from the Yellowstone geothermal area in Wyoming. These hot spots coincide with individual geysers, making the association of thermal emission with geysering activity hold at high as well as low resolution.

There are two main possible explanations for these relationships. One is that the heat is being produced today by tidal dissipation; the other is that we are seeing stored heat, generated over some period in the past and now escaping. An example of the former category is tidally driven frictional heating between opposing walls of the tiger stripe fractures, while an example of the latter is the ascent of warm water from a subsurface ocean. As discussed below, these different hypotheses have different consequences not only for the mechanism that produces the geysers and the source of the water in them, but for the orbital evolution of Enceladus.

Three lines of evidence favor the ascent of heat and water from depth. First, as mentioned earlier, the salty nature of some of the ice grains and the large fraction of solids in the eruptions suggest that the ultimate source is a subsurface ocean, and not sublimation of near-surface ice or the freezing of vapor upon expansion as it exits the surface vents. Second, the narrowness of the imaged thermal anomalies is inconsistent with tidal heating, which would be distributed over kilometers (in the case of frictional heating) or the whole SPT (in the case of distributed tidal heating). Third, the observed correlation between plume strength and orbital phase (see above) very likely implies that cracks are opening and closing on a tidal timescale, allowing subsurface water to erupt as ice and vapor. In this hypothesis, the observed heat flux is mainly due to recondensation of vapor in the cold near-surface ice. Consistent with this explanation is the recognition that liquid water in the cracks would probably inhibit any frictional heating within them. The implied rate of recondensation ($\sim$2000 kg/s) means that only about $\sim$10% of the vapor produced is actually escaping to form the plume. Individual fractures probably reseal themselves on timescales of a couple of years.

6. PRESENT-DAY STRUCTURE

Here we attempt to reconcile the observations described above into a coherent picture of Enceladus' interior (Figure 39.6).

The presence of liquid water beneath (at least) the SPT is strongly suggested by the detection of salty ice grains and the large solids/vapor ratio (Section 5.2). The depression of the SPT by $\sim$0.5 km suggests a regional sea, although it is not yet clear whether this sea forms part of a thin global ocean (see below). The phasing of the time variability of the plume directly implicates the role of cracks opening and closing in response to tides. Such cracks, if water-filled, can readily propagate upward on Enceladus through the majority of the ice shell, despite the relatively low ($\sim$1 bar) tidal stresses. The ascent through the remainder of the ice shell to the surface could easily be accomplished by the violent exsolution of dissolved gases, such as CO_2, from the

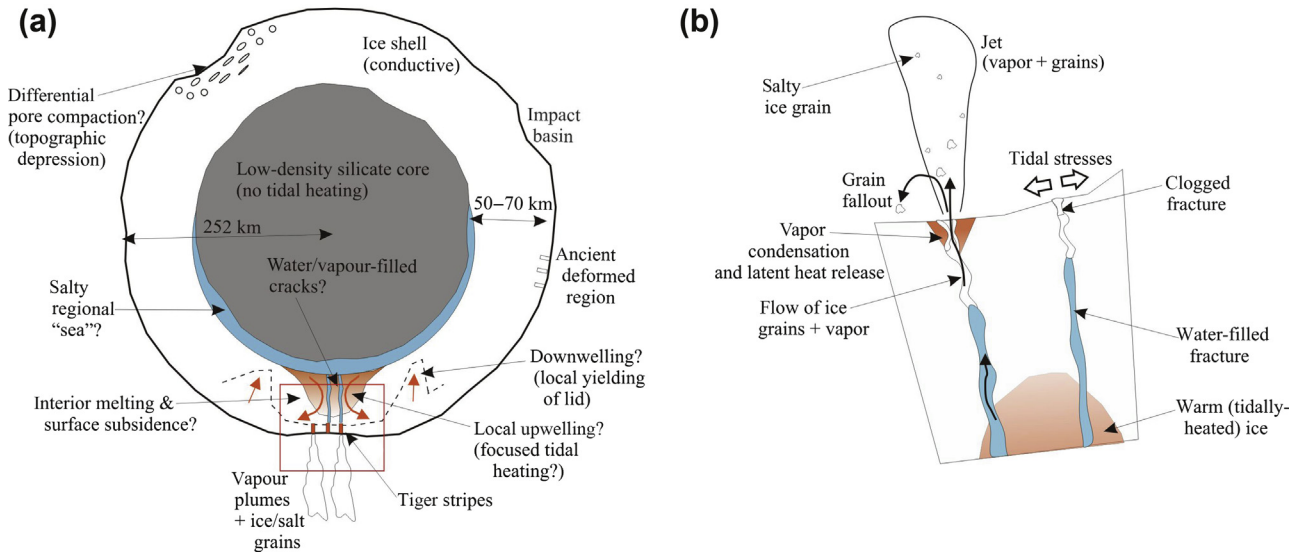

FIGURE 39.6 (a) Sketch interpretation of Enceladus' interior structure (see text). (b) Sketch interpretation of the near-surface structure at the SPT (see text).

liquid that would force water and vapor to the surface. When a crack opens, exposure of the water and vapor to vacuum will result in simultaneous boiling and freezing; a geyser forms. A spectrum of ice grain sizes is produced, with the larger grains readily falling out and the smaller grains in some cases escaping to replenish the E-ring. Much of the vapor produced recondenses on the near-surface walls of the conduit, releasing its latent heat there and generating the majority of the thermal anomaly observed and ultimately clogging the crack, causing the individual geyser to fail. This geysering model can explain how the integrated plume flux might vary with the changing tidal stresses, although individual geysers do not appear to; opening and closing of cracks during the tidal cycle modulates the strengths of individual geysers, but they remain active throughout the cycle. Geysers eventually fail and turn off, not on a daily timescale but when an individual vent becomes clogged, probably on a timescale of a year or two.

In terms of its bulk structure, the relatively low density inferred for the silicate core (Section 2) represents a surprise—most models previously assumed an anhydrous density similar to that of Io (roughly 3500 kg/m^3). However, the pressure at 100 km depth on Enceladus is equivalent to only 300 m depth on the Earth, so it should not be surprising if the silicate core were porous. Alternatively, a hydrothermally altered core is a possibility (especially if Enceladus accreted while radioactive ^{26}Al were still live) and might help to explain the composition of the plume.

Two major unanswered questions concerning Enceladus' interior structure are whether the ice shell is convecting, and whether the subsurface liquid is global in extent.

Although, as noted above, the source of the tiger stripe heat appears to be primarily advection of warm water from depth, a contribution from present-day tidal heating across the entire SPT region is not precluded. Certainly, the extreme tectonic deformation and young age of the surface is suggestive of yielding and lateral motion of material, perhaps in response to deeper seated convection. Convection in tidally heated bodies is subject to strong feedbacks, because warmer ice (e.g. in upwellings) is more easily tidally flexed and therefore more strongly heated. Furthermore, tidal heating is generally greater at the poles than at the equator. Thus, a local, tidally heated convective upwelling at the south pole seems quite likely. Such an upwelling has the additional property of insulating the underlying material, and calculations have shown that a local southern sea can consequently persist indefinitely under such conditions.

Whether convection is currently taking place elsewhere on Enceladus is much more open to debate. If regions other than the south pole lack a subsurface liquid layer, they will be subject to much weaker tidal heating and thus less likely to convect. The long-wavelength topography and ancient deformation features observed, however, may well be an indication of past activity and convection, perhaps suggesting that Enceladus has experienced multiple deformation episodes (see below). The symmetrical distribution of the deformed terrains (Figure 39.2) may perhaps be related to the tendency of convecting regions to undergo true polar wander, modulated by the tidally distorted shape of Enceladus. On the other hand, a globally convective Enceladus would be sufficiently dissipative that it would be hard to match the currently observed orbital configuration. The most likely solution is that convection is localized (very likely in space—the SPT—and perhaps also in time).

Although a regional sea can persist indefinitely under some conditions (see above), a global subsurface ocean

encounters severe thermal problems. The silicate core, even if hydrated, is very unlikely to be a significant source of tidal heating, and any initial heat (e.g. from ^{26}Al decay) will have long since diffused away. Thus, the only plausible heat source from the silicates is the decay of long-lived nuclides, and their contribution is simply too small to offset the heat loss through the ice shell, even in the absence of shell convection. A global ocean is thus expected to freeze in a few tens of million years (Myr) Once frozen, subsequent tidal heating is greatly diminished because the ice shell is then locked to the much more rigid silicates beneath. A regional sea, on the other hand, is likely to have none of these thermal problems.

7. EVOLUTION

The long-term evolution of Enceladus' interior is closely coupled to its orbital evolution, because the main heat source is energy extracted from its orbit (and ultimately from Saturn's rotation). Enceladus' current resonance with Dione causes its **eccentricity** to increase, while any tidal dissipation in Enceladus will cause the eccentricity to decrease. There is thus in principle an equilibrium in which the eccentricity remains constant. In this special case heat production in Enceladus does not depend on its interior structure but only on the rate at which energy is being dissipated within Saturn—which also determines the torque on Enceladus's orbit. Taking the dissipation factor of Saturn to be the generally accepted value ($Q > 18{,}000$) the equilibrium heat production rate within Enceladus has an upper bound of 1.1 GW. This is a factor of five or more less than the measured heat output. There are two possible scenarios to explain this discrepancy.

First, Enceladus is producing heat today at a much greater rate than the equilibrium value, and its eccentricity is consequently rapidly diminishing. Alternatively, Enceladus could be producing heat at the equilibrium rate, and the present-day large thermal output is coming from stored heat that has accumulated over a long period. These two scenarios have quite different consequences for the predicted eccentricity evolution, and can thus (in theory) be distinguished via **astrometry**. Both, however, imply some kind of nonmonotonic behavior, as discussed further below.

It has long been understood that the coupling between thermal and orbital evolution can lead to cyclic behavior, in which the state of the moon oscillates between brief periods of high heat production and rapid (approximately tens of Myr) eccentricity damping, and longer periods of low dissipation and slow (approximately hundreds of Myr) eccentricity growth. Such cyclic behavior could plausibly explain the different surface ages observed (Section 4). The total power output from the tiger stripes and the surrounding SPT regions is still quite uncertain; nor is it clear what fraction (if any) of the measured power output is being produced by present-day tidal heating. If Enceladus is currently in a highly dissipative state with decreasing eccentricity, the tidal stresses will also decrease over time and thus reduce the widths of the cracks that open and close. In this scenario we are seeing Enceladus today in the "active" part of its duty cycle, which probably represents only a few percentage of the total. The perhaps uncomfortable implication is that we are seeing Enceladus today at a very special time, a circumstance that has a rather low probability.

Alternatively, Enceladus may be producing heat at the constant (equilibrium) rate, but only releasing it episodically in bursts—one of which we are seeing now. There are plausible ways in which this might happen. For instance, convection beneath a weak lid can result in episodic, regional outbursts of heat, which share some characteristics with those inferred for the SPT of Enceladus. Similar scenarios can probably be constructed for situations in which the majority of this heat is advected along individual fractures (Figure 39.6(b)). For instance, progressive shell thickening leads to pressurization of the ocean and presumably more vigorous eruptions, which will depressurize the ocean and reset the process. If the surface heat flux is really being supplied by a flux of $\sim$2000 kg/s from the ocean, then a 10-km-thick ocean (representing 5% of Enceladus' mass) would be exhausted in 100 Myr. The energy required to remelt that mass (at the equilibrium rate of 1.1 GW) would take roughly 0.5 Gyr to accumulate. These kinds of timescales are roughly consistent with the inferred variations in surface ages. Whichever scenario is correct, it seems necessary to ensure that any body of liquid within the moon never freezes completely, because once fully frozen, subsequent tidal heating is reduced and remelting becomes much more difficult if not impossible. Localized tidal heating is one mechanism for ensuring a persistent regional sea of liquid (see Section 6); tidal heating within a shallow ocean itself may also be a possibility.

The lack of any equivalent to the SPT in the northern polar regions remains a puzzle, because tidal heating is expected to be symmetrical about the equator. Of course, once initiated, a runaway thermal process can take place locally, with tidal heating leading to a weaker rheology and thus more focused tidal heating. Nonetheless, something has to initiate the runaway to begin with. Some possibilities exist. A giant impact, which on other Saturnian moons (such as Iapetus) created large basins, might have deposited sufficient heat to soften the ice and initiate local tidal heating and convection. Or during the moon's formation, stochastic accretion of relatively large **planetesimals** could have formed an irregular silicate core, with liquid water surviving in pockets at the silicate/water interface. Through polar wander and reorientation, in both cases, the region containing liquid water underlying a thinner ice shell would have ended up at one of the poles.

A similar problem exists concerning Mimas; this body is closer to Saturn and more eccentric, yet it shows no signs of activity, either now or in the past. Again, one can appeal to a runaway tidal heating process at Enceladus, perhaps initiated by the fact that Enceladus has a slightly higher rock to ice ratio than Mimas, and thus more radiogenic heating, to explain why the moons are so different. But in all cases, one is left with having to appeal to poorly understood initial conditions to explain the observations. These examples illustrate our incomplete understanding of how Enceladus evolved.

8. CONCLUSIONS

Although our understanding of Enceladus is still evolving rapidly, Figure 39.6 provides a reasonable snapshot of the current state of knowledge. Enceladus has probably gone through several cycles of activity and dormancy, and we are very fortunate in seeing it in one of the former right now. The activity derives from tidally driven opening and closing of cracks, allowing warm water-filled fractures to periodically become exposed to vacuum, thus generating plumes of water vapor and salty ice grains. Enceladus possesses a regional sea beneath the SPT, but probably not a global ocean. Its shell may be undergoing convection locally beneath the SPT, but not globally. At earlier times, other parts of Enceladus' surface were probably undergoing processes similar to what we are seeing at the SPT today.

9. THE FUTURE

Future analysis of Cassini data may help to fill in some of the gaps in our understanding. For instance, astrometry of Enceladus' orbit could reveal whether or not Enceladus' eccentricity, and hence the physical state of its interior, are truly in equilibrium. Similarly, a detection of longitudinal librations by a thorough analysis of Cassini high-resolution images of its surface would help to determine whether the subsurface ocean is global or regional in extent.

Ultimately, future spaceflight missions will be required to make significant advances in understanding the nature and history of the moon's interior and its observed south polar activity. An Enceladus orbiter could more accurately map the moon's gravity field and surface topography, revealing its internal distribution of mass, confirming the thickness of the ice shell and the presence of any subsurface liquid layer and/or concentration of liquid under the SPT. A small lander, equipped with a seismometer, placed within a tiger stripe and close to a locale of high geysering activity could detect the motion of underground liquids. Both mission types, as well as simpler missions that merely fly-through the near-surface regions of the geysers, could be equipped to detect unambiguously, in a way that Cassini cannot, the presence of large organic compounds of biological interest. Such missions could also include a sample-return capsule to collect plume particles and return them to Earth.

The capability of detecting large organic compounds is of critical importance in assessing the astrobiological potential of Enceladus. Organic molecules, **biologically available nitrogen**, an energy source, and a long-lived reservoir of liquid water—four of the key attributes of a habitable environment—are all demonstrably present. Possible anaerobic ecologies that could thrive in a deep, sunlightless environment are present in subsurface environments on the Earth, metabolizing in the absence of sunlight by consuming molecular hydrogen and either carbon dioxide or sulfate. The possibility of oxidants produced at the surface by irradiation by high-energy particles and delivered by convection within the ice shell to the subsurface reservoir only increases its habitability. Since the geysers are likely directly connected to a long-lived water reservoir, itself in contact with silicates, they essentially provide "free samples" of that habitable environment below. This particular set of circumstances makes the habitable zone on Enceladus one of the most accessible in the solar system. If life has taken hold on Enceladus, it is there for the taking.

1. INTRODUCTION

Triton is the major moon of the planet Neptune. It is also one of the most remarkable bodies in the solar system (Figure 40.1). Its orbit is unusual, circular, and close to Neptune, but highly inclined to the planet's equator (by 157°). Furthermore, Triton's sense of motion is retrograde, meaning it moves in the opposite direction to Neptune's spin (Figure 40.2). Triton's history, therefore, must have been quite different from those of "regular" satellites, such as the moons of Jupiter, which orbit in a prograde sense in their primary's equatorial plane. The modern consensus is that Triton originally formed in solar orbit and was subsequently captured by Neptune's gravity.

Like nearly all solar system satellites, Triton has had its spin period increased by tides to be coincident with its orbital period and these effects have also shifted its spin axis to be nearly perpendicular to its orbital plane. Consequently, one hemisphere of Triton permanently faces Neptune. The combination of Neptune's axial tilt (29.6°) and Triton's inclined orbit gives Triton a complicated and extreme seasonal cycle. In the distant geological past, tides associated with Triton's capture may have strongly heated and transformed its interior.

Although Triton was discovered soon after Neptune, little was learned about it until the modern telescopic era, and even so, most of the information we have was acquired during the *Voyager 2* encounter with Neptune in 1989. Triton is a relatively large moon (1352 km in radius), larger than all the midsize satellites of Saturn and Uranus (200−800 km in radius), but not quite as large as the biggest icy satellites—the Galilean satellites and Titan (1570−2630 km in radius). It is a relatively dense world (close to 2 g/cm^3), rock rich, but with a substantial proportion of water and other ices. Ices comprise its reddish visible surface (Figure 40.1), and the freshness of the ices cause Triton to be one of the most reflective bodies in the solar system (its total or Bond albedo is ≈0.85). This, combined with the satellite's distance from the Sun (30 AU), makes Triton's surface a very cold place (≈38 K). Yet, despite these frigid surface conditions, *Voyager 2* discovered a thin atmosphere of nitrogen

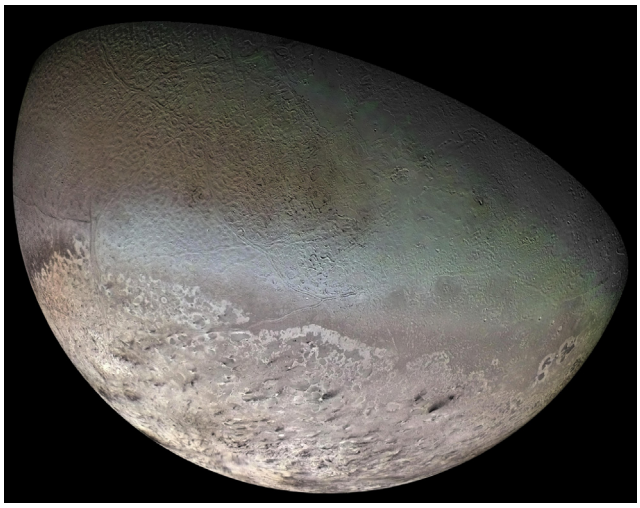

FIGURE 40.1 Digital photomosaic of Triton, centered on the Neptune-facing hemisphere at 15°N, 15°E. The latitude of the subsolar point at the time of the *Voyager* encounter was −45°, so the north polar region was in darkness. Triton's surface is covered with deposits of solid nitrogen with small admixtures of radiation-reddened and radiation-darkened methane; the bluish tinge is characteristic of fresh frosts. Because Triton's spin is tidally locked to Neptune, the eastern hemisphere (to the right) is also the leading hemisphere in its orbit. *Courtesy of the NASA Planetary Data System Photojournal.*

surrounding the satellite (14 μbar surface pressure, where 1 bar is the approximate surface pressure of the Earth's atmosphere). Triton's atmosphere is dense enough to support clouds and hazes and to transport particles across Triton's surface. It is also changing; since 1989 it has been warming and increasing in total mass and pressure.

As with all solid planets and satellites, Triton's history is written into the geological record of its surface. Triton, however, is a geologically young body. Most of the approximately 40% of the satellite's surface that was imaged by *Voyager* at sufficient resolution tells us that it is sparsely cratered. No heavily cratered terrains survive from early solar system times, an absence that may reflect an epoch of severe tidal heating. The geologic terrains that do survive are unique in the solar system. Particularly notable are the enigmatic "cantaloupe" terrain and a hemispheric-scale polar deposit or cap. The polar cap is thought to be predominantly solid nitrogen. Other ices that have been identified on Triton are, in approximate order of abundance, H_2O, CO_2, CH_4, CO, HCN, and possibly C_2H_6. The cap is a site of present-day geological activity, in particular the eruption of plumes or geysers of gas and fine particles.

In the following sections, Triton will be described in greater detail with emphasis on its geology, the interaction of its icy surface and atmosphere (including the plumes), and its probable origin and violent early evolution.

2. DISCOVERY AND ORBIT

Acting on the mathematical prediction of Urbain Le Verrier, astronomers at the Berlin Observatory first identified the planet Neptune on September 23, 1846. It was announced in England on October 1. On that day, Sir John

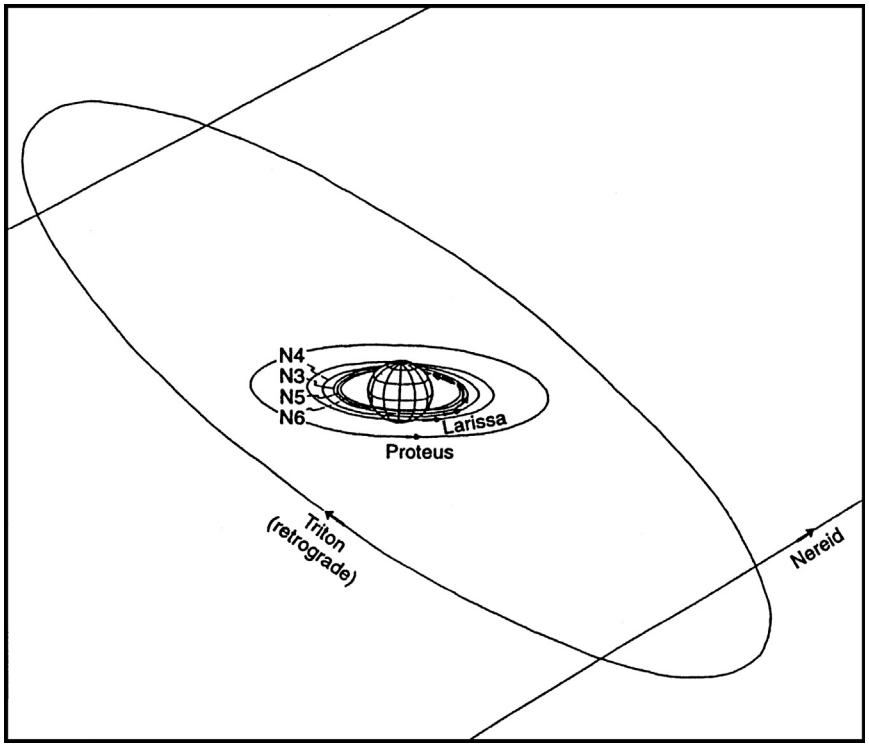

FIGURE 40.2 Orbits of Neptune's family of satellites, except distant irregulars. Shown is a perspective view along a line of sight inclined 18° to Neptune's equatorial plane. The innermost satellites are all relatively small and were not discovered until *Voyager 2* passed through the Neptune system. N3/N4/N5/N6 are Despina/Galatea/Thalassa/Naiad. They orbit in Neptune's equatorial plane, while the much more massive Triton circles outside them in an inclined, retrograde orbit. All the satellites have virtually circular orbits except for Nereid. The apparent crossing of Nereid's and Triton's orbits is an artifact of the projection. A new, small regular satellite was discovered in 2004 between Larissa and Proteus. *From Kargel, J. S. (1997).*

Herschel, son of the discoverer of Uranus, wrote to William Lassell, asking him to look for any satellites of the new planet "with all possible expedition", using his own 24-in reflector. Lassell was a brewer by profession, but he made his own telescopes and was a keen visual observer. Herschel was no doubt seeking to ease some of the sting of Neptune's being found by continental astronomers, given that he was aware of the independent prediction of Neptune's position by John Couch Adams and the unsuccessful search for the planet from English soil. Lassell wasted no time, making his first observations on October 2, and on October 10, 1846, he discovered Triton.

By 1930, it was established that Triton was a most unusual moon. Orbiting at 14.3 Neptune radii, or R_N (using the modern value of 24,760 km for Neptune's equatorial radius), the orbit was circular inasmuch as this could be measured, but distinctly retrograde compared with Neptune's prograde spin or sense of orbital motion. It was also *alone*. No new satellites would be found for over 100 years after Triton. The early contrast with the regular satellite systems of Jupiter, Saturn, and Uranus could hardly have been greater (*see* Neptune).

The year 1930 also marked the discovery of the dwarf planet Pluto. It was soon determined that Pluto actually crosses inside the orbit of Neptune for about 20 years of its 248-year orbital revolution. Although Pluto's orbit is also substantially inclined so that it does not actually intersect Neptune's, British astronomer R.A. Lyttleton argued that different precessions of the orbits could cause them to intersect, either in the future or in the past. In 1936, he published a paper that theoretically explored the possibility that such an orbital configuration once did exist and that Pluto was in reality an escaped satellite of Neptune. Although intriguing, this early theory is now rejected by planetary scientists. The modern view of Triton's origin, and that of Pluto and other bodies in the deep outer solar system, is discussed later in this chapter (*see* Pluto).

3. PRE-*VOYAGER* ASTRONOMY

3.1. Radius, Mass, and Spectra

Through the telescope, Triton is a faint, 14th magnitude object, never more than 17 s of arc from Neptune. Consequently, physical studies of the satellite from the ground have historically been very difficult. Because Triton shows no visible disk, only crude limits could be put on its size, or mass, for many years. But mid-twentieth century estimates implied it was one of the largest moons in the solar system and massive, possibly *the* most massive moon in the solar system. Triton was clearly a moon of mystery.

The first real breakthrough occurred in 1978, when infrared detector technology had improved to the point that a methane (CH_4) band was detected in Triton's infrared spectrum. Soon more bands were found. The relative depths of the new bands, plus their variability as Triton orbited Neptune, indicated that much (if not all) of the methane detected was in solid form, that is, an ice on the surface of Triton. Ices on the surface implied that Triton might be a relatively bright, smaller world, rather than a darker, larger body of the same visual magnitude (*see* Titan).

Methane ice on the surface also offered a potential explanation for Triton's reddish visual color. Experiments had shown that when solid methane is irradiated by solar ultraviolet (UV) rays, or bombarded by charged particles, it turns pink or red as hydrogen is driven off and the remaining carbon and hydrogen form various carbonaceous compounds. However, continued radiation or charged particle bombardment ultimately turns methane into a blackish carbon-rich residue, so Triton's persistent redness also implied that the satellite's methane ice is refreshed on a relatively short timescale.

3.2. Seas of Liquid Nitrogen?

An even more amazing discovery was made in the early 1980s. A single infrared spectral feature was found at $\approx$2.15 μm, a feature that could not be attributed to any of the usual spectral suspects (CH_4, H_2O, silicates, etc.). Nitrogen (N_2) does have an absorption at this wavelength, and because *Voyager 1* had recently determined the dominant atmospheric gas on Titan to be N_2 (not CH_4), finding nitrogen on Triton was not far fetched. The amount of nitrogen gas required to account for the absorption was quite large, however, as nitrogen, a homonuclear diatomic molecule, is a very poor absorber of infrared light. The astronomers concluded that in order to get the necessary path length for the absorption, the nitrogen had to be in condensed form, either solid or liquid. Liquid nitrogen was the favored interpretation, and a fantastic vista emerged—a satellite covered with a global or near-global sea of liquid nitrogen, along with methane-ice-coated islands or even floating methane "icebergs"!

The "problem" with liquid nitrogen is that it freezes at zero pressure at about 63 K. For Triton to have a global ocean at that temperature requires that (1) Triton should absorb most of the sunlight striking it (have a low albedo) and (2) Triton's surface should radiate infrared heat very inefficiently (have a low emissivity). For this and other reasons, planetary chemists offered a competing concept for Triton's surface, one in which both the nitrogen and methane were solid and distributed nonuniformly (Figure 40.3). Because of nitrogen's great volatility, it was argued that crystals of up to centimeter size could grow on Triton's surface over a decades-long season and so provide the path length for the 2.15-μm absorption. Methane, in contrast, would be only a minor surface component; it

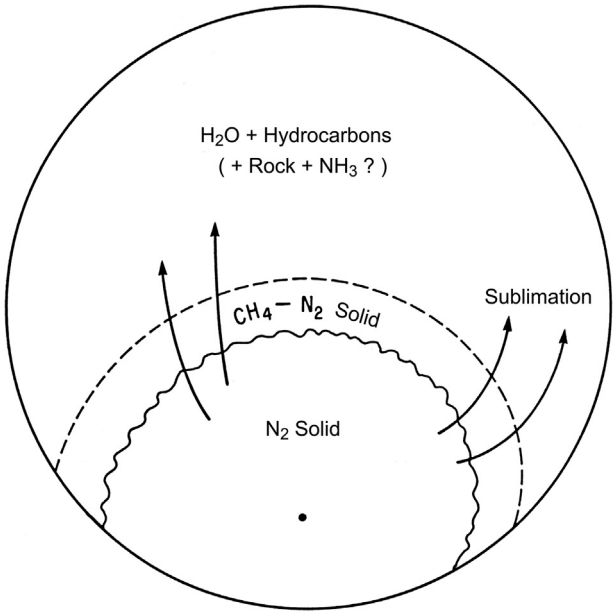

FIGURE 40.3 A pre-*Voyager* prediction for the state of Triton's surface. A subliming N_2 ice cap is centered on the illuminated south pole (dot). *From Lunine, J. I., & Stevenson, D. J. (1985).*

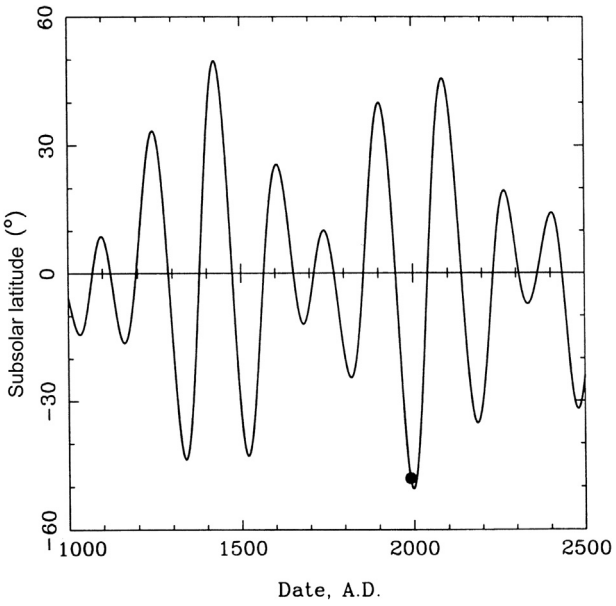

FIGURE 40.4 Seasonal excursion of the subsolar latitude on Triton. Dot shows the subsolar latitude at the time of the *Voyager* encounter. *From Kirk, R. L., et al. (1995).*

dominates Triton's near-infrared spectrum by virtue of the relative strength of its absorptions.

The difference between the two models for Triton's surface had important implications for the atmosphere and for Triton's seasons. Triton's seasonal cycle is complicated. Because of the precession of its orbit, its seasons vary in intensity and length, and in the decades before the *Voyager* encounter, Triton was moving toward the peak of maximal southern summer (Figure 40.4). Correspondingly, Triton's northern hemisphere was (and is) enduring prolonged darkness. The possibility of long-term cold traps at both poles, with strong seasonal atmospheric flows from pole to pole, was recognized. The illustration in Figure 40.4 was in fact based in part on an analogy with Mars, with N_2 replacing CO_2 as the dominant, and condensable, atmospheric constituent and CH_4 replacing H_2O as the secondary, less volatile component (an analogy that has strengthened, as will be discussed later). Specifically, a large cap of solid nitrogen was predicted for the south pole, sublimating slowly in the feeble summer sun.

3.3. Similarities with Pluto

As Triton was coming into clearer astronomical focus in the 1980s, parallel developments were occurring for other outer solar system bodies, especially Pluto. Methane ice had been discovered on Pluto prior to Triton, and overall, Pluto's visible and near-infrared spectrum bore a strong resemblance to that of Triton, although Pluto's methane absorptions were deeper. Their common bond was reinforced by their similar visual magnitudes (Pluto and its moon together are only ~0.3 magnitudes fainter than Triton when referenced to a common distance and solar phase angle).

Pluto's fundamental properties (mass and radius) were by the time of the *Voyager 2* encounter with Neptune (and Triton) relatively well constrained. Pluto's relatively large satellite, Charon, had been discovered in 1978, which allowed determination of the mass of the Pluto–Charon system by means of Kepler's third law. Careful monitoring of the Pluto–Charon system's light curve, plus observations of the occultation of a star by Pluto in 1988, established that Pluto's radius lay between 1150 and 1200 km. Pluto turned out to be a smallish, bright, more-or-less ice-covered world, and a relatively dense one as ice-rock bodies, go close to 2 g/cm^3 (*see* Pluto).

Pluto's density corresponds to a rock/ice ratio of about 70/30, and is, curiously, close to what is predicted for a body accreted in the deep cold reaches of the outer solar system. According to current thinking, the solar nebula at that distance from the Sun, when the Sun and planets were forming, was relatively cold and mostly unprocessed. The outer nebula thus retained many of the chemical signatures of the interstellar gas and dust (molecular cloud) that was the ultimate source of the solar nebula. Specifically, carbon would be in the form of organic matter and carbon monoxide (CO) gas. CO is very volatile, and the solar nebula was unlikely to have ever been cold enough for it to condense in bulk (although small amounts could be adsorbed on or trapped in water ice). The key point is that

volatile CO ties up oxygen that would otherwise be available to form water ice. Therefore, bodies formed in the outer solar system, but not near a giant planet, should have relatively *high* rock/water−ice ratios (at least initially). In contrast, in the high-pressure environment near a giant planet, CO combines with H_2 to make H_2O and CH_4, which can both condense. The resulting satellites are predicted to be much icier, with rock/ice ratios of 50/50 or less (*see* The Origin of the Solar System).

That Pluto was so rock rich was one line of reasoning that pointed to Pluto being an original solar-orbiting body and not an escaped satellite of Neptune. Dynamical evidence against Pluto being an escaped satellite also accumulated. By the 1980s it was being argued that Triton and Pluto should be considered as two independent solar system bodies, with independent histories. The link between the two, in terms of brightness (and presumably size) and composition, was that they formed in the same region—the outer solar nebula near or beyond Neptune. Essentially, they are surviving examples of large outer solar system protoplanets. Pluto became locked in a dynamical resonance with Neptune, which preserved its peculiar orbital geometry, whereas Triton was captured by Neptune's gravity (*see* Pluto).

If the analogy with Pluto is correct, then Triton should also be rock rich. If Triton had a relatively bright, icy surface like Pluto, Triton's visible magnitude implied it would probably be somewhat larger than Pluto, but its density would be similar to that of Pluto−Charon. Of course, the surface state and thus the size of Triton could not be pinned down before the *Voyager* encounter, but the consequences for Triton of being captured (as has been alluded to) were potentially spectacular. These include intense tidal heating and wholesale melting of the satellite. These ideas were appreciated by the planetary community on the eve of the *Voyager 2* encounter. So with the observational and theoretical backdrop just described, and with the promise of resolution of fundamental questions and the revelation of novelty, anticipation was high.

4. *VOYAGER* 2 ENCOUNTER

Future history will no doubt record the *Voyager* project as one of humankind's great journeys of discovery. Originally conceived as a "grand tour" of all the giant planets and Pluto, the *Mariner-class* spacecraft that were eventually launched in 1977 (and renamed *Voyager*) were only designed to encounter Jupiter and Saturn. If they worked, although, a highly capable complement of remote sensing instruments for the planets and satellites and in situ detectors for the magnetospheres and plasmaspheres would be carried into the outer solar system for the first time.

At Saturn, *Voyager 1* was targeted to pass close to Titan, a trajectory that sent it out of the ecliptic plane afterward. The trajectory of *Voyager 2* was carefully chosen to preserve the grand tour option, whereby each successive encounter would boost the spacecraft to a higher velocity and in just the right direction to reach the next giant planet, which were fortuitously arranged in the 1980s. There was no guarantee *Voyager 2* would survive the complete 12-year trip from the Earth to Neptune, many years past its design life. Problems did develop. One radio receiver went out and its backup was failing, and the articulated scan platform, on which the remote sensing instruments were mounted, could no longer move as easily as before. Nevertheless, after successful encounters at Jupiter, Saturn, and Uranus, the stage was set.

Each new *Voyager* encounter increased scientific and public awareness of the richness of the solar system. The *Voyager 2* flyby of Neptune and Triton in late August 1989 was going to be the last, and proved to be perhaps the most exciting of all. But there was one last hurdle. To get to Triton, *Voyager 2* would have to pass very close to Neptune's north pole in order for Neptune's gravity to bend its trajectory southward (Figure 40.5). This would be dangerously close (only 5000 km from the cloud tops) and in an unknown and potentially dangerous environment. To everyone's relief, *Voyager 2* made it past Neptune without incident just after midnight on August 25 (Pacific time), counting the more than 4 h it took for *Voyager's* radio signals to reach the Earth. After 5 h, it passed within 40,000 km of Triton, sending back a sequence of beautiful, mind-boggling images. These images form much of the basis for understanding, to the extent we do, Triton's geology and surface−atmosphere interactions.

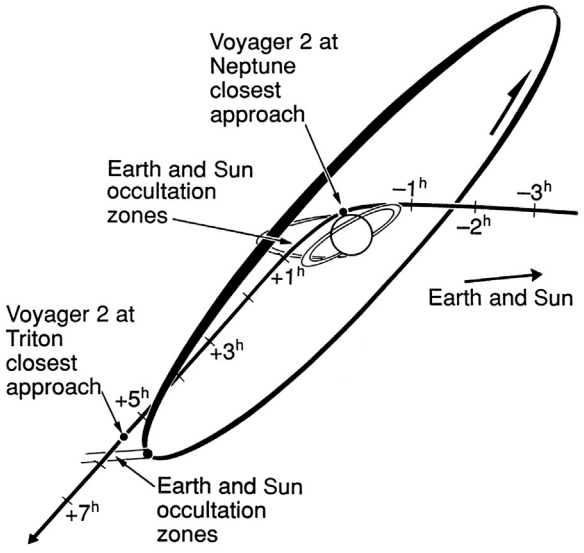

FIGURE 40.5 The trajectory of *Voyager 2* through the Neptune system. *From Chapman, C. R., & Cruikshank, D. P. (1995).*

5. GENERAL CHARACTERISTICS

Voyager 2 determined Triton to be even smaller, brighter, and hence colder than anticipated (Table 40.1). Its average geometric albedo of ≈0.7 is extreme even for an icy satellite. Triton's global appearance was revealed during the approach sequence (Figure 40.6). The view, mainly of the southern hemisphere, showed extensive bright polar materials, a bright equatorial fringe with streamers extending to the northeast, and darker low northern latitudes. Radio tracking of *Voyager* yielded a very precise mass for Triton, which when combined with the size, gave a very precise density of ≈2.065 g/cm^3. This density is essentially identical to that of the Pluto–Charon system.

With the size and mass known, internal structural models can be created based on a set of plausible chemical components; for bodies formed in the outer solar system, these would be rock, metal, ices, and carbonaceous matter. Such models provide context and to some extent guide interpretations of geological history. A calculation for Triton is illustrated in Figure 40.7. Given that little direct information exists on the internal makeup of Triton, the model shown simply matches Triton's density and assumes that the interior is hydrostatic (follows the fluid pressure–depth relation) and differentiated (the major chemical components are separated according to density). These last two assumptions are empirically consistent with Triton's surface appearance, which indicates a prolonged history of melting and separation of icy phases. In the model, ice, structurally represented by the most abundant solar system ice (H_2O), forms a deep mantle around a rock + metal core. A metallic (Fe, Ni,

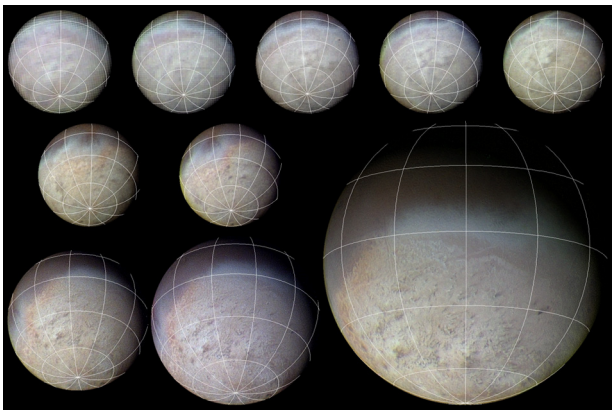

FIGURE 40.6 Triton approach sequence, overlaid with a latitude–longitude grid. Details on Triton's surface unfold dramatically as the resolution changes from about 60 km/pixel at a distance of 5 million km for the image in the upper left to about 5 km/pixel at a distance of 0.5 million km for the image in the lower right. Mainly looking at the southern hemisphere, Triton rotates retrograde (counterclockwise) over an observational period of 4.3 days. *Courtesy of Alfred McEwen, University of Arizona.*

TABLE 40.1 Properties of Triton

Radius, R	1353.5 km
Mass, M	2.140×10^{22} kg
Surface gravity, g	0.78 m/s^2
Mean density, ρ	2060 kg/m^3
Percent rock + metal by mass	65–70%
Distance from Neptune	354.8×10^3 km = 14.33 R_N
Distance from Sun	30.058 AU
Orbit period	5.877 days
Orbit period around Sun	164.8 years
Eccentricity	0.0000(16)
Inclination (present)	156.8°
Obliquity (estimate)	0.4°
Geometric albedo (average)	0.70
Bond albedo (average)	0.85
Surface temperature	38 K (1989), 39 K (2009)
Surface composition	N_2, H_2O, CO_2, CH_4, CO, HCN, C_2H_6 ices
Surface atmospheric pressure	14 μbar (1989), 40 μbar (2009)
Atmospheric composition	N_2, minor CH_4, CO
Tropopause height	8 km

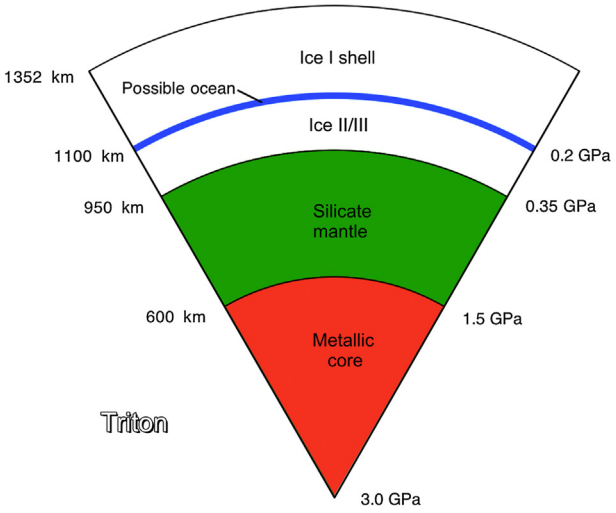

FIGURE 40.7 Internal structure model for present-day Triton. Depending on ocean composition and the amount of current tidal heating, the ocean may be much thicker, potentially reaching to the top of the rocky mantle.

and probably S) inner core is also shown. The proportions of rock and metal in the core are fixed to solar composition (carbonaceous chondrite) values, because relatively involatile rock and metal should have been completely condensed in the outer solar system. Melting and separation of metal from rock are justified by theoretical arguments for intense tidal heating in Triton's past, and by the example of Ganymede, where the *Galileo* orbiter's discovery of a dipole magnetic field demands that such an inner metallic core exists.

Whether Triton is also a magnetized body depends on when its tidal heating ended, but *Voyager 2* passed too far away to tell. Triton is, however, a sufficiently rock-rich body that solid-state convection in its icy mantle should be occurring today, powered by the heat released by the decay of U, Th, and ^{40}K in its rocky core and tidal heating due to Triton's small but finite orbital obliquity. Its icy mantle should also be warm enough to mobilize lower melting point ices such as ammonia and methanol, which are among the minor ices a body formed in solar orbit might have accreted. And if Triton formed in solar orbit, it should have also accreted a large carbonaceous component, upward of 10% by mass if comets such as Halley are a guide. But with or without these additional components, the heat flow from Triton today is sufficient to maintain an internal water layer or "ocean". Similar oceans have been discovered within the large Jovian moons Europa, Ganymede, and Callisto by *Galileo* and inferred for Saturn's Titan and especially so for Enceladus by *Cassini*, so there is no fundamental reason why Triton would not possess one as well.

Voyager 2 confirmed the presence of nitrogen ice on Triton's surface. Specifically, a thin nitrogen atmosphere was detected with a surface pressure and temperature consistent with N_2 gas in vapor pressure equilibrium with N_2 ice (see Section 7). All of Triton's surface appears to be icy; even the darker northern hemisphere shown in Figures 40.1 and 40.6 has a geometric albedo of ~0.55. Nitrogen is obviously very volatile, and theoretical models show that nitrogen ice grains on Triton's surface can rapidly (over many decades) anneal and densify into a transparent glaze or sheet. It is thought that such a nitrogen glaze covers much (but not necessarily all) of Triton.

As mentioned earlier, the overall redness of Triton's ices (Figure 40.1) is thought to be due to UV and charged particle processing of CH_4 (along with N_2), which can yield darker, redder chromophores—heavier hydrocarbons, nitriles, and other polymers. CH_4 exists as an atmospheric gas as well as surface ice. *Voyager's* ultraviolet spectrometer (UVS) solar occultation experiment determined the CH_4 mole fraction at the base of the atmosphere to be $\sim 2-6 \times 10^{-4}$, near or at saturation for 38 K. Dark streaks and patches on the polar cap and elsewhere may be methane rich; if they are depleted of N_2 ice, they should be warmer than the global mean surface temperature, which is buffered by the latent heat of nitrogen condensation and sublimation.

The nature and chemistry of Triton's surface ices have been determined by advanced ground-based spectroscopy (Figure 40.8). In 1991, astronomers detected the spectral absorptions of CO and CO_2 ice, along with CH_4 and N_2 ice. Later work confirmed the presence of water ice, and

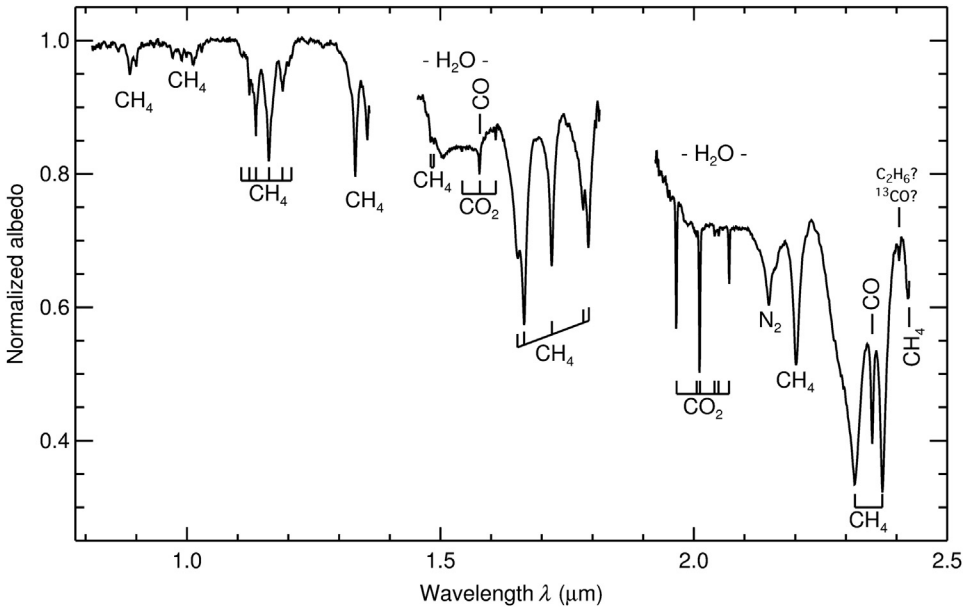

FIGURE 40.8 Modern, high-resolution, near-infrared telescopic reflectance spectra of Triton. Absorptions due to individual species are indicated. The spectral resolution ($\lambda/\Delta\lambda$) is a remarkable 1600−1700. *Modified from Grundy, W. M., et al. (2010).*

more recently, hydrogen cyanide and possibly ethane ice have been detected as well. The shapes of the absorption bands are so well determined that the abundances, grain sizes, and degree of mixing of various components can be modeled. It turns out that CH_4 and CO ice are dissolved in solid solution with the far more abundant N_2 ice, which covers about 55% of Triton's surface. The CH_4 abundance relative to N_2 could be as great as 5%, with the CO abundance less than that. CO is an important tracer of outer solar nebula or cometary chemistry (as discussed in Section 3.3), but is not expected to survive in giant planet satellite-forming nebulae. The detection of CO thus directly supports a capture origin for Triton. Some discrete CH_4 patches also exist, and the ethane ice is one of the "heavier hydrocarbons" predicted to form from methane. CO_2 and H_2O are distributed as discrete units covering the complementary 45% of the rest of the surface. Within these units, CO_2 ice particles represent about 10–20% of the material present. Water ice and CO_2 ice thus represent the composition of Triton's involatile "bedrock".

The geology revealed by the *Voyager* encounter is as remarkable as it was unprecedented. The surface is almost wholly **endogenic** in nature. Intrusive and extrusive volcanism (calderas, flows, diapirs, etc.) dominates the landscape outside the polar terrain, with tectonic structures (mainly ridges) being decidedly subsidiary. Impact cratering is an even more minor process. Triton's surface is geologically young and has apparently been active up until recent times. Triton's topography can be rugged, but does not exceed a kilometer or so in vertical scale (and usually no more than a few 100 m), due to the inherent mechanical weakness of most of the ices that comprise its surface. Polar ices appear to bury much of this topography, and so may in this sense constitute a true polar cap. Details of Triton's geology are pursued in the following section.

Triton's atmosphere is unique as well. It is too thin and cold for radiative processes to play a dominant role. Heat is transported by conduction throughout most of its vertical extent, which is by definition a **thermosphere**, up to an exobase of ~950 km, above which the mean free path of N_2 molecules exceeds the pressure/density scale height. The lowermost atmosphere is characterized by an interhemispheric, seasonal condensation flow and zonal winds. Turbulence near the ground forces the temperature profile to follow a convective, nitrogen-saturated lapse rate of approximately −0.1 K/km up to an altitude of ~8 km (as determined by observations of clouds, hazes, and plume heights), forming a **troposphere** or "weather layer". Unlike in the atmosphere of the Earth and other planets, there is no intervening radiatively controlled **stratosphere** between Triton's troposphere and thermosphere. Triton's atmosphere is further considered in Section 7.

6. GEOLOGY

Triton's surface, at least the 40% seen by *Voyager* at resolutions useful for geological analysis, can be roughly separated into three distinct regions or terrains: smooth, walled, and terraced plains; cantaloupe terrain; and bright polar materials. Each terrain is characterized by unique landforms and geological structures. Substantial variations within each terrain do occur, and the boundaries between each are in many locations gradational, but in general the classification of Triton's surface at any point is unambiguous. Certain geological structures are common to nearly all terrains, specifically, the tectonic ridges and fissures, and impact craters, naturally, can form anywhere.

Although Triton's surface is composed almost entirely of ices, many of the individual geological structures can be readily interpreted as variations of structures terrestrial planet geologists would find familiar, such as volcanic vents, lava flows, and fissures. The volcanic features in particular have inspired a designation **cryovolcanic** in order to distinguish them from those formed by more familiar silicate magmatic processes. The physics and physical chemistry are fundamentally the same, however, whether one deals with silicate or icy volcanism. There are in addition geological structures and features on Triton that are unusual and *not* readily interpretable in terms of terrestrial analogs. Some defy explanation altogether.

6.1. Undulating, High Plains

Plains units are found on Triton's eastern or leading hemisphere (referring to the sense of orbital motion, to the right in Figure 40.1) and to the north of the polar terrain boundary. Figure 40.9 shows a regional close-up of various plains near the terminator in the center of Figure 40.1. To the bottom and right of the image are flat-to-undulating smooth plains centered around circular depressions or linear arrangements of rimless pits. These plains are relatively high standing and bury preexisting topography, with edges that may be well defined or diffuse. There is little doubt that these high plains are the result of icy volcanism and that the various pits and circular structures are the vents from which this material emanated. In general, eruptions along deep-seated fissures or rifts often manifest as a series of vents, and the irregular, ~85-km wide circular depression toward the lower left resembles a terrestrial volcanic caldera complex. This feature, Leviathan Patera (all the features on Triton have been given names drawn from the world's aquatic mythologies), sits at the vertex of two linear eruption trends. Toward the terminator (northeast), one of these trends is anchored by another caldera-like depression of similar scale.

Volcanic activity on the Earth often occurs in cycles, whereby magma formed by partial melting in the mantle

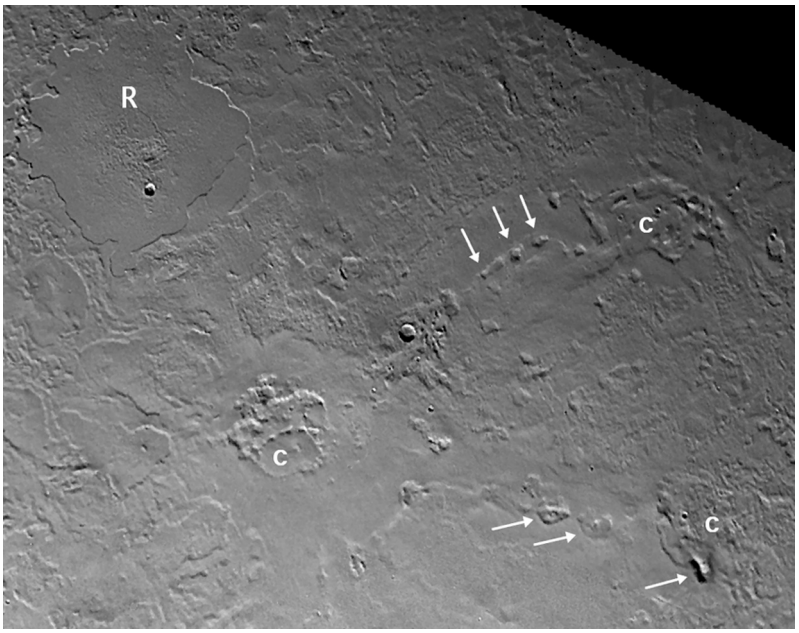

FIGURE 40.9 Young volcanic region on Triton. Toward the bottom and right, smooth undulating flows apparently emanate from complex caldera-like depressions (c) and linear alignments of volcanic pits and vents (arrows at examples), burying preexisting topography. At the upper left, terraced plains surround an exceptionally level plain, Ruach Planitia (R). This region, 675 km across in the image, is very sparsely cratered. North is up. *Courtesy of NASA/Paul Schenk, Lunar and Planetary Institute.*

rises due to buoyancy; accumulates at intermediate, crustal levels to form a magma chamber; and subsequently erupts; things are then quiescent until the magma is replenished and the cycle begins anew. The loss of magma volume often leads to collapse of the vent region over the magma chamber, forming a caldera. Cycles of eruption and collapse can create some complex forms, but calderas are generally composed of quasicircular elements. The two paterae (from the Latin for saucer) in Figure 40.9 are clearly of the caldera type in which renewed volcanism has occurred, because both are partially buried by younger icy lavas or cryoclastic "ash".

The compositions of the icy lavas are, strictly speaking, unknown. *Voyager 2* carried no remote sensing instruments designed to determine compositions. However, the icy plains-forming lavas shown in Figure 40.9 were clearly viscous enough to form thick-enough deposits to bury preexisting topography of a few hundred meters elevation, and the favored composition for viscous lavas on icy satellites has long been ammonia water. As outlined by pioneering planetary chemist J.S. Lewis, ammonia (NH_3) is the chemically stable form of nitrogen in a low-temperature gas of solar composition, and when condensed forms various hydrates with water ice, all of which have low melting points. Triton would not have accreted much ammonia if it formed in solar orbit, because N_2 would have been the dominant original form of nitrogen in the outer solar nebula for the same reasons CO and organic material were favored over CH_4 (see Section 3.3), but it still would have acquired some NH_3 based on cometary compositions (up to 1% or 2% compared with water). The predicted NH_3–H_2O ice mixture would, on heating in Triton's mantle to a rather mild 177 K, yield a lowest melting point (or eutectic) melt. This melt (or cryolava) would be ammonia rich (about 32 mol%) and have a viscosity similar to some types of basaltic magma.

Comets also contain a host of other exotic, presumably interstellar, ices, some of which may have been important in Triton's geological history. For example, methanol (CH_3OH) pushes the minimum melting temperature of ammonia–water ice down to ~152 K, and the resulting lava is even more viscous, equivalent to certain types of silicic lavas on the Earth. The range of viscosities available to liquids in the H_2O–NH_3–CH_3OH system is compatible with the appearance of the undulating smooth plains seen in Figure 40.9 (*see* Physics and the Chemistry of Comets).

