Bilirubin is not soluble in aqueous solution and is transported in plasma from sites of synthesis to the liver bound to albumin. Bilirubin dissociates from albumin (Listowsky *et al.*, 1978), and hepatocellular uptake is facilitated across the basolateral (sinusoidal) plasma membrane by the organic anion transport polypeptide (OATP), a sodium- and energy-independent process. OATP also has a role in the hepatic uptake of a wide range of other organic anions (e.g., certain drugs, other xenobiotics, sulfobromophlalein [BSP]) and in the sodium-independent hepatic uptake of bile salts (Hata *et al.*, 2003). The primary mechanism for the hepatic uptake of conjugated bile salts is sodium dependent and utilizes the sodium taurocholate cotransporting polypeptide (NTCP) (Hata *et al.*, 2003; Jacquemin *et al.*, 1991, 1994; Wolkoff *et al.*, 1985).

Localization of OATP in the sinusoidal plasma membrane of the hepatocyte is determined by PDZ1, a 70-kDa PDZ binding motif that is present in the liver and kidney. (PDZ is an acronym that combines the first letters of the three proteins in which its binding domain was first identified; Hung and Sheng [2002].) PDZ domains function in protein targeting and in the assembly of specific protein-protein complexes involved in signal transduction or transport. In PDZK1 knockout mice, the expression of OATP1a1 in the liver is almost normal, but OATP1a1 is present only in the cytoplasm and is absent from its normal position in the plasma membrane. BSP clearance is diminished in PDZK1 knockout mice, suggesting that oligomerization of OATP1a1 with PDZK1 determines the subcellular localization and the function of OATP1a1 (Wang *et al.*, 2005).

Upon entry into the hepatocyte, bilirubin binds to ligandin, a major cytosolic protein that has both transport and detoxification functions. Ligandin is a glutathione S-transferase that catalyzes conjugation of reduced glutathione with a variety of endogenous substrates and xenobiotics including porphyrins and certain steroid hormones including cortisol, BSP, and indocyanine green (Habig *et al.*, 1974; Kaplowitz *et al.*, 1973). By binding bilirubin and inhibiting the efflux of pigment back into the plasma, ligandin serves as a driving force for initial hepatic uptake (Listowsky *et al.*, 1978).

Conjugation of bilirubin with glucuronic acid is catalyzed by bilirubin uridine-diphosphate glucuronosyltransferase-1 (BUGT1) in a reaction in which one or both propionic acid side chains of bilirubin IX are esterified. BUGT1 is a microsomal isoenzyme that produces water-soluble bilirubin mono- and diglucuronide. The UGT family of enzymes is among the most important mammalian detoxification mechanisms.

Bilirubin diglucuronide represents more than 80% of the total bile pigment in healthy adult human bile. Glucuronic acid esters of bilirubin have been identified in the bile of a variety of species including the dog (Talafant, 1956), rat (Grodsky and Carbone, 1957), guinea pig (Schmid, 1956), and in the bile of the horse, pig, cat, sheep, and cattle (Cornelius *et al.*, 1960). Gordon *et al.* (1976) have shown that the diglucuronide is the major bilirubin conjugate excreted in canine bile. There is evidence, however, that the bile of dogs (Fevery *et al.*, 1971; Heirwegh *et al.*, 1975; Noir, 1976) and other species (Cornelius *et al.*, 1975a, 1975b) also contains bilirubin conjugates of glucose and xylose.

When the activity of bilirubin-UGT in the liver is diminished, production of bilirubin mono- and diglucuronide decreases. Reduction of conjugating enzyme activity to

approximately 30% of normal results in a modest increase in the serum bilirubin concentration. Greater deficiency of bilirubin-UGT leads to ineffective esterification of bilirubin and to more severe unconjugated hyperbilirubinemia and icterus. Bilirubin conjugation in the liver of neonatal animals is relatively low compared to the adult. Coupled with the high rate of bilirubin production related to accelerated neonatal erythrocyte turnover, the risk of hyperbilirubinemia and icterus may be increased in the neonate. Defective bilirubin conjugation as a result of inherited UDP-glucuronosyltransferase deficiency causes the severe unconjugated hyperbilirubinemia of the Crigler-Najjar syndrome of humans and the Gunn rat. Gilbert's disease is a more benign, inherited form of UDP-glucuronosyltransferase deficiency in humans that is characterized by intermittent unconjugated hyperbilirubinemia and icterus. A similar enzyme deficiency may explain the benign unconjugated hyperbilirubinemia observed in some horses.

The final step in hepatic excretion is the transport of conjugated bilirubin across the bile canaliculus and into the biliary system. The experimental intravenous infusion of unconjugated bilirubin at a rate that exceeds the maximal hepatic excretory capacity results in accumulation of conjugated bilirubin in plasma. This indicates that under normal conditions, the rate-limiting step in the transfer of bilirubin from plasma to bile is canalicular transport rather than either hepatic uptake or conjugation (Arias *et al.*, 1961). The concentration of bilirubin glucuronide in bile is 150-fold greater than in hepatocytes.

The unidirectional transport of bilirubin conjugates from the cytoplasm across the canalicular plasma membrane into bile is mediated by the multidrug resistance-associated protein 2 (Mrp2; ABCC2; canalicular multispecific organic anion transporter, cMOAT), a member of the ATP-binding cassette (ABC) superfamily, and an integral part of the bile canaliculus (Chowdhury *et al.*, 1994; Nies and Keppler, 2007). The Mrp2 transport mechanism is functionally distinct from the ATP-dependent, bile salt export pump of the canaliculus described later in the section on bile acids (Bsep; Alpert *et al.*, 1969; Arias *et al.*, 1993; Muller *et al.*, 1991; Stieger *et al.*, 2007). Although mechanistically separate from the Mrp2 system, bile salt excretion enhances bile flow and increases the maximum transport capacity for bilirubin and other organic anions (Goresky *et al.*, 1974).

Mutations of the Mrp2 gene are responsible for the Dubin-Johnson syndrome of humans, a benign, inherited hepatic disease associated with conjugated hyperbilirubinemia and accumulation of melanin like pigment in hepatocytes. A similar disease has been observed in two separate strains of rats. In the GY/TR(-) rat (Jansen *et al.*, 1985; Paulusma *et al.*, 1996) and in the similar Eisai hyperbilirubinemic rat (EHBR; Ito *et al.*, 1997, 2001; Takikawa *et al.*, 1991), genetic sequence variants lead to premature stop codons and to the absence of the Mrp2 gene product in the canaliculus. A similar genetic abnormality is likely in Corriedale sheep, which develop an inherited disease that is clinically and biochemically identical to the Dubin-Johnson syndrome of humans (Cornelius *et al.*, 1965a, 1968b) and rats (Kitamura *et al.*, 1990).

3. Extrahepatic Metabolism of Bilirubin

From the bile, conjugated bilirubin enters the intestine. Conjugated bilirubin, a polar compound, is poorly absorbed in the small intestine and passes to the large intestine where it is reduced to a series of colorless derivatives collectively called urobilinogens (stercobilinogens). Reduction is catalyzed by dehydrogenases of anaerobic colonic bacteria. In germ-free animals that lack intestinal microorganisms, bilirubin passes unaltered into the feces and urobilinogen is not produced (Gustafsson and Lanke, 1960). Most of the urobilinogen formed in the colon is passed in the feces, but some is absorbed into the portal circulation, transported to the liver, and most of that is excreted in the bile. A small fraction (1% to 5%) of absorbed urobilinogen, however, passes into the general circulation and is excreted by the kidney. In the dog, urobilinogen is excreted by both glomerular filtration and tubular secretion, the latter being enhanced in acid urine (Levy *et al.*, 1968).

Although the liver is the principal site of bilirubin conjugation and excretion, alternate pathways have been demonstrated. In normal animals, these alternate mechanisms are of minor significance but may become quantitatively more important in liver disease. After total hepatectomy, dogs have been shown to develop moderate hyperbilirubinemia and bilirubinuria. In addition to unconjugated bilirubin, the plasma of hepatectomized dogs contains the monoglucuronide conjugate (Hoffman *et al.*, 1960) and, in some studies, the diglucuronide of bilirubin (Royer *et al.*, 1965). The kidney and intestine both have been shown experimentally to be sites with the capacity to conjugate bilirubin (Royer *et al.*, 1974). Differences in extrahepatic metabolism of bilirubin may explain some of the remarkable differences between species in the bilirubin levels reached after bile duct obstruction (see the following section).

4. Icterus

The clinical sign of *icterus* or *jaundice* develops when the yellow pigment bilirubin accumulates in plasma and other tissues. Yellow discoloration of tissues can first be noted by careful observation when the plasma bilirubin value exceeds 2 to 3 mg/dl and can be appreciated even by an untrained observer when the concentration exceeds 3 to 4 mg/dl. The correlation between the plasma bilirubin concentration and the degree of clinical icterus is not, however,

perfect. Elevated plasma bilirubin values are usually present for one or more days before clinical icterus is apparent, and there may be a delay between the time plasma bilirubin returns to normal and the clearance of the yellow discoloration of tissues. Conjugated bilirubin is said to have a greater affinity for connective tissue than the unconjugated pigment, possibly because conjugated pigment is less avidly bound to albumin (With, 1968).

Visible yellow discoloration of tissues is readily recognized in animals in the unpigmented sclera. The normal red color of the visible mucous membranes makes detection of a slight yellow cast more difficult. It is possible to apply pressure to the mucous membranes and temporarily reduce blood flow to the area, so that the underlying discoloration of the tissue can be better assessed.

The color of plasma (icteric index) may be useful clinically in the evaluation of icterus. Normal canine, feline, and ovine plasma is often water clear and free of yellow color. The finding of yellow plasma in these species is highly suggestive of hyperbilirubinemia. Cattle absorb and transport significant quantities of carotene in plasma. Because in cattle the icteric index varies with the dietary intake of carotene, measurement has limited use in this species. Equine plasma normally has a high icteric index, which in part is due to a plasma bilirubin concentration that normally is higher than that of other domestic species. There are other, as yet uncharacterized, noncarotene pigments, however, that may contribute to the color of equine plasma.

Notable species differences occur in the frequency with which icterus is observed in association with liver disease. In sheep and cattle with terminal hepatic insufficiency, there usually is a significant biochemical elevation in plasma bilirubin, but elevation may be insufficient to result in clinical icterus (Finn and Tennant, 1974; Hjerpe *et al.*, 1971). This is due possibly to the residual capacity of the liver to excrete bilirubin or to extrahepatic mechanisms for bilirubin excretion or degradation. Clinical icterus in ruminants is often associated with hemolytic anemia in which production of bilirubin exceeds excretory capacity (e.g., anaplasmosis in cattle and copper poisoning in sheep). In severe fatty liver, cattle that are critically ill may exhibit some degree of clinical icterus.

The assessment of clinical icterus in the horse is somewhat more complicated than in other species. The sclera and visible mucous membranes of most normal horses do not appear icteric, but in 10% to 15% of normal horses, a slight but definite yellow discoloration of the sclera or oral mucous membranes can be detected (Tennant *et al.*, 1975). Scleral icterus of a moderate degree may also be observed in horses with a variety of illnesses that do not involve the liver directly (e.g., pneumonia, impaction of the large intestine, enteritis). Reduction in food intake is a common factor in such disorders, and fasting in the horse causes a rapid increase in plasma bilirubin concentration. In both hemolytic anemia and hepatic failure in the horse, the degree of icterus is usually remarkably greater than that seen under physiological conditions or that is associated with reduced food intake. In the horse, severe clinical icterus is almost invariably present in acute hepatic necrosis (Tennant *et al.*, 1975; Thomsett, 1971). However, in chronic hepatic disease, icterus may be a more variable sign. In a series of 34 cases of hepatic cirrhosis in the horse, significant icterus was a presenting sign in 70% (Tennant *et al.*, 1975). Icterus was even less frequent (40%) in another series of horses with cirrhosis (Gibbons *et al.*, 1950).

The dog and cat appear to be intermediate between ruminants and the horse in the propensity to develop clinical icterus. Hemolytic disease, severe hepatocellular dysfunction, and extrahepatic bile duct obstruction are characteristically associated with icterus in dogs and cats. In experimental extrahepatic bile duct obstruction in the dog, the plasma bilirubin increases at once following obstruction and clinical icterus is observed within 1 to 3 days. After 2 to 3 weeks, however, the plasma bilirubin of some dogs declines. As in sheep and cattle, this may be related to adaptation of extrahepatic mechanisms of bilirubin excretion, particularly the kidney. The kidney of the dog is capable of adapting so that the rate of renal excretion of bilirubin equals the rate of formation. In cats with complete extrahepatic bile duct obstruction, however, no such decrease is observed, and persistent hyperbilirubinemia and deep icterus are characteristic.

B. Hepatic Encephalopathy

Hepatic encephalopathy is the syndrome of disturbances in cerebral function that is caused by hepatic insufficiency or hepatic failure. Severity of neurological signs may vary from subtle and intermittent changes in behavior associated with lethargy or stupor, to bizarre, belligerent behavior, mania, convulsions, and hepatic coma. Typically, such signs are attributable to severe acute or chronic liver disease or in dogs to congenital malformation of the portal vein (portosystemic shunt).

Hepatic encephalopathy is a prominent clinical feature of hepatic failure in the horse. In one series of cases, 82% of horses presenting with acute hepatitis and 32% with cirrhosis had prominent neurological abnormalities (Tennant *et al.*, 1973). Varying degrees of CNS derangement may be observed. Some horses stand quietly with the feet apart and the head lowered, nodding the head occasionally and appearing somnolent. Pupillary response to light may be normal or moderately sluggish, but, in some cases, vision is lost. Compulsive walking in a circle or in a single direction may be observed, and affected individuals may appear oblivious to their surroundings, walking over or through objects in their path ("walking disease"; Rose *et al.*, 1957).

In fulminant cases, horses may become delirious with the head pressed forcibly against a wall for long periods of time, or they may assume a variety of other unusual positions or fall suddenly to the ground. Numerous unproductive attempts to rise can be followed by violent thrashing. When successful in rising, horses with hepatic encephalopathy may be completely uncontrollable, lunging forward violently and becoming a menace to attending personnel and equipment.

The syndrome of hepatic encephalopathy in cattle may have an abrupt onset and characteristically represents a terminal manifestation of chronic liver disease (Fowler, 1968; Pearson, 1977). Affected calves initially may be dull, anorectic, and stand apart from other calves in a herd. Behavioral abnormalities may include unprovoked, violent charging or unusual and unrestrained bawling. Progressive dysmetria and ataxia are followed by recumbency and affected cattle may be unable to rise or even to assume a sternal position. Tenesmus has been reported to be a conspicuous clinical feature associated with prolapse of the rectal mucosa and dribbling of urine. Characteristically, death occurs within 2 days after onset of CNS signs (Finn and Tennant, 1974).

Hepatic encephalopathy is observed frequently in dogs with congenital or acquired portosystemic vascular shunts and may be one of the most prominent presenting clinical features of this form of liver disease (Audell *et al.*, 1974; Barrett *et al.*, 1976; Cornelius *et al.*, 1975a, 1975b; Ewing *et al.*, 1974; Maddison, 1992; Schermerhorn *et al.*, 1996). Neurological signs associated with portosystemic shunts often are episodic and may be present for some months before recognition of the underlying hepatic disturbance. Depression and stupor with amaurotic blindness are observed in approximately half the cases of congenital portacaval shunts in dogs, with circling, head pressing, and intermittent seizures observed less frequently. Hepatic encephalopathy also has been associated with other primary diseases of the canine liver (Center, 1996; Oliver, 1965; Strombeck *et al.*, 1975b).

Inherited diseases involving the urea cycle are recognized in domestic animals in which failure of urea synthesis results in significant elevations in blood ammonia and in signs of encephalopathy. Two cases of encephalopathy in dogs have been reported that were linked to a deficiency of argininosuccinate synthetase (Strombeck *et al.*, 1975a). Inherited argininosuccinate synthetase deficiency has been described in neonatal cattle in which rapidly progressive and fatal encephalopathy was associated with hyperammonemia and citrullinemia (Harper *et al.*, 1986, 1988, 1989). The argininosuccinate synthetase gene of cattle has been cloned, sequenced, and the mutation of affected Holstein calves described (Dennis *et al.*, 1989). Suspected ornithine transcarbamylase deficiency has been described in a cat (Washizu *et al.*, 2004), and encephalopathy in two Morgan foals associated with elevated blood ammonia has been recognized and described as being similar to the human syndrome of hyperornithinemia, hyperammonemia, and homocitrullinuria (McCornico *et al.*, 1997). A syndrome of hyperammonemia and encephalopathy associated with acute gastrointestinal disease has been described in adult horses (Gilliam *et al.*, 2007; Hasel *et al.*, 1999; Peek *et al.*, 1997; Stickle *et al.*, 2006). The pathogenesis of this syndrome has not been fully explained, but the evidence suggests that increased production and absorption of ammonia from the colon are sufficient to exceed the detoxifying capacity of the liver (Stickle *et al.*, 2006).

Hepatic encephalopathy must be differentiated clinically from primary inflammatory, degenerative, or neoplastic diseases of the brain, and this can be accomplished by demonstrating the existence of underlying severe hepatic disease. In the horse with acute hepatitis, clinical icterus almost always is present at the time neurological signs are observed. In the dog and in cattle, frank clinical icterus is observed variably in animals with hepatic encephalopathy so that other tests of hepatic function or liver biopsy are required. In cases of primary hyperammonemia resulting from deficiency of urea cycle enzymes, conventional hepatic function tests are not expected to be abnormal (Strombeck *et al.*, 1975a).

Factors responsible for encephalopathy associated with hepatic failure are not completely understood. Ammonia is present in normal peripheral blood at a concentration of 2 to 5 mM/l. In portal venous blood, the concentration may be five times higher. Normally, most of the ammonia in the hepatic portal vein is removed by the normal liver to form urea, with only a small fraction passing into the systemic circulation. In hepatic failure, synthesis of urea is reduced, and in the horse (Cornelius *et al.*, 1965a, 1965b; Tennant *et al.*, 1975) and dog (Barrett *et al.*, 1976; Strombeck, 1975b), significant elevations of blood ammonia have been demonstrated. Ammonia has potent neurotoxic effects, and many of the neurological signs of hepatic encephalopathy can be produced when toxic doses of ammonium salts are administered intravenously (Hooper, 1972).

The reactions of blood ammonia are determined by the physicochemical principles that apply to gases in solution and to the dissociation of weak bases. The ammonia: ammonium ion buffer system of blood can be described by the Henderson-Hasselbalch equation:

$$\mathrm{pH} = \mathrm{pKa} - \log \frac{\mathrm{NH_3}}{\mathrm{NH_4^+}}$$

The pKa for this system in the dog is approximately 9.1 (Bromberg *et al.*, 1960), meaning that at physiological pH (7.4), almost all of the ammonia of blood is ionized to form (NH_4^+). As blood pH increases, the relative amount of free ammonia (NH_3) increases, and as pH decreases, NH_3 decreases. Cells are almost impermeable to NH_4^+ but are readily permeable to NH_3, passing through the plasma

membrane by nonionic diffusion (Castell and Moore, 1971; Stabenau *et al.*, 1959; Warren and Nathan, 1958). These principles are important in determining the amount of ammonia absorbed from the gastrointestinal tract or the amount that can pass from blood into the brain and to other tissues (Dimski, 1994).

Because of its influence on acid-base parameters, potassium status may be an important determinant of NH_3 toxicity. Potassium deficiency ultimately favors the development of metabolic alkalosis that, in turn, causes a shift in the NH_3/NH_4^+ equilibrium in the direction of the toxic freebase.

Blood ammonia ultimately is derived from dietary nitrogen. The gastrointestinal tract is the major source of blood NH_3, but other tissues also produce NH_3 (e.g., muscle and kidney). Renal ammonia is produced from glutamine and to a lesser extent from other amino acids. Synthesis of ammonium ion by the kidney represents a normal physiological mechanism for H^+ excretion. The renal excretion of NH_4^+ is related directly to the pH gradient between blood and urine, and total urinary excretion of NH_4^+ is high in acid urine and proportionately low in alkaline urine.

The gastrointestinal tract is the major source of blood NH_3 based on the high concentration of NH_3 found in portal blood compared to peripheral venous blood. Part of the ammonia in the hepatic portal vein is derived from the action of bacterial enzymes on dietary amino and amide nitrogen and part is derived from urea, which is present in alimentary tract secretions and is hydrolyzed by bacterial urease of the gastrointestinal tract. The question of whether gastrointestinal urease is produced in part by mammalian cells or is entirely of bacterial origin was the subject of controversy for many years. Using germ-free rats, it was demonstrated that gastrointestinal urease was exclusively of bacteria in origin (Levenson and Tennant, 1963), and this observation has been confirmed in germ-free dogs (Nance *et al.*, 1974).

The relative importance of NH_3 produced by gastrointestinal bacteria and that produced from nonbacterial sources is still not fully known. Nance *et al*. (1971, 1974) and Nance and Kline (1971) have demonstrated that germ-free dogs with Eck fistulae develop encephalopathy associated with hyperammonemia. This suggests that at least with vascular shunts, endogenous sources of NH_3 contribute to encephalopathy. The intestine metabolizes significant quantities of glutamine independent of intestinal bacteria, and at least 30% of the glutamine nitrogen that reaches the intestine appears in the portal blood as NH_3/NH_4^+ (Windmuller and Spaeth, 1974).

The liver plays a critical role in maintenance of the blood glucose concentration, and marked hypoglycemia is sometimes associated with liver failure. In fulminant hepatic failure in the horse, the blood glucose has been reported in some cases to be as low as 20mg/dl or less (Hjerpe, 1964; Tennant *et al.*, 1975). Hypoglycemia also has been reported in dogs with hepatic insufficiency associated with vascular shunts (Cornelius *et al.*, 1975b; Ewing *et al.*, 1974).

Other neurotoxic substances may be involved in the pathogenesis of hepatic encephalopathy, and the role of these factors has been reviewed (Center, 1996; Maddison, 1992). Indole and indolyl derivatives that are formed from tryptophan by intestinal bacteria have been suggested as encephalotoxic compounds capable of inducing coma (Zieve *et al.*, 1974). Other studies have incriminated short chain fatty acids and, in experimental models of hepatic failure, total volatile fatty acids (VFA) increase significantly before death (Zieve *et al.*, 1968). Increased plasma VFA concentrations also have been observed in spontaneous hepatic encephalopathy and, when infused intravenously into experimental animals, VFA produces cerebral depression followed by coma.

The etiological role of ammonia in hepatic encephalopathy is generally recognized, and there is convincing evidence that cerebral edema is important in pathogenesis (Ahboucha and Butterworth, 2007; Butterworth, 1994). Astrocytes are recognized as a target of ammonia in the CNS (Albrecht and Norenberg, 2006), but how ammonia brings about astrocyte swelling, brain edema, and cerebral hypertension is not fully understood. It has been suggested that as a result of ammonia detoxification, glutamine accumulates in astrocytes and the resulting osmotic force of glutamine leads to cell swelling. In experimentally induced hepatic encephalopathy, accumulation of cerebral ammonia was associated with increased cerebral glutamine, with the development of Alzheimer type II astrocytes, and with a significant increase in the level of water in the brain (Jover *et al.*, 2006). Based on studies of cultured astrocytes, Jayakuman *et al.* (2006) concluded, however, that glutamine was not acting as an osmolyte but rather that ammonia evoked oxidative stress or abnormalities of mitochondrial function (mitochondrial permeability transition) that caused injury and swelling of astrocytes (Albrecht and Norenberg, 2006; Norenberg *et al.*, 2005, 2007).

The management of hepatic encephalopathy involves restriction of protein intake and provision of a readily digestible dairy or vegetable protein source. Further control is directed at the reduction of the production and absorption of ammonia and other neurotoxic substances from the intestine. One approach is the oral administration of a nonabsorbable disaccharide such as lactulose, which upon reaching the colon is fermented by resident bacteria to produce short chain fatty acids and which has a cathartic effect. By decreasing colonic pH, the equilibrium between ammonium ion and the freebase is shifted to poorly absorbed ammonium ion. An alternative approach is the administration of a nonabsorbable, broad spectrum antibiotic. The antibiotic inhibits production of ammonia and other organic toxins produced by bacteria in the colon (Festi *et al.*, 2006; Rothenber and Keeffe, 2005).

C. Hepatic Photosensitivity

Photosensitivity is the result of hypersensitivity to sunlight induced by the presence of exogenous or of endogenously produced photodynamic substances. Clinical signs develop when photosensitive animals are exposed to light and are caused by inflammation and necrosis of unpigmented skin (photodermatitis). A distinction is made between sunburn and photosensitization. Animals with unpigmented skin that are maintained for long periods of time indoors and are abruptly exposed to sunlight may sustain sunburn, which is a direct response of the unpigmented and unprotected skin to ultraviolet radiation (320 μM). Photosensitization is, characteristically, a more severe reaction caused by the interaction of a photodynamic substance and solar radiation. The effective wavelength of light causing photosensitization is determined by the absorption spectrum of the photosensitizing substance, which may extend into the visible region of light. Sunburn and photosensitization also differ in that sunburn apparently can develop in the absence of molecular oxygen, whereas photosensitization occurs only in the presence of molecular oxygen (Cook and Blum, 1959; Schothorst *et al.*, 1970). With sunburn, there is a characteristic delay between exposure to light and the development of erythema of the skin, soreness, or pruritus. With photosensitization, initial clinical signs may be noted within minutes after exposure to sunlight.

In domestic animals, three forms of photosensitization are recognized. Photosensitivity may occur when a photodynamic substance not present normally in the diet is ingested and absorbed. Examples are the ingestion of the poisonous plants *Hypericum perforatum* (St. John's wort, Klamath weed) and *Fagopyrum esculentum* (buckwheat). Photosensitization caused by administration of the parasiticide phenothiazine also is a form of primary photosensitization. The photosensitizing compound is phenothiazine sulfoxide, which accumulates in the skin and in the aqueous humor inducing keratitis. A second form of photosensitization is caused by photosensitizing compounds that are produced endogenously. Congenital porphyria (pink tooth) of cattle is one of the best characterized examples in which a marked increase in production of uroporphyrin I results in deposition of the porphyrin in the teeth and bones, and large quantities are excreted in the urine. The teeth and urine readily fluoresce when exposed to ultraviolet light. The photodermatitis and hemolytic anemia associated with the disease are directly related to the photodynamic effects of endogenous porphyrins (Kaneko *et al.*, 1971; Scott *et al.*, 1979). Other inherited forms of porphyria in domestic animals (reviewed by Tennant [1998]) are described in Chapter 8.

A third group of diseases associated with photosensitivity are those that are secondary to hepatic disease (hepatic photosensitization). Photodermatitis associated with both acute and chronic liver disease is recognized primarily in herbivorous animals. The photodynamic agent responsible for hepatic photosensitivity is phylloerythrin, a porphyrin derivative from chlorophyll (Rimington and Quin *et al.*, 1934). Chlorophyll is converted to phylloerythrin by microorganisms of the rumen or large intestine that remove the magnesium atom from the chlorophyll molecule and hydrolyze the phytyl and carboxy methoxy side chains leaving the porphyrin nucleus of chlorophyll intact. Phylloerythrin produced in the alimentary tract is excreted primarily in the feces. A small fraction of the relatively nonpolar phylloerythrin is absorbed into the portal circulation. In normal animals, phylloerythrin is quantitatively removed by the liver and excreted in the bile and does not reach the peripheral circulation. Phylloerythrin may be found in the bile and feces of herbivores that are consuming chlorophyll-containing diets and may be demonstrated in other species that ingest chlorophyll. The comparatively large amount excreted by ruminants is attributed to their frequently high chlorophyll intake and to the favorable conditions for microbial production of phylloerythrin within the gastrointestinal tract.

In hepatic insufficiency, phylloerythrin is incompletely cleared from the hepatic portal circulation, enters the systemic circulation, and ultimately accumulates in the skin. In the superficial layers of the unpigmented skin, phylloerythrin absorbs solar energy resulting in formation of free radicals. Reactive oxygen species cause peroxidation of cellular lipids and cellular components (e.g., lysosomes). Inflammation and necrosis of the skin are the result of direct oxidative injury and the secondary action of lysosomal enzymes (Slater and Riley, 1966). The critical range of wavelengths (action spectrum) that result in photodermatitis in hepatic photosensitivity was shown in geeldikkop to be between 380 and 650 μm (Riemershmid and Quin, 1941) and in facial eczema between 400 to 620 σm, ranges that are consistent with the known absorption spectrum of phylloerythrin.

The types of hepatic disease of ruminants and horses that are associated with photosensitivity vary considerably, but the effects attributable to the photodynamic action of phylloerythrin are similar. The nature and severity of the cutaneous lesions depend on the amount of phylloerythrin in the skin and on the intensity and the duration of light exposure. The most common site of photodermatitis in the horse is the muzzle, which has a sparse protective covering of hair and often is unpigmented. Unpigmented areas of the distal extremities also are frequently affected (Fowler, 1965; Tennant *et al.*, 1973). In cattle, unpigmented areas of the muzzle, back, escutcheon, and the lateral aspects of teats are especially susceptible to photodynamic injury.

The areas of skin affected in sheep are those that receive the greatest exposure to light and that lack protection provided by black pigment or wool and include the ears, eyelids, face, lips, and coronets (Riemerschmid and Quin, 1941). The first clinical signs of photodermatitis in

sheep may be apparent restlessness with shaking of the head or rubbing of affected parts. Individual animals may seek relief in the shade. Erythema and edema are the first cutaneous manifestations of photosensitization. Swelling of the lips, ears, and face have led to the descriptive terms "big head" and "facial eczema." Following edema, serum may ooze from damaged skin. Ultimately, second- or third-degree burns may develop, and the morbidity and mortality attributable to lesions of the skin may be more important than any other aspect of the underlying liver disease (Riemerschmid and Quin, 1941). In the early stages of the disease, Southdown sheep with congenital photosensitivity have no morphological abnormalities of the liver, but the photodermatitis that is observed as soon as affected lambs begin to consume green plants is associated with significant biochemical defects in hepatic organic anion excretion (Cornelius and Gronwall, 1968).

D. Ascites

The clinical sign of ascites is the result of abnormal accumulation of fluid in the peritoneal cavity. In normal animals, there is significant bidirectional movement of fluid, electrolytes, and, to a lesser degree, protein across mesenteric capillaries, through the interstitial space, and across the peritoneal mesothelium into the abdominal cavity. Such movements are determined by osmotic and hydrostatic forces that are described by Starling's equation: plasma colloidal osmotic pressure minus ascitic fluid colloidal osmotic pressure equals portal capillary pressure minus intra-abdominal hydrostatic pressure. Normal portal capillary pressure on the arterial side of the capillary bed favors formation of an ultrafiltrate of plasma, which is nearly protein free. On the venous side of the capillary bed, reabsorption of interstitial fluid occurs because the hydrostatic pressure is below that of the colloidal osmotic pressure primarily exerted by plasma proteins within the capillary bed. Under normal conditions, only a small volume of free fluid is present in the peritoneal cavity.

During investigation of the mechanical factors that influence formation of lymph, Starling (1894) observed that obstruction of hepatic venous flow by ligation of the thoracic vena cava cranial to the site of entry of the hepatic veins produced significant increase in lymph flow through the thoracic duct, and the lymph was high in protein. Obstruction of the hepatic portal vein as it entered the liver also increased the flow of thoracic duct lymph, but the protein content was found to be low. Starling concluded that the increased flow of thoracic duct lymph following ligation of the thoracic vena cava arose from hepatic lymph, and after ligation of the portal vein, increased thoracic duct lymph was derived from mesenteric capillaries.

Hepatic lymph is produced primarily in the sinusoids and contributes 25% to 50% of lymph flow in the thoracic duct (Brauer, 1963). In the dog and other species, hepatic lymph has a much higher protein content than lymph from other tissues because hepatocytes are not associated with a conventional basement membrane and because of the unique permeability of the sinusoids to plasma proteins because of fenestrations between the endothelial cells that line the sinusoids (Bissel and Maher, 1996). In experimental cirrhosis in the dog and other species, the flow rate of thoracic duct lymph is increased two to five times and the protein content is higher than that of lymph derived from other tissues (Nix *et al.*, 1951a, 1951b).

Ascites caused by cirrhosis of the liver may be associated with increased portal vein pressure (portal hypertension). Experimental ligation of the portal vein before it enters the liver, however, results only in minimal and transient ascites or no ascites (Schilling *et al.*, 1952; Volwiler *et al.*, 1950). In the dog, ligation of either the hepatic vein (Orloff and Snyder, 1961a, 1961b; Orloff *et al.*, 1963, 1964a, 1964b, 1966) or the caudal vena cava at a site cranial to entry of the hepatic vein (Berman and Hull, 1952; Schilling *et al.*, 1952; Witte *et al.*, 1968, 1969a, 1969b) produces prompt and intractable ascites. Lymph fluid has been observed to form droplets said to "weep" from the surface of the liver following experimental obstruction of hepatic vein outflow (Hyatt *et al.*, 1955). Because of its origin as hepatic lymph, the protein content of such ascitic fluid may be 3.0 to 3.5 g/dl or higher. This observation is consistent with the finding that the protein content of ascitic fluid in the initial stages of cirrhosis may be higher than that of conventional transudates (a modified transudate) because of its hepatic origin. As progressive fibrosis and "capillarization" of the hepatic sinusoids develop (Bissell and Maher, 1996), the protein content of hepatic lymph decreases and correspondingly the protein content of ascitic fluid decreases. It is probable in cases of cirrhosis that there is increased production of both hepatic lymph and mesenteric lymph and that ascites develops when lymph from both sources fails to return to the systemic venous circulation (Witte *et al.*, 1971a, 1971b). The protein content of ascitic fluid is influenced not only by the relative proportions of mesenteric and hepatic lymph but by the protein concentration of plasma. In advanced cirrhosis, when hypoalbuminemia may be present, the protein content of ascitic fluid can be expected to be proportionately low.

Although experimental portal vein obstruction per se does not result in ascites, only transient portal hypertension is actually produced by this procedure. When persistent portal hypertension is produced experimentally by aortic-portal anastomosis or when such anastomoses occur congenitally, the ascitic fluid is characteristically low in protein content because of its origin in mesenteric capillaries.

Serum albumin is synthesized exclusively in the liver and is the major determinant of plasma and tissue fluid oncotic pressure. Hypoalbuminemia associated with

chronic liver disease has been considered a factor contributing to the development of ascites, but current evidence suggests the role is not primary. The intravascular and total body albumin pools may not be greatly diminished in cirrhosis, although the concentrations of albumin in plasma often are decreased (Rothschild *et al.*, 1973; Witte *et al.*, 1971a, 1971b). For ascites to develop, total body sodium and water must expand. Excessive sodium chloride intake greatly enhances development of ascites (Berman and Hull, 1952), and ascites is preceded by increased sodium retention by the kidney. Aldosterone levels have been shown to be significantly increased in dogs with ascites caused by hepatic vein obstruction (Howards *et al.*, 1968; Orloff *et al.*, 1965).

When associated with liver disease, ascites indicates a chronic process and characteristically presents with cirrhosis. There are important species differences in the occurrence of ascites in chronic liver disease. In dogs with advanced hepatic cirrhosis, ascites is a relatively common sign. Ascites is almost never observed in horses with cirrhosis (Tennant *et al.*, 1975), and conspicuous ascites is unusual in cattle with cirrhosis (Finn and Tennant, 1974; Whitlock and Brown, 1969) but may be observed at necropsy (Pearson, 1977). Ascites has been observed in cattle with thrombosis of the caudal vena cava secondary to liver abscess (Braun *et al.*, 1995), and, in such cases, marked hepatomegaly was characteristic (Breeze *et al.*, 1976; Selman *et al.*, 1974) and due apparently to obstruction of hepatic vein outflow. In sheep, ascites has been observed in cirrhosis but is unusual in cases of severe sclerosing cholangitis associated with fascioliasis (Hjerpe *et al.*, 1971).

It is important clinically to differentiate between ascites caused by liver disease and ascites caused by other primary diseases. Biochemical and cytological examination of ascitic fluid may be useful but alone is seldom diagnostic. The protein concentration of ascitic fluid associated with clinical cirrhosis may be variable depending on the stage of the disease (Center, 1996). In early stages, the protein content may be expected to exceed 2 to 2.5 g/dl because it is a reflection of the high protein content of hepatic lymph but later, when the serum albumin has decreased and when sinusoidal fibrosis and capillarization have developed, the protein content of ascitic fluid will be correspondingly lower (1 to 1.5 g/dl). The ascitic fluid associated with peritonitis is high, whereas in neoplastic diseases of the abdomen, the protein concentration is generally below 1.5 to 2.0 g/dl. Pembleton-Corbett *et al.* (2000) examined the serum albumin/peritoneal effusion albumin (SA/EA) gradient in dogs with ascites. They found the gradient was significantly higher in dogs with liver disease than in those with ascites of other causes. In 25 dogs with abdominal effusions associated with hepatic disease, 23 had serum albumin-effusion albumin (SA/EA) gradients equal to or greater than 1.1 and the median SA/EA gradient was 1.4 (range 0.7 to 3.1). In human patients, SA/EA gradients of 1.1 or greater are considered to indicate the presence of portal hypertension. The clinical observations of Pembleton-Corbett (2000) suggested that portal hypertension is a significant factor in the pathogenesis of ascites in dogs with hepatobiliary disease.