The abundances of original ices may also have been altered, and new ices created altogether, during Triton's tidal heating epoch (see Section 8). For example, *copious* NH_3 and CO_2 may have been chemically produced within Triton provided there was a sufficient supply of nitrogen and carbon. Despite these exciting possibilities, neither NH_3 nor CH_3OH ice have yet been discovered on Triton by ground-based spectroscopy (Figure 40.8), although they have been identified on other Kuiper belt objects.

6.2. Walled and Terraced Plains

Shown in the northwest corner of Figure 40.9 is a ~175-km-wide, remarkably flat plain, Ruach Planitia, that

is bounded on all sides by a rougher plains unit that rises in one or more topographic steps (scarps) from the plain floor. It is one of the four so-called walled plains identified on Triton; these are generally quasicircular in outline, with typical relief across the bounding steps or scarps of ~200 m. Ruach Planitia and the other walled plains are the flattest places seen on Triton, which implies infill by a very fluid lava or other liquid. Clusters of irregular, coalesced pits toward the centers of these plains have been likened to eruptive vents or drainage pits.

The planitia themselves have been likened to calderas, but they are generally much larger than the nearby paterae and do not resemble them structurally. Specifically, there is no evidence for collapse at the periphery of any of the walled plains. Rather, the outline of the inward-facing scarps is indented and crenulate, with islands of the bounding plains occurring in the interior. If anything, the outlines of walled plains resemble eroded shorelines. How erosion occurred and under what environmental conditions on Triton is unclear. If the fluid that filled the planitia was responsible for the erosion, it does not explain the similar outline of the plains that overlap the eastern edge of Ruach Planitia (Figure 40.9), which gives this area a terraced appearance and indicates that the rougher plains were laid down in layers. A distinct possibility is that the layers are composed at least in part of a more friable or volatile material, and that over time (or with higher heat flows) the layers disintegrated and the scarps formed by retreat. Similar processes of mass wasting, removal, and scarp retreat are believed to be responsible for the etched plains of the Martian south polar region and similar terrains on Jupiter's Io.

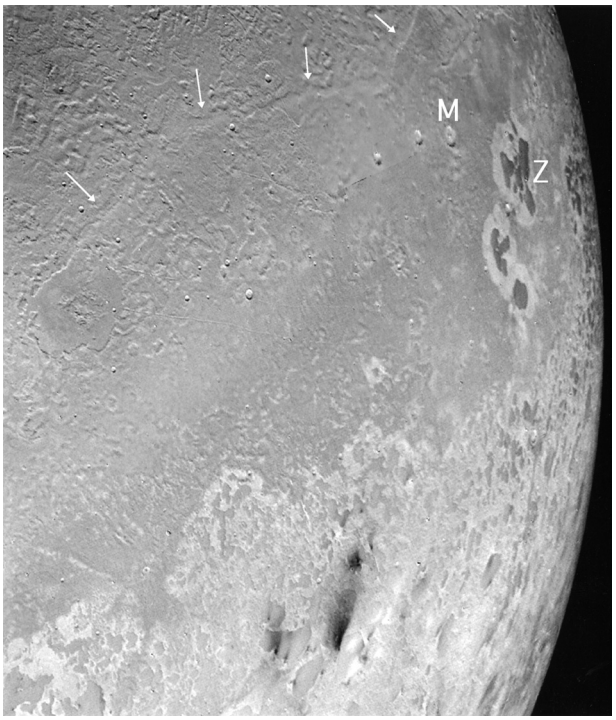

FIGURE 40.10 Southeastern limb of Triton, showing (from top) hummocky terrain, smooth terrain, and bright polar terrain. A prominent bulbous ridge zigzags across the top (arrows), and distinct bright-ringed dark features of uncertain origin, termed maculae (spots), are seen at the right, and more faintly, along the limb and in the bright terrain. The largest crater on Triton, the 25-km-diameter, central-peaked Mozamba (M), is to the left of the largest prominent macula, Zin (Z). *Courtesy of NASA/Paul Schenk, Lunar and Planetary Institute.*

6.3. Smooth Plains and Zoned Maculae

Other plains units can be seen in Figure 40.10, as well as the transition to the bright polar materials. At the top left is a hummocky terrain, composed of a maze of depressions and bulbous mounds. Stratigraphically, it is older than the volcanic plains to the north that overlap it, and appears older (more degraded) as well. The hummocky terrain gives way to a much smoother plains unit to the south. At the available resolution it is unclear whether this smoothness is due to volcanic flooding, volcanic or condensation mantling, or some other form of degradation. These hummocky and smoother units are the most heavily cratered regions on Triton, but by solar system standards are not heavily cratered at all.

Among Triton's most perplexing geological features are the large zoned maculae (spots) close to the eastern limb are shown in Figure 40.10. Each such macula consists of a smooth, relatively dark patch or patches surrounded by a brighter annulus or aureole. The width of any given annulus tends to be relatively constant (20–30 km for the three major maculae shown in Figure 40.10). The maculae betray almost no topographic expression, and so must vary in height across their extents by no more than a few tens of meters. The darkness and redness (Figure 40.1) of the central patches implies the presence of carbonaceous material, which probably means some methane ice is or was present. The brightness of the annuli is similar to that of the bright terrain, so they may consist of similar ices (mostly N_2).

The extreme eastern limb shown in Figure 40.10 is composed of a mosaic of maculae, and much of the bright terrain in the rest of the image contains similar, although generally less distinct, features (see also Figure 40.1). Perhaps the maculae are outliers of the southern polar cap, which should have been retreating at the season observed (late southern spring). Furthermore, another walled plain can be seen along the middle left edge of the frame. If this planitia were filled with bright ice, it would passably resemble, in plan and in albedo, the bright terrains to the south, especially those near the boundary with the smoother plains. Perhaps the maculae are planitia underneath.

6.4. Cantaloupe Terrain, Ridges, and Fissures

The entire western half of Triton's nonpolar surface shown in Figure 40.1 is termed cantaloupe terrain, as it appears covered by large dimples and crisscrossed by prominent quasilinear ridges. Much of the terrain displays a well-ordered structural pattern: at high resolution, the dimples become a network of interfering, closely spaced, elliptical and kidney-shaped depressions, termed cavi (Figure 40.11). Unlike impact craters, the cavi are of roughly uniform size, ~25–35 km in diameter, and do not overlap or cross-cut. They are clearly internal in origin, but the leading explanation is not volcanism, but *diapirism*.

Diapirism is triggered by a gravitational instability involving a less dense material rising through overlying denser material. The required buoyancy may be thermal or compositional. Probably the best known terrestrial examples of **diapirs** are salt domes, in which a layer of salt rises as a series of individual blobs, or diapirs, through overlying denser sedimentary strata. In one region of extreme dryness, the Great Kavir in central Iran, the salt diapirs breach the surface, rotating and pushing the overlying strata to the side. The shapes, close spacing, and interference relations of the diapirs of the Great Kavir in fact bear a significant resemblance to the cavi.

The implications of a diapiric origin for cantaloupe terrain are that Triton possesses distinct crustal layering, and based on the spacing of the cavi, that the overlying denser layer or layers are ~20 km thick. This crustal layer could simply be a weaker ice (possibly ammonia rich) that responded to heating from below, or it may be an ice denser than the ammonia–water ices presumably below (such as CO_2 ice).

Triton's surface is cross-cut by a system of ridges and fissures, which are best expressed in the cantaloupe terrain (Figure 40.1). The ridges occur in a variety of forms: pairs of low, parallel ridges bounding a central trough, ~6–8 km across crest to crest and a few hundred meters high; similar but wider ridge-bounded troughs with one or more medial ridges (one, Slidr Sulcus, can be seen in Figure 40.11); and single, broad, bulbous ridges (e.g., Figure 40.10). The fissures, which are less numerous, appear to be simple, long, narrow valleys only 2–3 km wide. All these fundamentally tectonic features appear to result from extension and/or strike-slip faulting of Triton's surface. The medial ridges may be due to dike-like intrusions of icy material, and the bulbous appearance of some may be due to overflow of such injected ice, which could also be a source for smooth plains deposits. Ridges on Triton bear more than a passing resemblance to those on Europa, and a similar mechanical origin has been proposed (*see* Europa).

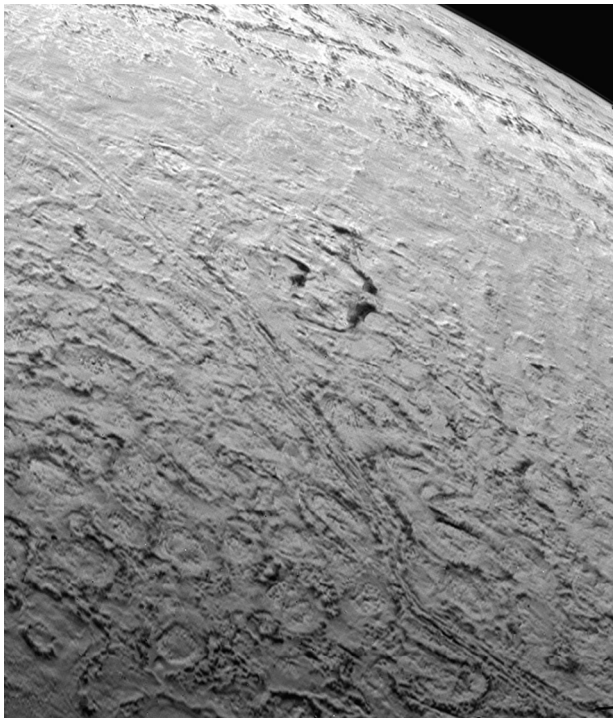

FIGURE 40.11 Cantaloupe terrain at the bottom and polar terrain at the top, in this high-resolution *Voyager* image taken from a distance of 40,000 km. Each cantaloupe "dimple" is about 25–35 km across. A tectonic ridge and fissure set runs through the cantaloupe terrain, probably formed (at least in part) by the extension of Triton's icy crust. Toward the south (upper right), smooth materials, and beyond them, brighter ice, appear to mostly bury cantaloupe and fissure topography.

6.5. Bright Polar Terrains

Most of Triton seen by *Voyager* is actually bright terrain of one type or another, but the imagery is generally not of sufficient quality for geological analysis. Interpretations are further confused by the numerous dark streaks, plumes, and clouds. Nevertheless, the bright terrains represent substantial, not superficial deposits. The view shown in Figure 40.11 looks across the edge of the cantaloupe terrain, into a band of subdued or mantled cantaloupe-like topography, and then into brighter materials beyond. Cantaloupe-like topographic elements and sections of a linear ridge appear engulfed by bright ice, probably up to a few hundred meters in thickness. The important questions are whether the bright ice thickness increases into the interior of the bright materials in the distance and does it become sufficiently deep to qualify as a true polar cap.

Low-resolution imagery shows that quasicircular elements can be made out at many locations well within the bright materials. Ridges also cross into the bright terrains, and one bright lineament is seen close to the south pole. The implication is that much of the polar topography is

incompletely buried. On the other hand, there are extensive bright, featureless regions as well (up to several 100 km across), which indicate either complete burial at these locations or obscuration by clouds. Overall thickness of the bright polar ice is therefore probably less than 1 km, but even if not organized as a uniform ice cap or sheet, a thick deposit of a volatile ice such as N_2 could be warm and deformable enough at its base to flow laterally. Although not literally a polar cap, much of the bright polar terrains may behave as if glaciated.

6.6. Geological History

The volcanic province shown in Figure 40.9 is one of two similar ones, with the second occurring to the southeast and together stretching across 1000 km of Triton's surface. The alignments of volcanic vents in both provinces suggest extension and rifting of Triton's relatively strong icy outer shell, or lithosphere. The volcanic plains shown in Figure 40.9 are also very sparsely cratered (the largest crater visible is 16 km across), much less cratered than, say, the lunar maria. Estimates of the rate at which comets bombard Triton suggest that these provinces are no more than 300 million years old, and possibly less than 50 million years old. A broad region of Triton's sublithospheric mantle was thus hot and partially molten very late in solar system history, and probably remains so. Such internal warmth is also consistent with a subsurface ocean (Figure 40.7).

The high volcanic plains postdate most of the other terrains on Triton. They stratigraphically overlie the terraced plains to the west and the hummocky plains to the east. The terraced plains grade into and appear to superpose the cantaloupe terrain. The relative age of the cantaloupe terrain cannot be determined by traditional crater counting methods, because the rugged topography there prevents reliable crater identification in *Voyager* images. Stratigraphically, however, cantaloupe terrain appears to be the oldest unit on Triton. The linear ridges obviously postdate the cantaloupe terrain, yet some ridges fade into the terraced plains to the east and another is discontinuous as it crosses the hummocky and smooth plains near the equator to the east (Figures 40.1 and 40.10); no ridges cut the high volcanic plains.

The eastern hummocky and smooth plains comprise the most heavily cratered region on Triton, and when due account is taken of the concentration of cometary impacts on Triton's leading hemisphere (Figure 40.12), appears to be somewhat older than the high volcanic plains to the north and northwest. The cantaloupe terrain, then, must be even older. The hummocky terrain may be a degraded version of cantaloupe terrain. Indeed, cantaloupe terrain has been suggested to underlie much of Triton's surface. (For example, cantaloupe-like topography extends well south into the bright region of the trailing hemisphere.)

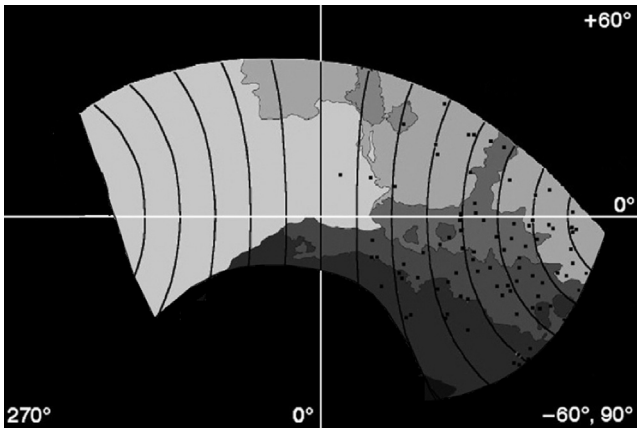

FIGURE 40.12 Distribution of craters (greater than 5 km across) on Triton. Craters are indicated by black dots on a simple cylindrical map, but only those regions with viewing geometries suitable for crater counting are shown. Circles represent concentric zones centered on the apex of motion at 10° intervals. Shadings indicate different geological units, with the major unit at the left being the cantaloupe terrain. *Modified from Schenk, P. M., & Zahnle, K. (2007).*

The youngest surfaces on Triton, naturally, involve the mobile materials of the bright terrains. These probably include the zoned maculae of the eastern hemisphere. The geological substrate on which the bright materials reside may of course be older. The walled plains themselves are locally the youngest stratigraphic units. Ruach Planitia and a larger planitia immediately to the west are less cratered than the high volcanic plains, albeit with a large statistical uncertainty. The filling of these walled plains may thus represent the most recent volcanic activity on the hemisphere of Triton seen by *Voyager*.

The concentration of craters on Triton's leading hemisphere is pronounced (Figure 40.12), so much so that it has been proposed that the dominant impactors are not comets, but rather, small bodies intrinsic to the Neptune system. Although no plausible source of such "planetocentric" impactors has been identified, if true, Triton's smooth and volcanic plains could be as young as 10 million years old, which would make Triton the most internally active icy satellite after Enceladus. What geologic richness awaits the future spacecraft tasked to more fully survey Triton's surface!

7. ATMOSPHERE AND SURFACE

7.1. Atmosphere

Triton is one of only seven solid bodies in the solar system with an appreciable atmosphere, and one of only four in which the major component of the atmosphere also condenses onto the surface. Triton's atmosphere is composed primarily of nitrogen. The complicated oscillation of the

subsolar latitude with time drives an exchange of N_2 and trace species between the atmosphere and surface frost deposits in the two hemispheres that is equally complicated and as yet not fully understood. Internal heating (which is comparatively important because of Triton's extreme distance from the Sun and large proportion of rocky materials containing radioactive elements) and even glacier-like creep of solid nitrogen caps may also play important roles in the interaction of atmosphere and surface (*see* Io; Mars: Atmosphere: History and Surface Interaction).

As described in Section 3, spectroscopic evidence prior to the *Voyager 2* encounter indicated that nitrogen existed on Triton in condensed form. *Voyager* showed Triton to be much smaller, brighter, and colder than had been guessed. Surface temperatures could be inferred from the visible reflectivity as well as measured directly by the Infrared Interferometer Spectrometer. Occultations (passage of the spacecraft or a star behind Triton) observed by the UVS and Radio Science Subsystem probed different parts of the atmosphere, revealing its temperature and density, from which pressure and composition could be deduced. These investigations revealed a consistent picture of a surface and lowermost atmosphere at about 38 K. The pressure at the surface was only 14 μbar, indicating that the gas was in equilibrium with solid nitrogen at the same temperature. The thermal structure of the lower atmosphere is not well constrained, but the temperature probably reaches a minimum at about 8 km height, above which it increases to about 100 K in the upper atmosphere because of heat deposited from space and conducted downward. In meteorological parlance, Triton's thermosphere directly overlays its troposphere.

The *Voyager* images and occultation data revealed a variety of condensates in the lower atmosphere. Most of the atmosphere contains a diffuse haze that can be seen against the background of space at Triton's limbs, and which probably consists of hydrocarbons and nitriles produced by the action of sunlight on trace gases such as methane. Discrete clouds were also seen at the limbs and beyond the terminator, where they formed east–west trending "crescent streaks" roughly 10 km wide, a few hundred kilometers long, and 1–3 km above the unlit surface. At the limbs, clouds could be distinguished from haze by being optically thicker and localized both in height (10 km or less) and in horizontal extent (patchy, and mainly concentrated at mid to high southern latitudes, where they cover one-third of the limb). The sharp upper boundary of the clouds suggests that they consist of condensed nitrogen rather than involatile solids like the haze.

The crescent streaks provide clues to atmospheric motion by their east–west orientation and the apparent eastward motion of the largest, highest cloud seen. Further clues come from markings on the surface. Over 100 dark "streaks" were seen in the southern hemisphere, mainly between latitudes of 15° and 45°S. The streaks range from 4 to over 100 km in length, and many are fan shaped. The vast majority extend to the northeast from their narrow end (presumably the origin); a smaller number are directed westward (Figure 40.13). These streaks resemble the "wind tails" that are common on Mars and are seen on the Earth and Venus as well—and which are created by deposition (or sometimes erosion) of loose material by localized eddies downwind of topographic features. It was initially difficult to understand how wind tails could form on Triton, because even the slightest "stickiness" would prevent dust grains from being lifted by the thin atmosphere.

The interpretation of the streaks as wind created was, nevertheless, strengthened by the discovery, shortly after closest encounter, that some of these features were actually atmospheric phenomena. Stereoscopic viewing of images obtained from varying angles as *Voyager 2* passed by Triton (Figure 40.14) revealed at least two with an altitude of roughly 8 km, the others being on the surface or too low (<1 km) to measure. These features were subsequently named Mahilani Plume (48°S 2°E, with a very narrow, straight cloud 90–150 km long) and Hili Plume (57°S 28°E, actually a cluster of several plumes with broadly tapering clouds up to 100 km long). Thus, it is clear that winds on Triton *do* transport suspended material, but the question is *how* the material becomes suspended.

The plumes were entirely unexpected, and explaining their vigorous activity became a major focus of research. What is clearest is that they complete a coherent picture of winds on Triton at the time of the encounter. Unlike most surface streaks, both plume clouds extend westward from their apparent sources (the plumes proper—narrow, possibly unresolved vertical columns linking the horizontal plume clouds with the surface). Images of Mahilani appear to show kilometer-sized "clumps" within the cloud moving westward at 10–20 m/s and elongation of the cloud from 90 to 150 km at a similar speed. Thus, putting all the descriptions above together (crescent streak clouds, dark surface streaks, and plume tails), the wind is northeast nearest the surface, eastward at intermediate altitudes, and westward at 8 km, the top of the troposphere.

This is precisely the circulation pattern predicted at the time of encounter, the height of summer in the southern hemisphere. Heating by sunlight is presently causing solid nitrogen in the south to sublimate (evaporate); meanwhile in the colder north, the atmosphere is condensing and precipitating. Because of the rotation of Triton once every 5.877 days, however, the wind cannot blow directly from south to north to make up the difference. Instead, gas is transported only in a thin "Ekman layer" near the surface in which the flow is northeastward. The atmosphere above this 1-km-thick layer circulates from west to east. The westward flow at the altitude of the plumes can be explained if Triton's atmosphere is slightly warmer over the equator

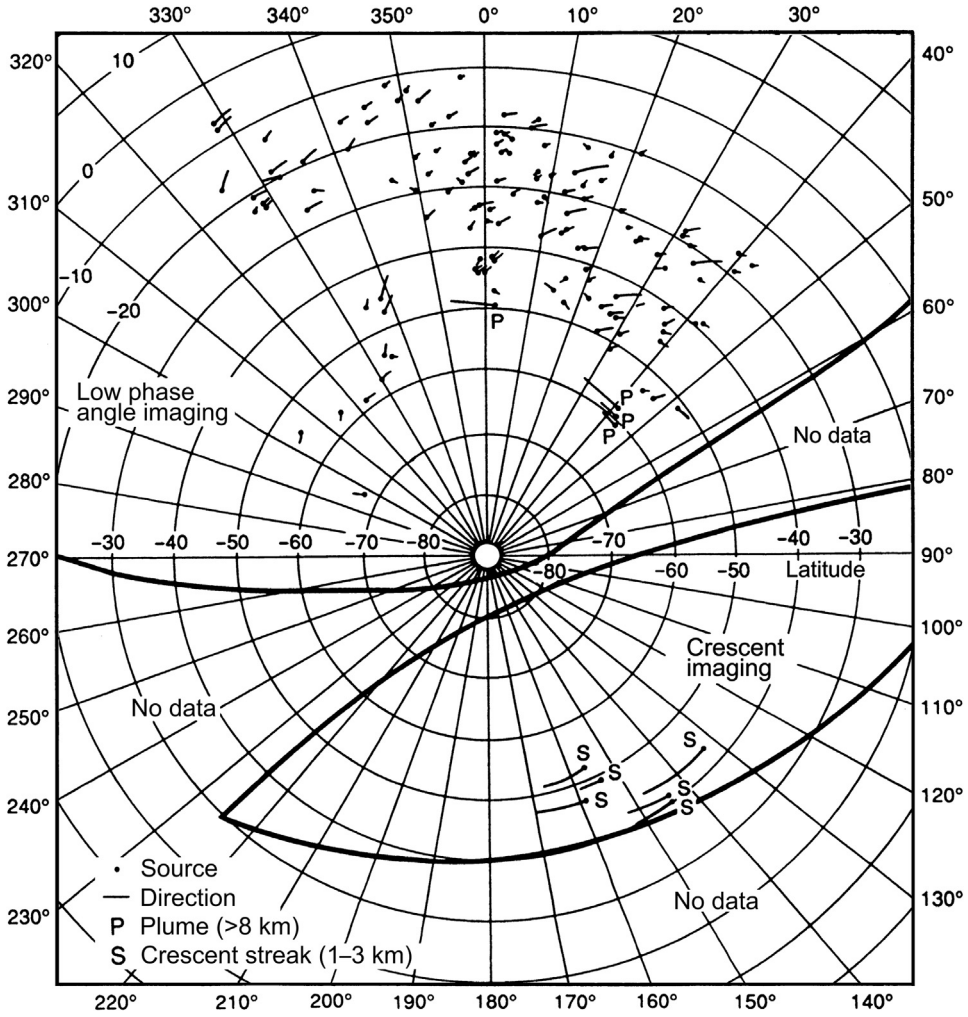

FIGURE 40.13 The geographic distribution and orientation of wind streaks, crescent streaks, and plumes on Triton as seen by *Voyager*. The latitude and longitude of each feature source is plotted as a dot; tails indicate streak or plume length and direction. *Modified from Hansen, C. J., et al. (1990).*

than at the south pole (perhaps because the equator is darker), in which case the temperature gradient will drive a thermal wind that causes the eastward flow to weaken and reverse with increasing altitude.

Basic properties of the plumes can be inferred from the images. The plume clouds do not settle out visibly (at the ~1-km resolution of the best images) over their length, so the suspended particles must be smaller than about 5 μm. From this particle size and the width and contrast of the clouds—about 5% darker when seen against Triton—one can further infer the amount of solids: about 10 kg/s must be discharged if the material is dark or twice as much if it is bright. (Bright material in a cloud would appear relatively dark against Triton's very bright surface, although not as dark as intrinsically dark material. However, bright particles deposited from such a cloud would not show up as a dark streak on the surface.) The cloud moves horizontally at the wind speed, 10−20 m/s, but the vertical velocity in the plume must be faster or the plumes would be blown visibly askew by the wind. The columns may be just barely resolved in the best images, so their diameters are 2 km or less. The source area must have similar (or smaller) dimensions. Little or no structure is visible in the columns, although a "sheath" of descending material around the plume has been described by some authors. The active lifetime of the plumes can be estimated at a few Earth years: shorter, and *Voyager* would have been unlikely to see any plumes active; longer and active plumes should have been more numerous compared with surface streaks.

7.2. Plume Models

Numerous attempts have been made to model the plumes in order to answer the questions of where the particulates, the

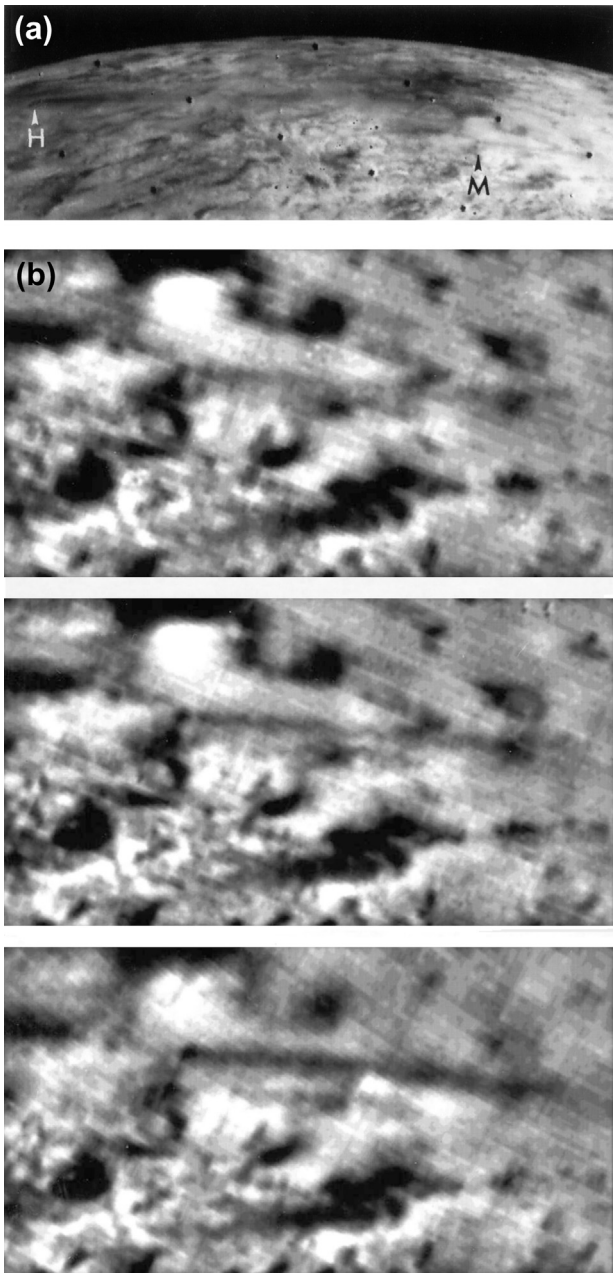

FIGURE 40.14 (a) *Voyager 2* image of the southern polar region of Triton in which geyser-like eruptions were discovered. Here plumes are viewed obliquely with Hili (H) and Mahilani (M) plumes marked. (b) Highly magnified images of Mahilani plume on Triton, taken from increasingly oblique angles and at increasing resolution (top to bottom). The images have been projected onto a spherical surface with a viewing geometry similar to that at the top. The increasing parallax from top to bottom makes the plume "stem" appear to grow taller. *Courtesy of NASA/USGS.*

gas suspending them, and the energy to drive the gas flow originate. Most models have taken their cue from the presence of the active plumes (and surface streaks) at mid to high southern latitudes at a season when the sun was almost directly overhead (Figures 40.4 and 40.13) and assumed that the plumes are somehow solar powered. It is also possible, however, that Triton's internal heat drives the plumes and that their location is determined not by the sun but by a local enhancement of this heat source (i.e., by cryovolcanic activity) or by the thickness of the nitrogen "cap", the equivalent area of the northern hemisphere being hidden in darkness during the encounter.

It is conceivable that the plumes are purely an atmospheric phenomenon. One early suggestion was that the plumes are dust devils, localized regions of spinning and ascending hot atmosphere formed above patches on the surface that are bare of N_2 frost and that can therefore be heated by the sun to higher temperatures than their frosty surroundings. Tritonian dust devils would have difficulty picking up dust from the surface and becoming visible, however, because their winds are not strong enough. If the source areas contained methane frost, though, they would give off clouds of methane gas. Being lighter than nitrogen, the methane would ascend, and might partially condense in the atmosphere, making the rising plume visible. Falling back onto the ground, the methane frost would over time darken from exposure to radiation, explaining the surface wind streaks. This model ingeniously solves the problem of how such a gently rising plume picks up or generates enough solids to become visible, but there is still the fundamental objection that such a plume would be blown sideways (as dust devils on the Earth and Mars are). A final variation on these types of plume model suggests that it is nitrogen rather than methane that is ascending and condensing, with the condensation releasing heat for buoyancy. But again, the nitrogen must somehow start off fast enough to pick up dust and to avoid being blown sideways by winds near the base of the plume.

How could a plume of nitrogen gas get started? One possibility is that they are geysers. Like geysers on the Earth, which consist of water and water vapor, those on Triton would be eruptions of volatile material that has been heated underground. The water in terrestrial geysers starts as a liquid and partially boils, whereas Tritonian geysers would start as hot gas that would partially condense as it expanded to the ambient pressure. This expansion could drive a gas flow powerful enough to pick up dust and form the observed plumes. Solar-powered nitrogen geysers have been studied in some detail. The pieces of the model are as follows.

7.2.1. Plumes as Jets

The energy needed to drive the plumes is determined by how much gas is involved and how fast it has to be erupted. The worst-case assumption is that the nitrogen does not condense as it rises. Instead of becoming buoyant and accelerating, it is denser than its surroundings because

of any inert dust entrained in it and the small amount of N_2 (several percent by mass) that crystallizes immediately on eruption. The plume is therefore slowed both by gravity and by interaction with the atmosphere around it. How high it will rise depends on both the size of the eruption and its speed and can be calculated based on laboratory simulations. As an example, a jet with a diameter of 20 m, a velocity of 230 m/s, and 5% solids by mass will reach the observed altitude of 8 km on Triton. The plumes might be this small, but they could be as big as 1−2 km in diameter, in which case they could be somewhat slower. As discussed, plumes erupting more slowly could also reach 8 km if condensation continues after eruption, but in either case the plume will stop at about 8 km because of the increasing atmospheric temperature (buoyancy) above this altitude.

7.2.2. Eruption Velocity and Temperature

Both the initial velocity of the gas and the amount of solid nitrogen that will condense can be calculated from the initial and final temperatures and the thermodynamic properties of nitrogen. The example given above (5% solids, 230 m/s) is attained for nitrogen expanding freely (no change in entropy) and cooling from 42 to 38 K. Thus, the subsurface gas must be heated about 4 K to power the geyser to the right altitude. We also learn from this calculation that the 10 to 20 kg/s of solids estimated to be feeding the plumes is accompanied by as much as 400 kg/s of gas. Given the latent heat of sublimation of nitrogen, about 100 MW of power is needed to convert solid to gas at this rate, which may be supplied by a "solid-state greenhouse."

The greenhouse effect usually describes heating of the Earth's atmosphere (or that of another planet) when sunlight at visible wavelengths penetrates the atmosphere before being absorbed, but longer wavelength thermal radiation is absorbed by the atmosphere and cannot escape to space as easily. A similar effect can take place in a transparent solid, for example, nitrogen ice on Triton, which is such a good insulator that heating by 4 K can be achieved with a greenhouse layer only 1−2 m thick.

7.2.3. Subsurface Energy Transport

What happens after sunlight is absorbed below Triton's surface and before hot gas is erupted? As just estimated, 100 MW are needed to heat the gas in a typical plume. This is the amount of power deposited by sunlight on a region of Triton about 10 km in diameter, much bigger than the 1- to 2-km size of the plume sources. We can therefore conclude that gas (or energy to produce gas by sublimation) is stored over time and then released quickly, or is transported horizontally from the larger area to the geyser, or both. Somewhat counterintuitively, gas is not mainly "stored" in voids in the nitrogen ice, but is produced on demand from hot ice, while heat is mainly transported by flowing gas rather than ordinary thermal conduction. Nitrogen ice can give off more than 100,000 times its own volume of gas as it cools just 4 K. If there are voids in the solid nitrogen, this gas will flow to colder areas and recondense, warming them by releasing its latent heat. This energy flow can be hundreds of times more efficient than conduction if the pores are large enough. Flow between meter-sized blocks of solid could readily supply a geyser, but when a path to the surface was first opened eruption would be vigorous at first and decline over a period of about a year, roughly the estimated lifetime of the plumes. Energy transport by production of gas, its flow through pores, and recondensation at colder points is known on the Earth: "heat pipes" containing a condensable gas (with a wick to return the liquid to the hot end) conduct heat better than metal and are used for baking potatoes from the inside out and for controlling the temperature of spacecraft, including *Voyager*! How a suitably fractured layer of nitrogen ice, overlain by a clear, gas-tight greenhouse layer, might form on Triton is discussed in the next section.

The idea of solar-powered geysers thus seems extremely promising, although much work remains to take the separate pieces that have been modeled so far and make sure that they fit together. Internally powered geysers (more similar to their terrestrial counterparts) have not been studied nearly as thoroughly, but other possibilities exist. As discussed below, the nitrogen "polar caps" on Triton may be so thick near their center (over a kilometer) that they begin to melt at the base. Liquid N_2 finding its way to the surface could erupt as a boiling geyser, with more than enough energy to power the plumes. Gases other than nitrogen could also be erupted from deeper in Triton's water ice mantle, driven by internal heating.

Additional light was unexpectedly shed on the physics of Triton's geysers by the discovery in the early 2000s that some transient, dark spots on the Martian seasonal polar caps are not simply patches of bare ground. Some such patches are fan shaped and typically form clusters with similar orientation corresponding to the prevailing winds predicted by atmospheric models (Figure 40.15). These features form shortly after the first light of spring, only on regions known on the basis of spectral, thermal, and albedo data to be covered by a translucent layer of carbon dioxide frost on the order of a meter thick, and they fade or vanish when the CO_2 layer sublimates away. These circumstances strongly suggest that the Martian fan deposits are formed by venting of dusty gas created by solar heating at the base of the frost layer. The analogy to models of Triton's geysers described above is strong and was noted early on.

The greatest difference between the Martian features and those on Triton is one of scale: typical Martian fans are

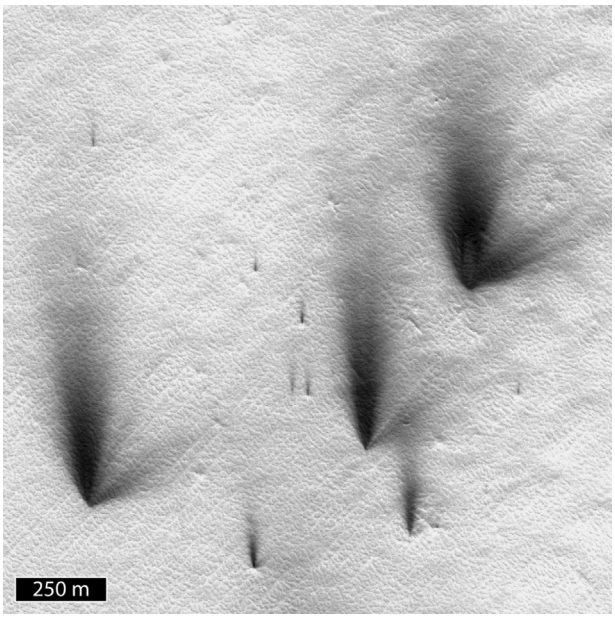

FIGURE 40.15 Fans on the south seasonal CO_2 cap of Mars. Located close to the south pole, these fans are aligned with the prevailing wind direction toward the top of the image, although secondary alignments are also visible. Similar but larger features on Triton (see Figure 40.10) may form from an analogous sunlight-driven process. *From Piqueux, S., & Christensen, P. R. (2008).*

~100 m (give or take a factor of a few) in length, and the elevation of the active plumes above the surface has not been distinguished in stereo images even at 0.3–3 m/pixel. Why should the Tritonian plumes be so much larger? Apart from the quantitative differences in temperature, volatility of the working fluid, insolation, length of season, and of course surface gravity, the greenhouse layer on Triton is believed to overlie a thick, possibly fractured permanent cap of the same (nitrogen) material. This may increase the available gas supply compared with Mars, where the frost layer sits on an inert surface of silicate soil. Radial patterns of channels eroded into this involatile layer by the flowing gas are visible around many of the Martian fan sources and are referred to as araneiforms or "spiders". Unfortunately, Voyager images are of too low resolution to show whether Triton spiders exist, or even if each Triton plume corresponds to a single, large vent or perhaps to a kilometer-scale field of smaller vents resembling those on Mars. If the latter, then the source geometry could be similar and the greater height of the geysers could be explained either by a larger eruption velocity or by buoyancy mechanisms already discussed.

7.3. Polar Cap and Climate

We turn now from the plumes to a consideration of how Triton's surface frosts and atmosphere change over time. Here, too, the *Voyager* images yielded a surprise: at the height of southern hemisphere summer (Figure 40.4), most of the southern hemisphere was covered with a bright deposit (a polar cap), but the visible portion of the northern, winter hemisphere was darker. Models of the redistribution of N_2 frost with the seasons can be constructed with varying degrees of complexity, but a fundamental expectation is that the summer hemisphere should have less of a polar cap than the winter one!

The basic physics of seasonal frost distribution models is as follows.

1. The whole atmosphere and all frosted areas are at very nearly the same temperature. If a frosted area were colder, more nitrogen would condense there and release of latent heat would raise the temperature. Conversely, a warm frost area would be cooled by sublimation. Winds would quickly even out the atmospheric pressure and temperature.
2. At this fixed temperature, sublimation occurs where frosts are exposed to the sun and condensation where the average input of solar energy is less. Sublimation/condensation rates can be calculated from the amount of sunlight absorbed at each point on Triton.
3. Bare (unfrosted) areas can be warmer than the atmosphere and frosts (if they are dark and/or well exposed to the sun), but they cannot be colder, or frost would immediately condense on them.

Using the albedo of the surface as measured by *Voyager*, models indicate that frost in most of the southern hemisphere is currently subliming, thinning the surface deposits. Nitrogen is presumably being deposited in the northern hemisphere and in a few of the brightest areas of the south where little sunlight is absorbed. Stellar occultations and infrared telescopic observations since *Voyager* have shown that Triton's surface pressure has measurably increased, to around 40 μbar. The surface temperature of the nitrogen ice, which controls the atmospheric pressure, must also have increased by 1–2 K. But what about the long run? By assuming that frost has some given albedo and that the surface underneath has some other albedo, one can model the redistribution of nitrogen over long periods. A layer of nitrogen frost about a meter thick is moved back and forth as the sun shines on one hemisphere and the other, and the pressure and temperature of the atmosphere change as well. Notably, such models predict that all nitrogen deposited in the southern hemisphere the last time it was winter there would have resublimated before *Voyager* arrived. Correspondingly, the northern hemisphere should be extensively frosted.

How can these predictions be reconciled with observation? The frost might deposit mainly in shadows and on north-facing slopes where *Voyager* could not see it, or it

could be glassy and transparent, hence invisible. There is some evidence for the last possibility, from laboratory observations of condensing nitrogen; calculations of the rate at which loose frost grains would merge or anneal into a dense, transparent layer; and even from observations of the light-scattering properties of Triton's equator. Such suggestions would each explain the dark, apparently frost-free northern hemisphere, but the bright "cap" in the south must be explained as well. Perhaps it is a much thicker deposit of nitrogen that never completely sublimes away (this is certainly the impression one gets geologically). Although nitrogen frost may be very transparent when first annealed, changing temperatures will make the residual cap expand and contract, fracturing it and making it appear bright. Thus, we are led to the idea of a clear, uncracked (i.e., gas-tight) seasonal frost layer over a thick, fractured permanent cap: precisely the kind of layering hypothesized above to explain the plumes as solar-powered geysers.

What controls the size of the residual cap, and why is one not seen in the north? A good candidate is solid-state creep, or flow, of the thick nitrogen deposit, similar to the flow of glaciers and spreading of polar caps on the Earth and Mars. Models based on terrestrial polar caps, combined with estimates of the rate at which solid nitrogen would flow, suggest that the permanent cap is about a kilometer thick at the center. Cap spreading also prevents the eventual disappearance of the seasonal frosts predicted by the models discussed above. Because the pole always receives less sunlight than the edges of the seasonal frost deposits, more frost will be deposited at the pole than at the edges, maintaining the cap. There may be a northern as well as a southern permanent cap. If this northern cap extends less than 45° from the pole, it would lie in the dark portion of Triton unseen by *Voyager*. The southern permanent cap might be larger because of hemispheric differences in the heat released from Triton's interior, or it might also extend only 45°, in which case the bright deposits extending almost to the equator have still to be explained. Some of this bright material may be nitrogen "snow" that condenses in the atmosphere into grains that are too big to anneal on a seasonal timescale into a transparent layer. It should be apparent from this discussion that, as with the plumes, we seem to have many pieces of the puzzle of the polar caps (and perhaps a few spurious pieces of unrelated puzzles), but they have yet to be assembled into a final picture of Triton's surface–atmosphere interaction.

Additional clues to the behavior of volatiles on Triton are presently being gathered from Earth-based spectroscopic measurements, and by the occultation of stars by Triton. As noted above, Triton's atmosphere is changing and becoming thicker and slightly warmer. Strong winds aloft are also indicated. Surface–atmosphere interactions on the polar caps of Mars are also being studied in great detail, and the lessons learned are being applied to Triton. And of course, continued monitoring and study of Pluto provides a valuable second case against which to test theoretical models.

8. ORIGIN AND EVOLUTION

Triton and Pluto turn out to be remarkably similar in size and density and in surface and atmospheric compositions as well. There is little doubt that they share a common heritage. Moreover, they are not isolated in the outer solar system. An entirely new reservoir of minor planets has been found orbiting near and beyond Neptune—the Kuiper belt. The first Kuiper belt object was found in 1992, and as of this writing, over 1400 have been discovered, if one includes the so-called scattered disk objects. A number are nearly as large as Pluto or Triton. One–Eris–is as big as Pluto, denser than Triton and also has methane and nitrogen ice on its surface (*see* Kuiper Belt Objects: Physical Studies).

The link between Triton, Pluto, and the Kuiper belt is strengthened by what is known of the orbital dynamics of this region. For example, a number of Kuiper Belt objects share the same dynamical resonance with Neptune that Pluto occupies (this orbital resonance prevents encounters between Neptune and Pluto and is one of the strong arguments against the Pluto-as-escaped-satellite hypothesis). In this sense, Pluto and its companion "Plutinos" are more like the Trojan or Hilda groups of asteroids (which are locked in orbital resonances with Jupiter), only that Pluto–Charon is the clearly dominant member of its group.

Dynamical calculations show that Pluto and its companions were probably swept into this orbital resonance as Neptune's orbit expanded early in solar system history. During this time the flux close to Neptune of bodies orbiting near and beyond Neptune would have been quite high, and even today Neptune continues to deplete the inner Kuiper belt population. It is perhaps not surprising then that Neptune should have had a catastrophic encounter with at least one escapee from the Kuiper belt: Triton (*see* Kuiper Belt: Dynamics).

Satellite capture does not occur easily. Generally, objects passing near a planet leave with the same speed that they came in with. Even complicated trajectories called temporary gravitational captures (enjoyed by Comet Shoemaker–Levy 9) are just that – temporary. To be permanently captured, a single cosmic body must lose energy (velocity) by running into or through something. In Triton's case, it could have collided with another stray body just passing by Neptune, but the probability of this having happened is quite low. Because Triton orbits close to Neptune, in the region usually occupied by regular satellites, it is much more likely that it ran into a regular satellite or its precursor protosatellite disk.

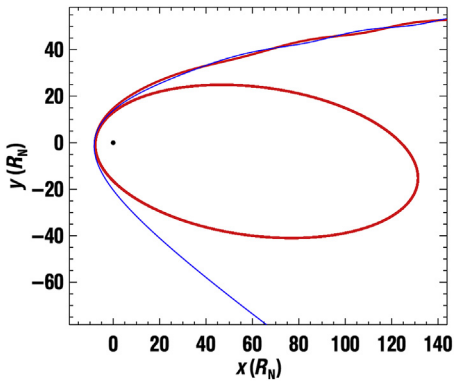

FIGURE 40.16 A possible capture mechanism for Triton. In this example "exchange capture" calculation, an equal mass Triton binary approaches from the upper right and is disrupted by tides from Neptune. One member of the binary (in red) is captured into an elliptical orbit with a semimajor axis of $\approx 70\,R_N$, while the other escapes (R_N is Neptune's radius). *Modified from Agnor, C. B., & Hamilton, D. P. (2006).*

An alternative model proposes that Triton was once part of a binary, and when it passed too close to Neptune, strong tides from the planet split the binary in two. One member of the binary escaped back into solar orbit, while the other stayed behind in Neptune orbit (Figure 40.16). In this case, the captured member of the binary loses orbital energy to the escaping member. While this may at first glance seem far fetched, we now know that a good fraction of Kuiper belt objects are binaries (>10%) and tidal stripping close to a much more massive planet such as Neptune simply requires a close passage. Although permanent capture of one of the original binary members is not assured, the probability is much greater than, say, being captured by colliding with an original Neptune satellite.

The inclination of Triton's postcapture orbit depends on the initial encounter geometry. Triton could have ended up either prograde or retrograde, but there is a preference for retrograde orbits because they are more stable at greater distances from Neptune. After capture, Triton's orbital evolution would be strongly influenced by tides. Every time Triton reapproached Neptune, Neptune's gravity would raise a tidal bulge on Triton. The periodic rise and fall of the bulge would dissipate energy as heat, which would be extracted from the energy of Triton's orbit. Because the tidal couple between Triton's bulge and Neptune would be (on average) radial, no change in Triton's orbital angular momentum would occur. Based on these constraints, and ignoring for the moment any encounters with original satellites, Triton's orbital configuration after capture could evolve as depicted in Figure 40.17. Triton may have begun with a semimajor axis of 1000 R_N or greater, or it may have begun closer in (as in Figure 40.16). The important point is that early on Triton's **periapse** (the closest point to Neptune in its orbit) would lie as low as half its present semimajor axis. Triton's tidal evolution probably took 100 million years or longer, so there would have been sufficient time for Triton's orbit to evolve through and interact with any preexisting satellites.

This point is emphasized in Figure 40.17(b), which includes the periodic effects of solar tides on Triton's evolving orbit. If Triton's initial capture orbit was very large and eccentric, its periapse would have fluctuated, and may have periodically been as low as 5 R_N! Triton would have had ample opportunity for collisions with Neptune's original satellites (if they were like Uranus' today), possibly accreting them in the process. It may also have scattered original satellites into distant orbits, caused them to crash into Neptune, or perhaps even ejected them from Neptune altogether (all the while speeding up its own orbital evolution).

There is now nothing left of Neptune's original system (if it indeed existed) other than the inner satellites and possibly Nereid. The inner satellites all lie within 5 R_N, however, which is perfectly consistent with this capture scenario. Nereid may also be a survivor of this orbital

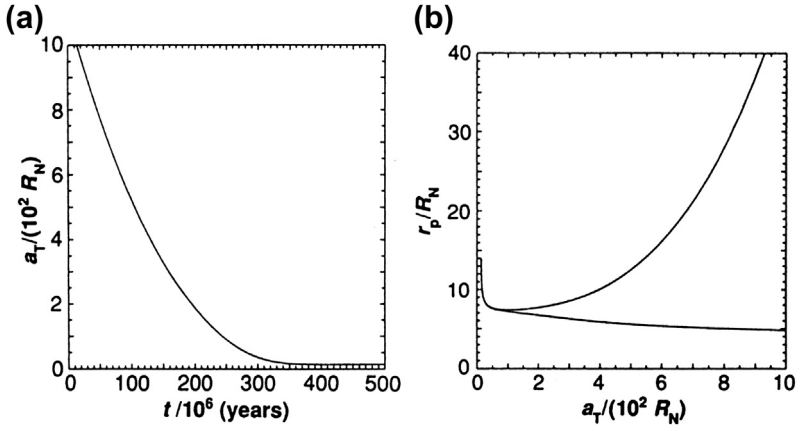

FIGURE 40.17 (a) Example evolution of Triton's semimajor axis, a_T, as a function of time, t, due to tidal dissipation within Triton. (b) Evolution of Triton's minimum and maximum periapse distance, r_p (the closest point to Neptune in its orbit), as a function of semimajor axis due to the combined influence of semiannual solar perturbations and tidal dissipation. The periapse distance oscillates between the two curves shown. *Adapted from Goldreich, P., et al. (1989).*

mayhem. Little is known about this distant moon, save its size (~340 km in diameter), reflectivity (~20%), and presence of surface water ice, but these facts make Nereid more akin to a regular satellite than a dark captured asteroid or comet. Recent dynamical studies have cast doubt on this scenario, however, at least as far as Nereid's stability is concerned. A favored solution is an earlier capture and orbital evolution for Triton, followed by a later capture of Nereid and other distant irregular satellites of Neptune.

The end state of Triton's orbital evolution is an extremely circular orbit. As such, the orbital energy potentially dissipated by tides within Triton represents an absolutely enormous reservoir, about 10^4 kJ/kg. It is sufficient to completely melt all the ice, rock, and metal within Triton 10 times over. The magnitude of Triton's temperature change, however, depends on the heating rate, and somewhat on the size of the initial capture orbit, and how much interaction there is with preexisting regular satellites or nebular gas. Two such models are illustrated in Figure 40.18. Tidal heating after capture in either model is at first modest, as the satellite spends most of its time far from Neptune. As its semimajor axis shrinks and its orbital period decreases, the average heating rate begins to rise. The epoch of greatest heating occurs when the relative change in semimajor axis is the greatest (because orbital energy is inversely proportional to semimajor axis), roughly when the semimajor axis drops below 100 R_N. Because the orbit can only evolve as fast as the tides can convert orbital energy to heat, the response of Triton to tidal flexing is crucial. If Triton responds as a dissipative elastic sphere, then the semimajor axis drops continuously (Figure 40.17(a)) and the tidal heating rises and then falls smoothly as the orbit becomes more circular (Figure 40.18, elastic sphere model). Note that the calculations in Figures 40.17(a) and 40.18 are for two different elastic sphere models, illustrating a range of possible timescales.

A dissipative elastic sphere is clearly an idealized and oversimplified model for Triton. Triton is in reality a complex rock, metal, organic matter, and ice body. More volatile ices especially should be melted and mobilized within Triton early in its history (e.g., ammonia), with or without tidal heating. A partially molten body is a particularly dissipative body, so when capture occurs and tidal heating begins, heat concentrates in the partially liquid regions. This causes more melting, which makes the body more dissipative, which results in greater tidal heating. Thus, within a few hundred million years after capture (perhaps well within), Triton in all probability went through an episode of runaway melting. This is schematically illustrated in Figure 40.18, where in the model labeled thin shells Triton melts spontaneously when enough energy has been accumulated to do so (in reality the runaway occurs much earlier). Thereafter, Triton is a nearly totally molten, but still dissipative body. Its tidal heating curve rises and falls sharply over the course of ~100 million years.

During this epoch of extreme tidal heating Triton's heat flow is an amazing ~2–4 W/m^2, equal to or greater than that measured today from Io. Its surface temperature is governed by this flux and corresponds to a blackbody temperature of 80–90 K. During and after this epoch there would likely have been large chemical exchanges between the global oceanic mantle with its dissolved volatiles and the hot rock core below. Much of Triton's volatiles may have been driven into a massive atmosphere. Atmospheric components plausibly include CO, CH_4, CO_2, and NH_3, or

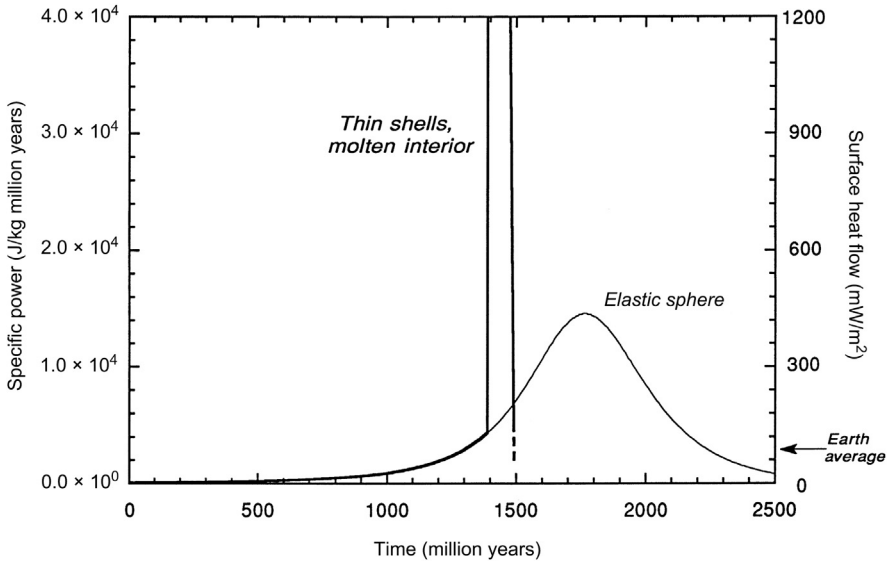

FIGURE 40.18 Power dissipated per unit mass and surface heat flow for Triton as its postcapture orbit shrinks and circularizes due to tides raised by Neptune. Two models are shown. One assumes Triton remains a uniform, undifferentiated sphere, while the second allows for melting. In both cases, the timescales are longer than in the calculations in Figure 40.17(a), due to updated parameters for Triton, but the periapse variations as a function of semimajor axis in Figure 40.17(b) are unchanged. The thin shells model is more realistic than the elastic sphere, but even here the meltdown of Triton has been artificially delayed; in reality a thermal runaway probably occurs much earlier. *From McKinnon, W. B., et al. (1995).*

even H_2 (from photolysis of methane or ammonia or as a minor component in Triton's original ice). Conservative assumptions yield an atmospheric greenhouse with surface temperatures well above 100 K; more extreme possibilities allow for surface temperatures greater than 200 K.

A most intriguing aspect of raising a massive greenhouse atmosphere by tidal heating is that it may persist well after the tidal heating input has tapered off and Triton's interior has begun to freeze. The atmosphere may only collapse after enough of it has been lost to space due to solar-UV-heating-driven hydrodynamic escape, which could have taken in excess of 1 billion years. While the atmosphere existed it would have kept Triton's surface warmer, and enhanced the geological mobility of the satellite's surface layers. Unfortunately, there are as yet no definitive indicators of the atmosphere's former presence (e.g. ancient eolian or fluvial features, peculiar crater shapes, etc.). If a thick atmosphere existed, Triton's continued geological activity has obscured the evidence.

Regardless, once massive tidal heating ended, Triton's interior should have begun to freeze. It would probably have taken a few 100 million years to do so, but even today such freezing would not be complete. Triton's ice mantle is probably warm enough, due to radiogenic heating from the core and continuing dissipative tidal heating from daily obliquity tides, that any ammonia- and methanol-rich fluids are stable (likely in an internal ocean), and Triton's inner core of alloyed iron, nickel, and sulfur should likewise be warm enough (more than $\approx$1250 K) to allow for a eutectic liquid mixture of those elements.

The possible persistence of cryomagmas in Triton's mantle due solely to radiogenic (and some tidal) heating has raised the question as to whether any of the geological observations in Section 6 actually *demand* that Triton was massively tidally heated. Certainly, solar-powered plume models do not require Triton to be internally active at all. Triton's surface, on the other hand, is peculiar, even unique. Furthermore, the extent and intensity of the geological activity recorded there is only seen on satellites that are undergoing active and substantial tidal heating (Io, Europa, and Enceladus). While no ironclad argument can be made, Triton's geology and chemistry in all likelihood indicate that it did indeed experience massive tidal heating, resulting in a geological wonderland.