Total nucleated cell counts in ascitic fluid from dogs with cirrhosis are seldom greater than 1000 to 2000 per μl. Bloody or turbid fluid typically results from inflammatory or neoplastic processes (e.g., feline infectious peritonitis, bacterial peritonitis, neoplasia), and nucleated cell counts are elevated. "Bile acites" or bile peritonitis is recognized most frequently in the dog and cat associated with abdominal trauma. In this case, the concentration of bilirubin in peritoneal fluid exceeds that of plasma.

IV. LABORATORY ASSESSMENT OF HEPATIC FUNCTION

The pathogenesis of the hepatic diseases of domestic animal species is remarkably complex, involving acute and chronic forms of hepatitis, cirrhosis, bile duct obstruction, intrahepatic forms of cholestasis, neoplasia, and disorders of hepatic vasculature. The frequency of these diseases varies with species, breed, age, and, in some cases, by environment (diet, geographical location). The differential diagnosis of hepatic disease involves the evaluation of clinical history, physical examination, biochemical tests, hepatic imaging, and histopathological examination of hepatic biopsies. The following section describes the biochemical tests used to assess hepatic disease.

There are several diagnostic categories with which the clinician dealing with problems of liver disease must be concerned. In clinical patients with a history and signs suggestive of hepatic disease, laboratory tests are used for confirmation. Laboratory tests are used to assess the severity of liver injury, to establish prognosis, to define treatable complications of hepatic insufficiency (e.g., ascites, encephalopathy), and to monitor clinical progress. Finally, biochemical tests of hepatic function may be performed on clinically healthy patients that are known to be at high risk of developing liver disease (e.g., exposure to infectious agents that cause hepatitis, or a familial history of chronic liver disease that requires screening for inherited diseases of the liver).

A. Hepatic Enzymes

The presence of liver disease often is recognized on the basis of elevated serum activities of enzymes of hepatic origin. Although they are sometimes referred to as "liver function tests," serum enzymes do not measure hepatic function directly but indicate alteration in the integrity of the cell membrane of the hepatocyte, necrosis of hepatocytes or biliary epithelium, impeded bile formation or bile

flow (cholestasis), or the induction of enzyme synthesis (Center, 2007).

The serum enzymes used in the clinical assessment of hepatobiliary disease have high activity in the liver. In hepatocellular or cholestatic forms of liver injury, these enzymes are released into the serum and the increased activity is used diagnostically. The duration of elevation in serum activity of the enzymes of hepatic origin depends on a variety of factors including molecular size, intracellular location, rate of plasma clearance, rate of enzyme inactivation, and, in some cases (e.g., alkaline phosphatase [AP]) and glutamyltranspeptidase [GGT]), the rate of hepatic synthesis.

The serum enzyme activities that increase when hepatic necrosis is present are alanine aminotransferase (ALT), aspartate aminotransferase (AST), ornithine carbamoyltransferase (OCT), glutamic dehydrogenase (GD), sorbitol dehydrogenase (SDH), and arginase. Elevated serum activities of AP, GGT, and 5′ nucleotidase (5′-ND) are considered to indicate either intrahepatic or extrahepatic cholestasis.

Because of its location between the splanchnic and systemic circulation, the liver is exposed to a wide variety of toxins, drugs and drug metabolites, bacterial toxins, and to infectious agents that may influence the serum activity of enzymes from the liver. The clinical assessment of aberrations in liver enzymes should consider the type of enzyme change (hepatocellular versus cholestatic), the degree of increase in serum enzyme activity, the rate at which the increase or decrease in serum activity occurs, and whether fluctuations in enzyme activity occur over time or if there is a unidirectional pattern of change in enzyme activity. The reference range is characteristically established as that within $+/-2$ standard deviations of the mean value observed in a "normal" animal population. By definition, this means that up to 2.5% of individuals from a "normal" population can be expected to have values above such a reference range.

1. *Serum Alanine and Aspartate Aminotransferases*

The serum activity of the aminotransferases, AST and ALT, are measured to detect hepatocellular injury. These enzymes catalyze the transfer of the α-amino nitrogen of aspartate or alanine to α-ketoglutaric acid resulting in formation of glutamate. AST and ALT have key roles in gluconeogenesis and in formation of urea. In the liver, ALT catalyzes the transfer of the α-amino nitrogen of alanine to α-ketoglutarate forming pyruvate, which can be utilized in gluconeogenesis. In muscle, ALT transaminates pyruvate to form alanine, which then transports non-ionized nitrogen from muscle to the liver for processing (glucose-alanine cycle).

The activity of ALT is higher in the liver than in other tissues and in the dog, hepatic ALT is 10,000-fold higher than in plasma. Hepatic ALT activity is also high in cats, humans, and experimental rodent species in which measurement of serum ALT is used routinely in the assessment of hepatocellular injury. Hepatic ALT activity is lower in horses, cattle, sheep, and swine, and in these species, serum ALT is not measured routinely.

The activity of AST is high in the liver of all domestic species and the serum activity is used routinely in all for evaluation of liver cell injury. However, AST activity also is high in the kidney, heart, and skeletal muscle, so elevations in serum AST are considered less specific for liver disease than elevations in serum ALT.

There are differences in the intracellular distribution of ALT and AST within the hepatocyte. In the dog, most hepatic ALT and AST activity resides within the cytosol. An important fraction of AST (20%) and a lesser component of ALT are present within mitochondria (Keller, 1981). Distribution of the transaminases within the zones of the acinus also differs. ALT has the highest activity in Zone 1 hepatocytes, and AST has the highest activity in Zone 3 hepatocytes and the relative activity of ALT or AST in serum may reflect the acinar zone in which liver injury occurs (Rej, 1989).

The largest increases in serum ALT are observed with hepatocellular inflammation and necrosis. In such conditions, progressive decreases in ALT activity may be a sign of recovery, and a 50% or greater reduction in serum ALT activity over several days is considered a favorable prognostic sign. Some animals with severe hepatic disease, however, may have normal serum ALT activity, and declining serum ALT activity may represent a significant reduction in viable hepatocytes or reduction in transaminase synthesis (e.g., microcystins, aflatoxin).

Following severe, acute hepatocellular necrosis, in the dog serum ALT activity may increase by more than 100-fold within 24 to 48 h, peaking during the first 5 postinjury days. If the source of the injury is eliminated, ALT activity will return more gradually to normal within 2 to 3 weeks. Hepatotoxicity induced by acetaminophen is associated with marked increases in serum ALT followed by a return to near normal values within 72 h (Hjelle and Grauer, 1986; Ortega *et al.*, 1985). Acute hepatocellular necrosis associated with infectious canine hepatitis (adenovirus) results in increased plasma ALT activity of 30-fold, peaking within 4 days (Wigton *et al.*, 1976). Thereafter, a sustained increase in ALT activity may indicate development of chronic hepatitis.

In all domestic species, the activity of AST is high in the liver and serum activity characteristically is increased in acute and chronic liver injury. Because AST activity also is high in the muscle, kidney, pancreas, and erythrocytes, when cells of these tissues are damaged, the AST activity of serum also can be expected to be elevated. There is no

simple, specific, or direct method for determining the origin of increased serum AST activity, but additional laboratory tests may be useful. When AST is increased because of skeletal muscle disease including trauma (e.g., intramuscular injections) or degenerative disease, it may be useful to measure serum creatine kinase (CK). In muscle disease, AST and CK both are expected to be elevated. In acute muscle injury, elevation in the CK activity of serum may occur before AST is maximally elevated, and CK activity characteristically decreases before AST activity fully declines. When coincidental myopathy and liver disease occur in dogs and cats, measurement of serum ALT may be useful, but severe primary muscle disease is sometimes associated with increased serum ALT activity.

Transaminase activity is known to increase following vigorous exercise in dogs (Valentine *et al.*, 1990), but the origin of the enzyme is not clear (Bolter and Critz, 1974; Loegering and Critz, 1971). A 1.4- to 2-fold increase in plasma AST in dogs associated with increases in CK and lactic dehydrogenase has been observed after short-term exercise and similar increases in plasma AST and lactic dehydrogenase activity were detected following electrophysiological stimulation of hind limb muscles (Heffron *et al.*, 1976).

The results of measurement of the half-life of transaminases following intravenous injection of hepatic homogenates have varied widely. In one study, three dogs injected with a 20% liver homogenate and sampled over 3 days, the average $T_{½}$ for AST was 263min and for ALT was 149min (Zinkl *et al.*, 1971). In another study, seven dogs received the supernatant of a liver homogenate intravenously, and a much longer time period was required for clearance with the $T_{½}$ for ALT determined to be 59 ± 9h and for AST 22 ± 1.6h (Dossin *et al.*, 2005). The plasma $T_{½}$ of AST in the cat has been estimated to be 77min (Nilkumhang and Thornton, 1979). Sustained elevations in transaminase in acute liver disease may be the result of delayed clearance. Catabolism of plasma transaminases, in part, is the result of endocytosis by hepatocytes, and enzyme clearance may be delayed because of the underlying hepatic disease (acquired portosystemic shunting, nodular regeneration, hepatic fibrosis; Horuichi *et al.*, 1985; Kamimoto *et al.*, 1985).

The major value of serum AST and ALT measurements is in detecting hepatocellular injury and monitoring clinical progress (Table 13-1). Because both enzymes are increased in a variety of hepatic diseases, they are of limited value for differential diagnosis. Although elevations of the aminotransferases are generally considered indicative of hepatocellular injury, in severe forms of liver disease, both hepatocellular and cholestatic forms of hepatic injury often coexist. The highest aminotransferase levels are associated with acute hepatitic injury, but more modest increases in aminotransferase activity are seen in chronic liver disease including chronic hepatocellular disease, cirrhosis, parasitic hepatopathy, and primary or metastatic neoplasia.

2. *Sorbitol Dehydrogenase*

Because of the relatively low ALT activity in the livers of large domestic species (Cornelius, 1963; Keller *et al.*, 1985), other liver-specific enzymes have been validated for clinical use. One of these, SDH, is a zinc metalloenzyme that is responsible for the conversion of sorbitol to fructose using NAD+ as a cofactor. SDH is one of the enzymes in the polyol pathway believed to have a central role in the pathogenesis of some of the complications of diabetes mellitus (Hoshi *et al.*, 1996; Lee *et al.*, 1995). SDH is found in abundance primarily in the liver and kidney, and the serum activity of SDH (Table 13-2) has been shown to be useful in assessment of hepatocellular injury in most domestic species including the dog (Noonan, 1981; Valentine *et al.*, 1990; Zinkl *et al.*, 1971), horses (Asquith *et al.*, 1980; Bortell *et al.*, 1983; Johnson *et al.*, 2006; Noonan, 1981), and ruminants (Kalaitzakis *et al.*, 2007). Clinically, SDH is used as a liver-specific enzyme primarily for the large domestic species. In dogs and cats, it appears to have no advantage over ALT (Center, 2006). SDH activity is not stable in serum and activity declines rapidly. Therefore, it is necessary to perform the assay for SDH as soon after the sample is taken as possible, optimally within 8 to 12h.

3. *Arginase*

Arginase is responsible for the terminal step of the urea cycle in which arginine is converted to urea and ornithine. In mammals, two isoforms of arginase exist, arginase type I and type II, which are encoded by different genes and differ in tissue distribution, intracellular location, and in molecular and immunochemical characteristics (Grody *et al.*, 1989; Jenkinson *et al.*, 1996). Arginase type I is a cytosolic enzyme (Ikemoto *et al.*, 1990) that is expressed primarily in the liver where it has a key role in urea synthesis. Arginase

type II is a mitochondrial enzyme that is expressed in most tissues including the kidney (Morris *et al.*, 1997; Shi *et al.*, 1998). Type II arginase appears to control the availability of the arginine used for nitric oxide synthesis (Gotoh and Mori, 1999) and has an important role in the synthesis of ornithine, which is a precursor of polyamines, glutamate, and proline (Jenkinson *et al.*, 1996).

Because the activity of arginase in liver is higher than in other organs (Aminlari and Vaseghi, 1992; Aminlari *et al.*, 2007), elevations in serum arginase activity have been considered to be liver specific (Cornelius *et al.*, 1963; Dittrich *et al.*, 1974) and a convenient assay has been validated for measurement (Mia and Koger, 1978). Following acute liver injury, serum arginase increases and then decreases rapidly (Aminlari *et al.*, 1994; Cornelius *et al.*, 1963). Sustained elevation in serum arginase activity suggests an unfavorable prognosis. Elevations in serum arginase have been demonstrated in naturally occurring liver disease of horses (Wolf *et al.*, 1967), cattle, sheep (Ross, 1966), goats, and dogs (Harvey and Hoe, 1971). When serum arginase and GGT activities are measured simultaneously, their respective specificities for hepatocellular injury and cholestasis can be useful (Noonan and Meyer, 1979).

4. *Glutamate Dehydrogenase*

GD is a mitochondrial enzyme with a key role in the detoxification of ammonia. GD serves as an ammonia scavenger by catalyzing the amination of α-ketoglutarate to form glutamate. Glutamate produced by GD is converted by mitochondrial AST to aspartate, which is urea synthesis. Glutamate also is used in the mitochondrial synthesis of N-acetylglutamate, the allosteric activator of carbamoyl phosphate synthase that is the enzyme responsible for the first step in urea synthesis (Caldovic and Tuchman, 2003; Caldovic *et al.*, 2006; Nissim *et al.*, 2003).

GD has been shown to be useful in the assessment of hepatic necrosis in sheep, goats, and cattle (Table 13-3). GD activity is highly concentrated in ovine and bovine liver (Keller, 1971) as well as in the liver of other domestic species (Keller *et al.*, 1985). Elevated GD activity has been reported in ruminants with hepatic necrosis (Fowler, 1971), associated with parturition (Treacher and Collis, 1977) and with obstruction of the bile duct (Ford and Gopinath, 1976).

5. *Ornithine Carbamoyltransferase*

OCT catalyzes the reaction between ornithine and carbamoyl phosphate forming citrulline and inorganic phosphate. The enzyme is located in mitochondria and functions as a part of the urea cycle. OCT is considered a liver-specific enzyme for the detection of hepatocellular necrosis in domestic species (Treacher and Sansom, 1969). Nearly all OCT activity is confined to the liver of cattle (Treacher and Collis, 1977) and of pigs (Dittrich *et al.*, 1974). OCT and ALT are similar in sensitivity as diagnostic tests for hepatic necrosis in the dog. A similar association of OCT with hepatocellular injury has been observed in swine (Wilson *et al.*, 1972), and Markiewicz *et al.* (1975) have reported that serum OCT activity is correlated with the severity of hepatic fascioliasis in cattle.

6. *Serum Alkaline Phosphatase*

The APs are a group of zinc metalloenzymes that are present in most tissues. High concentrations are found in the intestine, kidney, bone, and liver. Light and electron microscopic studies have demonstrated that alkaline phosphatase activity is highest on the absorptive or secretory surfaces of cells (Kaplan, 1972). Within liver cells, alkaline phosphatase is bound to membranes and AP activity sediments with the microsomal and plasma membrane fractions (Emmelot *et al.*, 1964).

The actual physiological functions of alkaline phosphatase are not fully understood. Localization of the enzyme to cell surfaces known to be responsible for active absorption or secretion suggests a role in membrane transport. There is evidence suggesting that the alkaline phosphatase of

osteoblasts may be involved in bone calcification. Activity against both natural and synthetic nucleotides suggests a role in nucleic acid metabolism.

In normal animals, the AP of serum (Table 13-4) originates primarily from liver and bone (Hoffman and Dorner, 1975; Rogers, 1976). Elevations of serum AP are observed in normal growing animals or in adult animals with increased osteoblastic activity. Serum AP activity may be elevated in acute and chronic liver diseases. More marked elevations indicate cholestasis, with the highest serum AP activities observed in animals with cholangitis, biliary cirrhosis, or extrahepatic bile duct obstruction.

The isozymes of alkaline phosphatase from various tissues may be differentiated on the basis of differences in heat stability, urea denaturation, inhibition by L-phenylalanine, or by electrophoretic mobility (Nagode *et al.*, 1969a, 1969b; Ruegnitz and Schwartz, 1971). Alternatively, the origin and significance of elevated serum AP may be determined by measuring other related serum enzymes that are specific for biliary tract disease. These include leucine aminopeptidase (Everett *et al.*, 1977), 5′/NT (Righetti and Kaplan, 1972), and GGT. When serum AP is significantly elevated, overt clinical signs may allow separation of diseases of the liver from those of tissues such as bone.

Unlike serum AST and ALT, elevations in AP are not due simply to leakage of enzyme from damaged cells. It was once believed that the high AP level of serum observed in cholestatic liver disease was the result of decreased biliary excretion of the enzyme because bile contains a great deal of AP activity. It now is known that experimental obstruction of bile flow stimulates *de novo* synthesis of hepatic AP (Kaplan and Righetti, 1969, 1970), and the newly synthesized enzyme is refluxed into the circulation. Partial hepatectomy also stimulates increased synthesis of AP in the regenerating liver (Pekarthy *et al.*, 1972). It seems likely that increased synthesis of AP is involved in clinical extrahepatic bile duct obstruction, in intrahepatic cholestasis, in infiltrative diseases of the liver (e.g., lymphoma, hepatic metastases) in which terminal branches of the biliary tree may be obstructed, and in the regenerative processes that occur following liver injury.

There are significant species differences in the magnitude of elevation of serum AP activity in bile duct obstruction (Fig. 13-2). It has been recognized that cats differed from dogs because in cases of extrahepatic bile duct obstruction in cats there was inconsistent or negligible elevation of AP. This was thought to be due to urinary excretion of AP. Other studies have established that cholestatic liver disease in cats can be expected to cause modest but significant elevations in AP (Everett *et al.*, 1977), and induction of alkaline phosphatase synthesis following bile duct obstruction occurs in cats as it does in other species (Sebesta *et al.*, 1964).

In dogs, three AP isoenzymes (intestinal, steroid induced, and hepatic) have been identified (Wellman *et al.*, 1982b). Two genes appear to be responsible for AP production in dogs (Hoffmann and Dorner, 1977; Solter and Hoffmann, 1995, 1999). The first is the AP gene responsible for the AP isoforms of the liver, bone, and kidney in which differences in posttranslational processing are responsible for differences in glycosylation patterns (Solter and Hoffmann, 1995). The second gene codes for intestinal AP and is specific for the AP isoenzyme of the intestinal mucosa (Solter and Hoffmann, 1995). AP can be induced in dogs, but not in cats, by endogenous or exogenous steroidogenic hormones and the steroid-induced isoenzyme is of hepatic origin (Wellman *et al.*, 1982a). Increased serum activity of the hepatic AP isoenzyme in cholestasis is due to enhanced translation and not to increased gene expression (Seetharam *et al.*, 1986). Hepatic AP enters the serum either from the biliary canaliculus via the paracellular shunt pathway or is derived directly from plasma membranes. Increased bile acid concentrations associated with cholestasis are believed to contribute to the release and transport of solubilized hepatic AP to the serum (Everett *et al.*, 1977; Sanecki *et al.*, 1987, 1990; Schlaeger *et al.*, 1982).

Although measurement of serum GGT activity has the advantage of specificity, total serum AP activity remains the test most often performed in the assessment of cholestasis in horses, dogs, and cats. Serum AP is less valuable in the evaluation of cholestatic syndromes of cattle and sheep because of wide fluctuations in normal AP activity (Ford, 1958; Harvey and Hoe, 1971).

Pig	35 ± 21	Rico *et al.* (1977c)
Piglet (8 weeks)	16 ± 8	Enigk *et al.* (1976)

Increases in serum AP have been described in a variety of canine cholestatic liver diseases (Abdelkader and Hauge, 1986; Center *et al.*, 1985b; Hoe and Jabara, 1967; Solter and Hoffmann, 1995, 1999). Modest increases in serum AP occur with hepatic necrosis (Noonan and Meyer, 1979). Following the experimental production of hepatic necrosis in dogs, the serum activities of arginase, ALT, and AP increase within 1 day, a time point at which GGT is not elevated. Following bile duct obstruction, the serum activity of both AP and GGT increases remarkably along with moderate elevations in ALT and AST, but arginase activity does not increase. This has suggested that arginase (for necrosis) and GGT (for cholestasis) may have the highest specificity in evaluating the type of hepatobiliary disease in the dog (Noonan and Meyer, 1979). Although serum GGT activity may be less affected during hepatocellular necrosis than AP, GGT activity may not be as highly elevated as AP in bile duct obstruction (Guelfi *et al.*, 1982).

7. γ-Glutamyltranspeptidase

GGT is a membrane-bound enzyme that catalyzes the transfer of γ-glutamyl groups from γ-glutamylpeptides such as glutathione to other amino acids or peptides. Glutathione and glutathione conjugates are the most abundant physiological substrates (Hanigan, 1998). GGT is found primarily in cells with high rates of secretion or absorption, and significant GGT activity is present in the liver, kidney, pancreas, and intestine. GGT is considered a serum marker primarily for diseases of the hepatobiliary system associated with cholestasis (Table 13-5; Braun *et al.*, 1983) and is in general used for the diagnosis of liver diseases of animals (Table 13-6). GGT activity is relatively high in the livers of cows, horses, sheep, and goats, but GGT activity is considerably lower in the livers of dogs and cats. Although activity is present in many tissues and is high in the kidney, remarkable elevations in serum GGT activity are observed primarily in diseases of the liver. Urinary excretion of GGT, however, has been measured to assess renal injury (Ford, 1974; Shaw, 1976).

In experimental bile duct obstruction, serum GGT activity is increased significantly in the dog (Noonan and Meyer, 1979; Shull and Hornbuckle, 1979), sheep (Ford, 1974), and cattle. The sensitivity of GGT has been reported to be similar to that of AP as an indicator of cholestasis in the cat (Spano *et al.*, 1983; Zawie and Garvey, 1984). Within a given species, there often is a direct relationship between the activities of serum GGT and serum AP in cholestatic liver injury. In primary hepatocellular disease, elevations in GGT characteristically are not increased as remarkably as AP (Meyer, 1983).

Acute exposure to oxidative stress increases GGT transcription, indicating that expression is an adaptive response protecting the cell from oxidative injury. Although increased enzyme synthesis contributes to elevated serum GGT activity in hepatocellular injury, elevations in cholestatic disorders are believed to be, in part, related to

mobilization ("solubilization") of GGT from its membrane anchor related to elevated levels of bile salts (Center, 2007).

Highest tissue levels of GGT in the dog and cat are present in the kidney and pancreas with lesser amounts in the liver, gallbladder, intestines, spleen, heart, lungs, skeletal muscle, and erythrocytes (Badylak *et al.*, 1982; Braun *et al.*, 1983; Guelfi *et al.*, 1982). The activity of GGT in serum is derived primarily from the liver although, as stated previously, there is considerable species variation in GGT activity within this organ. Hepatic localization has been demonstrated in the canaliculus, in bile ducts, and in Zone 1 hepatocytes (Aronsen *et al.*, 1968; Braun *et al.*, 1983; Center, 2005).

The diagnostic value of GGT has been assessed in clinical patients with and without liver disease (Center *et al.*, 1986, 1992; Guelfi *et al.*, 1982). Experimental studies in dogs and cats undergoing acute, severe diffuse necrosis have shown either no change in serum GGT or only mild increases in activity (1- to 3-fold normal) that resolve over the ensuing 10 days. In the dog, extrahepatic bile duct obstruction causes serum GGT activity to increase 1- to 4-fold within 4 days, and 10- to 50-fold within 1 to 2 weeks. Thereafter, values may plateau or continue to increase as high as 100-fold that of normal (Guelfi *et al.*, 1982; Kokot *et al.*, 1965; Noonan and Meyer, 1979). In the cat with extrahepatic bile duct obstruction, serum GGT activity may increase up to 2-fold within 3 days, 2- to 6-fold within 5 days, and 4- to 16-fold that of normal within 2 weeks (Meyer, 1983; Spano *et al.*, 1983).

Glucocorticoids and certain other microsomal enzyme inducers may stimulate production of GGT in the dog similar to the influence of such drugs or other xenobiotics on AP. Administration of dexamethasone (3mg/kg SID) or prednisone (4.4 mg/kg SID IM) increased GGT activity within 1 week 4- to 7-fold and up to 10-fold within 2 weeks (Badylak and Van Vleet, 1981, 1982; Stein *et al.*, 1989). It is assumed that the increased production of GGT following glucocorticoid administration originates in the liver. In comparison to glucocorticoid induction, dogs treated with the anticonvulsants phenytoin or primidone develop only modest increases in serum GGT activity up to 2- or 3-fold that of normal unless they develop serious anticonvulsant hepatotoxicosis (Bunch *et al.*, 1985, 1987).

Some cats with advanced necroinflammatory liver disease, major bile duct obstruction, or intrahepatic cholestasis develop relatively greater increases in GGT than in AP activity (Center *et al.*, 1986). In other species, cholestasis is known to enhance enzyme synthesis as well as membrane release of GGT. It remains undetermined whether glucocorticoids or other enzyme inducers increase the expression of GGT in cats. It is noteworthy that the normal range for feline serum GGT activity is narrower and lower than that of the dog, so the interpretation of feline GGT activity

using the canine reference range will lead to erroneous conclusions. Additionally, because of the comparatively low serum GGT activity of cats, assay sensitivity may be a problem and low GGT activity may be undetectable.

Remarkable elevations of serum GGT have been observed in dogs and cats with primary hepatic or pancreatic neoplasia. Although a unique GGT isozyme is associated with hepatocellular carcinoma in humans, it has not been determined that a similar phenomenon occurs in dogs or cats. In humans, GGT also is used in surveillance for hepatic metastasis but is not suitable for this application in either the dog or the cat.

Neonatal animals of several species develop elevated levels of serum GGT activity following the ingestion of colostrum. In neonatal calves, the direct relationship between serum GGT activity and immune globulin levels allows serum GGT activity to serve as a surrogate for successful passive immune transfer (Parish *et al.*, 1997; Perino *et al.*, 1993). Similar transient neonatal elevations of serum GGT are observed following ingestion of colostrum by neonatal lambs (Maden *et al.*, 2003; Tessman *et al.*, 1997), crias (Johnston *et al.*, 1997), and pups (Center *et al.*, 1991b) but apparently not kittens (Crawford *et al.*, 2006; Levy *et al.*, 2006).

B. Serum Bilirubin

Bilirubin in serum is measured by the van den Bergh or "diazo" reaction in which bilirubin is coupled with diazotized sulfanilic acid. Azo pigments produced by this reaction are dipyrroles that are stable, and this characteristic has been useful in studies of the structure of bilirubin conjugates. Conjugated bilirubin, which is water soluble, reacts promptly with diazotized sulfanilic acid in aqueous solution (the van den Bergh "direct reaction"), but unconjugated bilirubin reacts slowly. Only after addition of an accelerator such as methanol or ethanol to the aqueous solution can the diazo reaction with unconjugated bilirubin be completed ("the indirect reaction"). It is said that approximately 10% of the unconjugated bilirubin in plasma can react with the diazo reagent giving a false "direct" reaction.

The requirement of an organic solvent for the diazo reaction with unconjugated bilirubin to occur suggests the delay was related to water insolubility. There is evidence, however, that intramolecular hydrogen bonding may be more important than aqueous solubility in determining the reaction of unconjugated bilirubin with the diazo reagent (Fog and Jellum, 1963; Nichol and Morrell, 1969). The two propionic acid side chains of bilirubin that are esterified with glucuronic acid or other carbohydrates disrupt intramolecular hydrogen bonding (Fog and Jellum, 1963) and allow the direct diazo reaction to occur. Accelerators of the *van den Bergh* reaction may have a similar effect on the intramolecular hydrogen bonds of unconjugated bilirubin.

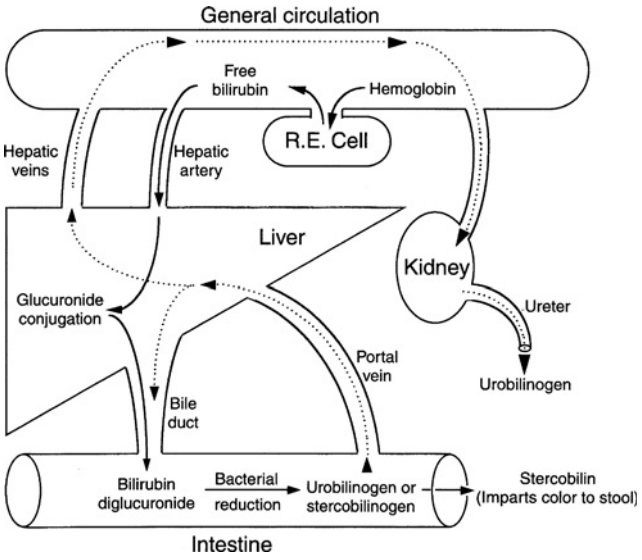

FIGURE 13-3 Normal formation, excretion, and enterohepatic circulation of bilirubin and other bile pigments.

The following is a discussion of the physiologic mechanisms of bilirubin conjugation and interpretation of the Van den Bergh reaction. There are limitations in clinical application, however, because of differences that exist in duration and severity between the spontaneous liver diseases of domestic animals and experimental liver disease models. Figure 13-3 summarizes the normal production and excretion of bilirubin and other bile pigments. Unconjugated hyperbilirubinemia is observed when there is increased production of bilirubin (e.g., hemolytic anemia) or when either hepatic uptake or conjugation of bilirubin is diminished. Although the unconjugated bilirubin of serum may be significantly increased in such disorders, essentially none of the albumin bound unconjugated bilirubin is filtered by the glomerulus. Consequently, bilirubinuria is not characteristic in animal patients with unconjugated hyperbilirubinemia. In hemolytic disease, the amount of bilirubin excreted by the liver and, therefore, the amount that reaches the intestine may be remarkably increased. This results in increased formation and urinary excretion of urobilinogen (Fig. 13-4).

Hyperbilirubinemia of the conjugated type is caused either by intrahepatic cholestasis (Fig. 13-5) or extrahepatic bile duct obstruction (Fig. 13-6). When the primary defect is impaired excretion of bilirubin into bile, hepatic uptake and conjugation may proceed at a relatively normal rate, but conjugated bilirubin is effluxed into the plasma. The plasma concentration of conjugated bilirubin increases, and the conjugated pigment, which is less avidly bound to albumin, is readily filtered by the glomerulus, resulting in bilirubinuria (Fulop *et al.*, 1965; Laks *et al.*, 1963). Because bilirubin excretion into the intestine is either significantly reduced or absent in cholestasis, formation of urobilinogen

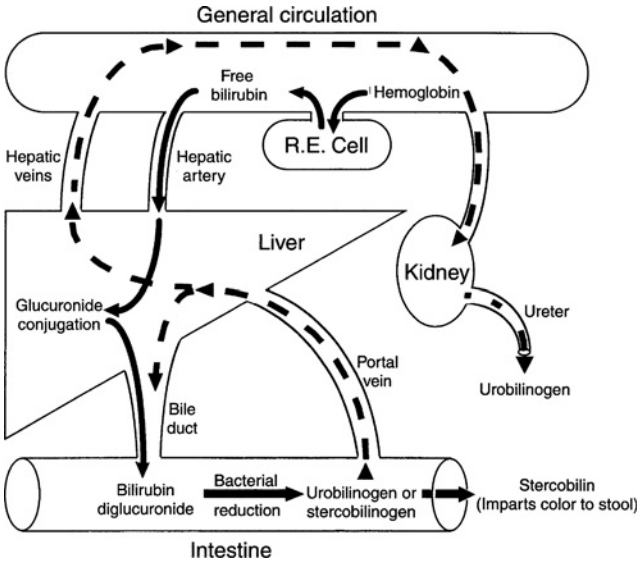

FIGURE 13-4 Formation, excretion, and enterohepatic circulation of bilirubin and other bile pigments associated with overproduction of bilirubin as a result of hemolysis.

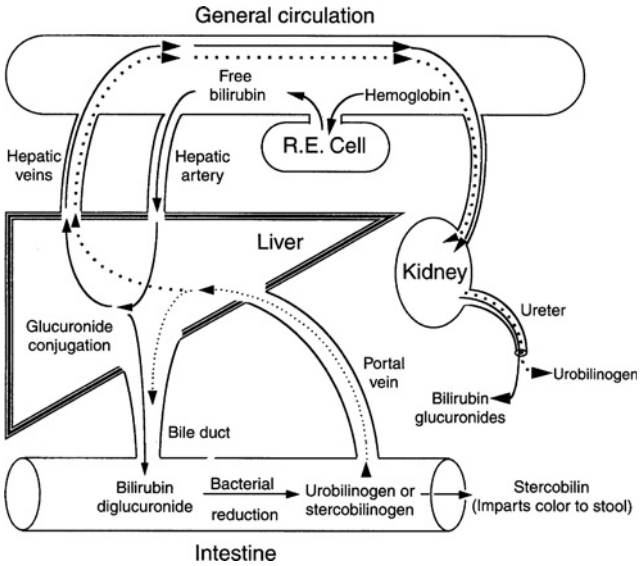

FIGURE 13-5 Formation, excretion, and enterohepatic circulation of bilirubin and other bile pigments associated with hepatocellular injury and intrahepatic cholestasis.

by intestinal bacteria is remarkably reduced, and the test for urinary urobilinogen is characteristically negative in complete extrahepatic obstruction (Fig. 13-6). The therapeutic administration of oral, broad-spectrum antibiotics to patients may diminish the metabolic activity of intestinal bacteria and result in a spuriously negative test for urobilinogen in the urine in the absence of cholestasis.

The biochemical differentiation between unconjugated and conjugated hyperbilirubinemia using the van den Bergh reaction can be useful in the assessment of prehepatic or posthepatic causes of hyperbilirubinemia. In severe primary hepatitic diseases of varying cause, the excretory steps of uptake, conjugation, and excretion all may be deranged and result in elevations of both conjugated and unconjugated pigment.

Important species characteristics should be considered when interpreting results of the van den Bergh reaction. In general, the interpretation in dogs and cats is similar. Typically, in cholestatic disease, the conjugated fraction is elevated, representing 50% to 75% of the total serum bilirubin (Fig. 13-7). The normal horse has a much higher total serum bilirubin than any of the other domestic species (Fig. 13-8), and values as high as 4.0 mg/dl or higher have been observed in otherwise healthy individuals. In addition to hepatic and hemolytic diseases, hyperbilirubinemia is observed in horses with intestinal obstruction and in a variety of other serious systemic diseases. Food restriction alone causes an abrupt increase in the unconjugated serum bilirubin of the horse (Gronwall and Mia, 1972; Tennant *et al.*, 1975), and decreased bile flow is a probable factor of the hyperbilirubinemia observed in fasting horses (Fig. 13-9).

In cattle and sheep, hyperbilirubinemia of sufficient magnitude to produce clinical icterus (≥3mg/dl) is caused

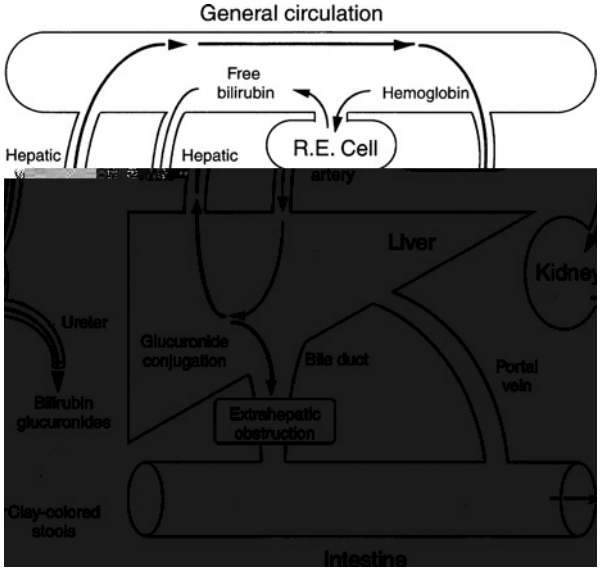

FIGURE 13-6 Formation, excretion, and enterohepatic circulation of bilirubin and other bile pigments in extrahepatic bile duct obstruction.

most frequently by hemolytic disease. Biochemical hyperbilirubinemia (1 to 2mg/dl) without clinical icterus may be observed in sheep and in cattle with fatty liver associated with ketosis/acetonemia, and in such cases, the predominant pigment is unconjugated bilirubin. Greater elevations in serum bilirubin and clinical icterus in ruminants associated with fatty liver and ketosis are unusual. Mild to moderate conjugated hyperbilirubinemia has been observed in sheep with sclerosing cholangitis caused by *Fasciola hepatica* infestation (Hjerpe *et al.*, 1971) and in cattle with hepatic cirrhosis (Finn and Tennant, 1974).