The proof of Triton's history and provenance requires further exploration of this extraordinary body. For example, determination of the compositions of Triton's icy lavas, and terrains in general, would be key constraints. Detailed exploration of the Neptune system by spacecraft is also a technically feasible proposition, given recent and projected technological advances. Instruments and electronics are being increasingly miniaturized, thereby requiring smaller launch vehicles. Missions to Triton can also take advantage of innovative flight strategies, such as using aerobraking in the Neptune atmosphere to go into initial Neptune orbit. Thereafter, a complement of advanced instruments can be trained on Triton during repeated encounters, filling out our picture of this amazing satellite. For the present, the *New Horizons* encounter with the Pluto system in 2015 promises to reveal much on how Triton-class worlds operate and evolve.

Regarding Triton's ultimate future, as a retrograde satellite its orbit is actually decaying due to tides it raises on Neptune. In the 1960s, it was estimated that Triton would closely approach Neptune and be torn apart by tides in a geologically short time. Present estimates imply less peril: Triton's orbit will perhaps shrink by no more than 15% over the next 5 billion years, giving Triton plenty of time for further geological and atmospheric adventures.

7.3. Probing the Planet's Magnetosphere 903
8. Age and Origins of Ring Systems **904**
Bibliography **905**

1. INTRODUCTION

Planetary rings are swarms of objects orbiting a central planet with vertical motions that are small compared to their motions within a common plane. This characteristic arises because their planets rotate fast enough that they bulge at their equators, thus defining a preferred orbital plane. This is a major contrast between rings and other **astrophysical disks**, such as spiral galaxies and young solar systems, which do not derive their shapes from an external gravity field but from the average **angular momentum** of the disk itself (in both cases, once a preferred plane is established, collisions among particles damp out the motions perpendicular to it). Planetary rings are also distinguished by a large planet/ring mass ratio, which greatly enhances the flatness of rings (their **aspect ratios** are as small as 10^{-7}). However, rings do have a number of similarities with other astrophysical disks, which add to the motivation for studying them. Unlike other known disk systems that are either many light-years away or (like the early stages of our solar system) far back in time, planetary rings can be studied up close and in real time.

By necessity, a dense ring resides inside its planet's **Roche limit**, the distance from a planet within which tides can pull a moon apart.[1] If, contrariwise, a dense ring were outside the Roche limit, it would most likely accrete into one or more moons. The Roche limit is not a sharp boundary; materials that are less dense or more porous can remain dispersed as a ring at the same location where denser material will accrete. Also, dense rings near the transition develop a microstructure as they try to accrete and are frustrated by tides (Section 4.1). Furthermore, this limit operates only for rings dense enough that the particles frequently collide with each other; tenuous rings (Section 6) can resist accretion regardless of their location because their particles do not interact much.

In this chapter, we will first discuss how we learn about rings in Section 2. Then we will give an overview of the

1. The Roche limit calculation involves only gravity. Small objects may hold themselves together by material strength despite the pull of tides, and thus may exist inward of the Roche limit. Individual ring particles are an example.

known ring systems (Figure 41.1), as well as systems where rings are unconfirmed but plausible, in Section 3. More detailed descriptions of various ring structures organized by type, with a focus on finding commonalities among rings in different locations that share certain qualities, can be found in Sections 4–6. In Section 7 we will discuss ways by which rings tell us about their surroundings, and in Section 8 we will discuss the age and origins of ring systems.

2. HOW WE LEARN ABOUT RINGS

The most straightforward way to observe rings, now in use for over 400 years, is by images (or, equivalently, with the human eye). When light from the Sun falls on a ring, varying amounts of light are reflected backward (or to the side, depending on the orientation of the surface it encounters), diffracted forward, or absorbed. **Diffraction** is strongest when the particle size is comparable to the

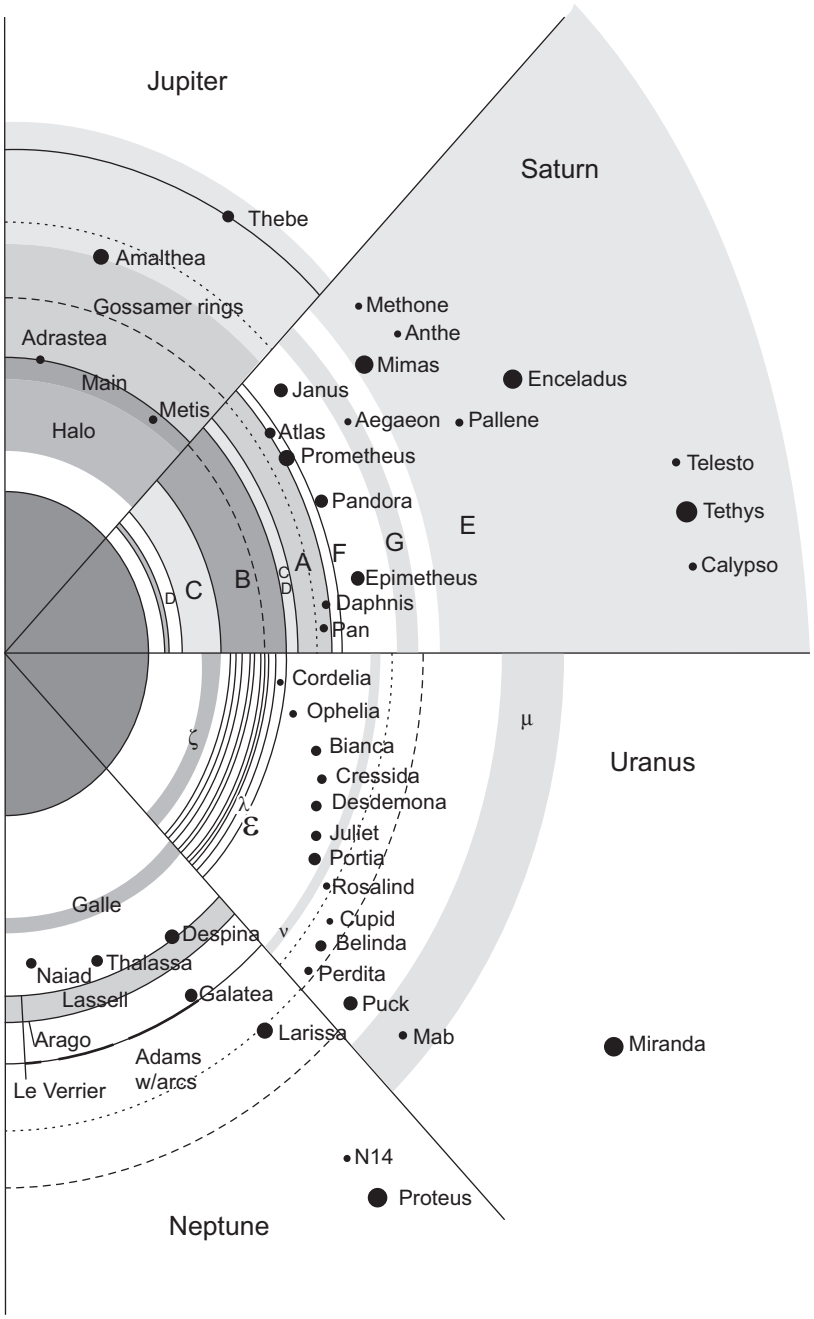

FIGURE 41.1 A graphic schematic of the ring-moon systems of the giant planets scaled to a common planetary radius. The planet is the solid central circle, ring regions are shaded, and nearby satellites are plotted at the correct relative distances. Dotted lines indicate the Roche radius for a satellite of density 0.9 g/cm^3, and dashed lines show the position of synchronous orbit where an object's orbital period matches the planet's rotation period. The Roche radius is outside the synchronous distances for Jupiter and Saturn but inside it for Uranus and Neptune due to the more rapid spins of the larger planets.

wavelength of the light, while larger particles primarily reflect the light that falls on them. Thus, rings with a high fraction of dust[2] tend to be bright at high **phase angles**,[3] when the camera is best positioned to detect the forward-scattered (diffracted) light. By the same token, rings dominated by pebble-sized or larger particles are brightest at low phase angles, when the camera sees light reflected more or less back toward the source.

Because the Earth is much closer to the Sun than is any ring-bearing planet, only low phase angles are accessible from the ground, and one advantage of a spacecraft is the ability to sample a wide variety of phase angles. Because particles of different sizes have different **phase functions** (i.e. the profile of how they scatter light at various phase angles), the ring's **particle-size distribution** can be inferred in this way.

Because rings are generally semitransparent, they can also be studied by means of **occultations**, in which an observer watches a light source pass behind the ring and measures how much of the light the ring blocks. The two primary forms of this are **stellar occultations**, in which a camera on Earth or onboard a spacecraft watches a star pass behind the ring, and **radio occultations**, in which a spacecraft beams a radio signal that passes through the ring and is received on Earth. Occultations often allow more finely detailed observations of ring structure, but only in a single dimension along the projected path of the source. Occultations directly measure the **optical depth** (a measure of the ring's transparency, or equivalently of the fraction of light that it blocks), while imaging observations must infer the optical depth indirectly from the measured brightness.

Although most images of rings are dominated by scattered sunlight, other factors such as **planetshine** can be important, especially when sunlight is reduced (e.g. in the planet's shadow). Rings can be viewed not only on the side illuminated by the Sun (the lit face) but also on the opposite side (the unlit face). On the lit face, a region with higher optical depth appears brighter simply because there is more material to scatter light toward the observer. This is also true on the unlit face for moderately dense rings, but highly dense rings can exhibit a **contrast reversal**, in which higher optical depth leads to a darker appearance on the unlit side as the ring becomes more opaque.

As with any material, much can be learned about a ring from studying its **spectrum**, or the profile of its brightness at different wavelengths of light. These wavelengths can extend beyond **visible light** to include **infrared** or **ultraviolet** and more. A ring's spectrum is akin to a fingerprint, and comparing it to spectra taken of controlled samples in a laboratory can yield important information about its chemical composition, surface texture, temperature, and other characteristics. Different parts of a ring can have different spectra, and these can be investigated using a **spectrometer** with a sufficiently narrow **field of view** and pointing it at different parts of the ring at different times, or by using an **imaging spectrometer**, which builds up an image in which each pixel is a spectrum with anywhere from dozens to thousands of color measurements.

A spacecraft flying near or through a ring can also study it by sensing it directly. A dust detector can measure the velocity, size, and composition of dust particles that strike the spacecraft. Detectors of magnetic fields and charged particles can analyze the interaction between a ring and its planet's **magnetosphere** (e.g. *see* "Planetary Magnetospheres" and Section 3.6).

Rings can also be studied through computer simulations. Advances in simulation techniques, alongside advances in computing hardware and software, have allowed simulations to become an increasingly important part of the study of orbital dynamics in the solar system (including rings) since the early 1990s. For simple systems, it is sufficient to enter a suite of particles with their initial positions and velocities and to see where gravity and other forces will take them. For dense rings (Section 4), however, the number of mutually interacting particles in the entire ring is far too large for a computer to handle, so a line of simulations has been developed that follows a relatively small "patch" of the ring surrounded by "mirror patches" (Figure 41.2). Computer simulations have become a vital tool for understanding not only ring microstructure such as self-gravity wakes (SGWs, see Section 4.1), but also the mechanics of sharp edges (see Section 4.2) and propellers (see Section 4.2) and other ring properties including the rotational states, thermal properties, and particle-size distributions of ring particles.

3. RINGS BY LOCATION

3.1. The Rings of Saturn

Saturn possesses by far the most massive and the most diverse of the known ring systems (Figure 41.3). The only ring system known before recent decades, Saturn's rings have been the focus of much productive study by astronomers over the past four centuries. Saturn's appendages were among the first objects observed through a telescope (by Galileo Galilei in 1610), first understood to be a disk by Christiaan Huygens in 1655, and proved to consist of individual particles on independent orbits by James Clerk Maxwell in 1859. The main part of the rings comprises the solar system's only known broad and dense disk (Section 4),

2. To describe a material as "dust" is to describe the size of its particles, regardless of composition (rock, ice, etc.). Particles less than a few tens of microns (μm) across are usually considered dust.

3. The phase angle is formed by the light path from Sun to object to observer.

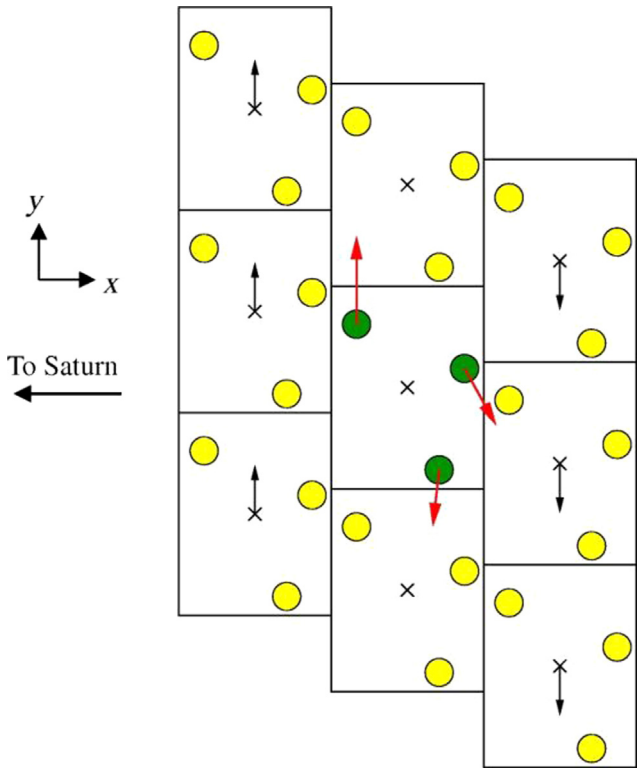

FIGURE 41.2 Schematic representation of a ring-patch simulation with sliding boundary conditions. The simulation cell (center, with green particles) is surrounded on all sides by replicant cells (with yellow particles) for the purpose of calculating the particles' gravitational effects on each other. In this representation, increasing radius is to the right and Keplerian orbital motion is up. When a particle leaves the simulation cell in the azimuthal direction (uppermost and lowermost green particles), it simply reappears at the same location on the other side (equivalently, it enters the neighboring replicant cell). When a particle leaves the simulation cell in the radial direction (right-hand green particle), its appearance on the other side is governed by how the replicant cells slide past the simulation cell according to Kepler's third law (black X's and arrows).

which G. D. Cassini found in 1675 was divided into two parts—now called the A and B rings, separated by what is now called the Cassini Division. The latter is now known to be not an empty gap but simply a region of the disk with more moderate surface density, similar in character to the C ring, which lies inward of the B ring and was discovered in 1850. Subsequent observations from ground-based telescopes and spacecraft have revealed that these rings consist of water-ice-rich particles millimeters to meters wide.

There are a small number of truly empty radial gaps in the dense disk of the main rings, most of them in the C ring and Cassini Division but two in the outer A ring, all of them sharp-edged. The two A ring gaps are held open by moons at their centers, and the C ring's Colombo Gap is held open by a resonance with Titan, but most of the gaps remain unexplained. A diverse array of narrow rings and ringlets resides within ring gaps, some of them dense and sharp-edged and others diffuse and/or dusty. These structures, which can be compared with narrow rings around other planets, are discussed in Section 5.

The Saturn system also contains the most diverse retinue of tenuous dusty ring structures known in the solar system, discussed in Section 6. The main components are the D ring situated innermost between the main rings and Saturn's atmosphere, the dense F ring just off the edge of the A ring, and the G and E rings farther out.

Saturn also possesses the largest known ring in the solar system, the Phoebe ring, which was discovered in 2009 by the Spitzer Space Telescope. The Phoebe ring is some 30 million km across but is exceedingly tenuous, containing only about 10 dust particles per cubic kilometer. It is also the only known ring to be tilted from its planet's equatorial plane (it lies in the plane of Saturn's orbit, as the Sun's perturbations are much more important than Saturn's equatorial bulge at its distance) and is likely the

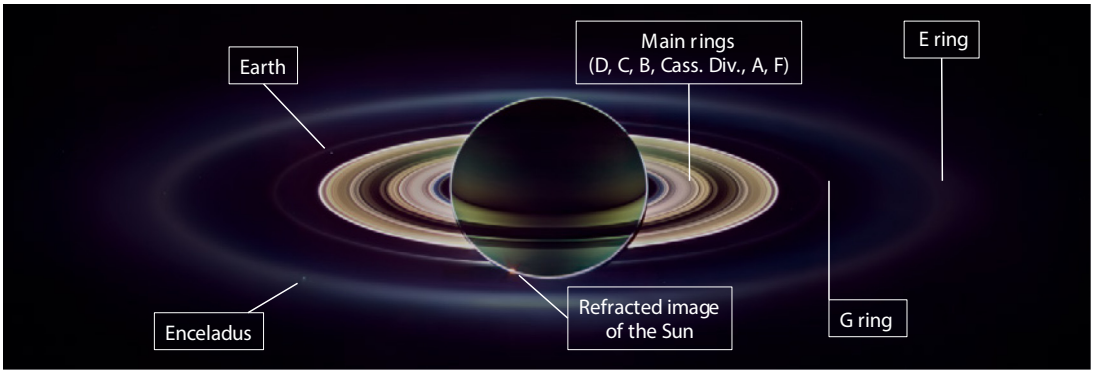

FIGURE 41.3 This Cassini image mosaic shows Saturn's tenuous dusty rings (D, E, and G) with comparable brightness to the main disk, which occurs because the viewing geometry is at high phase angle (in fact, in eclipse) and also views the unlit face of the main disk. The darkest part of the main disk is actually the densest and most opaque, namely, the mid- to outer B ring. The Sun, which is actually behind Saturn, can be seen refracted through the planet's atmosphere at 7 o'clock. Enceladus (actually, only its geyser plume is bright in this geometry) can be seen embedded in the E ring at 8 o'clock. The Earth can be seen as a pinpoint of light between the F and G rings at 10 o'clock.

only known ring whose particles orbit in the retrograde direction (following its presumed source-moon, Phoebe). As particles in the Phoebe ring spiral inward due to electromagnetic effects, they preferentially impact one side of the moon Iapetus, leading to a strong divide between bright and dark regions on the surface of that moon.

3.2. The Rings of Uranus

In contrast to the broad disk of Saturn, all of Uranus' main rings are narrow, and many are eccentric and/or inclined. But in contrast to the dusty rings of Jupiter and Neptune, many of Uranus' rings are dense and sharp-edged. Thus, the Uranian ring system is unique, one that truly deserves the label of "rings" in the plural. The main set of 10 narrow rings is compact and lies inward of Uranus' 13 small inner moons, except for the ε ring, which lies just outside the orbit of Uranus' innermost moon Cordelia (Figure 41.4). A panoply of unnamed dusty rings was seen interspersed with the main rings in the single high-resolution high-phase image taken by Voyager 2 (Figure 41.5).

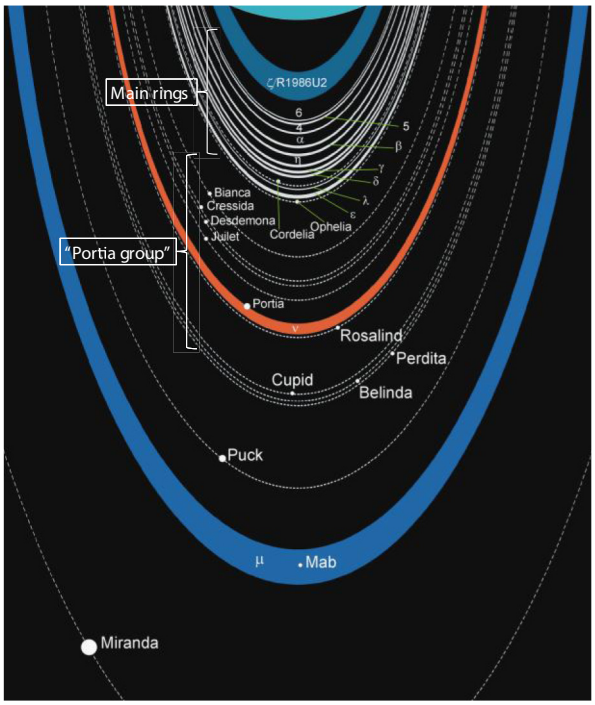

FIGURE 41.4 Uranus' main rings are situated immediately inward of a retinue of small moons. If one were to spread the mass of Uranus' "Portia group" of moons evenly over the annulus they occupy, the surface density would be similar to that of Saturn's A ring. This moon system may be thought of as an accretion-dominated ring, similar in many respects to the known ring systems except that its natural density is larger than the Roche critical density (i.e. it is beyond the "Roche limit"; see Section 1) so that any moon that gets disrupted by a collision (which ought to have happened many times over the age of the solar system) will simply reaccrete.

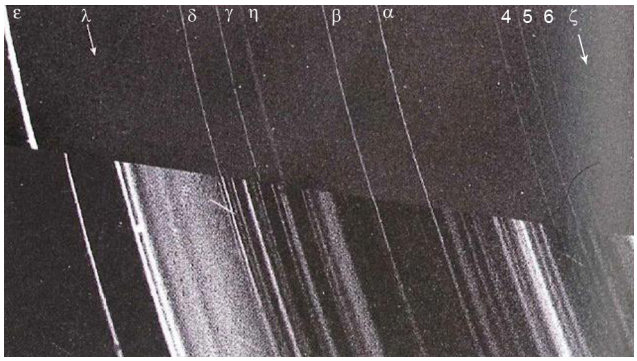

FIGURE 41.5 This composite image of Uranus' main rings in back-scattered (upper) and forward-scattered (lower) light shows that a network of dust structures is interleaved with the planet's dense main rings. The disjoint in the ε ring is due to its eccentricity. Note that the λ ring, the ζ ring, and many other dusty structures are only visible in the lower panel. As the lower panel is the only high-phase image ever successfully taken of Uranus' rings (by the postencounter Voyager 2), the detailed workings of the dust structures remains largely unknown.

The orbits of Uranus' inner moons are also tightly packed, so close that simulations indicate they can persist for only some millions of years (a small fraction of the age of Uranus) without some kind of collision. The dusty ν ring, which lies between two of the moons in this group, may well be the detritus of a recent significant collision. If we could see the Uranian system some 50 million years in the future, we might find that the ν ring has reaccreted into a new moon, while one or more of the present moons may have collided and formed a new dusty ring. In this way, these inner moons of Uranus may be best thought of as a collective system, something like a "ring" except that they are outside the Roche limit—that is, far enough from their planet to be constantly accreting into discrete moons (Section 1).

The composition of the Uranian rings is almost entirely unknown, as Voyager 2 did not carry an infrared spectrometer capable of detecting the rings. However, it is clear from their low albedo that at least the surfaces of the ring particles cannot be primarily water ice. Color imaging indicates that the Uranian rings are dark at all visible wavelengths, indicating a spectrum similar to that of carbon.

3.3. The Rings of Neptune

Neptune's ring system, like that of Uranus, consists primarily of a few narrow rings, although Neptune's are generally less dense, higher in dust, less sharp in their edges, and farther from their planet than those of Uranus (Figure 41.6). The most substantial of these is the Adams ring, which is best known for its series of arcs, the first ever discovered (Section 6.3).

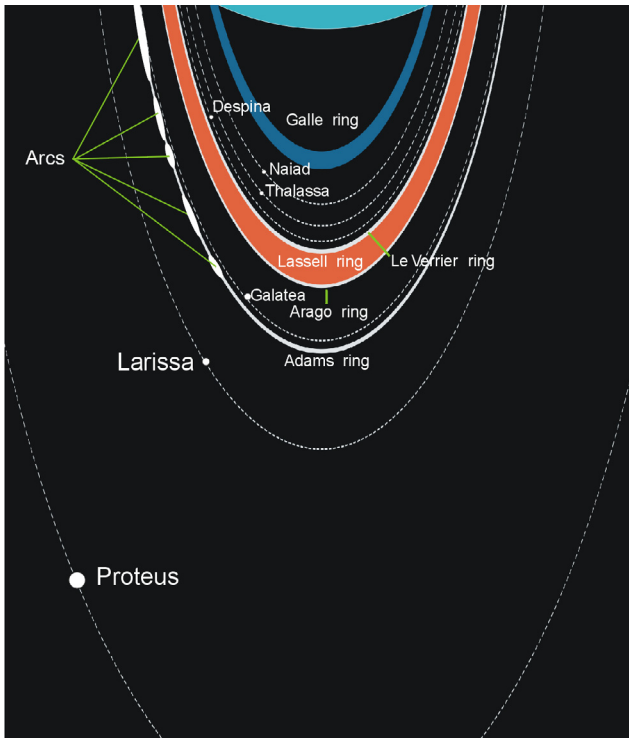

FIGURE 41.6 In Neptune's ring system, uniquely, narrow rings and diffuse rings and moons are all interspersed together.

The composition of the Neptunian rings, like that of the Uranian rings, is unknown due to Voyager's inability to detect them in the infrared. However, again like the Uranian rings, the low albedo of Neptunian ring particles makes it clear that at least their surfaces cannot be primarily water ice.

3.4. The Rings of Jupiter

Jupiter is adorned by the simplest of the known ring systems. All its rings are tenuous and composed of dust-sized particles. As the only confirmed ring system without any dense component, and by far the least massive, Jupiter's is the only ring system to have been discovered by spacecraft without having previously been seen from Earth either by direct imaging (as Saturn's) or by stellar occultations (as Uranus' and Neptune's).

Each component of Jupiter's ring system is closely related to one or two source moons. Dust particles enter the ring as **ejecta** from micrometeoroid impacts onto the moon, then their orbits evolve inward due to electromagnetic effects. As a result of this, the two dusty Gossamer rings are shaped like two nested "tuna cans" enveloping the Main ring (Figures 41.7 and 41.8). The Main ring additionally has a core of centimeter size and larger particles occupying the ~1000 km annulus between the orbits of Adrastea and Metis. This core is the only component of the ring system not composed of dust and the only one that appears bright at low phase angles (Figure 41.9).

Furthermore, the New Horizons spacecraft spotted several azimuthal clumps in one of the core's ringlets (see Section 6.3).

When the dust moving inward from the Main ring reaches a radius of 122,800 km from Jupiter's center, its vertical motions become excited by a 3:2 **resonance** between its orbital period and the rotation period of Jupiter's magnetic field. Inward of this location, the vertical extent of the ring increases dramatically, forming the toroidal Halo ring. Material in the Halo ranges tens of thousands of kilometers above Jupiter's ring plane, although most of its material is concentrated within just a few hundred kilometers.

3.5. The Rings of Mars and Pluto

The four giant planets are the only bodies known to have rings, as just described. But rings may exist in other places as well, although yet unobserved.

Mars is predicted to have a tenuous ring system comprised of dust grains ejected from its moons Phobos and Deimos by meteoroid impactors. The Sun's perturbations should cause

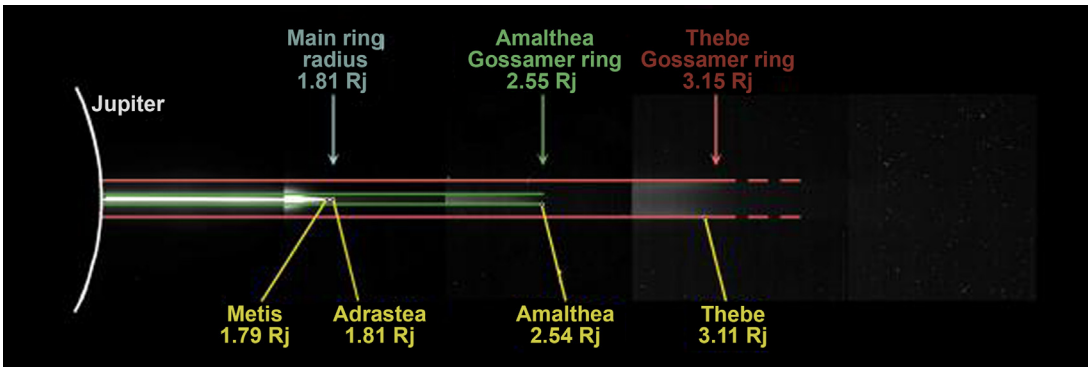

FIGURE 41.7 Galileo image mosaic of Jupiter's rings, seen nearly edge-on at very high phase angle, annotated to show the primary components of the ring system. Image sensitivity increases from left to right, in order to show the increasingly faint structure.

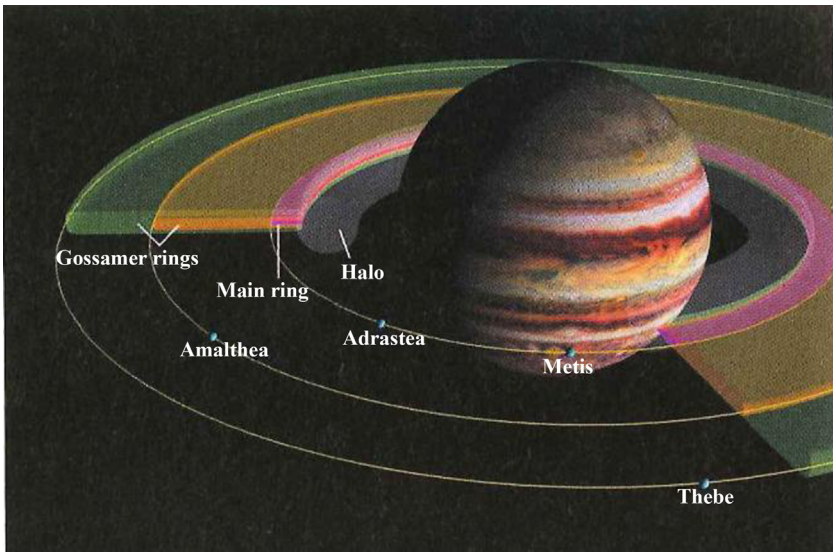

FIGURE 41.8 A schematic of Jupiter, its innermost four moons, and its ring components (shown in different colors). The vertical thickness of the Halo ring is caused by an electromagnetic effect operating on dusty grains, while the vertical thicknesses of the Main ring and the two Gossamer rings are due to the orbital inclinations of the moons that generate those rings. The four well-known Galilean moons are too far from Jupiter to be shown here.

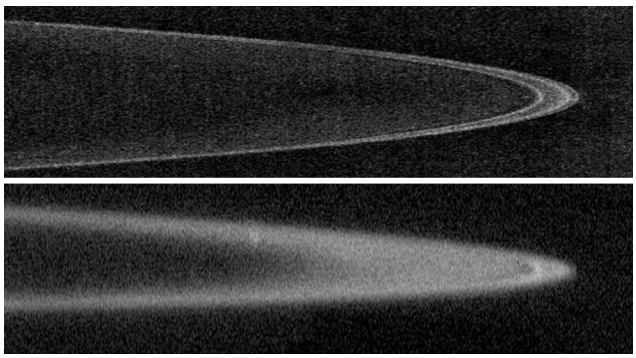

FIGURE 41.9 New Horizons images of Jupiter's Main ring at low phase (upper panel) and at high phase (lower panel), showing respectively the structures composed of macroscopic particles and the dusty envelope.

this ring to be offset away from the Sun and tilted out of Mars' equatorial plane. However, the failure to observe any Martian rings to date, despite sophisticated attempts, may make it necessary to alter the original theory. Perhaps dust is produced at lower rates than expected, or perhaps the destruction of dust as solar radiation pressure pushes it onto orbits that impact the planet proceeds faster than expected.

Compared to the giant planets, Mars (*see* "Mars: Surface and Interior") is a more challenging place to look for faint rings because it lacks a dense atmosphere. For the giant planets, atmospheric gases like methane absorb light strongly at certain infrared wavelengths; faint rings can more easily be detected at those wavelengths because glare from the planet is dim. Planets also furnish a dark background at high phase angles (when, by definition, we are viewing the night side), but this method is also less effective for detecting rings at Mars because forward-scattering dust particles should be depleted from the Martian rings due to radiation pressure.

Pluto, like Mars, could harbor a tenuous ring system of dust derived from its small moons Styx, Nix, Kerberos, and Hydra. This possibility raises concerns about the safety of the New Horizons spacecraft, set to fly past Pluto (*see* "Pluto") in 2015, and more sensitive observations are being attempted. However, both the handicaps discussed above for Mars, the lack of a dense atmosphere and the loss of smaller dust grains due to radiation pressure, are also likely to hamper the detection of any Plutonian rings.

3.6. The Rings of Rhea and Iapetus

Rhea, the largest of Saturn's airless moons, is in the opposite situation from Mars and Pluto, with no clear theoretical prediction but a claim that rings have been observed. Cassini scientists reported a symmetric pattern of dropouts in detected electrons (which can be likened to the way a person driving in a blinding rain can perceive having driven under a bridge by the sudden cessation of raindrops hitting the windshield) during Rhea flybys, which were announced as the first evidence for rings around any moon. The following year, Cassini color imaging of Rhea's surface revealed a narrow chain of discrete bluish splotches aligned nearly along Rhea's equator, which was interpreted as the signature of ring material falling out onto the surface.

However, after an extensive search using Cassini images, the present existence of rings around Rhea was practically ruled out. It seems most likely that the electron-absorption signatures are due to some magnetospheric phenomenon, and not to rings of solid material around Rhea. It has been suggested that the chain of bluish splotches is evidence that Rhea (*see* "Planetary Satellites") had rings in the past, even if it has them no longer, but the

best that can be said of this idea is that it has not been disproven.

Saturn's moon Iapetus is another object that could have had a ring in the past. Among its many remarkable features, the best known of which is that one hemisphere is 10× brighter than the other, is one of the highest mountain ranges in the solar system, aligned directly along Iapetus' equator. Here, as for Rhea, the fallout of a past ring system has been invoked by some scientists to explain this equatorial feature; such a theory may even explain some of Iapetus' other oddities as well.

3.7. The Rings of Exoplanets

While hundreds of planets have now been detected in orbit about other stars, no exoplanet (*see* "Exoplanets") yet has a confirmed ring system. The best observed exoplanet systems are mostly "hot Jupiters" that orbit very close to their stars, but several factors combine to make it difficult for rings around such planets both to survive and to be observed. However, the situation should be more agreeable for planets not much closer to their stars than Mercury is to the Sun (which might be called "warm Saturns"). If such a ring system were observed to **transit** its star (e.g. by the Kepler spacecraft), the pattern in which the rings block the starlight may yield information about the planet's spin and its interior.

The only known exoplanet for which a ring system has been specifically proposed is Fomalhaut b, which in 2008 was one of the first exoplanets to be directly seen (rather than perceived indirectly, e.g. by the way its gravity tugs on its star or by the way it blocks its star's light). In order to account for its observed brightness, Fomalhaut b would need to reflect more starlight than a reasonably sized planet can reflect, but this difficulty can be resolved if Fomalhaut b is adorned by a ring system that is so large that it extends far beyond the planet's Roche radius. But as we discussed in Section 1, such a large disk would not be stable against accretion and thus would perhaps be more of a dynamically evolving protosatellite disk than a stable ring system.

4. DENSE BROAD DISKS

Saturn	C ring
	B ring
	Cassini Division
	A ring

Although the idea that Saturn's main ring system is composed of "countless tiny ringlets" continues to appear even in the professional literature, it is inaccurate. It is much better to say that the main ring system is a broad disk; its density does vary in the radial direction, but there are only a few true gaps that would separate one "ring" from another. Furthermore, waves constantly travel radially through the disk (Section 4.3), and ring material can move radially as well, although more slowly.

The components of Saturn's main ring system are quite different from each other in structure, as well as in location

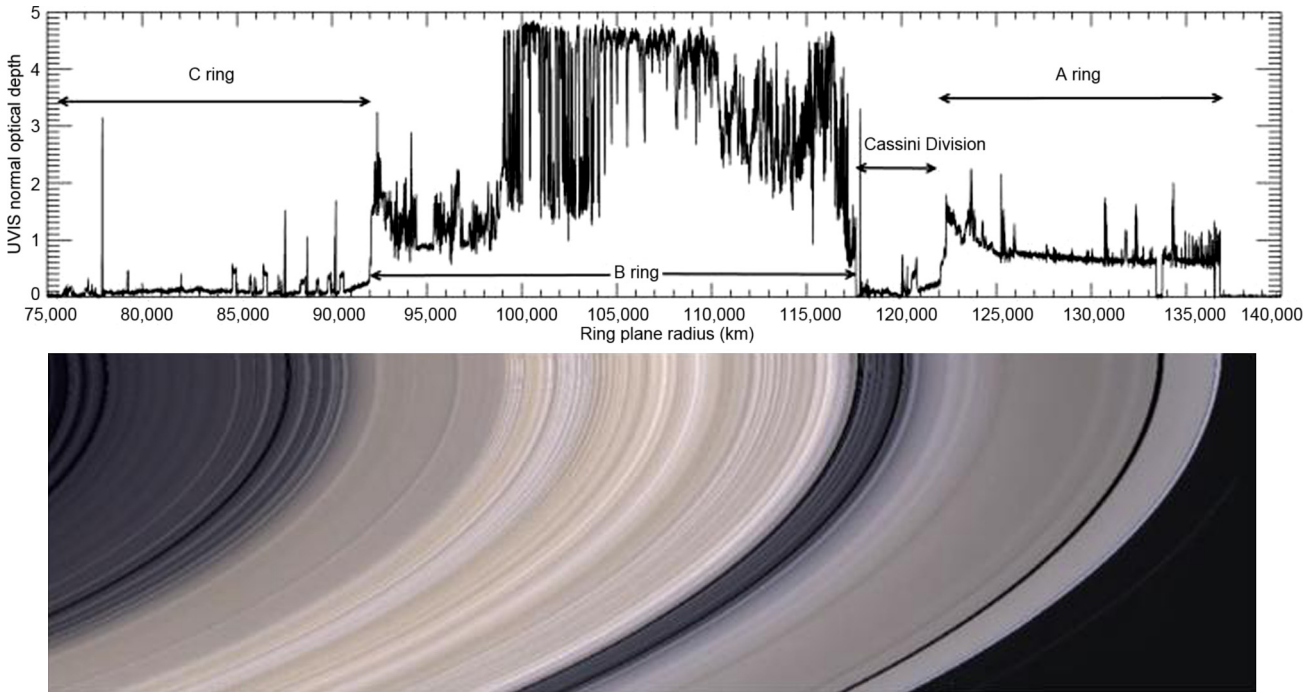

FIGURE 41.10 An optical depth profile (top) and true-color image (bottom) of Saturn's main ring system.

and density. The B ring is by far the most dense, and its particles interact with each other the most vigorously. The A ring is intermediate in both respects, while the C ring and Cassini Division are much more tenuous (Figure 41.10). The B ring's position astride the **synchronous orbit distance**, at which the orbital period of particles equals the rotation period of the planet (and thus of its magnetic field) is thought to influence at least some of its properties (see the discussion of spokes in Section 7.3), while the A ring's outermost position causes it to be more susceptible to both accretion-related processes and perturbations from exterior moons.

Saturn's rings are primarily composed of pebble-sized to house-sized chunks (cf. Section 6). The characteristics of these individual particles, whether they are rotating quickly or slowly and how deeply they are covered by a blanket of fractured material, can be inferred by using infrared observations to "take their temperature".

Broad, dense rings possess a diverse array of structures. Many of these are still not well understood, such as a series of sharp-edged bands called "plateaux" in the C ring (Figure 41.11) and nearly all the multifaceted structure in the B ring. However, other features in the rings have been explained as the result of particle interactions and perturbations from nearby and distant moons.

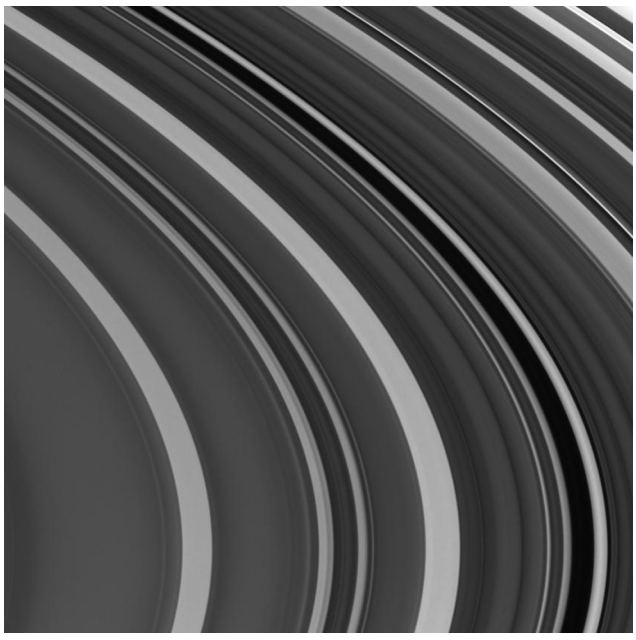

FIGURE 41.11 The broad bright sharp-edged bands seen in this image are the "plateaux" (singular: "plateau"), named for their high flat appearance in a one-dimensional plot of the ring's brightness with radius. They can be 100 km or more in breadth, and are sometimes called "embedded ringlets" because they are similar in character to dense narrow rings (Section 4), except that they are surrounded not by empty gaps but by more tenuous regions of the ring. It is not known why the plateaux exist, nor why they only occur in the outer C ring.

4.1. Structures Formed Spontaneously by the Disk

4.1.1. Self-Gravity Wakes

The boundary between the two regimes discussed in Section 1—accretion-dominated regions (in which a disk would tend to coalesce into a moon) and disruption-dominated regions (in which disks are stable)—is not a sharp one. In the outer parts of the region of stability for disks, the mutual self-gravity of ring particles can drive temporary accretion that is quickly disrupted again by tides, forming a disk microstructure known as self-gravity wakes. SGWs generally have a webbed structure of elongated particle aggregates extending in a characteristic direction (Figure 41.12, Movie M1), usually a few tens of degrees from azimuthal.

Because of their nonaxisymmetric structure and their finite vertical thickness, the brightness of a disk pervaded by SGWs depends on the observer's longitude. An observer looking along the direction of the elongated wake structures will see more of the gaps between the wakes than an observer looking across the wakes (Figure 41.13), especially at low **elevation angles**. Even before the Voyager encounters, the effects of SGWs were observed as an azimuthal asymmetry in the brightness of the A ring, and considerable light has been shed on their properties in recent years due to a combination of

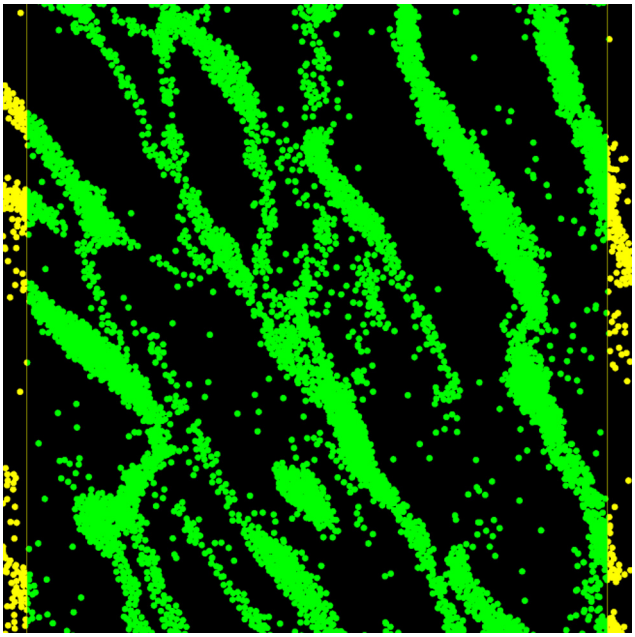

FIGURE 41.12 Simulated self-gravity wakes (SGWs). This microstructure develops within dense rings as particles clump together under their mutual self-gravity but are ripped apart again by Saturn's tides. *This figure is a still from Movie M1.*

FIGURE 41.13 A ring with simulated self-gravity wakes (SGWs) is viewed (left) along the prevailing direction of the SGWs and (right) across that direction. It is evident that the transparency is higher in the first case. This leads to an azimuthal variation in the reflectivity or transparency of rings containing SGWs, depending on the viewing angle.

sophisticated numerical simulations and repeated occultation observations by Cassini with varying geometries.

SGWs have a dramatic effect on how the ring's density might be inferred from its brightness or optical depth. Numerical simulations have found that adding more mass to a ring merely adds mass to the already-opaque wakes and only weakly increases the overall optical depth, so that the mass of the B ring may be higher than Voyager-era estimates by a factor of 10 or more, approaching twice the mass of Mimas. See Section 8 for a discussion of the impact of this finding on the age and origin of Saturn's rings.

4.1.2. Overstabilities

Regions of axisymmetric microstructure have been found by occultations in the inner A ring and in the B ring. These regions contain patterns with wavelengths of a few hundred meters with such regularity that they can act as a **diffraction grating** for the Cassini radio occultation signal. This structure has been explained in terms of **viscous overstability**, a phenomenon so named because the restoring force that would usually equalize any random variations in density becomes overactive, overshooting the equilibrium and thus driving oscillations instead of damping them (Movie M2). Work is ongoing to characterize the appearance of "overstability waves" in Cassini data, as well as to simulate their behavior in response to various environmental factors.

4.2. Structures Formed by Nearby or Embedded Moons

4.2.1. Gap Edges and Moonlet Wakes

There are 14 named gaps within Saturn's main rings. Most of them have no clear origin, though the Encke and Keeler gaps in the A ring contain known moons (Pan and Daphnis, respectively) that hold the gaps open through their gravity's effect on nearby ring material, and some gaps in the C ring seem to be held open by resonances. Furthermore, even the two gaps that do contain known moons exhibit a surprising amount of unexpected behavior at their edges.

The way a moon holds open a gap is ostensibly straightforward. When a ring particle passes a nearby moon (which is orbiting at a different rate due to **Kepler's third law**), its orbit acquires an eccentricity as well as being very slightly pushed away[4] from the moon's orbit. On its now-eccentric orbit, the ring particle oscillates in and out once per orbit, while Kepler's third law requires it to move laterally over the same period of time in the moon's frame of reference by a distance $3\pi\Delta a$ (where Δa is the radial distance between the two orbits). The result is that the gap edge develops a wavy structure with a wavelength $3\pi\Delta a$ (Figures 41.14 and 41.15). Furthermore, as one moves into the disk from the gap edge, streamlines still have wavelength $3\pi\Delta a$, but that wavelength increases as the distance from the moon Δa increases. The result is a spiraling *moiré* pattern called "moonlet wakes"[5] that rotates with the gap-moon (Figures 41.14 and 41.15).

Wavy gap edges and moonlet wakes are often easier to see than the moons that cause them. In fact, before Pan or any other gap-moon had been discovered, it was the wavy edges of the Encke Gap and the nearby moonlet wakes that were first tracked. Careful analysis of these features led to a prediction of where the responsible moon should be orbiting, which led to the discovery of Pan in decade-old archival Voyager images.

Some edges also exhibit vertical structure. The moon Daphnis, at the center of the Keeler Gap, has an inclined orbit that ventures ~9 km above and below the ring plane. The resulting vertical corrugation of nearby portions of the gap edge were highlighted by their shadows cast during the 2009 **equinox** (Figure 41.16). A region of vertical structure, possibly due to embedded moonlets on inclined orbits, has also been detected and tracked in the outer edge of the B ring (Figure 41.17).

4.2.2. Propellers

A disk-embedded moon that is too small to open a full circumferential gap may still create a local disturbance in the disk. Because of Kepler's third law, the radially inward portion of the disturbance is carried forward and leads the

4. This may seem counterintuitive, since gravity is a force of attraction. The moon does indeed attract the ring particle, but there is a paradoxical effect in orbits by which (for example) an object that speeds up is taken farther from its planet, which (by Kepler's third law) puts it in the end on a slower orbit.

5. Moonlet wakes have little in common with the "self-gravity wakes" discussed in Section 4.1, despite an unfortunate similarity in terminology.

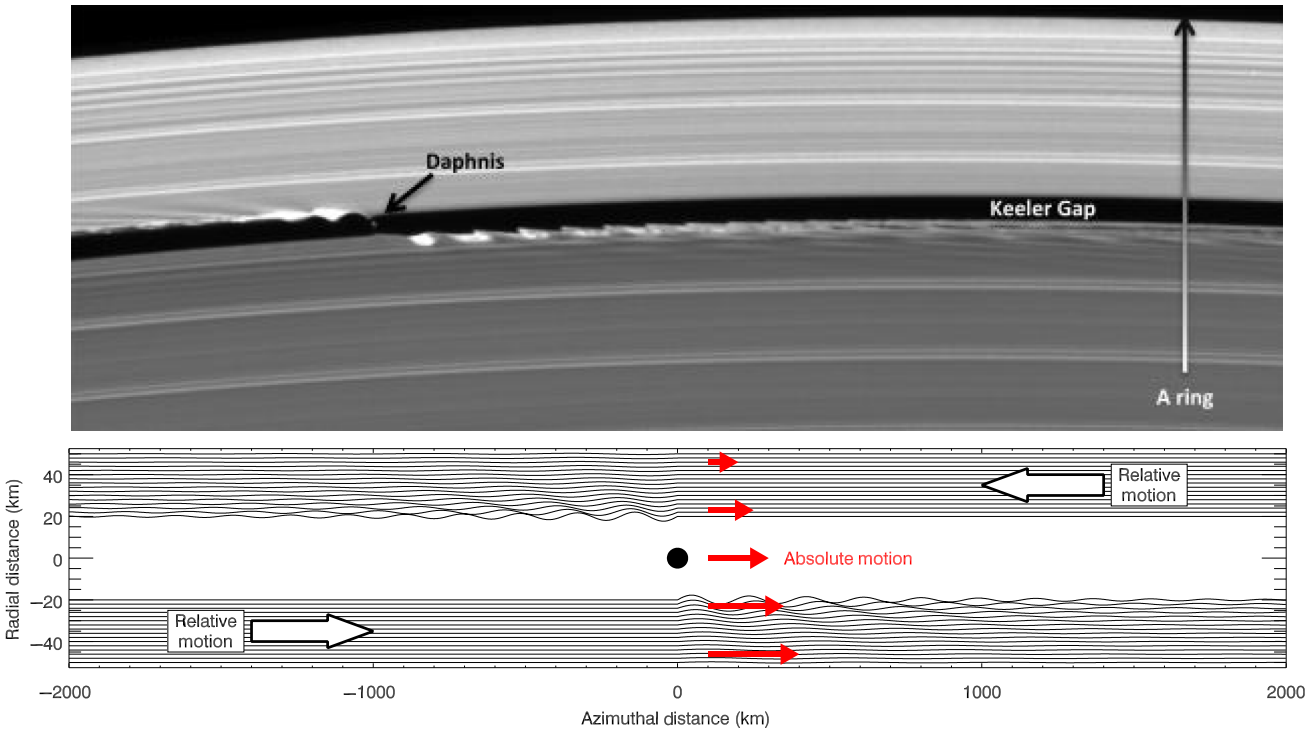

FIGURE 41.14 (Top) Wavy edges and moonlet wakes are seen at the edges of the Keeler Gap, surrounding the position of the gap-moon Daphnis. (Bottom) Streamline diagram showing the $3\pi\Delta a$ wavelength setup as ring material passes a gap-moon. Different wavelengths at different radial distances Δa set up the "moonlet wakes" pattern. By Kepler's third law, inner material is moving faster than outer material (red arrows); by the same token, in the moon's frame of reference, inner material moves forward and outer material moves backward (white arrows).

FIGURE 41.15 In this detailed image of the Encke Gap, Saturn is far to the left and orbital motion is upward. The moon Pan is several frame-widths below, and the $3\pi\Delta a$ wavy edges and the moonlet wakes can be seen on the inward (left-hand) edge. Several faint narrow rings are seen in the gap; the brightest central one is centered on Pan's orbit. A few spiral density waves can also be seen at the far left and far right.

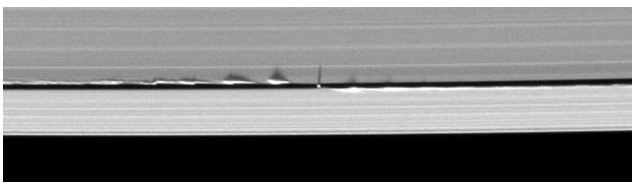

FIGURE 41.16 In this image of the Keeler Gap, taken when the Sun shone nearly edge-on to the rings during the 2009 equinox, not only Daphnis but the vertically corrugated gap edges cast shadows on the nearby A ring.

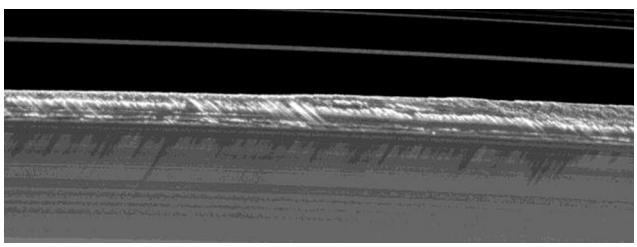

FIGURE 41.17 In this image of the outer edge of the B ring, taken when the Sun shone nearly edge-on to the rings during the 2009 equinox, part of the edge ramps up into a "wall" several kilometers high that casts a shadow.

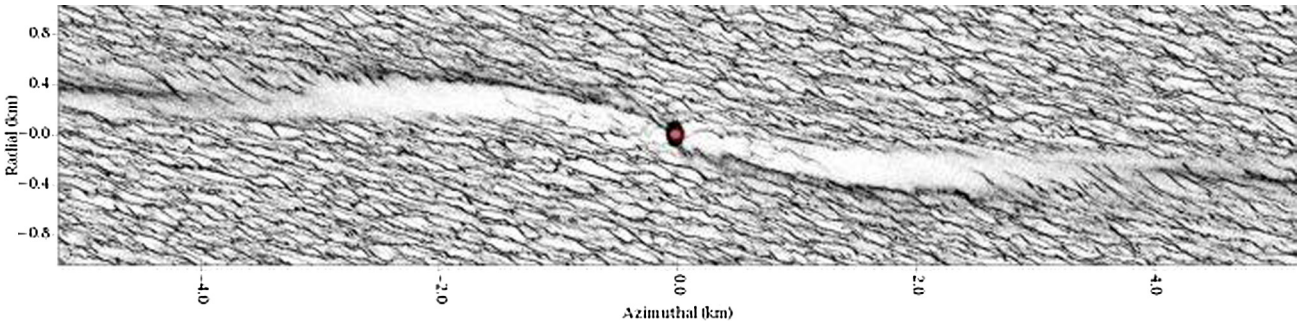

FIGURE 41.18 Simulated "propeller" disturbance in the A ring due to an embedded moonlet. Note the texture of (SGWs) in the unperturbed regions, and the near-horizontal regions of depletion (white) and enhancement (black) in density due to the moonlet.

moon while the radially outward portion trails the moonlet (Figures 41.18 and 41.19). Due to this characteristic shape, such moonlet-caused disturbances have been named "propellers". A propeller-shaped disturbance can be thought of as a moon's unsuccessful attempt to form a full circumferential gap, which is frustrated as collisions among ring particles allow particles to diffuse back into the disturbed region and fill the gap back in before it can fully extend azimuthally. Propellers in a range of sizes have been observed in Cassini images.

In all cases, only the propeller-shaped disturbance is directly seen, while the responsible moon at the center is inferred. The physical size of the moon is a few times smaller than the tell-tale radial offset between the two azimuthally aligned lobes (labeled as Δr in Figure 41.19(b)).

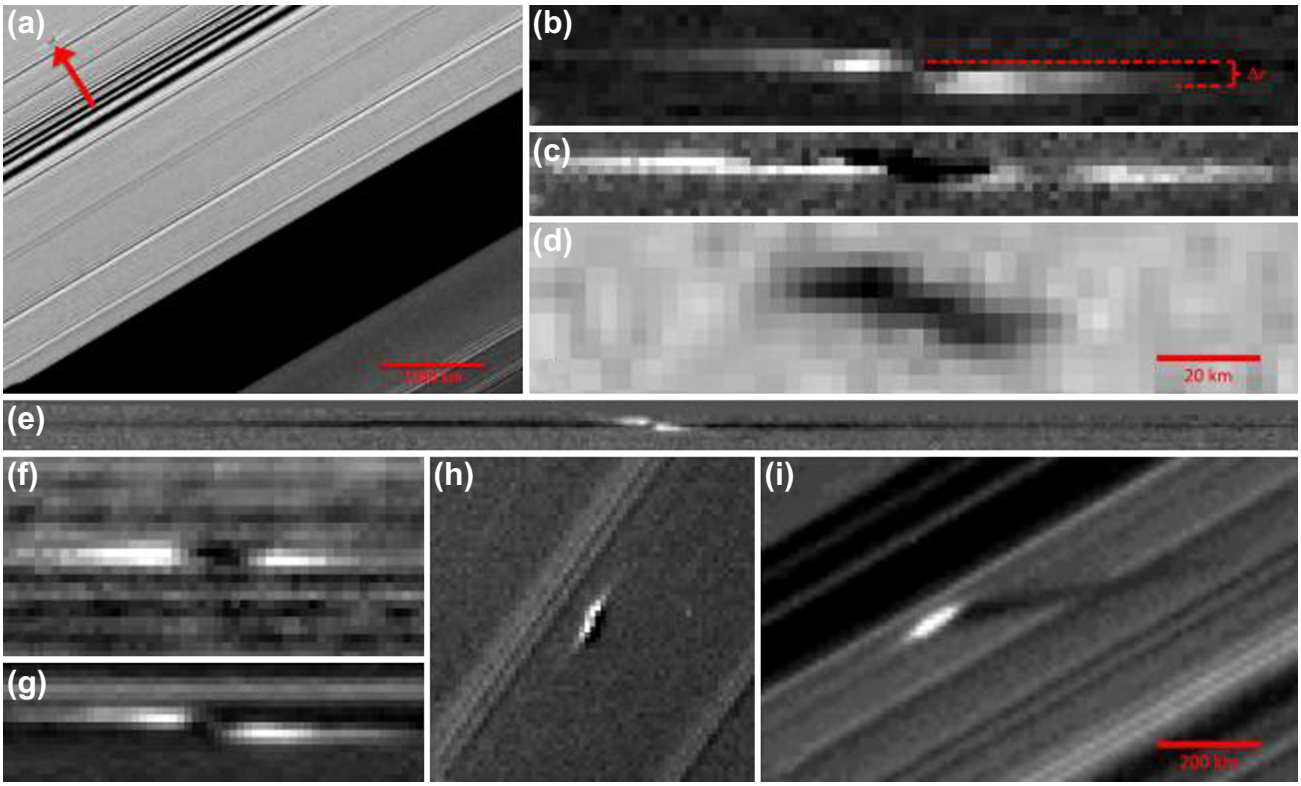

FIGURE 41.19 Propellers as seen in selected Cassini images. Panel (a) shows a propeller in context of the Encke Gap and several density waves. Panel (b) illustrates the radial offset Δr between the two azimuthally aligned lobes, proportional to the size of the unseen central moonlet. Panels (b), (c), and (d) show three views of the same propeller at the same scale, demonstrating how its appearance changes with viewing geometry. Nonequinox views are on the lit (b, e, g) or unlit (a, c, d, f) face of the rings, while panels (h) and (i) show propellers casting shadows near the Saturnian equinox. The scale bar in panel (d) also applies to panels (b), (c), (f), and (g). The scale bar in panel (i) also applies to panels (e) and (h).

Several "Propeller Belts" in the mid-A ring contain swarms of small propellers, due to moons about a few hundred meters in diameter. A separate class of "giant propellers," due to moons up to a few kilometers in diameter, has been found in the outermost A ring, outward of the Encke Gap.

In the Propeller Belts, the propellers are so numerous that, even if the same object were seen on multiple occasions, it would be very difficult to have much certainty that it was the same object due to the many nearby similar objects.[6] By contrast, the giant propellers are larger and more prominent and also much less numerous. Taken together, these factors allow giant propellers to be studied individually and tracked over a period of years. The moons within giant propellers are thus the only objects ever to have had their orbits tracked while embedded in a disk, rather than while orbiting in free space. The interactions between disks and embedded masses, such as has long been thought to occur in other disks such as young planetary systems, are being directly observed for the first time.

Orbital tracking of giant propellers has revealed that their orbits are indeed evolving. The largest and best observed propeller, nicknamed "Blériot",[7] has experienced at least three clear changes in its orbit and may additionally be subject to constant small changes. The leading theories agree that Blériot's orbit evolution is likely driven by random "kicks" that it receives from smaller ring particles and/or SGW clumps (Section 4.1), either through physical collisions or through gravitational interactions during close encounters, while one theory posits that radial density structure in the disk (Section 4.3) also plays an important role. Cassini is expected to continue tracking propeller orbits through 2017, and should further illuminate our understanding of how embedded masses interact with their disks.

The 2009 equinox event revealed that the propeller-shaped disturbance around an embedded moon extends vertically as well as in the ring plane. A giant propeller in the A ring, nicknamed "Earhart", was seen to cast a shadow (Figure 41.19(i)), and the shadow clearly is cast by the entire propeller disturbance and not by the central moon (which remains unseen). A bright feature designated S/2009 S 1, which was seen casting a shadow in the outermost part of the B ring (Figure 41.20), is also most likely an unresolved propeller.

4.3. Structures Formed by Distant Moons

4.3.1. Spiral Waves

Spiral density waves and spiral bending waves are the most widespread well-understood phenomena in dense rings. They were first proposed for the case of galaxies, and are also important for the evolution of protoplanetary disks, but they have been observed in Saturn's rings in far more detail than anywhere else.

Each spiral wave is generated by a **resonance**, which is the "beating in time" of ring-particle orbits with the orbit of a perturbing moon. A common example is a playground swing, which will swing higher if the pusher times the pushes to coincide with the frequency at which the swing is swinging. The two frequencies may be identical (a 1:1 resonance), but more often are related by a whole number ratio (for example, if a ring particle completes 5 orbits around Saturn in the time it takes a moon to complete 3 orbits, that would be a 5:3 resonance). Furthermore, a broad ring contains particle orbits that cover a large array of frequencies (orbits closer to Saturn are faster, those farther from Saturn are slower, in accordance with Kepler's third law); this can be likened to an array of transistor radios, each tuned to a different frequency and together covering the entire FM spectrum so that every radio station is being received on one boom box or another. Similarly, a large array of resonances find expression somewhere or another in the ring, but the lion's share are in the outermost A ring, simply because resonances become more numerous as one moves closer to the moons that cause them (or, continuing the analogy, the radio stations are more common at one end of the spectrum).

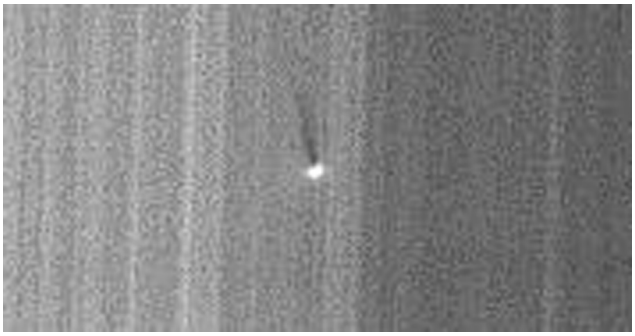

FIGURE 41.20 The feature known as S/2009 S 1, identified by the shadow it cast during equinox, was seen only in this image.

6. This criterion may be useful for drawing a distinction, should one wish to do so, between a "moon" and a "moonlet". Basing such a distinction upon size is arbitrary and lacks any wide agreement, as there is no major physical threshold crossed by objects in the kilometer-size range. We suggest that any object be called a "moon" if it can be singled out for long-term study, while a "moonlet" is a member of a population or swarm that prevents individual tracking. This may still not be a bright line, but at least it's based on a physical property. The question of whether propeller-causing objects deserve to be considered as full-fledged moons is further complicated by the fact that, although their positions have been tracked over long periods, they are not directly seen but hidden within the surrounding propeller-shaped disturbance.

7. For ease of reference, propellers that are being tracked have been nicknamed after pioneers of aviation.

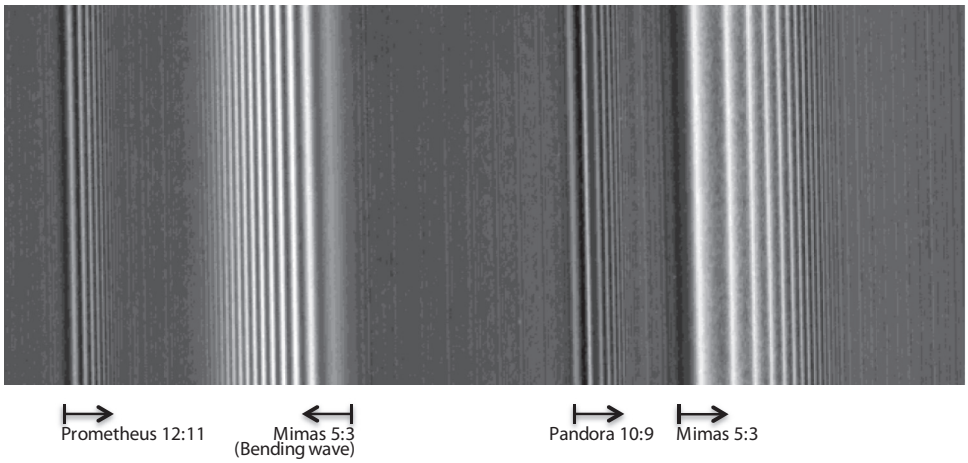

FIGURE 41.21 Spiral density waves and bending waves are seen in this close-up image of Saturn's A ring. The radial width of the area shown is 1000 km, and the center of the image is ~132,000 km from Saturn's center (which would be far to the left). Three density waves—due to the moons Prometheus, Pandora, and Mimas—are labeled along the bottom with rightward arrows, since density waves propagate outward from the location of the resonance. As an example, the resonance at left occurs where ring particles orbit Saturn 12 times in the same interval that it takes Prometheus to orbit 11 times. Mimas also generates a bending wave, which is labeled with a leftward arrow, since it propagates inward from the resonance. A close look at the image background reveals dozens of fainter waves, mostly due to the smaller moons Pan and Atlas.

The most common type of resonance excites radial motions in the ring particle's orbit (i.e. it makes the ring particle's orbit more **eccentric**). The resulting **spiral density wave** is a compression wave, alternating bands of higher and lower densities that propagate radially outward from the resonant location. Other resonances excite vertical motions in the ring particle's orbit (making the orbit more **inclined**). The resulting **spiral bending wave** is a transverse wave, a corrugation in the ring plane that propagates radially inward. Figure 41.21 shows examples of each kind of wave.

Spiral waves are useful phenomena that can be thought of as scientific instruments that have been placed in the rings for our benefit. The ring's local density and **viscosity** can be inferred by carefully measuring how the wave's **wavelength** and amplitude evolve as it propagates. This has been used to build detailed profiles of these characteristics, especially for the A ring, where spiral waves are most plentiful.

4.3.2. Confinement of Edges and Ringlets

Some resonances are so powerful that the disk cannot coherently respond with a wave, resulting in a gap whose edges are sculpted by the resonance (Section 4.2). One example is the Colombo Gap in the C ring, located at a resonance between ring particle **precession** (the slow rotation of the noncircular orbit) and the orbit period of Titan; in the middle of this gap is an eccentric narrow ringlet (Section 5) that keeps its long axis always pointed toward Titan. The Keeler Gap, in which Daphnis orbits, has a 32-lobed inner edge sculpted by a 32:31 resonance with Prometheus.

Resonances can also provide a barrier to the outward diffusion of ring material, resulting in a sharp outer edge to a ring. The outer edge of the B ring (which is also the inner edge of the Cassini Division) is maintained by a 2:1 resonance with Mimas. In a similar fashion, the outer edge of the A ring is governed by a 7:6 resonance with the co-orbital moons Janus and Epimetheus.

5. DENSE NARROW RINGS

Dense narrow rings (see the upper part of Figure 41.5) are a unique assemblage of matter, behaving as a coherent self-contained object on planetary length scales yet ephemerally thin; they are only 1−100 km in radial width, compared to ~100,000 km in diameter. How and why these highly organized

Saturn	Titan ringlet
	Maxwell ringlet
	Bond ringlet
	Huygens ringlet
	"Strange" ringlet
	Herschel ringlet
	Jeffreys ringlet
	Laplace ringlet
Uranus	6 ring
	5 ring
	4 ring
	α ring
	β ring
	η ring
	γ ring
	δ ring
	ε ring

dynamical systems form is almost entirely unknown, and even their present dynamics are only partly understood.

Nearly all known dense narrow rings are either noncircular or inclined to the main ring plane, or both. Furthermore, nearly all dense narrow rings have edges that are quite sharp; as with dense disks, the existence and stability of such sharp edges requires some confinement mechanism to counteract the natural process of radial viscous spreading. Confinement may be due to an external moon or to the ring's own self-gravity, and in some cases to processes yet to be understood.

The "shepherding" mechanism by which a moon opens a gap (Section 4.2) or maintains an edge in a disk (Section 4.3) can also occur with two shepherd moons on either side of a narrow ringlet. However, the only example of a dense narrow ring with a known shepherd on either side is Uranus' ε ring, although Saturn's F ring (see Section 6.1) is a variation on that idea. Indeed, as observations seeking for them continue to pile up, the scarcity of shepherd moons at both Saturn and Uranus is becoming more and more conspicuous, lending indirect support to theories that narrow rings are instead maintained by resonances or by self-sustaining mechanisms.

A number of narrow ringlets are eccentric and appear to precess about their planet as a rigid body. At first blush, this appears to contradict Kepler's third law, by which the inner edge would be expected to precess faster than the outer edge, with the ring eventually smearing out to a circular shape after only a few years. However, the ring's own self-gravity and/or interparticle collisions can counteract this effect, altering the precession rate by different amounts in different parts of the ring so that the whole ring precesses as if it were a rigid body. In its simplest form, this effect will occur only if the ring has a positive "eccentricity gradient", which is to say that the eccentricity increases from the ring's inner edge to its outer edge, and indeed several narrow rings appear to have outer edges that are more eccentric than their inner edges.

6. DUSTY RINGS

All the giant planets possess rings composed primarily of particles less than 100 microns across. The distribution, structure and dynamics of these dusty rings are quite different from those of the dense rings described above.

Narrow Dusty Rings	
Saturn	"Charming" ringlet
	Encke Gap ringlets
	F ring
Uranus	λ ring
Neptune	Le Verrier ring
	Arago ring
	Adams ring

Diffuse Dusty Rings	
Jupiter	Halo ring
	Main ring
	Amalthea Gossamer ring
	Thebe Gossamer ring
Saturn	D ring
	Roche Division
	Janus/Epimetheus ring
	G ring
	Methone ring
	Pallene ring
	Anthe ring
	E ring
	Phoebe ring
Uranus	ζ ring
	ν ring
	μ ring
Neptune	Galle ring
	Lassell ring

For example, dusty rings are typically much more tenuous than dense rings, so collisions between particles are rare, and the material in these rings cannot efficiently aggregate into larger bodies. Hence these dusty rings can exist outside the planet's Roche limit. Furthermore, dust-sized particles can be destroyed by collisions with micrometeoroids or ions on timescales of years to decades, so these rings must be constantly resupplied with material from larger source bodies. These rings' appearance can therefore respond rapidly to processes that affect the rates of particle production, destruction, or transport (see Section 6.1). The high surface area-to-volume ratios of these small particles also make them extremely sensitive to various nongravitational perturbations (see Section 6.2). These rings therefore are highly dynamic systems.

6.1. Dust Production and Destruction

The primary mechanism for producing orbiting dust particles is micrometeoroid bombardment of larger orbiting bodies. A notable exception is Saturn's E ring, which is supplied by the cryovolcanic plume emerging from the south pole of the 500 km moon Enceladus. The distinctive origin of the E ring manifests itself in its unusual particle-size distribution. Because they respond more readily to the escaping fast-moving gas, smaller particles are launched at higher average speeds, and only particles less than a few microns across escape the moon's gravity to enter the E ring. The dearth of larger particles gives the E ring a distinctive blue color when viewed at low phase angles.

Besides Enceladus, the moons associated with detectable dusty rings are typically rather small. At Saturn, dusty rings are found along the orbits of Pan (with a diameter of 28 km), the co-orbitals Janus and Epimetheus (180 km/120 km), Aegaeon (0.5 km), Methone (3 km), Anthe (2 km), Pallene (5 km), and Phoebe (210 km). Jupiter's main rings are associated with the moons Metis (60 km) and Adrastea (20 km), while its Gossamer rings appear to be derived from Amalthea (170 km) and Thebe (100 km). Finally, Uranus' μ ring is found around the orbit of Mab (25 km). Small moons are probably more efficient sources

of dusty rings because their surface gravities are low, which allows impact-generated debris to escape from the moon and enter orbit around the planet. This debris typically contains a broader distribution of particle sizes, giving these rings a neutral or red color (with the still-puzzling exception of the μ ring).

The boulder-sized particles in the dense rings are another potential source of small grains that can form dusty rings. Indeed, such debris is likely the source of a few dusty rings found in gaps within and adjacent to Saturn's and Uranus' main rings. Similarly, the dusty material in Saturn's F ring is probably derived from a population of larger particles embedded within the ring. Neptune's dusty rings may have a similar origin, but the available data for these systems are relatively sparse.

Assuming these rings are more or less in a steady state, then the production of fine grains must be balanced by various loss processes. This includes erosion due to magnetospheric ions and micrometeoroids, as well as reaccretion onto larger particles. The latter is particularly important for the dusty rings found in close association with dense rings. Indeed, aside from the transient spokes (discussed in Section 7.3 below), Saturn's main rings are remarkably dust-free, with dusty ringlets only occupying nearly empty gaps in the A ring, Cassini Division, and C ring.

6.2. Nongravitational Forces

Between their creation and destruction, the orbital properties of these small grains evolve under the influence of various nongravitational forces. For example, several narrow dusty ringlets occupying gaps within Saturn's main rings have the unusual property that the geometric center of the ringlet appears to be consistently displaced away from Saturn's center toward the Sun. This "heliotropic" behavior likely arises because solar **radiation pressure** can significantly perturb the orbits of these tiny particles. There are also structures in the innermost dusty rings around Jupiter and Saturn that can be attributed to resonances with the rotation period of the planet's magnetosphere (see Section 7.3). These structures indicate that the relevant dust grains can be charged enough to make them susceptible to electromagnetic forces.

In other dusty rings, we have evidence that material is being transported radially toward or away from the planet. Jupiter's Gossamer rings and Saturn's enormous Phoebe ring all extend inward from their putative source moons, while Saturn's G ring extends outward from its most likely source. This directional transport of material can be attributed to drag forces. For the Gossamer rings and the Phoebe ring, the drag force can be attributed to the asymmetric scattering of solar photons, also known as **Poynting–Robertson drag**. By contrast, the outward drift of material in the G ring is due to collisions between the dusty ring particles and magnetospheric ions. These ions move around the planet much faster than the ring particles as they are pulled along by the planet's rotating magnetic field (the G ring is well beyond synchronous orbit). Hence the collisions between the ions and the ring particles tend to accelerate the particles and cause them to spiral outward.

6.3. Resonantly Confined Material

Given the number of nongravitational forces affecting dusty rings, and how quickly the small grains can be transported or destroyed, one might naturally expect that all dusty rings would be rather broad and diffuse. However, in reality, many dusty rings are highly structured, and several exhibit significant azimuthal brightness variations.

Ring Arcs	
Saturn	G ring (Aegaeon ring arc)
	Methone ring arc
	Anthe ring arc
Neptune	Galatea ring arc
	Adams ring (?)

Azimuthal Clumps	
Jupiter	Main ring
Saturn	Encke Gap ringlets
	F ring
Neptune	Adams ring (?)

Left to itself, any clump of material orbiting a planet should spread out into a ring fairly quickly. This is because, by Kepler's third law, material at the inner edge of the clump is moving faster than material at the outer edge, and the one will soon "lap" the other by an entire orbit. Narrow clumps will spread into a ring more slowly, but even a compact initial clump ~1 km wide will spread into a ring within a few decades. However, certain azimuthal brightness variations, known as ring-arcs, appear to persist for years or decades without any obvious spreading.

The first-discovered and best known set of these ring arcs are found in Neptune's Adams ring. These are the densest components of Neptune's ring system and were oftentimes the only component detectable in pre-Voyager Earth-based occultations, leading to much confusion as to whether the detected signatures were rings at all until Voyager 2 settled the question. There are five arcs ranging from a few degrees to ~10° in length extending over a region of ~40° in longitude (Figures 41.6, 41.22 and 41.23).

A closer look at these arcs indicated that they could be maintained and confined by a corotation resonance. Unlike the resonances that produce spiral density waves, in which the perturbing moon pumps up a ring particle's eccentricity (Section 4.3), corotation resonances tend to azimuthally confine particles into an orbit commensurate with that of the perturbing moon. Initial analysis of the Voyager 2 images indicated that the Adams ring arcs might be governed by the nearby 43:42 corotation resonance with the

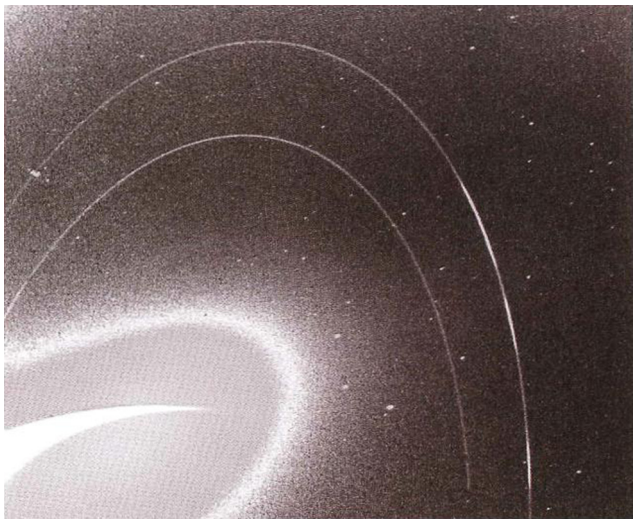

FIGURE 41.22 The brightest two Neptunian rings, Le Verrier (inner curve) and Adams (outer curve) are revealed in this Voyager image. Neptune is overexposed to lower left, indicating the difficulties in searching for faint features near planets. A short-exposure crescent-shaped Neptune has been overlayed to indicate the planet's true size and phase. Three of the famous ring arcs are visible in the outer Adams ring, while the Le Verrier ring has no such features.

moon Galatea, although there was some difficulty in that the azimuthal lengths of the arcs do not easily match the 4° periodicity expected from the resonance. The 1999 reacquisition of the arcs with Earth-based imaging ruled out the simplest version of this model, but a more complex version was suggested and remains plausible. Further Earth-based observations also revealed significant changes in the arcs' structure over the 20 years in which they have been observed in detail (Figures 41.22 and 41.23).

More recently, Cassini has found several examples of ring-arcs in Saturn's dusty rings. These rings are much more tenuous than Neptune's Adams ring, and thus provide somewhat simpler examples of resonantly confined debris.

The most prominent of these arcs is found near the inner edge of Saturn's G ring (Figure 41.24). This arc, along with the tiny moon Aegaeon embedded within it, appears to occupy the 7:6 corotation resonance with Saturn's moon Mimas. The arc orbits the planet seven times in roughly the same time it takes Mimas to orbit the planet six times. Furthermore, the arc's location and azimuthal extent

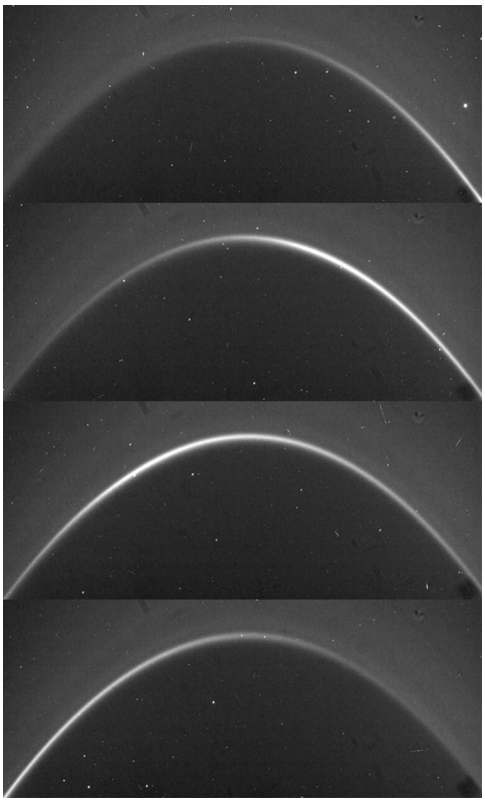

FIGURE 41.24 The G ring arc, passes through the field of view.

matches the predicted distribution of material trapped by this resonance.

This arc probably represents the source of the G ring, which is much brighter than most other rings generated by small moons. Measurements of charged particles in the vicinity of the arc indicate that in addition to the small moon Aegaeon, this region contains a population of boulder-sized objects that are trapped in the resonance and can serve as source bodies for fine debris. These dust grains can escape from the arc under the influence of nongravitational forces, migrating outward (Section 6.2) to populate the rest of the G ring.

Two other arcs, even more tenuous than the G ring's, surround the small moons Anthe and Methone

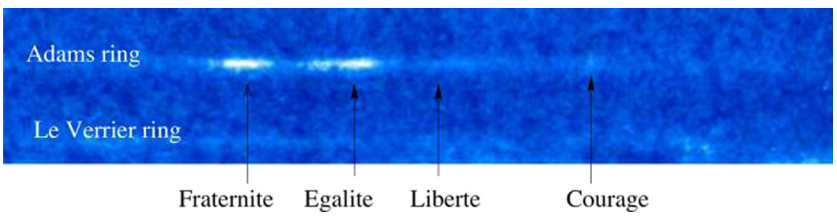

FIGURE 41.23 Reprojected ground-based image of the Adams ring (with arcs) and the Le Verrier ring acquired in October 2003. The orbital direction is to the right and the radial direction (away from Neptune) is up. The leading arc Liberté was originally seen by Voyager 2 (Figure 41.22) to be as bright as the other two main arcs, but here is much dimmer.

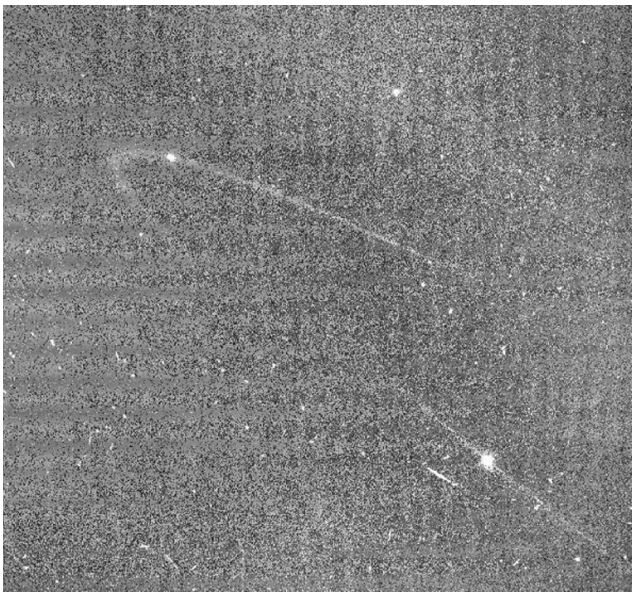

FIGURE 41.25 The moons Anthe (top left) and Methone (bottom right) share their orbits with arcs of dust.

(Figure 41.25), and are compatible with the 10:11 and 14:15 corotation resonances with Mimas, respectively.

6.4. Azimuthal Clumps and Kinks

In addition to the relatively stable and persistent arcs that are likely confined by resonances, dusty rings can also exhibit more transient and variable azimuthal structure.

The F ring is the granddaddy of narrow dusty ringlets, and by far the best studied (Figure 41.26, Movie M3). Located a few thousand kilometers off the outer edge of Saturn's main rings, its relatively large vertical thickness effectively frustrates any attempt to see the rest of the main rings in edge-on viewing geometries. Its high fraction of forward-scattering dust makes it by far the brightest component of Saturn's ring system when viewed at high-phase geometries.

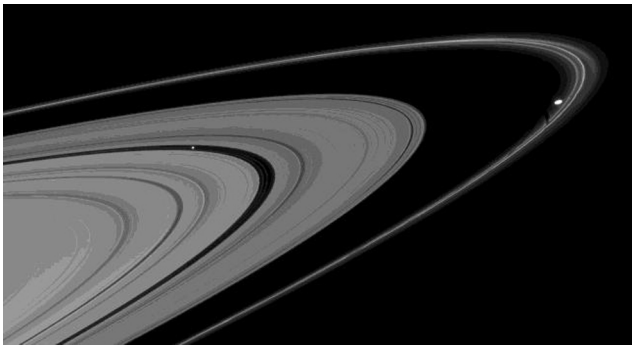

FIGURE 41.26 The F ring is a multifaceted ribbon lying off the outer edge of Saturn's main disk (see also Movie M3). The moon Prometheus, lying just inward, carves out "streamer channels" as it dips into the F ring (see also Figure 41.27 and Movies M4–M6). Also visible at center-left is the moon Pan, orbiting within the Encke Gap, with the three dusty ringlets that share the gap and the "moonlet wakes" trailing behind it on the outward side of the gap.

In general, the F ring's core is a complex region, possessing transient bright "clumps", as well as "kinks" in its apparent radial position. These structures form, merge, split, and dissipate on a wide range of timescales, and only the largest features can be tracked over time with any amount of reliability. Rather than being produced by resonances, these structures instead probably reflect localized sculpting of the dust population by nearby moons and embedded boulders.

As mentioned in Section 5, the F ring is one of only two narrow rings to have known "shepherd" moons orbiting on either side of it. However, it has not been conclusively shown how (or even that) the moons Prometheus and Pandora actually constrain the F ring in its place, and in fact they appear to stir the ring up at least as much as to maintain it. Prometheus, in particular, has an eccentric orbit that allows it to occasionally pass through the core of the F ring once per orbit. These close encounters generate "streamer channel" features in nearby dust strands that subsequently moves downstream and shears under Keplerian motion (Figure 41.27, Movies M4–M6).

Other structures in this ring may be generated by kilometer-sized moonlets hiding within the ring. The moonlets are known to be there because of their absorption of charged particles, from direct detection by occultations, from the characteristic "fan" structures they create in surrounding dust (Figure 41.27, Movie M7), and from shadows cast during the 2009 Saturnian equinox (Figure 41.27). Some of the brightest clumps in the ring, as well as the dusty lanes or "strands" lying on either side of the core may represent debris produced by collisions into or among these objects.

All these interwoven phenomena make the F ring the solar system's foremost natural laboratory for studying accretion and disruption processes. However, even with all this time variability, the F ring core nevertheless maintains over decadal timescales the shape of a freely precessing eccentric inclined ellipse; the orbital solution formulated to account for Voyager and other pre-Cassini data has, somewhat surprisingly, remained a good predictor of the core's position as seen by Cassini.

Besides the F ring, the clumpiest dusty rings are the three narrow ringlets occupying the Encke Gap in Saturn's outer A ring (Figure 41.28). These ringlets all possess "clumps" (azimuthal brightness variations) and "kinks" (radial offsets). However, in this case the clumps move slowly enough relative to each other that they can be tracked over several years. These clumps do not follow the expected trajectories of test particles in the combined gravitational fields of Saturn and Pan, and there is not

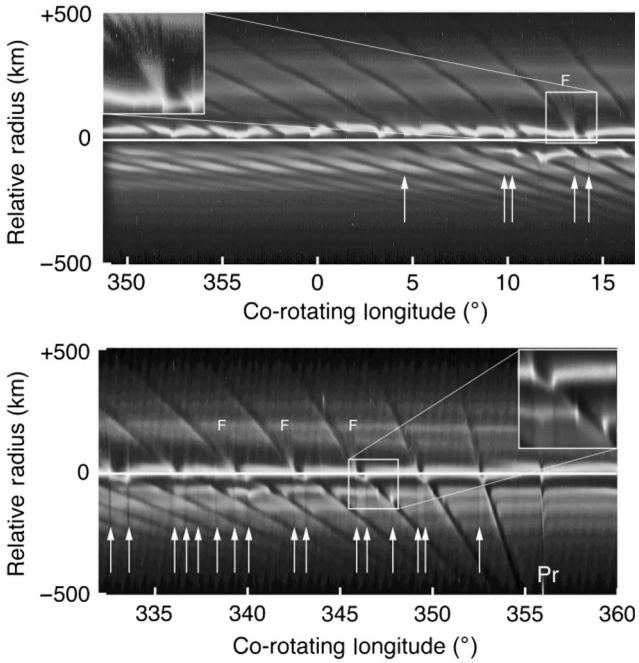

FIGURE 41.27 In each of these two mosaics, ~8% of the azimuthal extent of the F ring is projected onto a radius-longitude grid. The bright core of the F ring is at zero radius, and parallel strands can be seen on either side of it. The white arrows mark inward-pointing shadows cast by moonlets within the bright F ring core. The letter "F" marks "fan" structures, also seen in the insets and illustrated in Movie M7, which are the dust sheet's response to an embedded moonlet on an eccentric orbit. The narrow dark stripes trending from upper left to lower right are sheared "streamer channels" created as the moons Prometheus and Pandora dip into the ring (see also Movies M4–M6).

yet any clear evidence for larger objects embedded in these ringlets. Hence these clumps could instead reflect collective phenomena or instabilities within the dusty material.

Images from the 2007 New Horizons flyby of Jupiter found several azimuthal clumps in the core of the Main ring (Figure 41.29) that fall close to the 115:116 and 114:115 corotation resonances with Metis, the same kind of resonance invoked to explain Neptune's Adams arcs. Furthermore, continuing the analogy with Neptune's Adams arcs, the azimuthal spacing of the clumps does not correspond to the periodicity expected from the resonances. Thus these features could also represent transient features like the clumps found in Saturn's F ring and Encke Gap ringlets.

It is remarkable that all the obviously clumpy dusty rings (Jupiter's Main ring, Saturn's F ring, and Encke Gap ringlets, and even perhaps Neptune's Adams ring), are located close to the planet's Roche limit. By contrast, narrow dusty rings found closer to the planet, like Uranus' λ ring, Neptune's Le Verrier or Arago rings, appear to be much more sedate.

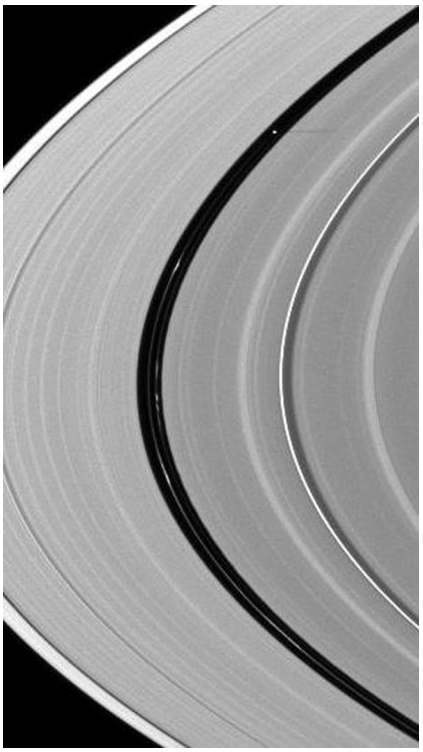

FIGURE 41.28 Azimuthal clumps and kinks can be seen both in the central and inner Encke Gap ringlets, here leading Pan in its orbit.

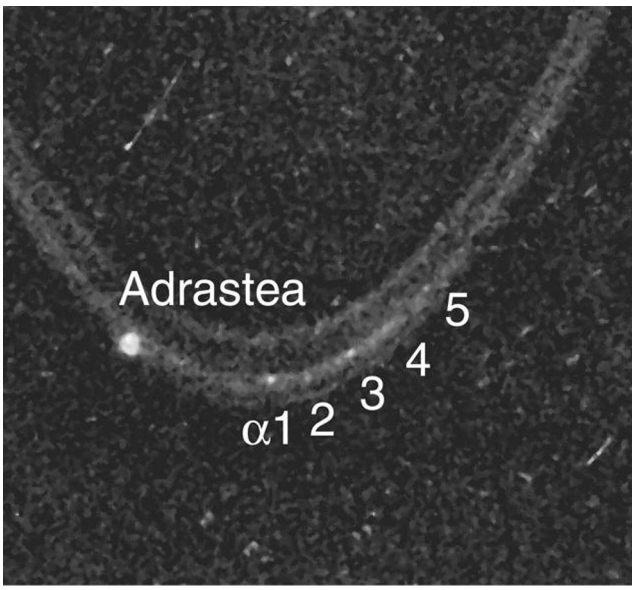

FIGURE 41.29 Azimuthal clumps in the Main ring of Jupiter lie slightly inward of the moon Adrastea's orbit.

7. USING RINGS TO PROBE THE SOLAR SYSTEM

As delicate dynamical systems covering vast areas, rings sometimes function as useful detectors of their

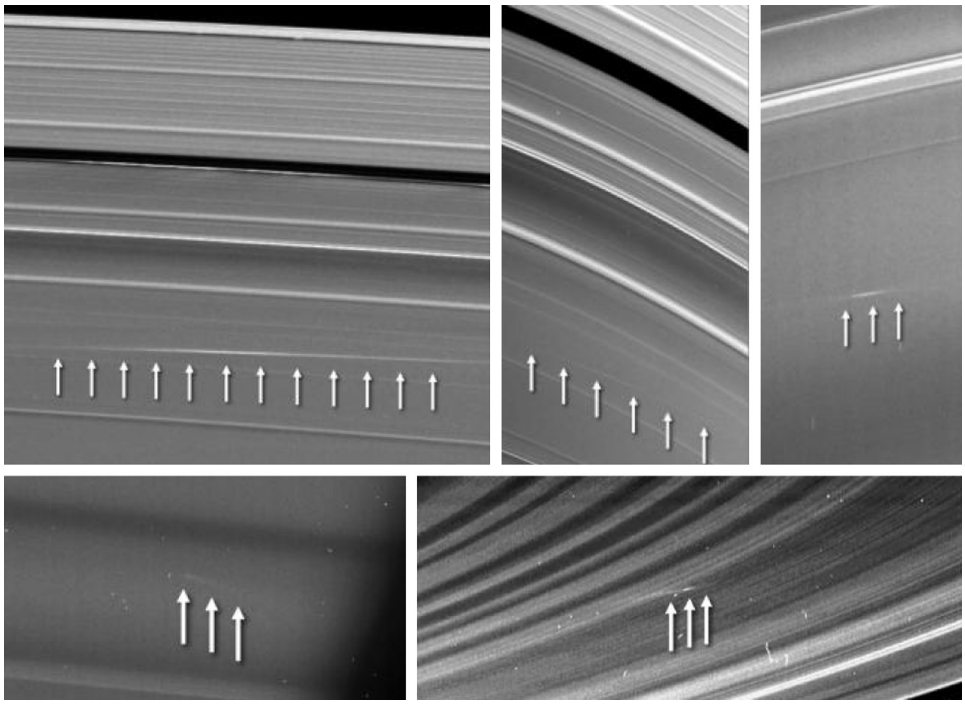

FIGURE 41.30 Ejecta clouds in Saturn's rings are canted from the azimuthal direction by an angle of a few degrees, due to Kepler's third law.

surrounding environment. The structure of the planet's gravity and magnetism, changes in the orbits of its moons, and the population of meteoroids in the outer solar system are all illuminated by phenomena observed in the rings.

7.1. Probing Interplanetary Meteoroids

We are used to the idea that, when a **meteoroid** strikes a planetary surface, **ejecta** flies in all directions and the result is a crater structure such as Meteor Crater in Arizona or the countless craters that punctuate the surface of the Moon. However, the result is very different when the "target" is not a solid surface but rather a ring composed of countless particles that are constantly in motion. Not only does the impact result in no discernible crater (instead, one or more pieces of the target ring are simply pulverized[8]), but also the expanding ejecta cloud soon becomes hijacked by Kepler's third law and assumes a linear shape that is canted from the azimuthal direction by an angle of a few degrees (Figure 41.30).

Several ejecta clouds have been observed by Cassini, yielding the first direct knowledge of particles in the outer solar system that are larger than dust but smaller than moons. These impacts occur continually, but the ejecta clouds are usually too faint to be visible. Cassini saw them best during the 2009 equinox, when the Sun's edge-on illumination yielded a dark ring background while ejecta rising above the ring plane caught full sunlight.

The time elapsed since the cloud was formed can be directly calculated from the cant angle, using Kepler's third law. In one case (the first two panels of Figure 41.30), the same cloud was seen 24 h apart, and the ages derived from the cant angle were also 24 h apart, confirming that we are properly interpreting these observations.

In contrast to the constant influx of meteoroids of meter-size and smaller, larger impacts are rare and can leave reverberations that persist for decades or more. The momentum of the impacting material can give the rings a slight tilt, which then winds up into a spiral corrugation because inclined orbits in the inner part of the disk precess faster than those in the outer part (a principle related to Kepler's third law). The wavelength of the spiral and the rate at which it is winding up give two independent measures of the time elapsed since the impact. One such corrugation appears to have been created in Jupiter's Main ring by debris from comet Shoemaker-Levy 9, which crashed into Jupiter in 1994. Another corrugation, permeating Saturn's C and D ring (Figure 41.31), appears to have been caused by a similar unseen event that occurred around 1983.

8. If the meteoroid is much smaller than typical ring particles (e.g. it is a speck of dust), then a target ring particle may indeed survive and sport a small crater. However, in this section we are discussing centimeter-size to meter-size impactors.

7.2. Probing the Planet's Gravity

When a planet's interior structure is not perfectly symmetric, it causes orbits around that planet to precess (that is, the orbit path itself slowly rotates or revolves, similar to the midplane of a spinning top). The rate of precession directly yields information about the planet's internal structure, which is expressed through its gravitational field. Spacecraft can use this method to probe the internal structure of any object they fly past, by precisely tracking changes in its own trajectory, but precision increases dramatically when the orbit is closer to the object being probed. Thus, the most precise gravity measurements for both Saturn and Uranus come from spacecraft observing the precession of their dense narrow rings (Section 5).

Precession is driven by planetary asymmetries in the latitude direction; asymmetries in the longitude direction can drive spiral waves in much the same way as orbiting moons (Section 4.3). Voyager observations revealed a small group of mysterious spiral waves in the C ring, Saturn's closest dense ring, which did not have any connection with the orbit of a known moon that might drive the waves. Suspicion fell on **normal modes**, a hypothetical sloshing back-and-forth of portions of Saturn's interior, but no more could be said given the quality of the Voyager data.

This mystery is starting to yield not only to the greater frequency (measuring the waves at many different points within their oscillations) but also to the greater sensitivity (seeing the waves at each measurement in more detail) of Cassini's observations. The first use of a ring system as a seismometer is underway and is likely to pinpoint specific modes in which Saturn's interior operates and evolves.

7.3. Probing the Planet's Magnetosphere

"Spokes" are near-radial markings on Saturn's B ring, likely composed of dust levitating above the ring plane due to electromagnetic forces (Figures 41.32 and 41.33 and Movie M8). Spokes appear in the central B ring at radial locations near to (and often astride) **synchronous orbit**, where the orbital period of a ring particle matches the rotation period of the planet, and thus also of the magnetic field. Observations by the Hubble Space Telescope and by Cassini have revealed that spokes are a seasonal phenomenon, more abundant near **equinox** and absent near **solstice**.

Spokes are likely triggered by **meteoroid** impacts onto the ring, but their growth is governed by the interaction between impact-ejected dust and Saturn's magnetic field, which causes the dust to levitate above the ring. Strong periodicities in the occurrence of spokes appear to be correlated with periodicities in Saturn's magnetic field.

Canted patterns in the D ring and the Roche Division, the tenuous dusty sheets on either side of Saturn's main rings, are driven by resonances (see Section 4.3) with the rotation period of the planet's magnetic field. Tenuous dusty sheets are populated by tiny grains that are easily charged and thus subject to electromagnetic forces, making them especially sensitive detectors of the planet's magnetism. The complex observed structures pinpoint multiple pattern speeds, furnishing a major source of information for the complex rotation of Saturn's enigmatic magnetic field.

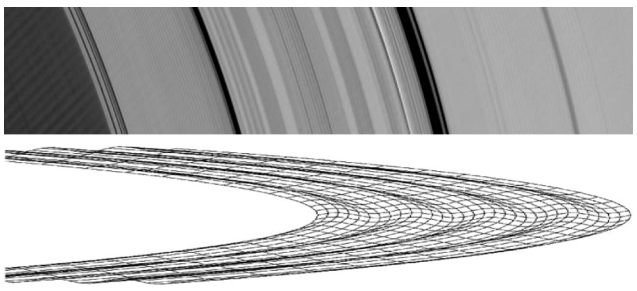

FIGURE 41.31 (Top) Cassini image mosaic of the D (far left) and C rings, taken during the 2009 equinox, showing a pervasive undulation. (Bottom) model demonstrating how such an undulation can be caused by a corrugation in the ring plane.

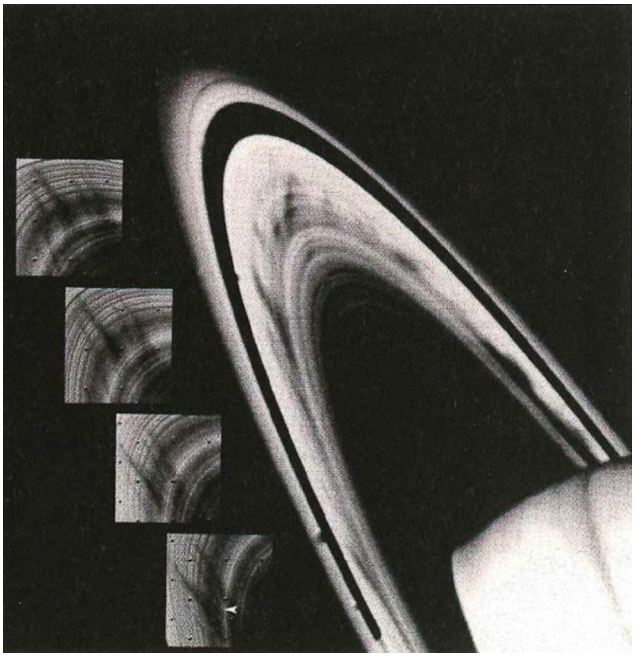

FIGURE 41.32 A Voyager image of dark spokes seen against Saturn's sunlit B ring. Small dust particles appear dark under this lighting condition, hinting and the still poorly understood physical processes behind spoke creation. The inset panels show the change of a given feature with time.

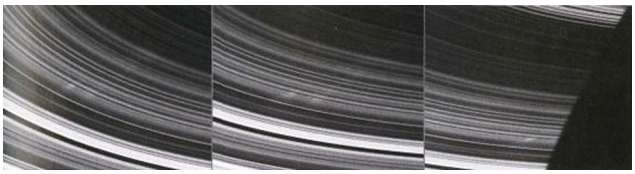

FIGURE 41.33 A three-panel Cassini image of bright spokes seen against the dark side of Saturn's B ring. Small dust particles appear bright under this lighting condition. The motion of the spokes can be seen clearly by comparing the three panels.

8. AGE AND ORIGINS OF RING SYSTEMS

The question of the age of a ring system is actually two separate questions, one being the age of the material and the other the age of the structure currently in place. This distinction is particularly important for diffuse dusty rings (Section 6.1). For example, if Amalthea, Thebe, Adrastea, and Metis were to suddenly disappear, or to suddenly cease emitting dust, Jupiter's rings would dissipate within 100,000 years at the most. Thus, the age of individual particles in a diffuse ring is on the order of the mean residence time, while the age of the overall structure is related to how long the sources have been in place.

The distinction between material age and overall structural age also turns out to be useful for Saturn's main rings. Several aspects of the rings are difficult to reconcile with a ring age comparable to that of Saturn. For example, the exceptionally pure water-ice composition of the A and B rings is difficult to reconcile with the constant pollution of the rings by infall of interplanetary micrometeoroids. Furthermore, the same infall should significantly erode ring particles, especially in more tenuous regions. Finally, the orbits of nearby moons are migrating outward, pushed by the density waves they raise in the rings (Section 4.3), and this process can only be "rewound" for about 10–20 million years. On the other hand, the "young rings" scenario is difficult to imagine because there are few plausible objects in the modern solar system that are large enough to yield Saturn's massive ring system if pulled apart.

Most solid material in the outer solar system is relatively dark because carbon-rich compounds are mixed with the ice. By contrast, Saturn's rings are highly reflective at both visible and radio wavelengths, which indicates that dark organic materials like those seen on comets are relatively rare there, likely composing less than 1% of the material on the ring particles' surfaces. This is surprising because cometary debris is constantly raining down on the rings, which should rapidly cause the rings to darken. Indeed, there is evidence that this darkening is occurring to some limited extent. The particles in the Cassini Division and the C ring are significantly darker than the particles in the A and B rings, which makes sense because the C ring and Cassini Division have less material overall and thus would become contaminated more quickly.

One potentially viable theory suggests that the B ring core is ancient, dating from the early history of the solar system, when collisions with **planetesimals** were much more frequent (*see* "Origin of the Solar System"), but that much of the specific organization of material in Saturn's rings is only about 10–20 million years old. Recent indications that the B ring's mass has previously been underestimated (see Section 4.1) provide an increased buffer against interplanetary pollution, as well as making the ring precursor body even larger and thus a recent ring origin even more unlikely. Erosion of ring particles might also have been slower if ring particles have spent most of their history more densely packed (thus, exposing less surface to erosion) than we now find them. The current ring-moons may also have formed within the rings and emerged only recently.

It is easier to imagine that the rings of Uranus and Neptune, with their lower masses and much darker surfaces, have remained little changed over the age of the solar system. The Uranian rings, as well as the nearby group of moons, may be part of a system that has oscillated between accretion and disruption for billions of years (Section 3.2). But why are the rings where they are? Do their positions simply reflect where source material became available, or did dynamical processes sculpt them into their current configurations? On the planetary level, why does Saturn have its glorious broad dense disk while Uranus and Neptune have much more modest systems and Jupiter has only moon-generated dust? None of these questions has a clear answer as yet.

Supplementary Video

The following supplementary video related to this chapter can be found at http://dx.doi.org/10.1016/B978-0-12-415845-0.00041-4:

Movie M1: Simulated self-gravity wakes (SGWs). This microstructure develops within dense rings as particles clump together under their mutual self-gravity but are ripped apart again by Saturn's tides. Figure 41.12 is a still from this movie.

Movie M2: Simulated viscous overstability.

Movie M3: Bright knots, caused by embedded moonlets, pass continually through the core of the F ring.

Movie M4: As Cassini's camera stares at a single point on the F ring, Prometheus and Pandora march through the field of view, attended by a suite of streamer channels generated by Prometheus.

Movie M5: In this simulation, Prometheus moves in and out as it goes around on its eccentric orbit, dipping into the F ring and generating streamer channels that "breathe" in and out. Compare to the Cassini observations in Movie M6.

Movie M6: Cassini's camera stares at Prometheus as it goes around on its eccentric orbit, dipping into the F ring and generating a streamer channel. Compare to the simulation in Movie M5.

Movie M7: In this simulation, an embedded moonlet on an eccentric orbit generates a "fan". Compare to the Cassini images in Figure 41.27.

Movie M8: As Voyager's camera stares at a single point on the B ring, spokes pass through the field of view. See the related Voyager images in Figure 41.32 and the Cassini images in Figure 41.33.

Space Science and Engineering Division, Southwest Research Institute, Boulder, CO, USA

Chapter Outline

1. Historical Background **909**
1.1. Overview 909
1.2. The Discovery of Pluto's Satellites 910
2. Pluto's Orbit and Spin **911**
2.1. Pluto's Heliocentric Orbit 911
2.2. Pluto's Lightcurve, Rotation Period, and Pole Direction 911
2.3. Charon's Orbit and the System Mass 912
3. The Mutual Events **913**
3.1. Background 913
3.2. Radii and Average Density of Pluto and Charon 913
4. Pluto's Surface Properties and Appearance **914**
4.1. Albedo and Color 914
4.2. Solar Phase Curve 914
4.3. Surface Composition 914
4.4. Surface Temperature 915
4.5. Surface Appearance and Markings 916
5. Pluto's Interior and Bulk Composition **917**
5.1. Density 917
5.2. Bulk Composition and Internal Structure 917
6. Pluto's Atmosphere **918**
6.1. Atmospheric Composition 918
6.2. Atmospheric Structure 919
6.3. Atmospheric Escape 920
7. Charon **920**
8. The Origin of Pluto's Satellite System **922**
8.1. The Formation of Pluto's Satellite System 922
8.2. The Origin of Pluto Itself 922
8.3. The Context of Pluto in the Outer Solar System 923
Bibliography **924**

Pluto is the prototype of the dwarf planets common in the Kuiper Belt and beyond. It is in an elliptical, 248 year orbit that ranges from 29.6 to 48.8 **astronomical units** (AU) from the Sun. Its largest satellite, Charon, is close enough to Pluto in size that the pair is widely considered to be a double planet. Pluto's four other known satellites, Styx, Nix Kerberos and Hydra, orbit beyond Charon but in Charon's orbital plane, and are relatively small. Almost nothing is known about these moons save their orbits (see Figure 42.1), approximate sizes, and their neutral, Charon-like colors. Both Pluto and Charon are rich in ices, but their surface compositions, **albedos**, and colors are very different. Unlike Charon, Pluto is known to possess distinct surface markings, polar caps, and an atmosphere. Major questions under study about the Pluto system include the fate of Pluto's atmosphere, the degrees of internal activity Pluto and Charon exhibit, and the origin of the system.

1. HISTORICAL BACKGROUND

1.1. Overview

Pluto was discovered in February 1930, at Lowell Observatory in Flagstaff, Arizona. This discovery was made by Clyde Tombaugh (1906–1997), an observatory staff assistant working on a search for a long-suspected perturber of the orbits of Uranus and Neptune. That search, which was first begun in 1905 by the observatory's founder, Percival Lowell, never located the large object originally being searched for because the positional discrepancies of Uranus and Neptune, which prompted that search, were fictitious. Still, the search for Lowell's "Planet X" resulted in the discovery of the tiny planet Pluto, which itself heralded the discovery of the Kuiper Belt some 70+ years later.

Within a year of Pluto's discovery, its orbit was well determined. That orbit is both eccentric and highly inclined

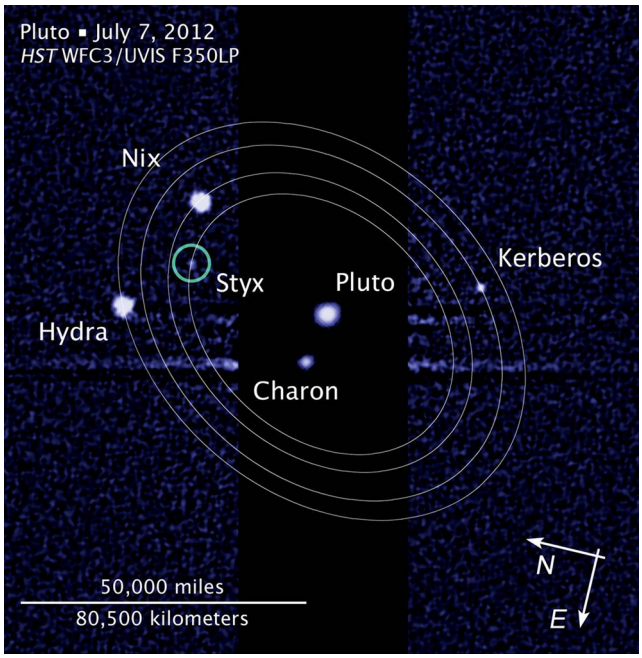

FIGURE 42.1 The Pluto System. This Hubble Space Telescope image shows Pluto and the orbits of it five known moons as of early-2014. *Credit: NASA/STScI.*

to the plane of the **ecliptic**, compared to the orbits of the other planets (see Table 42.1). However, no important discoveries about Pluto's physical properties were made until the early 1950s. This lack of information was largely due to the difficulty of observing Pluto with the scientific instruments available in the 1930s and 1940s. Between 1953 and 1976, however, technological advances in photoelectric photometry made possible several important findings. Among these were the discovery of Pluto's ~6.387 day rotation period, the discovery of Pluto's reddish surface color, and the discovery of Pluto's high axial tilt, or **obliquity**.

Between 1976 and 1989, the pace of discoveries increased more dramatically. In rapid succession, there was the discovery of methane (CH_4) on Pluto's surface; the detection of Pluto's largest satellite Charon; the prediction, detection, and then study of a set of once-every-124-year mutual eclipse events between Pluto and Charon; and the occultation by Pluto of a bright star, confirming the presence of an atmosphere. In addition, the 1989 Voyager 2 encounter with the Neptune system gave us detailed insights into the object believed to be Pluto's closest analog in the solar system, Triton, thereby showing how complex and scientifically interesting Pluto would be under close scrutiny by spacecraft. In the 1990s, it was discovered that Pluto's surface consists of a complex mixture of low-temperature volatile ices, that this surface displays large-scale bright and dark units, and that Pluto's atmosphere consists primarily of nitrogen gas, with trace amounts of carbon monoxide and only a trace of methane. Additionally, Pluto's small moons were discovered, and Pluto's context in the solar system became understood only after the discoveries of many smaller objects in the region of the solar system beyond Neptune called the Kuiper Belt.

TABLE 42.1 Pluto's Heliocentric Orbit

Orbital Element	Value
Semimajor axis, *a*	39.48 AU
Orbital period, *P*	247.688 years
Eccentricity, *e*	0.2488
Inclination, *i*	17.16°

Longitudinal perihelion, ω	224.07°
Perihelion epoch, *T*	05.1 September 1989 Universal Time

Note: Osculating elements on JD 2449000.5, referred to the mean ecliptic and equinox of J2000.0.