C. Serum Bile Acids

Synthesis of the primary bile acids is the principal pathway for catabolism of cholesterol. Multiple enzymatic

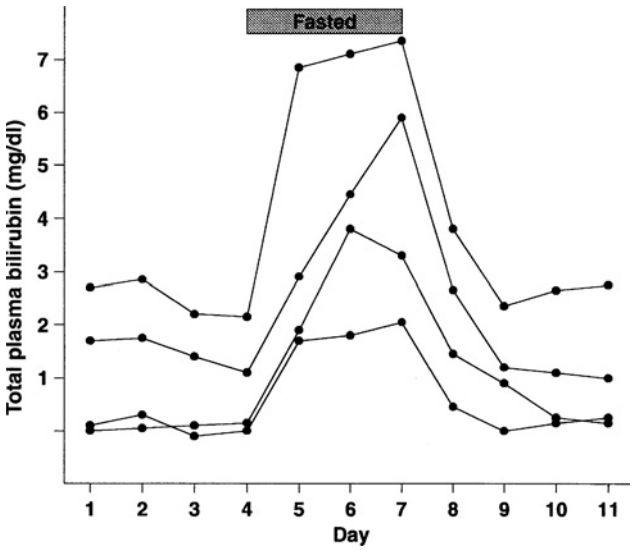

FIGURE 13-9 Serum bilirubin of horses before, during, and following a 3-day period of total fasting.

steps are required for hepatic synthesis of the primary bile acids of most species, cholic acid and, chenodeoxycholic acid (Fig. 13-10). In swine, hyocholic acid is derived in the liver from chenodeoxycholic acid and is the major primary bile acid of swine. The classic pathway of bile acid synthesis is initiated by the liver-specific enzyme, cholesterol 7α-hydroxylase (CYP7A1), which converts cholesterol to 7α-hyroxycholesterol. This is the initial, rate-limiting step in the synthesis of cholic acid. Alternate pathways are recognized that are initiated by (1) sterol 27-hydroxylase (CYP27), an enzyme expressed in the liver and in multiple other tissues; (2) cholesterol 25-hydroxylase that is present in the heart, lung, and kidney; or (3) cholesterol 24-hydroxylase (CYP46) that is present primarily in the brain. Oxysterols produced by these three enzymes are transported by the circulation to the liver where 25- and 27-hydroxycholesterol are hydroxylated further by an oxysterol 7α-hydroxylase (CYP7B1) and where 24-hydroxycholesterol is hydroxylated by another 7α-hydroxylase (CYP39A1). The 7α steroids produced by the alternate pathways are preferentially utilized as precursors of chenodeoxycholic acid (Beigneux *et al.*, 2002). In knockout mice in which the CYP7A1 gene is missing (CYP7A1[-/-]), CYP7A1 activity was not detectable, but total oxysterol 7α-hydroxylase activity in CYP7A1(-/-) mice was similar to that of controls. Bile acid synthesis in CYP7A1(-/-) mice was remarkably reduced and total bile acid secretion was diminished. Because oxysterol 7α-hydroxylase activity was not elevated in CYP7A1(-/-) mice, the results suggested that in normal mice the alternate pathway may account for as much as 40% of total bile acid synthesis (Schwarz *et al.*, 1998).

Following synthesis, primary bile acids are conjugated either with taurine or glycine and transported across the bile canalicular membrane primarily by the bile salt export

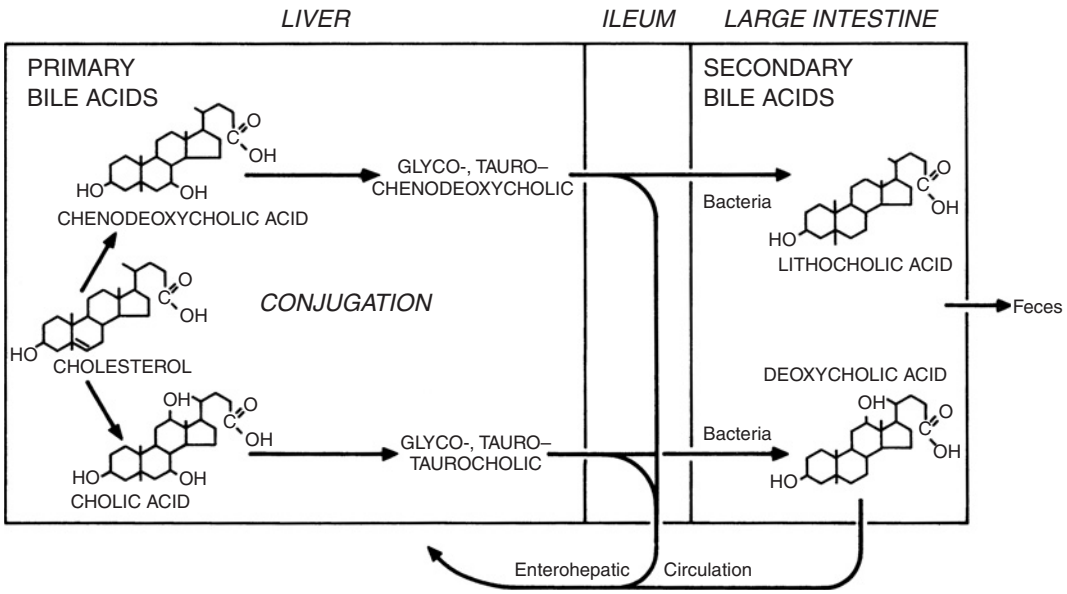

FIGURE 13-10 Metabolism of bile acids in the liver and intestinal tract. The primary bile acids are formed in the liver and the secondary bile acids in the large intestine.

pump (BSEP, Sister of P-glycoprotein [Spgp], ABCB11) a multidrug resistance P-glycoprotein that belongs to the ATP-binding cassette (ABC) superfamily of transport proteins. The sodium and ATP-mediated BSEP carrier determines the bile salt dependent fraction of canalicular bile flow. The important bile salt independent fraction of bile flow is determined by canalicular MrP2 which is responsible for transport of glutahione, glutathione conjugates, and conjugates of glucuronic acid including bilirubin glucuronide. In the dog, horse, and sheep, taurine conjugates of bile acids predominate, and in the cat, bile acids are conjugated exclusively with taurine. In cattle, the bile is rich in taurine conjugated bile acids and contains glycine conjugates of chenodeoxycholate and deoxycholate (Haslewood, 1967). Bile acids are transported from the canaliculus through bile ducts to the lumen of the duodenum. In the duodenum and jejunum, bile acids have an important role in the digestion and absorption of dietary fat and other lipids including fat-soluble vitamins.

In the terminal ileum, almost all of the bile acids secreted by the liver are absorbed by highly efficient transport mechanisms of the ileal epithelium and enter the hepatic portal vein (the enterohepatic circulation; see Chapter 14). Normally, only a small fraction (5%) of the bile acids that enter the duodenum reach the large intestine where bacteria are responsible for deconjugation and for the formation of secondary bile acids by dehydroxylation. Dehydroxylation of cholic acid at the 7α position results in formation of deoxycholic acid, and 7α dehydroxylation of chenodeoxycholic acid results in production of lithocholic acid. The secondary bile acids formed in the large intestine may be absorbed and return to the liver by the enterohepatic circulation or excreted in the feces.

Taurocholate is the major bile acid of mice and rats. These species have the unique capacity to rehydroxylate deoxycholate at the C-7α position in the liver to reform cholic acid (Haslewood, 1967). The entire bile acid pool passes from the liver to the intestine and back to the liver via the enterohepatic circulation several times each day and under steady state conditions, approximately 5% of the bile acid pool is lost and replaced by hepatic synthesis.

The primary and secondary bile acids are transported to the liver via the hepatic portal vein and are transferred across the sinusoidal (basolateral) cell membrane of the hepatocyte by the NTCP, which is responsible primarily for the absorption of conjugated bile acids or by the sodium-independent OATP. Following entry, unconjugated bile acids are conjugated with taurine or glycine, are bound to cytosolic bile acid binding proteins, and finally are transferred actively across the bile canaliculus by the BSEP. Cholestasis may be caused by drugs that inhibit BSEP and by hereditary defects of BSEP that prevent BSEP expression and result in severe progressive familial intrahepatic cholestasis in which the bile contains almost no bile acids (Alrefai and Gill, 2007).

The canalicular Mrp2 transporter, which has a primary role in the excretion of bilirubin conjugates, BSP, and a wide range of glutathione, glucuronic acid, and sulfate conjugates (see Section III.A.2), mediates the canalicular transport of bile acid conjugates of sulfate or glucuronic acid but lacks the capacity to transport monovalent bile acids (Ito *et al.*, 2001; Trauner and Boyer, 2003). The canaliculus also contains the multidrug resistance 2 P-glycoprotein (Mdr2), which is responsible for the transport of cholesterol and phospholipids into bile. Defects in the Mdr2 gene product or the absence of Mdr2 in the canaliculus results in

cholestatic liver injury and in susceptibility to development of hepatocellular carcinoma (Mauad *et al.*, 1994). Finally, Mdr1 that is present in the canaliculus is responsible for transport of organic cations (Trauner and Boyer, 2003).

In cholestasis, bile acids may accumulate in hepatocytes and their toxicity may cause cell death (Webster *et al.*, 2002; Webster and Anwer, 1998, 2001). In cholestatic syndromes, expression of the multidrug resistance-associated protein 3 (Mrp3), another ABC transporter located in the sinusoidal plasma membrane, is increased. Mrp3 has broad affinity for organic anions, has the capacity to excrete both mono- and divalent bile acids (Hirohashi *et al.*, 2000; Ito *et al.*, 2001), and is believed to compensate for impaired function of BSEP or Mrp2 in cholestatic syndromes (Bohan *et al.*, 2003; Chen *et al.*, 2007).

In liver disease, synthesis of primary bile acids may be decreased, the proportions of cholic acid and chenodeoxycholic acid may be altered, or unusual bile acids may be produced. Removal of bile acids from the hepatic portal vein may be diminished by impaired hepatocellular function or by vascular shunts, which divert portal blood from the liver vasculature to the peripheral circulation. This is particularly noticeable after meals in animals with congenital or acquired hepatoportal shunts. The plasma bile acid concentration is increased continuously in biliary obstruction and, characteristically, urinary excretion of bile acids is increased. Increases in the serum bile acid concentration are seen in many forms of hepatic disease.

The measurement of total serum bile acids for assessment of liver disease has been greatly facilitated by development of a spectrophotometric assay that has now been validated for use in most domestic species. The predictive value of the serum bile acid test is remarkably high in the dog (Center, 1993; Center *et al.*, 1984, 1991a). In dogs with portocaval vascular shunts, the fasting serum bile acid concentration may be within normal limits but is increased diagnostically 2 h following a meal (Center *et al.*, 1985a). Serum bile acid concentrations $\leq$20 μM/L in cats and $\leq$25 μm/L in dogs are predictive of significant histopathological abnormalities of the hepatobiliary system or of portosystemic vascular anastomoses (Center *et al.*, 1991a, 1995).

The serum bile acid concentration has been used to assess clinical hepatic function in cattle (Craig *et al.*, 1992; Garry *et al.*, 1994; Pearson *et al.*, 1992; West, 1991) and in horses (Barton and LeRoy, 2007; Durham *et al.*, 2003; McGorum *et al.*, 1999). In the horse, fasting alone has been reported to increase the plasma bile acid concentration by decreasing hepatic clearance (Engelking and Gronwall, 1979), so in the horse it is necessary to consider food intake when interpreting the serum bile acid values.

D. Serum Proteins

The liver is the exclusive site of synthesis of albumin, the most abundant of the plasma proteins. Unlike most plasma proteins, which are glycoproteins, albumin contains no carbohydrate. Degradation of albumin occurs in the liver and in other tissues including muscle, kidney, and skin. Degradation of albumin is probably favored in the liver because of the fenestrated endothelial lining cells that allow access of plasma proteins directly to the space of Disse and to the sinusoidal surface of the hepatocyte. In the general circulation, albumin has two major functions. It is the most important determinant of plasma oncotic pressure (colloid osmotic pressure) and is a major transport protein for hydrophobic or amphophilic metabolites and xenobiotics that, because of albumin binding, remain in stable aqueous solution in the plasma.

The plasma albumin concentration is determined by the hepatic synthetic rate that normally is in equilibrium with degradation. Hypoalbuminemia may be caused by defective albumin synthesis associated with severe hepatocellular disease or may be caused by increased albumin loss resulting from either glomerulopathy (protein-losing nephropathy), severe intestinal inflammation, or intestinal lymphangiectasia (protein-losing enteropathy). In severe, chronic hepatopathy, there is a tendency for elevations in IgM, IgG, and IgA. Both decreased albumin and increased globulin result in a decrease in the albumin/globulin (A/G) ratio.

The liver is the exclusive site of synthesis of coagulation factors I (fibrinogen), II (prothrombin), V, VII, IX, X, XI, and of protein C, protein S, and antithrombin. Factor VIII is synthesized both in the liver and in multiple other organs including the kidney and spleen (Hollestelle *et al.*, 2001; Wion *et al.*, 1985). Synthesis of coagulation proteins tends to be diminished in liver disease, and decreased plasma prothrombin synthesis is associated with a corresponding increase in the prothrombin time. Factors that contribute to increased prothrombin time include diminished hepatic protein synthesis, increased consumption of clotting factors associated with hemorrhage or hypercoagulation states, and, in some cases, vitamin K deficiency related to decreased intake or diminished absorption. Vitamin K is essential not only for the hepatic synthesis of prothrombin but also for factors VII, IX, X, and protein C. Parenteral administration of vitamin K to individual animal patients may result in improvement in prothrombin time, but coagulation time may remain prolonged. Individuals with obstructive jaundice absorb vitamin K poorly, and defects in their clotting tests can be improved rapidly by parenteral vitamin K administration. Fibrinogen is an acute phase reactant, and its concentration in plasma may be greatly increased in chronic inflammatory diseases or in neoplasia. Plasma fibrinogen is generally normal in mild or moderate liver disease, but it may be detectably decreased in more severe acute or chronic liver disease. Because of the rapid turnover of fibrinogen and prothrombin, the concentrations of these proteins in the plasma may decrease rapidly in fulminant hepatic injury. The turnover rate of albumin is longer and the concentration of albumin

is diminished primarily in chronic liver disease in which there is significant loss of hepatocellular mass.

Measurement of protein C has been validated for use as a biomarker for the assessment of experimental liver injury (Saha *et al.*, 2007), and when combined with other conventional laboratory tests, it was shown to be of value in the recognition of portosystemic shunts and other severe clinical forms of hepatobiliary disease in dogs (Toulza *et al.*, 2006).

Plasmin, a serine protease synthesized by the liver, is necessary for the degradation of fibrin. Antithrombin has potent protease activity against thrombin, plasmin, and other coagulation factors, and its primary physiological function is to modulate the activity of thrombin. Heparin enhances the inhibition of thrombin by antithrombin.

The complement system plays a critical role in the inflammatory response and in host defense mechanisms against infection, and most of the plasma proteins of the complement system are synthesized in the liver. *De novo* synthesis of C2, C3, C4, factor B, and other complement proteins has been demonstrated in cultured mammalian hepatocytes (Anthony *et al.*, 1985; Ramadori *et al.*, 1986). The liver also is the site of synthesis of the protease inhibitor α-1-antitrypsin, a major plasma protein that inhibits serine proteases including granulocyte elastase, and α-2-macroglobulin, an inhibitor of a variety of other proteases.

E. Dye Excretion

The rate of removal of organic anions can be measured and used to assess the functional capacity of the liver and hepatic blood flow. Sulfobromophthalein (BSP, bromsulphalein; Fig. 13-11) and indocyanine green (ICG; Fig. 13-12) have been used most frequently to assess hepatic function. Following bolus intravenous administration, these dyes are removed rapidly from the plasma primarily by the liver and excreted in the bile. Delayed plasma clearance is taken to be indicative of abnormal hepatocellular or biliary tract function or hepatic circulation (Center *et al.*, 1983c).

The overall process of hepatic excretion of BSP is similar but not identical to that of bilirubin. Hepatic uptake of BSP across the sinusoidal plasma membrane is facilitated primarily by sodium-independent OATP, but the sodium-dependent NTCP also may contribute significantly (Hagenbuch *et al.*, 1996; Hata *et al.*, 2003). Within the cell, BSP competes with other organic anions for binding to cytosolic ligandin, which by serving as an ion "sink" is a driving force for hepatic uptake (Levi *et al.*, 1969). The conjugation mechanisms for bilirubin and BSP are completely separate. BSP is conjugated with glutathione by action of the cytosolic enzyme glutathione-S-aryl transferase-B. Although conjugation appears to facilitate BSP excretion, it is not a required step because approximately 50% of the BSP in bile is unconjugated. The canalicular transport of BSP is similar to that of conjugated bilirubin and involves Mrp2.

Hepatic uptake of ICG is similar to that of BSP, but canalicular transport into bile is remarkably different and involves Mdr2, the canalicular transport protein responsible for transport of cholesterol and phospholipids into bile (Huang and Vore, 2001).

In the icteric patient, the question arises whether competition between BSP and bilirubin alters the results of the BSP excretion test. In general, the BSP test is seldom justified in hyperbilirubinemic patients because hepatic disease is evident and no important additional information is likely to be provided. In general, dye excretion tests are most useful for situations in which a suggestion of occult liver disease exists but in which the results of other liver function tests are equivocal. The net competitive effect of bilirubin on BSP excretion is not great. For example, horses starved for 72 h developed a three-fold elevation in total serum bilirubin Fig. 13-9, but BSP excretion was delayed less than 25% (Tennant, unpublished).

In the dog and cat, a standard dose of 5mg/kg of BSP is administered as an intravenous bolus. A sample of blood is removed at 30 min, and the BSP concentration is determined spectrophotometrically. It is assumed that the original dose of BSP (5mg/kg) is distributed in a plasma volume of 5 ml/kg so that the concentration of BSP in plasma at time zero is (by definition) 1 mg/ml. The percentage retention at 30min is calculated from the ratio of the concentration at time zero and at 30 min. Retention of 5% or less is considered to be within normal limits (Cornelius, 1970).

In the large domestic species, because it is inconvenient or impossible to obtain body weight, plasma clearance of BSP is measured. The initial slope of the disappearance curve is independent of BSP dose and a standard 1.0 g dosage is administered to normal-sized horses (450 kg) or a dose of 0.5 g to smaller horses. Blood samples are obtained at 6, 9, and 12 min following injection and the fractional clearance rate or plasma half-life ($T_{1/2}$) is calculated (Fig. 13-13). In the horse, normal plasma $T_{1/2}$ values range from 2.5 and 3.5min. In cattle, the rate of BSP excretion is similar to the horse. Sheep have a more rapid excretion rate requiring samples to be taken at 3, 5, and 7min following injection. Normal $T_{1/2}$ values for sheep range from 1.6 to 2.7min (Cornelius, 1970).

The BSP test is safe although the dye is irritating if infiltrated perivascularly. The test should be used only when cardiovascular function is normal. If hypovolemia or hypotension is present, hepatic perfusion will be reduced and erroneously prolong the rate of BSP clearance.

The clearance rate of ICG provides a useful estimate of hepatic excretory function. Since the hepatic extraction ratio approaches 1, and hepatic clearance corresponds to hepatic blood flow. In contrast to BSP, the plasma disappearance of ICG generally follows a single exponential after mixing. Unlike BSP, ICG is available commercially and is the dye excretion test most readily available for clinical use.

ICG clearance has been used to estimate circulation time and hepatic blood flow. The ICG clearance rate from

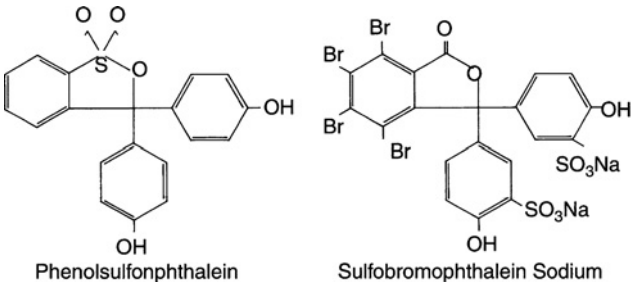

FIGURE 13-11 Phenolsulfonphthalein (PSP) is a dye that is cleared exclusively by the kidney and used in renal function tests. Sulfobromophthalein (BSP) is closely related structurally, but the modifications result in excretion almost entirely by the liver and its use in assessment of hepatic function.

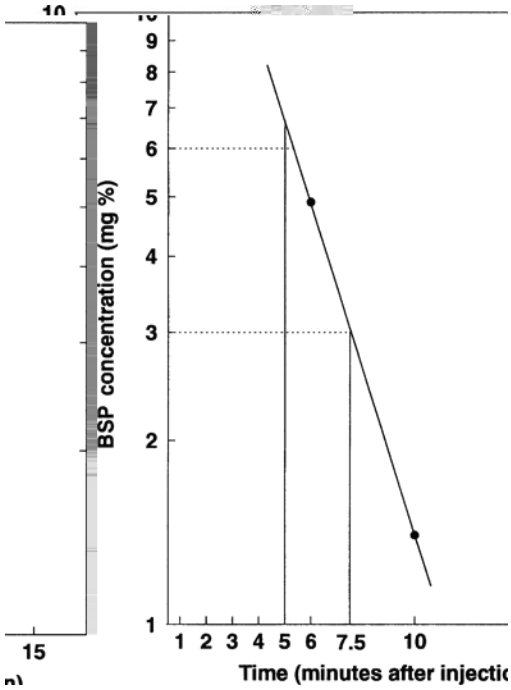

FIGURE 13-12 Calculation of $T_{½}$ for sulfobromophthalein (BSP) in the horse. After bolus injection intravenously, serum samples were obtained at 6 and 10 min, and the $T_{½}$ was calculated to be 2.5min (normal).

plasma is measured after the intravenous injection of bolus doses of dye (Warren *et al.*, 1984). Because disappearance of the dye from plasma follows Michaelis-Menten kinetics, Lineweaver-Burke analysis provides apparent K_m and V_{max} values for the removal of ICG (Paumgartner *et al.*, 1970). The maximal dye removal capacity can be estimated from a small number of submaximal clearance values. Although such multiple tests are not useful for routine practice, they provide clinical investigators a sensitive index of hepatic dye clearance that is independent of blood flow.

For clinical application liver function test as a $T_{½}$ and fractional clearance (K) is determined after a single intravenous injection of ICG. Three plasma samples are usually taken between 3 and 15 min after administration and the ICG concentration measured spectrophotometrically. It also is possible to estimate plasma volume and hepatic blood flow (Ketterer *et al.*, 1960). Normal ICG plasma $T_{½}$ and *K* values for the dog using 0.5 mg/kg ICG (0.64 μmol/kg) were reported to be 8.4 ± 2.3 min and 0.089 ± 0.027/minute (Bonasch and Cornelius, 1964). Using an ICG dose of 1.0 mg/kg (1.3 μmol/kg), Center *et al.* (1983c) reported an ICG $T_{½}$ for dogs of 9.0 ± 2.0 min, a clearance rate 3.7 ± 0.7 ml/min/kg, and a 30-min retention of 14.7 ± 5.0%. In cats that received an ICG dose of 1.5 mg/kg, Center *et al.* (1983b) reported a $T_{½}$ of 3.8 ± 0.9 min, a clearance rate of 8.6 ± 4.1, and 30-min retention of 7.3 ± 2.9%. Using an ICG dose of 0.5mg/kg (0.64 μmol/kg) in sheep, Sato (1984) reported a $T_{1/2}$ of 4.8 ± 0.5 min, and for heifers using a dose of 0.75 mg/kg (0.97 μmol/kg), the $T_{½}$ was 3.5±0.8 min.

V. OVERVIEW AND CONCLUSIONS

Conventional tests for hepatic disease provide information about the integrity of the hepatocytes (ALT, AST, SDH) and the status of the biliary system (AP, GGT). Hepatic function can be assessed by estimating the excretory capacity (bilirubin, bile acids NH_3) and synthetic functions (NH_3/urea, albumin, fibrinogen, and prothrombin) of the liver.

For the results of clinical laboratory tests to be of optimal value, it is essential that the specific purpose(s) of the test(s) being performed be defined. Tests for hepatic disease are performed for a variety of purposes including to confirm the existence of liver disease, to assess the nature (e.g., hepatocellular injury, cholestasis) and severity of the disease to determine prognosis, to monitor the clinical course and response to therapy, and to screen individuals at risk for the existence of occult liver disease.

Many of the standard tests for liver disease are based on rather simple biochemical procedures that have been automated for use in multichannel autoanalyzers. One seldom obtains the result of a single test for liver disease but rather a panel of results or a "liver profile." In some situations, the results of multiple tests of liver injury and function may be received even when there is no specific clinical indication for them because, with autoanalyzers, it may be more efficient to perform a large series of tests than to be selective.

In a given population of animals, some will have liver disease and some will not. If a test is applied to the whole population, a certain number of those with the disease will have a positive test result (true positives), and some with the disease will have a negative test result (false negatives). Similarly, among those without the disease, some will have a positive test result (false positives), and in some, the test

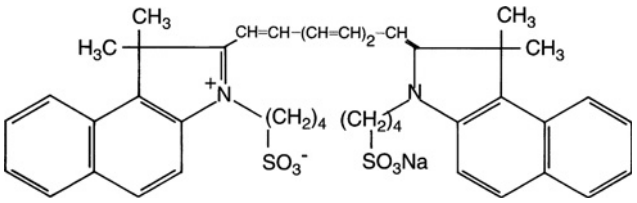

FIGURE 13-13 Indocyanine green used for quantitative assessment of hepatic excretory function.

will be negative (true negatives). A laboratory test is said to be sensitive to the extent that it detects individuals with the disease (true positives divided by the total number with the disease [i.e., true positives plus false negatives]). The test is said to be *specific* to the extent that a negative result detects patients that are free of the disease (true negatives divided by the number of subjects without the disease [i.e., true negatives plus false positives]).

In the clinical setting, the sensitivity and the specificity of hepatic tests are less important than the *positive predictive value*, defined as the probability that a positive test result indicates the presence of the disease (true positives divided by true positives plus the false positives), and the *negative predictive value*, the probability that a negative test result indicates the absence of the disease (true negatives divided by the true negatives plus false negatives). The predictive value of a test, unfortunately, depends on the population being studied and the proportion of individuals in the population with the disease (prevalence). Even when test sensitivity and specificity are high and the number of false-positive tests is low, if there are few subjects with the disease in the population, a positive test result will have relatively low positive predictive value, whereas a negative test result will have proportionately high negative predictive value. If the prevalence of a disease in a population is high, however, a positive result for a test with even low sensitivity and specificity will have high positive predictive value, whereas a negative result would have proportionately low predictive value for the absence of the disease.

Although the sensitivity of a test is often discussed, the prevalence of the disease and the positive and negative predictive values of tests are often ignored in discussions of interpretation of laboratory results. Importantly, laboratory test results from a selected group of individuals with a high prevalence of liver disease cannot be compared to a population in which the prevalence is low or to that in which the predictive value of a test in one population is similar to that of the other population.

As indicated previously, it is unusual that a single test for hepatic injury or function is performed, but rather a "profile" of hepatic test results ordinarily is obtained. The combined results of a panel of tests often provide increased sensitivity and specificity and improved predictive value in assessing severity or in differentiating between acute and chronic forms of liver disease. It often is impossible to differentiate between different hepatic diseases on the basis of multiple laboratory tests alone, and hepatic imaging or liver biopsy is required. Hepatic tests, however, continue to have an important place in evaluating and monitoring clinical patients with liver disease and in understanding the underlying pathophysiological mechanisms essential for successful treatment.

I. INTRODUCTION

The digestive system is composed of the gastrointestinal (GI) tract or the alimentary canal, salivary glands, the liver, and the exocrine pancreas. The principal functions of the gastrointestinal tract are to digest and absorb ingested nutrients and to excrete waste products of digestion. Most nutrients are ingested in a form that is either too complex for absorption or insoluble and therefore indigestible or incapable of being digested. Within the GI tract, much of these substances are solubilized and further degraded enzymatically to simple molecules, sufficiently small in size and in a form that permits absorption across the mucosal epithelium. This chapter describes the normal biochemical processes of intestinal secretion, digestion, and absorption. Once these issues have been put in perspective, the chapter explores the pathogenesis of the important gastrointestinal diseases of domestic animals and the biochemical basis for their diagnosis and treatment.

II. SALIVARY SECRETIONS

A. Mechanisms of Secretion

Saliva is produced by three major pairs of salivary glands and by small glands distributed throughout the buccal mucosa and submucosa. Two types of secretory cells are found in the acinar portions of the salivary glands: (1) the mucous cells, which contain droplets of mucus, and (2) the serous cells, which contain multiple secretory granules.

In those species that produce salivary amylase (e.g., pig and human), the secretory granules are the zymogen precursors of this enzyme. A third cell type is found lining the striated ducts. The striations along the basal borders of these cells are caused by vertical infoldings of the cell membrane, a characteristic of epithelial cells involved in rapid movement of water and electrolytes. The primary secretion of the acinar cells is modified by active transport processes of the ductal epithelium.

The distribution of the different types of secretory cells in the salivary glands varies among species. The parotid glands of most animals are serous glands, which produce a secretion of low-specific gravity and osmolality containing electrolytes and proteins including certain hydrolytic enzymes. The mandibular (submaxillary) and sublingual glands are mixed salivary glands that contain both mucous and serous types of cells and produce a more viscous secretion that contains large amounts of mucus (Dukes, 1955).

B. Composition of Saliva

1. *Mucus*

Mucus is an aqueous mixture of proteoglycans and glycoproteins. One of the most completely studied glycoproteins is mucin. Salivary mucins are O-glycosylated and consist of peptides with many oligosaccharides linked covalently to the hydroxyamino acid serine or threonine. The carbohydrate portion of submaxillary mucin from sheep is a disaccharide of N-acetylneuraminic acid (sialic acid) and N-acetylgalactosamine (Carlson *et al.,* 1973). The enzymes that link protein with hexosamine have been purified from the mandibular glands of sheep (Carlson *et al.,* 1973) and swine (Schachter *et al.,* 1971).

The physiological functions of mucin are related to its high viscosity. N-acetylneuraminic acid is the component responsible for the formation of viscous aqueous solutions and, at physiological pH, causes expansion and stiffening of the mucin molecule. The resistance of mucin to enzymatic breakdown is also due to the presence of disaccharide residues. Removal of terminal N-acetylneuraminic acid residues by action of neuraminidase significantly increases the susceptibility of peptide bonds to trypsin.

2. *Electrolytes*

The principal inorganic constituents of saliva are sodium, potassium, chloride, and bicarbonate, which, with the exception of bicarbonate, originate directly from the plasma. Rates of salivary flow vary depending on stimulation, and there are wide variations in electrolyte concentration. Saliva is formed by a process that initially requires uptake of sodium and other electrolytes from the interstitium of the terminal structural unit of the salivary gland, the acinus or end piece. Water flows passively. This primary or precursor fluid has a sodium concentration similar to plasma, and the potassium concentration is similar to or slightly higher than plasma. As the primary fluid passes from the acinus along the duct system, the concentration of sodium, potassium, and other electrolytes changes. In most species, there is net sodium absorption and potassium secretion. Wide variations in electrolyte composition may occur depending on the flow rate (Young and Schneyer, 1981), the salivary gland of origin, and the species (Table 14-1).

3. *Amylase*

The saliva of rodents contains the α-amylase, ptyalin, but this enzyme activity is absent in the saliva of dogs, cats, horses, cattle, and sheep (Dukes, 1955; Young and Schneyer, 1981). Salivary amylase splits the α1,4-glucosidic bonds of various polysaccharides. Salivary amylase is similar in major respects to pancreatic α-amylase, which is described in Section V.B. Salivary amylase initiates digestion of starch and glycogen in the mouths of those species that secrete the enzyme. The optimal pH for amylase activity is approximately 7, so that this activity ceases when the enzyme mixes with acidic gastric contents.

TABLE 14-1 Electrolyte Concentration of Mandibular Gland and Parotid Gland Saliva Observed during Maximum Rates of Secretion (mmol/l)

	Mandibular Gland			Parotid Gland		
	Na^+	K^+	HCO_3^-	Na^+	K^+	HCO_3^-
Sheep	20	7	23	160–175	9–10	113–140
Dog	70–100	12–15	10–30	80–110	6–14	50
Cat	40–51	9–10	26	—	—	—
Rabbit	50–100	10–40	25	110–140	10	12–30

4. *Lipase*

Lingual lipase is secreted by Von Ebner's gland of the tongue and is important in the digestive processes of the human newborn, rats, and preruminant calves (Cook *et al.,*1994; Plucinski *et al.,* 1979).

C. Functions of Saliva

Saliva continuously bathes the oral cavity, which protects the surface epithelium. Ingested food is moistened and lubricated by saliva, thereby facilitating mastication and swallowing. Saliva also protects teeth from decay by washing food particles from the surfaces of the teeth and using its buffering capacity to neutralize the organic acids produced by bacteria normally present in the mouth. Saliva is necessary for vocalization, and, in some species that groom themselves, saliva promotes cooling as it evaporates. Additionally, it may be a source of pheromones. Salivary glands contain large numbers of growth factors, vasoactive serine proteases, and regulatory peptides (Cook *et al.,* 1994). There is reason to believe that these glandular constituents affect a wide range of biological functions not necessarily limited to the alimentary system.

Ruminants produce much greater quantities of saliva than do simple-stomached animals, and their saliva has a higher pH and bicarbonate ion concentration. In ruminants, saliva serves several unique functions (Phillipson, 1977). It is required for maintenance of the fluid composition of the contents of the rumen. The great buffering capacity of ruminant saliva is necessary to neutralize the large amounts of organic acids that are end products of rumen fermentation.

Rumen bacteria for protein synthesis can utilize the urea in saliva. Protein synthesized in the rumen is then used to meet dietary protein requirements. In this way, urea nitrogen can be "recycled" through the amino acid pool of the body, and in ruminants it need not be considered an end stage in protein catabolism. The ability to reutilize urea has also been demonstrated in the horse, and this may be of particular benefit during periods of protein deficiency (Houpt and Houpt, 1971).

III. GASTRIC SECRETIONS

The stomach is divided into two main regions on the basis of secretory function. The oxyntic gland area corresponds approximately to the body of the stomach in most species of domestic animals and also to the fundus in the dog and cat. The oxyntic glands contain (1) oxyntic or parietal cells that produce hydrochloric (HCl) acid, (2) peptic (zymogenic, chief) cells that produce pepsinogen, and (3) mucous cells. The pyloric gland area contains mucus-producing pyloric glands whose secretion is slightly alkaline. This area also contains the G cells, which produce the polypeptide hormone, gastrin.

A. Composition of Gastric Secretions

1. *Basal versus Stimulated Secretion*

There are two components of gastric secretion. The surface epithelial cells and other mucus-producing cells continuously secrete the basal component. This component is neutral or slightly alkaline pH. The electrolyte composition is similar to that of an ultrafiltrate of plasma (Table 14-2). The basal secretion contains large amounts of mucus, which has a cytoprotective effect on the epithelium. The secretory component produced by the oxyntic gland cells in response to stimulation contains free HCl and pepsinogen, the principal enzyme of gastric digestion.

The composition of gastric juice depends on the relative amounts of the basal and secretory components in the juice and, in turn, is a function of the flow rate of each. In the dog, gastric juice is produced in the resting state at a rate of approximately 5 ml/h. The composition is similar to that of the basal component, containing practically no peptic activity or HCl. When the flow of gastric juice is stimulated maximally, the dog may produce 80 ml or more per hour of a secretion containing large amounts of peptic activity and HCl. Na^+, the principal cation in the basal secretion, is replaced to a large extent by H^+ ion. The concentration of K^+ is similar in both basal and stimulated secretions and, therefore, remains relatively constant at the various rates of flow.

HCl and pepsinogen are secreted by separate mechanisms, but their production appears closely linked under physiological conditions. Stimulation of the vagus nerve or intravenous injection of gastrin increases pepsinogen and HCl levels together. Other stimuli may affect the two processes differently; for example, in the dog histamine infusion stimulates HCl production maximally but appears to inhibit pepsinogen secretion (Emas and Grossman, 1967).

TABLE 14-2 Composition of Parietal and Nonparietal Secretions of Canine Gastric Mucos[a]

Component	Parietal Secretion[a] (mmol/liter)	Nonparietal Secretion[a] (mmol/liter)	Nonparietal Secretion[b] (mmol/liter)
Na^+	—	155.0	138.0
H^+	159.0	—	—
K^+	7.4	7.4	4.0
Ca^{2+}	—	3.7	5.0
Cl^-	166.0	133.0	117.0
pH	<1.0	7.54[c]	7.42

[b] *Determined* in vitro *with isolated gastric mucosa* (Altamirano, 1963).
[c] *Calculated from bicarbonate concentration assuming* pCO_2 *of* 40 Torr.

2. *Pepsin*

Pepsinogen is the zymogen, or inactive precursor, of pepsin, the principal proteolytic enzyme of gastric juice. Pepsinogen was first crystallized from the gastric mucosa of swine, and several pepsinogens have now been separated. The porcine pepsinogen has a molecular weight of approximately 43 kd and is composed of the pepsin molecule and several smaller peptides. One of these peptides has a molecular weight of 3.2 kd and is an inhibitor of peptic activity. Activation of pepsin from pepsinogen occurs by selective cleavage of this small basic peptide from the parent pepsinogen (Neurath and Walsh, 1976). Autocatalytic conversion begins below pH 6. At pH 5.4, the inhibitor peptide dissociates from the parent molecule, and at pH 3.5 to 4, the inhibitor is completely digested by pepsin.

Pepsin has a very acidic isoelectric point and is stable in acidic solution below pH 6, but it is irreversibly denatured at pH 7 or above. In contrast, pepsinogen is stable in neutral or slightly alkaline solution. The optimal pH for peptic activity is generally between 1.6 and 2.5, but the effect of pH may vary with the substrate. Pepsin is capable of hydrolyzing peptide bonds of most proteins, mucin being one important exception. Pepsin splits bonds involving phenylalanine, tyrosine, and leucine most readily but can hydrolyze almost all other peptide bonds.

3. *Gastric Lipase*

In canines, gastric lipase is secreted in response to pentagastrin, histamine, prostaglandin E_2, and secretin (Simpson, 2005). It parallels the secretion of gastric mucosa and plays a role in fat digestion. Unlike pepsin, it is not dependent on an acid pH, remains active in the small intestine, and constitutes up to 30% of the total lipase secreted over a 3-hour period. Gastric lipase as well as pepsin are not essential in fat digestion, but resulting fatty acids and peptides help coordinate gastric emptying and pancreatic secretion.