1.2. The Discovery of Pluto's Satellites

Charon (pronounced correctly as "Kharon", but more colloquially pronounced as "Sharon") was discovered by J. W. Christy and R. S. Harrington on a series of photographic plates made in 1978 at the US Naval Observatory's Flagstaff Station in Arizona. Interestingly, these images were taken less than 4 miles from Lowell Observatory, where Pluto had been discovered 48 years before. Charon was apparent on the 1978 Naval Observatory images as a bump or elongation in Pluto's apparent shape. This elongation of Pluto had occasionally been seen on photographic plates made in the 1960s, but it had not been recognized to be a satellite. This was because the elongation of Pluto's image by Charon was attributed to turbulence in the Earth's atmosphere causing a distortion of Pluto's pointlike image (the two are <1 **arc second** (arcsec) apart, and blended together by atmospheric seeing). What Christy and Harrington recognized in 1978 was that although Pluto was distorted, none of the stars in the photographs were. This led them to look for a periodicity in the elongations. The recognition that the bump was in fact a close-in satellite was made when it was determined that this bump regularly cycled around Pluto in a 6.387 day period, which matched Pluto's

rotation period, implying that the elongation was due to an object that circled Pluto.

In the first few months after Charon's discovery, Christy and Harrington determined that Charon's orbit is synchronous with Pluto's rotation and also in Pluto's equatorial plane, and therefore highly inclined to the plane of the ecliptic. During that same year, 1978, Leif Andersson recognized that Pluto's orbital motion would cause Charon's orbital plane to sweep through the line of sight to the Earth for a period of several years every half Pluto orbit, or 124 terrestrial years. Mutual eclipses (also called mutual events) would then begin occurring every 3.2 days (half Charon's orbit period). These eclipses were predicted to progress over a period of 5–6 years, from shallow, partial events to central events lasting up to 5 h, then to recede again to shallow grazing events. It was widely recognized that such a series of mutual eclipses and occultations would be scientifically valuable events. Fortuitously, these mutual events began occurring in 1985 and ended in 1990. These events (described in Section 3) yielded a wealth of data on both Pluto and Charon. Searches for other satellites of Pluto were made in the early and mid-1990s by ground-based observatories and Hubble Space Telescope (HST) images obtained for other Pluto studies, but no moons were detected.

In May 2005, however, a much more sensitive, dedicated satellite search by an HST observing team led by H. A. Weaver and S. A. Stern yielded the detections of two small satellites. These bodies, which were subsequently named Nix and Hydra, orbit in circular orbits in Pluto's equatorial plane, as Charon does. Nix and Hydra orbit Pluto somewhat further out than Charon, with Nix being near 48,700 km from Pluto's center and Hydra near 64,800 km. These orbits are close to or in resonance with Charon, with the Charon:Nix:Hydra periods being very close to or at 1:4:6. Figure 42.1 depicts the satellite orbits of Nix and Hydra in relation to Charon. Based on their observed magnitudes, we can make reasonable assumptions about their albedos yield size estimates of approximately 40–160 km diameters for both. Initial color measurements made with HST indicate both satellites are neutrally reflecting, much like Charon. No compositional results are available.

In 2011 and 2012, two even smaller satellites, later named Styx and Kerberos, were also found by HST.

2. PLUTO'S ORBIT AND SPIN

2.1. Pluto's Heliocentric Orbit

Relative to the eight previously discovered planets, Pluto's orbit is unusually eccentric (eccentricity $e \approx 0.25$), highly inclined (inclination $i \approx 17°$), and large (semimajor axis $a \approx 39.4$ AU). Pluto's orbit period is 248 years, during which the planet ranges from inside Neptune's orbit (Pluto's perihelion is near 29.7 AU) to nearly 48.8 AU. The Pluto–Charon **barycenter** passed its once-every-248-year perihelion at 05.1 ± 0.1 September 1989 UT; this will not occur again until AD 2236.

Current orbit integrations using osculating elements are able to predict Pluto's position to 0.5 arcsec accuracy over timescales of a decade. Pluto's perihelion is closer to the Sun than Neptune's. The large change in Pluto's heliocentric distance as it moves around the Sun causes the surface **insolation** on Pluto and Charon to vary by factors of three, which has important implications for Pluto's atmosphere (see Section 6). Pluto's perihelion lies slightly inside Neptune's orbit.

In the mid-1960s, it was discovered through computer simulations that Pluto's orbit librates in a 2:3 resonance with Neptune, which prevents mutual close approaches between the objects. This discovery has been verified by a series of increasingly longer and more accurate simulations of the outer solar system now exceeding 4×10^9 years. It is likely that Pluto was caught in this resonance and had its orbital eccentricity and inclination amplified to current values as Neptune migrated outward during the clearing of the outer solar system by the giant planets.

Pluto and Neptune can never closely approach one another, owing to this resonance, and the fact that the argument of Pluto's perihelion (i.e. the angle between the perihelion position and the position of its ascending node) librates (i.e. oscillates) about 90° with an amplitude of approximately 23°. This ensures that Pluto is never near perihelion when it is in conjunction with Neptune. Thus, Pluto is "protected" because Neptune passes Pluto's longitude only near Pluto's aphelion, never allowing Neptune and Pluto to come closer than ≈ 17 AU. Indeed, Pluto approaches Uranus more closely than Neptune, with a minimum separation of ≈ 11 AU, but still too far to significantly perturb its orbit.

In the late 1980s, it was discovered that Pluto's orbit exhibits a high degree of sensitivity to initial conditions. This is called "orbital chaos" by modern dynamicists. This discovery of a formal kind of chaos in Pluto's orbit does not imply Pluto undergoes frequent, dramatic changes. However, it does mean that Pluto's position is unpredictable on very long timescales. The timescale for this dynamical unpredictability has been established to be 2×10^7 years by Jack Wisdom, Gerald Sussman, and their coworkers.

2.2. Pluto's Lightcurve, Rotation Period, and Pole Direction

As previously indicated, since the mid-1950s Pluto's photometric brightness has been known to vary regularly

with a period of about 6.387 days; more precisely, this period is 6.387223 days. Despite Pluto's faintness as seen from Earth, its period was easily determined using photoelectric techniques because the planet displays a large lightcurve amplitude, 0.35 magnitudes at visible wavelengths, which is equivalent to 38%.

From at least 1955 until about 1990, it has also been known that Pluto's lightcurve increases in its amplitude with time but that trend has since reversed. Although the 6.387223 day period is identical to Charon's orbit period, Charon's photometric contribution is too small to account for the lightcurve's amplitude. This in turn implies that the lightcurve's structure is caused by surface features on Pluto. Figure 42.2 shows the shape of the combined Pluto–Charon lightcurve and its evolution over the past few decades.

The first study of Pluto's polar obliquity (or tilt relative to its orbit plane) was reported in 1973. By assuming that the variation of the lightcurve amplitude from the 1950s to the early 1970s was caused by a change in the aspect angle from which we see Pluto's spin vector from Earth, it was then determined that Pluto has a high obliquity (i.e. $90° \pm 40°$). In 1983, additional observations allowed the obliquity to be refined to $118.5° \pm 4°$. Even more recently, the results of the Pluto–Charon mutual events (or eclipses, see following discussion) have given a very accurate value of $122° \pm 1°$.

It is important to note, however, that torques on the Pluto–Charon pair cause Pluto's obliquity to oscillate between $\sim 105°$ and $\sim 130°$ with an $\sim 3.7 \times 10^6$ year period. Thus, although Pluto presently reaches perihelion with its pole vector nearly normal to the Sun and roughly coincident with the orbit velocity vector, this configuration is only coincidental. The pole position executes a 360° circulation with a 3.7×10^6 year precession period.

2.3. Charon's Orbit and the System Mass

The discovery that Charon orbits Pluto with a period equal to Pluto's rotation period immediately implied the pair has reached spin-orbit synchronicity. This is an unprecedented situation among the planets in the solar system.

Table 42.2 gives a solution to Charon's orbital elements obtained from various data. This fit relies on a semimajor axis determination of $a = 19{,}636 \pm 8$ km derived from ground-based and HST data; it is statistically indistinguishable from ground-based results obtained in the mid-1980s of $a = 19{,}640 \pm 320$ and of $a = 19{,}558 \pm 153$ km.

Based on Charon's known orbital period and the 19,636 km semimajor axis, the system's (i.e. combined Pluto + Charon) mass is $1.46 \pm 0.003 \times 10^{25}$ g; this is very small, just 2.4×10^{-3} times Earth's mass.

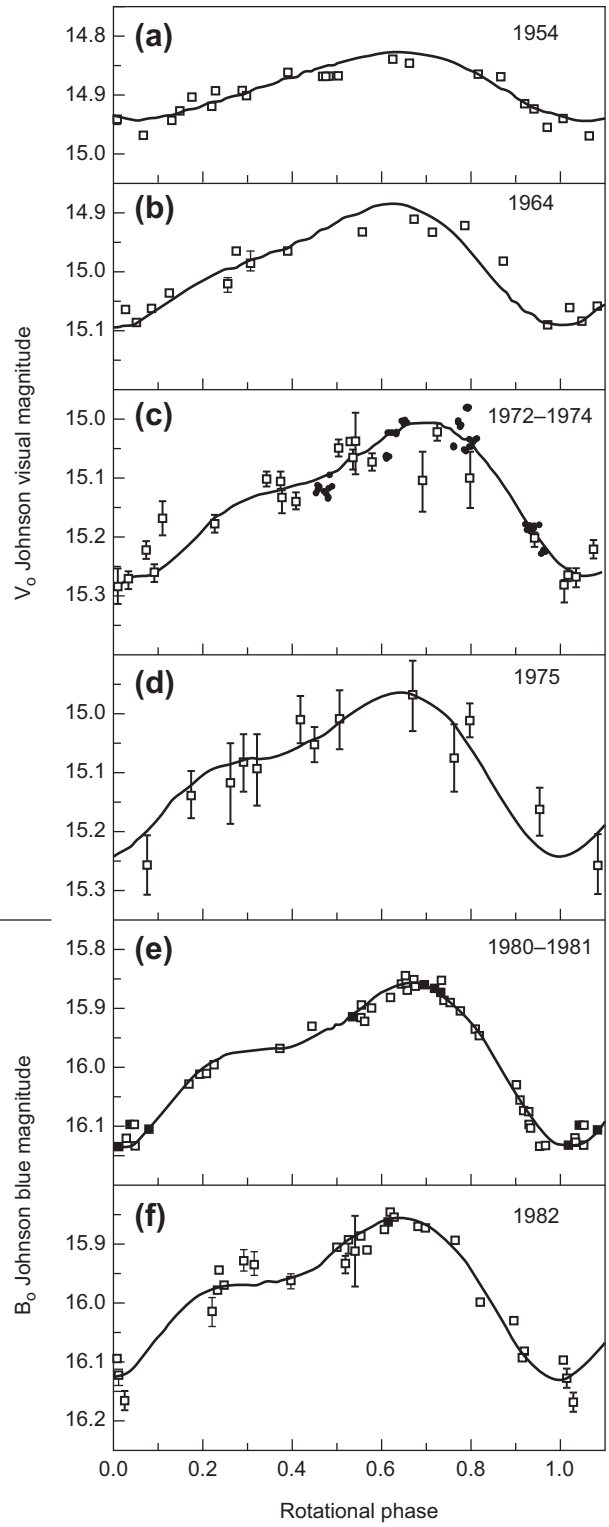

FIGURE 42.2 The evolution of Pluto–Charon's lightcurve over several decades. *Adapted from Marcialis, R. L. (1988).*

TABLE 42.2 Charon's Orbit[1]

Orbital Element	Value
Semimajor axis, a	19636 ± 8 km
Orbital period, P	6.387223 ± 0.00002 days
Eccentricity, e	0.0076 ± 0.003
Inclination, i	$96.2° \pm 0.3°$
Longitudinal perihelion, ω	$222.99° \pm 0.5°$
Mean anomaly, M	$34.84° \pm 0.35°$

[1]*These elements are referred to the epoch 17 January 13.0 UT 1993. See Tholen, D. J. & Buie, M. W. (1997). In S. A. Stern & D. J. Tholen (Eds.),* Pluto & Charon. *Tucson: Univ. Arizona Press.*

3. THE MUTUAL EVENTS

3.1. Background

After Charon's discovery, the realization that mutual eclipses between Pluto and Charon would soon occur opened up the possibility of studying the Pluto–Charon system with the powerful data analysis techniques developed for eclipses between binary stars. Initial predictions by Leif Andersson indicated that the events could begin as early as 1979. As Charon's orbit pole position was refined, however, the predicted onset date moved to 1983–1986 (this was fortuitous because knowledge of the pole could have changed to indicate that the events had already just ended in the mid-1970s). After a multiyear effort by several groups to detect the onset of these events, the first definitive eclipse detections were made on February 17, 1985, by Richard Binzel at McDonald Observatory and were confirmed during an event 3.2 days later on February 20, 1985, by David Tholen at Mauna Kea. These first, shallow events ($\sim$0.01–0.02% in depth) revealed Pluto and Charon grazing across one another as seen from Earth.

The very existence of these eclipses proved the hypothesis (by 1985 widely accepted) that Charon was in fact a satellite, rather than some incredible topographic high on Pluto. The mutual eclipses persisted until October 1990, and dozens of events were observed. Important results from the 1985–1990 mutual events included reconstructed surface "maps" of Pluto and Charon; individual albedos, colors, and spectra for each object; and improvements in Charon's orbit. First, however, was the opportunity to use event timing to accurately determine the radii of Pluto and Charon.

3.2. Radii and Average Density of Pluto and Charon

Prior to the mutual events, the radii of Pluto and Charon were highly uncertain. Because Pluto and Charon remained unresolved in terrestrial telescopes (their apparent diameters are each $<$0.1 arcsec), direct measurements of their diameters were not available. A well-observed, near-miss occultation of Pluto in 1965 had constrained Pluto's radius to be $<$3400 km, but no better observations were available until the mutual events. However, circumstantial evidence that Pluto was smaller than 3400 km was inferred from the combination of Pluto's V astronomical $\approx$14 magnitude and the 1976 discovery of CH_4 frost (see Section 4.3), which exhibits an intrinsically high albedo. The small system mass determined after the discovery of Charon in 1978 strengthened this inference, but Pluto's radius was still uncertain within the bounds 900–2200 km.

The first concrete data to remedy the situation came when a fortuitous **stellar occultation** by Charon was observed on April 07, 1980. The 50 s length of the star's disappearance, observed by a 1-m telescope at Sutherland, South Africa, gave a value for Charon's radius of 605 ± 20 km. Improved results from subsequent stellar occultations yield 603.5 ± 3 km.

As noted earlier, accurate radius measurements for Pluto resulted from both stellar occultations and from fits of mutual event lightcurves, yielding solutions between 1150 and 1200 km. The range of uncertainty in Pluto's radius, which is significantly larger than in Charon's, results primarily from uncertainties in Pluto's atmospheric depth.

The two striking implications of the small radii and comparable masses of Pluto and Charon are (1) that Pluto is a very small planet—even smaller than the seven largest planetary satellites (the Moon, Io, Europa, Ganymede, Callisto, Titan, and Triton), and (2) that Pluto and Charon form the only known example of a binary planet (with the system barycenter outside of Pluto). Based on the radii and the total mass of the pair, it is possible to derive an average density of 2.03 ± 0.06 g/cm^3, where the

error bar is dominated by the uncertainty in the radius of Pluto. Any density of 1.8 g/cm^3 or higher implies that the system is compositionally dominated by rocky material, probably hydrated chondrites, as opposed to ices. This result and its implications will be discussed in more detail in Section 5.

4. PLUTO'S SURFACE PROPERTIES AND APPEARANCE

Pluto's surface properties have been studied since the 1950s. Photometric, spectroscopic, and polarimetric techniques have been applied, and the explorable wavelength regime has expanded from the ground-based window to the reflected infrared (IR) and the **space ultraviolet** (UV). Thermal-IR and millimeter-wave measurements have also been made.

4.1. Albedo and Color

Two of the most basic photometric parameters one desires to know for any solid body are its albedo and color. Accurate knowledge of Pluto's albedo was obtained only after the onset of the mutual events because until then Pluto's radius was unknown, and there was no definitive way of removing Charon's contribution.

The very first report of eclipse detections revealed a factor of 2 difference in depth between partial eclipses of Charon and Pluto, indicating Pluto's geometric albedo is substantially higher than Charon's. Once the eclipse season was complete, a more complete data set became available for analysis. Comprehensive models for the analysis of mutual event lightcurve data simultaneously solve for the individual radii of Pluto and Charon, the individual albedos, and Charon's orbital elements. The modeling of these parameters is complicated by solar phase angle effects, the presence of shadows during eclipse events, and instrumental and timing uncertainties. To derive the albedo lightcurve for Pluto alone, Pluto's albedo at the longitude of the total superior eclipses (in which Charon was completely hidden) must first be determined. Albedos at other rotational epochs are then derived from this anchor point, assuming Charon's **rotational lightcurve** contributes only a small constant to the combined Pluto + Charon lightcurve. The assumption that a constant Charon contribution can be removed is not unreasonable, because (1) its geometric cross-section is small (one-fourth of Pluto's), and (2) its eclipsed hemisphere has a geometric albedo only about 50–60% of Pluto's. However, HST observations have shown that Charon does vary somewhat in brightness ($\approx$8%) as it rotates on its axis. Analysis of a large set of mutual event data in the way just described has found that Pluto's maximum, disk-integrated, B-bandpass ($\sim$4360 Å) geometric albedo is 0.61. Rotational variations cause this albedo to range from values as low as 0.44 to values as high as 0.61 as Pluto rotates.

Information on Pluto's color comes from both photometry and the mutual events. As described in Section 1, Pluto's visible-bandpass color slope has been known to be red since the 1950s. Analysis of premutual event photometry yields B-V and U-B color differences of 0.84 and 0.31, respectively, for Pluto + Charon. Eclipse data have revealed that the B-V color of Pluto itself is very close to 0.85 astronomical magnitudes. By comparison, this color is much less red than the **refractory** surfaces of Mars (B-V = 1.36) and Io (B-V = 1.17), and slightly redder than its closest analog in the solar system, Triton (B-V = 0.72).

4.2. Solar Phase Curve

The photometric behavior of a planet or satellite as it changes in brightness on approach to opposition can be used to derive surface scattering properties, and therefore its microphysical properties. Knowledge of the complete solar phase curve is also required to transform geometric albedos into bolometric Bond albedos. HST observations in the 1990s gave linear phase coefficients for Pluto and Charon of 0.029 ± 0.001 magnitudes/deg and 0.866 ± 0.008 magnitudes/deg, respectively, though non-linear effects have now been detected.

Pluto's maximum solar phase angle (ϕ_{max}) as seen from Earth is just $\approx 1.9^\circ$. Therefore, no measurements of the large-angle scattering behavior have been possible until recently with New Horizons. Without measurements at large phase angles, no definitive determination of Pluto's phase integral q or Bond albedo A can be made. However, what is really needed are flyby spacecraft measurements of Pluto at high phase angles. For the present, the best available phase integral to use for Pluto is probably Triton's (Pluto and Triton also have similar linear phase coefficients). Triton's q has been measured by Voyager, giving $q = 1.2$ (at green wavelengths) to 1.5 (at violet wavelengths). If Pluto is similar, then its surface may have Bond albedos ranging from 0.3 to 0.7.

4.3. Surface Composition

Progress in understanding Pluto's surface composition required the development of sensitive detectors capable of making moderate spectral resolution measurements in the IR, where most surface ices show diagnostic spectral absorptions. Although this technology began to be widely exploited as early as the 1950s in planetary science, Pluto's faintness (e.g. 700 times fainter than the Jovian Galilean satellites) delayed compositional discoveries about it until the mid-1970s.

The first identification of a surface constituent on Pluto was the discovery by Dale Cruikshank, Carl Pilcher, and David Morrison in 1976 of CH_4 ice absorptions between 1 and 2 μm (a wavelength of 1 μm = 10,000 Å). Cruikshank et al. made this discovery using IR photometers equipped with customized, compositionally diagnostic filters. In their report, Cruikshank et al. also presented evidence against the presence of strong H_2O and NH_3 absorptions in Pluto's spectrum. Confirmation of the methane detection came in 1978 and 1979 when both additional CH_4 absorption bands and true IR spectra of Pluto became available.

In mid-1992, another breakthrough occurred when Toby Owen, Dale Cruikshank, and other colleagues made observations using a new, state-of-the-art IR spectrometer at the UK Infrared Telescope on Mauna Kea. These data revealed the presence of both N_2 and CO ices on Pluto. These molecules are much harder to detect than methane because they produce much weaker spectral features. Their presence on Pluto indicates the surface is chemically more heterogeneous, and more interesting than had previously been thought. Because N_2 and CO are orders of magnitude more **volatile** (i.e. have higher vapor pressures) than CH_4, their presence also implies they play a highly important role in Pluto's annual atmospheric cycle. Abundance inversions of Pluto reflectance spectra make clear that N_2 dominates the composition of much of Pluto's surface, with CO and CH_2 being trace constituents.

In 2006, ethane (C_2H_6) was detected on Pluto's surface. This and other hydrocarbons and nitriles had long been predicted to reside on Pluto as a result of photochemical and radiological processing of Pluto's surface ices and atmosphere.

Rotationally resolved spectra of Pluto's CH_4 absorption bands have been reported by a number of groups. Their studies showed that Pluto's methane is present at all rotational epochs, but the band depths are correlated with the lightcurve so that the minimum absorption occurs at minimum light. Mutual event spectroscopy has now demonstrated that Charon is not the cause of this variation, since Charon's surface is devoid of detectable CH_4 absorptions (see Section 6). This important discovery suggests that Pluto's dark regions could contain reaction products resulting from the photochemical or radiological conversion of methane and N_2 to complex nitriles and higher hydrocarbons.

We thus have the following basic picture of Pluto's surface composition: CH_4 appears rotationally ubiquitous, but with its surface coverage more widespread in regions of high albedo. In many areas, the methane is dissolved in a matrix of other ices, but in some locations the CH_4 is seen as pure ice. CO and N_2 have also been detected. In the bright areas of the planet where these ices are thought to mainly be located, N_2 dominates the surface abundance, and the CO is more abundant than the previously known (but more spectroscopically detectable) CH_4. Ethane, a by-product of CH_4 chemistry, was detected in 2006. Pluto's strong lightcurve and red color demonstrate that other widespread, probably nonvolatile surface constituents exist. This may be due to either rocky material, or hydrocarbons resulting from radiation processing of the CH_4 due to long-term exposure to UV sunlight, or both. Whether the volatile frost we are seeing is a surface veneer or the major component of Pluto's crust has not yet been established.

4.4. Surface Temperature

Results from the Infrared Astronomical Satellite (IRAS) indicated that Pluto's perihelion-epoch surface temperature was in the range of 55−60 K, close to that expected in radiative equilibrium with solar insolation. However, it has subsequently become appreciated that the situation on Pluto's surface is more complicated.

One line of evidence for this conclusion comes from millimeter-wave measurements of Pluto's Rayleigh−Jeans blackbody spectrum. Such measurements, reported first by Wilhelm Altenhoff and collaborators, and then later by Alan Stern, Michel Festou, and David Weintraub, and independently confirmed by David Jewitt, indicate that a significant fraction of Pluto's surface is significantly colder than 60 K, most likely in the range 35−42 K. A second line of evidence came in 1994 from high-resolution spectroscopy of the temperature-sensitive 2.15 μm N_2 ice absorption band, which Kimberley Tryka and her coworkers found indicates a surface temperature of about 40 K for the widespread nitrogen ices on Pluto. As described by Stern et al. in 1993, although the surface pressure of N_2 is not well known, it must be less than ≈60 μbar. This is consistent with an N_2 ice temperature of ≈40 K, assuming vapor pressure equilibrium between the N_2 ice and the atmosphere. This, combined with the IRAS measurements, led to the conclusion that Pluto's surface must exhibit both warm and cold regions. This was subsequently confirmed by rotationally resolved studies of Pluto's thermal emission spectrum by the Infrared Space Observatory and the Spitzer Infrared Space Telescope Facility. These space telescopes also revealed that Pluto's coldest regions are correlated with bright surface units, and that the warmer regions are correlated with darker surface units with lower abundances of sublimating ices.

It is now well established that Pluto's surface temperature varies from place to place on the surface, with ≈40 K regions where N_2 ice is sublimating and ≈55−60 K regions where N_2 ice is not present in great quantities. The strong temperature contrasts across Pluto's surface imply

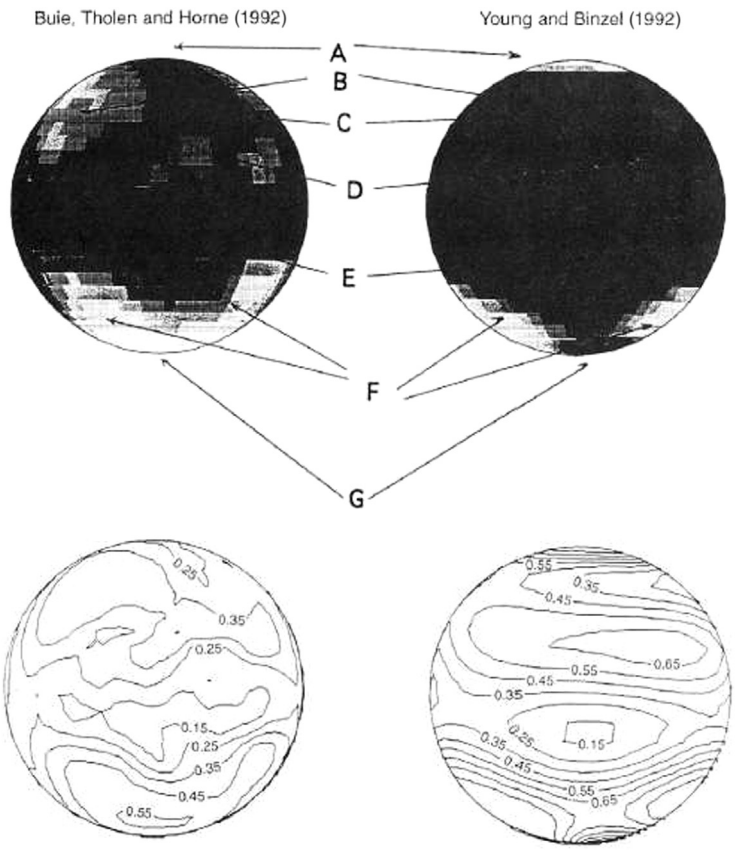

FIGURE 42.3 Two maps of Pluto's Charon-facing hemisphere. The map on the left was derived by M. Buie, K. Horne, and D. Tholen using both mutual event and lightcurve data. The map on the right was derived by E. Young and R. Binzel from their mutual event data. Although the fine details of these maps differ, their gross similarities are striking. Here north is up for the right-hand rule convention. *See Binzel, R. P. et al. (1997).*

strong wind speeds and significant lateral transport of material across the surface.

4.5. Surface Appearance and Markings

Because Pluto is less than 0.1 arcsec across as seen from Earth, its disk could not be resolved until the advent of the HST. However, evidence for surface markings has been available since the mid-1950s, when lightcurve modulation was first detected. Because Pluto is large enough to be essentially spherical (and indeed, mutual event and stellar occultation data show it actually is), the distinct variation in this lightcurve must be related to large-scale albedo features.

From the lightcurve in Figure 42.2, it can be seen that Pluto's surface must contain at least three major longitudinal provinces. Information on the latitudinal distribution of albedo can be gained by observing the evolution of this lightcurve as Pluto moves around its orbit while the pole position remains inertially fixed, assuming, of course, that the surface albedo distribution is time invariant.

The most complete 1990s mapping products obtained from photometric data inversions (variously using rotational lightcurves and mutual event lightcurves) were obtained by two teams. The first team, led by Marc Buie of Lowell Observatory, has used both mutual event lightcurves and rotational lightcurve data compiled from 1954 to 1986 to compute a complete map of Pluto. The second group, consisting of Richard Binzel and Eliot Young, of Massachusetts Institute of Technology (MIT) and Southwest Research Institute (SwRI), numerically fit a spherical harmonic series to each element of a finite element grid using the Charon transit mutual event lightcurve data as the model input. Because Young and Binzel used only mutual event data, their map is limited to the hemisphere of Pluto that Charon eclipses. Because the two groups used different data sets and different numerical techniques, their results are complementary and serve to check one another on the Charon-facing hemisphere they share in common.

These two maps are shown in Figure 42.3. There are differences between the two maps, but it must be remembered that each map has intrinsic noise. The common features of these maps are (1) a very bright south polar cap, (2) a dark band over midsouthern latitudes, (3) a bright band over midnorthern latitudes, (4) a dark band at high northern latitudes, and (5) a northern polar region that is as bright as the southern cap. Later results, including some color information, were subsequently obtained by Eliot Young and colleagues.

In 1990, HST imaged Pluto, but owing to its then-severe optical aberrations, these images, obtained by R. Albrecht

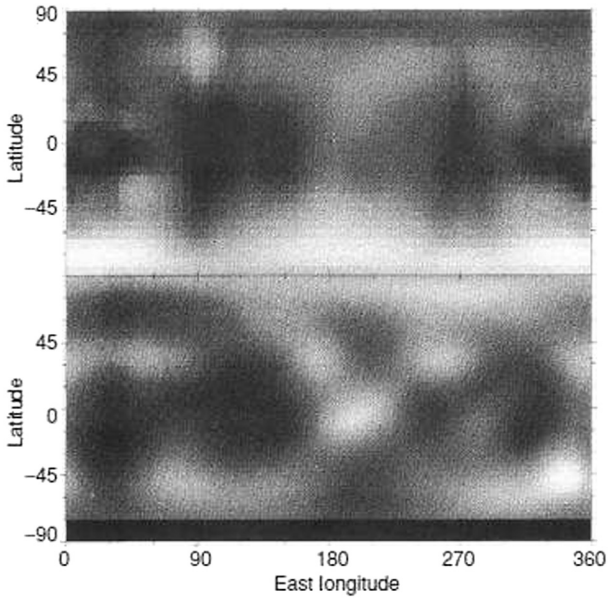

FIGURE 42.4 A map derived from direct imaging of Pluto using HST images made in 1994. Again, north is up. *Adapted from Stern et al. (1997).*

and a team of collaborators, cleanly separated Pluto and Charon, but did not reveal significant details about the surface of Pluto. After HST was repaired by an astronaut crew in late 1993, its optics were good enough to resolve crude details on Pluto's surface. And in mid-1994, it obtained the first actual images of Pluto that revealed significant details about Pluto's surface. These images were made by Alan Stern, Marc Buie, and Laurence Trafton using the Faint Object Camera of the HST. The 20-image HST data set is longitudinally complete and rotationally resolved and obtained at both blue and UV wavelengths. The various images that HST obtained were combined to make blue and UV maps of the planet, such as the one shown in Figure 42.4. The HST images and derived maps reveal that Pluto has (1) a highly variegated surface, (2) extensive, bright, asymmetric polar regions, (3) large midlatitude and equatorial spots, and (4) possible linear features hundreds of kilometers in extent. The dynamic range of albedo features across the planet detected at the Faint Object Camera's resolution in both the 410 and 278 nm bandpasses exceeds 5:1. New HST images were obtained in 2002 by a team led by Marc Buie using HST's Advanced Camera for Surveys, but they do not have better resolution.

5. PLUTO'S INTERIOR AND BULK COMPOSITION

5.1. Density

To determine the separate densities of Pluto and Charon, one must either obtain precise astrometric measurements that detect the barycentric wobble between Pluto and Charon or use orbit solutions for Pluto's small satellites. Since 1992, both HST and ground-based measurements have been gathered to address the mass ratio, and therefore the relative masses and densities of Pluto and Charon. These are very difficult measurements. A good density determination for Pluto due to Buie and coworkers, who analyzed the orbits of Nix and Hydra in a 2006 publication gave 2.03 ± 0.06 g/cm^3 for a reference radius of 1153 km.

5.2. Bulk Composition and Internal Structure

The 1980s discovery that the Pluto–Charon system's average density is near 2 g/cm^3 was a major surprise resulting from the mutual events. Many scientific papers had previously predicted values closer to the density of water ice ($\sim$1 g/cm^3), or even lower. Thus, contrary to earlier thinking, the Pluto–Charon pair is known to be mass dominated by rocky material. Based on this information, a three-component model for Pluto's bulk composition and internal structure can be derived. In such a model, Pluto's bulk density is assumed to consist of three of the most common condensates in the outer solar system: water ice ($\rho = 1.00$ g/cm^3), "rock" ($2.8 < \rho < 3.5$ g/cm^3, depending upon its degree of hydration), and methane ice ($\rho = 0.53$ g/cm^3).

From three-component models, it is believed that Pluto's rock fraction is in the range of 60–80%, with preferred values close to 70%. By comparison, the large (e.g. $R > 500$ km) icy satellites of Jupiter, Saturn, and Uranus have typical rock fractions in the range 50–60% by mass. Only Io, Europa, and Triton rival Pluto in terms of their computed rock content. Pluto's high rock (i.e. nonvolatile) mass fraction is in contrast to the $\approx$1:1 rock:ice ratio predicted for objects formed from solar nebula material according to many nebular chemistry models and our present-day understanding of the nebular C/O ratio. This high rock fraction indicates that the nebular material from which Pluto formed was CO rich rather than CH_4 rich. As such, roughly half of the available nebular oxygen should have gone into CO, rather than H_2O formation, which in turn would lead to a high rock:ice ratio.

There are two possible ways out of the apparent nebular chemistry dilemma imposed by Pluto's high rock fraction. One is that Pluto's minimum estimated radius of 1150 km may be too small; a value near 1200 km, as suggested by some stellar occultation models, would solve the problem. Alternatively, William McKinnon and the late Damon Simonelli independently suggested that a giant impact may have induced volatile loss from an already differentiated Pluto, which may have raised Pluto's rock fraction somewhat (perhaps 20%) to reach its present value. As we

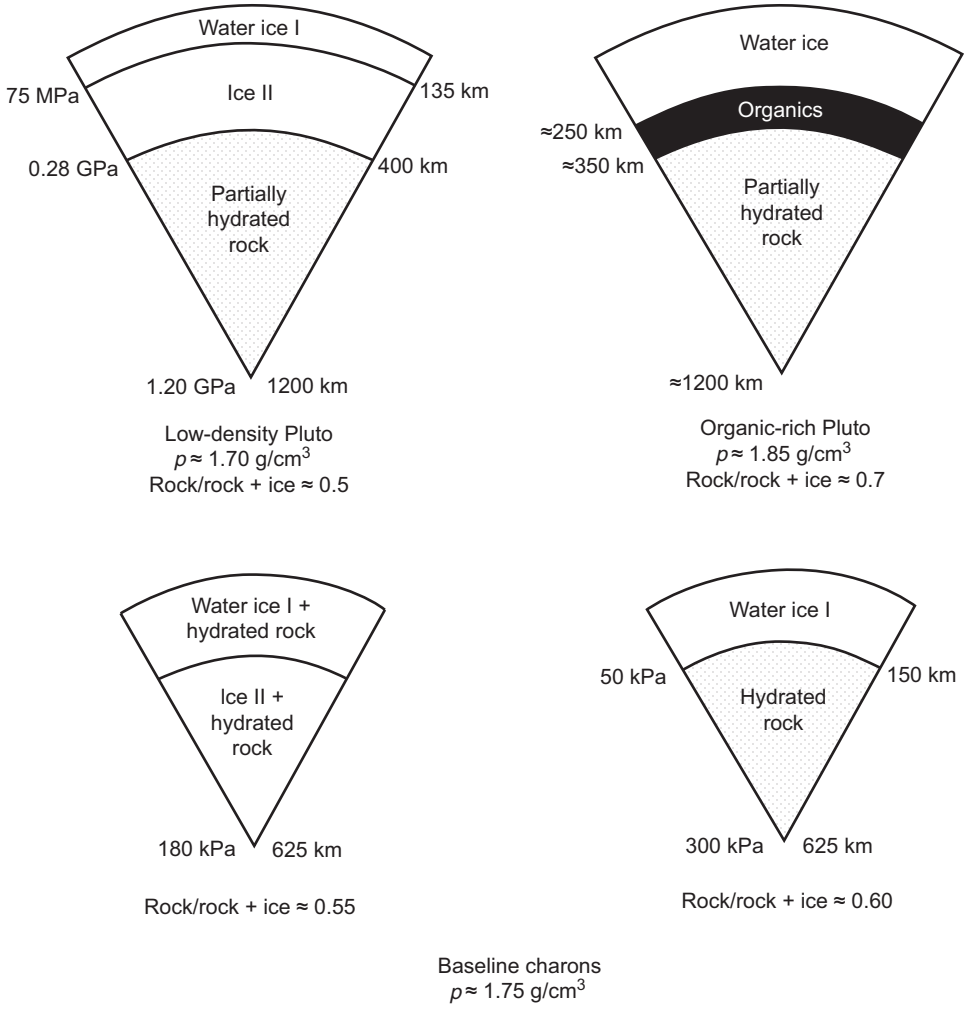

FIGURE 42.5 Typical interior structural models for Pluto and Charon. *Adapted from. McKinnon, W. B. et al. (1997).*

discuss in Section 8, such an impact is thought to be responsible for the formation of Pluto's satellite system.

The gross internal thermal structure of Pluto depends on several factors, virtually all of which are uncertain. These include material viscosities in the interior, the internal convection state, the actual rock fraction and radioisotope content, and the internal density distribution (i.e. most fundamentally, the differentiation state). It would appear likely that Pluto's deep interior reaches temperatures of at least 100−200 K, but not much higher. Whether or not Pluto is warm enough to exhibit convection in its ice mantle depends on both the internal thermal structure and the radial location of water ice in its interior.

Based on the results just given and laboratory equations of state, Pluto's central pressure can be estimated to lie between 0.6 and 0.9 GPa (gigapascals) if the planet is undifferentiated, or 1.1−1.4 GPa if differentiation has occurred. As such, the high-pressure water ice phase Ice VI is expected in the deep interior if the planet has not differentiated. If differentiation has occurred, as is likely, then a higher pressure form of water ice called Ice II may be present, but only near the base of the convection layer. If Pluto did differentiate, then its gross internal structure may be represented by a model like that shown in Figure 42.5.

6. PLUTO'S ATMOSPHERE

6.1. Atmospheric Composition

The existence of an atmosphere on Pluto was strongly suspected after the discovery of methane on its surface in 1976, largely because at the predicted surface temperatures (∼40−60 K), sufficient methane vapor pressure should be obtained to constitute a significant atmosphere. This circumstantial argument was supported by the high reflectivity of Pluto's surface, which suggested some kind of resurfacing—most plausibly due to volatile laundering through an orbitally cyclic atmosphere. Still, however,

there was no definitive evidence for an atmosphere until the late 1980s.

The formal proof of Pluto's atmosphere came from the occultation of a 12th magnitude star by Pluto in 1988, by providing the first direct observational evidence for an atmosphere. The best measurements of the occultation were obtained by Robert Millis and James Elliot, and their various MIT, Lowell Observatory, and Australian collaborators. These teams used both National Aeronautics and Space Administration's mobile, Kuiper Airborne Observatory (which contained a 36-inch-diameter telescope), and ground-based telescopes to observe the occultation event. They discovered that light from the star was diminished far more gradually than it would be from an airless body. The apparent extinction of starlight observed during the occultation was caused by atmospheric refraction (i.e. the degree of bending of the starlight by the atmosphere), which varies with height. The rate at which the refractivity of the atmosphere varies with altitude depends on the ratio of atmospheric temperature (T) to atmospheric mean molecular weight (m). The 1989 Pluto occultation data implied $T/m = 3.7 \pm 0.7$ K/g at and above an altitude of 1215 km. If the atmosphere were composed entirely of methane ($m = 16$ g/mole), the implied atmospheric temperature would be 60 K, whereas an N_2 or CO atmosphere ($m = 28$ g/mole) would be at a temperature near 106 K.

From the stellar occultation data alone it was impossible to separately determine the mean atmospheric molecular weight and temperature of Pluto's atmosphere. However, theoretical calculations of the atmospheric temperature made by Roger Yelle and Jonathan Lunine of the University of Arizona indicated a value of 106 K in the upper atmosphere, under a variety of assumed compositions. This is relatively high compared with the surface temperature ($\sim$40–55 K) because the efficiency at which the atmosphere radiates and cools is very small. An upper atmospheric temperature near 106 K implies that the atmospheric mean molecular weight is close to 28 g/mole. This is consistent with an atmosphere dominated by N_2 or CO gas, with trace amounts of other species.

The detection of N_2 ice absorption features on Pluto's surface (see Section 4), coupled with the discovery by Voyager 2 that Triton's atmosphere also consists predominantly of N_2 and only a trace of CO, suggests that Pluto's atmosphere is likely to be N_2 dominated. Nevertheless, if the high-temperature (106 K) atmospheric model is correct, then at least a few percent methane is thought to be required because methane (which is efficient at atmospheric heating) is thought to be responsible for the elevated atmospheric temperatures.

A nitrogen-dominated atmosphere with only a minor amount of methane was significantly strengthened in 1994 when Leslie Young and colleagues at MIT detected CH_4 gas in Pluto's atmosphere for the first time. This discovery, which was made possible by sensitive, high-resolution IR spectroscopy of the 2.3 μm CH_4 band system, indicated a total methane mixing ratio of <1%, and perhaps as little as 0.1% in the atmosphere. Subsequent high-resolution observations by Young and colleagues revealed that the CO abundance in Pluto's atmosphere must also be very low.

6.2. Atmospheric Structure

The 1988 occultation data exhibited interesting behavior at altitudes below 1215 km, as shown in Figure 42.6. The starlight, which was decreasing gradually at higher altitudes, dropped suddenly to a value close to zero below this level; this is called lightcurve steepening. The drop is still not as sudden as would be expected from the setting of a star behind the limb of an airless planet, however. Two possible explanations have been proposed for this change.

In one model, the steepening was caused by the presence of aerosol hazes in the lower atmosphere. (Condensation clouds can be ruled out as an explanation for the aerosol layer because of the temperature structure of the atmosphere.) Because reproducible albedo features

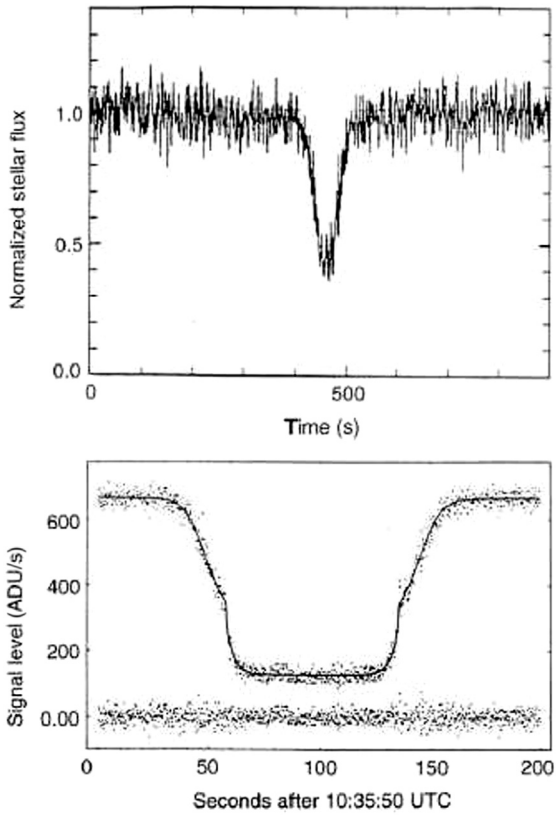

FIGURE 42.6 Stellar occultation data showing the refractive signature of Pluto's atmosphere and the steepening of the lightcurve around the half-light level that is discussed in the article. The upper panel is a ground-based data product; the lower panel was obtained from the Kuiper Airborne Observatory. *Adapted from Elliot et al. (1989).*

have been seen on Pluto's surface, any such aerosol layer must be transparent when viewed from above, but relatively opaque when viewed horizontally. The aerosols must also extend around most of the planet since the steepening of the occultation lightcurve was seen in both immersion and emersion. It has been suggested that the aerosols could be "photochemical smog" similar to the aerosols discovered on Titan and Triton (and a distant cousin to the air pollution in the industrial basins on Earth, such as Los Angeles).

In a second model, the sudden drop in the brightness of starlight below 1215 km was caused by a change in the vertical thermal structure of the atmosphere near the half-light level. Such a gradient is not unexpected from theoretical modeling (see earlier discussion) because atmospheric temperatures are expected to be higher than surface temperatures. Changes in atmospheric temperature cause a variation of refractivity with height in the atmosphere that could be manifested as the accelerated diminution of starlight seen in the occultation.

The haze layer and temperature gradient explanations imply differences in the way that the color of starlight changes during an occultation. Future occultations may help decide between the two explanations if simultaneous observations can be made at two or more well-separated wavelengths. If the temperature gradient explanation is correct, Pluto's surface radius is likely near 1206 ± 11 km. If the haze layer explanation is correct, Pluto's surface radius is more difficult to determine, but it is probably closer to 1180 km.

In either case, the occultation implies a radius that is a few percentage larger than the mutual event solution (1151 km); in the case of the haze model, the radius cannot be much less than 1180 km or else the haze would be so thick as to completely obscure the surface. Clearly, there is a discrepancy between the radii determined from the occultation and those derived from the mutual events, which future research will have to resolve.

The subsequent well-observed occultation of a star by Pluto occurred on July 20, 2002. Both large fixed telescopes and small portable instruments observed the event. Fortuitously, yet another event occurred on August 21, 2002, which was successfully observed from large telescopes on Mauna Kea. From these events, it was determined that the "kink" or "knee" seen in the 1988 data is largely absent from the 2002 data, implying that large changes in Pluto's atmospheric thermal structure, or its haze profile, or both, occurred during the intervening interval.

Further analysis of the data reveals that the pressure in Pluto's atmosphere more than doubled between 1988 and 2002. This is likely due to pressure fluctuations associated with seasonal change, and may even be related to instabilities in the atmosphere prior to complete atmospheric collapse. Further observations will be required to sort this out.

Another occultation was observed on June 12, 2006. This event showed that the lightcurve kink near the half-light level remained less distinct than in 1988 and that the turbulence level in Pluto's lower atmosphere had increased. Fortunately, Pluto is still moving through the dense star fields of Sagittarius, and additional events have now been observed annually through 2014.

6.3. Atmospheric Escape

A particularly interesting feature of Pluto's atmosphere is the very rapid rate at which it escapes to space. Because of Pluto's low mass and consequently weak gravitational binding energy, combined with the 100 K gas temperature in Pluto's upper atmosphere, sufficiently energetic molecules at the top of the atmosphere are able to escape the gravitational pull entirely. This can result in a condition called **hydrodynamic escape**, in which the high-altitude atmosphere achieves an internal thermal energy greater than the planetary gravitational potential energy acting on the atmosphere.

The time-averaged rate of escape from Pluto's atmosphere is likely to be of order $1-10 \times 10^{27}$ molecules/second. This corresponds to a total loss of up to several kilometers of material from the surface over the age of the solar system.

Escape rate estimates also indicate that the present escape rate may be so high that Pluto's tenuous atmosphere may be lost to the escape process (thus requiring replenishment from sublimating surface ices) on timescales possibly as short as a few hundred years. Relatively speaking, the atmosphere of Pluto is escaping at a rate far greater than any other planetary atmosphere in the solar system.

Another interesting feature of Pluto's atmosphere is its strong orbital variability. This is driven by the fact that the strength of solar heating varies by a factor of almost 4 around Pluto's orbit, which in turn causes the vapor pressures of N_2, CO, and CH_4 to vary by factors of hundreds to thousands. Therefore, unlike any other planet, Pluto's atmosphere is thought to be essentially seasonal, with the perihelion pressure being many times the aphelion pressure. Indeed, some models predict that Pluto's atmosphere will largely condense onto the surface, a condition called atmospheric collapse: other models disagree.

7. CHARON

As previously described, Pluto's largest satellite, Charon, was discovered in 1978. Charon's radius of ≈ 604 km is about half of Pluto's, giving a Charon:Pluto mass ratio near 0.12. By comparison, typical satellite:planet mass ratios are

1000:1 or greater, and even the mass ratio of the Moon to the Earth is only 81:1.

The Pluto–Charon mutual event observations resulted in several key discoveries. These included the fact (1) that Charon's average visible surface albedo is 30–35%, much lower than Pluto's, and (2) that Charon's visible surface color is quite neutral, unlike Pluto's clearly reddish tint. Another major set of advances that resulted from the eclipse events was the first set of constraints on Charon's basic surface composition. These came from the subtraction of spectra made just prior to eclipse events from those made when Charon was completely hidden behind Pluto. The resulting "net" spectrum thus contains the Charon-only signal. As shown in Figure 42.7, this technique has been applied both in the visible (0.55–1.0 μm) and IR (1–2.5 μm) bandpasses. The visible light data show that Charon's surface does not display the prominent CH_4 absorption bands that Pluto does, indicating that Charon's surface has little or (more likely) no substantial methane on it.

Additionally, there is no evidence for strong absorptions due to a number of other possible surface frosts, including CO, CO_2, H_2S, N_2, or NH_4HS, on Charon. The IR spectra of Charon show that Charon does, however, display clear evidence of water ice absorptions, which Pluto does not. It is tempting to speculate (as some authors have) that Charon may have lost its volatiles through the escape of a primordial atmosphere or by heating resulting from its formation in a giant impact.

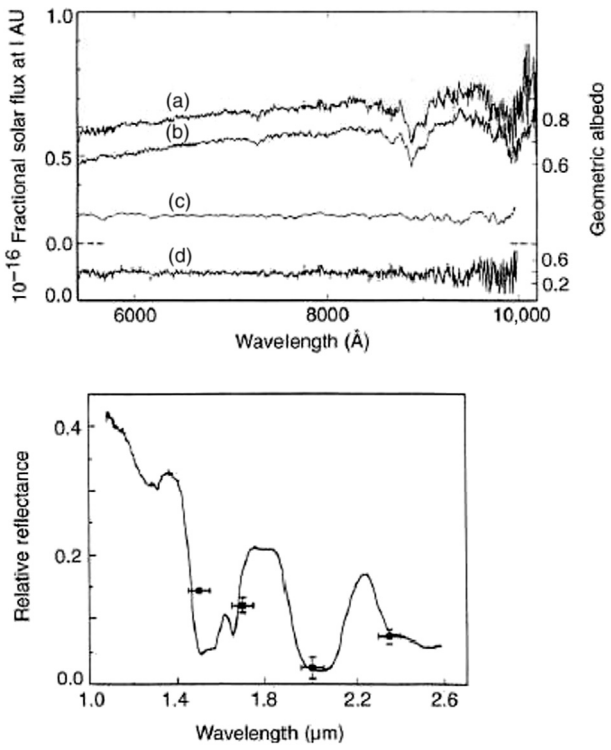

FIGURE 42.7 Pluto and Charon spectra. Top panel shows spectra of (a) Pluto + Charon made prior to eclipse; (b) Pluto-only after second contact with Charon hidden; (c) Charon-only smoothed to 80 Å resolution resulting from the subtraction of (b) from (a); and (d) the raw Charon-only spectrum resulting from the subtraction of (b) from (a). Notice that the strong methane absorption bands present in Pluto's spectrum are not detected in the Charon-only spectrum. (*Adapted from Fink and DiSanti, 1988.*) Bottom panel shows Marcialis et al.'s (1987) detection of water ice in Charon's reflectance spectrum (data points) against a laboratory spectrum of water ice at 55 K. *Adapted from Marcialis et al. (1987).*

Since the launch of HST, it has been possible to routinely separate Charon's light from Pluto's, and to learn Charon's phase coefficient, UV albedo, and rotational lightcurve. Most notably among these, Marc Buie and Dave Tholen have determined that Charon displays a small but significant lightcurve variation near 8% as it rotates on its axis.

Because the major identified surface constituent of Charon is water ice, which is not volatile at the expected 50–60 K surface radiative equilibrium temperature at perihelion, one does not expect Charon to have an atmosphere. The fact that CH_4 is not present on the surface supports this expectation. However, absence of evidence is not the same as evidence of absence. One published interpretation of the 1980 Charon stellar occultation claims there is some evidence for a weak atmospheric refraction signal. To definitively resolve the issue of Charon's atmosphere, either a better observed stellar occultation event or a spacecraft flyby is required.

In 2001, groups led by Mike Brown of Caltech and Will Grundy of Lowell Observatory used IR ground-based telescopes to find spectroscopic evidence for both crystalline water ice and ammonia (NH_3) or ammonium hydrates on Charon's surface. If these identifications are correct, they imply the possibility of recent geologic activity on Charon.

Table 42.3 compares some basic facts about Pluto and Charon.

TABLE 42.3 Pluto and Charon Comparison

Parameter	Pluto	Charon
Rotation period	6.387223 days	6.387223 days
Radius	1150–1200 km	602–606 km
Density	≈2.1 gm/cm^3	≈1.3 gm/cm^3
Perihelion, V_0	13.6 magnitude	15.5 magnitude
Mean B geometric albedo	0.55	0.38
Rotational lightcurve	38%	8%
B-V color	0.85 magnitude	0.70 magnitude
V-I color	0.84 magnitude	0.70 magnitude
Known surface ices	CH_4, N_2, CO	H_2O, NH_3OH
Atmosphere	Confirmed	None detected

8. THE ORIGIN OF PLUTO'S SATELLITE SYSTEM

In the past few years, much progress has been made in understanding Pluto's likely origin and its context in the outer solar system. This work began with theoretical consideration in the late 1980s and early 1990s, and was advanced considerably by the discovery of numerous 100- to 1600-km-diameter objects in the Kuiper Belt, where Pluto also resides.

Any scenario for the origin of Pluto must of course provide a self-consistent explanation for the major attributes of the Pluto–Charon system. These include (1) the existence of the exceptionally low, ~0.12 satellite-to-planet mass ratio of Pluto:Charon; (2) the synchronicity of Pluto's rotation period with Charon's orbit period; (3) Pluto's inclined, elliptical, Neptune-resonant orbit; (4) the high axial obliquity of Pluto's spin axis and Charon's apparent alignment to it; (5) Pluto's small mass ($\sim 10^{-4}$ of Uranus's and Neptune's); (6) Pluto's high rock content—the highest among all the outer planets and their major satellites; and (7) the dichotomous surface compositions of Pluto and Charon. This formidable list of constraints on origin scenarios is very clearly dominated by Charon's presence, the unique dynamical state of the binary, and the low mass of Pluto/Charon compared to other planets.

8.1. The Formation of Pluto's Satellite System

Several scenarios have been examined for the origin of the Pluto–Charon system. These include coaccretion in the solar nebula, mutual capture via an impact between proto-Pluto and proto-Charon, and rotational fission. Gravitational capture of Pluto by Charon without physical contact is not dynamically viable. The formation of Pluto and Charon together in a subnebular collapse is not considered realistic because of their small size; standard planetary formation theory suggests bodies in the Pluto and Charon size class formed via solid-body accretion of planetesimals. Similarly, the rotational fission hypothesis is unlikely to be correct because the Pluto–Charon system has too much angular momentum per unit mass to have once been a single body.

The more likely explanation for the origin of the Pluto system is an inelastic collision between two bodies, Pluto and proto-Charon, which were on intersecting heliocentric orbits. A similar scenario has been proposed for the origin of the Earth–Moon binary, based in part on its relatively high mass ratio (81:1) and high specific angular momentum. In the collision theory, Pluto and the Charon-impactor formed independently by the accumulation of small planetesimals and then suffered a chance collision that dissipated enough energy to permit binary formation.

An important qualitative difference between the Pluto–Charon and Earth–Moon giant impacts is that the relative collision velocities, and hence the impact energies of the Pluto–Charon event, were much smaller. This enormously reduced the thermal consequences of the collision. Thus, the Earth may have been left molten by the Mars-sized impactor necessary to have created the Moon, whereas the proto-Charon impactor would probably have raised Pluto's global mean temperature by no more than 50–75 K. This would have been insufficient to melt either body, but may have been sufficient to induce the internal differentiation of either. It would have also produced a substantial short-lived, hot, volatile atmosphere with intrinsically high escape rates. Such an escaping atmosphere could have interacted with the Charon-forming orbital debris, and also perhaps affected Pluto's present-day volatile content.

Until recently, only scaling calculations showing the plausibility of the giant impact hypothesis has been performed, and it was accepted largely because it is the only scenario that remains viable given the various constraints—most particularly the high specific angular momentum of the binary. In 2005, however, Robin Canup of the Southwest Research Institute published the first detailed giant impact simulations demonstrating the viability of Pluto–Charon formation owing to the collision of Pluto with another large body. Canup's work further demonstrated that the most promising candidate impacts involved an oblique collision by an impactor with 30–100% of Pluto's mass, approaching at a relative speed up to 1 km/s.

The discovery of Pluto's small satellites yielded additional support for the giant impact hypothesis. This support comes in two forms: the fact that all three satellites orbit in a single orbital plane and the near or perfect orbital period resonance of the three. The orbital coplanarity would be unlikely for other satellite formation mechanisms like capture, but naturally result from the giant impact scenario. The orbital resonance line of evidence naturally suggests the three bodies were together caught up in the outward tidal migration of Charon following its formation closer in.

8.2. The Origin of Pluto Itself

The presence of volatile ices, including methane, nitrogen, and carbon monoxide on Pluto, and water and other ices on Charon, argues strongly for their formation in the outer solar system. The average density and consequent high rock content of these two bodies also argues for formation from the outer solar nebula, rather than from planetary subnebula material. As described earlier, it is thought that the two objects (or more precisely Pluto and a Charon progenitor) formed independently and subsequently collided, thus forming the binary either through direct,

inelastic capture or through the accretion of Charon from debris put in orbit around Pluto by the impact.

The first widely discussed theory for Pluto's origin was R.A. Lyttleton's (1936) suggestion, which was based on the fact that Pluto's orbit is Neptune-crossing. In Lyttleton's well-remembered scenario, Pluto was formerly a satellite of Neptune, ejected via a close encounter between itself and the satellite Triton. According to Lyttleton, this encounter also reversed the orbit of Triton. Variants on the "origin as a former satellite of Neptune" hypothesis were later proposed. However, all these scenarios were dealt a serious blow by the discovery of Charon, which severely complicates the Pluto-ejection problem by requiring either (1) Charon to also be ejected from the Neptune system in such a way that it enters orbit around Pluto, or (2) Charon to be formed far beyond Neptune where Pluto currently orbits and then captured into orbit around Pluto (presumably by a collision).

Other strong objections to scenarios like Lyttleton's also exist. First among these is the fact that any object ejected from orbit around Neptune would be Neptune-crossing and therefore subject to either accretion or rapid dynamical demise. It is implausible that such an object would be transferred to the observed 2:3 Neptune:Pluto resonance, because stable 2:3 libration orbits are dynamically disconnected in orbital phase space from orbits intersecting Neptune. Further, because Pluto is less massive than Triton by about a factor of 2, it is impossible for Pluto to reverse Triton's orbit to a retrograde one, as is observed. Further still, Pluto's rock content is so high that it is unlikely that Pluto formed in a planetary subnebula. Of course, none of these facts were known until decades after Lyttleton made his original (and then quite logical) suggestion that Pluto might be a former satellite of Neptune.

As described in Section 2, it is likely that Pluto was caught in the 2:3 resonance and had its orbital eccentricity and inclination amplified to current values as Neptune migrated outward during the clearing of the outer solar system by the giant planets.

The heliocentric formation/giant collision scenario described earlier for the origin of the satellites can account for most of the major attributes of the system, including the elliptical, Neptune-crossing orbit, the high axial obliquities, and the $\approx$8.5:1 mass ratio. Further, the present tidal equilibrium state would naturally be reached by Pluto and Charon in 10^8–10^9 years—a small fraction of the age of the solar system.

Still, such a scenario begs two questions. First, why is Pluto so small? And, second, how could Pluto and the Charon progenitor, alone in over 10^3 AU^3 of space, "find" each other in order to execute a mutual collision? That is, the giant impact hypothesis still fails to explain (1) the existence of Pluto and Charon themselves; (2) the very small masses of Pluto and Charon compared to the gas giants in general, and Neptune and Uranus in particular; (3) the fact that the collision producing the impact was highly unlikely; and (4) the system's position in the Neptune resonance.

In 1991, Alan Stern of the Southwest Research Institute suggested that the solution to (1)–(3) lies in the possibility that Pluto and Charon were members of a large population (300–3000) of small ($\sim 10^{-5}$ g) **ice dwarf** planets present during the accretion of Uranus and Neptune in the 20–30 AU zone. Such a population would make likely the Pluto–Charon collision, as well as three otherwise highly unlikely occurrences in the 20–30 AU region: the capture of Triton into retrograde orbit and the tilting of Uranus and Neptune. Similar conclusions based on different considerations were reached by William McKinnon of Washington University in the late 1980s. According to this work, the vast majority of the ice dwarfs were either scattered (with the comets) to the Oort cloud or ejected from the solar system altogether by perturbations from Neptune and Uranus. Only Pluto–Charon and Triton remain in the 20–30 AU zone today, specifically because they are trapped in unique dynamical niches that protect them against loss to such strong perturbations.

If this is correct, it implies that Pluto, Charon, and Triton are important "relics" of a very large population of small planets, dubbed ice dwarfs first by Stern (1991), which by number (but not mass) dominate the planetary population of the solar system. As such, these three bodies would no longer appear as isolated anomalies in the outer solar system and would be genetic relations from an ancient, ice dwarf ensemble, and therefore worthy of intense study as a new and valuable class of planetary body unto themselves.

8.3. The Context of Pluto in the Outer Solar System

When the existence of the ice dwarf population was first suggested, the solar system beyond Neptune appeared to only be inhabited by Pluto and the numerous comets scattered out of the planetary region during the accretion of the giant planets.

Since late 1992, however, our concept of the outer solar system has evolved considerably, owing to a rapid set of discoveries of faint largish bodies orbiting between 30 and 50 AU in what is known as the Edgeworth–Kuiper Belt. The first such objects were detected by David Jewitt and Jane Luu using the University of Hawaii's 2.2 m telescope on Mauna Kea.

As of this writing at the end of 2014, over 1600 worlds with diameters of 100–2000 km have been discovered in the Kuiper Belt, including some objects that have clearly been scattered out of the giant planets' region. Many of

these are apparently in the 2:3 mean-motion resonance with Neptune that Pluto also occupies. The largest discovered Kuiper Belt body is almost Pluto's size. Some have satellites. Beyond the Kuiper Belt, in the so-called scattered belt, lie other large bodies, including Eris, almost as large as Pluto.

Because the Kuiper Belt census obtained to date has covered only a tiny fraction of the ecliptic sky, it is estimated that many times the discovered population exists. Current models of the population of the region between 30 and 50 AU from the Sun now indicate that some 100,000 or more objects with diameters larger than approximately 100 km and perhaps several billion comets 1−20 km in diameter reside there. The total mass of bodies currently in the 30−50 AU zone may amount to as much as 0.01 $M_{\oplus}$, exceeding the mass of the asteroid belt by more than an order of magnitude.

Both the discovery of the rapidly expanding cohort of objects found in the 30−50 AU zone, and the circumstantial evidence that this region of the solar system was much more heavily populated when the solar system was young, finally provide a context for Pluto (and the putative Charon progenitor as well). We now see that Pluto did not form in isolation and does not exist so today. Instead, Pluto is simply one of a large number of significant miniplanets that grew in the region beyond Neptune when the solar system was young. Pluto's presence there today is in large measure due to its location in the stable 2:3 resonance with Neptune. The question now has moved from why a small planet like Pluto formed in isolation, to why a large population of objects hundreds and thousands of kilometers in diameter formed in the 30−50 AU zone without progressing to the formation of a larger planet there.

The name Kuiper Belt generically refers to a population of small bodies, the orbits of which have a **semimajor axis**—and hence orbital period—larger than those of Neptune. The Kuiper Belt objects (KBOs)—having formed at large distances from the Sun—are rich in water ice and other volatile chemical compounds and have physical properties similar to those of comets. Indeed, the existence of the Kuiper Belt was first deduced from observations of the **Jupiter-family comets**, a population with short orbital periods and small to moderate orbital inclinations, of which the Kuiper Belt is the source.

In 20 years since the discovery of the first object, about 1500 KBOs have been detected. Of these, ~1000 objects have been observed for at least 2 years, a necessary condition to compute their orbital parameters with significant precision. The results of this detailed observational exploration of the Kuiper Belt structure have provided several surprises. Indeed, it was expected that the Kuiper Belt preserved the pristine conditions of the protoplanetary disk. But it is now evident that this picture is not correct: The Kuiper Belt has been affected by a number of processes that have altered its original structure.

The Kuiper Belt may thus provide us with a large number of clues to understand what happened in the outer solar system during the primordial ages. Potentially, the Kuiper Belt might teach us more about the formation of the giant planets than the planets themselves. And, as in a domino game, a better knowledge of the formation of giant planets would inevitably boost our understanding of the subsequent formation of the solar system as a whole. Consequently, Kuiper Belt research is now considered a priority of modern planetary science.

1. HISTORICAL PERSPECTIVE

Since its discovery in 1930, Pluto has traditionally been viewed as the last vestige of the planetary system—a lonely outpost at the edge of the solar system, orbiting beyond Neptune with a 248-year period.

Pluto itself has always appeared to be an oddity among the planets. Traditionally, the planets are divided into two main groups. The first group, the terrestrial planets, formed in the inner regions of the solar system where the material from which the planets were made was too warm for water and other volatile gases to be condensed as ices. These planets, which include the Earth, are small and rocky. Farther out from the Sun, the cores of the planets grew from a combination of rock and condensed ices and captured significant amounts of nebula gas. These are the Jovian planets, the giants of the solar system; they most likely do not have solid surfaces. But, then there is Pluto, unique, small (its radius is only ~1180 km, only two-thirds that of the Earth's Moon) and made of a mix of rock and frozen ices.

The planets formed in a disk of material that originally surrounded the Sun (see "Origin of the Solar System"). The formation of the disk occurred because the molecular cloud

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00043-8

that gave origin to the Sun had necessarily a slight global spin. Thus, as it collapsed, the spin rate had to increase in order to conserve **angular momentum**. The cloud could not form a single star with the amount of angular momentum it possessed, so it shed a disk of material (gas and dust) that contained very little mass (as compared with the mass of the Sun), but most of the angular momentum of the system. As such, the planets formed in a narrow disk structure; the plane of that disk is known as the invariable plane. But then there is Pluto, unique, having an orbital inclination of 15.6° with respect to the invariable plane.

The orbits of the planets are approximately ellipses with the Sun at one focus. As the planets formed in the original circumsolar disk, they tended to evolve onto orbits that were well separated from one another. This was required so that their mutual gravitational attraction would not disrupt the whole system. (Or to put it another way, if our system had not formed that way, we would not be here to talk about it!) But, then there is Pluto, unique, having an orbit that crosses the orbit of its nearest neighbor, Neptune.

So, the historical view was that Pluto was an oddity in the solar system, unique for its physical makeup and size as well as its dynamical niche. But, this view changed in September 1992 with the announcement of the discovery of the first of a population of small (compared to planetary bodies) objects orbiting beyond the orbit of Neptune, in the same region as Pluto. Since that time, roughly 1500 objects with radii between a few tens and ~1000 km have been discovered. One object, 136199 Eris, even turned out to be about the same size as Pluto. Moreover, a modeling of the detection efficiency of the performed surveys suggests that there are approximately 100,000 objects larger than a few tens of kilometers occupying this region of space, approximately between 30 and 50 astronomical units (AU) from the Sun. There are inevitably many more smaller ones. As discussed in more detail in the following sections, these objects likely have a similar physical makeup to that of Pluto, and many have similar orbital characteristics. Thus, in the past 20 years, Pluto has been transformed from an oddity, to the founding member of what is perhaps the most populous class of objects in the planetary system.

The discovery of the Kuiper Belt, as it has come to be known, represents a revolution in our thinking about the solar system. First predicted on theoretical grounds and later confirmed by observations, the Kuiper Belt is the first totally new class of bodies to be discovered in the solar system since the first asteroid was found on New Year's day, 1801. Its discovery has radically changed our view of the outer solar system.

Speculation on the existence of a trans-Neptunian disk of icy objects dates back over 100 years. In the early 1900, Campbell, Aitken, and Leuschner considered the possibility of trans-Neptunian planets and speculated on the orbital distribution of small bodies in the outer planetary system. In the 1940s and early 1950s, a more comprehensive approach to the problem was made independently by Kenneth Edgeworth and Gerard Kuiper. They noticed that if one were to grind up the giant planets and spread out their masses to form a disk, then this disk would have a very smooth distribution, with a density that slowly decreases as the distance from the Sun increases. That holds until Neptune, at which point there is an apparent edge beyond which there was thought to be nothing except tiny Pluto. Edgeworth and Kuiper suggested that perhaps this edge was not real. Perhaps the disk of planetesimals (i.e. small bodies, potentially precursors of planet formation) that formed the planets extended past Neptune, but the density was too low or the formation times too long to form large planets. If so, they argued, these planetesimals should still be there in nearly circular orbits beyond Neptune. The idea of a trans-Neptunian disk received little attention for many years. The objects in the hypothetical disk were too faint to be seen with the telescopes of the time, so there was no way to prove or disprove their existence. Comet dynamicists showed that the lack of detectable perturbations on the orbit of Halley's comet limited the mass of such a disk to no more than 1.3 Earth masses ($M_\oplus$) if it was at 50 AU from the Sun.

However, the idea was resurrected in 1980 when Julio Fernandez proposed that a cometary disk beyond Neptune could be a possible source reservoir for the short-period comets (those with orbital periods <200 years). Subsequent dynamical simulations showed that a comet belt beyond Neptune is the most plausible source for the low-inclination subgroup of the short-period comets, named the Jupiter-family comets. This work led observers to search for KBOs. With the discovery of the first object, 1992 QB_1, by D. Jewitt and J. Luu, the Kuiper Belt ceased to be a speculation and became a concrete entity of the solar system.

2. ORBITAL AND DYNAMICAL STRUCTURE OF THE TRANS-NEPTUNIAN POPULATION

Figure 43.1 shows the distribution of the objects with semimajor axis larger than 30 AU whose orbits have been determined from observations spanning over at least 3 years.

A glance at the figure reveals that the orbits of the trans-Neptunian objects can be very diverse. The majority of the discovered objects are clustered in the 36–48 AU range, but several others form a "tail" structure extending beyond 50 AU. Their semimajor axes range up to several 100 AU, but probably go much farther. Their perihelion distances are generally between 30 and 38 AU (dotted curves in the bottom right panel of Figure 43.1), so that on average the orbital eccentricities increase with semimajor axes. Many

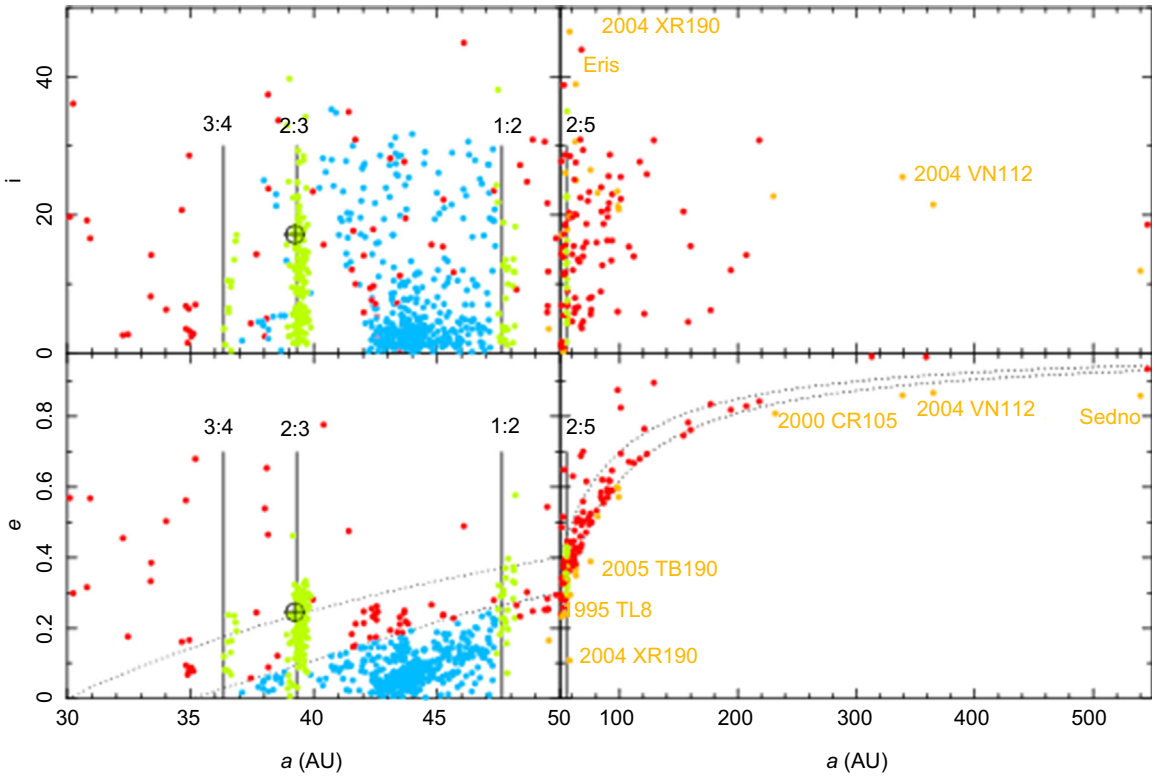

FIGURE 43.1 The distribution of the objects with well-determined orbits, as of October 29, 2013. The upper and lower panels show, respectively, the inclination and the eccentricity vs semimajor axis. Two different semimajor axis scales are used to illustrate the Kuiper Belt (left panels) and the scattered disk (right panels) distributions. Red dots correspond to the scattered disk, orange dots to the extended scattered disk, blue dots to the classical Kuiper Belt, and green dots to the resonant populations. The big, crossed circle denotes the orbit of Pluto. The vertical lines labeled 3:4, 2:3, and 1:2 mark the location of the corresponding mean-motion resonances with Neptune. The two dotted curves on the lower panels correspond to perihelion distances $q = 30$ AU and $q = 35$ AU on the left, and $q = 30$ AU and $q = 38$ AU on the right. These curves approximately bound the scattered disk orbital distribution.

of these objects are dynamically unstable because they suffer sufficiently close encounters with Neptune. At each encounter, they receive an impulselike acceleration, which changes the semimajor axis of their orbits. The perihelion distance remains roughly constant during an encounter, so that the **eccentricity** changes together with the semimajor axis. Thus, under the scattering gravitational action of Neptune (located at 30 AU), these objects move in a sort of random walk in the region confined by the dotted curves. For this reason, the population of unstable objects is now called the **scattered disk**. The name "disk" is justified, because the orbital inclinations, although large, are significantly smaller than 90°, giving this population a disklike structure.

Up to now, we have used "Kuiper Belt" to denote generically the population of objects with $a > 30$ AU. However, the existence of the scattered disk suggests that we should reserve the name "Kuiper Belt" for the population of objects that do not suffer encounters with Neptune and therefore have orbits that either do not significantly change with time or do so very slowly. Adopting this definition, the objects of the Kuiper Belt are plotted with blue and green dots in Figure 43.1, while the scattered disk objects are plotted in red. As one sees, scattered disk objects can also have $a < 50$ AU, provided that they have a small perihelion distance and, for reasons discussed below, are not in one of the more prominent **mean-motion resonances** with Neptune (indicated by the vertical lines labeled 3:4, 2:3, 1:2 and 2:5 in Figure 43.1). All solar system bodies should have accreted on quasicircular and coplanar orbits. This is a necessary condition for small planetesimals being able to stick together and form larger objects. Indeed, if the eccentricities or the **inclinations** are large, the relative encounter velocities are such that, upon collisions, planetesimals do not grow, but fragment into smaller pieces. This consideration suggests that the scattered disk objects formed much closer to Neptune, on quasicircular orbits, and have been transported outward by the scattering action of that planet. The fact that the scattering action is still continuing implies that the origin of the scattered disk does not necessarily require that the primordial solar system was different from the current one.

However, recent observations have revealed that, in addition to the Kuiper Belt and the scattered disk, there is a third category of objects, represented with orange dots in Figure 43.1. Their orbital distribution mimics that of the scattered disk objects, but their perihelion distance is somewhat larger, so that they avoid the scattering action of Neptune. Their orbits do not significantly change over the age of the solar system. Among the objects with these orbital properties are 1995 TL_8 ($a \sim 52$ AU, $q \sim 40$ AU), 2000 CR_{105} ($a \sim 225$ AU, $q \sim 44$ AU), 90377 Sedna ($a \sim 500$ AU, $q \sim 76$ AU), 136199 Eris ($a \sim 67.5$ AU, $q = 38$ AU, the second Pluto-sized trans-Neptunian object known so far), and 2004 XR_{190} ($a \sim 57.4$ AU, $q \sim 51$ AU—exceptional for its inclination of about 45°). For the previously listed reasons, these bodies also should have formed closer to Neptune on much more circular orbits, and presumably they have been transported outward through close encounters with the planet. However, given that they do not undergo close encounters now, their existence suggests that the solar system was different in the past (either the planetary orbits were different or the environment was different—massive objects crossing the Kuiper belt passing stars, etc.), so that the scattered disk extended further out in perihelion distance during the primordial times. For this reason we call this population the **extended scattered disk**.

In Figure 43.1, the red and orange dots seem to be outnumbered by the blue and green dots. However, the scattered and extended scattered disk objects are more difficult to discover, given that most of them have very elongated orbits and spend most of the time very far from the Sun. Accounting for this difficulty, astronomers have estimated that the scattered disk and the Kuiper Belt should constitute roughly equal populations.

If we look at Figure 43.1 more in detail (left panels), the Kuiper Belt can also be subdivided in a natural way into subpopulations. Several objects (green dots) are located in mean-motion resonances with Neptune. Mean-motion resonances provide a protection mechanism, so that resonant objects can avoid close encounters with Neptune even if their perihelion distance is smaller than 30 AU. Let us take Pluto as an example. Pluto is locked in a mean-motion resonance where it goes around the Sun twice every time Neptune goes around three times. So, every time Pluto crosses the trajectory of Neptune, the giant planet is always in one of three specific locations on its orbit, all very far away from Pluto's position. Thus Pluto and Neptune avoid mutual encounters. Given this resonant protection mechanism, resonant KBOs can be on much more elliptic orbits than the nonresonant ones, the eccentricities of the former ranging up to ∼0.4. The objects in the 2:3 mean-motion resonance with Neptune are usually called the plutinos (because they share the same resonance as Pluto), while those in the 1:2 resonance are sometimes called twotinos. In Figure 43.1, the resonant population seems to constitute a substantial fraction of the Kuiper Belt population. However, resonant objects are easier to discover because at perihelion they come closer to the Sun than the nonresonant ones. When accounting for this fact, astronomers estimate that, all together, the objects in mean-motion resonances constitute between 10% and 40% of the total Kuiper Belt population.

The nonresonant KBOs (blue dots) are usually referred to as classical. This adjective is attributed because their orbital distribution is the most similar to what the astronomers were expecting, before the discoveries of trans-Neptunian objects began: that of a disk of objects on stable, low-eccentricity, nonresonant orbits. However, even the classical population has unexpected properties. Their eccentricities are moderate—a necessary condition to avoid encounters with Neptune, given that they are not protected by any resonant mechanism. Nevertheless, the eccentricities are definitely larger than those of the protoplanetary disk in which the objects had to form. Some mechanism must have excited the eccentricities, making them grow from almost zero to the current values.

The same is true, and even more striking, for the inclinations (top panel of Figure 43.1). The inclinations are related to the relative encounter velocities among the objects, so that the Kuiper Belt bodies had to grow in a razor-thin disk. Despite this, the current inclinations range up to 30°−40°. Figure 43.1 gives the impression that large-inclination bodies are a modest fraction among the classical objects. However, one should take into account that the discovery surveys have been concentrated near the ecliptic plane, so that large-inclination bodies have a lower probability of being discovered than low-inclination ones. Accounting for this selection effect, astronomers have computed that the real inclination distribution of the classical objects is bimodal (Figure 43.2). There is a cluster of objects with inclination smaller than 4° and a second group of objects with a very distended inclination distribution. The former constitute what is now usually called the cold population and the latter constitute the hot population. The adjectives "hot" and "cold" do not refer to physical temperature (it is always very cold out there) but to the encounter velocities inside each population, in an analogy with gas kinetic theory. The cold and the hot populations should contain roughly the same number of objects.

The last striking property of the Kuiper Belt is its outer edge (Figure 43.1). For very low-eccentricity and low-inclination objects the edge is near 45 AU, although the classical belt as a whole ends at the location of the 1:2 mean-motion resonance with Neptune. For several years, the astronomers suspected that this edge is only apparent, due to the fact that more distant objects are more difficult to discover. However, with an increasing statistical sample, it turned out that this is not true. It has been shown that more distant objects should have been discovered by now, unless

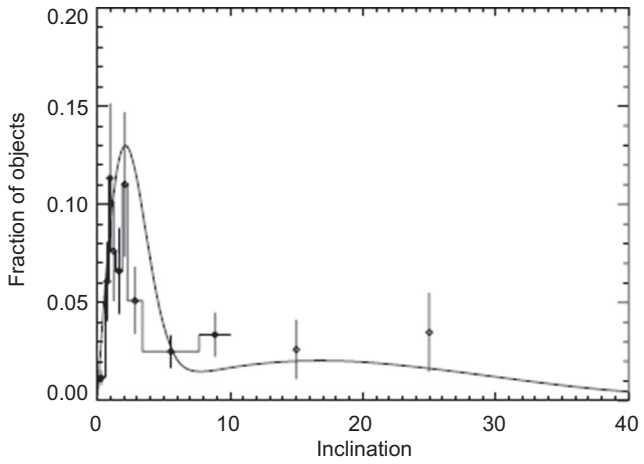

FIGURE 43.2 The inclination distribution (in degrees) of the classical Kuiper Belt after observational biases have been subtracted, according to the classical work of M. Brown (2001). The points with error bars show the model-independent estimate constructed from a limited subset of confirmed classical belt bodies, while the smooth line shows a best fit bimodal population model. In this model, ~60% of the objects have $i > 4°$.

either the Kuiper Belt population steeply decays in number beyond 48–50 AU or the maximal size of the objects beyond this limit is much smaller than that in the observed Kuiper Belt. For various reasons, astronomers tend to favor the former hypothesis: the existence of a physical outer edge of the Kuiper Belt.

An important issue is to understand which of the orbital properties discussed earlier is due to the dynamical processes that are still occurring in the Kuiper Belt. For instance, do the eccentricities and the inclinations slowly grow due to some dynamical phenomenon? Are the low-eccentricity objects beyond 48 AU unstable? If these are the cases, then the existence of large eccentricities and inclinations, as well as the outer edge of the Kuiper Belt could be simply explained. In the opposite case, these properties—like the existence of the extended scattered disk—reveal that the solar system was different in the past.

Dynamical astronomers have studied in great detail the dynamics beyond Neptune, using numerical simulations and semianalytic models. Figure 43.3 shows a map of the dynamical lifetime of trans-Neptunian bodies on a wide range of initial semimajor axes, eccentricities, and inclinations. This map has been computed numerically, by simulating the evolution of thousands of massless particles

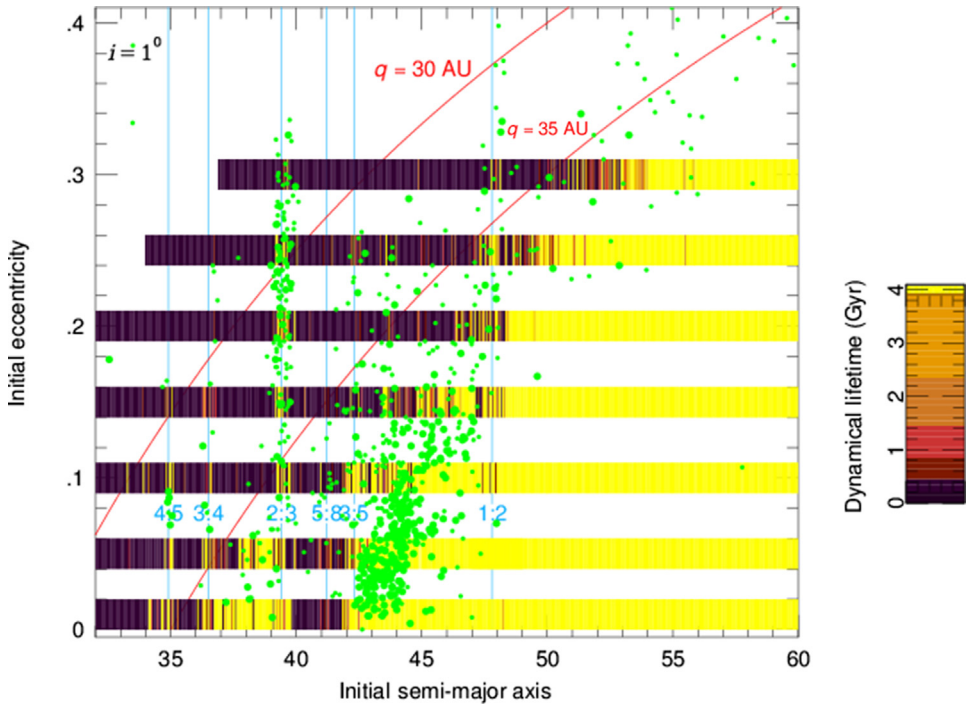

FIGURE 43.3 The dynamical lifetime for small particles in the Kuiper Belt derived from 4-billion-year integrations by Duncan, Levison, and Budd (1995). Each particle is represented by a narrow vertical strip of color, the center of which is located at the particle's initial eccentricity and semimajor axis (initial orbital inclination for all objects was 1°). The color of each strip represents the dynamical lifetime of the particle. Strips colored yellow represent objects that survive for the length of the integration, 4×10^9 years. Dark regions are particularly unstable on these timescales. For reference, the locations of the important Neptune mean-motion resonances are shown in blue and two curves of constant perihelion distance, q, are shown in red. The orbital distribution of the real objects is also plotted. Big dots correspond to objects with $i < 4°$, and small dots to objects with larger inclination. Remember that the dynamical lifetime map has been computed assuming $i = 1°$.

under the gravitational perturbations of the giant planets. The latter have been assumed to be initially on their current orbits. Each particle was followed until it suffered a close encounter with Neptune. Objects encountering Neptune would then evolve in the scattered disk for a time of order $\sim 10^8$ years until they are transported by planetary encounters into the inner planets region or are ejected to the **Oort cloud** or to interstellar space. In Figure 43.3, the colored strips indicate the length of time required for a particle to encounter Neptune as a function of its initial semimajor axis and eccentricity. The initial inclination of the particles was set equal to 1°. Strips that are colored yellow represent objects that survive for the length of the simulation, 4×10^9 years, the approximate age of the solar system. For comparison, the observed objects with good orbital determination are overplotted with green dots. Big dots refer to bodies with $I < 4°$, consistent with the low inclination at which the stability map has been computed. Small dots refer to objects with larger inclination and are plotted only for completeness.

As can be seen in the figure, the Kuiper Belt can be expected to have a complex structure, although the general trends are readily explained. Objects with perihelion distances less than ~35 AU (shown as a red curve) are unstable, unless they are near, and presumably librating about, a mean-motion resonance with Neptune. Indeed, the results in Figure 43.3 show that many of the Neptunian mean-motion resonances (shown in blue) are stable for the age of the solar system. Objects at low inclination with semimajor axes between 40 and 42 AU are unstable. This is presumably due to the presence of three overlapping **secular resonances**. Due to the perturbations exerted by the planets, the orbits of the planets themselves as well as those of small bodies precess in space. A secular resonance arises when the precession rate of the orbit of a body is equal to the precession rate of the orbit of one of the planets. In this case, the 40- to 42-AU region is affected by secular resonances with both Neptune and Uranus. These resonances tend to excite the eccentricities of the KBOs, which then can encounter Neptune and are ultimately removed from the Kuiper belt. Notice from Figure 43.3 that there are some objects in the 40–42 AU semimajor axis range, but they all have high inclination orbits (small dots). In fact, the destabilizing secular resonances are present only at low inclination in this region.

The conclusion to be drawn from a comparison between the distribution of the real low-inclination KBOs and the stability map in Figure 43.3 is that most observed objects (with the exception of scattered disk bodies) are associated with stable zones. Their orbits do not significantly change over the age of the solar system. Thus, their current excited eccentricities and inclination cannot be obtained from primordial circular and coplanar orbits in the framework of the current planetary system orbital configuration. Likewise, the region beyond the 1:2 mean-motion resonance with Neptune is totally stable. Thus, the absence of bodies beyond 48 AU cannot be explained by current dynamical instabilities.

Therefore, it is evident that the orbital structure of the Kuiper Belt has been sculpted by mechanisms that are no longer at work, but presumably were active when the solar system formed. The main goal of dynamical astronomers interested in the Kuiper Belt is to uncover these mechanisms and from them deduce, as far as possible, how the solar system formed and early evolved.

3. CORRELATIONS BETWEEN PHYSICAL AND ORBITAL PROPERTIES

The existence of two distinct classical Kuiper Belt populations, called the hot ($i > 4°$) and cold ($i < 4°$) classical populations, could be caused in one of two general manners. Either a subset of an initially dynamically cold population was excited, leading to the creation of the hot classical population, or the populations are truly distinct and formed separately.

One manner in which we can attempt to determine which of these scenarios is more likely is to examine the physical properties of the two classical populations. If the objects in the hot and cold populations are physically different, it is less likely that they were initially part of the same population.

The first suggestion of a physical difference between the hot and the cold classical objects came from the observation that the intrinsically brightest classical belt objects (those with lowest **absolute magnitudes**) are preferentially found with high inclination. Figure 43.4 shows the distribution of the classical objects in an inclination vs absolute magnitude diagram. As one sees, for an absolute magnitude $H > 5.5$, there is a given proportion between the number of objects discovered in the cold and the hot populations. This ratio is completely different for $H < 5.5$, where cold population objects are almost absent. All the biggest classical objects, such as 50000 Quaoar, 20000 Varuna, 19521 Chaos, 28978 Ixion, 136472 Makemake, and 136108 Haumea, have inclinations larger than 5°. Their median inclination is 20°. It has been shown that this result is not an artifact produced by observational biases.

The second possible physical difference between hot and cold classical KBOs is their colors. With the name "color" astronomers generically refer to the slope of the spectrum of the light reflected by a trans-Neptunian object at visible wavelengths, relative to that of the light emitted by the Sun. "Red" objects reflect more at long than at short wavelengths, while "gray" objects have a more or less uniform reflectance. Colors relate in a poorly understood manner to objects' surface composition. It has been shown

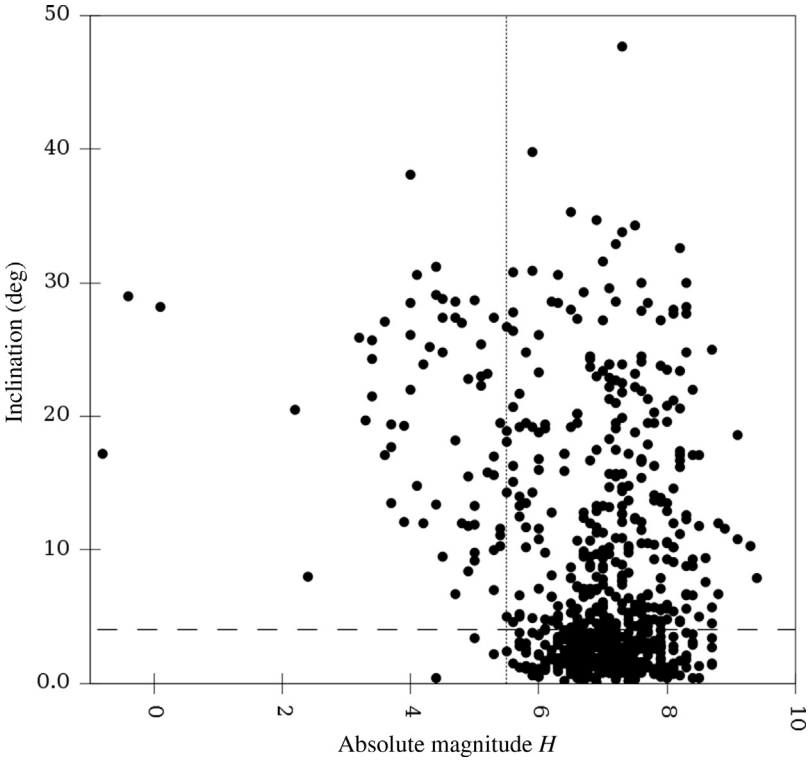

FIGURE 43.4 The inclination of the classical Kuiper Belt objects as a function of their absolute magnitude. The horizontal dashed line at $i = 4°$ separates the cold from the hot population. The vertical dotted line is plotted at $H = 5.5$. The distribution on the left side of the dotted line is clearly different from that on the right-hand side. The largest classical objects are all in the hot population.

and repeatedly confirmed that, for the classical belt, the inclination, and possibly the perihelion distance, is correlated with color. In essence, the low-inclination classical objects tend to be redder than higher inclination objects. More interestingly, colors naturally divide into distinct red and gray populations at precisely the location of the divide between the inclinations of the hot and cold classical objects. These populations differ at a 99.9% confidence level. Interestingly, the cold classical population also differs in color from the plutinos and the scattered objects at the 99.8 and 99.9% confidence level, respectively, while the hot classical population appears identical in color to these other populations.

It has been suggested that the colors of the objects, rather than being markers of different populations, are actually *caused* by the different inclinations. For example, the higher average impact velocities of the high-inclination objects could cause large-scale resurfacing by fresh water ice and carbonaceous materials, which could be gray in color. However, a similar color inclination trend should be observed also among the plutinos and the scattered disk objects, which is not the case. A careful analysis shows that there is no clear correlation between average impact velocity and color.

The idea that the cold population represents a distinct physical class of objects is reinforced by a third observation. Many KBOs are binaries, i.e. consisting of two objects in orbit around one another. Some of these binary objects are composed of a system of small satellites orbiting a major primary, like in the case of 136108 Haumea and 136199 Eris. These binaries are probably of collisional origin. However, the vast majority of known binaries are made of two components of roughly equal size and large separation. These binaries most likely are primordial, in the sense that their members became bound to each other at the time of KBO accretion. Interestingly, the fraction of the KBO population which is "primordial" binary is very different in the cold and hot populations. In the former, about 30% of the objects are binaries. Instead the fraction is only 5% in the hot population. This, again, argues that the cold population has had a distinct evolution.

In summary, the significant differences (color, size, binary fraction) between the hot and cold classical objects imply that these two populations are physically different in addition to being dynamically distinct.

4. SIZE DISTRIBUTION OF THE TRANS-NEPTUNIAN POPULATION AND TOTAL MASS

As briefly described in Section 1, the disk out of which the planetary system accreted was created as a result of the Sun shedding angular momentum as it formed (see also "Origin

of the Solar System"). As the Sun condensed from a molecular cloud, it left behind a disk of material (mostly gas with a little bit of dust) that contained a small fraction of the total mass but most of the angular momentum of the system. It is believed that the dust grains sedimented toward the midplane of the disk and started to stick to each other through electrostatic forces, forming pebble-sized objects, of the order of centimeters in diameter. These objects then formed larger objects through a still not fully understood process of accretion, leading to the origin of asteroids, comets, and planets (or the cores of the giant planets, which then accreted gas directly from the solar nebula). Understanding this process is one of the main goals of planetary science today.

There are few clues in our planetary system about this process. We know that the planets formed, and we know how big they are. Unfortunately, the planets have been so altered by internal and external processes that they preserve almost no record of their formation process. Luckily, we also have the Asteroid Belt, the Kuiper Belt, and the scattered disk. These structures contain the best clues to the planet formation process because they are regions where the process started, but for some reason, did not run to completion (i.e. a large planet). Thus, the size distribution of objects in these regions may show us how the processes progressed with time and (hopefully) what stopped them. The Kuiper Belt and the scattered disk are perhaps the best places to learn about the accretion process.

Because the size of the object is not a quantity that can be easily measured and the absolute magnitude is readily obtained from the observations, astronomers generally prefer the absolute magnitude distribution, instead of the size distribution. The absolute magnitude is related to size via the **albedo**, where large H corresponds to small sizes and vice versa.

The magnitude distribution is usually given in the form $\log N(< H) \propto H^{\alpha}, \quad \alpha > 0$ where N is the cumulative number of objects brighter than absolute magnitude H. The slope of this distribution, α, contains important clues about the physical strengths, masses, and orbits of the objects involved in the accretion process.

Bernstein et al. (2004, see Bibliography) were the first to argue that the H-distribution of the Kuiper belt population shows a change in α near $H \sim 7{-}9$. For bodies fainter than this threshold α is small (later it was determined to have $\alpha \sim 0.4{-}0.5$), whereas for brighter bodies α is much bigger, making the H-distribution steeper in a plot like that of Figure 43.5

This change in α, which is now well established by modern observations, can be interpreted in two ways. One possibility is that it is the result of collisional evolution. There are two extremes to the accretion process. If two large, strong objects collide at low velocities, then the amount of kinetic energy in the collision is small compared to the amount of energy holding the objects together. In this case, the objects merge to form a larger object. If two small,

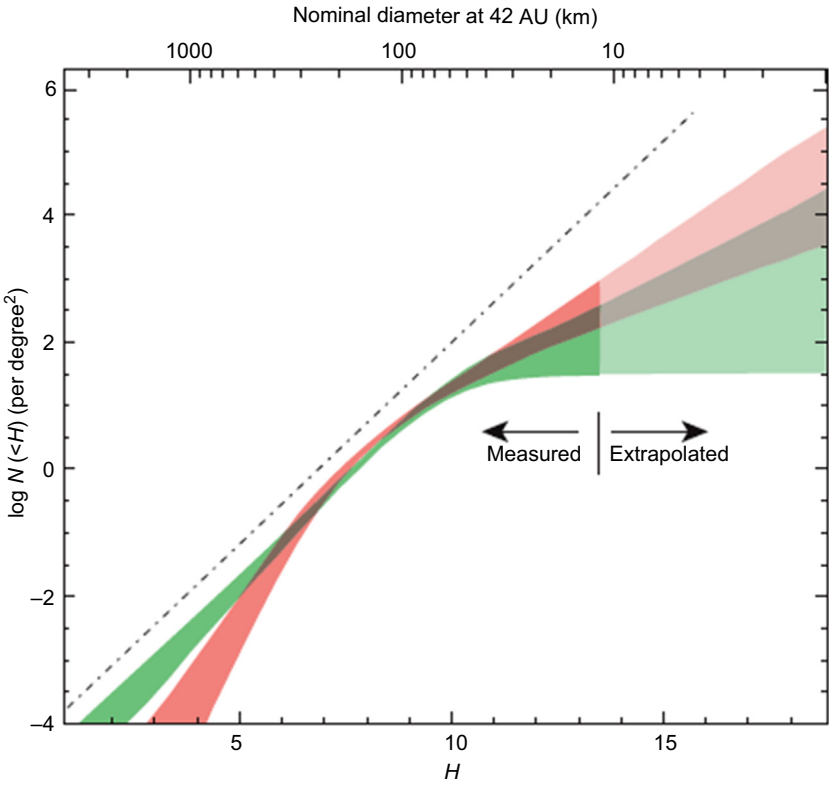

FIGURE 43.5 The cumulative magnitude distribution of the cold population (red) and hot population and scattered disk (green) according to a recent analysis by Bernstein et al. (2004). A turnover of the magnitude distribution is detected around $H \sim 7{-}9$. The slope of the magnitude distribution was very uncertain beyond this limit at the time this plot was made but is now well determined ($\alpha = 0.4{-}0.5$).

weak objects collide at high velocities, then the energy in the collision overpowers the gravitational and material binding energies. In this case, the objects break apart, forming a large number of much smaller objects. In this view, originally the H-distribution was steep at all magnitudes and the observed break in the current H-distribution marks the transition from accretional to disruptive collisions. The alternative interpretation is that the observed H-distribution is a primordial signature of the formation process and not the result of collisional erosion over the eons. In this view, the break represents the characteristic size (or H) at which most KBOs formed (i.e. 100−200 km in diameter). If true, this would be an important diagnostic of the overall formation process of KBOs.

Interestingly, the hot and the cold classical population seems to have two different H-distributions in the steep part. Originally, it was thought that the hot population and the scattered disk have a value of α smaller than that of the cold population (Figure 43.5). More recent dedicated observations, however, show that the H-distribution of the hot population is complex, looking like the cold population for $H \gtrsim 5$, but having a very small value of α for brighter objects. This is consistent with the fact that the largest bodies are all in the hot population, and yet the hot and cold populations and the scattered disk contain roughly the same number of bodies bigger than 100 km.

It is possible to integrate under the magnitude distribution shown in Figure 43.5 in order to estimate the total mass in the Kuiper Belt between 30 and 50 AU. Such an integration with limits between $R = 1$ and 1200 km (the approximate radius of Pluto) and assuming a density of 1 g/cm^3(the measured densities of KBOs fall in the range 0.3−3 g/cm^3) shows that the total mass is about one-hundredth of an Earth mass. Given the uncertainties, it is possible that the mass is of order of 0.1 $M_\oplus$, but not significantly larger.

As with many scientific endeavors, the discovery of new information tends to raise more questions than it answers. Such is the case with the preceding mass estimate. Edgeworth's and Kuiper's original arguments for the existence of the Kuiper Belt were based on the idea that it seemed unlikely that the disk of planetesimals that formed the planets would have abruptly ended at the current location of the outermost known planet. An extrapolation into the Kuiper Belt (between 30 and 50 AU) of the current surface density of nonvolatile material in the outer planets region predicts that there should originally have been about 30 $M_\oplus$ of material there. However, as stated previously, our best estimate is over 200 times less than that figure!

Edgeworth's and Kuiper's argument is not the only indication that the mass of the primordial Kuiper Belt had to be significantly larger in the past. In fact, even if the primoridal orbits had been much less eccentric and inclined than they are now (a necessary condition for accretion), the current abundance of solid material in the Kuiper Belt would not allow the growth of ∼100-km bodies (the characteristic size of most KBOs) over the age of the solar system. A massive and dynamically cold primordial Kuiper Belt is required.

Therefore, understanding the ultimate fate of the 99% (or 99.9%) of the initial Kuiper Belt mass that appears to be no longer in the Kuiper Belt is a crucial step in reconstructing the history of the outer solar system.

5. ECLIPTIC COMETS

As described in Section 1, the current renaissance in Kuiper Belt research was prompted by the suggestion that the Jupiter-family comets originated there. We now know that there are mainly two populations of small bodies beyond Neptune: the Kuiper Belt and the scattered disk. Which one is the dominant source of these comets?

To answer this question, we need to examine a few considerations on the origin of the scattered disk. We have seen in Section 2 that the bodies in the scattered disk have intrinsically unstable orbits. The close encounters with Neptune move them in semimajor axis, until they either evolve into the region with $a < 30$ AU or reach the Oort cloud at the frontier of the solar system. In both these cases, the bodies are removed from the scattered disk. Despite this possibility of dynamical removal, we still observe scattered disk bodies today. How can this be?

There are a priori two possibilities. The first one is that the scattered disk population is sustained in a sort of steady state by the bodies escaping from the Kuiper Belt. This means that on a timescale comparable to that for the dynamical removal of scattered disk bodies, new bodies enter the scattered disk from the Kuiper Belt. For example, a similar situation occurs for the population of **near-Earth asteroids** (NEAs, see Near Earth Asteroids). NEAs' dynamical lifetimes are only of a few million years because they intersect the orbits of the terrestrial planets. Nevertheless, the population remains roughly constant because new asteroids enter the NEA population from the Main Asteroid Belt at the same rate at which old NEAs are eliminated.

The second possibility is that the scattered disk that we see today is only what remains of a much more numerous population that has been decaying in number since planetary formation. Numerical simulations show that roughly 0.1−1% of the scattered disk bodies can survive in the scattered disk for the age of the solar system. Thus, the primordial scattered disk population should have been about 100−1000 times more numerous.

Which of these possibilities is true? In the first case, we would expect that the Kuiper Belt is much more populated than the scattered disk. For instance, the Asteroid Belt contains about 1000 times more objects than the NEA

population, at comparable sizes. However, observations indicate that the population of the scattered disk is a substantial fraction of that of the Kuiper Belt. Thus, the second possibility is more likely. Scattered disk objects most likely formed in the vicinity of the current positions of Uranus and Neptune. When these planets grew massive, they scattered them away from their neighborhoods. In this way, a massive scattered disk of about 10 $M_\oplus$ formed. What we see today is just the last vestige of that primordial population, which is still decaying in number.

The fact that the scattered disk is not sustained in steady state by the Kuiper Belt, but it is still decaying, implies that the scattered disk provides more objects to the giant planet region ($a < 30$ AU) than it receives from the Kuiper Belt. Thus, the outflow from the scattered disk is more important than the outflow from the Kuiper Belt. This implies that the scattered disk, not the Kuiper Belt, is the dominant source of Jupiter-family comets.

A significant amount of research has gone into understanding the dynamical behavior of objects that penetrate into the $a < 30$ AU region from the scattered disk. These studies show that the encounters with the planets spread them throughout the planetary system. These objects are usually called ecliptic comets, even if at large distances from the Sun they typically do not show any cometary activity. The distribution of these objects as predicted by numerical integrations is shown in Figure 43.6.

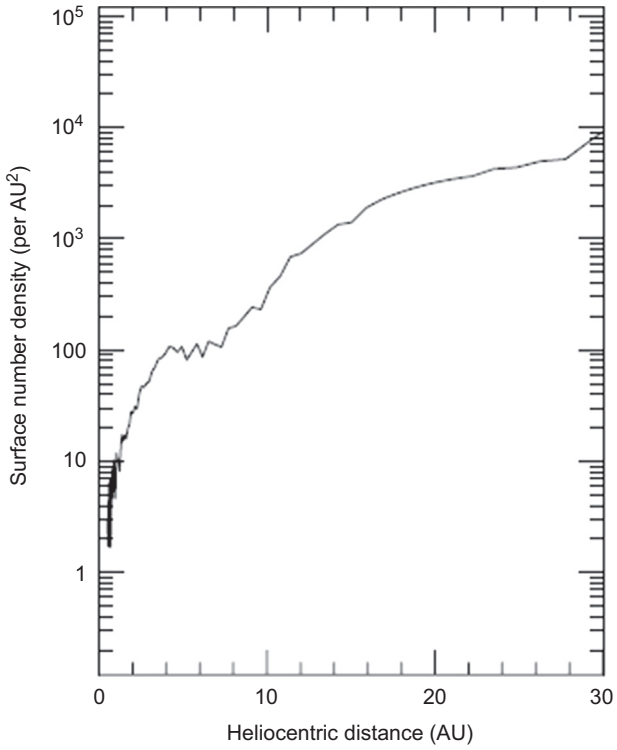

FIGURE 43.6 The surface number density (on the plane of the ecliptic) of ecliptic comets as determined from numerical integrations by Duncan and Levison (1997). There are approximately 10^6 comets larger than about 1 km in radius in this population.

The ecliptic comets that get close to the Sun become active. When their semimajor axis is smaller than that of Jupiter, they are called Jupiter-family comets. It is somewhat surprising that up to about one-third of the objects leaving the scattered disk in the simulations spend at least some of their time as Jupiter-family comets. The Jupiter-family comets that we see today are, in majority, small, $R \lesssim 10$ km. However, if our understanding of the size distribution of these objects is correct (see Section 5), we should expect to see a 100-km-sized Jupiter-family comet about 0.4% of the time. What a show that would be in the night sky!

Those ecliptic comets between Jupiter and Neptune are called the Centaurs (only the largest of which are observable). The simulations predict that there are $\sim 10^6$ ecliptic comets larger than about 1 km in radius currently in orbits between the giant planets.

6. THE PRIMORDIAL SCULPTING OF THE TRANS-NEPTUNIAN POPULATION

In the previous sections, we have seen that many properties of the Kuiper Belt cannot be explained in the framework of the current solar system:

1. The existence of the resonant populations.
2. The excitation of the eccentricities in the classical belt.
3. The coexistence of a cold and a hot population with different physical properties.
4. The presence of an apparent outer edge at the location of the 1:2 mean-motion resonance with Neptune.
5. The mass deficit of the Kuiper Belt.
6. The existence of the extended scattered disk population.

These puzzling aspects of the trans-Neptunian population reveal that it has been sculpted when the solar system was different, due to mechanisms that are no longer at work. Like detectives on the scene of a crime, trying to reconstruct what happened from the available clues, the astronomers try to reconstruct how the solar system formed and evolved from the traces left in the structure of the Kuiper Belt.

Planet migration has been the first aspect of the primordial evolution of which the astronomers found a signature in the Kuiper Belt. It is widely accepted that the giant planets fully formed during a short period (less than 10 My) when most of the protoplanetary disk was gas. Once the planets formed and the gas disappeared, the planetesimals that failed to be incorporated in the planets' cores had to be removed from the planets' vicinity by the gravitational scattering action of the planets themselves. If a planet scatters a planetesimal outward, the latter gains

energy. Because of energy conservation, the planet has to lose energy, moving slightly inward. The opposite happens if the planet scatters the planetesimal toward the inner solar system. A planet is much more massive than a planetesimal, thus the displacement of the planet is infinitesimal. However, if the number of planetesimals is large, and their total mass is comparable to that of the planet, the final effect on the planet is not negligible. This is a general process. We now come to what should have happened in our solar system.

Numerical simulations suggest that only a small fraction of the planetesimals originally in the vicinity of Neptune was scattered outward: less than 1% ended up in the scattered disk, and 5%, in the Oort cloud. The remaining 94% of the planetesimals eventually were scattered inward toward Jupiter, which, given its large mass, ejected from the solar system almost everything that came to cross its orbit. Thus, the net effect was that Neptune took energy away from the planetesimals and moved outward, while Jupiter gave energy to them and moved inward. Numerical simulations show that Saturn and Uranus also moved outward. Following Neptune's migration, the mean-motion resonances with Neptune also migrated outward, sweeping the primordial Kuiper Belt until they reached their present position. During this process, some of the KBOs swept by a mean-motion resonance could be captured into resonance. Once captured, these bodies had to follow the resonance in its migration, while their eccentricity had to steadily grow. Thus, the planetesimals that were captured first ended up on very eccentric resonant orbits, while those captured last could preserve a small eccentricity inside the resonance. Numerical simulations show that this process produces an important population of resonant bodies inside all the main mean-motion resonances with Neptune. To reproduce the observed range of eccentricities of resonant bodies, Neptune had to migrate more than 7 AU, thus starting not further than 23 AU (see Figure 43.7). The existence of resonant bodies in the Kuiper Belt thus provides a strong indication that planet migration really happened.

However, as Figure 43.7 also shows, several important properties of the Kuiper Belt cannot be explained by this simple model invoking resonance sweeping through a dynamically cold, radially extended disk. The eccentricity of the classical belt is only moderately excited, and the inclination remains very cold. The planetesimals are only relocated from the classical belt to the resonances, and only a minority of them are lost, which cannot explain the mass depletion of the belt. Finally, the region beyond the 1:2 mean-motion resonance is unaffected by planet migration, and therefore the existence of an outer edge requires a different explanation.

Four plausible models have been proposed so far to explain the formation of an outer edge: (1) the outer part of the disk was destroyed by the passage of a star; (2) it was photoevaporated by the radiation emitted by massive stars originally in the neighborhood of the Sun; (3) planetesimals beyond some threshold distance could not grow because of the enhanced turbulence in the outer disk which prevented the accumulation of solid material; and (4) distant dust particles and/or planetesimals migrated to smaller heliocentric distance during their growth, as a consequence of gas drag, thus forming sizeable objects only within some threshold distance from the Sun. The first two scenarios require that the Sun formed in a dense stellar environment, consistent with recent observations showing that stars tend to form in clusters which typically disperse in about 100 My. The entire protoplanetary disk—both the gas and the planetesimal components—would be truncated by these mechanisms. The third and the fourth scenarios, conversely, form a truncated planetesimal disk out of an extended gaseous disk.

Whatever mechanism formed the edge, it is intriguing that said edge is now at the location of a resonance with Neptune, despite the fact that Neptune did not play any role in the edge formation. Is this a coincidence? Probably not. It may suggest that originally the outer edge of the planetesimal disk was well inside 48 AU, and that the migration of Neptune pushed somehow a small fraction of the disk planetesimals beyond the disk's original boundary. These pushed-out planetesimals are now identified with the current members of the Kuiper Belt. The fact that the Kuiper Belt is mass deficient all over its radial extent (36–48 AU), in addition suggests that the original edge was inside 36 AU. In fact, if the original edge had been somewhere in the 36–48 AU range, we would see a discontinuity in the current radial mass distribution of the Kuiper Belt, which is not the case. An edge of the planetesimal disk close to 30 AU also helps to explain why Neptune stopped there and did not continue its outer migration beyond this limit.

Several mechanisms have been identified to push beyond the original disk edge a small fraction (of order 0.1%) of the disk's planetesimals, and to implant them on stable Kuiper Belt orbits. They are described next. More mechanisms might be identified in the future.