4. *Rennin*

Rennin is another proteolytic enzyme produced by the gastric mucosa and has characteristics that are similar to those of pepsin. It has been separated from pepsin in preparations from the stomachs of newborn calves. Rennin splits a mucopeptide from casein to form paracasein, which then reacts with calcium ion to form an insoluble coagulum. The coagulated milk protein probably delays gastric emptying and increases the efficiency of protein digestion in young calves.

5. HCL

The oxyntic cells produce HCl. When the normal mucosa is stimulated, both Cl^- and H^+ are secreted together, but current evidence suggests that H^+ and Cl^- are secreted by separate, closely coupled mechanisms. Unstimulated oxyntic cells continuously secrete small amounts of Cl^- in the absence of H^+ secretion, and this mechanism is responsible for the negative charge of the resting mucosal surface of the stomach relative to the serosa. For every H^+ secreted, an electron is removed that ultimately is accepted by oxygen to form OH^-, which is neutralized within the cell by H^+ from H_2CO_3. The HCO_3^- then enters the venous blood by means of a Cl^-/HCO_3^- exchange ("alkaline tide"), and during HCl secretion, the pH of gastric venous blood frequently is greater than that of arterial blood (Davenport, 1966).

The membrane-bound enzyme responsible for transport of H^+ by the oxyntic cell is a K^+-stimulated ATPase (Sachs *et al.,* 1976; Wallmark *et al.,* 1980) that serves as an H^+/K^+ exchange pump. At the time of oxyntic cell stimulation, the secretory membrane is altered to provide augmented K^+ and Cl^- conductances (Wolosin, 1985). KCl leaves the apical cell membrane passively, and net production of HCl results from the electroneutral exchange of K^+ for H^+ (Fig. 14-1).

B. Control of Gastric Secretion

1. *General*

A variety of stimuli can initiate gastric secretion. The sight or smell of food or the presence of food within the mouth causes gastric secretion by a reflex mechanism involving the vagus nerve. The presence of certain foods within the stomach or distension of the stomach alone can also initiate both intrinsic and vagal nerve reflexes, which cause secretion of gastric fluid. In addition to neural reflexes, these stimuli also cause the release of the gastrin from the pyloric gland area, which enters the bloodstream, stimulating gastric secretion. The release of gastrin from G cells is inhibited by excess H^+, and this negative feedback mechanism is important in the control of HCl production.

2. *Gastrin*

Gastrin has been isolated in pure form from the antral mucosa of swine (Gregory *et al.,* 1964). When administered intravenously, the purified hormone causes the secretion of HCl and pepsin and stimulates gastrointestinal motility and pancreatic secretion. Two separate peptides have been obtained from porcine gastric mucosa and have been designated gastrin I and gastrin II. Gastrin is a heptadecapeptide amide, with a pyroglutamyl N-terminal residue and with the amide of phenylalanine as the C-terminal residue (Fig. 14-2). In the center of the molecule is a sequence of five glutamyl residues, which give the molecule its acidic properties. Gastrin II differs from gastrin I only in the presence of a sulfate ester group linked to the single tyrosyl residue. The C-terminal tetrapeptide amide,

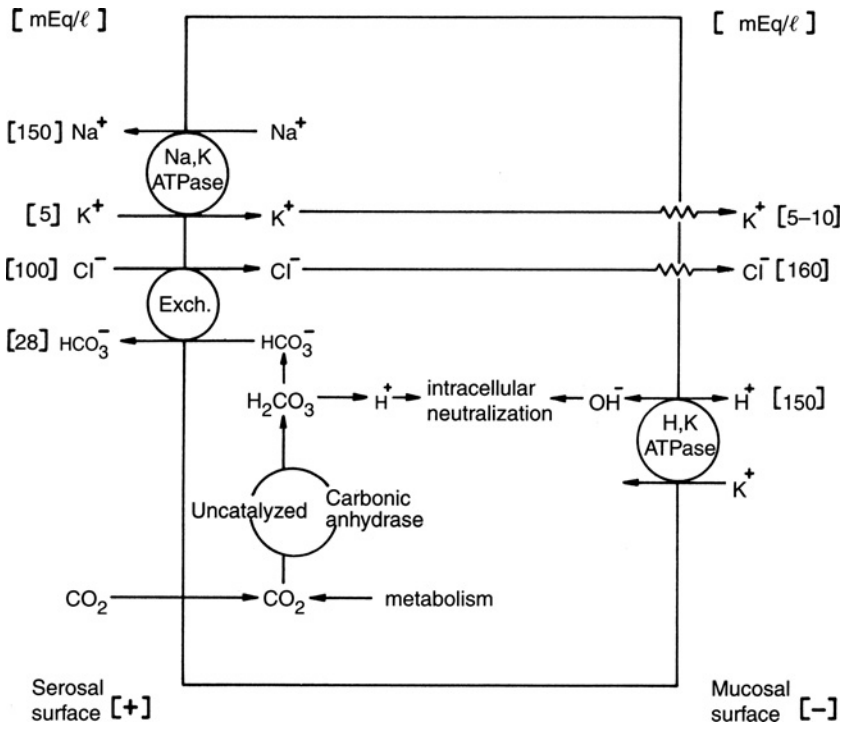

FIGURE 14-1 Movement of ions across the mucosal (apical) and serosal (basal) cell membranes of the parietal during HCl secretion.

FIGURE 14-2 Amino acid sequence of porcine gastrin I (Gregory, 1966). Gastrin II differs from gastrin I by the presence of a sulfate ester group on the single tyrosyl residue.

Trp-Met-Asp-Phe-NH_2, is identical in all species so far studied (Gregory, 1967). The tetrapeptide has all of the activities of the natural hormone. It is not as potent as the parent molecule, but lengthening of the peptide chain can increase activity.

Gastrin-releasing peptide—as well as luminal peptides, digested protein, and acetylcholine—stimulates gastrin secretion from G cells and affects histamine release from enterochromaffin-like cells (Simpson, 2005). Gastrin is the only hormone known to simulate HCl (Walsh and Grossman, 1975).

3. H*istamine*

Histamine secreted locally within the mucosa has a major effect on the function of oxyntic cells (Soll and Grossman, 1978). For many years, histamine has been recognized as a potent stimulant of HCl production, but this effect was not inhibited by traditional antihistaminic drugs (H_1 antagonists), and until the demonstration by Black *et al.* (1972) of H_2 receptors in the stomach (the atrium and uterus), the physiological role of histamine in HCl secretion was controversial. Specific H_2 antagonists (cimetidine) now have been shown to inhibit the secretory response not only to histamine but to other secretory stimuli as well (Grossman and Konturek, 1974).

The complex of oxyntic cell receptors involved in the control of oxyntic cell function is shown in Figure 14-3. When the H_2 receptor of the oxyntic cell is occupied by histamine, basal lateral adenylate cyclase is activated, resulting in increased cellular cyclic AMP (cAMP) and in a sustained secretory response. The secretogogue action of cAMP is mediated by the activity of cAMP-dependent protein kinases (Chew, 1985).

Cholinergic stimulation of the oxyntic cell involves type I muscarinic receptors and a calcium activation pathway. Calmodulin inhibitors such as trifluoroperazine inhibit H^+ secretion (Raphael *et al.,* 1984). The Ca-calmodulin system may influence the rate of cAMP synthesis, and a more distal site of action has been suggested by the identification of a Ca-dependent protein kinase activity in a membrane fraction prepared from oxyntic cells that was rich in H^+, K^+-ATPase (Schlatz *et al.,* 1981). A specific receptor for gastrin has been demonstrated on oxyntic cells and a specific gastrin antagonist, proglutamide, inhibits H^+ production. Gastrin appears to act synergistically with histamine and acetylcholine (AcCh) to regulate H^+ production but the actual mechanism of action of gastrin is unknown.

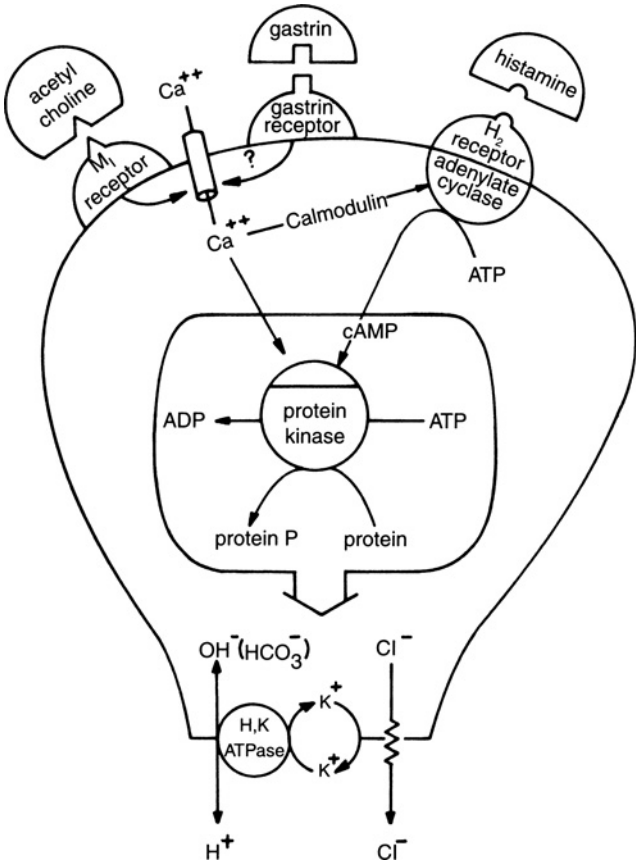

FIGURE 14-3 Pathways of secretagogue action on the parietal cell. Stimulation by gastrin and acetylcholine is mediated by entry of Ca^{2+} onto the cell. Histamine activates adenylate cyclase with production of cAMP, the action of which is mediated by protein kinase.

TABLE 14-3 Inhibitors of Oxyntic Cell Function

A. Inhibitors of H^+, K^+-ATPase: omeprazole, verapamil, vanadate
B. Inhibitors of carbonic anhydrase: acetazolamide
C. Inhibitors of cell activation or response 1. Calcium channel antagonists: verapamil, lanthanum 2. Prostaglandin E_2
D. Receptor antagonists 1. H_2-receptor antagonists: cimetidine, ranitidine 2. Gastrin antagonists: proglumide, benzotript 3. Anticholinergic agents: atropine
E. Inhibitors of calmodulin: trifluoroperazine

4. *Prostaglandins*

Prostaglandins, in addition to inhibiting HCl secretion, also act on a mucosal cell population that is distinct from oxyntic cells, which secrete cytoprotective substances (mucin, glycosaminoglycans). The ulcerogenic effects of inhibitors of prostaglandin synthesis (indomethacin, aspirin) apparently are the result of inhibition of the protective effect of endogenous prostaglandins.

Knowledge of the molecular aspects of receptor function of HCl secretion by oxyntic cells now provides the opportunity for specific pharmacological intervention for the control and treatment of ulcerative diseases of the upper gastrointestinal tract that appear to be the result of HCl-induced mucosal injury (Aclund *et al.,* 1983; Becht and Byars, 1986; Campbell-Thompson and Merritt, 1987). Potential therapeutic target sites are listed in Table 14-3. Famotidine is commonly administered to dogs and cats. Injectable ranitidine is administered to foals and horses during critical stages of gastrointestinal ulceration before switching to oral administration of omeprazole.

IV. BILIARY SECRETIONS

A. Composition of Bile

The hepatocytes continuously secrete bile into the bile canaliculi; it is transported through a system of ducts to the gallbladder, where it is modified, concentrated, and stored. During digestion, bile is discharged into the lumen of the duodenum, where it aids in emulsification, hydrolysis, and solubilization of dietary lipids. The digestive functions of bile are accomplished almost exclusively by the detergent action of its major components, the bile salts and phospholipids.

B. Properties of Bile

The carboxyl group of the bile acids is completely ionized at the pH of bile and is neutralized by Na^+ resulting in the formation of bile salts. These bile salts are effective detergents. They are amphipathic molecules that have both hydrophobic and hydrophilic regions. In low concentrations, bile salts form molecular or ideal solutions, but when their concentration increases above a certain critical level, they form polymolecular aggregates known as micelles. The concentration at which these molecules aggregate is called the critical micellar concentration (CMC).

Bile salt micelles are spherical and consist of a central nonpolar core and an external polar region. Fatty acids, monoglycerides, and other lipids are solubilized when they enter the central core of the micelle and are covered by the outside polar coat. Solubilization occurs only when the CMC is reached. For the bile salt-monoglyceride-fatty acid-water system present during normal fat digestion, the CMC is approximately 2 mM, which normally is exceeded both in bile and in the contents of the upper small intestine (Hofmann, 1963, 1967). Phospholipids, principally lecithin, are also major components of bile. In the lumen of

the small intestine, pancreatic phospholipase catalyzes the hydrolysis of lecithin, forming free fatty acid and lysolecithin. The latter compound also is a potent detergent, which acts with the bile salts to disperse and solubilize lipids in the aqueous micellar phase of the intestinal contents.

C. Synthesis of Bile Acids

The primary bile acids (BA) are C-24 carboxylic acids synthesized by the liver from cholesterol. BA synthesis is the major end-stage pathway for cholesterol metabolism (Danielsson, 1963). Cholic acid (3α,7α,12α-trihydroxy-5β-cholanoic acid) (CA) and chenodeoxycholic acid (3α-,7α-dihydroxy-5β-cholanoic acid) (CDCA) are the primary BA synthesized by most species of domestic animals. In swine, CDCA is hydroxylated at the 6α position by the liver to yield hyocholic acid (HCA), which is a major primary BA in this species.

BA are secreted as amino acid conjugates of either glycine or taurine. Taurine conjugates predominate in the dog, cat, and rat. In the rabbit, the conjugating enzyme system appears to be almost completely specific for glycine (Bremer, 1956). Both taurine and glycine conjugates are present in ruminants. In the newborn lamb, 90% of the bile acids are conjugated with taurine. As the lamb matures, glycine conjugates increase to reach one-third of the total BA in mature sheep (Peric-Golia and Socic, 1968).

Under normal conditions, only conjugated BA are present in the bile and in the contents of the proximal small intestine. In the large intestine, the conjugated BA are hydrolyzed rapidly by bacterial enzymes so that in the contents of the large intestine and in the feces, free or unconjugated BA predominate. Several genera of intestinal bacteria, including clostridium, enterococcus, bacteroides, and lactobacillus, are capable of splitting the amide bonds of conjugated BA.

Intestinal bacteria also modify the basic structure of the BA. One such reaction is the removal of the α-hydroxyl group at the 7 position of CA or CDCA. These bacterial reactions yield the secondary BA, deoxycholic acid (DCA), and lithocholic acid (LCA) (Gustafsson *et al.,* 1957). LCA is relatively insoluble and is not reabsorbed to any great extent (Gustafsson and Norman, 1962). DCA is reabsorbed from the large intestine in significant quantities and is either rehydroxylated by the liver to CA and secreted (Lindstedt and Samuelsson, 1959) or secreted as the conjugated DCA. The extent to which bacteria transform the primary BA depends on the nature of the diet, the composition of the intestinal microflora, and the influences of these and other factors on intestinal motility (Gustafsson, 1969; Gustafsson *et al.,* 1966; Gustafsson and Norman, 1969).

D. Enterohepatic Circulation of Bile Acids

The enterohepatic circulation begins as conjugated BA enter the duodenum and mix with the intestinal contents, forming emulsions and micellar solutions. The BA are not absorbed in significant amounts from the lumen of the proximal small intestine. Absorption occurs primarily in the ileum (Lack and Weiner, 1961, 1966; Weiner and Lack, 1962) where an active transport process has been demonstrated (Dietschy *et al.,* 1966). The absorbed conjugated BA pass unaltered into the portal circulation (Playoust and Isselbacher, 1964) and return to the liver, where the cycle begins again. This arrangement provides for optimal concentrations of BA in the proximal small intestine where fat digestion occurs and then for efficient absorption after these functions have been accomplished. Absorption of unconjugated BA from the large intestine accounts for 3% to 15% of the total enterohepatic circulation (Weiner and Lack, 1968).

In dogs, the total BA pool was estimated to be 1.1 to 1.2 g. The half-life of the bile acids in the pool ranged between 1.3 and 2.3 days, and the rate of hepatic synthesis was 0.3 to 0.7 g/day. Because the daily requirement for bile acids greatly exceeds the normal synthetic rate, the repeated reutilization of the BA is facilitated by the enterohepatic circulation. Under steady-state conditions, the total BA pool passes through the enterohepatic circulation approximately 10 times each day.

The size of the BA pool depends on the diet, the rate of hepatic synthesis, and the efficiency of the enterohepatic circulation. Surgical removal of the ileum in dogs interrupts the enterohepatic circulation, thereby increasing the BA turnover and reducing the size of the BA pool (Playoust *et al.,* 1965). In diseases of the ileum, there may be defective BA reabsorption and a bile salt deficiency. If the deficiency is severe, the utilization of dietary fat may be impaired, resulting in steatorrhea and impaired absorption of the fat-soluble vitamins.

V. EXOCRINE PANCREATIC SECRETIONS

The exocrine pancreas is an acinus gland with a general structure that is similar to the salivary glands. The cytoplasm of the secretory cells contains numerous zymogen granules, which vary in size and number depending on the activity of the gland. These granules contain the precursors of the hydrolytic enzymes responsible for digestion of the major components of the diet. Cells of the terminal ducts appear to secrete the HCO^{3-} responsible for neutralizing the HCl, which enters the duodenum from the stomach.

A. Composition of Pancreatic Juice

1. *Electrolyte Composition*

The cation content of pancreatic secretion is similar to that of plasma, Na^+ being the predominant cation and the concentrations of K^+ and Ca^{2+} being much lower. A unique

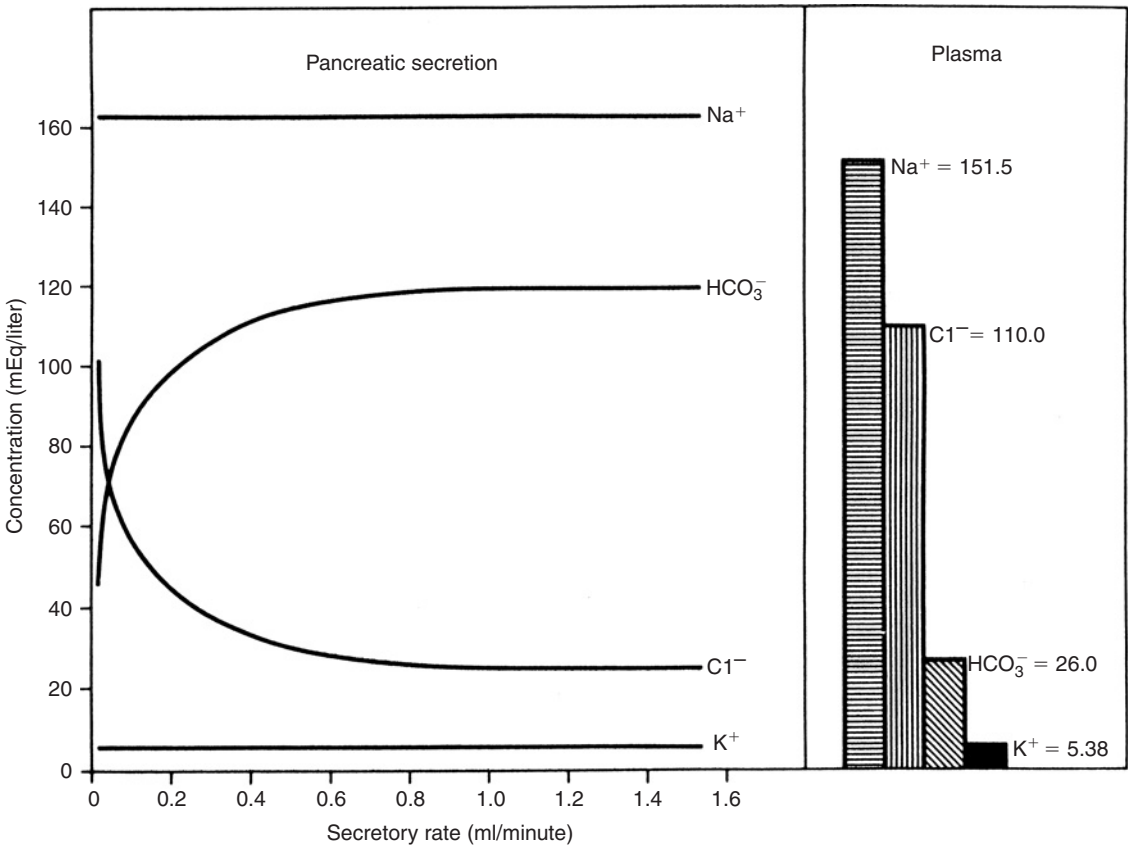

FIGURE 14-4 Influence of secretory rate on the electrolyte composition of canine pancreatic juice. From Bro-Rasmussen *et al.* (1956).

characteristic of pancreatic fluid is its high HCO_3^- concentration and alkaline pH. In the dog, the pH ranges from 7.4 to 8.3, depending on HCO_3^- content. The volume of pancreatic secretion is directly related to its HCO_3^- content, and the pH increases and Cl^- concentration decreases as the rate of flow increases. The Na^+ and K^+ concentrations and osmolality appear to be independent of the secretory rate (Fig. 14-4).

2. α-Amylase

The amylase produced by the pancreas catalyzes the specific hydrolysis of α-1,4-glucosidic bonds, which are present in starch and glycogen (α-1,4-glycan-4-glycan hydrolase). Pancreatic amylase appears to be essentially identical to the amylase of saliva. It is a calcium-containing metalloenzyme. Removal of calcium by dialysis inactivates the enzyme and markedly reduces the stability of the apoenzyme. Pancreatic amylase has an optimal pH for activity of 6.7 to 7.2 and is activated by Cl^-.

After synthesis of pancreatic α-amylase in the ribosomes, the enzyme is transferred from the endoplasmic reticulum to cytoplasmic zymogen granules for storage. It is secreted in active form upon stimulation of the acinar cells. Newborn calves and pigs secrete amylase at a significantly lower rate than mature animals. The rate of synthesis is also influenced by diet. Animals fed a high-carbohydrate diet synthesize amylase at several times the rate of animals on a high-protein diet.

Unbranched α-1,4-glucosidic chains, such as those found in starch, are hydrolyzed in two steps. The first is rapid and results in formation of the maltose and maltotriose. The second step is slower and involves hydrolysis of maltotriose into glucose and maltose. Polysaccharides such as amylopectin and glycogen contain branched chains with both α-1,4- and α-1,6-glucosidic linkages. When α-amylase attacks these compounds, the principal products are maltose (α-1,4-glycosidic bond), isomaltose (α-1,6-glucosidic bond), and small amounts of glucose. Final hydrolysis of the maltose and isomaltose occurs at the surface of the mucosal cell, where the enzymes maltase and isomaltase are integral parts of the microvillous membrane.

3. Proteolytic Enzymes

The proteolytic enzymes of the pancreas are responsible for the major portion of protein hydrolysis, which occurs within the lumen of the gastrointestinal tract. The pancreas secretes two types of peptidases. Trypsin, chymotrypsin, and elastase are endopeptidases that attack peptide bonds along the polypeptide chain to produce smaller peptides.

TABLE 14-4 Relationships among the Activities of Pancreatic Endopeptidases and Exopeptidases

Enzyme	Type	Activity
Trypsin	Endopeptidase	Produces peptides with C-terminal basic amino acids
Carboxypeptidase B	Exopeptidase	Removes C-terminal basic amino acids
Chymotrypsin	Endopeptidase	Produces peptides with C-terminal aromatic amino acids
Elastase	Endopeptidase	Produces peptides with C-terminal nonpolar amino acids
Carboxypeptidase A	Exopeptidase	Removes C-terminal aromatic and nonpolar amino acids

The exopeptidases attack either the carboxy-terminal or amino-terminal peptide bonds, releasing single amino acids. The principal exopeptidases secreted by the pancreas are carboxypeptidases A and B. The endopeptidases and exopeptidases act in complementary fashion (Table 14-4), ultimately producing free amino acids or very small peptides. The free amino acids are absorbed directly, and the small peptides are further hydrolyzed by the aminopeptidases of the intestinal mucosa.

The pancreatic peptidases are secreted as the inactive proenzymes (zymogens), trypsinogen, chymotrypsinogen, and the procarboxypeptidases A and B. Trypsinogen is converted to active trypsin in two ways. At alkaline pH, trypsinogen can be converted autocatalytically to trypsin. The activated enzyme is then capable of converting more zymogen to active enzyme. Trypsinogen also can be activated by the enzyme enterokinase, which is produced by duodenal mucosa. The latter reaction is highly specific in that enterokinase will activate trypsinogen but not chymotrypsinogen. Chymotrypsinogen, proelastase, and the procarboxypeptidases A and B are converted to active enzymes by the action of trypsin.

The amino acid sequences and other structural characteristics of bovine trypsinogen and chymotrypsinogen have been determined (Brown and Hartley, 1966; Hartley *et al.,* 1965; Hartley and Kauffman, 1966). The polypeptide chain of trypsinogen contains 229 amino acid residues. Activation of trypsinogen occurs with hydrolysis of a single peptide bond located in the 6 position between lysine and isoleucine. As the C-terminal hexapeptide is released, enzyme activity appears along with a helical structure of the parent molecule. Chymotrypsinogen A is composed of 245 amino acid residues and has numerous structural similarities to trypsinogen. Activation of the chymotrypsinogen also occurs with cleavage of a single peptide bond.

4. *Lipase*

The pancreas produces several lipolytic enzymes with different substrate specificities. The most important of these from a nutritional viewpoint is the lipase responsible for hydrolysis of dietary triglyceride. This enzyme has the unique property of requiring an oil-water interface for activity so that only emulsions can be effectively attacked. The principal products of lipolysis are glycerol, monoglycerides, and fatty acids. The monoglycerides and fatty acids accumulate at the oil-water interface and can inhibit lipase activity. Transfer of these products from the interface to the aqueous phase is favored by HCO_3^- secreted by the pancreas and by the bile salts.

Two other carboxylic ester hydrolases have been characterized in pancreatic secretion. Both enzymes have an absolute requirement for bile salts, in contrast to glycerol ester hydrolase, which is actually inhibited by bile salts at pH 8. One of the enzymes requiring bile salts is a sterol ester hydrolase responsible for hydrolysis of cholesterol esters, and the other enzyme hydrolyzes various water-soluble esters. The pancreas also secretes phospholipase A, which in the presence of bile converts lecithin to lysolecithin, an effective detergent that contributes to the emulsification of dietary fat.

B. Control of Pancreatic Secretions

1. *Hormonal Control*

Pancreatic secretion is controlled and coordinated by both neural and endocrine mechanisms. When ingesta or HCl enters the duodenum, the hormone secretin, which is produced by the duodenal mucosa, is released into the circulation. Secretin increases the volume, pH, and HCO_3^- concentration of the pancreatic secretion.

Secretin is a polypeptide hormone containing 27 amino acid residues, and all 27 amino acids are required to maintain the helical structure of the molecule and its activity (Bodanszky *et al.,* 1969). The C-terminal amide of secretin is a property shared with other polypeptide hormones such as gastrin and vasopressin, which act on the flow of water in biological systems (Mutt and Jorpes, 1967). In addition to its effects on the pancreas, secretin also increases the rate of bile formation.

The secretin-stimulated pancreatic juice has a large volume, high HCO_3^- concentration but a low enzyme activity.

TABLE 14-5 Gastrointestinal Peptide Hormones

Hormone	Source	Action
Gastrin	G cells of pyloric antrum	Gastric acid secretion
Secretin	S cells of duodenum and jejunum	Pancreatic fluid and HCO_3^- secretion, bile secretion
Cholecystokinin (pancreozymin)	Duodenal and jejunal mucosa; myenteric plexus	Pancreatic enzyme secretion, gallbladder contraction, and sphincter of Oddi relaxation
Somatostatin	D cells of pancreas, CNS, gastric and intestinal mucosa	Inhibits effect of gastrin on gastric secretion, inhibits pancreatic enzyme secretion, stimulates ileal water and NaCl
Enteroglucagon	L cells of small intestine, canine stomach	Control of intestinal cell growth
Gastric inhibitory polypeptide	Duodenal and jejunal mucosa	Inhibits gastric secretion and stimulates intestinal secretion
Motilin	Upper small intestinal mucosa	Stimulates gastrointestinal motility

Stimulation of the vagus nerve causes a significant rise in pancreatic enzyme concentration. This type of response also is produced by cholecystokinin (pancreozymin), another polypeptide hormone produced by the duodenal mucosa, which also causes contraction of the gallbladder. The C-terminal pentapeptide of cholecystokinin-pancreozymin is exactly the same as that of gastrin. This fascinating relationship suggests that gastrin and cholecystokinin-pancreozymin participate in some integrated yet poorly understood system of digestive control.

Several molecular forms of cholecystokinin (CCK) exist (Ward and Washabau, 2005). CCK-33, CCK-39, and CCK-59 are the predominant forms that account for most of the gastrointestinal hormone responses. Endocrine cells in the duodenum and jejunum secrete CCK in response to intraduodenal fatty acids, amino acids, and H^+ ion. CCK-8 is particularly important in cats. Intraluminal distension will activate CCK-8 containing neurons, resulting in acetylcholine release from the myenteric plexus and subsequent peristaltic reflexes in the ileum and colon. CCK-8 neurons in the brain are involved in mediating the satiety response following eating.

VI. OTHER GASTROINTESTINAL HORMONES

A large number of polypeptides have been isolated from the gastrointestinal mucosa and have been classified as gut hormones (Table 14-5). Some of these substances have not yet met all the rigid physiological requirements of true hormones. Some may have paracrine rather than endocrine activities—that is, their actions are on cells and tissues in the immediate vicinity of the cells of origin rather than being released into the vascular system.

A. Motilin

Motilin is a polypeptide containing 22 amino acids that was originally isolated from porcine duodenal mucosa (Brown *et al.,* 1971). The amino acid composition and sequence have been described (Brown *et al.,* 1972, 1973). Immunoreactive motilin has been found in the enterochromaffin cells of the duodenum and jejunum of several species (Polak *et al.,* 1975), and, by means of radioimmunoassay, motilin has been identified in the plasma of dogs (Dryburgh and Brown, 1975). Motilin has been shown to stimulate pepsin output and motor activity of the stomach (Brown *et al.,* 1971) and to induce lower esophageal sphincter contractions (Jennewein *et al.,* 1975). Studies by Itoh *et al.* (1978) suggest that motilin plays an important role in initiating interdigestive gastrointestinal contractions, which are referred to as the interdigestive motility complex or the migrating motility complex (MMC).

The cyclic release of motilin from the intestinal mucosa coordinates gastric, pancreatic, and biliary secretions with phase III of the MMC (Ward and Washabau, 2005). Erythromycin has been shown to induce an MMC similar to motilin and, along with other macrolide-like antibiotics, might be useful in selected cases with motility disorders.

B. Somatostatin

Somatostatin, which is named for its activity of inhibitory release of growth hormone from the pituitary gland, has been purified from ovine and bovine hypothalamus. The hypothalamic hormone is composed of 14 amino acids. Somatostatin also has been demonstrated in the stomach, pancreas, and intestinal mucosa in concentrations higher than in the brain (Pearse *et al.,* 1977). Somatostatin from porcine intestine has been isolated and sequenced, and it

contains 28 amino acids and apparently is a prohormone (Pradayrol *et al.,* 1980). Somatostatin is a potent inhibitor of insulin and glucagon release. It also inhibits gastrin release and gastric acid secretion (Barros D'Sa *et al.,* 1975; Bloom *et al.,* 1974), apparently acting independently on parietal cells and on G cells. These and a variety of other physiological effects suggest that somatostatin has important gastrointestinal regulatory functions.

C. Enteroglucagon

Enteroglucagon is the hyperglycemic, glycogenolytic factor isolated from the intestinal mucosa. It occurs in two forms, one a 3.5 kd form and another somewhat larger (Valverde *et al.,* 1970). Enteroglucagon differs from pancreatic glucagon biochemically, immunologically, and in its mode of release. The physiological function of enteroglucagon is not known, but its release from the mucosa following a meal and the associated increase in circulating blood levels have suggested a regulatory role on bowel function (Pearse *et al.,* 1977). Enteroglucagon also differs significantly from the glucagon produced by the A cells of the gastric mucosa of the dog (Sasaki *et al.,* 1975). Canine gastric glucagon is biologically and immunochemically identical to pancreatic glucagon. Gastric glucagon appears to be unique to the dog, similar activity not being observed in the stomach of the pig or the abomasum of cattle and sheep.

VII. DIGESTION AND ABSORPTION

A. Water and Electrolytes

1. *Mechanisms of Mucosal Transport*

The microvillous membrane of the intestinal mucosa, because of its lipid composition, acts as a barrier to water and water-soluble substances. Water and polar solutes penetrate the mucosa in one of three ways. They may pass through aqueous pores or channels that connect the luminal surface of the cell with the apical cytoplasm, they may attach to membrane carriers that facilitate passage through the lipid phase of the mucosal cell membrane, or they may pass paracellularly through tight junctions (shunt pathway). Transport of water and water-soluble compounds is influenced by the permeability characteristics of the limiting membrane and by the nature of the driving forces that provide energy for transport. Passive movement occurs either by simple diffusion or as a result of concentration gradients (activity), pH, osmotic pressure, or electrical potential that may exist across the membrane. The movement of an ion in the direction of an electrochemical gradient is considered passive in nature. Active transport is said to occur when a substance moves in a direction opposite that of an established electrochemical gradient.

Most water-soluble compounds, such as monosaccharides and amino acids, cannot diffuse across the intestinal mucosal membrane at rates that are adequate to meet nutritional requirements. The transport of these nutrients requires membrane carriers, which are integral parts of the membrane and their binding is highly specific. Carrier-mediated transport systems can be saturated and competitively inhibited by related compounds.

Three types of carrier transport mechanisms are recognized (Curran and Schultz, 1968). (1) *Active transport*, as stated previously, involves movement of electrolytes against an electrochemical gradient. In the case of nonelectrolytes such as glucose, active transport is defined as movement against a concentration gradient. Active transport requires metabolic energy and is inhibited by various metabolic blocking agents or by low temperature. (2) *Facilitated diffusion* occurs when the passive movement of a substance is more rapid than can be accounted for by simple diffusion. Facilitated diffusion systems may increase the rate of movement across the membrane by two or three orders of magnitude. The responsible carrier mechanism is similar to that involved in active transport in that it displays saturation kinetics, may be inhibited competitively, and is temperature dependent. However, transport does not occur against concentration or electrochemical gradients, and direct expenditure of energy is not required. (3) *Exchange diffusion* is a transfer mechanism similar to facilitated diffusion and was postulated originally to explain the rapid transfer of radioactive Na^+ across epithelial cell membranes *in vitro*. The mechanism involves the exchange of one ion for another of like charge (e.g., Na^+ and H^+ or Cl^- and HCO_3^-), not giving rise to net transport but contributing in a major way to unidirectional flux rate.

In the intestine, net water absorption is the result of bulk flow through pores. Diffusion in the usual sense plays no important role in water movement. When bulk flow of water occurs, it is possible for solutes to move across the membrane in the direction of flow by a phenomenon called *solvent drag*. The effect of solvent drag on the transport of a given solute depends on the rate of volume flow and on the reflection coefficient, an expression of the relationship between the radius of membrane pores and the radius of the solute molecule being transported. By means of solvent drag, it is possible for a solute such as urea to be transported by the intestine against a concentration gradient (Hakim and Lifson, 1964).

2. *Sodium and Chloride Absorption*

Na^+ and Cl^- are the major ions in the fluid that are transported by the intestine during absorption or secretion, and under most conditions, transport of these two ions is coupled. The transport of water and electrolytes by the intestinal mucosa is a dynamic process, with rapid unidirectional fluxes of both occurring continuously. Net absorption occurs when the flow from lumen to plasma exceeds that from plasma to lumen. Active transport of Na^+ can occur along

the entire length of the intestine, but the rate and net absorption is greatest in the ileum and colon. Na^+ transport is by an energy-requiring "sodium pump" mechanism that is intimately associated with the Na^+-K^+-ATPase located within the basolateral cell membrane of the absorptive epithelial cell. Three mechanisms exist for the entry of Na^+ at the brush border: (1) electrodiffusion down a concentration gradient, (2) cotransport of electrolytes that either enter (Cl^-) or exit (H^+) the cell as Na^+ enters, and (3) Na^+ entry coupled with organic nonelectrolytes (glucose, amino acids). Current evidence suggests that in the absence of the absorption of nonelectrolytes, electroneutral uptake accounts for most NaCl absorption. At the brush border, Na^+ enters down a concentration gradient but exits at the basolateral cell surface against a substantial gradient. Maintenance of the transmembrane Na^+ gradient by the Na pump requires continual metabolism and generation of ATP. The Na^+-K^+-ATPase can be inhibited by cardiac glycosides such as ouabain, which are effective inhibitors of Na^+ transport. The Na^+ gradient ultimately serves as an energy source for transport of other solutes (Schultz and Curran, 1970).

In the jejunum, net absorption of sodium occurs slowly unless nonelectrolytes, such as glucose or amino acids, are absorbed simultaneously. In the ileum, Na^+ absorption is independent of glucose absorption. Net water absorption in the jejunum is almost entirely dependent on the absorption of glucose and other nonelectrolytes, whereas absorption from the ileum is unaffected by glucose. The differential effect of glucose on absorption from the jejunum and ileum is the result of fundamental differences in electrolyte transport mechanisms in these two regions of the intestine.