As Neptune moved through the disk on a quasicircular orbit, it scattered the planetesimals with which it had close encounters. Through multiple encounters, some planetesimals were transported outward on eccentric, inclined orbits. A small fraction of these objects still exist today and constitute the scattered disk. Occasionally, some scattered disk objects entered a resonance with Neptune. Resonances can modify the eccentricity of the orbits. If decreased, the perihelion distance is lifted away from the planet; the sequence of encounters stops, and the body becomes "decoupled" from Neptune like a KBO. If Neptune had not been migrating, the eccentricity would have eventually increased back to Neptune-crossing values—the dynamics

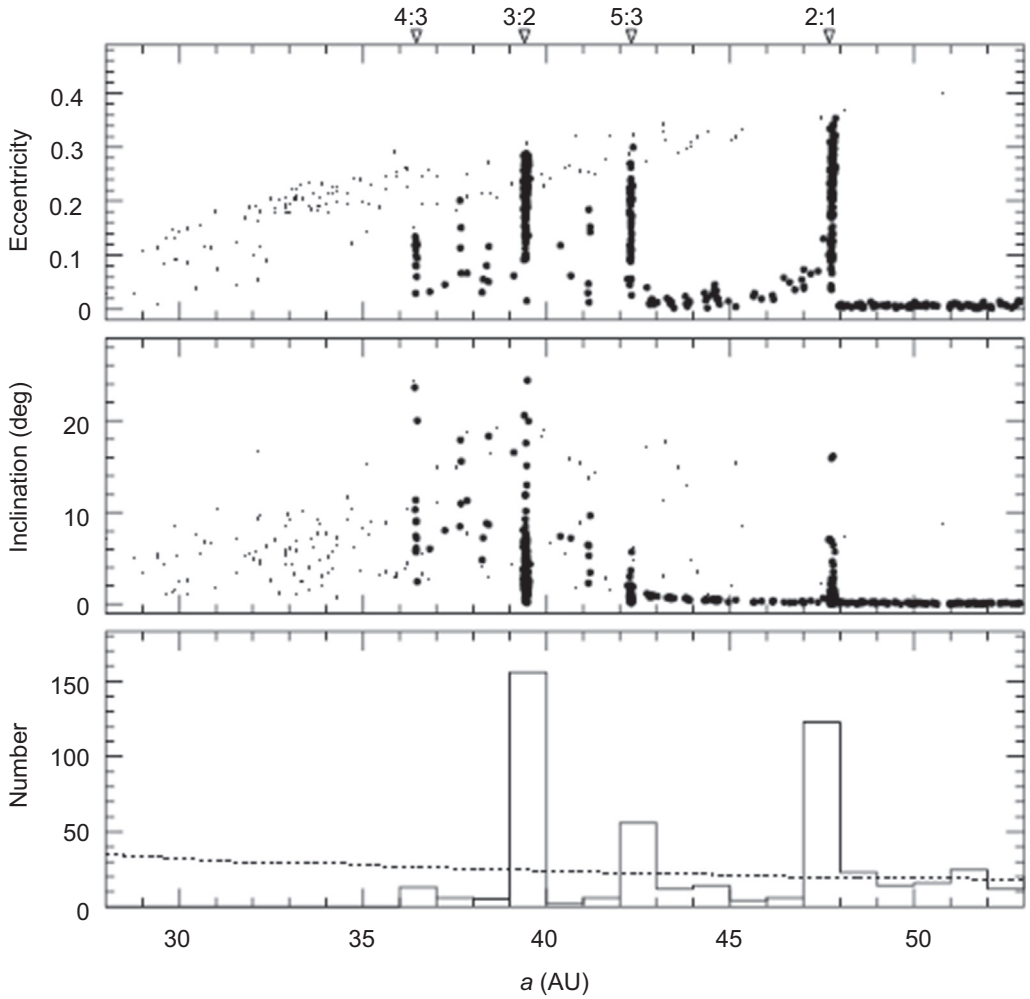

FIGURE 43.7 Final distribution of the Kuiper Belt bodies according to a simulation of the sweeping resonances scenario by Malhotra (1995). The simulation is done by numerical integrating, over a 200-My time span, the evolution of 800 test particles on initial quasicircular and coplanar orbits. The planets are forced to migrate (Jupiter, −0.2 AU; Saturn, 0.8 AU; Uranus, 3 AU; Neptune, 7 AU) and reach their current orbits on an exponential timescale of 4 My. Large solid dots represent "surviving" particles (i.e. those that have not suffered any planetary close encounters during the integration time); small dots represent the "removed" particles at the time of their close encounter with a planet. In the lowest panel, the solid line is the histogram of semimajor axis of the surviving particles, and the dotted line is the initial distribution. Most of the initial mass of the Kuiper Belt is simply relocated from the classical belt to the resonant populations. The mass lost is only a small fraction of the total mass.

being reversible—and the sequence of encounters would have restarted again. Neptune's migration broke the reversibility so that some of the decoupled bodies managed to escape from the resonances and remained permanently trapped in the Kuiper Belt. These bodies preserved the large inclinations acquired during the Neptune-encountering phase, and they can now be identified with the "hot" component of the Kuiper Belt population.

At the same time while Neptune was migrating through the disk, its 1:2 and 2:3 resonances swept through the disk, capturing a fraction of the disk planetesimals as explained earlier. When the 1:2 resonance passed beyond the edge of the disk, it kept carrying its load of objects. Because the migration of Neptune was presumably not a perfectly smooth process, the resonance was gradually dropping objects during its outward motion. Therefore, like a farmer seeding as he advances through a field, the resonance disseminated its previously trapped bodies all along its way up to its final position at about 48 AU. This explains the current location of the outer edge of the Kuiper Belt. Because the 1:2 resonance does not significantly enhance the orbital inclinations, the bodies transported by the resonance preserved their initially small inclination and can now be identified with the cold component of the Kuiper Belt.

This scenario, reproduced in numerical simulations, explains qualitatively the orbital properties of the trans-Neptunian population, but it has difficulties explaining why the hot and the cold classical populations have different physical properties. Indeed, the members of these two populations should have formed more or less in the

same region of the disk, although they followed two different dynamical pathways toward the Kuiper Belt. These different pathways can explain the differences in binary fractions because only the hot population suffered close encounters with Neptune, which could dynamically strip the binaries, but definitely they cannot explain the different colors or size distributions.

An alternative possibility is that the hot population formed as explained earlier, but the cold population formed in situ, where it is now observed. Thus, the formation places being well separated, the corresponding physical properties could be different. However, this model has difficulties explaining how the cold population lost most of its primordial mass. It has been proposed that the objects ground down to dust in a collisional cascade process, but the latter is effective and consistent with the available observational constraints only if most of the mass was in subkilometer objects.

A further possibility is offered by a model of the evolution of the outer solar system, that has been developed in order to explain the origin of the so-called **Late Heavy Bombardment** (LHB; see "Solar System Dynamics: Regular and Chaotic Motions and Planetary Impacts") of the terrestrial planets. LHB is a cataclysmic period characterized by huge impact rates on all planets that occurred between 4.1 and 3.8 Bya, namely, about 400−700 My after planet formation. To explain the LHB, this model assumes that when the gas was removed from the solar system, the giant planets were on quasicircular and coplanar orbits, with orbital separations significantly smaller than the current ones. In particular, this model postulates that the planets were all in mean-motion resonance with one another, which is expected as a result of their previous evolution in the disk of gas. The model also assumes that the planets were surrounded by a remaining disk of planetesimals, containing 30−50 $M_\oplus$ out to $\sim$35 AU.

Due to the gravitational interactions with this disk of planetesimals, the planets were eventually (i.e. at the time of the LHB) extracted from their multiple resonance. As we said in Section 2, resonances have a strong stabilizing effect against close encounters. Once the planets were extracted from their mutual resonances, this stabilizing effect ended. The planets rapidly became unstable, because they were too close to each other. The planetary orbits became chaotic and started to approach each other. Both Uranus and Neptune were scattered outward, onto large eccentricity orbits ($e \sim 0.3$−0.4) that penetrated deeply into the planetesimal disk. This destabilized the full disk and triggered the LHB. The interactions with the planetesimals damped the planetary eccentricities, stabilizing the planetary system once again and forcing a residual short radial migration of the planets, which eventually reached final orbits when most of the disk was eliminated. Simulations show that this model is consistent with the current orbital architecture of the giant planets of the solar system and several other observational constraints.

In this model, objects can be implanted into the current Kuiper Belt during the large eccentricity phase of Neptune. In fact, the full Kuiper Belt is unstable at that time, so that it can be visited by objects that leave the original planetesimal disk when the latter is destabilized. When Neptune's eccentricity is damped, the Kuiper belt becomes stable so that the objects which, by chance, are in the Kuiper Belt region at that time, become trapped forever. Because the large eccentricity phase of Neptune is short, the inclinations of these objects remain predominantly small, consistent with the cold population of the current Kuiper Belt. The objects with the largest inclinations, conversely, are captured later, during the final bit of Neptune's migration, as explained before. As Figure 43.8 shows, this model reproduces the structure of the Kuiper Belt reasonably well. It is also consistent with its low mass because in the simulations the probability of capture in the Kuiper Belt is roughly of 1/1000 (which predicts a final mass of 0.03 $M_\oplus$). Moreover, the KBOs with final low inclinations and those with final large inclinations are found to come predominantly from different portions of the original planetesimal disk (respectively, outside and inside 29 AU), which can explain, at least at a qualitative level, the correlations with physical properties, with one exception.

Indeed, the main problem with this model is that the objects that end up in the cold population should have suffered a phase of close encounters with Neptune. It has been shown that such encounters would have disrupted the binaries with the widest observed separations.

Consequently, we can conclude that none of the models proposed to date are fully satisfactory. Reconstructing the primordial sculpting of the Kuiper belt is an active field of research.

We finally come to the issue of the origin of the extended scattered disk. Simulations show that, in the same process described earlier, bodies are also delivered to orbits with moderate semimajor axis and perihelion distance, like that of the extended scattered disk object 1995 TL_8 and its companions. The origin of Sedna is probably different. The key issue is that bodies with comparably large perihelion distances ($\sim$80 AU) but smaller semimajor axis ($a < 500$ AU) have never been discovered despite the more favorable observational conditions. Therefore, they probably do not exist. If this is true, and the population of extended scattered disk bodies with large perihelion distance starts only beyond several hundreds of astronomical units, then an "external" perturbation is required. The best candidate is a stellar passage at about 1000 AU from the Sun, lifting the perihelion distance of the distant members of the primordial, massive scattered disk. Such a stellar encounter is very unlikely in the framework of the current galactic environment

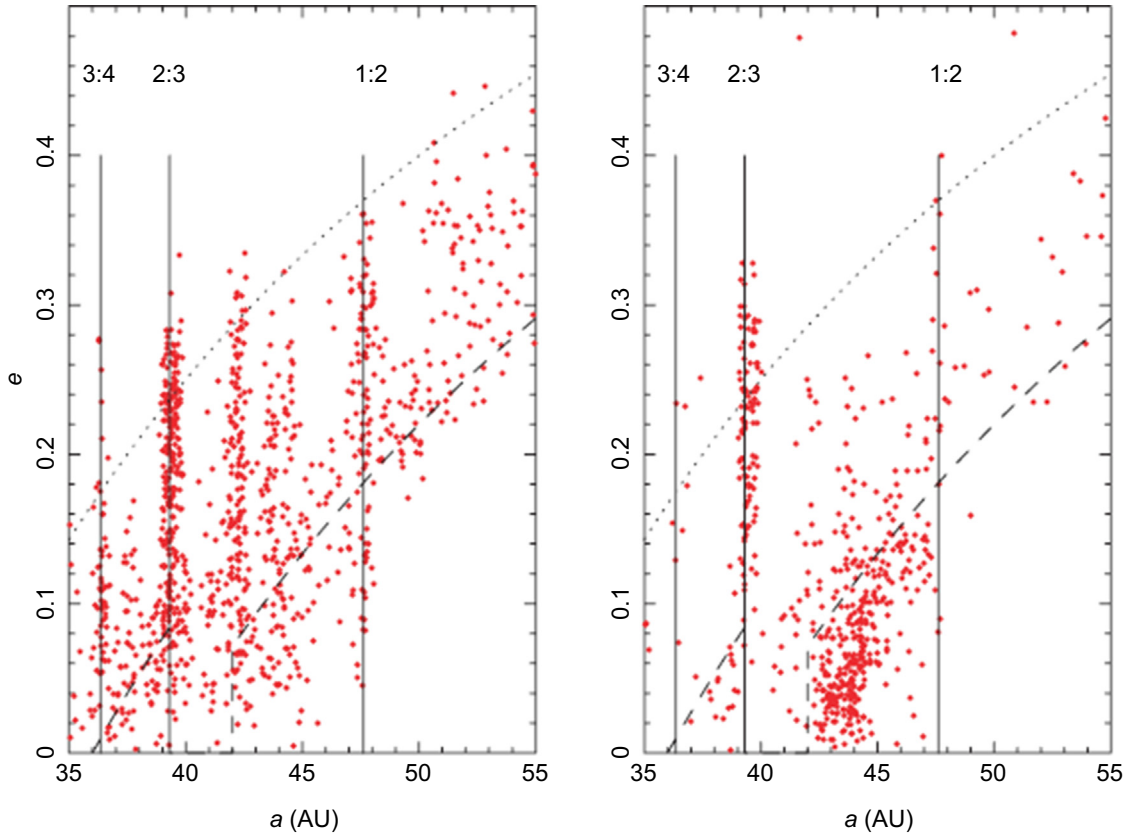

FIGURE 43.8 The distribution of semimajor axes and eccentricities in the Kuiper Belt. Left panel: result of a simulation based on the recent model on the origin of the LHB. Right panel: the observed distribution. The model reproduces fairly well the outer edge of the Kuiper Belt at the 1:2 resonance with Neptune, the characteristic shape of the (a, e) distribution of the classical belt, the scattered and the extended scattered disks, and the resonant populations. The vertical solid lines mark the main resonance with Neptune. The dotted curve denotes perihelion distance equal to 30 AU, and the dashed curve delimits the region above which only high-inclination objects or resonant objects can be stable over the age of the solar system. The overabundance of objects above this curve in the simulation is therefore an artificial consequence of the fact that the final orbits of the giant planets are not exactly the same as the real ones. *From Levison et al. (2008).*

of the Sun, but it would have been probable if the Sun formed in a moderately dense cluster, as mentioned earlier.

7. CONCLUDING REMARKS

At the time of the first edition of this book, 60 objects had been discovered in the Kuiper Belt. Now, we know 25 times more objects, and our view of the Kuiper Belt has become much more precise. It is now clear that the trans-Neptunian population has been sculpted in the primordial phases of the history of the solar system, by processes that are no longer at work.

It has been argued that the explanation of the most important observed properties of the trans-Neptunian population require a "cocktail" with three ingredients: (1) a truncated planetesimal disk; (2) a dense galactic environment, favoring stellar passages at about 1000 AU from the Sun; and (3) the outward migration of Neptune with, presumably, a phase of large eccentricity of the planetary orbits. Some problems still remain open, and the details of some mechanisms have still to be understood, but the basic composition of the cocktail is getting defined. This is a big step forward with respect to our understanding of solar system formation, before the discovery of the Kuiper Belt.

What is next? The upcoming generation of telescopic surveys will probably increase by another order of magnitude the number of discovered trans-Neptunian objects with good orbits. Thus, in the fourth edition of the book, we might have a different story to tell. It is unlikely that our view will totally change with the new discoveries (or at least we hope so!), but certainly there will be some surprises. We are anxious to know more precisely the absolute magnitude distributions of the various subpopulations of the Kuiper Belt, their color properties, the real nature of the outer edge and its exact location, and the orbital distribution of the extended scattered disk. This information will allow us to refine the scenarios outlined earlier, possibly to reject some and design new ones, in an attempt to read with less uncertainty the history of our solar system that is written out there.

Bibliography **955**

Our solar system began as a slowly spinning cloud of gas and dust about 4.5 billion years ago. As gravity caused the cloud to shrink in size, conservation of angular momentum required it to spin faster and evolve into a thin disk of gas, ice, and dust surrounding the young Sun. In the outer region of the disk, cold material accreted to first form boulder-sized objects, then mountain-sized objects, and then comet nucleus-sized (1−10 km) objects. Eventually, a small number of objects reached the size of planetary cores. Two cores eventually grew in size to become Uranus and Neptune. As Uranus and Neptune grew in size, their gravitational influence stopped the numerous remaining smaller objects from forming an additional large planet.

The first hint of a debris disk of icy material in the outer solar system came in 1930 with the discovery of Pluto by Clyde Tombaugh of Lowell Observatory in Flagstaff, Arizona. It soon became clear that Pluto was much smaller than any other planet in the solar system. Pluto's small size did not follow the pattern of planetary properties—four small, rocky terrestrial planets (Mercury, Venus, Earth, and Mars) close to the Sun followed by four giant, hydrogen-rich Jupiter-like planets (Jupiter, Saturn, Uranus, and Neptune) farther from the Sun. Why was Pluto not a giant like the other Jupiter-like planets? In 1978, J. W. Christy and R. S. Harrington added to the inventory of small bodies beyond Neptune by discovering Pluto's satellite, Charon (pronounced either "Kharon" or "Sharon"), on images taken at the US Naval Observatory's Flagstaff station. Figure 44.1 illustrates the small sizes of Pluto and Charon by comparing them to the dimensions of the United States.

Perhaps the most important clue to solving the mystery of Pluto's small size came in 1988, when Martin Duncan, Thomas Quinn, and Scott Tremaine presented an extensive series of numerical simulations of the evolution of comet orbits due to the gravitational perturbations of the giant planets. Their simulations provided a dynamical proof that a belt in the outer solar system is a far more likely source of Jupiter-family comets than the Oort cloud. The calculations set David Jewitt and Jane Luu of the University of Hawaii looking for the belt. In 1992, they discovered an object much smaller and fainter than Pluto and Charon orbiting beyond Neptune. At the present time,

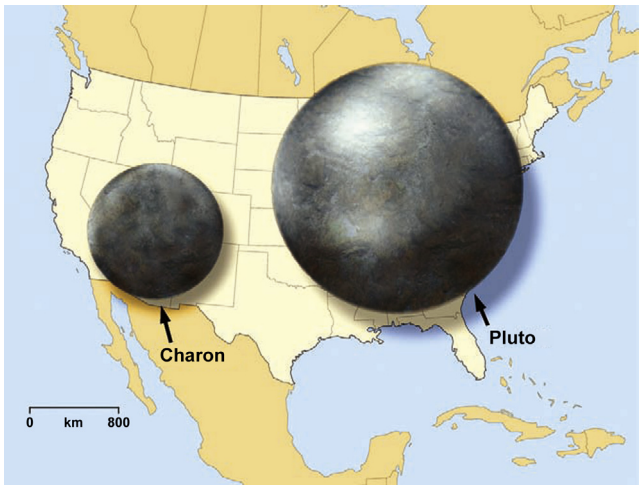

FIGURE 44.1 The diameter of Pluto (2302 km) and its moon Charon (1186 km) in comparison to the size of the United States. The diameters of both Pluto and Charon are smaller than that of Earth's Moon, 3476 km. *Courtesy of Dan Boone and NAU Bilby Research Center.*

~1000 objects ranging in size from a large comet nucleus to Pluto are known. It is now clear that Pluto, Charon, and the numerous smaller objects are what remain of the ancient disk of icy debris that did not accrete into a giant, Jupiter-like planet beyond the orbit of Neptune (Figure 44.2). The discovery of an object slightly larger than Pluto by Michael Brown of the California Institute of Technology in 2003 triggered the International Astronomical Union (IAU) to downgrade Pluto from its status as a planet in 2006. The icy debris disk beyond Neptune is commonly called the **Kuiper Belt** in honor of the Dutch–American astronomer Gerard P. Kuiper, who postulated its existence in 1951.

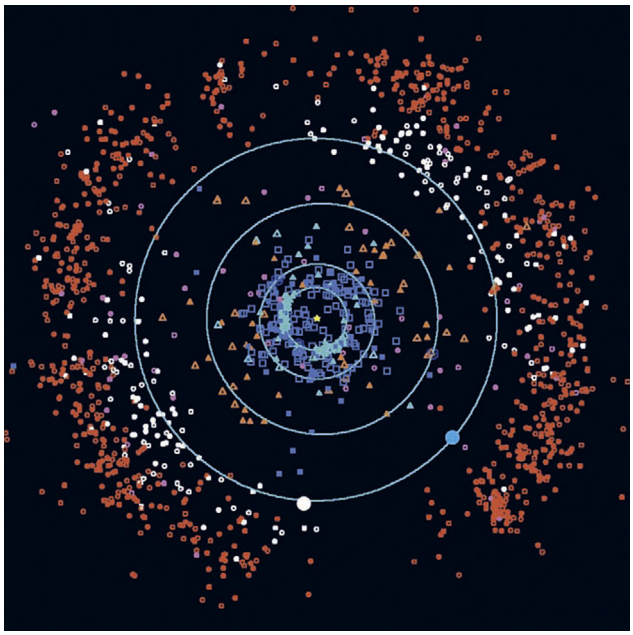

FIGURE 44.2 Positions of known bodies in the outer solar system on September 24, 2006. The orbits of the outer planets are shown in light blue. The location of Neptune is marked by a large blue circle on the outermost orbit. Pluto is marked by a large white circle. Kuiper Belt objects (KBOs) are marked as red (classical KBOs), white (Plutinos), and magenta (SDOs) circles. Centaur objects are marked as orange triangles. Comets are marked as blue squares. *Courtesy of Minor Planet Center.*

There are several dozen icy bodies that make up a class of objects closely related to Kuiper Belt objects (KBOs). These **Centaur objects** are recent escapees from the Kuiper Belt. They are on elliptical orbits about the Sun that cross the near-circular orbits of Saturn, Uranus, and Neptune. Within a few tens of millions of years after a Centaur object escapes from the Kuiper Belt, the giant planets scatter it out of the solar system, into the Sun or a planet, or cause it to migrate into the region of the terrestrial planets where it becomes a Jupiter-family comet. Centaurs are quite important because they come closer to the Sun and Earth than KBOs. By virtue of their "close" approach, many of them become bright enough for certain physical studies that are not possible on fainter KBOs. However, it is important to remember that Centaur objects experience a warmer environment than KBOs, and the warmth may alter their physical and chemical properties away from their initial properties at the time of their formation in the Kuiper Belt.

By studying KBOs and Centaurs, we are studying the preserved building blocks of a planet, and we can therefore shed some light on the process of planet building in our solar system as well as extrasolar planetary systems. After more than a decade of study, fundamental physical properties of KBOs and Centaurs—diameter, **albedo**, period of rotation, shape, mass, and surface composition—are being measured with accuracy.

1. DISCOVERING KUIPER BELT AND CENTAUR OBJECTS

Centaur objects and KBOs orbit the Sun every 30–330 years. In addition to their own intrinsic motion about the Sun, the Earth's motion about the Sun imparts an apparent (parallactic) motion on these objects as well. These two motions distinguish KBOs and Centaurs from the multitude of background stars and galaxies and thereby make it possible to discover them.

Figure 44.3 illustrates the motion of the Centaur 1994 TA against the "fixed" pattern of much more distant stars and galaxies. Each panel of Figure 44.3 is a 300-s exposure of 1994 TA taken with the Keck II 10-m telescope and a charge-coupled device (CCD) camera in October 1998. The image on the right was taken about an hour after the image on the left.

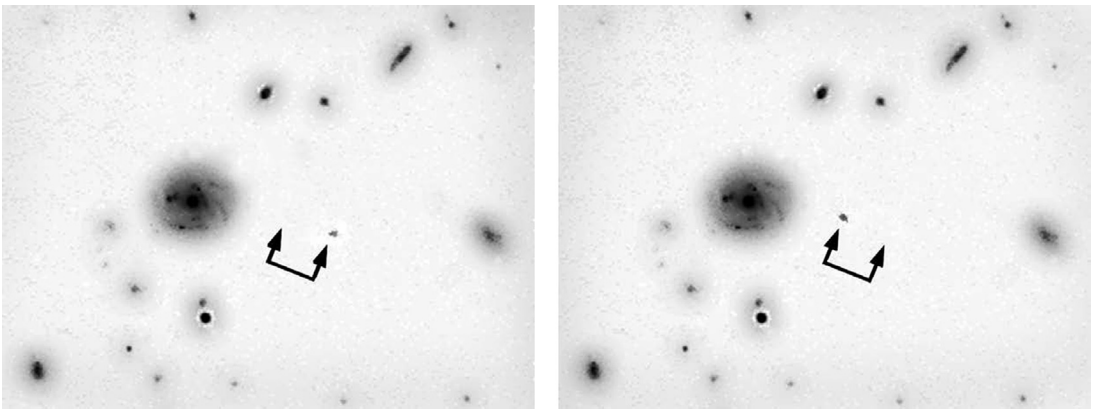

FIGURE 44.3 The motion of a solar system object relative to the background stars and galaxies. Two 300-s images of the Centaur 1994 TA taken with the Keck 10-m telescope and a CCD camera in October 1998. The image on the right was taken about an hour after the image on the left. Because of the Earth's and 1994 TA's revolution about the Sun, 1994 TA moves relative to the fixed pattern of background stars and galaxies. Such motion is how we discover KBOs and Centaur objects; however, the motion complicates physical studies of a known KBO or Centaur when the image of the KBO or Centaur comes close to an image of a background star or galaxy.

2. NAMING OBJECTS

After a Centaur object or KBO is discovered, it needs a name. The IAU is responsible for naming celestial objects. The IAU names KBOs and Centaurs the same way it names asteroids. Upon discovery, an object is given a preliminary designation consisting of a four-digit number indicating the year of discovery, a letter to indicate the half month of discovery, another letter to indicate the order of discovery within the half month, and another number to indicate the number of times the second letter was repeated within the half month period. For example, the provisional name of the KBO 2002 LM_{60} tells us the object was discovered between June 1 and 15 of 2002. After the orbit of a KBO about the Sun becomes well enough known that it is not likely to be lost, the KBO is given a number. It can take observations over several years to establish a good orbit for a KBO. The number of 2002 LM_{60} is 50,000. No other solar system object has the number 50,000. After an object receives a number, it receives a name. For example, 2002 LM_{60} is known as Quaoar. In this case, the same KBO has three names. After an object has a number and name, it is rarely called by its provisional name. If a KBO or Centaur object has a number or name, we know that its orbit about the Sun is well established and that there is very little chance of losing it.

3. DATABASES OF KNOWN OBJECTS

The IAU maintains an Internet listing of known KBOs and Centaurs as well as elements that describe their orbits about the Sun. In addition, the IAU, Lowell Observatory, and National Aeronautics and Space Administration's (NASA's) Jet Propulsion Laboratory in Pasadena, California, provide Internet tools that enable observers to figure out where to point telescopes to see a specific KBO or Centaur object on a specific night. Links to these tools are given in Table 44.1.

4. DYNAMICAL CLASSES

It is possible to divide KBOs into dynamical classes. This section provides a brief discussion of the classes and likely interconnections between the classes. A thorough discussion of KBO dynamics can be found in chapter 43 by Allesandro Morbidelli and Harold Levison in this book. (See Kuiper Belt: Dynamics.)

Classical KBOs are on orbits with perihelion distances, q, larger than 40 AU; semimajor axes, a, between 42 and 45 AU; eccentricities, e, less than 0.1; and inclination angles, i, less than 10°. It appears that classical KBOs did not experience strong perturbations by Neptune and hence they probably formed at or near their present location. Resonant KBOs are a subset of classical KBOs that became trapped in mean-motion resonances during the primordial migration of the planets. The process of resonance trapping tends

TABLE 44.1 KBO and Centaur Internet Tools

Institution	Web Addresses
Lowell Observatory	http://asteroid.lowell.edu/cgi-bin/asteph
NASA/JPL	http://ssd.jpl.nasa.gov/?tools
IAU	http://mpc.cfa.harvard.edu//mpc/summary

to increase the **eccentricity** and inclination of trapped objects. Plutinos are objects trapped in the 2:3 mean-motion resonance of Neptune at $a = 39.6$ AU, just like Pluto. Scattered disk objects (SDOs) are thought to have originated in the primordial inner belt, $a < 40$ AU, and the primordial Uranus–Neptune region. They were subsequently scattered by Neptune onto orbits with large inclination angles, $i > 15°$; large eccentricities, $e > 0.3$; and large semimajor axes, $a > 45$ AU.

Centaur objects are on outer planet crossing orbits with $q > 5.2$ AU and $a < 30.1$ AU. Relatively recent gravitational interactions between SDOs and Neptune, and to a lesser extent between classical KBOs and Neptune, result in Centaur objects. Because Centaur objects cross the orbits of the outer planets, they are dynamically unstable and have mean lifetimes of ~106 years. As mentioned above, some Centaurs evolve into Jupiter-family comets, others are ejected from the solar system, and yet others impact the giant planets. In addition, some Jupiter-family comets evolve back into Centaurs.

5. BRIGHTNESS

5.1. Apparent Magnitude

The first physical property measured for a KBO is typically its brightness. A KBO is brightest in visible light (4000–8000 Å) by virtue of the sunlight it reflects toward the Earth. It is possible to isolate the brightness of a KBO in a particular bandpass by placing a colored glass filter in front of a CCD camera at the focal plane of a telescope. For example, a blue, green, or red filter in front of a CCD camera makes it possible to measure the brightness of blue, green, or red light from a KBO, i.e. its B ($\lambda_{center} = 4500$ Å), V ($\lambda_{center} = 5500$ Å), or R ($\lambda_{center} = 6500$ Å) magnitudes. Table 44.2 lists V

TABLE 44.2 KBO Magnitudes, Albedos, and Diameters[1]

Name	Number	Prov Des	V[2]	H_v[3]	p_v[4]	D[5]

magnitudes of the brightest KBOs. At the other extreme of brightness, Gary Bernstein used the Hubble Space Telescope (HST) to discover and measure the brightness of the faintest known KBO, $V \sim 28$. The Centaur in Figure 44.3, 1994 TA, has $V = 24.31 \pm 0.05$. For comparison, the Sun has $V = -26.74$ and the faintest star visible in the sky with the unaided eye has $V \sim 6$.

5.2. Luminosity Function

There are many more faint KBOs than bright KBOs. Figure 44.4 comes from KBO discoveries made by a number of surveys, and shows the number of KBOs per unit magnitude per square degree on the sky near the **ecliptic** plane as a function of brightness (R-band magnitude), a luminosity function. Surveys find ~ 100 KBOs with $27 < R < 28$, ~ 2 KBOs with $23 < R < 24$, and only ~ 0.001 KBO with $19 < R < 20$, all per square degree of sky. For reference, the full Moon occupies almost one quarter of a square degree of sky and the Sun has $R = -27.10$.

5.3. Absolute Magnitude

The apparent magnitude of a KBO or Centaur depends on its heliocentric distance, r, and geocentric distance, Δ, in astronomical units. For example, a KBO receding from the Sun and Earth will become fainter and its apparent magnitude will become larger in value. The absolute magnitude, H, of a KBO is a way to compare the intrinsic brightness of one KBO with another KBO and it does not depend on distance. The absolute magnitude of the same KBO receding from the Sun and Earth will not change. The absolute magnitude of a KBO is the brightness it would have if it were located at a distance of 1 AU from the Sun and 1 AU from the Earth, and had a Sun−KBO−Earth (phase) angle, α, of 0°. The relation between absolute magnitude, H_v, and apparent magnitude, V, is given by

$$H_v = V - 5\log(r\Delta) + 2.5\log[(1-G)\Phi_1(\alpha) G\Phi_2(\alpha)],$$

where the last term of the equation is an empirical phase function that describes how H_v of an object varies with phase angle. $G = 0.15$ and Φ_1 and Φ_2 are given by

$$\Phi_i(\alpha) = \exp\left[-A_i\left(\tan\frac{1}{2}\alpha\right)^{B_i}\right]$$

where $i = 1$ and 2, $A_1 = 3.33$, $B_1 = 0.63$, $A_2 = 1.87$, and $B_2 = 1.22$ seem most appropriate for KBOs. H_v values for discovered KBOs and Centaurs range from about −1 to 15. Table 44.2 lists KBOs with the brightest H_v values.

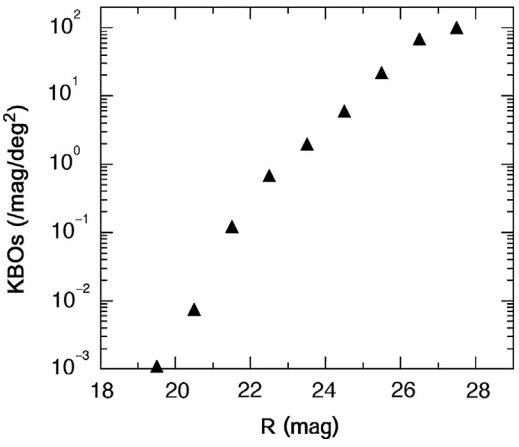

FIGURE 44.4 Number of KBOs per unit magnitude interval per square degree of sky vs R-band magnitude. There are many more faint KBOs than bright KBOs. This is typical of small body populations in the solar system that have been collisionally processed. *Courtesy of Gary Bernstein.*

6. DIAMETER

Size is among the most fundamental physical properties of an astronomical object, yet we are only beginning to get accurate diameter measurements for KBOs and Centaurs. The most direct way to measure the diameter of a KBO, D (in kilometer), is to measure its angular diameter, θ (in arcsec), and geocentric distance, Δ (in astronomical units). Geometry gives

$$D = 727\Delta\theta.$$

Unfortunately, KBOs and Centaurs have sufficiently small values for D and sufficiently large values for Δ that the resulting values for θ are too small for measurement even by the HST. Michael Brown pushed the HST to its limits and measured $\theta = 0.0343 \pm 0.0014$ arcsec for the KBO Eris, which was at a geocentric distance of 96.4 AU at the time of their observations. They found a diameter of 2400 ± 100 km for Eris, making it slightly larger than Pluto, $D = 2302$ km. For KBOs and Centaurs with θ too small for measurement, it is possible to estimate their diameters from their brightness,

$$p\Phi D^2 = 9x10^{16} r^2 \Delta^2 10^{0.4(m-V)},$$

where, as before, r and Δ are the heliocentric and geocentric distance, respectively, in astronomical units; m is the V-band brightness of the Sun (−26.74); V is the brightness of the KBO; p is the albedo of the object, and

$$\Phi = [(1-G)\Phi_1(\alpha) + G\Phi_2(\alpha)].$$

Since Jupiter-family comets come from Centaurs and the Kuiper Belt, most KBO diameter estimates assume an albedo similar to albedo measurements for a handful of Jupiter-family comets, i.e. $p = 0.04$. Diameter estimates from V magnitudes for about 100 objects range between $D = 25$ km for 2003 BH91 and $D = 2400$ km for Eris. KBO

and Centaur object diameters on the scale of Figure 44.1 range from the tiniest specks to Pluto.

The assumption of a cometlike albedo, although reasonable, is dangerous because Jupiter-family comets come much closer to the Sun than KBOs and Centaur objects. The frequent close proximity of short-period comets to the Sun results in the sublimation of H_2O ice and produces surfaces largely covered by a dark, refractory-rich, lag deposit. The surfaces of Jupiter-family comets may have chemical and physical properties quite different from those of the surfaces of Centaurs and KBOs. Charon has a relatively large albedo of 0.37. If we assume that a KBO has $p = 0.04$, but it actually has $p = 0.4$, we will estimate a diameter that is more than three times too large. Measurements of albedos are essential for accurate measurements of KBO and Centaur object diameters.

7. ALBEDO

By measuring the brightness of sunlight *reflected* from a KBO at visible wavelengths and the brightness of heat emitted by the same KBO at thermal infrared wavelengths, it is possible to disentangle albedo from diameter, and thereby measure separate values for both quantities. The Spitzer Space Telescope, an infrared telescope in orbit about the Sun, is enabling John Stansberry of the University of Arizona, Dale Cruikshank of NASA's Ames Research Center, William Grundy of Lowell Observatory, and John Spencer of Southwest Research Institute to observe much fainter levels of heat from KBOs and Centaurs than is possible with telescopes on the Earth. As a result of their work, we have accurate diameters and albedos for more than a dozen KBOs (Table 44.2).

8. BRIGHTNESS VARIATION

KBOs and Centaurs may have weak internal constitutions (i.e. rubble pile-type interiors) due to fracturing by past impacts between objects. In other words, it is possible that KBOs and Centaurs are nearly strengthless bodies, held together primarily by their own self-gravity. If so, then some objects may deform from spheres into triaxial ellipsoids with axes $a > b > c$ as a result of their rotation. The rotation of an ellipsoid can result in periodic variation of its projected area on the sky and hence a periodic variation of the sunlight it reflects and its brightness (Figure 44.5). Monitoring such a brightness variation can result in a wealth of physical data about the object (e.g. its period of rotation, shape, and perhaps even its density and porosity).

8.1. Period of Rotation

If we can determine the form of the periodic brightness variation (light curve) for a KBO or Centaur, its period of rotation can be determined. Figure 44.6 shows a plot of V magnitude vs time in hours for the Centaur Pholus. At the time of observation in 2003, Pholus was ~18 AU from the Sun, nearly the same distance as Uranus. We see that the two maxima are of nearly equal brightness, but one minimum (at ~5 h) is ~0.03 magnitude (3%) fainter than the other minimum (at 0 h). The pattern of two maxima and two minima repeats every 9.980 ± 0.002 h, Pholus' period of rotation on its axis.

Determining the period of rotation for a KBO or Centaur takes a significant amount of telescope time. In the

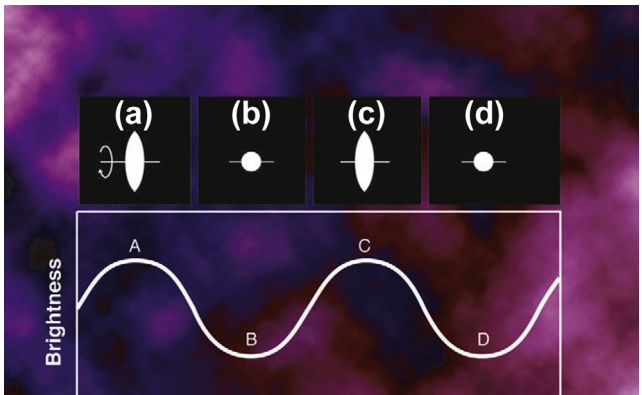

FIGURE 44.5 (a) The rotation of a nonspherical KBO or Centaur object results in a periodic variation of the object's projected area on the plane of the sky and hence a periodic variation in its brightness. (b) Brightness vs time (light curve) for the rotation of a nonspherical object. During one rotation of the object, it goes through two maxima (points A and C) and two minima (points B and D) in brightness. *Courtesy of Ron Redsteer and NAU Bilby Research Center.*

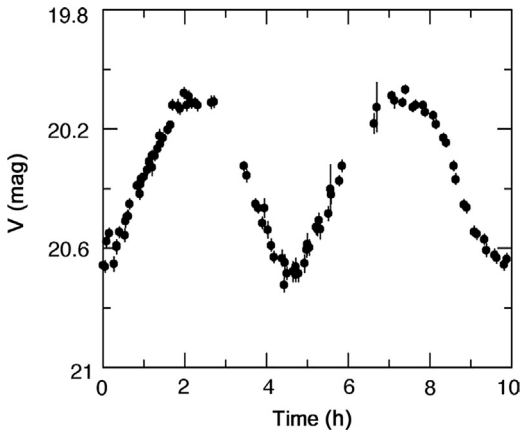

FIGURE 44.6 Light curve for the Centaur Pholus. The brightness pattern of two nearly equal brightness maxima and two brightness minima (at ~0 and ~5 h) that differ by 0.03 magnitude (3%) repeats every 9.980 h. The maximum peak-to-trough brightness variation of Pholus is 0.60 magnitude. From the light curve, we know that Pholus rotates once about its axis every 9.980 h.

case of Pholus, each of the 99 points in Figure 44.6 represents a brightness measurement from a 300-s CCD image. Because of their faintness, measurements of KBO and Centaur **light curves** require telescopes with moderately large apertures, typically with diameters $\geq$2 m. A large amount of time on moderate-sized telescopes is difficult to obtain, so periods of rotations are available for only a handful of objects (Table 44.3). Groups led by William Romanishin of the University of Oklahoma and Scott Sheppard of the University of Hawaii are responsible for many light curve measurements. They find periods of rotation between 4 and 14 h (Table 44.3).

8.2. Amplitude

In Figure 44.6, Pholus has a maximum brightness of $V_{max} = 20.09$ and a minimum brightness of $V_{min} = 20.69$, i.e. each time through its repeating pattern it has a maximum brightness variation or light curve amplitude of $\Delta m = V_{min} - V_m = 0.60$ magnitude. Since

$$\Delta m = 2.5 \log \frac{F_{max}}{F_{min}},$$

the ratio of maximum to minimum brightness is $F_{max}/F_{min} = 1.74$. From Table 44.3, we see that KBOs and Centaurs exhibit $0.1 \leq \Delta m \leq 1.1$ magnitude.

8.3. Shape

If a KBO or Centaur light curve is due to the rotation of a triaxial ellipsoid about its shortest axis, c, we can in principle determine its shape (i.e. the ratio of its axes a/b and c/b). How? As a KBO or Centaur orbits the Sun, we observe it at different aspect angles. Aspect angle is the angle between lines originating at the center of the body and toward the Earth and the north rotational pole of the body. Figure 44.7 illustrates how a change in aspect angle results in a change in light curve amplitude. At point A, we are looking at the object equator-on (aspect angle of 90°), and we see a light curve with an amplitude as large as it gets for the object. A quarter of a revolution about the Sun later, at point B, we are looking down the rotation axis of the body (aspect angle of 0°), and we will not see any brightness variation. If we observe the amplitude change of a body's light curve over a significant portion of the object's revolution about the Sun, it is possible to use a computer to search through all possible combinations of shape and orientation of the rotation axis to find a shape that best simulates the observed amplitude changes.

Figure 44.8 shows three light curves of Pholus from 1992, 2000, and 2003. The x-axis is labeled with the rotational phase of Pholus. The rotational phase interval of 0–1 is equal to a time interval of 9.980 h, the time it takes Pholus to complete one rotation about its axis. The amplitude of the light curves grew from 0.15 to 0.39 to 0.60

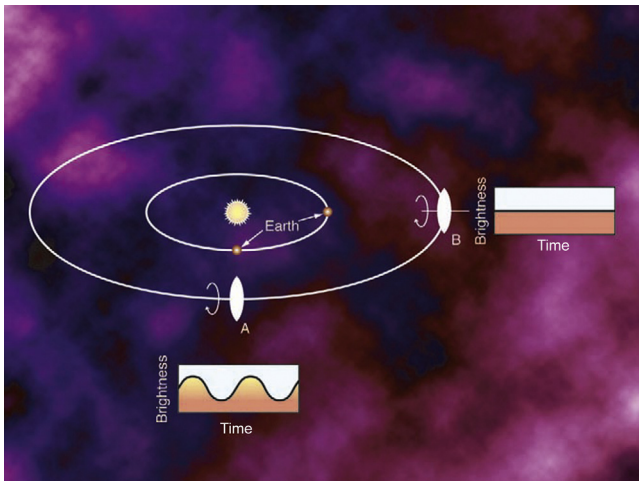

FIGURE 44.7 Changes in aspect angle result in changes in light curve amplitude. When the object is at point A, the angle between two lines originating at the center of the body and toward the Earth and the north rotational pole of the body, the aspect angle, is 90°. We see the object with an equator-on aspect and the light curve of the object has its maximum amplitude. When the body moves to point B, the aspect angle is 0° and we are looking down on the rotational pole. At point B, the object does not exhibit any brightness variation; its light curve amplitude is zero. By monitoring changes in the light curve amplitude of a body as it orbits the Sun, it is possible to calculate the shape of the body. *Courtesy of Ron Redsteer and NAU Bilby Research Center.*

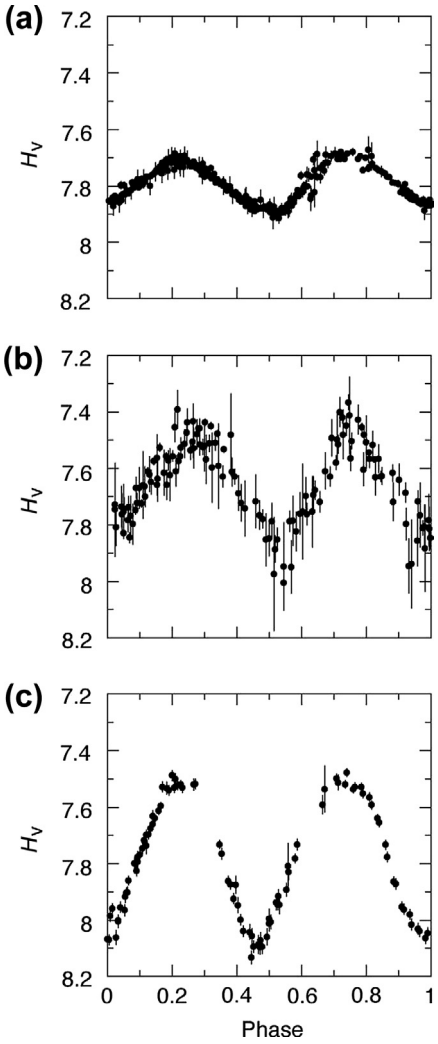

FIGURE 44.8 Evolution of Pholus light curve. (a) The light curve observed by Marc Buie and Bobby Bus in 1992 has an amplitude of 0.15 magnitude. (b) The light curve observed by Tony Farnham in 2000 has an amplitude of 0.39 magnitude. (c) The light curve observed by Bill Romanishin and Guy Consolmagno in 2003 has an amplitude of 0.60 magnitude. The period in 1992, 2000, and 2003 remained constant at 9.980 h; however, the increasing amplitude indicates that we were seeing Pholus more equator-on with each passing year between 1992 and 2003.

magnitude. A computer search of orientations of the rotation axis and shapes for Pholus yields four possible orientations for the rotational axis, all with the same shape of $a/b = 1.9$ and $c/b = 0.9$. Pholus appears to have a significantly elongated shape.

The amplitude measurements of Pholus span little more than 10% of its 92-year period of revolution about the Sun. Confirmation of the shape for Pholus will require additional amplitude measurements two or three decades into the future.

KBO shape measurements require amplitude measurements over more than a century. Yet, we can still say something about the shapes without waiting a century. For example, the KBO Varuna has $\Delta m = 0.42 \pm 0.02$ magnitude. If we assume we are seeing Varuna with an "equator-on" aspect (i.e. an aspect angle of 90°), which corresponds to the largest possible light curve amplitude, we can relate the amplitude of the light curve to an axial ratio,

$$\Delta m = 2.5 \log \frac{a}{b}.$$

Such an assumption gives $a/b = 1.5$ for Varuna. Since we do not know if they are viewing Varuna "equator-on", Δm and a/b are lower limits. At the present time, all KBO axial ratios are lower limits.

8.4. Density

Besides periods of rotation and shapes, light curves allow us to estimate densities for KBOs and Centaurs. If nonspherical shapes are the result of rotational deformation, then we can use the formalism developed by Chandrasekhar that relates the period of rotation and shape to the density of a strengthless ellipsoid. Application of Chandrasekhar's formalism to Pholus, the object with the best shape estimation ($a/b = 1.9$ and $c/b = 0.9$) and period of rotation ($P_{\rm rot} = 9.980$ h), gives an average density of $\rho_{avg} = 0.5$ g/cm^3. It is interesting to note that the similar-sized Saturnian satellites Janus, Epimetheus, Prometheus, and Pandora have average densities of 0.61, 0.64, 0.42, and 0.52 g/cm^3. In the case of KBO Varuna, its assumed shape ($a/b = 1.5$ and $c/b = 0.7$) and period of rotation ($P_{\rm rot} = 6.3442$ h) yield $p_{\rm avg} = 1.0$ g/cm^3. Average densities ≤ 1 g/cm^3 suggest that KBOs and Centaurs likely have ice-rich and porous interiors.

8.5. Porosity

Porosity is the fraction of void space in a KBO or Centaur. If a KBO is some mixture of ice, refractory material (dust), and empty space, the average density of a KBO is given by

$$\rho_{\rm avg} = f_{\rm i}\rho_{\rm i} + f_{\rm r}\rho_{\rm r},$$

where $f_{\rm i}$ and $f_{\rm r}$ are the fractional volumes occupied by icy and refractory material and $\rho_{\rm i}$ and $\rho_{\rm r}$ are the densities of icy and refractory material. In addition, the sum of the parts must equal the whole, so

$$f_{\rm i} + f_{\rm r} + f_{\rm v} = 1,$$

where $f_{\rm v}$ is the fraction of void space or the porosity. The fraction of total mass locked up in refractories, ψ, is given by

$$\psi = \frac{\rho_{\rm r} f_{\rm r}}{\rho_{\rm r} f_{\rm r} - \rho_{\rm i} f_{\rm i}}.$$

By combining the above three equations, it is possible to obtain an algebraic expression for the porosity of a KBO or Centaur,

$$f_v = 1 - \frac{\rho_{avg}}{\rho_i}\left[1 + \psi\left(\frac{\rho_i}{\rho_r} - 1\right)\right].$$

Assuming reasonable values of $\rho_{avg} = 1$ g/cm^3, $\rho_i = 1$ g/cm^3, $\rho_r = 2$ g/cm^3, and $\psi = 0.5$ for Varuna, Jewitt and Sheppard estimate that Varuna has a porosity $\sim$0.25. For comparison, beach sand has $f_v \sim 0.4$ and basaltic lunar regolith has $0.4 < f_v < 0.7$.

9. COMPOSITION

9.1. Surface Color

An early expectation was that all KBOs should exhibit a similar red surface color. Why? Initially, KBOs were thought to form over a small range of heliocentric distances where the temperature in the young solar nebula was the same. The similar temperature suggested that KBOs formed out of the solar nebula with the same mixture of molecular ices and the same ratio of dust to icy material. In addition, their similar formation distance from the Sun suggested that KBOs should experience a similar evolution. Specifically, the irradiation of surface CH_4 ice by solar ultraviolet light and solar wind particles should have converted some surface CH_4 ice into red, complex, organic molecules. By their nature, the complex organic molecules were expected to absorb more incident blue sunlight than red sunlight. Therefore, the light reflected from the surfaces of KBOs was expected to consist of a larger ratio of red to blue light than the incident sunlight. It was a surprise to find that KBOs exhibit a range of surface colors rather than just red colors. At one extreme, some KBOs reflect sunlight equally at all wavelengths (i.e. exhibit neutral or gray surface colors). On the Johnson−Kron−Cousins photometric system such KBOs have B-R = 1.0. At the other extreme, some KBOs have extraordinary red colors, i.e. B-R = 2.0.

Because it is a painstaking process to measure the color of a KBO or Centaur, taking as much as 3 h of telescope time to obtain an accurate color for a single object, the first color surveys consisted of only 10 to 20 objects. These small samples lumped KBOs and Centaurs together and resulted in a controversy. Some groups found their samples to exhibit a uniform distribution of colors from gray (B-R = 1.0) to extraordinarily red (B-R = 2.0). These groups suggested that KBOs and Centaurs experienced a steady reddening of their surfaces by solar radiation, and occasional impacts by smaller objects punctured the red surfaces and excavated gray, interior material. Such a radiation-reddening and impact-graying mechanism would explain the uniform distribution of colors. Another group found that their sample of KBOs and Centaurs divided into two distinct color groups—gray objects with $1.0 <$ B-R < 1.4 and red objects with $1.5 <$ B-R < 2.0. They found almost no objects with $1.4 <$ B-R < 1.5. They did not have a physical explanation for their surprising result. Everyone agreed that KBOs and Centaurs did not exhibit only red surface colors.

As the groups pressed hard at telescopes to measure more surface colors and test their initial findings, sample sizes grew from 10 to more than 100 objects. Once the sample sizes became large enough, it became apparent that different dynamical classes of KBOs had different color signatures.

9.1.1. Centaur Objects

Figure 44.9(a) shows a histogram of the number of objects vs B-R color for a sample of 22 Centaur objects. Fourteen objects have B-R < 1.3 and eight objects have B-R > 1.7. Notice that there are no objects with $1.3 <$ B-R < 1.7. Is it possible that Centaurs actually exhibit a uniform distribution of B-R colors and either insufficient sampling or chance is responsible for the apparent split into two B-R color groups? Application of statistical tests like the "dip test" tell us that the probability of making observations in Figure 44.9(a) for an actual uniform distribution of B-R colors is about 1 in 100. The split into two B-R color groups appears to be real. Unlike the earlier controversy, two groups, one led by Nuno Peixinho and the other by this author, find the same highly unusual split. What makes the split so unusual is that there does not seem to be any other physical property that correlates with the color of a Centaur object. For example, if Centaurs that came closest to the Sun were all gray, we might suspect that the warmth of the Sun was chemically or physically altering the surfaces and graying them. But there is no statistically significant correlation between color and **perihelion distance** or any other orbital element.

9.1.2. Classical KBOs

Figure 44.9(b) shows a histogram of the number of objects vs B-R color for a sample of 21 classical KBOs. All 21 classical objects have B-R > 1.5, i.e. there are no gray objects at all in the sample. Classical KBOs exhibit the color signature originally expected for all KBOs.

9.1.3. Scattered Disk Objects

Figure 44.9(c) shows a histogram of the number of objects vs B-R color for a sample of 20 SDOs. Seventeen of the 20 objects exhibit B-R < 1.5. There appears to be a deficit of red objects among this group.

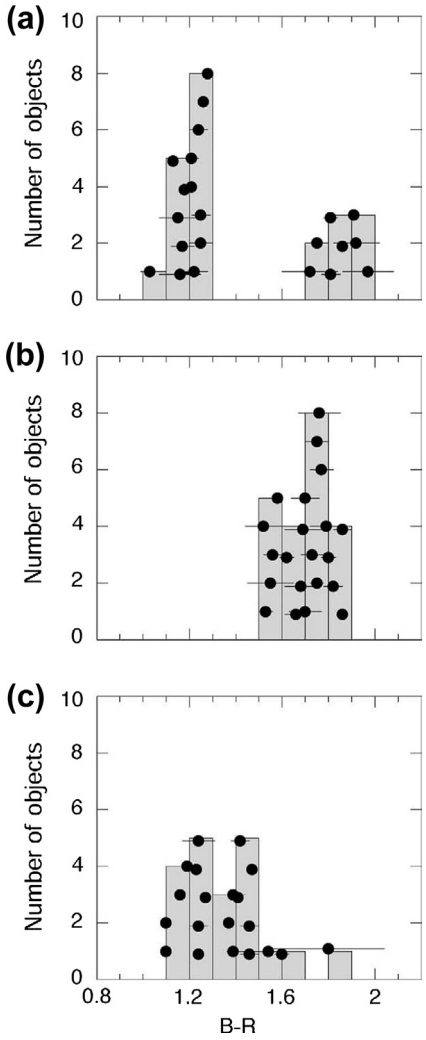

FIGURE 44.9 Correlations between colors and orbital properties of KBOs and Centaurs. (a) A sample of 22 Centaurs neatly divide into two color groups; 14 objects exhibit B-R < 1.3 and eight objects exhibit B-R > 1.7. Surprisingly, there are no Centaurs with $1.3 <$ B-R < 1.7. (b) All 21 objects of a sample of classical KBOs with $q > 40$ AU, $e < 0.1$, and $e < 10°$ are red (B-R > 1.5). (c) A sample of 20 SDOs are mostly gray (B-R < 1.5). The mechanisms responsible for these correlations between color and orbital properties are not well understood yet.

9.1.4. Reasons for Color Patterns

What could cause these color signatures? One possibility is the radiation-reddening and impact-graying mechanism discussed earlier in Section 1. However, such a mechanism should result in a uniform distribution of B-R colors for Centaurs and not two clusters of B-R colors. In addition, gray impact craters and their ejecta blankets would be randomly distributed on the surface so that one hemisphere might have more than another, resulting in measurable color changes as the object rotates. However, repeated and random measurements of individual rotating KBOs and Centaurs give the same B-R color. Also, extensive observations of Pholus suggest that it has a highly homogeneous surface color. Figures 44.10(a) and 44.10(b) show the R-band brightness and B-band brightness of Pholus as a function of a single rotation phase taking 9.980 h Figure 44.10(c) is the difference of panel a from panel b, yielding the B-R color across the entire surface of Pholus as it makes one rotation about its axis. The solid horizontal line is the average of the points. The dashed lines are ± 1 standard deviation, $\sigma = 0.04$. Any variation in the B-R surface color of Pholus must be smaller than 0.04 magnitude (4%). Again, there is no evidence of gray impact craters on a radiation-reddened surface.