As Na^+ is transported across the mucosa, an equivalent amount of anion must be transported to maintain electrical neutrality. A major fraction of Cl^- absorption can be accounted for by passive cotransport with Na^+. Under certain circumstances, Cl^- enters the cell in exchange for HCO_3^-.

3. Potassium Absorption

Dietary K^+ is absorbed almost entirely in the proximal small intestine. Absorption across the intestinal mucosa occurs down a concentration gradient (high luminal concentration to a low concentration in plasma). The intestinal fluid reaching the ileum from the jejunum has a K^+ concentration and a Na^+/K^+ ratio that are similar to plasma. In the ileum and colon, the rate of Na^+ absorption is much greater than that of K^+ so that, under normal conditions, the Na^+/K^+ ratio in the feces is much lower than that of plasma, approaching a ratio of 1.

4. Water Absorption

The absorption of water has been one of the most extensively studied aspects of intestinal transport. Water movement is the result of bulk flow through membranous pores, and simple diffusion plays only a minor role. The question of whether water is actively or passively transported has been the subject of considerable controversy, and the controversy itself points to the fundamental difficulties that arise in trying to establish a definition of active transport. Hypertonic saline solutions can be absorbed from canine intestine *in vivo* and from canine and rat intestine *in vitro*. These observations indicate that water absorption can occur against an activity gradient and that the process is dependent on metabolic energy. This suggests that an active transport process is involved, but Curran (1965) presented an alternate interpretation, which is now generally accepted. This view is that water transport occurs secondarily to active solute transport and is the result of local gradients established within the mucosal membrane. Water transport is then coupled to the energy-dependent processes responsible for solute transport but is one step removed from it.

In the dog and probably other carnivores, the ileum is the main site of net Na^+ and water absorption. In the dog, the colon accounts for no more than perhaps 20% of the total. In herbivorous animals that have a well-developed large intestine, there may actually be a net secretion of water within the small intestine during digestion. For example, in the guinea pig (Powell *et al.,* 1968) and horse (Argenzio, 1975), all net absorption of water takes place in the cecum and colon.

Vasoactive intestinal polypeptide (VIP) and acetylcholine have an important role in fluid and electrolyte balance (Hall and German, 2005). As mediators of secretion, they increase intracellular calcium and cyclic adenosine monophosphate (cAMP), inhibit neutral sodium and chloride absorption, and facilitate transcellular chloride efflux. Some bacterial infections result in diarrhea because of an increase in cAMP; functional tumors of VIP-producing cells can also produce diarrhea. Noradrenaline, somatostatin, and opioids, which are the important regulators of absorption, lower intracellular cAMP and calcium concentrations and stimulate neutral NaCl absorption. For these reasons, they can have antidiarrheal effects.

B. Carbohydrate Digestion and Absorption

1. Polysaccharide Digestion

a. Starch and Glycogen

Carbohydrate is present in the diet primarily in the form of polysaccharides. The most common polysaccharides are starch, glycogen, and cellulose. Starch and glycogen are composed of long chains of glucose molecules linked together by repeating α-1,4-glucosidic bonds. Branch points of the chains are linked by α-1,6-glucosidic bonds. In those species that secrete salivary amylase, digestion of starch and glycogen begins in the mouth when this enzyme mixes with food. The action of salivary amylase is interrupted in the stomach, however, because of the low pH of the gastric secretion.

Starch digestion begins again in the proximal small intestine with the highly specific action of pancreatic amylase

TABLE 14-6 Enzymes of the Intestinal Brush Border

Enzyme	Substrate	Product	Reference
Lactase	Lactose	Glucose, galactose	Alpers (1969), Forstner *et al.* (1968)
Sucrase	Sucrose; 1,4% dextrins	Glucose, fructose; residual 1,6-oligosaccharides	Gray *et al.* (1979)
Isomaltase	1,6% Dextrins	Glucose	Gray *et al.* (1979), Rodriguez *et al.* (1984)
%-Limit dextrinase	1,6% Dextrins	Glucose	Taraval *et al.* (1983)
Trehalase	Trehalose	Glucose	Eichholtz (1967), Nakano *et al.* (1977)
Enterokinase	Trypsinogen	Trypsin	Grant and Herman-Taylor (1976)
Aminopeptidase A	Acidic amino-terminal amino acids	Acidic amino acids	Benajiba and Maroux (1980)
Aminopeptidase N	Neutral amino-terminal amino acids	Neutral amino acids	Kim and Brophy (1976), Erickson *et al.* (1983)
(-Glutamyl transferase)	Peptides with (-glutamyl bonds)	(-Glutamyl amino acids)	Benajaba and Maroux (1980), Hughey and Curthoys (1976)
Alkaline phosphatase	Phosphate esters	Inorganic phosphate	Eichholz (1967), Forstner *et al.* (1968)

on α-1,4-glucosidic bonds. This enzyme catalyzes a series of stepwise hydrolytic reactions, resulting in formation of the principal end products of starch digestion, the disaccharides maltose and isomaltose, and small amounts of glucose. Glucose is absorbed directly by the intestinal mucosa and transported to the portal vein. Enzymes of the intestinal cell brush border hydrolyze the disaccharides further.

b. Cellulose

Cellulose, like starch, is a polysaccharide of glucose but differs from starch in that the glucose molecules are linked by β-1,4-glucosidic bonds. All species can utilize starch, but only animals that have extensive bacterial fermentation within the gastrointestinal tract utilize cellulose indirectly as a significant source of energy. Ruminant species digest cellulose most efficiently, but other animals in which the large intestine is well developed (e.g., the horse) also utilize cellulose as an important energy source.

In ruminants, hydrolysis of cellulose is accomplished by cellulitic bacteria, which are part of the complex rumen microflora. The primary end products of cellulose fermentation are short-chain fatty acids: acetic, propionic, and butyric acids. These are absorbed directly from the rumen and serve as the major source of energy for ruminants. Propionic acid is the major precursor for carbohydrate synthesis in mature ruminants.

2. *Disaccharide Digestion*

Maltose and isomaltose are the disaccharides (glucose-glucose) produced as end products of starch digestion. The diet also may contain lactose (galactose-glucose) and sucrose (fructose-glucose). There is general agreement that disaccharide digestion is completed at the surface of the cell by disaccharidases (Gray, 1975), which are components of the brush border (Table 14-6).

The disaccharidases have been solubilized from the brush border and partially purified. Sucrase and isomaltase have been purified together as a two-enzyme complex (Gray *et al.,* 1979; Kolinska and Semenza, 1967), and this enzyme complex accounts for the total hydrolysis of the products of amylase digestion (Gray *et al.,* 1979; Rodriguez *et al.,* 1984). The mutual mucosa contains two enzymes with lactase activity. One of these is a nonspecific β-galactosidase that hydrolyzes synthetic β-galactosides effectively but hydrolyzes lactose at a slow rate. This enzyme has an optimal pH of 3 and is associated with the lysosomal fraction of the cell. The other lactase hydrolyzes lactose readily, is associated with the brush border fraction of the cell, and is the enzyme of primary importance in the digestive process (Alpers, 1969).

Maltase, isomaltase, and sucrase are almost completely absent from the intestine in newborn pigs (Dahlqvist, 1961) and calves. The activity of these disaccharidases increases after birth and reaches adult levels during the first months of life. Lactase activity is highest at birth and decreases gradually during the neonatal period. The relatively high lactase activity may be an advantage to the newborn in utilizing the large quantities of lactose present in their diets. Bywater and Penhale (1969) demonstrated lactase deficiency following acute enteric infections and suggested that lactose utilization may be decreased in such cases.

3. *Monosaccharide Transport*

a. Specificity of Monosaccharide Transport

Regardless of whether monosaccharides originate in the lumen of the intestine or are formed at the surface of the mucosal cell, transport across the mucosa involves processes that have a high degree of chemical specificity. Glucose and galactose are absorbed from the intestine more rapidly than other monosaccharides. Fructose is absorbed at approximately half the rate of glucose, and mannose is absorbed at less than one-tenth the rate of glucose (Kohn *et al.,* 1965).

Glucose and galactose can be absorbed against a concentration gradient. The monosaccharides that are transported most efficiently against gradients have common structural characteristics: (1) the presence of a pyranose ring, (2) a carbon atom attached to C-5, and (3) a hydroxyl group at C-2 with the same stereoconfiguration as D-glucose, but these features are not absolute requirements. Both D-xylose, which has no substituted carbon atom at C-5, and D-mannose, which lacks the appropriate hydroxyl configuration at C-2, can be transported against concentration gradients under specific experimental conditions (Alvarado, 1966b).

Glucose transport is competitively inhibited by galactose (Fisher and Parsons, 1953) and by a variety of substituted hexoses that compete with glucose for carrier binding sites. The glucoside phlorizin is a potent inhibitor (Alvarado and Crane, 1962; Parsons *et al.,* 1958). Phlorizin also competes for binding sites but has a much higher affinity for these sites than does glucose.

The absorptive surface of the mucosal cell is the microvillous membrane, or brush border. It is through this part of the plasma membrane that glucose must pass during the initial phase of mucosal transport. Techniques have been developed for isolating highly purified preparations of microvillous membranes from mucosal homogenates (Forstner *et al.,* 1968). Faust *et al.* (1967) studied the binding of various sugars to these isolated membrane fractions. They found that D-glucose was bound by the membrane preferentially to L-glucose or to D-mannose and that glucose binding was completely inhibited by 0.1mM phlorizin. The specificity of their observations suggested that binding represented an initial step in glucose transport, namely, attachment to a membrane carrier.

b. Sodium Requirement

The absorption of glucose and other monosaccharides is influenced significantly by Na^+ (Kimmich, 1973; Schultz and Curran, 1970). When Na^+ is present in the solution bathing the intestinal mucosa, glucose is absorbed rapidly, but when Na^+ is removed and replaced by equimolar amounts of other cations, glucose absorption virtually stops (Bihler and Crane, 1962; Bihler *et al.,* 1962; Csaky, 1961; Riklis and Quastel, 1958). Glucose absorption is inhibited by ouabain, digitalis, and other cardiac glycosides that are also inhibitors of Na^+-K^+-ATPase activity and Na^+ transport

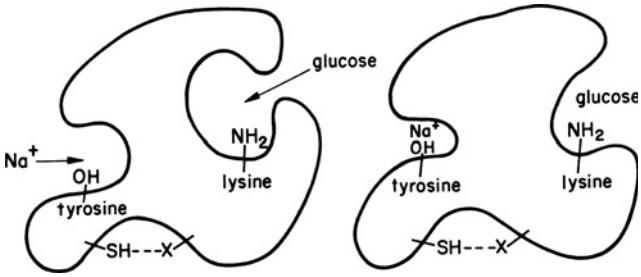

FIGURE 14-5 Model of a Na^+-activated glucose carrier of the intestinal brush border. (From Wright and Peerce, 1985).

(Csaky and Hara, 1965; Schultz and Zalusky, 1964). These observations demonstrate the close relationship between the transport of glucose and Na^+.

c. Characteristics of the Na^+-Glucose Transporter (Carrier)

The concentrative step in the active transport of glucose occurs at the brush border membrane, and energy for this process is derived from an electrochemical Na^+ gradient (Schultz, 1977; Schultz and Curran, 1970). Under conditions of net influx, Na^+ and glucose enter in a ratio of 1:1 (Goldner *et al.,* 1969; Hopfer and Groseclose, 1980). Cotransport of glucose and Na^+ involves a membrane transporter or carrier that is believed to be a 75-kd polypeptide (Wright and Peerce, 1985). Na^+ activates glucose transport primarily by increasing the affinity of the carrier for glucose. A model showing two hypothetical forms of the glucose carrier is presented in Figure 14-5. A galent channel or pore mechanism has been proposed in which the glucose binding site is located within the membrane. The translocation of glucose in this model is believed to be the result of a Na^+-induced conformational change in the transporter (Semenza *et al.,* 1984).

C. Proteins

1. *Enzymatic Hydrolysis*

The initial step in protein digestion is the enzymatic hydrolysis of peptide bonds by proteases with formation of smaller peptides and amino acids. The endopeptidases hydrolyze peptide bonds within the protein molecule and also hydrolyze certain model peptides. Exopeptidases hydrolyze either the carboxy-terminal (carboxypeptidase) or the amino-terminal (aminopeptidase) amino acids of peptides and certain proteins. Thus, a mixture of exopeptidases and endopeptidases cleaves long chain polypeptides from the ends as well as within the length of the chain resulting in sequentially shorter and shorter polypeptide chains and amino acids.

Dietary proteins first come in contact with proteolytic enzymes in the stomach. The best known of the gastric proteases is the family of pepsins (Samloff, 1971), which

hydrolyze most proteins with the exception of keratins, protamines, and mucins. Pepsins are relatively nonselective and hydrolyze peptide bonds involving many amino acids, the most readily hydrolyzed of which involve leucine, phenylalanine, tyrosine, and glutamic acid.

The extent of proteolysis in the stomach depends on the nature of the dietary protein and the duration of time the protein remains in the stomach. The food bolus mixed with saliva has a neutral or slightly alkaline pH as it enters the stomach, and a period of time is required for it to mix with gastric secretions and become acidified. Proteolytic digestion begins when the pH of the gastric contents approaches 4 and occurs optimally in two pH ranges, 1.6 to 2.4 and 3.3 to 4 (Taylor, 1959a, 1959b). Because of the relative lack of specificity of the pepsins, some peptide bonds of almost all dietary proteins are split during passage through the stomach. The gastric phase of protein digestion may have a minor and possibly dispensable role in overall protein assimilation (Freeman and Kim, 1978), but the reservoir function of the stomach contributes to the gradual release of nutrients, ensuring more efficient utilization in the small intestine.

Partially digested peptides pass from the stomach to the duodenum, where the acidic contents are neutralized by sodium bicarbonate present in bile and pancreatic juice. Peptic activity persists in the duodenum only during the period required to raise the pH above 4. The major peptidases that are active within the lumen of the small intestine are the pancreatic enzymes trypsin, chymotrypsin, elastase, and carboxypeptidases A and B. The action of these enzymes is integrated so that the endopeptidases produce peptides with C-terminal amino acids, which then become substrates for the exopeptidases. Trypsin produces peptides with basic C-terminal amino acids that are particularly suited for the action of carboxypeptidase B. Chymotrypsin produces peptides with aromatic amino acids in the C-terminal position, and elastase produces peptides with C-terminal amino acids that are nonpolar. Carboxypeptidase A hydrolyzes both types of C terminal peptide bonds (Table 14-4).

The final steps in peptide digestion are associated with mucosal epithelial cells. Almost all of the aminopeptidase activity is associated with the mucosa, and very little activity is present in luminal contents. Mucosal aminopeptidase activity is located both in the cytosol and in the brush border membrane fractions of the epithelial cell (Heizer and Laster, 1969; Kim *et al.,* 1972). These physically separate enzymes have remarkably different substrate specificities (Kim *et al.,* 1974). The brush border enzyme has more than 50% of the activity for tripeptides yet less than 10% of the total activity for dipeptides relative to the cytosolic enzyme(s) (Kim *et al.,* 1972; Peters, 1970). Almost all activity for tetrapeptides is present in the brush border (Freeman and Kim, 1978). Proline-containing peptides are hydrolyzed almost exclusively by cytosolic peptidases, whereas leucine aminopeptidase activity is located primarily in the brush border. The brush border peptidases appear to have digestive functions similar to the disaccharidases and oligosaccharidases of the brush border. Endopeptidase activity of the intestinal mucosa is associated primarily within the lysosomal fraction of the cell.

2. *Absorption of Proteolytic Products*

Despite the long interest in the subject of this section, the relative amounts of the various protein digestion products (i.e., peptides versus amino acids) that are actually absorbed by intestinal mucosal cells during normal digestion remain problematic. It is a difficult process to investigate because the products of proteolysis are absorbed rapidly after they are formed and, therefore, studies of luminal contents give only an estimate of the overall rate of protein digestion. Equally important, dietary protein is continually mixed with endogenous protein in the form of digestive secretions and extruded mucosal cells. Most endogenous proteins are hydrolyzed and the amino acids absorbed in a manner similar to that of dietary protein, and the two processes occur simultaneously. Endogenous protein accounts for a significant part of the amino acids of the intestinal contents. Even when dietary protein is labeled with a radioactive tracer, there is such rapid utilization that the tracer soon reenters the lumen in the form of endogenous protein secretion.

In adult mammals, protein is not absorbed from the intestine in quantities of nutritional significance without previous hydrolysis. Most neonatal animals absorb significant amounts of immunoglobulin and other colostral proteins, but this capacity is lost soon after birth. The intestinal mucosa, however, is not totally impermeable to large polypeptide molecules. The absorption of insulin (MW 5700; Danforth and Moore, 1959; Laskowski *et al.,* 1958), ribonuclease (MW 13,700; Alpers and Isselbacher, 1967), ferritin, and horseradish peroxidase (Warshaw *et al.,* 1971) has been demonstrated.

During the digestion of protein, the amino acid content of portal blood increases rapidly, but attempts to demonstrate parallel increases in peptides in the portal blood have not been uniformly successful. This has been regarded as evidence that only amino acids can be absorbed by the intestinal mucosa and that the absorption of peptides does not occur. Although it seems clear that most dietary protein is absorbed by the mucosal epithelium in the form of free amino acids, peptides also may be taken up by the mucosal cell in quantitatively significant amounts. Peptides so absorbed may be hydrolyzed either at the cell surface or intracellularly, and individual amino acids finally enter the portal circulation via the basolateral cell membrane.

Small peptides, under certain circumstances, may cross the intestinal epithelium intact and enter the portal circulation. Webb (1986) suggested that intact peptide absorption accounted for more than half of luminal amino acid nitrogen in the calf. The amount of peptide nitrogen entering the portal circulation in other species characteristically has

been lower and variable depending on the source of protein and on the digestibility of the peptide being investigated (Gardner, 1984).

3. *Transport of Amino Acids*

Amino acids, like glucose and certain other monosaccharides, are absorbed and transferred to the portal circulation by active transport processes. The same type of saturation kinetics observed in studies of monosaccharide absorption are observed with amino acids, which suggests the presence of carrier transport mechanisms. Certain monosaccharides inhibit amino acid transport (Newey and Smyth, 1964; Saunders and Isselbacher, 1965), and whereas inhibition generally has been of the noncompetitive type, competitive inhibition between galactose and cycloleucine has been demonstrated (Alvarado, 1966a), which suggests that a common carrier may be involved.

Most amino acids are transported against concentration and electrochemical gradients, and the overall transport process requires metabolic energy. The chemical specificity of these transport mechanisms is shown by the fact that the natural l-forms of various amino acids are absorbed more rapidly than the corresponding d-forms and that only the l-amino acids appear to be actively transported. For most transport systems, Na^+ is necessary for absorption of amino acids as it is for a variety of other nonelectrolyte substances (Gray and Cooper, 1971; Schultz and Curran, 1970).

Separate transport systems exist for different groups of amino acids. Each member of a group inhibits the transport of other members competitively, suggesting that they share the same carrier. There is demonstrable overlap between groups, indicating that the overall transport process is complex (Christensen, 1984, 1985; Stevens *et al.,* 1984). The following is a summary of the designations and substrates of the recognized amino acid transport systems of the intestinal brush border (Stevens *et al.,* 1984):

1. The neutral brush border (NBB) pathway is responsible for monoaminomonocarboxylic (neutral) amino acids and histidine. Na^+ is required, and these amino acids show mutual competition for transport.
2. The monoaminodicarboxylic acids (aspartic and glutamic acid) pathway (XGA) requires Na^+. Aspartic and glutamic acids are not transported against concentration gradients. Following uptake, they are transaminated by the intestinal mucosa and under physiological conditions enter the portal vein as alanine.
3. Imino acids (IMINO), proline, hydroxyproline, methylaminoisobutyric acid, and N-substituted glycine derivatives sarcosine (N-methyl glycine) and betaine (N-dimethylglycine). This pathway also has a Na^+ requirement.
4. Dibasic amino acids (Y^+), including lysine, arginine, ornithine, and the neutral amino acid cystine.
5. Phenylalanine and methionine share the PHE amino acid transport system.

The ϑ-glutamyl cycle has been proposed as a possible transport system for amino acids (Meister and Tate, 1976). ϑ-Glutamyltransferase (GGT) is a membrane-bound enzyme that is present in a number of mammalian tissues and catalyzes the initial step in glutathione degradation. The 0-glutamyl moiety of glutathione is transferred to amino acid (or peptide) receptors with the production of cysteinylglycine:

$$\text{glutathione} + \text{amino acid} \xrightarrow{\text{GGT}} \vartheta\text{-glutamyl-amino acid} + \text{Cys-Gly}$$

The highest GGT activity is present in tissues that are known to transport amino acids actively (e.g., the jejunal villus, the proximal convoluted tubule of the kidney and liver). Meister and his colleagues (1976) have suggested that GGT may function in translocation by interaction with extracellular amino acids and with intracellular glutathione. The hypothetical mechanism involves the noncovalent binding of extracellular amino acids to the plasma membrane, whereas intracellular glutathione interacts with GGT to yield a ϑ-glutamyl-enzyme complex. When the ϑ-glutamyl moiety is transferred to the membrane-bound amino acid, a ϑ-glutamyl-amino acid complex is formed, which, when released from the membrane binding site, moves into the cell. The ϑ-glutamyl-amino acid complex is split by the action of ϑ-glutamyl cyclotransferase, an enzyme appropriately located in the cytosol. Glutathione is regenerated by means of the ϑ-glutamyl cycle, which is a good substrate for GGT (Thompson and Meister, 1975).

The ϑ-glutamyl cycle does not require sodium, and the cycle would not explain the previously demonstrated sodium dependence for amino acid transport. The cycle is not considered to be the only amino acid transport system, and its quantitative significance in individual tissues is unknown.

4. *Neonatal Absorption of Immunoglobulin*

At birth, most domestic species, including the calf, foal, lamb, pig, kitten, and pup, absorb significant quantities of colostral protein from the small intestine. Immune globulin (Ig) either is absent in the serum of domestic species at birth or the level is low. Within a few hours after ingestion of colostrum, the serum Ig levels rise. This represents the principal mechanism by which the young of most domestic animal species acquire maternal immunity. Under normal environmental conditions, ingestion of colostrum is an absolute requirement for health during the neonatal period. The rabbit is the exception in that maternal Ig is received primarily *in utero* by transplacental transfer.

Protein enters the neonatal absorptive cell by pinocytosis and passes through the cell to the lymphatics. The process

is not selective because many proteins other than Ig can be absorbed (Payne and Marsh, 1962). The ability to absorb intact protein is lost by domestic species soon after birth. In the piglet, "closure" occurs within 1 to 2 days (Leary and Lecce, 1978; Westrom *et al.,* 1984) beginning in the duodenum and occurring last in the ileum. In rodents, protein absorption normally continues for approximately 3 weeks. The mechanism of intestinal "closure" was studied, and researchers found that complete starvation of pigs lengthened the period of protein absorption to 4 to 5 days, whereas early feeding shortened the period (Lecce, 1965; Lecce and Morgan, 1962; Leece *et al.,* 1964). Feeding different fractions of colostrum including lactose and galactose resulted in loss of protein absorptive capacity. The route of feeding may not be the critical factor, however. Calves that are prevented from eating but that receive nutrients parenterally lose the ability to absorb protein at the same time as control calves (Deutsch and Smith, 1957).

In the neonatal calf, Ig deficiency resulting from a failure of colostral Ig absorption plays a role in the pathogenesis of Gram-negative septicemia (Gay, 1965; Smith, 1962). Most calves deprived of colostrum develop septicemia early in life and may develop acute diarrhea before death (Smith, 1962; Tennant *et al.,* 1975; Wood, 1955). Hypogammaglobulinemia is almost always demonstrable in calves dying of Gram-negative septicemia and is the result either of insufficient Ig intake or of insufficient intestinal absorption. The Ig fraction is the essential factor in colostrum that protects against systemic infections (Penhale *et al.,* 1971).

Serum immunoglobulin values of neonatal calves vary, and a 10% incidence of hypogammaglobulinemia may occur in clinically normal calves (Braun *et al.,* 1973; House and Baker, 1968; Smith *et al.,* 1967; Tennant *et al.,* 1969; Thornton *et al.,* 1972). Most such individuals probably have insufficient colostrum intake. Even when calves were given the opportunity to ingest colostrum, however, a surprising number were hypogammaglobulinemic. Some of the reasons for varying gammaglobulinemia values are recognized, but the relative importance of each is not known. The concentration of lactoglobulin, the volume consumed (Selman *et al.,* 1971), the time elapsed from birth to ingestion of colostrum (Selman *et al.,* 1971), and the method of ingestion (natural suckling versus bucket feeding) may have an important influence on the serum IgG (McBeath *et al.,* 1971; Smith *et al.,* 1967). Calves that suckle their dams usually attain serum IgG concentrations that are higher than those attained by calves given colostrum from a bucket. The frequency of hypogammaglobulinemia may be influenced by season (Gay *et al.,* 1965b; McEwan *et al.,* 1970a), although this relationship is not consistent (Smith *et al.,* 1967; Thornton *et al.,* 1972). Familial factors also may influence development of hypogammaglobulinemia (Tennant *et al.,* 1969).

Regardless of cause, the mortality of hypogammaglobulinemic calves is higher than that of calves with normal serum IgG levels (Boyd, 1972; Gay, 1965; House and Baker, 1968; McEwan *et al.,* 1970a; Naylor *et al.,* 1977; Thornton *et al.,* 1972). In addition to having more septicemic infections (Gay, 1965; McEwan *et al.,* 1970a; Roberts *et al.,* 1954; Smith, 1962; Wood, 1955), hypogammaglobulinemic calves have a greater prevalence of acute diarrheal disease (Boyd, 1972; Gay *et al.,* 1965a; Naylor *et al.,* 1977; Penhale *et al.,* 1970), which indicates that the local protective effects of Ig in the intestine are important (Fisher *et al.,* 1975; Logan and Penhale, 1971).

The prevalence of hypogammaglobulinemia and the high mortality associated with it has led to the development of several rapid tests for identification of hypogammaglobulinemic calves (Aschaffenburg, 1949; Fisher and McEwan, 1967b; McBeath *et al.,* 1971; Patterson, 1967; Stone and Gitter, 1969). The zinc sulfate turbidity test (Kunkel, 1947) was the first to be used to determine the serum immunoglobulin concentrations of neonatal calves (McEwan *et al.,* 1970b). A close correlation has been established between test results and the amount of serum IgG and IgM (Fisher and McEwan, 1967b, 1967b; McEwan *et al.,* 1970b).

The sodium sulfite turbidity test is similar to the zinc sulfate test and also has been used to identify hypogammaglobulinemic calves (Pfeiffer and McGuire, 1977; Stone and Gitter, 1969). Failure of turbidity to develop when serum is added to a saturated solution of sodium sulfite indicates immunoglobulin deficiency. A semiquantitative assessment of the Ig concentration is made by grading the degree of turbidity (Stone and Gitter, 1969).

The refractometer is used as a rapid test for Ig deficiency (Boyd, 1972; McBeath *et al.,* 1971). There is a close relationship between the concentration of IgG and total serum protein (TSP) in neonatal calves (Tennant *et al.,* 1969), and the wide variations in TSP were due to variations in IgG. Direct linear correlation between the refractive index (RI) and the Ig concentration has also been observed (McBeath *et al.,* 1971). The regression line for this relationship was independently confirmed (Tennant *et al.,* 1978). The Y intercepts in these studies were identical (4 g/dl). The refractometer has a value as a rapid field instrument for the assessment of Ig status, but in cases of hemoconcentration it has limitations (Boyd, 1972).

The glutaraldehyde coagulation test was used originally in cattle to detect hypergammaglobulinemia in samples of whole blood (Sandholm, 1974). Glutaraldehyde has also been used in a semiquantitative test to evaluate IgG in canine (Sandholm and Kivisto, 1975) and human serum (Sandholm, 1976). This procedure has been modified to detect hypogammaglobulinemic calves. Calves with a negative test result (serum IgG #0.4 g/dl) had markedly higher mortality than calves with positive results (Table 14-7) (Tennant *et al.,* 1979), which is similar to results obtained by using the zinc sulfate turbidity test (Gay *et al.,* 1965a; McEwan *et al.,* 1970a) or other estimates of circulating IgG. Many tests can be initiated quickly using the glutaraldehyde coagulation test, and results can be evaluated rapidly without instrumentation.

TABLE 14-7 Relationship between Results of the Glutaraldehyde Coagulation Test, Serum (-Globulin) Concentration, and Death Rate

Source of Calves	No.	Glutaraldehyde Reaction	Serum (-Globulin (/dl))		Death Rate (%)
			Mean (±SD)	Extremes	
Calves before ingestion of colostrums	10	Negative	0.18 (±0.06)	0.1–0.25	—[a]
Calves from production unit	60	Negative	0.35 (±0.13)	0.11–0.63	16.7[b]
	13	Incomplete	0.60 (±0.13)	0.42–0.85	7.7
	208	Positive	1.46 (±0.63)	0.42–4.4	3.4

[a] *Samples of serum were obtained at birth, but no follow-up of calves was made.*
[b] *The death rate of calves that were test-negative was significantly* ($p < 0.01$) *greater than that of test-positive calves, using t-test for significance of differences between two percentages.*

D. Lipids

1. *Absorption of Fats*

a. Luminal Phase

The fat in the diet is primarily in the form of triglycerides or long-chain fatty acids. In the dog, gastric lipase plays a credible role in fat digestion, leading to the formation of fatty acids, which help coordinate gastric emptying and pancreatic secretions. In other species, the initial step in utilization of triglycerides occurs in the lumen of the proximal small intestine, where hydrolysis is catalyzed by pancreatic lipase. The pancreas secretes lipase in active form. The enzyme requires an oil-water interface for activity, so only emulsions of fat can be hydrolyzed. Enzyme activity is directly related to the surface area of the emulsion, so the smaller the emulsion particle, the greater the total surface area of a given quantity of triglyceride and the greater the rate of hydrolysis (Benzonana and Desnuelle, 1965). Bile salts are not an absolute requirement but favor hydrolysis by their detergent action, which causes formation of emulsions with small particle sizes and by stimulating lipase activity within the physiological pH range of the duodenum. A colipase is present in the pancreatic secretion, which facilitates the interaction of lipase with its triglyceride substrate and protects lipase from inactivation (Borgstrom and Erlanson, 1971).

Pancreatic lipase splits the ester bonds of triglycerides preferentially at the 1 and 3 positions so that the major end products of hydrolysis are 2-monoglycerides and free fatty acids. Both compounds are relatively insoluble in water but are brought rapidly into micellar solution by the detergent action of bile salts. The mixed micelles so formed have a diameter of approximately 2nm and are believed to be the form in which the products of fat digestion are actually taken up by the mucosal cell (Hofmann and Small, 1967). The intraluminal events that occur in fat absorption are schematically summarized in Figure 14-6.

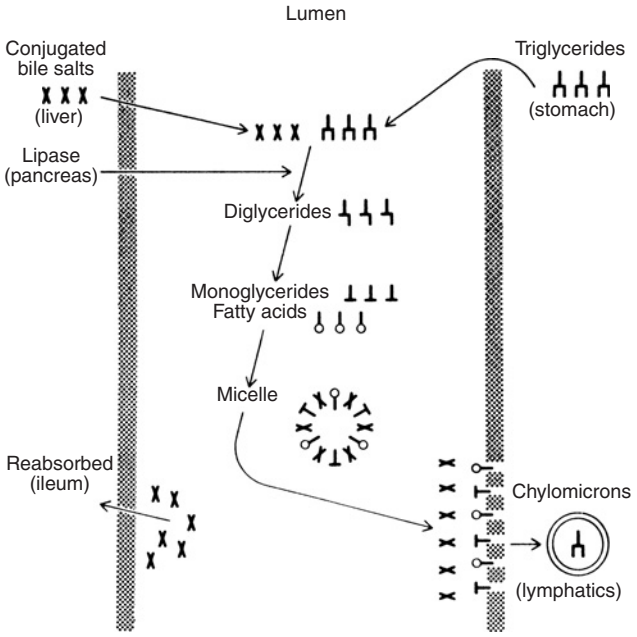

FIGURE 14-6 Intraluminal events during fat absorption. From Isselbacher (1967).

b. Mucosal Phase

The initial step in intestinal transport of fat is the uptake of fatty acids and monoglycerides by the mucosal cell from micellar solution. The precise mechanism is yet unclear, but present evidence suggests that the lipid contents of the micelle are somehow discharged at the cell surface and enter the mucosal cell in molecular rather than micellar form (Isselbacher, 1967). The net effect is the absorption of the end products of lipolysis and the exclusion of bile salts, which are absorbed farther down the intestine, primarily in the ileum. Uptake of fatty acids appears to be a passive process having no requirement for metabolic energy.

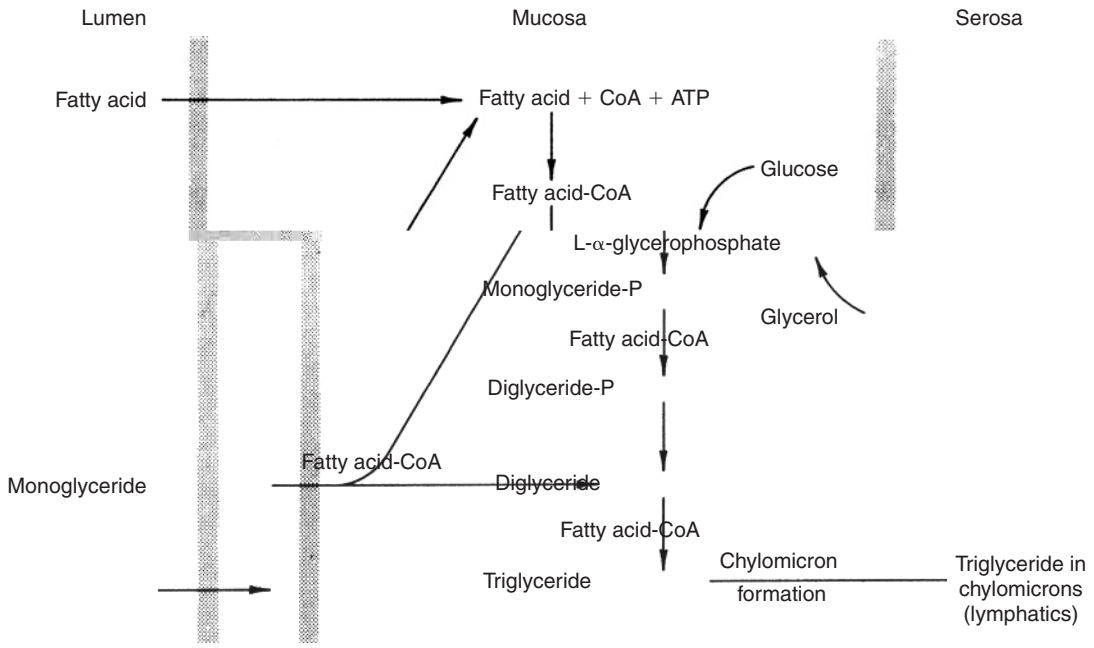

FIGURE 14-7 Biochemical reactions involved in intestinal transport of long chain fatty acids and monoglycerides. From Isselbacher (1966).

Within the mucosal cell, the fatty acids are transported by a soluble binding protein to the endoplasmic reticulum, where the fatty acids and monoglycerides are rapidly reesterified to triglyceride (Ockner and Isselbacher, 1974; Ockner and Manning, 1974). The two biochemical pathways for triglyceride biosynthesis in the intestine are summarized in Figure 14-7. Direct acylation of monoglyceride occurs in the intestine and is the major pathway for lipogenesis in the intestine during normal fat absorption. The initial step in this series of reactions involves activation of fatty acids by acyl-CoA synthetase, a reaction that requires Mg^{2+}, ATP, and CoA and that has a marked specificity for long-chain fatty acids. This specificity explains the observation by Bloom *et al.* (1951) that medium- and short-chain fatty acids are not incorporated into triglycerides during intestinal transport but enter the portal circulation as nonesterified fatty acids. The activated fatty acids then react sequentially with mono- and diglycerides to form triglycerides in steps catalyzed by mono- and diglyceride transacylases. The enzymes responsible for this series of reactions are present in the microsomal fraction of the cell (Rao and Johnston, 1966). These enzymes occur together in the endoplasmic reticulum as a "triglyceride-synthetase" complex.

An alternate route that is available for fatty acid esterification involves L-α-glycerophosphate derived either from glucose or from dietary glycerol by the action of intestinal glycerokinase. Activated fatty acid CoA derivatives react with L-α-glycerophosphate to form lysophosphatidic acid (monoglyceride phosphate), which by a second acylation forms phosphatidic acid (diglyceride phosphate). Phosphatidic acid phosphatase then hydrolyzes the phosphate ester bond, forming diglyceride, and by means of a transacylase step similar to that described previously, triglyceride is formed. Although this pathway appears to be of minor importance for triglyceride synthesis in the intestine, intermediates in this sequence of reactions are important in the synthesis of phospholipids, which are essential for stabilization of the chylomicron.

The next step in fat transport is formation of chylomicrons within the endoplasmic reticulum. The chylomicron is composed primarily of triglyceride and has an outer membranous coating of cholesterol, phospholipid, and protein (Zilversmit, 1965). The β-lipoprotein component of the chylomicron is synthesized by the intestinal mucosal cell. Inhibition of protein synthesis by puromycin or acetoxycycloheximide interferes with chylomicron formation and significantly reduces fat transport (Sabesin and Isselbacher, 1965).

The final step in fat absorption is extrusion of the chylomicra into the intercellular space opposite the basal lateral portion of the absorptive cell by reverse pinocytosis. From the intercellular space, the chylomicra pass through the basement membrane and enter the lacteal. The chylomicra then pass from the lacteals into lymph ducts and into the general circulation, thereby completely bypassing the liver during the initial phase of absorption.

2. *Absorption of Other Lipids*

a. Cholesterol

Dietary cholesterol is present in both free and esterified forms, but only nonesterified cholesterol is absorbed.

Cholesterol esters are hydrolyzed within the lumen of the intestine by sterol esterases secreted by the pancreas. Bile salts are required both for the action of this enzyme and for the absorption of nonesterified cholesterol. In the mucosal cell, cholesterol is reesterified and transferred by way of the lymph to the general circulation. The type of triglyceride present in the diet significantly affects the absorption of cholesterol and its distribution in lymph lipids (Ockner *et al.,* 1969).

b. Vitamin A

The diet contains vitamin A activity in two principal forms: (1) as esters of preformed vitamin A alcohol (retinol) and fatty acids and (2) as provitamin A, primarily β-carotene. Vitamin A ester is hydrolyzed by a pancreatic esterase within the lumen (Murthy and Ganguly, 1962), and the free alcohol is absorbed in the upper small intestine. Vitamin A alcohol is reesterified in the mucosa primarily with palmitic acid. The vitamin A ester is absorbed by way of the lymph, and after reaching the general circulation, it is rapidly cleared from the plasma and stored in the liver. In the postabsorptive state, vitamin A circulates as the free alcohol, the form released as needed from the liver by the action of hepatic retinylpalmitase esterase. The blood level of vitamin A is independent of liver reserves, and, as long as a small amount of vitamin A is present in the liver, the blood level remains normal (Dowling and Wald, 1958).

In diets that lack animal fat, the carotenes, primarily β-carotene, serve as the major precursor of vitamin A. The intestinal mucosa has a primary role in conversion of provitamin A to the active vitamin, although conversion can occur to a limited degree in other tissues. The mechanism involves central cleavage of β-carotene into two active vitamin A alcohol molecules that are subsequently esterified and absorbed by the lymphatics as with preformed vitamin A.

Bile salts are required for the mucosal uptake of β-carotene and for the conversion of β-carotene to vitamin A. Uptake of carotene and release of vitamin A ester into the lymph are rate-limiting steps. Cattle absorb substantial amounts of β-carotene without prior conversion to vitamin A, and these pigments are responsible for much of the yellow color of the plasma. Most other species have no β-carotene in the plasma, and extraintestinal conversion is thought to be more efficient in these species than in cattle (Ganguly and Murthy, 1967).

c. Vitamin D

Vitamin D, like cholesterol, is a sterol that is absorbed by the intestine and transported via the lymph (Schachter *et al.,* 1964). Intestinal absorption differs, however, in that vitamin D is transported to the lymph in nonesterified form. The uptake of vitamin D by the mucosal cell is favored by the presence of bile salts. Simultaneous absorption of fat from micellar solutions increases transport of vitamin D out of the cell into the lymph, the limiting step.

One of the major actions of vitamin D is to enhance the intestinal absorption of calcium. Wasserman and coworkers (1968) (Wasserman and Taylor, 1966, 1968) have described the mechanism of action of vitamin D. They have shown that vitamin D causes synthesis of a calcium-binding protein that plays a central role in the transport of calcium.

E. Cobalamin

Following ingestion, cobalamin is released from food in the stomach (Batt and Morgan, 1982; Simpson *et al.,* 2001). It is then bound to a nonspecific cobalamin-binding protein of salivary and gastric origin called haptocorrin. Intrinsic factor (IF), a cobalamin-binding protein that promotes cobalamin absorption in the ileum, is produced by parietal cells and cells at the base of antral glands in the dog but not the cat; IF is produced in the pancreas of cats. The affinity of cobalamin for haptocorrin is higher at acid pH than for IF, so most is bound to haptocorrin in the stomach. Upon entering the duodenum, haptocorrin is degraded by pancreatic proteases, and cobalamin is transferred from haptocorrin to IF, a process facilitated by the high affinity of IF for cobalamin at neutral pH. Cobalamin-IF complexes traverse the intestine until they bind to specific receptors (previously called IFCR, but recently dubbed cubilin) located in the microvillous pits of the apical brush border membrane of ileal enterocytes. Cobalamin is then transcytosed to the portal bloodstream and binds to a protein called transcobalamin 2(TC II), which mediates cobalamin absorption by target cells. A portion of cobalamin taken up by hepatocytes is rapidly (within an hour in the dog) reexcreted in bile bound to haptocorrin. Cobalamin of hepatobiliary origin, in common with dietary derived cobalamin, undergoes transfer to IF and receptor mediated absorption, thus establishing enterohepatic recirculation of the vitamin.

Low serum cobalamin concentrations in dogs have been associated with exocrine pancreatic insufficiency (EPI), severe intestinal disease, IF-Cbl receptor abnormalities, and conditions associated with the proliferation of enteric bacteria (e.g., stagnant loops). Cobalamin deficiency in cats and dogs results in a significant metabolic disorder, which can be ameliorated by treatment or correction of the underlying cause.

Dietary folate polyglutamate is deconjugated by folate deconjugase to folate monoglutamate, which is absorbed by specific carriers in the proximal small intestine. Folate deconjugase is a jejunal brush border enzyme. Folic acid, which is produced by microorganisms in the small intestine, is also absorbed and can increase existing serum levels of folate. Serum levels of folate are expected to decrease when the absorptive capacity of the proximal intestine is severely compromised, as might occur with infiltrative bowel disease.

VIII. DISTURBANCES OF GASTROINTESTINAL FUNCTION

A. Vomition

Vomiting is a coordinated reflex act that results in rapid, forceful expulsion of gastric contents through the mouth. The reflex may be initiated by local gastric irritation caused by a variety of toxic irritants, infectious agents, foreign bodies, gastric tumors, obstructions of the pyloric canal or the small intestine, or by drugs such as apomorphine or other toxic substances that act centrally on the "vomiting center" of the medulla.

Severe vomiting produces loss of large quantities of water and of $H^+$and $C1^-$ ions. These losses cause dehydration, metabolic alkalosis with increased plasma HCO_3^-, and hypochloremia. Chronic vomiting may also be associated with the loss of significant tissue K^+ and with hypokalemia. The K^+ deficit is caused primarily by increased urinary excretion resulting from alkalosis (Leaf and Santos, 1961). Gastric secretions contain significant quantities of K^+, and losses in the vomitus also contribute to the K^+ deficiency. K^+ deficiency, which develops initially because of the alkalosis, perpetuates the alkalotic state by interfering with the ability of the kidney to conserve H^+ (Brazeau *et al.,*1956; Darrow, 1964). Both K^+ and the hypovolemia caused by dehydration may result in renal tubular damage and in renal failure.

Vomiting occurs frequently in the dog, cat, and pig but is an unusual sign in the horse, which has anatomical restrictions of the esophagus that interfere with expulsion of gastric contents. In cattle, sheep, and goats, the physiological process of rumination utilizes neuromuscular mechanisms similar to those involved in vomiting. Uncontrolled expulsion of ruminal contents is an uncommon sign, most frequently occurring after ingestion of toxic materials or associated with traumatic reticulitis and resulting "vagal indigestion." The contents of the abomasum are not expelled directly even when the pyloric canal is obstructed. Pyloric outflow obstruction does occur in cattle, which is similar metabolically to that observed in nonruminants. This obstruction may be observed in right-sided displacement of the abomasum with or without torsion, occasionally with left-sided displacement of the abomasum, in cows with functional pyloric obstruction as a result of reticuloperitonitis and from "vagal indigestion." When the pylorus is obstructed, abomasal contents are retained, causing distension of the abomasum, which in turn stimulates further secretion and retention. Retained abomasal contents may be regurgitated into the large reservoir of the rumen and sequestered there from other fluid compartments of the body. The net result is loss of H^+ and Cl^- ions and development of metabolic alkalosis, hypochloremia, and hypokalemia. This metabolic syndrome often is associated with fluid distension of the rumen related to pyloric outflow obstruction. Similar distension of the rumen in the absence of hypochloremic, hypokalemic metabolic alkalosis suggests more proximal obstruction of rumen outflow, namely the omasum.

Brachycephalic, middle-aged, small breed dogs (e.g., Shih Tzus) seem predisposed to hypertrophy of the pyloric mucosa or muscularis (Simpson, 2005); this syndrome, as well as other causes of pyloric outflow obstruction, can result in vomiting, metabolic alkalemia, and paradoxic aciduria. Chronic hypertrophic gastritis, which resembles Menetrier's disease in humans, has been demonstrated in the dog (Happe and van der Gagg, 1977; Kippins, 1978; van der Gagg *et al.,* 1976; Van Kruiningen, 1977). Van Kruiningen's series of cases were basenjis that had concomitant lymphocytic-plasmocytic enteritis. The primary disease, however, has been observed in other breeds without intestinal lesions. Signs of illness usually involve chronic vomiting, weight loss, and occasionally diarrhea. Hypoalbuminemia occurs in most cases. In humans, hyperchlorhydria or achlorhydria can occur. The morphological changes in the stomach wall (hypertrophic rugae) and some of the clinical features help to differentiate this disease from gastric neoplasia.

Functional gastrinomas have been rarely diagnosed in the dog and have been compared to the Zollinger-Ellison syndrome in humans (English *et al.,* 1988; Straus *et al.,* 1977; van der Gagg and Happe, 1978). Clinical disease is associated with hypergastrinemia, hyperchlorhydria, hypertrophic gastritis, peptic esophagitis, and duodenal ulcers. A more recent overview by Simpson (2000) revealed a wide variety of breeds with a mean age of 9 years; no sex bias was identified. The diagnostic workup usually centered around the problems of vomiting, weight loss and anorexia, and the pursuit of localizing findings of melena, hematemesis, and abdominal pain. Some of these dogs had signs associated with gastrointestinal preformation/peritonitis. Surgical treatment or medical management, to include omeprazole, famotidine, sucralfate, or octreotide, is indicated. Because metastasis is frequently present, the prognosis for recovery is poor.

B. Gastric Dilatation-Volvulus

Gastric dilatation-volvulus (GDV) is an acute gastrointestinal disorder associated with high mortality (Leib and Blass, 1984; Morgan, 1982). It typically occurs in large deep-chested dogs but has been reported in smaller dogs, the cat, and other species. Gastric dilatation precedes development of volvulus and is the result of the accumulation of gas and fluid in the stomach as a result either of mechanical or functional disturbances in pyloric outflow. As the stomach distends and rotates about the distal esophagus, displacement and occlusion of the pylorus and duodenum occur. Necrosis and perforation of the stomach wall and peritonitis are common causes of death.

Distension and displacement of the stomach cause obstruction of the caudal vena cava and portal vein resulting

in venous stasis and sequestration of blood in splanchnic, renal, and posterior muscular capillary beds. This decrease in circulating blood volume (venous return) and subsequent decrease in cardiac output, arterial blood pressure, and tissue perfusion culminate in hypovolemic shock. Endotoxemia, a consequence of portal vein occlusion, contributes to the shock syndrome. The release of myocardial depressant factors from ischemic pancreatic tissue impairs the clearance of endotoxins by the reticuloendothelial system as well as causing direct cardiodepressant effects. Altered microvascular perfusion with hypoxemia and endotoxemia favors development of disseminated intravascular coagulopathy (DIC) (Lees *et al.,* 1977).

Increased plasma gastrin immunoreactivity has been reported in dogs with GDV (Leib *et al.,* 1984). Preexisting conditions of relative hypergastrinemia may predispose to GDV. Gastrin can increase caudal esophageal sphincter pressure, delay gastric emptying, and predispose to pyloric outflow obstruction by causing gastric mucosal and pyloric muscular hypertrophy.

Experimental gastric dilatation and dilatation with torsion have been studied in the dog (Wingfield *et al.,* 1974). Hyperkalemia and hyperphosphatemia were consistent findings in dogs with gastric dilatation and torsion (Wingfield *et al.,* 1974). This was the result of hypovolemia, decreased renal perfusion, and renal insufficiency on the one hand and the loss of intracellular K^+ from damaged tissue on the other. Increased blood urea nitrogen (BUN) and serum creatinine (Cr) levels persisted after decompression of the stomach. Hemoconcentration and increased TSP were attributed to fluid shifts from the vascular compartment into the lumen of the alimentary tract, wall of the stomach, and peritoneal cavity. Increased alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were most apparent following decompression of the stomach and were attributed to alteration of hepatocytes and smooth muscle of the stomach and spleen. Increased levels of creatine kinase (CK) resulted from the effects of tissue hypoxia on striated muscle. Metabolic acidosis was attributed in part to increased production of lactic acid caused by tissue hypoxia.

A wide range of acid-base and electrolyte disturbances has been reported in clinical patients with GDV (Kagan and Schaer, 1983; Muir, 1982; Wingfield *et al.,* 1982). Dogs presenting with GDV may have normal acid-base status. Metabolic acidosis and hypokalemia commonly occur. Metabolic alkalemia and respiratory alkalosis also have been observed. Hyperkalemia is unusual. The absence of an increase in anion gap in one study indicated that the production of volatile fatty acids and lactic acid was not excessive (Wingfield *et al.,* 1982).

C. Ischemia-Reperfusion Injury

Ischemia-reperfusion injury is a contributing cause of death in horses with strangulating intestinal obstruction (Moore *et al.,* 1995) and in dogs with GDV. Together with luminal occlusion of the alimentary tract, functional constriction or mechanical obstruction of intestinal vasculature occurs. Depending on the duration and severity of ischemia, oxygenation of tissue is compromised, and there is a subsequent attenuation of oxidative phosphorylation and a decrease in ATP. Anaerobic glycolysis ensues, leading to intracellular acidosis and increased intracellular concentrations of Ca^{2+}. Unless timely restoration of blood flow and oxygenation occurs, these metabolic derangements eventually contribute to cellular edema, lysosomal release of degradative enzymes, autolytic destruction of cellular organelles, and cell death.

When intestinal obstruction is relieved and tissue perfusion is reestablished, reoxygenation of tissue can result in a cascade of biochemical events that can aggravate ischemic-induced tissue injury. The resulting reperfusion injury is caused in part by oxygen-free radicals (OFR), particularly superoxide (O_2^-) and hydroxyl-free radicals (OH.), and is characterized by increased microvascular and mucosal permeability and mucosal necrosis (Moore *et al.,* 1995). The formation of OFRs is preceded by accumulation of hypoxanthine in endothelial cells and intestinal mucosal cells during ischemia. The conversion of xanthine dehydrogenase to xanthine oxidase also occurs during ischemia, a reaction that is facilitated by high intracellular levels of calcium ions and the protease, calpain. When reperfusion occurs, xanthine oxidase converts hypoxanthine to uric acid and superoxide radicals. O_2^- and hydrogen peroxide (H_2O_2), a product of superoxide dismutase (SOD) reduction, are converted to highly reactive OH. in the presence of an iron catalyst. OH. initiates structural and functional cellular membrane damage via lipid peroxidation. The release of inflammatory mediators attending lipoperoxidation contributes to tissue injury.

Malondialdehyde (MDA) is a stable by-product of lipoperoxidation, and investigators can utilize its detection as an indicator of ischemia-reperfusion injury (Moore *et al.,* 1995).

Neutrophils are recruited into ischemic and reperfused tissue by xanthine oxidase-derived OFRs and chemoattractants released from cellular membranes during lipid peroxidation. Increased cytosolic calcium concentrations during ischemia and subsequent lipoperoxidation activate phospholipase A2, which in turn causes the release of platelet-activating factor (PAF), metabolites of arachidonic acid (leukotrienes and prostaglandins), and lysophosphatidylcholine. Leukotriene B4, thromboxane A2, and PAF are the primary products of phospholipid metabolism that promote infiltration and degranulation of neutrophils in affected tissue.

When neutrophils attach to endothelium, they release elastase and lactoferrin, which promotes extravasation (Moore *et al.,* 1995). The conversion of oxygen to O_2^- within neutrophils is facilitated by the NADPH oxidase

system. These O_2^- are metabolized to H_2O_2, and the latter reacts with Cl^- to form hypochlorous acid. Myeloperoxidase (MPO), an enzyme contained in neutrophils, catalyzes this reaction. MPO activity in intestinal mucosa correlates well with the degree of neutrophil infiltration and mucosal injury.

Serine proteases are believed to play a contributing role in ischemia-reperfusion injury (Moore *et al.,* 1995). The pancreas is an important source of endoproteases (trypsin, chymotrypsin, and elastase), which can cause mucosal injury, particularly in the small intestine. Proteases produced by granulocytes, as well as lysosomes, are more important in mucosal injury of the large bowel, elastase, neutral proteases, and cathepsin G are released from granulocytes during phagocytosis. Cathepsin B is a lysosomal protease that has trypsin-like activity.

Several pharmacological agents have been used in experimental and clinical studies of ischemia-reperfusion injury (Moore *et al.,* 1995). The mechanistic rationale for many of these agents is comparable to the role of endogenous antioxidants. Examples of commonly used agents include xanthine oxidase inhibitors (allopurinol), deferoxamine, 21-aminosteroids, inhibitors of PLA2, cyclooxygenase, and lipoxygenase. Superoxide dismutase (SOD), catalase, and glutathione peroxidase (Gpx) are free radical scavenging enzymes. Mannitol, albumin, dimethyl sulfoxide (DMSO), dimethyl thiourea, and manganese chloride represent nonenzymatic free radical scavengers. Other agents that have been studied include nitric acid, protease inhibitors, hydroxyethyl starch, and neutrophil-directed agents. Although there has been demonstrable efficacy of the aforementioned agents in some studies, there are many inconsistencies. From a clinical perspective, success has been limited with single agents, and there is more interest in combination or multimodal therapy.

D. Acute Diarrheas

The term *diarrhea* is used to generically describe the passage of abnormally fluid feces with increased frequency, increased volume, or both. The significance of diarrhea depends primarily on the underlying cause and on the secondary nutritional and metabolic disturbances that are caused by excessive fecal losses.

There are theoretically three factors that can act independently or in combination to produce diarrhea. An increase in the rate of intestinal transit is one factor believed important in functional disorders of the gastrointestinal tract in which "hypermotility" has been considered to be the primary cause. Although increased intestinal motility may be a factor in certain types of diarrheal disease, when motility patterns have been investigated, diarrheal disease has actually been associated with decreased motility (Christensen *et al.,* 1972). A second factor in the pathogenesis of diarrhea is decreased intestinal assimilation of nutrients that may result either from decreased intraluminal hydrolysis of nutrients (e.g., *maldigestion* resulting from pancreatic exocrine insufficiency), bile salt deficiency, or defective mucosal transport of nutrients (i.e., *malabsorption*) that results from various types of inflammatory bowel disease, villus atrophy, intestinal lymphoma, or intrinsic biochemical defects in the mucosal cell that interfere with digestion or absorption. Finally, increased intestinal secretion of water and electrolytes is a major factor in the pathogenesis of certain types of acute diarrhea.

Enteropathogenic strains of *Escherichia coli* produce soluble enterotoxins (Kohler, 1968; Moon, 1978; Smith and Halls, 1967), which alter bidirectional Na^+ and water flux (Fig. 14-8). The most extensively studied enterotoxin is that produced by *Vibrio cholerae.* This bacterium produces a large-molecular-weight, heat-labile toxin (CT), one subunit of which has properties similar to those of the heat-labile (LT) enterotoxin produced by certain strains of *E. coli* (Richards and Douglas, 1978). The mechanism of action of CT is believed to involve the activation of adenylate cyclase. This membrane-bound enzyme converts ATP to cAMP, which through the action of protein kinase is responsible for the greatly increased secretion of water and electrolytes by the intestinal mucosa. Although species differences have been observed (Forsyth *et al.,* 1978), this mechanism appears to be important in the mode of action of LT of *E. coli* as well (Richards and Douglas, 1978).

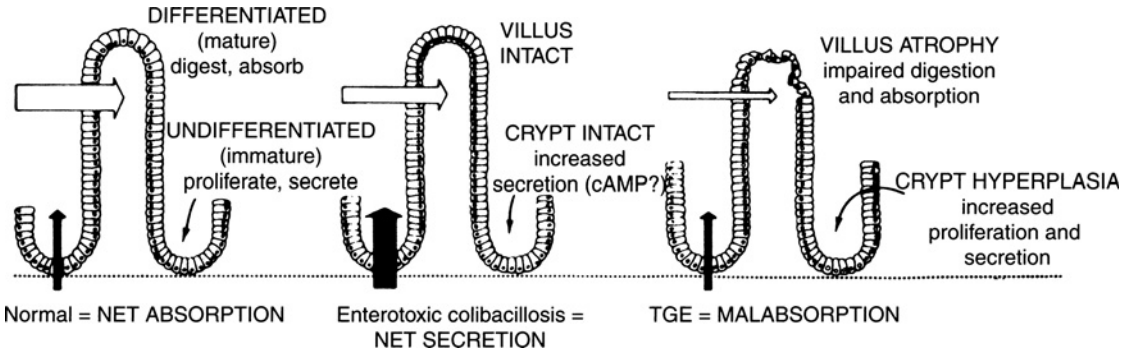

FIGURE 14-8 Pathogenesis of diarrhea caused by *E. coli* enterotoxin and by coronaviruses. From Moon (1978).

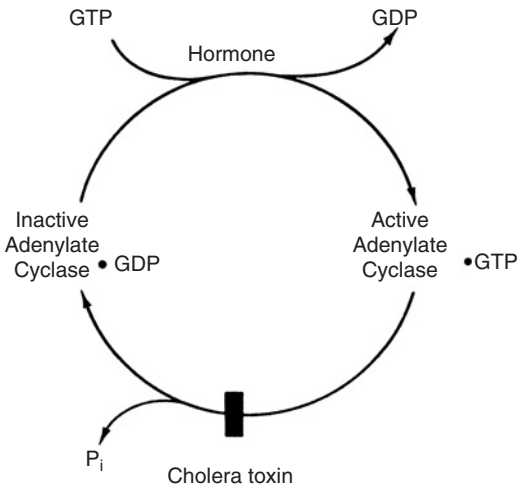

FIGURE 14-9 Mechanism of action of cholera toxin, which inhibits hydrolysis of GTP, thereby increasing adenylate cyclase activity. From Cassell and Selinger (1978).

Additional extensive studies have centered on the molecular mechanism of action of CT. Under physiological conditions, adenylate cyclase is activated by the binding of guanosine triphosphate to the inactive enzyme. An associated GTPase inactivates the enzyme by converting enzyme-bound GTP to GDP and inorganic phosphate. This GTP-GDP system plays a critical role in the physiological regulation of adenylate cyclase. Cholera toxin is believed to bind to the adenyl cyclase in a way that inhibits hydrolysis of GTP, thereby maintaining the enzyme in an activated state (Cassel and Pfeuffer, 1978; Johnson *et al.,* 1978; Levinson and Blume, 1977) (Fig. 14-9).

Certain enteropathogenic strains of *E. coli* produce a low-molecular-weight, heat-stable toxin (ST) alone or in addition to LT (Moon, 1978; Richards and Douglas, 1978). In epidemiological studies of neonatal diarrheal diseases of calves, most isolated strains of *E. coli* produce only ST (Braaten and Myers, 1977; Lariviere *et al.,* 1979; Moon *et al.,* 1976). In contrast to LT and CT, which induce intestinal Na^+ and water secretion only after a lag phase of several hours, ST induces intestinal secretion immediately. ST induces intestinal secretion by activating guanylate cyclase and the mediator of intestinal secretion induced by ST is cyclic 3′,5′-guanosine monophosphate (Field *et al.,* 1978; Hughes *et al.,* 1978).

Enterotoxin-induced intestinal secretion may be blocked by cycloheximide, an inhibitor of protein synthesis (Serebro *et al.,* 1969). The lack of specificity and the toxicity of cycloheximide precluded its clinical use, but acetazolamide has been shown to inhibit intestinal fluid secretion (Moore *et al.,* 1971; Norris *et al.,* 1969). Ethacrynic acid, another potent diuretic, has been shown to inhibit enterotoxin-induced fluid secretion (Carpenter *et al.,* 1969). Unfortunately, the diuretic effects of these drugs preclude their clinical use but similar drugs with "intestinal specificity" would have significant therapeutic potential. Adenosine analogues also have been shown to inhibit cholera toxin-stimulated intestinal adenylate cyclase.

Prostaglandin E_1 (PgE_1) and CT have similar effects on electrolyte transport in rabbit ileum. Application of either to the mucosa inhibits NaCl absorption and stimulates Cl^+ secretion. Both indomethacin (Gots *et al.,* 1974) and aspirin (Farris *et al.,* 1976) inhibit enterotoxin-induced intestinal secretion in laboratory animal models, and the prostaglandins do not function as mediators in the pathogenesis of cholera (Schwartz *et al.,* 1975). However, Jones *et al.* (1977) demonstrated a positive therapeutic response to a new prostaglandin inhibitor in calves with acute enteritis.

The effects of the *E. coli* ST can be inhibited *in vitro* by the calcium channel blockers diltiazem and lodoxamide tromethamine and the prostaglandin synthesis inhibitors indomethacin and quinacrine (Knoop and Abbey, 1981; Thomas and Knoop, 1983). Neither class of drug blocks the effect of cGMP, suggesting that calcium and prostaglandin influence the earliest step(s) in ST response: either its brush border binding or the activation of guanylate cyclase.

The autonomic nervous system has important effects on intestinal ion transport and water absorption (Tapper *et al.,* 1978). Catecholamines stimulate formation of cAMP in a variety of mammalian cells (Schultz *et al.,* 1975), apparently by activating the GTP-GDP system described above (Cassel and Selinger, 1978). Adrenergic blocking agents, such as chlorpromazine (Holmgren *et al.,* 1978) and propranolol (Donowitz and Charney, 1979), have significant inhibitory effects on enterotoxin-induced intestinal secretion. Although the mechanism of action of these two adrenergic blockers is not known, they represent still another class of drugs that may be of therapeutic benefit.

The intestinal "adsorbent" drug, Pepto Bismol, containing bismuth subsalicylate, and attapulgite, a heat-treated silicate, have antienterotoxic effects (Drucker *et al.,* 1977; Ericsson *et al.,* 1977; Gyles and Zigler, 1978). Therapeutic trials with bismuth subsalicylate have significant therapeutic benefit in certain large-volume diarrheal diseases of humans, which are enterotoxigenic in origin (DuPont, 1978; DuPont *et al.,* 1977; Portnoy *et al.,* 1976). The mechanism of the intestinal secretion inhibition is not known, but the chemical relation of bismuth subsalicylate to other known prostaglandin inhibitors is known. It is possible that such drugs, by decreasing endogenous production of prostaglandin, decrease the basal level of cyclic nucleotides, which in turn causes an increase in the threshold of response to enterotoxin. Salicylates also may stimulate sodium chloride absorption (Powell *et al.,* 1979). Collectively, these observations suggest that new, innovative methods for therapy and control of acute clinical diarrheal disease may be developed.

Acute diarrhea represents the leading cause of morbidity and mortality in neonatal calves and pigs. The pathogenesis

of the neonatal enteric infection is complex, often involving nutritional or environmental factors as well as infectious agents, such as enteropathogenic strains of *E. coli*, the transmissible gastroenteritis virus (TGE), rotaviruses, and other bacterial and viral pathogens. The severe clinical signs and frequently fatal outcome of acute diarrheal disease are often directly related to dehydration and to associated H^+ and electrolyte disturbances (Dalton *et al.,* 1965; Fisher and McEwan, 1967a; Tennant *et al.,* 1972, 1978).

In acute diarrhea with large-volume, watery stools, the fecal fluid originates primarily from the small intestine. The electrolyte composition of the stool in such cases is similar to that of the fluid found normally in the lumen of the small intestine, which in turn is similar to that of an ultrafiltrate of the plasma. The rapid dehydration that accompanies acute enteritis in the newborn soon produces hemoconcentration and leads to hypovolemic shock. These cases are characterized by metabolic acidosis (Dalton *et al.,* 1965) caused by (1) decreased excretion of H^+ resulting from decreased renal perfusion and (2) increased production of organic acids, the result of which is observed characteristically in young, severely dehydrated animals. Hyperkalemia in such cases is the result of increased movement of cellular K^+ into the extracellular fluid and to decreased renal excretion. Cardiac irregularities caused by hyperkalemia can be demonstrated with the electrocardiogram, and cardiac arrest related to hyperkalemia is a direct cause of death in calves with acute diarrhea (Fisher, 1965; Fisher and McEwan, 1967b). Marked hypoglycemia also has been observed occasionally before death in calves with acute enteric infections. Hypoglycemia is believed to be due to decreased gluconeogenesis and increased anaerobic glycolysis, the result of hypovolemic shock (Tennant *et al.,* 1968). The sequence of metabolic changes that occur during acute neonatal diarrhea is summarized in Figure 14-10.

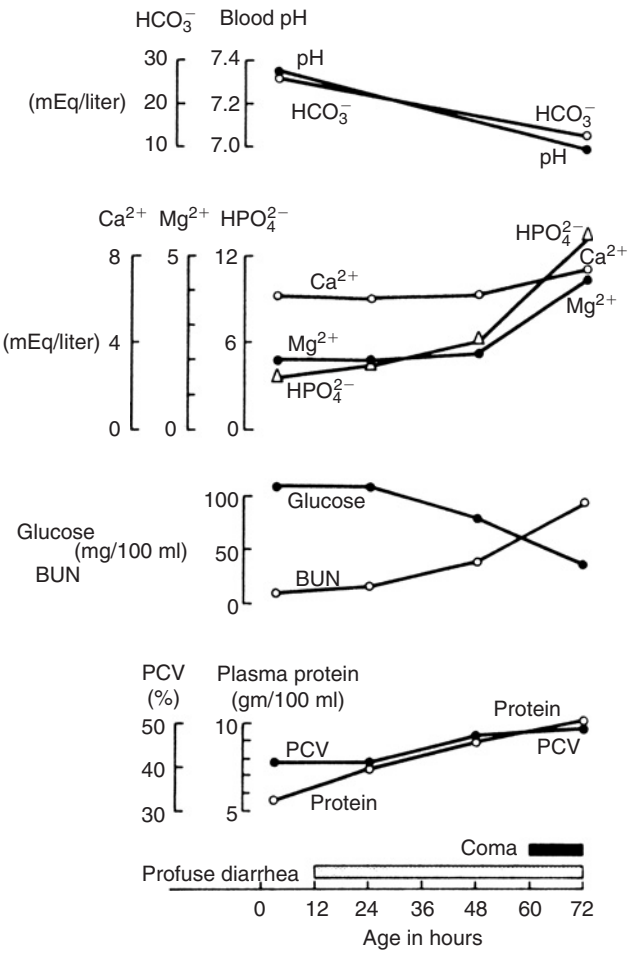

FIGURE 14-10 Metabolic alterations during the course of fatal enteric infection in a neonatal calf. From Tennant *et al*. (1972).

In chronic forms of diarrheal disease, excessive fecal losses of electrolyte and fluid are compensated in part by renal conservation mechanisms and in part by ingestion. If water is consumed without adequate ingestion of electrolytes, hyponatremia and hypokalemia may develop (Patterson *et al.,* 1968). In such cases, the osmolality of the plasma is significantly decreased and hypotonic dehydration occurs. In longer-standing cases of chronic diarrhea, the plasma K^+ concentration may become dangerously low. It is imperative, in this case, that intravenous fluids contain sufficient K^+ to prevent further reduction in concentration and to avoid additional cardiac irregularities or cardiac arrest.

E. Malabsorption

Decreased absorption of nutrients may occur either as a result of defective intraluminal digestion (maldigestion) associated with pancreatic insufficiency (juvenile pancreatic atrophy, chronic pancreatitis) or because of defects in mucosal transport (malabsorption). Intestinal malabsorption is associated with several types of intestinal disease including chronic inflammatory diseases (lymphocytic-plasmacytic enteropathy, eosinophilic enteritis), granulomatous diseases (Johne's disease, intestinal parasitism), and lymphoma. The cardinal clinical signs of malabsorption include persistent or recurrent diarrhea, steatorrhea, and weight loss. In the horse, small intestinal malabsorption such as that associated with granulomatous enteritis may be associated with weight loss, but diarrhea may not be present because of the compensatory capacity of the uninvolved cecum and colon.

The initial reports of primary or idiopathic intestinal malabsorption in dogs (Kaneko *et al.,* 1965; Vernon, 1962) were compared to nontropical sprue (adult celiac disease, gluten-induced enteropathy) of humans, but association with gluten sensitivity was not demonstrated. Wheat-sensitive enteropathy has been described in the Irish setter breed (Batt *et al.,* 1984). Most of the dogs were seen between 7 months to 2 years of age and had poor weight gain, weight loss, inappetence, or hyperphagia. Diarrhea was not a consistent observation. The most consistent morphological abnormality in peroral jejunal biopsies was partial villus atrophy.

Enzymatic changes included decreased mucosal alkaline phosphatase and peptidases, whereas disaccharidases and GGT activities were unaffected. Recovery of morphological and biochemical abnormalities occurred in affected dogs that received cereal-free diets but recurred when wheat flour was added to the ration. A variety of other causes of intestinal malabsorption have been reported in the dog (Anderson, 1975, 1977; Burrows *et al.,* 1979; Ewing, 1971; Hill, 1972; Hill and Kelly, 1974; Schall, 1974; Van Kruiningen, 1968; Van Kruiningen and Hayden, 1973). An enteropathy said to resemble tropical sprue in humans has been described in German shepherds (Batt *et al.,* 1983, 1984). Affected dogs were 5 years of age or older and had diarrhea and weight loss for at least 4 months before the diagnosis was made. Peroral jejunal biopsies revealed partial villus atrophy and variable infiltrations of lymphocytes and plasma cells in the lamina propria. Subcellar biochemical studies of jejunal enterocytes revealed decreased activity of many brush border enzymes and increased lysosomal enzymes.

Enteropathy associated with bacterial overgrowth of the small intestine also has been observed in German shepherds (Batt and McLean, 1987). The dogs were 2 years of age or younger, and all had chronic histories of intermittent diarrhea with or without weight loss. Bacterial counts of greater than 10^6 colonies per milliliter were observed in duodenal fluid. *Enterococci*, *E. coli*, and *Clostridium* spp. were identified in cultures. Peroral jejunal biopsies revealed no characteristic histopathological changes. A deficiency of the immunoglobulin, IgA, may explain the vulnerability of these German shepherds to intestinal bacterial overgrowth (Whitbread *et al.,* 1984).

Early reports of intestinal malabsorption in the cat (Wilkinson, 1969) gave the impression that this condition was more common in dogs. This has changed since inflammatory bowel disease or intestinal infiltrations of small cell lymphoma have been diagnosed more often in cats. Malabsorption syndromes similar to those recognized in dogs are being recognized with increased frequency in farm animals (Blood *et al.,* 1979). Cimprich (1974), Merritt *et al.* (1976), and Meuten *et al.* (1978), have reported malabsorption in the horse secondary to chronic granulomatous enteritis, and specific amino acid malabsorption has been reported in Johne's disease (Patterson and Berrett, 1969).

Steatorrhea, the presence of excessive amounts of fat in the feces, is a prominent sign of intestinal malabsorption in dogs. The stools are bulky, gray or tan, and, grossly, may have an oily appearance. The normal dog excretes 3 to 5 g of fat in the stool each day. This level of fecal fat is quite constant and is independent of dietary fat intake over a wide range of 15 to 48g/day. In intestinal malabsorption, the ability to absorb fat is decreased and fecal fat excretion increases significantly. Under these conditions, the amount of fecal fat excreted becomes proportional to dietary intake.

Merritt *et al.* (1979) reported that body weight is an important factor in fat output. In small dogs (i.e., less than 10 to 15 kg body weight) with intestinal malabsorption, the abnormality in fecal fat output was quantitatively less severe than in larger dogs. Fecal fat excretion for normal dogs was 0.24 ± 0.01 g/kg body weight per day.

Steatorrhea can be documented qualitatively by staining the fresh stool with a lipophilic stain, such as Sudan III, and observing increased numbers of oil droplets under the light microscope. In experienced hands, this method is a reliable diagnostic procedure (Drummey *et al.,* 1961). The following methods can be used to demonstrate neutral and split fats. For neutral fat, two drops of water are added to a stool sample on a glass slide and mixed. Two drops of 95% ethanol are then added and mixed followed by several drops of a saturated solution of Sudan III in 95% ethanol. A coverslip is applied to the mixture, which is then examined for yellow or pale orange refractile globules of fat, particularly at the edges of the coverslip. Normally, two or three fat droplets per high-power field are present. A large number of neutral fat droplets suggest a lack of pancreatic lipase activity (i.e., exocrine pancreatic insufficiency).

For free fatty acids (split fats), several drops of 36% acetic acid are added to a stool sample on a glass slide and mixed. Several drops of Sudan III solution are then added and mixed. A coverslip is applied, and the slide is gently heated over an alcohol burner until it begins to boil. The slide is air-cooled and then quickly heated again; this procedure is repeated two or three times. The warm slide is examined for stained free fatty acid droplets, which, when warm, appear as deep orange fat droplets from which spicules and soaps, resembling the pinna of the ear, form as the preparation cools. Normal stools may contain many tiny droplets of fatty acids (up to 100 per high-power field). With increasing amounts of split fats, the droplets become larger and more numerous, which suggests an abnormality in fat absorption.