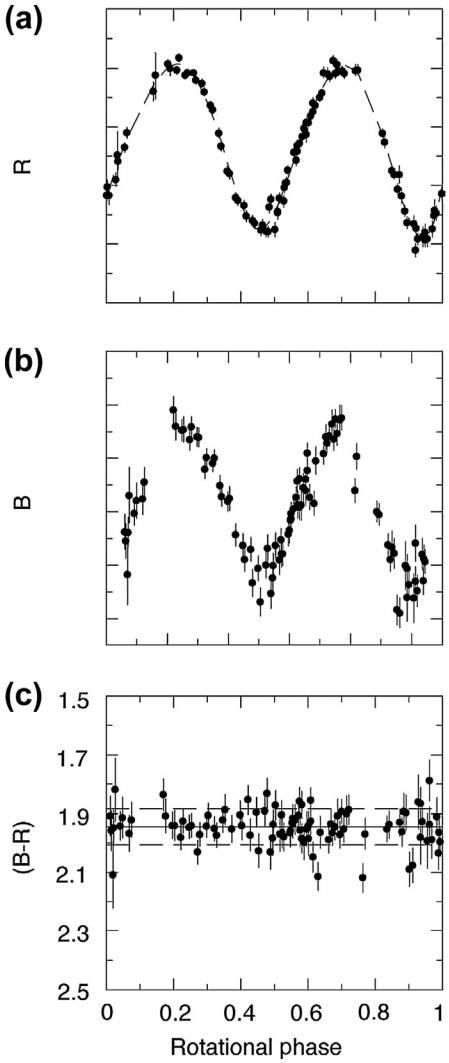

FIGURE 44.10 Homogeneous B-R surface color of Pholus. (a) R-band magnitude vs rotation phase. The x-axis spans a time interval of 9.980 h (b) B-band magnitude vs rotational phase. (c) Difference between the above two panels yields B-R color vs rotational phase. The solid line is the average of the 94 points. The dashed lines are plus or minus one standard deviation, σ, of 0.04 magnitude. Any variation in the surface color of Pholus as it completes one rotation on its axis must be less than 0.04 magnitude (4%). Pholus exhibits a homogeneous surface color.

Another possibility is that the colors of KBOs are the remaining signature of a temperature-induced, primordial composition gradient. The small, rocky terrestrial planets (Mercury, Venus, Earth, and Mars) close to the Sun and the giant, hydrogen-rich gas giant planets (Jupiter, Saturn, Uranus, and Neptune) farther away from the Sun are the result of such a gradient. In the inner solar system, temperatures were so high that only metal- and rock-forming elements could condense from the nebular gas to form small, rocky, and metal-rich solids. At and beyond the orbit of Jupiter, the hydrogen-dominated nebular gas was cold enough for the H_2O to condense out. We may be seeing a similar effect on the colors of KBOs and Centaurs. We now suspect that KBOs did not all form at about the same distance from the Sun. Perhaps the red classical KBOs formed farther out in the nebula where it was cold enough to hang on to their CH_4 ice reddening agent. Perhaps the gray KBOs formed closer to the Sun and were not able to hang on to their CH_4 ice reddening agent.

Additional work is necessary to figure out whether the radiation-reddening and collisional-graying mechanism, the temperature-gradient mechanism, or some other mechanism is responsible for the colors of KBOs and Centaurs.

9.2. Spectroscopy

There are only a handful of KBOs and Centaurs that are known to exhibit ice absorption bands in their spectra. H_2O-ice bands are seen in the spectra of Charon, 19308 (1996 TO_{66}), Varuna, Quaoar, Orcus, Pholus, and Chariklo. CH_4-ice bands are seen in the spectra of Pluto; Neptune's satellite Trition, which may be a captured KBO; Eris; and 136472 (2005 FY_9).

Perhaps one of the most intriguing spectroscopic results comes from David Jewitt and Jane Luu's observations of Quaoar. Specifically, they find not only the H_2O-ice bands at 1.5 and 2.0 μm, but also another H_2O band at 1.65 μm (Figure 44.11). The latter band suggests the surprising result that the H_2O ice has a crystalline rather than an amorphous structure. The H_2O molecules of crystalline ice have a periodic structure, whereas the H_2O molecules of amorphous ice do not. Crystalline H_2O on Quaoar is a surprise because Quaoar's maximum surface temperature is only $\sim$50 K. At such a low temperature, it is difficult for the H_2O molecules to arrange themselves into a coordinated structure of a crystal lattice; somewhere around 100 K, amorphous ice arranges itself into an ordered crystalline lattice. In other words, the 1.65-μm band suggests that the H_2O ice on Quaoar was somehow heated to temperatures above 100 K.

An intriguing possibility for the source of the "warm" H_2O on Quaoar is NH_3—H_2O volcanism. Long ago, long-lived radioactive elements heated the interior of Quaoar,

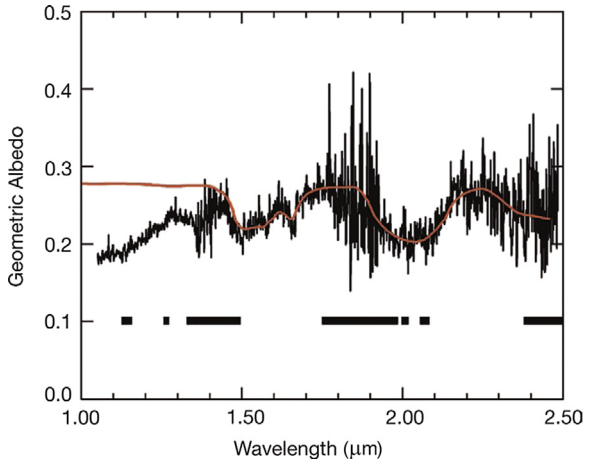

FIGURE 44.11 Near-infrared reflection spectrum of Quaoar (black) compared to a spectrum of H_2O ice (red). The broad absorption bands near 1.5 and 2.0 μm reveal the presence of H_2O ice on the surface of Quaoar. The narrow absorption band near 1.65 μm indicates the presence of crystalline H_2O ice and is not present in amorphous ice. *Courtesy of David Jewitt and Jane Luu.*

and that heat may still be propagating through its interior. The heat may have been sufficient to create a melt of H_2O and NH_3. The lower density melt may have percolated upward, perhaps forming fluid-filled cracks all the way or nearly all the way to the surface in the surrounding, higher density icy—rock mixture. Eventually, the cooling "lava" containing crystalline H_2O ice and crystalline ammonium hydrate might become exposed by occasional impacts on Quaoar's surface. What makes this mechanism even more intriguing is that Jewitt and Luu claim that there is evidence for an ammonia hydrate band in their spectra of Quaoar. Ammonia—water volcanism as the source of the crystalline H_2O ice is highly speculative. Some other mechanism, not requiring a warm interior and volcanoes, may explain the presence of the crystalline H_2O ice on Quaoar.

Figure 44.12 illustrates that Quaoar has a spectrum similar to Charon, but quite different from Pluto. Quaoar and Charon exhibit the 1.5- and 2.0-μm H_2O-ice bands as well as the 1.65-μm crystalline band, but none of the strong CH_4-ice bands seen on Pluto. Note that Quaoar has the 1.65-μm band despite having a larger semimajor axis, $a = 43.6$ AU, than Pluto, $a = 39.8$ AU.

Another intriguing spectroscopic result comes from Javier Licandro's observations of 136472 (2005 FY_9). He finds that CH_4-ice bands in the spectra of 136472 (2005 FY_9) are much deeper than the CH_4-ice bands in the spectra of Pluto, implying that the abundance of CH_4 on the surface of 136472 (2005 FY_9) could be higher than on the surface of Pluto. This author finds that the CH_4-ice bands in his spectrum and Javier Licandro's spectrum of 136472 (2005 FY_9) are blue shifted by

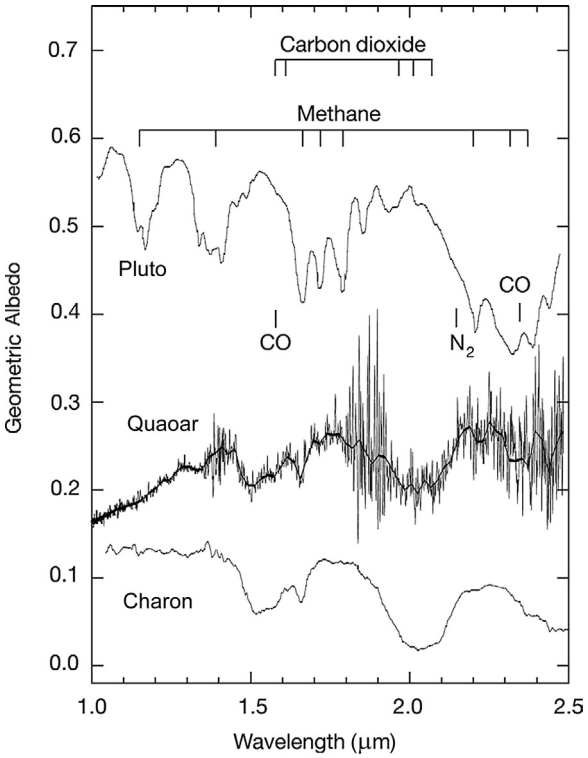

FIGURE 44.12 Near-infrared spectrum of Quaoar compared to near-infrared spectra of Pluto and Charon. The spectra of Quaoar and Charon are similar in that they exhibit three strong H_2O-ice absorption bands at 1.5, 1.65, and 2.0 μm, but no CH_4-ice bands. The spectrum of Pluto exhibits strong CH_4-ice bands. *Courtesy of David Jewitt and Jane Luu.*

3.25 Å relative to the positions of pure CH_4-ice bands (Figure 44.13). Such a shift suggests the presence of another ice component on the surface of 136472 (2005 FY_9), possibly N_2 ice, CO ice, or Ar. In addition,

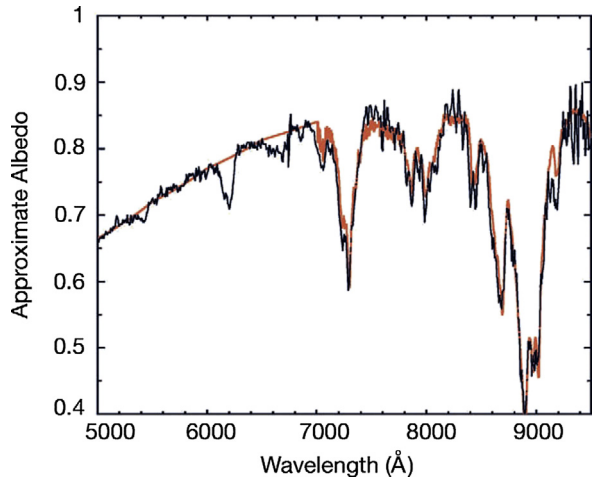

FIGURE 44.13 Optical spectrum of 136472 (2005 EY_9) (black line) and a Hapke model of pure CH_4 ice (red line). The CH_4 absorption bands of 136472 (2005 FY_9) are blue shifted by 3.25 ± 2.25 Å relative to the pure CH_4 model indicating the presence of another molecular ice, possibly N_2, CO, or Ar.

Licandro finds CH_4-ice bands blue shifted in a spectrum of Eris.

It is odd that some KBOs exhibit strong CH_4 bands and others exhibit strong H_2O bands. Pluto and Charon are part of the same system, yet they exhibit very different spectra. Perhaps the difference is due to Pluto's size, it may have experienced some form of methane ice volcanism. In the end, we may find that only the largest KBOs exhibit CH_4-ice bands. Eris, Pluto, and possibly 2005 FY_9 are the three largest KBOs and they all exhibit CH_4-ice bands.

10. KBO BINARIES

In 2001, Christian Veillet announced the discovery of two components to the KBO 1998 WW_{31}. Over the next few years, Keith Noll used the superior imaging resolution of HST to observe 122 KBOs for additional binaries. His survey was sensitive to binaries with separations $\geq$0.15 arcsec and a magnitude difference between components $\leq$1 magnitude. Noll discovered six more binaries. Currently, 22 KBO binaries are known (Table 44.4).

10.1. System Mass

Two KBOs of a binary pair revolve about their common center of mass. However, it is far more convenient to observe the position of the fainter of the two components as it makes a complete revolution about the brighter component on the plane of the sky, i.e. to observe the apparent relative orbit. Figure 44.14 illustrates the apparent relative orbit of 1998 WW_{31}. The true orbit of the KBO binary system will not happen to lie exactly in the plane of the sky. Hence, the apparent relative orbit is merely a projection of the true relative orbit onto the plane of the sky. Techniques exist to determine the inclination of the true orbit relative to the plane of the sky. Once the period of revolution, P, and the semimajor axis, a, of the true relative orbit are known, it is possible to use Kepler's Third Law to calculate the combined mass of the binary system,

$$m_1 + m_2 = \frac{4\pi^2 a^3}{GP^2}.$$

From the HST observations in Figure 44.14, Veillet and Noll found that 1998 WW_{31} has a true relative orbit with a semimajor axis of 22,300 km, an eccentricity of 0.8, and a period of revolution of the fainter component about the brighter component of 574 days. The 1998 WW_{31} system has a combined mass of 2.7×1018 kg, much smaller than the Pluto–Charon system combined mass of 1.46×1022 kg. Table 44.4 lists the true relative orbital properties and combined masses for the better studied binary systems.

10.2. Mutual Events

Between 1985 and 1990, Pluto's orbital motion about the Sun caused the Pluto–Charon orbital plane to sweep through the line of sight to the Earth. As a result, mutual eclipses (also known as mutual events) occurred every 3.2 days (half of Charon's orbital period). Because of the mutual events, observers were able to accurately measure diameters of 2302 ± 12 km and 1186 ± 26 km for Pluto and Charon, and with the total mass of the binary, they were able to derive an average density for the system of 1.95 ± 0.10 g/cm^3.

A key objective of current binary KBO work is to discover as many binaries as possible and to determine their orbits sufficiently well to predict when the onset of mutual events will occur. By observing KBO mutual events, we will obtain radii and density measurements that only a spacecraft encounter could improve upon. At present, no

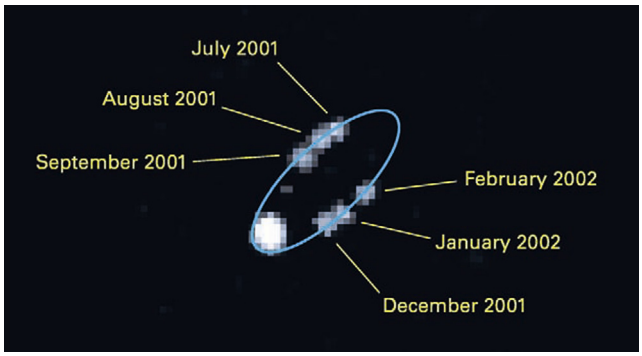

FIGURE 44.14 Binary KBO. The apparent orbit of the fainter component of 1998 WW_{31} relative to the brighter component on the plane of the sky. *Courtesy of Christian Veillet, Keith Noll, and NASA.*

KBO binary orbit (other than Pluto and Charon) is known well enough to predict the onset of a mutual event with confidence.

10.3. Origin of KBO Binaries

Two of the most unusual features of KBO binaries, compared to main belt asteroid and near-Earth asteroid binaries, are the wide separation and similar diameter of each pair of components. These unusual features make it unlikely that collisions between two KBOs created each binary system, as in the case of the Earth and the Moon. Similarly, it is not likely that one KBO gravitationally captured another KBO to form a binary system. A mechanism put forth by Stuart Weidenschilling suggests that it is possible to create a loosely bound KBO binary by collision and capture in the presence of a third body. His mechanism requires many more KBOs than are seen today; perhaps such a mechanism operated long ago in a more densely populated Kuiper Belt (see the next section). Peter Goldreich put forth a mechanism wherein capture takes place during a close encounter as a result of the dynamical friction with the many surrounding small bodies. Each of these mechanisms produces its signature on the population of binaries we see today. For example, Weidenschilling's mechanism favors the production of wide binary pairs, and Goldreich's mechanism favors the production of closer pairs. Only the discovery of many more binaries will allow us to determine whether either of these mechanisms or some other mechanism is responsible for the formation of KBO binaries.

11. MASS OF THE KUIPER BELT

What is the mass of the entire Kuiper Belt? Gary Bernstein combined his HST survey for the faintest KBOs with ground-based telescope surveys for brighter KBOs, and assumed that KBOs have an albedo of 0.04 and a density of 1 g/cm^3, to estimate a Kuiper Belt mass of $\sim$3% of the Earth's mass, or about 14 times the mass of Pluto. A major source of uncertainty in his mass estimate is the uncertainty in the albedos and densities of KBOs.

It appears that the Kuiper Belt did not always have a mass of $\sim$3% of the Earth's mass. Specifically, the present number of KBOs per AU^3 is too small to grow KBOs larger than $\sim$100 km in diameter by accretion in less time than the age of the solar system. Since 1000-km sized KBOs exist, it is likely that the Kuiper Belt initially had many more KBOs per AU^3 than today. Calculations by Alan Stern suggest that the initial Kuiper Belt probably had a mass 10 times the mass of the Earth, and as Neptune grew to a fraction of its present size, it stirred KBOs from their initial circular orbits to more eccentric orbits, resulting in frequent disruptive, rather than accretive collisions especially between KBOs smaller than 40–60 km in diameter. These collisions probably eroded the Kuiper belt mass down to its current value.

12. NEW HORIZONS

Because astronomers can discover and then measure the physical properties of many KBOs, their work is important as it gives us a global view of the Kuiper Belt and context for in situ spacecraft measurements. In January 2006, NASA's New Horizons spacecraft departed the Earth on a journey that will culminate in the first flyby of the Pluto–Charon system in 2015, and hopefully the first flyby of a KBO sometime before 2020. The $500 million spacecraft weighs only 416 kg (917 lb) and has four instrument packages: (1) a CCD camera; (2) an ultraviolet, optical, and near-infrared imaging spectrometer; (3) a charged particle detector; and (4) a radio telescope.

These instrument packages will provide in-depth observations impossible with telescopes on and near the Earth. For example, if New Horizons comes within a few thousand kilometers to a KBO, it could image the surface of the KBO with a resolution of 25 m/pixel. For comparison, HST can only image a KBO at 42 AU with a resolution of about 1200 km/pixel.

What kind of surface might the spacecraft image? If New Horizons visits a small KBO, perhaps it will image a surface with numerous craters, suggestive of an ancient surface bombarded by other small bodies (KBOs and comets) over the age of the solar system? On the other hand, if New Horizons visits a large KBO, perhaps it will see few craters on the surface, suggestive of some process erasing older craters. Perhaps the images of a large KBO will show long linear features in an icy crust, and some roughly round basins that appear flooded by liquids from the interior, much like the Voyager spacecraft images of Triton. Perhaps the spacecraft will catch a geyser erupting, and shooting a plume of gas and ice above the surface.

There are some problems concerning New Horizon's flyby of a KBO. The spacecraft trajectory is fixed since first it will fly by Pluto. In addition, the spacecraft has a limited fuel supply for adjusting its trajectory after the Pluto encounter. At present, none of the almost 1000 currently known KBOs are close to the spacecraft's trajectory. A flyby of a KBO by New Horizons depends on discovering a candidate close to the spacecraft's trajectory. Perhaps New Horizons will have enough fuel to visit one of the smaller (50 km diameter) and more common KBOs. The chances for the spacecraft visiting one of the larger (1000 km diameter) and rarer KBOs appear slim at the moment.

13. FUTURE WORK

It is likely that future work on the physical properties of KBOs and Centaurs will be driven by future state-of-the-art observatories. The 6-m James Webb Space Telescope near the L2 point will be able to obtain images and spectra of very large numbers of KBOs and Centaurs from 0.6 to 27 μm. It should be possible to measure diameters, albedos, surface colors, and optical and infrared spectra for many more objects than possible today. A large increase in the number of objects with physical property measurements will make it possible to look for statistically significant correlations between many more physical properties than possible with today's telescopes, and thereby better constrain the important formation and evolution mechanisms in the outer solar system.

Large ground-based telescopes of the future will likely play a big role in the field too. For example, the Giant Magellan Telescope, a configuration of six off-axis 8.4-m mirror segments around a central on-axis segment that is equivalent to a filled aperture 21.4 m in diameter, and the Thirty Meter Telescope, a configuration of more than 700 hexagonal-shaped mirror segments that is equivalent to a filled aperture 30 m in diameter, will make it possible to obtain higher signal precision optical and infrared spectra than possible with current 10-m telescopes. Better spectra and models will make it possible to map surface concentration of ices (e.g. the CH_4/N_2 concentration) as a function of depth and as a function of rotational phase over the surfaces of numerous objects. Such measurements will provide a wealth of data for constraining cosmochemistry models of the outer solar system. Finally, the Atacama Large Millimeter Array (ALMA), a configuration of about sixty-four 12-m antennas located at an elevation of 16,400 ft in Chile, may reveal extrasolar Kuiper Belts for comparison with our Kuiper Belt. ALMA may provide density and temperature profiles as well as chemical measurements through the detection of spectral lines in the belts. ALMA may initiate a new field of study, comparative Edgeworth−Kuiper Belt object ology, i.e. comparative EKO-logy.

Bibliography **977**

1. INTRODUCTION

Extrasolar planets—planets outside the solar system—were a mystery for astronomers for a long time. Are planets also orbiting stars other than the Sun? Is our solar system unique, or is planet formation a natural by-product of star formation and is our galaxy thus teeming with planets? The answers to these questions eluded astronomers for many centuries. It was only over the past two decades that we finally obtained unambiguous evidence for the existence of extrasolar planets. The reason why it took so long to find these objects is the fact that planets are dark objects very close to an extremely bright source, their host star. In visual light, a planet is more than a billion times fainter than a star. But the main problem is not the planet's faintness—today's best telescopes and instruments are sensitive enough to detect them in isolation—but that the light of the close-by star overwhelms the feeble light coming from the companion. Planets are also smaller and much less massive than stars. Astronomers usually rely on indirect methods to discover and characterize extrasolar planets, but a few planets have also been directly detected over the past few years.

The history of research into extrasolar planets consists of three major stages or eras: the first era belongs to the so-called **radial velocity technique**, where tiny variations in the line-of-sight velocity of a star are used to infer the presence of unseen companions. Over the past 15 years, radial velocity surveys have detected hundreds of planetary companions to stars in our galaxy. The majority of these objects are presumably gas giant planets, but some are also planets with lower masses. The structures of most known extrasolar planetary systems are very different from those in our solar system, with giant planets often very close to the star and with a wide range of orbital eccentricities. The second era in extrasolar planet research belongs to planets discovered by the **transit photometry technique**. With this technique, astronomers find the planet when it crosses in front of the star and blocks part of its luminous surface, making the star appear slightly dimmer while the planet moves across. This is the extrasolar equivalent of a Mercury or Venus transit with the obvious difference that the stellar surface is unresolved. To detect a transit of an extrasolar planet, one thus needs very precise measurements of the luminosity of a given star over time. These data can be used to estimate the radius of the transiting planet. In combination with an estimate for the mass, which can often be obtained using radial velocity data, we can derive a mean bulk density. It is precisely this capability, to place planets on a mass–radius diagram, that makes the transit technique so powerful. By doing this, we can compare the measured radii, masses, and densities of planets to models for their

Encyclopedia of the Solar System. http://dx.doi.org/10.1016/B978-0-12-415845-0.00045-1

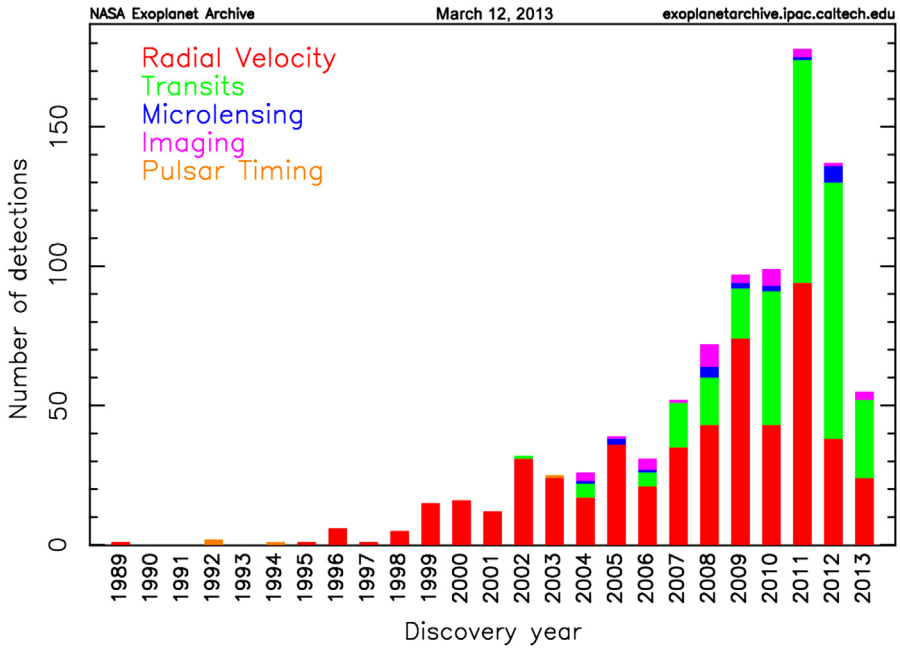

FIGURE 45.1 Detection statistics of the nearly 1000 known exoplanets. The different colored bars show the numbers of planets discovered with the respective astronomical techniques. *Image courtesy of NASA Exoplanet Archive: http://exoplanetarchive.ipac.caltech.edu/.*

internal composition. We can therefore distinguish between gas giant planets, icy giants that contain significant amounts of volatiles, and terrestrial, rocky planets. We can also probe the atmospheres of these planets and measure their temperatures. All this additional information, that we can obtain only for transiting planets, makes this technique so important for our understanding of planetary bodies.

We are currently in the third era of extrasolar planet research, an era that began with the launch of National Aeronautics and Space Administration's **(NASA's) Kepler mission** *in March 2009*. The *Kepler* spacecraft is also using the transit technique but its unprecedented measurement precision, by avoiding Earth's atmosphere, combined with the nearly continuous monitoring of approximately 160,000 stars has revealed a vast population of small planets that have not been seen before. The primary science goal of *Kepler* is to derive the first estimate of the frequency of Earth-size planets in the habitable zone of Sun-like stars. This parameters is called η_{Earth}. The nominal mission duration was 3.5 years and in 2012, the mission was extended for four more years. Unfortunately, in April 2013, a mechanical malfunction ended the extended mission early. Up to this point, *Kepler* collected 4 years of very high-quality photometric transit data and the detailed analysis of all these data will take many years. But this means that we are close to a truly historical moment, not only in astronomy, but in all sciences: we will know in a few years if planets similar to the Earth are common or rare in our galaxy. This measurement of η_{Earth} will have obvious astrobiological implications for how common biospheres on planetary surfaces are, and therefore how likely it is that complex life-forms similar to us have emerged somewhere else in the universe.

So far, the combined efforts of the diverse astronomical methods to detect extrasolar planets have found about 1000 confirmed planets around other stars (Figure 45.1), and *Kepler* alone has produced nearly 4000 candidates for extrasolar planets. All these results have revealed not only a stunning diversity of planetary systems but also a completely new type of planet, the so-called "**super-Earths**". Super-Earths have masses ranging from 1 to 10 Earth masses and radii between 1 and 3−4 Earth radii. Such a planet does not exist in the solar system, but they appear to be quite common around other stars.

The next years will be extremely interesting in the field of extrasolar planets. We move steadily from mere detection to a more detailed characterization of extrasolar planets. But even in detection there are still large unexplored white areas in our galactic map of planetary systems. We will explore these areas and fill in the necessary information to obtain a galactic overview of planetary systems that will allow us to put our own solar system firmly into a cosmic context.

2. DETECTION TECHNIQUES

2.1. Astrometry

Astrometry is the science of positional astronomy, which measures the location of a celestial object and its movement

within the plane of the sky. This was one of the first techniques used to search for planets around other stars. As in other indirect methods, astronomers seek to detect the orbit of the central star around the **barycenter** of the star/planet system. The orbit is measured as the change of the position of the star on the plane of the sky, usually compared to a number of more distant background stars, which define an astrometric reference frame.

The amplitude S of an astrometric signal is given by

$$S = \frac{m}{M}\frac{r}{d}$$

where m is the mass of the unseen companion, M is the mass of the central star, r is the semimajor axis of the companion's orbit, and d is the distance to the star. For r in astronomical units and d in parsec (pc), S is given in seconds of arc (1 arcsec is 1/60 of an arcmin, which itself is 1/60 of a degree). For the Sun/Jupiter system with $m/M = 0.001$ and $r = 5.2$ AU, the amplitude of the signal would be 0.001 arcsec (1 mas) seen from a distance of 5 pc and 0.5 mas from 10 pc (1 pc = 3.26 light years).

From the preceding equation, it is obvious that astrometry is most sensitive to companions with large mass ratios (massive planets around less massive stars) at large orbital separations r and nearby stars (d is small). Because of the r-dependence, this technique is a complementary method to the radial velocity technique (which will be discussed next).

As is the case for most of the detection methods, the largest hurdle to overcome in detecting extrasolar planets by astrometry is the need for very precise measurements and the extreme care required to avoid systematic errors, such as instrumental effects. This is necessary to prevent the introduction of spurious signals, which may be misinterpreted as real planets over a long time baseline. The astrometric signals for most extrasolar planets are typically less than 1 mas and are beyond the scope of most current state-of-the-art instruments. The European Space Agency's (ESA's) satellite *Hipparcos* was a space mission entirely dedicated to stellar astrometry. Although its precision was not sufficient to detect planetary companions, the *Hipparcos* data placed very useful upper limits on the masses of some companions detected by other methods.

The highest astrometric precision can be achieved by using interferometry. By letting the light that arrives from the same source at two different locations (two or more telescopes positioned on a well-defined baseline) interfere, one can measure the small difference in the arrival time at these points and thus determine the angle between the source and the baseline very precisely. The Fine Guidance Sensors onboard the *Hubble Space Telescope* (*HST*) can actually be used as an interferometer and they yield currently the best astrometric precision.

The ESA's *Global Astrometric Interferometer for Astrophysics* (*GAIA*)* mission is designed to achieve an astrometric precision of a few microarcseconds. Over its mission lifetime of 5 years, *GAIA* is planned to observe nearly a billion stars and will detect a large number of extrasolar planetary systems with the astrometric technique.

2.2. The Radial Velocity Method

Astronomers, using the radial velocity technique, measure the line-of-sight component of the space velocity vector of a star (hence the term "radial", i.e. the velocity component along the radius between observer and target). The radial velocity of a star can be determined in absolute values, or differentially if only changes of the velocity are of interest.

In order to measure stellar radial velocities, we rely on the well-known Doppler effect. Depending on whether the star moves toward us or away from us, its light will be blue- or redshifted, as compared to a nonmoving source. Such a shift reveals itself as a change in the wavelength position of the absorption lines in the spectrum of the star. Therefore, astronomers use high-resolution spectrometers to perform radial velocity studies. The incoming light of the star is split up into its individual wavelengths, and the spectrum is recorded on a detector. As in astrometry, this method tries to detect the reflex motion of the primary object around the common center of mass with an unseen companion. However, this time this motion reveals itself as a change in the velocity rather than a change in position of the star.

The radial velocity method is traditionally used in stellar astronomy for the discovery and characterization of binary stars. In a binary system, the barycenter of the system is located somewhere between the two stars (the exact location is defined by the mass ratio), and the observed velocity amplitudes are of the order of several kilometers per second. The same method is applied to the search for extrasolar planets, which induce a much smaller reflex orbit on their host star and produce much smaller velocity amplitudes.

For a system of two gravitationally bound objects m_1 and m_2 in a circular orbit, the radial velocity semiamplitude K_1 of m_1 can be calculated by using:

$$K_1 = \frac{(m_2 \sin i)}{(m_1 + m_2)}\sqrt{G\frac{(m_1 + m_2)}{a}}$$

where m_1 is the more massive object and m_2 is the less massive secondary companion, i denotes the angle between

* *GAIA* originally stood for Global Astrometric Interferometer for Astrophysics. As the project evolved, the single interferometer concept was replaced by a new payload design. The mission name remained, however, even though it no longer reflects the methods used to perform the science operations.

the orbital plane and the plane of the sky, G is the gravitational constant, and a is the semimajor axis of the orbit. It is immediately clear that for face-on systems ($\sin i = 0$), K_1 is zero.

Using Kepler's famous third law, which relates orbital separation to orbital period P, we can recast this:

$$K_1 = \left(\frac{2\pi G}{P}\right)^{1/3} \frac{(m_2 \sin i)}{(m_1 + m_2)^{2/3}}$$

We are interested in the case of a planet orbiting the star, where $m_2 \ll m_1$ (and thus $m_1 + m_2 \approx m_1$), which simplifies the equation to

$$K_1 = \left(\frac{2\pi G}{P}\right)^{1/3} \frac{(M_2 \sin i)}{m_1^{2/3}}$$

Now we have an expression that relates $m_2 \sin i$ to the observables K_1 (or simply K if only the spectrum of m_1 is detectable) and P. Using units of years for P, m/s for K, and solar mass for m_1, $m_2 \sin i$ is given in Jupiter masses by the following expression:

$$m_2 \sin i = K \frac{\left(P m_1^2\right)^{1/3}}{28.4}$$

With a good estimate for m_1, we thus calculate $m_2 \sin i$ of an unseen companion. The $m_2 \sin i$ value represents a lower limit to the true mass of m_2. The $\sin i$ ambiguity is one of the limitations of the radial velocity technique. However, the $m_2 \sin i$ value is probably close to the real value of m_2. Just by assuming a random distribution of orbital planes, we have a 90% statistical probability that m_2 is within a factor of 2.3 of the observed $m_2 \sin i$.

Jupiter induces a K of 12.5 m/s in the Sun when observed in the plane of its orbit ($\sin i = 1$) and Saturn gives a K of only 2.8 m/s. Detection of planets analogous to the two gas giants in our solar system thus calls for measurement uncertainties of a few meters per second or better over many years to decades. More massive planets and also planets at smaller orbital separations produce larger K amplitudes, but the desired velocity precision is still of the order of several meters per second. It is also desirable and often necessary to obtain a sufficiently large number of observations over time to study the noise characteristics of the data in detail.

Obtaining a radial velocity precision of a few meters per second or better is a complex task that requires highly precise and sensitive data reduction techniques and instruments. Over the past years (even decades), two approaches have been successfully used to attain such a high level of precision: (1) the gas absorption cell method and (2) the simultaneous Thorium–Argon (Th–Ar) method in combination with stabilized spectrometers. In the first method, the star light is passed through a small glass cell that is filled with a suitable gas (in most cases iodine vapor), which superimposes its own dense absorption spectrum onto the stellar spectrum. This reference spectrum not only yields a simultaneous wavelength calibration but also can be used to keep track of the imaging properties of the spectrograph. This allows preventing small changes in the image of the stellar absorption lines, which are caused by fluctuations in the light path from the telescope to the detector, from being misinterpreted as Doppler shifts. In the second approach, the emission spectrum of a Th–Ar lamp is imaged parallel to the stellar lines on the charge-coupled device (CCD) frame. Again, this allows a simultaneous wavelength calibration. In recent years, the standard Th–Ar comparison spectrum is sometimes replaced by a more stable reference spectrum generated by a laser, a so-called "laser comb". This method only works in combination with highly stabilized spectrometers. To minimize any instrumental effects, these spectrographs have no movable parts and are placed in pressure- and temperature-stabilized environments. To assure the highest level of precision, some instruments are enclosed in a vacuum tank. This eliminates variations in the light path due to changing refractive index values of air caused by pressure changes. Also, by using optical fibers, the light path from the telescope to the instrument is kept as constant as possible. Both approaches have been demonstrated to reach a radial velocity precision of a few meters per second, and in the best cases even 1–0.5 m/s.

2.3. Transit Photometry

In the special case that the orbital plane of an extrasolar planet is close to perpendicular to the plane of the sky, the planet will appear to move across the disk of the host star. In our own solar system, this phenomenon can be observed from the Earth for the two inner planets, Mercury and Venus. Because we cannot spatially resolve the disk of another star, a transiting extrasolar planet can only be observed as a reduction of the light output coming from the star (i.e. by means of precise photometric measurements).

Assuming random orientations of planetary orbits, the probability P_{trans} of the visibility of a transit event is a function of both the radius of the star and the planet and its orbital separation a:

$$P_{\text{trans}} = \frac{\left(R_{\text{star}} + R_{\text{planet}}\right)}{a}$$

For a random location in our galaxy, P_{trans} is less than 1% to observe transits of the inner terrestrial planets in the solar system and for the outer planets it decreases from 0.1% (Jupiter) to 0.01% (Pluto). But for giant planets orbiting at very small separations ($a \sim 0.04$ AU), P_{trans} is around

10%. A transit of such a planet produces an ∼1% dip in the so-called light curve (i.e. the time series of brightness measurements) of a star. This effect can be detected from the ground with state-of-the-art photometric instruments, which allow a precision of ∼0.1%.

Currently, numerous ground-based photometric transit surveys are searching for short-periodic giant planets. These surveys usually use small-aperture telescopes with a wide field of view to survey a large amount of stars, typically hundreds or thousands per CCD image.

Detection of smaller planets requires higher photometric precision than ground-based photometry can achieve because of the limitations imposed by our atmosphere. Space-borne telescopes, on the other hand, should be capable of detecting even the miniscule (∼80 ppm) photometric transit of an Earth-like planet orbiting a solartype star at 1 AU.

If photometric data of a transit event can be combined with radial velocity measurements, then the sin i ambiguity in the planetary mass is removed. Furthermore, the transit depth allows an estimate of the radius of the companion and thus an estimate of the mean density. Comparisons of high-resolution spectroscopic observations during and outside a planetary transit reveal spectral signatures of the planetary atmosphere. Clearly, we can gain a tremendous amount of information from planetary transit observations.

2.4. Microlensing

According to Einstein's theory of general relativity, photons are affected by the presence of a gravitational field. Because gravity can be viewed as the changing curvature of the space−time continuum, the path of a photon follows this shape and is "bent" when it passes close to a massive object. In certain geometric cases, this can lead to a focusing of the light from a distant source by a foreground object. This gravitational bending of light has been measured directly during total solar eclipses when the effect of the Sun's gravitational field can be observed as positional changes of stars close to the Sun's disk.

In astronomy, this effect is also seen on a much larger scale: entire galaxies or even clusters of galaxies act as massive gravitational lenses for the light of more distant objects in the background. However, as already demonstrated by our Sun, every object with mass can be a gravitational lens: a star, a brown dwarf, or even a planet.

As in the transit method, microlensing is caused by a geometric alignment: when a foreground object (the "lens") moves in front of a more distant background object (the "source"), the light of the source passing close to the lens is bent toward the observer. The observer can see several images of the background object separated by milliseconds of arc, which merge into a full ring called the Einstein ring at the moment the lens is directly in front of the source. Because the gravitational lensing of the source magnifies the image, the total amount of detected light is increased and the apparent brightness of the distant source is enhanced. The magnification factor depends on the exact geometric situation, and the maximum occurs when the lens is at its smallest projected distance from the source. For microlensing events in our galaxy and for stars acting as both sources and lenses, the images cannot be spatially resolved, and only the change in brightness is observed. However, the magnification can be large and theoretically even infinite for point sources. The position where infinite magnification occurs is called a caustic. Because stars are not perfect point sources, the magnification will not be infinite, but can still be very large.

If the lens is not a single object but a binary, then the caustic is no longer a single point but an extended geometric figure, symmetric around the binary axis. Thus, the microlensing technique represents an elegant method to search for planetary companions to stars in our galaxy. Binary lenses reveal themselves by a characteristic shape of their light curve (the time series of the brightness measurements during the lensing event). The light curve of a binary lens contains sharp peaks of even larger magnification due to the crossing of the caustics. The mass ratio q of the two lenses can be derived from modeling the light curve. If the resulting mass ratio is very small (typically $q > 0.001$), the second object in this binary might be a planet.

Like transit surveys, microlensing planet searches have to observe a large number of targets because the probability of observing a single event for a given target is negligible. For microlensing, the situation is even more complex because of the need of a sufficiently large reservoir of lenses moving in front of a high-density sample of background sources. Moreover, microlensing events for a particular lens do not repeat. Each microlensing event is a single isolated transient in the light curve. There is only one chance to observe it. Hence microlensing surveys monitor regions like the bulge of our galaxy (the central cluster of stars that surround the galactic center) where microlensing events can be observed more frequently.

2.5. Timing Method

The timing method is exceptional with respect to the other techniques because it actually is the method that led to the very first detection of planets outside the solar system. As in the astrometric and radial velocity techniques, the fact that a host star has to orbit the common center of mass with an orbiting planet is utilized to detect the unseen companion. But this time the reflex orbit is observed by the change of the arrival time of signals coming from the star. The change is caused by the difference in the distance the signal has to travel from the source to the observer.

If the star is at the location in its orbit where it is the farthest away from the Earth, then the signal needs the longest time to arrive here, and vice versa for the smallest separation. Because reflex motions due to planets are small compared to the speed of light the changes in arrival time are very small.

The timing method can only be applied to cases where (1) a very short duration signal is emitted by a source with a constant periodicity and (2) the observers are able to measure the arrival time of the signal with very high precision. One astrophysical case where these conditions are met is the so-called pulsar. Pulsars are rapidly rotating neutron stars, which are the remnants of a supernova explosion which ended the life of a massive star with 15−30 times the mass of the Sun. A neutron star has a diameter of only 10−20 km, but has a mass of about 1.4 times the mass of the Sun. Hence it is a very dense object which also rotates very fast. Rotation periods of neutron stars can be as short as milliseconds. Strong magnetic fields produce bipolar jets of radio waves and high-energy radiation such as X-rays and gamma rays. Because the magnetic field axis is misaligned with the rotational axis, these stars act like cosmic lighthouses from which we see a pulse every time the jet sweeps over the Earth. Pulsars were first discovered by radio telescopes in 1967, and the timing method can be applied to the fastest rotators (such as the millisecond pulsars) to detect orbiting companions.

A second case where the timing method is applicable is stably pulsating white dwarf stars. White dwarfs are the end stage of the life of stars that are not massive enough to form a neutron star (like our Sun). They are also small (about the size of the Earth) and very dense objects. These stars undergo nonradial pulsations for certain temperature ranges that can be detected by precise photometric observations. The periods of these pulsations are of the order of a few minutes. Some of the white dwarfs exhibit the same pulsation modes over decades and are thus suitable targets for the timing method.

2.6. Direct Imaging

Obtaining a direct image of an extrasolar planet is the type of observation the public expects. Besides the obvious advantage of discovering planets with only a few observations, the images might also allow us to characterize the planets in new depth. From the colors and albedos, we might obtain thermal and chemical information. After the direct detection, follow-up observations can be carried out to collect spectra or other data of the planet.

In many ways, direct imaging of a planet around a nearby star represents the largest challenge in the development of telescope/instrument systems. Surprisingly, it is not the faintness of an irradiated extrasolar planet that is the hurdle to overcome (the HST is sensitive enough to detect these faint objects) but rather their proximity to a much brighter source of photons: the planet's own host star.

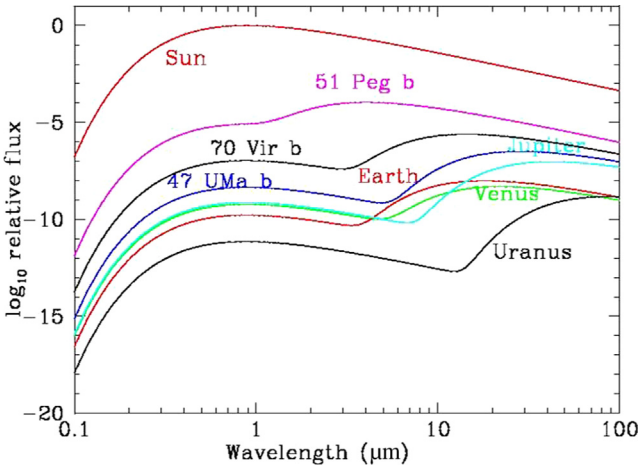

FIGURE 45.2 The relative flux of planets compared to the Sun's emission as a function of wavelength. Four planets of our solar system and three extrasolar planets (51 Peg b, 70 Vir b, and 47 UMa b) are shown. The difference in flux ranges from 10^{-6} to 10^{-12} in the optical (<1 μm) and generally improves toward the infrared (>1 μm), where the planet's thermal emission dominates.

The distances to even the nearest stars are so large that, due to the perspective, any image of a companion orbiting at separations comparable to our solar system would be located in the side wings of the image of the central object. In the optical, the flux difference between a solartype star and a giant planetary companion is of the order of a billion. In the infrared, the difference is more of the order of a million (see Figure 45.2). But the light coming from the planet is completely overwhelmed by the large amount of scattered light from the star.

There are several techniques to minimize the scattered light from the host star. From the ground, the observations are also affected by atmospheric turbulence, called "*seeing*". Seeing usually prevents telescopes from obtaining images at their theoretical resolving power even at the best observing sites in the world. In the near infrared, atmospheric turbulence can be compensated by an adaptive optics (AO) system. AO systems use wave front sensors to measure the wave front errors caused by turbulence in the atmosphere above the telescope and then to adjust the optical path to compensate for these errors using deformable mirrors. This helps to attain images at a spatial resolving power close to the limit set by the diffraction of light. AO imaging improves the situation for high-contrast imaging, but the real goal is to remove the image of the central star entirely from the observations.

The most commonly used instrument to perform this task is the coronagraph. The coronagraph was invented by the French astronomer Bernard Lyot in the 1930s to study the outer parts of the solar atmosphere (the corona) without

being totally overwhelmed by the intense glare of the Sun's disk. He managed to remove the light of the Sun's photosphere by introducing an opaque mask (of the same size as the image of the Sun) into the telescope's light path in such a way that it blocked the photons coming from the disk but not from the surrounding environment. This makes a coronagraph the ideal instrument for direct imaging of extrasolar planets. For ground-based searches the highest image quality is achieved by combining a coronagraph with an AO system.

However, no optical system is perfect and even coronagraphic images contain residual scattered light from the central star close to the edge of the opaque mask and other image artifacts produced by diffraction on telescope parts. This makes the detection very close to the central object still very difficult. And even for the nearest stars, the expected angular separations for planetary companions are small compared to the size of typical coronagraphic masks. At a distance of 5.2 pc (=17 light years), an analogous planet to Jupiter would appear 1 arcsec away from the star at maximum projected separation. At 10 pc, the maximum separation is only about 0.5 arcsec. These angles are comparable to the typical dimensions for coronagraphic masks of current state-of-the art instruments (e.g. the HST instrument Near Infrared Camera and Multi-Object Spectrometer (NICMOS) has a coronagraphic mask with a diameter of 0.8 arcsec).

The image area around the central obscuration contaminated by scattered light is called the halo. In very short exposures, this halo is resolved into smaller bright and dark spots called "speckles". Speckles are interference phenomena produced by atmospheric seeing and by the superposition of light coming from all parts of a telescope mirror with imperfect smoothness. At the location of a dark speckle, the light of the star is canceled out by destructive interference. The image of a faint companion can be recovered if it is located at the position of a dark speckle, where the light from the star is severely reduced. By taking a great number of short exposures, the companion can be detected by a proper data analysis algorithm simply by the fact that in every image the speckle pattern is different and that a dark speckle never appears at the location of the companion. This method is called dark speckle coronagraphy. In combination with large aperture ground-based telescopes or the next-generation space telescope, this method should have the sensitivity to detect extrasolar planets around the nearest stars.

Another technique to achieve high-contrast images is nulling interferometry. In theory, it is possible to combine the wave fronts arriving at two or more telescopes in such a way that a wave maximum coming from one telescope is canceled out by a wave minimum from another telescope. In this way, it produces a null image of the central object while it leaves the light from the circumstellar environment unaffected. First trial runs using ground-based telescopes have already been successfully performed. A nulling interferometer is currently built for the Large Binocular Telescope, which consists of two 8-m class telescopes mounted side by side on the same support structure. One of the most ambitious ideas is the plan for a space-based nulling interferometer operating in the infrared that potentially could directly image and characterize Earth-like planets around nearby stars.

3. OBSERVATIONAL RESULTS OF EXTRASOLAR PLANETS

3.1. The Pulsar Planets

The first definitive discovery of planets outside our solar system was announced in 1992. This discovery would set the tone for all subsequent discoveries of extrasolar planets in terms of their strangeness. The planets were found orbiting the millisecond pulsar PSR B1257+12 using the Arecibo radio telescope and the timing method described in Section 2.

The first surprise was that the planets orbit a "dead" star, which had undergone a previous supernova explosion. It is unlikely that these planets existed before the star went supernova. The more plausible scenario is that these planets somehow formed after the explosion. Millisecond pulsars are believed to achieve their high rotation rates due to spin up by infalling material accreted from a companion star. The planets might have formed during this process in the accretion disk around the pulsar.

The planetary companions to PSR B1257+12 are also remarkable in a different way: they have very small masses. Due to the extreme sensitivity of the timing method in the case of millisecond pulsars (where the arrival time of a pulse can be measured with microsecond precision), even companions with the mass of our Moon or less can be detected.

Table 45.1 summarizes the properties of the PSR B1257+12 planetary system. Soon after the system was discovered, the mutual gravitational perturbations, that were predicted by a dynamical study of this system of the

TABLE 45.1 The PSR B1257+12 Planetary System

Planet	$M \sin i$ (Earth mass)	Orbital Period, P (days)	a (AU)
A	0.015	25.34	0.19
B	3.400	66.54	0.36
C	2.8	98.22	0.47

planets on each other, were indeed confirmed by subsequent timing data. This demonstrated that the residuals in the pulse times are indeed due to orbiting planets and not due to a previously unknown effect, intrinsic to the pulsar.

These companions, with masses between ~3 Earth masses and 1 Moon mass, represent some of the lowest mass objects known to orbit a star other than the Sun. However, they must be barren and dead worlds because of the constant bombardment by high-energy radiation coming from the pulsar.

More recently, evidence was presented for a fourth object with a mass of only 15% the mass of Pluto orbiting the pulsar at a distance of 2.7 AU. This new object, however, qualifies as an asteroid or comet rather than a planet.

3.2. Planets Around Sun-like Stars: The Success of the Radial Velocity Technique

In fall 1995, the astronomical community, as well as the public, was stunned by the announcement of the discovery of the first extrasolar planet around a Sun-like star. Precise radial velocity measurements of the Sun-like star 51 Pegasi revealed a periodic variation of 4.2 days and an amplitude consistent with an $m \sin i = 0.5$ Jupiter mass companion (Figure 45.3). The minimum mass of the object firmly places this companion into the gas giant planet mass range. The detection was achieved by precise data from a stabilized spectrograph at the Haute-Provence Observatory in France.

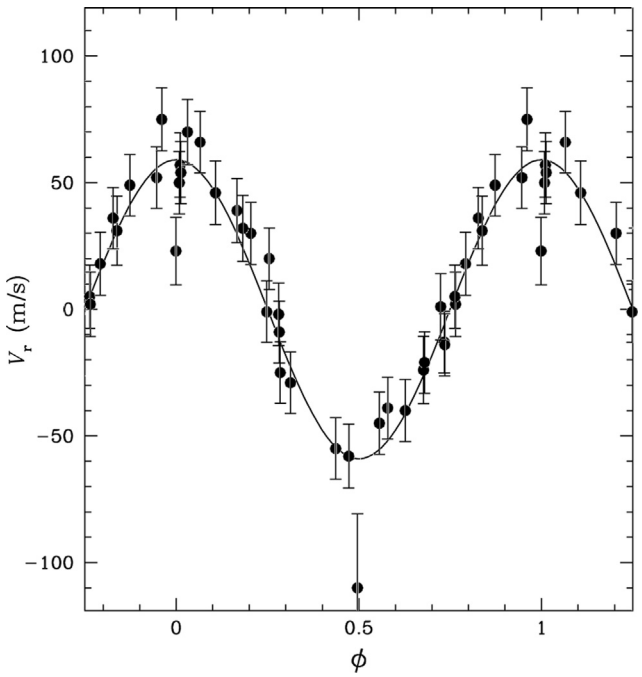

FIGURE 45.3 The radial velocity measurements (dots with error bars) of the solartype star 51 Pegasi phased to the orbital period of its planetary companion. The sinusoidal variation is caused by a companion with $m \sin i = 0.5$ Jupiter masses in a circular orbit with $a = 0.05$ AU and an orbital period of 4.2 days. *Reproduced with permission from Nature.*

The extremely short orbital period and small orbital separation of 0.05 AU of the proposed planet, named 51 Peg b, were surprising in many ways, and alternative explanations for the radial velocity modulation were put forward. Stars more evolved than the Sun show similar variability, which is caused by pulsations rather than by Keplerian motion. But 51 Peg passed every test for this type of variability, and soon the claim of having found the very first planet orbiting a "normal" star was generally accepted.

The planet 51 Peg b represents the prototype of a new class of planets that soon emerged from the results of the radial velocity surveys, the **hot Jupiters**. Because of their close proximity to the host star, these gas giant planets have estimated upper atmosphere temperatures of more than 1000 K.

In the 2 years following the discovery of 51 Peg, astronomers from the United States announced the discovery of seven more extrasolar planets orbiting Sun-like stars. All these detections were based on years of precise radial velocity measurements of these stars using telescopes and spectrographs at Lick, McDonald, and Whipple Observatories. Table 45.2 lists the first eight extrasolar planets discovered by the radial velocity technique along with their orbital characteristics. In 1999, the teams of Lick and Whipple Observatory Doppler surveys announced the discovery of the first extrasolar multiplanetary system around a Sun-like star. The radial velocities of υ Andromedae deviated progressively from the originally derived, single-planet velocity curve, and with the additional years of data it became apparent that a triple Keplerian model is required to describe the complex reflex motion of this star. In addition to the previously found hot Jupiter, this system contains two more giant planets with $m \sin i = 1.89$ and 3.75 Jupiter masses at separations of 0.8 and 2.53 AU. Also their orbits have significantly nonzero eccentricities (0.28 and 0.27), making this system again quite different from our solar system.

Over the following decade, the radial velocity technique demonstrated its effectiveness in detecting numerous giant planets and nearly a 100 multiplanet systems around nearby stars. At the time of this writing, more than 500 planetary companions in nearly 400 systems were found by the cumulative effort of several radial velocity surveys operating in both hemispheres. The most successful programs were using the 10-m Keck telescope and the High Resolution Echelle Spectrometer (HIRES) spectrograph in Hawaii and the CORALIE and High Accuracy Radial velocity Planet Searcher (HARPS) instruments at La Silla Observatory in Chile. Many characteristics of extrasolar planetary systems detected by radial velocity surveys differ significantly from the planets in our solar system.

TABLE 45.2 The First Eight Radial Velocity Planets

Star	*m* sin *i* (Jupiter mass)	Orbital Period, *P* (days)	*a* (AU)	Eccentricity, *e*
51 Peg	0.5	4.2	0.05	0
70 Vir	7.4	117	0.48	0.4
47 UMa	2.5	1089	2.09	0.06
ρ^1 Cancri	0.84	14.7	0.12	0.02
τ Boo	4.13	3.3	0.05	0.01
υ And	0.69	4.62	0.06	0.012
16 Cyg B	1.69	799	1.67	0.67
ρ Crb	1.11	39.9	0.23	0.13

One of major difference with the giant planets in the solar system is the very small separation where the radial velocity method detected extrasolar planets. These small orbital separations ($\sim$0.04 AU for a hot Jupiter) are difficult to reconcile with current models of the formation of gas giant planets. In the classical "core accretion" model of planet formation, gas giants form most easily near (and beyond) the so-called "ice line" in the protoplanetary nebula. The ice line is the distance from the star where the temperatures in the nebula drop low enough so that ices can condense out of the gas. This leads to an increase in the surface density of condensed material and allows the formation of massive cores (mixed with rocky material and dust grains) onto which nebula gas can accrete. It was therefore commonly expected to find gas giants only at large orbital separations similar to our Jupiter at 5 AU and more. It appears that, in most cases of the observed extrasolar giant planets, moderate to massive orbital migration has occurred, which moved the planets from the place where they formed to their current location close to the star.

Another remarkable difference is the abundance of moderate to high orbital eccentricities (e) of radial velocity planets. Most of them have more elongated orbits than the planets in our solar system. The eccentricities are distributed quite uniformly and are practically indistinguishable from the eccentricity distribution of stellar binaries, especially for planets at larger separations. The hot Jupiters all have $e = 0$ (or close to 0) because tidal forces between the star and the planet at these small distances tend to circularize the orbit on much shorter timescales than the typical lifetime of the star. The origin of the nonzero eccentricities is not well understood; possible explanations are a more dynamic formation history than in the case of the solar system, in which mutual dynamical interaction between planet embryos pumped up their eccentricities. Also, planet/disk interactions and gravitational perturbation by stellar companions and planet–planet scattering are possible causes of high eccentricity.