Quantitation of fecal fat is the most accurate method of assessing steatorrhea (Burrows *et al.,* 1979) with dietary fat balance being determined for a period of 48 to 72 h. Fecal fat is analyzed using a modification of the technique of van de Kamer *et al.* (1949), which employs ether extraction of fecal lipid and titration of fatty acids. The results are expressed as grams of neutral fat excreted per 24 h. Merritt *et al.* (1979) have suggested that dogs be fed 50 g fat per kilogram per day for 2 to 3 days before fecal collection. Analysis of a 24-hour collection of stool when this is done is believed to be as accurate as a 72-hour stool collection. Results are expressed as fat excretion in grams per kilogram body weight.

In addition to malabsorption of fat, the canine malabsorption syndrome is associated with decreased absorption of other nutrients. These defects in absorption are responsible for the progressive malnutrition that is a cardinal feature of the disease. There may be malabsorption of vitamin D or calcium that results in osteomalacia. Anemia may result from malabsorption of iron or of the B vitamins required for normal erythropoiesis. Malabsorption of vitamin K can result in hypoprothrombinemia and delayed

clotting of blood. Glucose malabsorption has been documented by Kaneko *et al.* (1965) and it is likely that amino acids are similarly malabsorbed at the small intestinal level. Carbohydrate and fat malabsorption unquestionably contribute to the energy deficit that results in weight loss. Amino acid malabsorption may contribute to the development of hypoproteinemia, although increased intestinal loss of plasma proteins is believed to be more important.

The diagnosis of idiopathic canine malabsorption is made only after ruling out other primary inflammatory, neoplastic, or parasitic diseases of the intestine and diseases of the pancreas, liver, or stomach that result in defective intraluminal digestion. The presence of parasitic infection is established by examining the feces for parasite cysts or ova. Other inflammatory or neoplastic diseases of the intestine may be suggested on the basis of clinical or radiological examination, but a definitive diagnosis usually depends on histopathological examination of an intestinal biopsy specimen.

Both idiopathic and secondary intestinal malabsorption must be differentiated from those diseases in which there is decreased intraluminal hydrolysis of nutrients. The latter are due most frequently to pancreatic exocrine insufficiency as a result of chronic pancreatitis or juvenile atrophy. In these diseases, hydrolysis of the major dietary constituents is reduced because of the lack of pancreatic enzymes. Intraluminal hydrolysis of fat may also be decreased because of a deficiency of bile salts caused either by decreased hepatic secretion or by bile duct obstruction. Experimentally, however, complete diversion of bile flow in the dog actually has a quantitatively small effect on fat absorption (Hill and Kidder, 1972a).

A radioimmunoassay for trypsin-like immunoreactivity (TLI) is currently widely used to identify dogs with pancreatic exocrine insufficiency (Williams *et al.,* 1987) and is useful in differentiating maldigestion from primary malabsorption. The TLI in normal dog serum is trypsinogen. The route of entry of trypsinogen into the systemic circulation is believed to be the pancreatic venous or lymphatic vessels. Trypsinogen release in inflammatory pancreatic disease (i.e., acute or chronic pancreatitis) may increase TLI values. Increased TLI values have been reported in a dog with confirmed pancreatic exocrine insufficiency that had normal PABA values and fecal proteolytic activity (Williams and Batt, 1986). In most cases of pancreatic exocrine insufficiency, TLI is remarkably reduced compared to normal dogs or dogs with intestinal malabsorption (Williams and Batt, 1988).

An indirect method to detect chymotrypsin activity has been described as a means to differentiate dogs with pancreatic exocrine insufficiency from those with intestinal malabsorption (Batt *et al.,* 1979; Batt and Mann, 1981; Imondi *et al.,* 1972; Strombeck, 1978; Strombeck and Harrold, 1982; Zimmer and Todd, 1985). The synthetic peptide N-benzoyltyrosine-P-aminobenzoic acid (bentiromide) is orally administered to dogs. If chymotrypsin is present in the duodenum, hydrolysis of the bentiromide occurs, and P-aminobenzoic acid (PABA) is released, which is subsequently absorbed and then excreted in the urine within 6 h. The urine or plasma is analyzed for PABA. Less than 43% PABA excretion identifies dogs with suspected pancreatic exocrine insufficiency (Strombeck, 1978). Thirty- or 60-min blood levels of PABA are used to detect dogs with pancreatic exocrine disease (Zimmer and Todd, 1985), but this method did not identify dogs with exocrine pancreatic insufficiency as consistently as the 6 h urinary excretion (Strombeck and Harrold, 1982). Factors that may influence results of the bentiromide test include the rate of gastric emptying, intestinal absorption of the PABA, and the peptide cleavage by other peptidases (Batt *et al.,* 1979).

F. Tests of Malabsorption

1. *Cobalamin and Folate Absorption*

The measurement of circulating serum concentrations of cobalamin and folate (Batt and Morgan, 1982; Waters and Mollin, 1961) may give an indication of the site of intestinal dysfunction in dogs and cats, but it does not define the existing lesion or etiology. The use of cobalamin and folate concentrations as an indirect indicator of intestinal and pancreatic disease has been reported less frequently in the cat; the authors have documented cobalamin deficiency in cats with severe inflammatory bowel disease and intestinal lymphosarcoma. Low concentrations have also been encountered in cats with pancreatitis and exocrine pancreatic insufficiency. Low cobalamin levels are associated with increased levels of methylmalonic acid (Ruarux *et al.,* 2005; Simpson *et al.,* 2001).

Plasma concentrations of cobalamin and folate are labile and reflect the balance among dietary intake, bacterial utilization and production, intestinal absorption, and body losses. The interpretation of plasma concentrations of cobalamin and folate concentrations with regard to small intestinal disease is only valid if exocrine pancreatic insufficiency, oral supplementation, and parenteral administration have been excluded and attention is paid to dietary vitamin content. Plasma cobalamin and folate concentrations may also be affected by certain medications (e.g., sulfasalazine). Although serum folate levels can decrease markedly within several days, the folate concentration within erythrocytes decreases much more slowly, so low erythrocyte folate values may be a more accurate indicator of a chronic disorder.

Low serum cobalamin concentrations have been observed in dogs with EPI, severe intestinal disease, and apparent idiopathic small intestinal bacterial overgrowth (SIBO). Absolute cobalamin deficiency has been recognized in giant schnauzers with inappetence and failure to thrive with laboratory findings of anemia, leukopenia, and methylmalonyl aciduria. This deficiency appears to be a consequence of the

defective synthesis of the ileal cobalamin-intrinsic factor receptor and signs are completely reversed by the parenteral administration of cobalamin. Some shar-peis also appear to have a deficiency of cobalamin. The physiological significance of the low cobalamin concentrations detected in other gastrointestinal diseases has not been reported.

Low serum folate concentrations have been observed in dogs with severe jejunal disease and some Irish setters with a gluten-sensitive enteropathy. High folate concentrations have been reported in experimentally induced SIBO (blind loops), EPI, German shepherds with antibiotic-responsive enteropathy, and other Irish setters with gluten-sensitive enteropathy.

In the authors' experience, the finding of a low folate or low cobalamin concentration is useful in supporting the presence of an intestinal problem. Where low cobalamin is detected and EPI and intestinal abnormalities of the GI tract (blind loops) have been excluded, localization of the problem to the ileum can be inferred. Serum cobalamin and folate are inadequate markers of predicting response to antibiotics. Concomitant increases in folate and cobalamin are consistent with high intake or supplementation. Finally, normal serum concentrations of cobalamin and folate neither exclude nor support a diagnosis of intestinal disease.

2. *Glucose Absorption*

The absorption of glucose can be evaluated by the oral glucose tolerance test (OGTT) where an oral test dose of glucose is given and the blood glucose levels are measured at half-hour intervals for 3 to 4h. In canine malabsorption, the OGTT curve of blood glucose is diminished or flat (Kaneko *et al.,* 1965). The test also has been used in the horse for evaluation of small intestinal malabsorption (Roberts and Hill, 1973). Dogs with pancreatic exocrine deficiency may have "prediabetic" or high OGTT curves (Hill and Kidder, 1972b). The major disadvantage of this test is that it does not differentiate between decreased intestinal absorption and increased tissue uptake after absorption. This problem can be alleviated by comparing results of the OGTT with those of the intravenous glucose tolerance test (IVGTT). Hill and Kidder (1972b) reported that normal dogs on low-carbohydrate/high protein diets can have "diabetic" tolerance curves so that test dogs should be on a high-carbohydrate diet for 3 to 5 days before testing.

3. D-X*ylose Absorption*

D-xylose is used clinically to evaluate intestinal absorption (Craig and Atkinson, 1988). The body does not metabolize D-xylose to any significant degree, and the problems of evaluating tissue utilization that occur with glucose are avoided. Because large amounts of D-xylose must be used, the rate of absorption is proportional to luminal concentration and independent of active transport processes.

Van Kruiningen (1968) has described a D-xylose absorption test for dogs. In this procedure, a standard 25-g dose of D-xylose is administered by stomach tube. During the 5-h period after administration, the patient is confined in a metabolism cage and urine is collected. At the end of the 5-h test period, the urine remaining in the bladder is removed by catheter and the total quantity excreted in 5 h is determined. Normal dogs excreted an average of 12.2 g of the 25-g dose during the test period, with a range of 9.1 to 16.5 g. Because this test is dependent on the rate of intestinal absorption as well as the rate of renal excretion, it is necessary to establish that kidney function is normal.

A modified D-xylose tolerance test is now most widely used clinically (Hayden and Van Kruiningen, 1973; Hill *et al.,* 1970). Dogs are fasted overnight, a baseline blood sample is taken, and D-xylose is administered by stomach tube at the rate of 0.5 g/kg. A control test is performed on a normal dog simultaneously. Blood samples are taken at 0.05, 1, 2, 3, 4, and 5 h after administration. The D-xylose concentration in the blood is determined by the phloroglucinol microassay (Merritt and Duelly, 1983). The phloroglucinol procedure is more economical, requires less plasma, and is technically easier than the orcinol-ferric chloride procedure of Roe and Rice (Merritt and Duelly, 1983). Maximal blood levels of D-xylose are normally reached at 1h after administration. A D-xylose level of at least 45mg/dl within 60 to 90 min is expected in normal dogs (Hill *et al.,* 1970).

The D-xylose absorption test is also used for differential diagnosis of equine diarrheal diseases (Roberts, 1974). Bolton *et al.* (1976) reported that a dosage of 0.5-g D-xylose/kg bw was useful in detecting horses with intestinal malabsorption. The peak plasma concentration in normal horses is less than one-third that seen in normal dogs given D-xylose at comparable doses.

4. *Oleic Acid and Triolein Absorption*

Several tests have been developed for the clinical evaluation of intestinal absorptive capacity. The absorption of ^{131}I-labeled oleic acid and ^{131}I-labeled triolein has been studied extensively in normal dogs (Michaelson *et al.,* 1960; Turner, 1958), and Kaneko *et al.* (1965) used this test to study dogs with intestinal malabsorption. The day before administration of the ^{131}I-labeled compound, a small amount of Lugol's iodine solution is administered to block thyroidal uptake of the isotope. Tracer amounts of the test substances are mixed with nonradioactive carrier and are administered orally. Absorption is determined by measuring the radioactivity of the plasma at intervals following administration and calculating the percentage of the dose absorbed on the basis of plasma volume.

The ^{131}I-oleic acid and ^{131}I-triolein tests performed in sequence are used to differentiate steatorrhea caused by pancreatic enzyme deficiency from that caused by a primary defect in absorption (Kallfelz *et al.,* 1968). If steatorrhea is

caused by a lack of pancreatic lipase, oleic acid absorption will be normal, whereas that of triolein, which requires lipolysis for absorption, will be significantly reduced. The absorption of both compounds is reduced in intestinal malabsorption.

5. *Vitamin A Absorption*

The vitamin A absorption test measures intestinal lipid absorption (Hayden and Van Kruiningen, 1976). Normal absorption of vitamin A requires secretion of bile and pancreatic enzymes. After oral administration of 200,000 units of vitamin A in normal dogs, serum vitamin A concentrations reach their peak at 6 to 8h, with values ranging between three and five times fasting serum levels. There are small differences in vitamin A absorption between breeds and delayed gastric emptying will also alter results.

6. *Other Tests for Assessment of Intestinal Function*

Simultaneous evaluation of pancreatic exocrine function and intestinal absorptive function is used in dogs (Rogers *et al.,* 1980; Stradley *et al.,* 1979) and cats (Hawkins, *et al.,* 1986; Sherding *et al.,* 1982). The combined bentiromide and D-xylose absorption tests have proved to be useful diagnostically in dogs. Blood is normally taken at 0, {½}, 1, 1{½}, 2, 2{½}, and 3 h after oral administration of the test solution but a single blood sample taken at 1{½}h was adequate for differential diagnostic purposes (Stradley *et al.,* 1979). The combined bentiromide/D-xylose absorption test was of limited usefulness in cats because of marked individual variations. Peak blood PABA levels (60 to 120 min) and peak blood D-xylose levels (30 to 120 min) in healthy cats were less than those of normal dogs, and blood D-xylose levels in cats with infiltrative small bowel disease were not abnormal (Hawkins *et al.,* 1986).

The content of exhaled hydrogen gas has been evaluated as an indicator of carbohydrate malassimilation in the dog (Washabau *et al.,* 1986), cat (Muir *et al.,* 1991), calves (Holland *et al.,* 1986), and humans (Perman, 1991). Unabsorbed carbohydrate is fermented by bacteria in the colon to H_2 and organic acids. Ten to 14% of the H_2 is absorbed and excreted by the lungs (Washabau *et al.,* 1986). Increases in pulmonary H_2 excretion can occur in normal dogs fed rations containing wheat or corn flour. Increased H_2 excretion normally occurs in most species receiving lactulose. Mild increases in H_2 excretion occur in normal humans and dogs receiving xylose but not in the cat.

Breath H_2 excretion has diagnostic value in determining mouth-to-cecum transit time and for identifying small intestinal bacterial overgrowth (Muir *et al.,* 1991). False-negative H_2 breath tests have been seen in humans receiving antibiotics. Diet as well as variations in bacterial flora can also cause false-positive test results.

The nitrosonaphthol test qualitatively measures urinary excretion of 4-hydroxyphenylacetic acid and related compounds, which are intestinal bacterial degradation products of tyrosine. The test has been used to differentiate pancreatic or small intestinal diarrheal diseases from those associated primarily with large bowel disease (Burrows and Jezyk, 1983). The test was positive in 77% of the dogs with pancreatic and small intestinal disease and in only 9.5% of those dogs with large bowel disease. Positive tests were associated with bacterial overgrowth of the small intestine and became negative during antibiotic treatment that resulted in clinical improvement. The test may be useful in dogs to select patients with small intestinal bacterial overgrowth, which might respond to antibiotic therapy.

G. Bacterial Overgrowth

The bacterial flora of the canine intestine increases in number from the duodenum to colon. Factors maintaining this aboral gradient are luminal patency, intestinal motility, limited substrate availability, various bacteriostatic/cidal secretions, and an intact ileocecocolic valve. Abnormalities of these control mechanisms facilitate small intestinal bacterial overgrowth (SIBO). SIBO is usually secondary to another disease process, but it has been reported as a primary idiopathic form. Many clinicians prefer to use the term *antibiotic-responsive diarrhea* instead of *idiopathic SIBO* (German *et al.,* 2003). Regardless, bacterial overgrowth can interfere with the absorption of nutrients and fluid by reducing microvillar enzyme activity, increasing cellular or intercellular permeability, deconjugating bile acids, and hydroxylating fatty acids.

A number of diseases (Rutgers *et al.,* 1988, 1993, 1995; Simpson *et al*., 1990; Williams *et al*., 1987) need to be ruled out before making a diagnosis of idiopathic SIBO. This includes exocrine pancreatic insufficiency (EPI), partial or complete intestinal obstruction, intestinal stasis, resection of the ileocecocolic valve, and intestinal mucosal diseases that cause malabsorption (e.g., moderate to severe inflammatory bowel disease), lymphoma, and lymphangiectasia. Dogs and cats with partial intestinal obstruction often have a history of chronic diarrhea and weight loss, which responds to antibiotics (Batt *et al.,* 1988). Much of the literature pertains to German shepherd dogs (GSD) with subnormal levels of IgA (Delles *et al*., 1993, 1994; Willard *et al*., 1994a, 1994b). SIBO has also been reported in beagles with normal IgA levels (Batt *et al*., 1992).

In the dog, total bacterial counts exceeding 10^5 colony-forming units per milliliter (cfu/ml) of proximal jejunal or duodenal fluid and anaerobic bacterial counts exceeding $\geq 10^5$ cfu/ml have been reported (Burrows *et al*., 1994). Culture of duodenal juice has been regarded as the gold standard for detecting bacterial counts $\geq 10^5$ cfu/ml; this assumption has been questioned because of the variability

of counts in other reports, which detail duodenal bacterial counts ranging from $\leq 10^2$ to 10^7 cfu/ml; counts of $\geq$10cfu/ml in clinically healthy GSD, beagles, and greyhounds.

Healthy cats have higher numbers of bacterial flora in their small intestine than do other species (Johnston *et al*., 1993), in numbers that approximate those for SIBO in dogs and humans. Bacterial counts $\geq 10^5$ cfu/ml are being increasingly documented in other breeds with clinical signs of weight loss, chronic diarrhea, borborygmi, intestinal cramping, or vomiting, with no evidence of intestinal obstruction, EPI, or severe mucosal infiltrates; clinical signs are often responsive to antibiotic therapy.

A comprehensive review of the literature, to include the aforementioned studies, by Johnston (1999) refuted the existing criterion for defining bacterial overgrowth. She concluded that defining SIBO as greater that 10 fifth cfu/ml in the duodenum or proximal jejunum was not appropriate for dogs and cats. Furthermore, she believed future investigations need to separate patients who have SIBO from those who have other antibiotic-responsive enteropathies.

Dogs with idiopathic SIBO may be subclinical or have chronic gastrointestinal signs. Chronic SIBO can cause inflammatory bowel disease. The lesions consist of villus atrophy and infiltrations of lymphocytes and plasmacytes in the lamina propria. There is substantial but reversible biochemical injury to enterocytes of the brush border membrane (Batt and McLean, 1987). Aerobic bacteria, such as enterococci and *Escherichia coli*, cause a selective loss of brush border alkaline phosphatase activity and peroxisomal catalase, as well as changes that are consistent with mitochondrial disruption. There are exceptions but aerobic overgrowth is typical for the dog, in contrast to anaerobic overgrowth in humans. The high floral counts in the intestine of cats are thought to predispose them to certain nutritional deficiencies, such as taurine deficiency, and intestinal disturbances attributed to deconjugated bile salts (Johnston *et al*., 1993).

The culturing and quantitation of intestinal bacterial flora (Simpson *et al*., 1990) are the definitive means of diagnosing SIBO. Less invasive diagnostic methods include determination of serum cobalamin/folate levels, the measurement of breath hydrogen or intestinal permeability, and the nitrosonaphthol test on urine (Burrows *et al*., 1995; Simpson, 2005). Deconjugation of bile acids by intestinal flora, with subsequent disproportionate increase in unconjugated bile acids in the circulation, is seen in humans with bacterial overgrowth (Einarsson *et al*., 1992).

The treatment of SIBO is directed at correcting the underlying structural abnormalities, treating EPI, and controlling the abnormal flora with antibiotics. Patients with IBD often require treatment of SIBO and the mucosal infiltrate. In dogs with suspected idiopathic SIBO, antibiotic therapy is usually given for 28 days. Suitable antibiotics include oxytetracycline (10 to 20 mg/kg TID PO), tylosin (10 mg/kg TID PO), or metronidazole (15 mg/kg BID PO). Dietary supplementation with fructooligosaccharide in IgA-deficient German shepherds resulted in decreased bacterial counts in luminal fluid and intestinal mucosa tissue (Willard *et al*., 1994a, 1994b). Plasma-cell infiltrations in jejunal villi were decreased by feeding different protein sources (Edwards *et al*., 1995). There is also anecdotal evidence that supports the use of highly digestible, low-fat diets, which may less be likely to metabolize to hydroxy fatty acids and stimulate colonic secretions.

The overall prognosis for idiopathic SIBO is guarded and the prognosis for secondary SIBO depends on the underlying disease. Many animals with suspected idiopathic SIBO relapse when antibiotics are stopped and require further courses or long-term maintenance.

H. Helicobacteria

Helicobacter pylori have been associated with chronic gastritis, atrophic gastritis, peptic ulcers, and gastric adenocarcinoma and lymphosarcoma in humans (Handt *et al.,* 1994; Isaacson 1994; Paarsonnett *et al.,* 1991). Studies in other animals have led to the discovery of *H. mustelae* in ferrets with gastritis and peptic ulcers, *H. acinonychis* in cheetahs with severe gastritis, and *H. Heilmannii* in pigs with gastric ulcers. The presence of gastric *Helicobacter*-like organisms (HLO) in the stomachs of dogs and cats has been known for many years, but the relationship of these organisms to gastric disease remains controversial. *H. felis*, *"H. heilmannii," H.bizzozeronii*, and *H. pametensis* have been detected in gastric mucosa of pet cats. *H. bizzozeronii*, *H. heilmannii*, *H. felii*, *H. salomonis*, *H. rappini*, and *H. bilis* have been isolated from dogs. Simultaneous colonization of the stomach with multiple species of *Helicobacter* has been observed in the dog and cat.

Helicobacter pylori, which is the predominant pathogen in humans, can cause infection in other animals (anthroponosis). Although it has not been isolated from the stomachs of pet dogs and cats, experimental infections have been produced in the nonhuman primates, cats, dogs, and pigs. Studies of the pathogenicity of *H. felis*, as well as *H. pylori*, in laboratory cats have demonstrated gastritis, lymphoid follicular hyperplasia, and seroconversion. Many of these cats did not exhibit clinical signs of illness. "*H. heilmannii*," the predominant species in pet cats and 20% to 40% pet dogs, is also found in the mucosa of 0.4% to 4.0% of people. The zoonotic risk posed by dogs and cats was regarded as small because their 16s rDNA sequences were not consistent with *H. heilmanii type I*, which is the principal subtype in people; subtypes in dogs and cats were predominantly types II and IV.

Heliocobacter spp. isolated from the stomachs of dogs and cats are spiral-shaped or curved or sometimes coccoid Gram-negative bacteria that inhabit the glands, parietal cells, and mucus of the stomach. They are morphologically indistinguishable by light microscopy and are classified into several

Helicobacter spp. on the basis of 16S rRNA sequencing, DNA hybridization, and electron microscopic appearance. The majority of studies in cats and dogs with naturally acquired *Helicobacter* infections demonstrates that the fundus and cardia are more densely colonized than the pylorus. Large HLO colonize the superficial mucus and gastric glands and may also be observed intracellularly. Degeneration of the gastric glands, with vacuolation, pyknosis, and necrosis of parietal cells, is more common in infected than uninfected dogs and cats. Inflammatory infiltrates in the gastric mucosa of infected animals are generally mononuclear and range from mild to moderate in severity.

Analysis of gastric juice and biopsies from kittens in an *H. pylori*-infected cat colony, using rapid urease tests, *UreB* PCR patterns, and histopathology demonstrated *H. pylori* in nine of 17 kittens by 8 weeks and in 16 by 14 weeks of age. *UreB* PCR patterns and sequences of PCR products from gastric mucosa were identical in mothers and kittens. Bacterial densities were similar in the stomach and the presence of circulating anti-*Helicobacter* IgG antibodies and histopathological findings were consistent with infection.

Studies have been done in cats chronically infected with *H. pylori* to measure the development of inflammatory and immune responses, and their relationship to the putative bacterial virulence factors *cag* pathogenicity island (*cag*PAI), *vacA* allele, and *oipA* in combination with bacterial colonization density. Infecting *H. pylori* strains were positive for *vacAsI* but lacked the *cag*PAI and an active *oipA* gene. Colonization density was uniform throughout the stomach. Up-regulation of IFN-gamma, IL-1a, IL-B, IL-8, and increased severity of infiltrates and fibrosis were observed in infected cats. The median number and total area of lymphoid aggregates were five and ten times greater, respectively, in the stomachs of infected cats than uninfected cats. Secondary lymphoid follicles were frequent and positive for BLA.36, CD79a, and CD3 but negative for B220. Cats with *H. pylori* can also develop antigastric antibodies that cross-react with *Helicobacter* antigens, as well as changes in gastric acid secretion and serum gastrin levels.

The evaluation of cytokines in cats with naturally acquired *Helicobacter* spp. seems to complement histopathological changes in the stomach. Compared to uninfected cats, infected cats have up-regulation of IL-8 and IL-1beta, but not IFN-gamma or IL-10 and gastric lymphoid follicle hyperplasia is more common and extensive. Circulating anti-*Helicobacter* IgG has been detected in sera of naturally infected cats. To date, there has been no association made between infection and gastrointestinal ulcers or gastric neoplasia in cats. Spontaneous gastritis in the dog is typically consistent with lymphoplasmacytic infiltrations and the expression of IL-10 and IFN-gamma. *Helicobacter* spp. infection is associated with increased expression of TGF-β and fibrosis.

HLO have been observed in gastric biopsies from 41% to 100% clinically healthy cats, 67% to 100% healthy dogs, 57% to 100% of vomiting cats, 74% to 90% vomiting dogs, and 100% laboratory beagles. The prevalence of individual *Helicobacter* spp. has not been thoroughly investigated because of specialized techniques. The high prevalence of gastric colonization with HLO in healthy and sick dogs and cats indicates that there is no simple "infection = disease" relationship. An uncontrolled treatment trial of pets with gastritis and *Helicobacter* infection showed that clinical signs in 90% of 63 dogs and cats responded to treatment, with a combination of metronidazole, amoxicillin, and famotidine, and that 74% of 19 animals reendoscoped had no evidence of *Helicobacter* in gastric biopsies. However, controlled studies in asymptomatic cats suggest that it is difficult to eradicate gastric organisms with a variety of therapeutic agents.

I. Intestinal Permeability

Changes in intestinal mucosal permeability can be a factor in the pathogenesis of mucosal injury and subsequent gastrointestinal disease (Burrows *et al.,* 1995; Sanderson and Walker 1993). Whether as a primary or secondary disorder, increased permeability predisposes to the passage of intraluminal macromolecules across the intestinal mucosa. Depending on the noxious or antigenic characteristics of these macromolecules, pathological features of toxic or immune-mediated injury may occur. A primary mucosal permeability defect is suspected in humans and Irish setters with gluten-induced enteropathy (Hall and Batt, 1991a, 1991b). Enhanced mucosal permeability resulting from small intestinal bacterial overgrowth has been reported in clinically healthy beagles (Batt *et al.,* 1992). Secondary permeability disorders have been resolved by appropriate treatment of giardiasis and bacterial overgrowth in dogs (Hall and Batt, 1990).

Clinicopathological evaluation of intestinal permeability is based on the oral administration of simple, nondigestible molecules (probes) and their recovery in urine (Elwood *et al.,* 1993; Papasouliotis *et al.,* 1993). Inappropriate levels of these probes in urine indicate abnormal macromolecular permeation through transcellular or paracellular pathways. Polyethylene glycols, ^{51}CR-labeled ethylenediaminetetraacetate (^{51}EDTA) (Batt *et al.,* 1992; Hall *et al.,* 1989; Hall and Batt 1991a, 1991b), and nonhydrolyzable sugars have been used in permeability tests. The disaccharides, cellobiose and lactulose, and the monosaccharides, mannitol and L-rhamnose, are unable to penetrate healthy enterocytes (Papasouliatis *et al.,* 1993). In the presence of abnormal mucosal permeability, the disaccharides diffuse passively through the mucosa via paracellular pathways, and the monosaccharides passively diffuse transcellularly.

Differential sugar absorption and calculated disaccharide-to-monosaccharide excretion ratio are preferred over single sugar measurements. The use of lactulose and

mannitol in the evaluation of intestinal permeability has been reported in healthy cats (Papasouliotis *et al.,* 1993). The cellobiose-to-mannitol urinary excretion ratio was increased in Irish setters with gluten-sensitive enteropathy (Hall and Batt, 1991a, 1991b). Simultaneous quantification of rhamnose, lactulose, 3-O-methyl-D-glucose, and xylose in urine by a unique chromatographic technique has been reported to assess both intestinal function and permeability (Sorensen *et al.,* 1993).

J. Protein-Losing Enteropathy

Albumin, IgG, and other plasma proteins are present in low concentration in normal gastrointestinal secretions. Because protein usually undergoes complete degradation within the intestinal lumen, it has been suggested that the gastrointestinal tract must have a physiological role in the catabolism of plasma proteins. The relative significance of this pathway, however, has been the subject of considerable controversy. Some investigators have concluded, for example, that as much as 50% or more of the normal catabolism of albumin (Campbell *et al.,* 1961; Glenert *et al.,* 1961, 1962; Wetterfors, 1964, 1965; Wetterfors *et al.,* 1965) and ϑ-globulin (Andersen *et al.,* 1963) may occur in the gastrointestinal tract. Others believe that the physiological role of the intestine in plasma protein catabolism is far less significant, accounting for about 10% of the total catabolism (Franks *et al.,* 1963a, 1963b; Katz *et al.,* 1961; Waldmann *et al.,* 1967, 1969).

Regardless of questions concerning the physiological significance of the gastrointestinal tract in plasma protein catabolism, it is well established that normal intestinal losses are substantially increased in a variety of gastrointestinal diseases, collectively referred to as the protein-losing enteropathies (PLE). The increased loss causes hypoproteinemia (especially hypoalbuminemia), which may be observed in various types of chronic enteric diseases. The excessive losses are the result of ulcerations or other mucosal changes that alter permeability or obstruct lymphatic drainage from the intestine. If severe, hypoalbuminemia may result in retention of fluid with development of ascites and subcutaneous edema of pendant areas.

Excessive plasma protein loss has been seen in swine with chronic ileitis (Nielsen, 1966), in calves with acute enteric infections (Marsh *et al.,* 1969), in cattle with parasitic or other inflammatory abomasal disease (Halliday *et al.,* 1968; Murray, 1969; Nielsen and Nansen, 1967), and in Johne's disease (Patterson *et al.,* 1967; Patterson and Berrett, 1969). In addition to the classic mucosal and submucosal lesions of Johne's disease, secondary intestinal lymphangiectasia can occur. Meuten *et al.* (1978) observed PLE associated with granulomatous enteritis in two horses.

PLE is seen with some frequency in the dog (Campbell *et al.,* 1968; Farrow and Penny, 1969; Finco *et al.,* 1973; Hayden and Van Kruiningen, 1973; Hill, 1972; Hill and Kelly, 1974; Mattheeuws *et al.,* 1974; Milstein and Sanford, 1977; Olson and Zimmer, 1978). The most common cause appears to be lymphocytic-plasmacytic enteropathy. Intestinal lymphangiectasia also has been reported as a cause of increased intestinal protein loss; it is most commonly seen in small terrier breeds (e.g., Yorkshire, Maltese) and the Norwegian Lundehund, suggesting a genetic predisposition (Simpson, 2005). Increased plasma protein loss from the stomach has been seen in dogs with hypertrophic gastritis.

Familial protein-losing enteropathy (PLE) and protein-losing nephropathy (PLN) have been described in soft-coated wheaten terriers (Littman *et al.,* 2000). Dogs with PLE were diagnosed earlier than dogs with PLN or with both diseases. Clinical signs included vomiting, diarrhea, weight loss, pleural and peritoneal effusions, and thromboembolic disease. Panhypoproteinemia and hypocholesterolemia were consistent findings and intestinal lesions included inflammatory bowel disease, dilated lymphatics, and lipogranulomatous lymphangitis. In another study, food hypersensitivities were identified in six affected dogs (Vaden *et al.,* 2000), but the presence of preexisting inflammatory disease made it impossible to determine if food allergies were the cause or result of enteric disease.

Increased intestinal protein loss is the most likely cause of the hypoalbuminemia associated with certain other enteric diseases including lymphoma and malabsorptive syndromes. Munro (1974) demonstrated that protein loss in dogs with experimentally induced protein-losing gastropathy occurs by an intercellular route. Isotope-labeled polyvinylpyrrolidone (^{131}I-PVP), ^{51}Cr-labeled ceruloplasmin, and ^{51}Cr-labeled albumin have been used to evaluate enteric protein loss in the dog (Finco *et al.,* 1973; Hill and Kelly, 1974; Olson and Zimmer, 1978; van der Gagg *et al.,* 1976).

Fecal alpha 1-proteinase inhibitor (α1-PI) is minimally degraded as it passes down the gastrointestinal tract. In conditions where there is excessive loss of plasma protein into the gut, there is an increase in fecal α1-PI (Williams *et al.,* 1990). The value of this test has been reported in dogs with chronic gastrointestinal disease (Murphy *et al.,* 2003; Ruaux *et al.,* 2004) and in cats with inflammatory bowel disease or gastrointestinal neoplasia (Fetz *et al.,* 2006a, 2006b).

Murphy *et al.* (2003) reported that fecal α1-PI concentrations in dogs with gastrointestinal diseases associated with histological abnormalities (median 60.6μg/g, range 7.4–201.7μg/g) were higher than dogs with gastrointestinal disease and normal histology (median 3.8, 0.7–74) and control dogs (9.9, 0.0–32.1). Although there was no direct correlation with serum albumin levels, the fecal α1-PI was believed to be a useful test in identifying early stages of PLE before decreased levels of serum albumin occurred. Moreover, the test was useful in justifying gastrointestinal biopsies in some cases. Ruaux *et al.* (2004) reported that

increased fecal loss of α1-proteinase inhibitor in dogs with PLE is associated with a significant decrease in fecal proteolytic activity and may result in a false-positive diagnosis of exocrine pancreatic insufficiency.

The studies performed by Fetz *et al.* (2006b) proved that cats with chronic gastrointestinal disease can be associated with gastrointestinal protein loss. The upper limit of the reference range for mean fecal α1-PI concentrations in healthy cats was 1.6μg/g; the concentrations in eight of the nine study cats ranged from 2.2 to 180.77. Fetz *et al.* (2006a) reported that increased fecal α1-PI concentrations in association with low serum albumin and total protein levels are common findings in cats with inflammatory bowel disease (IBD) and gastrointestinal neoplasia. Furthermore, fecal α1-PI concentrations tend to be higher in cats with severe IBD or neoplasia when compared to cats with mild to moderate IBD.

K. Ulcerative Colitis

Canine ulcerative colitis, including granulomatous colitis of boxer dogs, has been reported (Ewing and Gomez, 1973; Gomez *et al.,* 1977; Kennedy and Cello, 1966; Koch and Skelley, 1967; Russell *et al.,* 1971; Sander and Langham, 1968; Van Kruininger *et al.,* 1965). In boxer dogs, the disease is characterized by intractable diarrhea that is often hemorrhagic. Histopathologically, there is a granulomatous or histiocytic submucosal infiltrate and the macrophages are laden with periodic-acid-Schiff-positive material. Immunopathological studies describe an increase in IgG3 and IgG4 plasma cells, PAS positive macrophages and CD3-T cells, L1- and MHC11-positive cells, with pathological lesions similar to human ulcerative colitis (German *et al.,* 2003). Electron photomicrography demonstrated bacteria in the macrophages (Russell *et al.,* 1971), and, in some instances, these organisms resembled *Chlamydia. Mycoplasma* has been cultured from the colon and regional lymph nodes in four boxers, but attempts to reproduce granulomatous colitis with *Mycoplasma* have been unsuccessful. Until recently, this failure to identify or isolate an infectious agent has led to the belief that granulomatous colitis of boxers is an immune-mediated disease.

The development of culture-independent techniques utilizing PCR probes has renewed suspicion that granulomatous colitis in normal dogs is an infectious disease (Simpson *et al.,* 2006). Colonic biopsies from affected dogs (13 boxers with colitis) and 38 control dogs were examined by fluorescent *in situ* hybridization (FISH) with a eubacterial 16s rRna probe. Culture, 16s rDNA sequencing, and histochemistry were used to define invasive flora and guide subsequent FISH. Intramucosal bacteria, predominantly Gram-negative coccobacilli, were present in the affected boxers, but none of the controls. Culture and 16s rDNA sequencing yielded mostly *Enterobacteriaceae* and invasive bacteria hybridized with FISH probes to *E. coli.* These findings complement the observation that affected boxers often respond to enrofloxacin alone or in combination with amoxicillin and metronidazole.

Cases of ulcerative colitis in dogs have also been attributed to trichuriasis, balantidiasis, protothecosis, histoplasmosis, eosinophilic ulcerative colitis, or neoplasia (Lorenz, 1975). Severe ulcerative colitis has also been reported in cats and in some the feline leukemia virus (FeLV) is demonstrated. Feline panleukopenia can also cause colonic lesions.

Biochemical manifestations of ulcerative colitis depend on the duration and severity of illness, the degree of colorectal involvement, and the presence of systemic complications. In severe cases of long duration with extensive colorectal involvement, hypoalbuminemia and hypergammaglobulinemia are often observed. Hypoalbuminemia is attributed to increased loss of plasma through the denuded and inflamed colorectal mucosa and hypergammaglobulinemia is the response to continuing chronic inflammation.

L. Equine Hyperammonemia

Hyperammonemia and subsequent neurological signs have been documented in horses with liver disease (Divers *et al.,* 2006), adult horses with gastrointestinal disease and presumed bacterial overgrowth (Desrochers *et al.,* 2003; Peek *et al.,* 1997; Sharkey *et al.*, 2006), nursing foals with portosystemic shunts (Fortier *et al.,* 1996), and weanling Morgan foals with a genetic abnormality in hepatic ammonia metabolism (McCornico *et al.,* 1997). The shunt foals and Morgan weanlings are discussed elsewhere.

Pertinent to this chapter is the incidence of hyperammonemia in horses with gastrointestinal dysfunction (i.e., colic and diarrhea) that do not have hepatic disease. There is an increased absorption of ammonia across inflamed intestinal mucosa, or massive overproduction of ammonia within the lumen of the gut, or a combination of both. Under normal circumstances, ammonia is delivered to liver via portal circulation and is metabolized by the Krebs-Hensleit cycle to urea and glutamine. Systemic hyperammonemia results when this cycle is overwhelmed. Ammonia readily crosses the blood-brain barrier and, in high concentrations, has a toxic effect on neuronal cell membranes. Resulting encephalopathic signs may be reversible if the underlying intestinal lesion or ammonia-producing bacteria are treated in an appropriate manner.

A diagnosis of idiopathic hyperammonemia of intestinal origin is based on the absence of infectious, toxic, or developmental causes. In some of the reported cases, recent travel or suspected changes in feeding or husbandry preceded the acute onset of gastrointestinal signs. Increased blood ammonia levels and subsequent encephalopathy developed within a matter of hours. Hyperglycemia and metabolic acidemia were also unique to the cases described by Peek *et al.*

(1997). Although Gram-negative bacilli such as *Escherichia coli*, *Klebsiella*, *Proteus*, and *Pseudomonas* spp. are known to be potent ammonia producers, reports pertaining to the role of specific organisms in affected horses has been limited to *Clostridium sordelli* (Desrochers *et al.,* 2003).

Urea toxicity and ammonia intoxication, as well as ingestion of high protein feeds, were ruled out as causes of hyperammonemia in horses described by Peek *et al.* (1997). Horses would have to ingest a large amount of urea to become toxic for a couple of reasons: (1) most of the urea is absorbed in the small intestine before reaching the caecum, which is the predominant site of urease activity; (2) urease activity in the horse's caecum is much less than that in the cow's rumen. Although horses are much more susceptible to ammonia salts than urea, none of the horses were on pastures that had been fertilized with ammonia salts.

M. Clostridial-Associated Diseases in Horses and Cows

Clostridium difficile has been reported in several sources as a cause of colitis in horses and various small bowel disorders in horses, foals, and ponies. The potential role of this organism in causing duodenitis-proximal jejunitis (DPJ) in horses was proposed by Arroyo *et al.* (2006). DPJ was previously thought to be an idiopathic condition characterized by inflammation and edema of the duodenum and jejunum. Affected horses acutely developed signs of colic, depression, ileus, fluid accumulation in the small intestine and stomach, and endotoxemia. In the study reported by Arroyo and his coinvestigator, toxigenic strains of *C. difficile* were isolated from 10/10 horses with DPJ, and only 1 of 16 horses with other causes of nasogastric reflux. *C. perfrigens* or *Salmonella* spp. were ruled out as causes of DPF in affected horses.

Horses with proximal enteritis are predisposed to hepatic injury (Davis *et al.,* 2003). When compared to horses with small intestinal strangulation obstruction (SISO), horses with proximal enteritis had significantly higher serum gamma-glutamyltransferase (GGT), aspartate aminotransferase, and alkaline phosphatase activities. Horses with proximal enteritis were 12.1 times more likely to have high GGT activities than were horses with SISO. Suspected mechanisms for hepatic injury were ascending infection from the common bile duct, absorption of endotoxin or inflammatory mediators from the portal circulation, or hepatic hypoxia resulting from systemic inflammation and endotoxemic shock.

Hemorrhagic bowel syndrome (HBS) or jejunal hemorrhage syndrome is an acute sporadic enteric disease recognized most frequently in dairy cattle (Berghaus *et al.,* 2005). Affected cows develop clinical signs consistent with intestinal obstruction, which is attributed to segmental necrohemorrhagic enteritis and large intraluminal blood clots. *Clostridium perfringens* and *Aspergillus fumigatus* have received the most attention as possible etiological agents. The implementation of management practices to achieve high mild production, as well as increased consumption of high-energy rations, seems to be predisposing a risk factor. The fatality risk is very high, and seldom does medical and surgical intervention change the outcome.

IX. DISTURBANCES OF RUMEN FUNCTION

The digestive process of ruminants differs from that of other animals because rumen microbial digestion occurs before other normal digestive processes. The short-chain fatty acids (acetic, propionic, and butyric acids) are the primary end products of rumen fermentation and are the chief sources of energy available to ruminants from the diet. Cellulose, which undergoes only limited digestion in most simple-stomached animals, is readily digested because of the cellulitic bacteria in the rumen. Ruminal bacteria can also use significant quantities of nonprotein nitrogen (NPN) for protein synthesis, and this bacterial protein subsequently can be utilized to meet the protein requirements of the animal. Under experimental conditions, ruminants may grow and reproduce while receiving diets containing only NPN (e.g., urea) sources of nitrogen. Bacterial production of vitamins can also meet essentially all the requirements of ruminants.

Although nutritionally essential, bacterial fermentation within the rumen presents certain unusual hazards for ruminants. For example, when rapid changes in diet occur, the products of fermentation can be released more rapidly than they can be removed or utilized. Acute rumen tympany, acute indigestion or D-lactic acidosis, and urea poisoning are diseases that result from such abrupt changes in diet (Hungate, 1966, 1968).

A. Acute Rumen Indigestion (Rumen Overload, Lactic Acidosis)

Acute rumen indigestion occurs in sheep or cattle consuming high-roughage diets when they inadvertently are allowed access to large amounts of readily fermentable carbohydrate (e.g., grain or apples) (Dunlop, 1972). *Streptococcus bovis* is the rumen microorganism believed to be chiefly responsible for rapid fermentation and for production of large quantities of lactic acid (Hungate *et al.,* 1952; Krogh, 1963a, 1963b).

When lactic acid accumulates more rapidly than it is absorbed, rumen pH falls and rumen atony develops. Rumen bacteria produce a racemic mixture of lactic acid. Some L-lactate is absorbed and metabolized by the liver and other tissues, but D-lactate cannot be utilized and contributes significantly to the acid load of the body. The excessive lactic acid production results in metabolic acidosis

characterized by reduced blood pH and HCO_3^- concentration and by a fall in urine pH from a normal alkaline value to as low as pH 5. Fluid accumulates in the rumen because of the increased osmolality of the rumen fluid. This accumulation of fluid into the rumen causes hemoconcentration, which in turn may lead to hypovolemic shock and death. If affected animals survive the initial period of rapid fermentation, chemical rumenitis induced by the hyperosmolality of the rumen fluid and by the excess lactic acid may develop. Secondary mycotic rumenitis may then follow, which in severe cases can be fatal. In surviving cattle, metastatic hepatic abscesses may also occur.

B. Acute Rumen Tympany (Bloat)

The rumen of mature cattle can produce 1.2 to 2 liters of gas per minute (Hungate *et al.,* 1955, 1961). The gas is the product of rumen fermentation and is composed primarily of carbon dioxide (CO_2) and methane. CO_2 is also released when salivary HCO_3^- comes in contact with the organic acids in the rumen. Under normal conditions, these large amounts of gas are continually removed by eructation.

Any factor that interferes with eructation can produce acute tympany of the rumen (bloat) leading to rapid death. Interruption of the normal eructation reflex or mechanical obstruction of the esophagus typically results in free gas bloat. The most important form of bloat, however, is seen in cattle consuming large quantities of legumes or in feedlot cattle on high-concentrate diets. The primary factor in these more common forms of bloat is a change in the ruminal contents to a foamy or frothy character because of altered surface tension. Gas becomes trapped in small bubbles within the rumen and cannot be eliminated by eructation (Clarke and Reid, 1974).

The chemical changes that cause foam to form within the rumen are not fully understood. Some reports (Nichols, 1966; Nichols and Deese, 1966) suggest that plant pectin and pectin methyl esterase, a plant enzyme, are critical factors. The enzyme acts on pectin to release pectic and galacturonic acids, which greatly increase the viscosity of the rumen fluid, resulting in formation of a highly stable foam. A soluble legume protein fraction with ribulose diphosphate carboxylase activity has been suggested as another important dietary factor in the pathogenesis of bloat (Howarth, 1975). Slime-producing bacteria also have been incriminated in the pathogenesis of frothy bloat. These microorganisms produce an extracellular polysaccharide that results in stable foam formation.

Effective medical treatment and control are directed toward decreasing or preventing foam formation. This has been accomplished with certain nonionic detergents with surfactant properties that break up or prevent formation of foam within the rumen (Bartley, 1965). Another approach has been the prophylactic administration of sodium alkyl sulfonate, which inhibits pectin methyl esterase activity and prevents foam formation by eliminating the products of this enzyme reaction (Nichols, 1963). Antifoaming agents such as poloxalene administered before ingestion of bloat-producing diets have been shown to be effective prophylactically (Howarth, 1975). Silicone antifoaming agents also have been used for this purpose (Clark and Reid, 1974). Genetic selection of cattle that are less susceptible to rumen tympany has also been pursued (Howarth, 1975).

C. Urea Poisoning

Unlike monogastric animals, ruminants, via their microbial flora, can effectively use nonprotein nitrogen (NPN) to meet some of their dietary protein requirements. Urea, biuret (Oltjen *et al.,* 1969), and ammonium salts (Webb *et al.,* 1972) can serve as dietary NPN sources. Urea, which is the most frequently used, is hydrolyzed by ruminal bacterial urease into CO_2 and NH_3. The free NH_3 is incorporated into amino acids and protein by the rumen microorganisms. The bacterial protein is digested and absorbed in the abomasum and small intestine along with dietary protein.

Signs of urea poisoning typically develop within minutes after consumption of food containing toxic amounts of urea. Clinical manifestations reflect the encephalotoxic effects of excess absorbed NH_3 (Word *et al.,* 1969). Tolerance to urea may be significantly increased by increasing the amount of urea in the diet gradually or by adding readily fermentable carbohydrate to the diet. Ruminants can actually adapt and thrive on a diet in which urea is the sole source of dietary nitrogen. However, if urea is fed at more than 3% in the diet in unadapted animals, toxic effects are likely to occur.

Urea poisoning may occur accidentally when animals engorge on large amounts of urea-containing dietary supplement, when there has been an error in formulation of bulk feed, or when the urea-containing additive is incompletely mixed. Oral administration of acetic acid has been shown to reduce acute urea toxicity, apparently by decreasing absorption of free NH_3 from the rumen. Normally, NH_3 is in equilibrium:

$$NH_3 + H^+ \rightarrow NH_4^+$$

with only 1% in the free form. Acidification shifts the equilibrium farther to the right, thereby reducing the amount of the NH_3. Because only the free form crosses cell membranes, the net effect is a reduction of absorption of NH_3 by the cell. Acetic acid is used as a treatment for urea poisoning, but it is of more value as a prophylactic agent (Word *et al.,* 1969).

Chapter 15

Skeletal Muscle Function

Stephanie J. Valberg

University of Minnesota
St. Paul, Minnesota

I. INTRODUCTION

This chapter outlines skeletal muscle form and function, reviews mechanisms of assessment, and introduces selected neuromuscular diseases that highlight the close relationship between muscle form and function. Skeletal muscle comprises approximately 50% of the body's mass. It is largely composed of long multinucleated spindle shaped skeletal muscle cells (myofibers) that are highly specialized by virtue of a structured array of muscle-specific contractile proteins and conductile membranes containing ion channels and pumps. Muscles in the body differ in their constituent myofiber populations and vascular and nerve supply, which affects the speed and force developed during muscle contraction as well as the neuromuscular disorders with which they are afflicted.

II. SPECIALIZATION OF THE SARCOLEMMA AND SARCOPLASM FOR MUSCULAR CONTRACTION

A. Neuromuscular Transmission: Excitation-Conduction

The plasmalemma (sarcolemma) of the skeletal myofiber is an electrically excitable membrane that can activate the contractile machinery in response to signals received from the motor nerve. The properties of excitation and conduction largely result from the presence of membrane-spanning ion conducting pathways and channel gaits that regulate the selective and nonselective conductance of sodium, potassium, calcium, and chloride across the sarcolemma. They activate (open) in response to ligands,

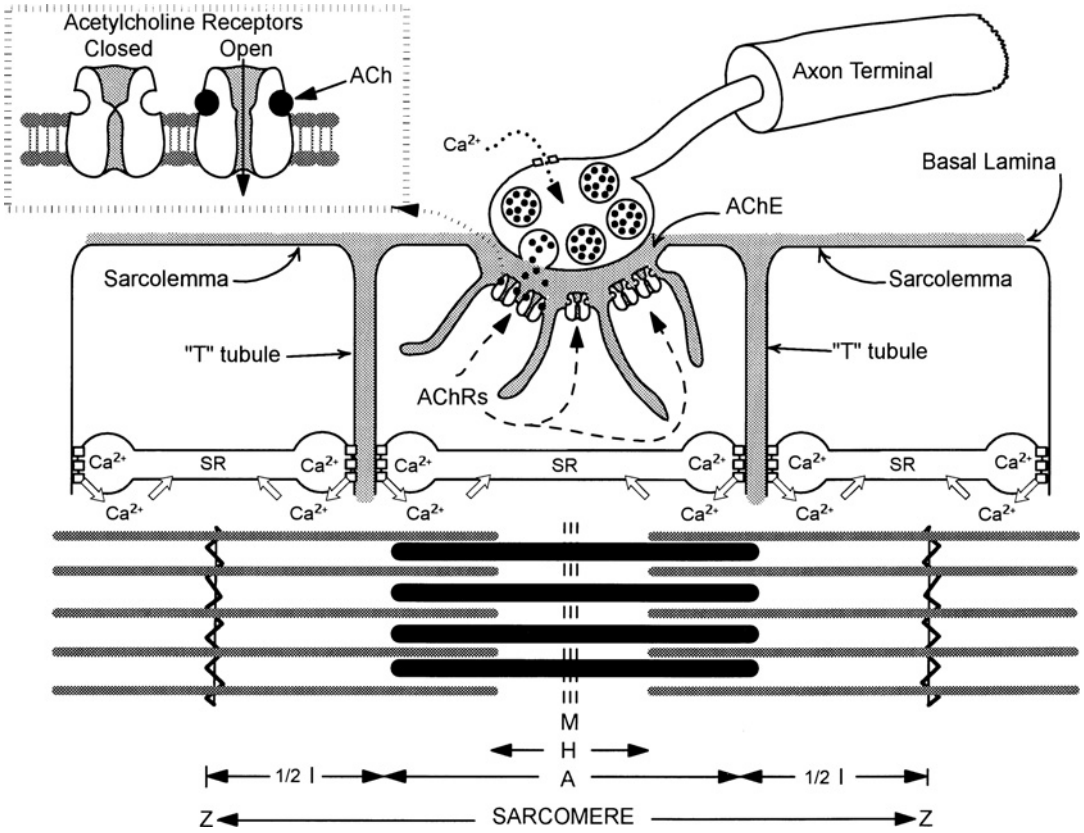

FIGURE 15-1 Excitation of myofibers to contract involves neuromuscular transmission and the subsequent release of calcium ions into the sarcoplasm. Arrival of an impulse at the axon terminal activates voltage-gated calcium ion channels, resulting in the influx of calcium ions that initiate the calcium-dependent release of the neurotransmitter acetylcholine (ACh) by exocytosis. Liberated ACh diffuses across the synaptic cleft to bind with ACh receptors (two molecules of ACh per receptor) on the postsynaptic sarcolemma. Binding of ACh with AChRs increases the conductance of sodium and potassium ions across the postsynaptic membrane to produce a local end-plate potential at the neuromuscular junction. The end-plate potential generates a muscle action potential that spreads away from the neuromuscular junction in all directions over the surface of the myofiber and into its depths via the transverse (T) tubules. Within the depths of the myofibers, excitation is coupled to contraction through the release of calcium ions from terminal cisternae of the sarcoplasmic reticulum (SR) through calcium release channels of the terminal cisternae. The calcium release channels form small "feet" that extend from the terminal cisternae to the T tubules. The liberated calcium ions bind to the regulatory protein troponin and release the inhibitory action of the regulatory proteins on the contractile events that lead to sliding of the thin (actin) and thick (myosin) filaments. The liberated ACh is subsequently hydrolyzed by AChE (acetylcholinesterase) within the basal lamina of the synaptic cleft.

transmitters, or changes in voltage and inactivate (close) by intrinsic regulatory processes. Voltage-gated channels contain additional voltage-sensing transmembrane domains and are essential for the generation and modification of action potentials. Ligand-gated ion channels are essential for setting myoplasmic calcium concentrations and establishing signal transduction pathways. Abnormal function of these ion channels produces muscle weakness or altered muscle contractions through altered excitability of the sarcolemma.

The neuromuscular junction or motor end plate is the synaptic site for chemical transmission of excitation from the presynaptic axon terminal of a motor neuron to the postsynaptic skeletal myofiber (Fig. 15-1). The position of the neuromuscular junction on a muscle fiber can vary among species, among muscles in a species, and among fibers in a given muscle. The axon terminal rests within a primary depression of sarcolemma, the primary cleft, and contains numerous small vesicles that contain acetylcholine (ACh), the neurotransmitter for excitation of skeletal myofibers. Each vesicle contains a quantum of neurotransmitter, consisting of 6000 to 8000 molecules of ACh. Arising from the primary cleft underlying the axon terminal are numerous smaller secondary clefts and complementary folds. The space within the primary and secondary clefts, located between the axon terminal and the postsynaptic sarcolemma, comprises the synaptic cleft. This space is filled with basal lamina containing acetylcholinesterase (AChE). The synaptic

basal lamina also plays an important role in the development and regeneration of the neuromuscular junction.

The arrival of a nerve action potential at the axon terminal results in activation of voltage-gated calcium ion channels in the presynaptic membrane. The calcium influx initiates a calcium-dependent exocytosis of ACh-containing vesicles from the active zone of the presynaptic membrane. Voltage-gated potassium channels in the presynaptic membrane close the voltage-gated calcium channels and restore resting membrane potential in the axon. The ACh released diffuses across the synaptic cleft to bind with acetylcholine receptors (AChRs), which are concentrated on the crests of the secondary folds of the postsynaptic sarcolemma. The structure of the AChR is similar among animal species. The AChR molecule is an integral transmembrane protein that is formed of five homologous subunits that form a central pore through which ions can flow. It consists of two alpha subunits and single δ, γ, and ε subunits, which possesses a binding site for ACh at the external interfaces of the α/δ and the α/ε subunits. Somewhat deeper within the troughs of the secondary folds are voltage-gated sodium ion channels, which are also present within the sarcolemma throughout nonjunctional regions of the myofiber (Engel, 2004).

Excitation of the myofiber is initiated by the reversible binding of ACh with AChRs. The binding of ACh with AChR (two ACh molecules/receptor) results in a local depolarization of the postsynaptic membrane caused by the transient-increased conductance of the AChR cation ion channels to sodium and potassium ions. The amplitude of the end-plate potential (depolarization) is proportional to the number of ACh-AChR complexes formed. At rest, individual quanta of ACh are spontaneously released at a slow rate and cause transient, low-amplitude depolarizations at the end plate. These are referred to as miniature end-plate potentials (MEEPs). The interior of a resting muscle fiber has a resting potential of about $-95\,\text{mV}$. The binding of ACh to AChRs is transient, and its effects are abolished by diffusion of ACh away from the receptors and its hydrolysis by AChE. With the arrival of a nerve action potential, approximately 200 quanta of ACh are released, and with the increased number of ACh-AChR combinations, there is a greater conductance of sodium and potassium ions that form a large amplitude depolarization, the end-plate potential (EEP). When the amplitude of the EEP exceeds threshold (approximately $-50\,\text{mV}$), a wave of depolarization (muscle action potential, MAP) is generated over the sarcolemma, away from the end plate in all directions. The MAP is propagated by voltage-gated sodium channels over the surface of the myofiber and into its depths via transverse (T) tubules. The T tubules are invaginations of the sarcolemma that tranverse the long axis of the myofiber, and their lumina openly communicate with the extracellular fluid space (Engel, 2004).

B. Coupling Excitation to Contraction

Excitation-contraction coupling involves the transformation of depolarizing events in the sarcolemma into the initiation of mechanical shortening of the myofibrils within the myofiber by calcium ions released from the terminal cisternae of the sarcoplasmic reticulum (SR). These events occur within the depths of the myofiber at "triads" where the T tubules form junctional complexes with adjacent terminal cisternae of the SR. A triad occurs twice in each sarcomere. The sarcoplasmic reticulum functions in the uptake, storage, and release of calcium ions to regulate the concentration of calcium ions in the aqueous sarcoplasm bathing the myofilaments and other organelles. The concentration of calcium in the SR is aided by the presence of calsequestrin, a calcium-binding protein that is maintained in the lumen of the cisternae by triadin and junctin.

At the T-SR junctional complex of triads, the sarcolemma contains voltage-sensitive dihydropyridine receptors (DHPRs) and the terminal cisternae of the SR possess ryanodine-sensitive calcium ion channels (ryanodine receptors) that form "feet" that fill the gap between the terminal cisternae and T tubules. Accessory proteins that regulate ryanodine receptor function include calmodulin and FK-506 binding protein. With depolarization of the sarcolemma within the T tubules, DHPRs interact with ryanodine receptors to mediate the voltage-dependent release of calcium ions from the SR into the sarcoplasm, elevating the calcium ion concentration from 10^{-7} to 10^{-5}M. This elevation in calcium ion concentrations initiates contraction through its interaction with the calcium binding proteins such as troponin C and calmodulin, a component of the myosin light chain kinase system (Magleby, 2004).

Relaxation is initiated by a reduction in the sarcoplasmic calcium ion concentration through active transport of calcium ions into the lumen of the SR by the SR calcium-ATPase (SERCA). At low calcium concentrations, SERCA activity is inhibited by phospholamban. However, relaxation is promoted by SERCA at higher myoplasmic calcium concentrations generated by stimulation of the ryanodine receptor. Further details concerning the structures and functions involved in neuromuscular transmission and coupling of excitation to contraction are available elsewhere (Engel, 2004; Magleby, 2004; Martonosi and Pikula, 2003; Numa *et al.*, 1990).

C. Muscular Contraction

The ability of skeletal muscle to contract is conferred by the elementary contractile unit, the sarcomere (Fig. 15-2). The sarcomere has three crucial properties: (1) the ability to shorten rapidly and efficiently, (2) the ability to switch on and off in milliseconds, and (3) precision self-assembly and structural regularity. There are three major functional classes

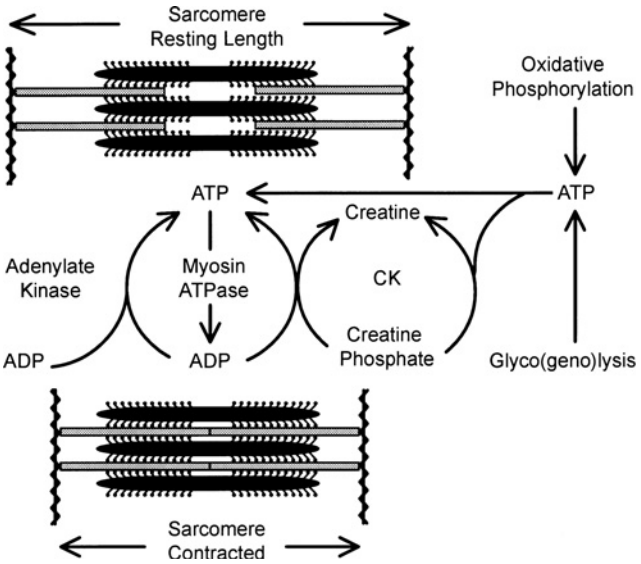

FIGURE 15-2 Muscular contraction involves the shortening of sarcomeres by sliding of the overlapping arrays of thick (myosin) and thin (actin) myofilaments. The energy for contraction is derived from the hydrolysis of ATP in the presence of an actin-activated ATPase present within the head regions of the myosin thick filament cross-bridges. The ATP is generated by the energy metabolism of the myofiber, principally by anaerobic glycolysis or oxidative phosphorylation. The utilization of ATP may be direct from those sources or indirect from the phosphorylation of ADP from creatine phosphate by creatine kinase (CK).

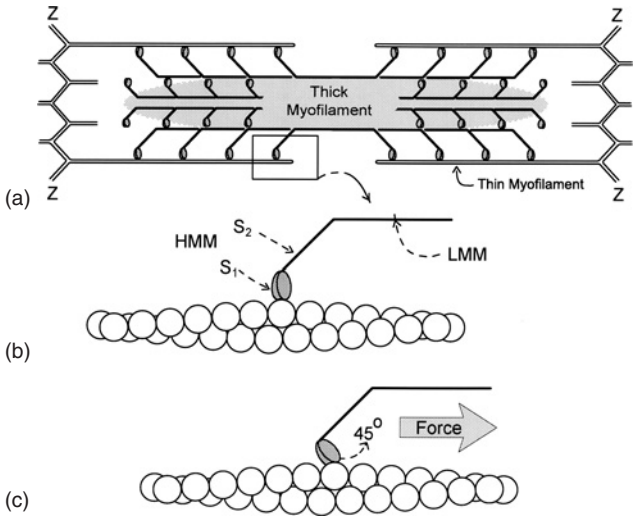

FIGURE 15-3 Schematic presentation of myosin cross-bridges on thick myofilaments. Portions of the myosin molecules (cross-bridges) project from the thick myofilaments and make contact with the thin myofilaments (a). The light meromyosin (LMM) portion of myosin molecules forms the major structural component (backbone) of the thick myofilament, whereas the heavy meromyosin (HMM) component forms the cross-bridge connections between the thick and thin myofilaments (b). The cross-bridges of myosin are composed of two fractions: (1) the S_1 fraction, a globular protein fraction composed of two heads, each possessing binding capacities for ATP and actin and the actin-activated ATPase activity of myosin, and (2) the S_2 fraction, a fibrous protein fraction that forms the flexible linkage between the S_1 fraction and the LMM portion of myosin (b). The force for sliding of the myofilaments results from a change in the angle of attachment (i.e., a change from 90 to 45 degrees) between the S_1 globular head and actin filament (c).

of constituent proteins that form the sarcomere: contractile, regulatory, and structural.

1. *Myofilaments and Contractile Proteins*

Together, myosin, the principal contractile protein component of thick myofilaments, and actin, the principal component of thin myofilaments, account for more than 70% of myofibrillar protein. Lateral projections of the myosin thick myofilaments (myosin cross-bridges) form reactive sites with actin, which cyclically associate and disassociate during contraction and relaxation. The force-generating step for sliding of the filaments past each other results from changes in the angle of the cross-bridge attachments (Fig. 15-3).

a. Thick Myofilaments and Myosin

To understand the physicochemical changes that occur at the cross-bridges, the composition and properties of myosin need to be considered. Myosin is an asymmetric protein with both structural and enzymatic properties. It is composed of two identical heavy chains (polypeptide chains with an approximate molecular mass of 200kDa) and two pairs of light chains (polypeptide chains with molecular masses ranging from 16 to 27kDa). The two myosin heavy chains are arranged in a double helix to form a long stable tail at one end, and at the other end each heavy chain is folded to form one globular pear-shaped head. The four myosin light chains are contained within the globular heads (two per head) near the junction of the head and neck domains.

The composition of myosin heavy chains within sarcomeres varies among species, among individual muscles, and among individual muscle cells. Mammalian skeletal muscle cells may express six distinct heavy chain genes: perinatal (or neonatal), fast type IIa, fast type IIx (or IId), fast type IIb, and extraocular. The speed of contraction of these myosin heavy chain isoforms increases in the order listed here. Three additional sarcomeric myosin heavy chain genes (super fast, slow A, and slow B) exist, but their expression is unknown, with the exception of expression of superfast myosin in jaw muscles (Sweeney and Houdusse, 2004).

A range of myosin light chain isoforms also exist in skeletal muscle that may affect their function. Skeletal muscle possesses both fast skeletal and slow skeletal muscle isoforms of essential light chains as well as regulatory light chains. Biochemically, two classes of light chains can be distinguished: (1) two identical DTNB light chains, which disassociate from their globular heads with the thiol reagent 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), which correspond to regulatory light chains, and (2) two related

but different species of 1/alkali light chains (AI and A2), which disassociate at a high pH corresponding to essential light chains (Lowey *et al.*, 1969; Sweeney and Houdusse, 2004; Weeds, 1969).

The myosin molecule is composed of head, neck, and tail domains. Proteolytic digestion with trypsin results in the formation of two fragments: (1) heavy meromyosin (HMM), which is composed of the two globular heads of myosin and a short neck domain composed of the initial segment of the fibrous portion; and (2) light meromyosin (LMM), the tail domain composed of the remaining long fibrous portion. The HMM fragments correspond structurally to the cross-bridges, whereas the LMM fragments comprise the bulk of the thick filaments (Fig. 15-3). The actin-binding capacity, ATP-binding capacity, and actin-activated ATPase activity of myosin reside in the globular head. The actin-activated ATPase activity of myosin appears to reside primarily in the heavy chains and is greatly boosted by interaction of the heads with myosin (Sweeney and Houdusse, 2004).

b. Thin Myofilaments and Actin

The thin filaments are composed of two F-actin strands arranged in a double helical configuration. The F-actin strands are polymers of the globular protein G-actin, and each G-actin monomer possesses a complementary binding site for the myosin globular head. Upon combining with myosin, actin activates the ATPase activity of the myosin globular head (Huxley *et al.*, 1983).

2. *Regulatory Proteins*

Two proteins (tropomyosin and troponin) work in concert with calcium to regulate muscle contraction. Tropomyosin, a fibrous protein, is arranged along the length of the thin filaments, within the grooves of the two F-actin strands. Troponin is a globular protein complex composed of three subunits: TN-I (troponin inhibitory component), TN-T (tropomyosin-binding component), and TN-C (calcium-binding component). The TN-T component attaches the complex to tropomyosin at intervals along the thin myofilaments. With low sarcoplasmic calcium concentrations (10^{-7}M), tropomyosin molecules block the myosin-binding sites on actin, which prevents the interaction of actin and myosin. At higher concentrations (10^{-6}M), calcium ions combine with the TN-C component to initiate a conformational change in the TN-I component, which results in the movement of tropomyosin to free the myosin-binding sites on actin. With the myosin-binding site on actin exposed, actin and myosin combine and initiate the cyclical changes associated with that interaction. When calcium ion concentrations are reduced through uptake of calcium by SERCA, the process is reversed and the interaction of actin and myosin is inhibited.

3. *Structural Proteins*

The organization of myofilaments within sarcomeres and the organization of myofibrils are supported by a complex cytoskeletal network of intermediate filaments (Wang and Ramirez-Mitchell, 1983). Intermediate filaments, and a number of accessory proteins that form fine filaments, (1) maintain the alignment of myofilaments and sarcomeres, (2) attach and maintain alignment of adjacent myofibrils, (3) attach the sarcomeres of peripheral myofibrils to the sarcolemma, and (4) connect terminal sarcomeres to the sarcolemma at myotendinous junctions. Collectively, the cytoskeletal filaments maintain the structural and functional relationships of the myofilaments and transfer the forces developed by the myofilaments to the sarcolemma.

a. Alignment of Myofilaments, Sarcomeres, and Myofibrils

Thick myofilaments are attached to Z lines by small filaments composed of the protein titin (Labeit *et al.*, 1997; Maruyama, 1999). The titin filaments arise near the M line within the axes of the thick filaments and span the length of the thick filament as well as the I-band region to attach to the Z line. Within the I-band region, the titin filaments provide an elastic attachment to the Z line, which imparts a passive elasticity to sarcomeres. Myosin-binding proteins attach to the thick filaments and titin and appear to serve a structural role as well as a role in myofibrillogenesis. An additional protein, nebulin, forms small filaments that run the length of thin myofilaments and may regulate the length of thin myofilaments. The M line within the sarcomere stabilizes the thick filament lattice by linking neighboring filaments to each other and has an enzymatic role as well. It is composed of creatine kinase, myomesin, and M protein (Craig and Padron, 2004).

At the periphery of myofibrils, adjacent Z lines within the same sarcomere are connected by intermediate filaments of desmin. Also, intermediate filaments of desmin encircle the circumference of Z lines and appear to form linkages with Z lines of adjacent myofibrils to aid in the alignment of sarcomeres in register with adjacent myofibrils.

b. Attachment of Myofilaments to the Sarcolemma

At the periphery of myofibrils adjacent to the sarcolemma there are riblike attachments (costomeres), which are present on either side of Z lines (Franzini-Armstrong and Horowitz, 2004; Maruyama, 1999). Desmin filaments appear to be anchored to the sarcolemma by a number of adhesion proteins such as vinculin. At myotendinous junctions, the thin myofilaments of the last sarcomere attach to the sarcolemma, which is thrown into numerous villous projections. The thin myofilaments are anchored by the proteins α-actinin and vinculin, among others. Growth in the length of muscle fibers occurs at the myotendinous junctions by the addition of new sarcomeres (Griffin *et al.*, 1971).

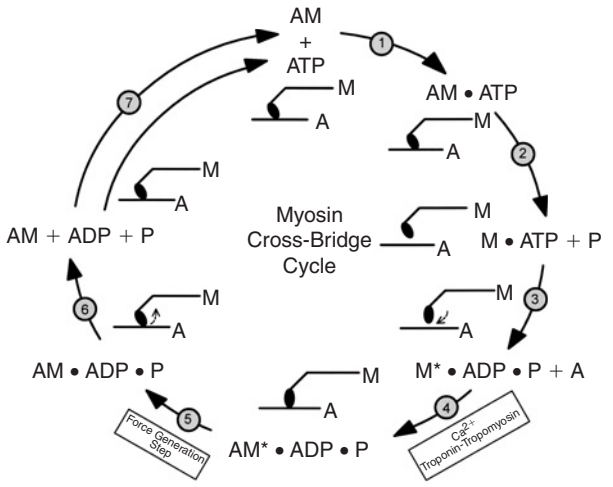

FIGURE 15-4 Muscular contraction results from the cyclical association and disassociation of actin (A) and myosin (M) in which conformational changes occur in the cross-bridge linkages between the thick and thin myofilaments, associated with the hydrolysis of ATP.

D. Muscular Energetics

Muscular contraction results from the transformation of chemical energy into mechanical energy. The energy for contraction is derived from the hydrolysis of adenosine triphosphate (ATP) into adenosine diphosphate (ADP) and inorganic phosphate (Fig. 15-2) catalyzed by myosin adenosine triphosphatase (ATPase) activity in the myosin head. Chemically, the transformation of energy is associated with the cyclical association and disassociation of the contractile proteins actin and myosin, whereas mechanically the transformation is associated with shortening of sarcomeres, which is achieved by conformational changes of the myosin molecules that result in sliding of the overlapping arrays of thick and thin myofilaments (Fig. 15-4) (Eisenberg *et al.*, 1972; Huxley *et al.*, 1983; Lymn and Taylor, 1971).

In the noncontracting state, actin and myosin are combined at the cross-bridges (step 1, Fig. 15-4), and the angle of attachment between the cross-bridge heads and the actin filaments is 45 degrees. Binding of ATP to each globular head (two molecules ATP/myosin molecule) results in a rapid disassociation of actin and myosin (step 2, Fig. 15-4). ATP hydrolysis is rapid when myosin is not associated with actin resulting in the release of phosphate and ADP. The globular head of myosin moves to a new location on the thin filament (step 3, Fig. 15-4), which permits the angle of attachment to become 90 degrees when the globular head recombines with the actin filament (step 4, Fig. 15-4). This recombination step between the globular head and actin is controlled by the regulatory proteins troponin and tropomyosin in response to calcium ion concentrations. The force for contraction is generated by movement of the cross-bridge head to a 45 degree angle of attachment (step 5, Fig. 15-4), and the cycle is completed with the detachment of the hydrolytic products of ATP from the head (step 6, Fig. 15-4). With the formation of ATP through rephosphorylation (step 7, Fig. 15-4), the cycle may be repeated. Measurements indicate that each cycle (stroke) shortens a sarcomere by 12 nm (Barden and Mason, 1978).

Rigor mortis, the rigid and stiff condition of skeletal muscles that develops following death, involves cessation of the cross-bridge cycle in the post-force-generating step (step 6, Fig. 15-4). After death, when all ATP stores have been utilized, disassociation of actin and myosin will not occur, and the contraction cycle is terminated with a large number of actin myosin complexes formed with the myosin heads set at 45 degrees.

III. HETEROGENEITY OF SKELETAL MUSCLE

A. Gross Muscle Coloration

The first indication that different muscles had different physiological prosperities arose from the observation that there was variation in muscle coloration not only among species of animals, but also among individual muscles within the same individual. As a result of these differences in coloration, the terms "red" and "white" were introduced to distinguish between muscles of different gross coloration. Red coloration of muscles was subsequently found to be due to the presence of myoglobin and other cytochromes within the myofibers. Numerous biochemical, histochemical, and physiological studies have since been conducted to detail a variety of differences in both the metabolic and contractile properties of "red" and "white" skeletal muscle.

B. Physiological Properties

The speed of contraction of red muscles was most often found to be slower than that of white muscles in a variety of animals. In addition, redness of a muscle was associated with the development of tetanus at lower frequencies of stimulation, the development of smaller twitch tensions, and a greater resistance to fatigue. Conversely, white muscles required greater frequencies of stimulation for the development of tetanus, developed larger twitch tensions, and tended to fatigue quickly. From this data, the terminology of slow-contracting or slow-twitch and fast-contracting or fast-twitch muscles evolved. Moreover, because speed of contraction was closely associated with gross muscle coloration, the terms "red" and "white" came to be used interchangeably with "slow" and "fast," respectively. However, there are numerous exceptions to this association of gross coloration with physiological properties of contraction. Therefore, direct associations must not be assumed.

C. Motor Units

The morphological and functional unit of skeletal muscles is the motor unit (Fig. 15-5). The motor unit is composed

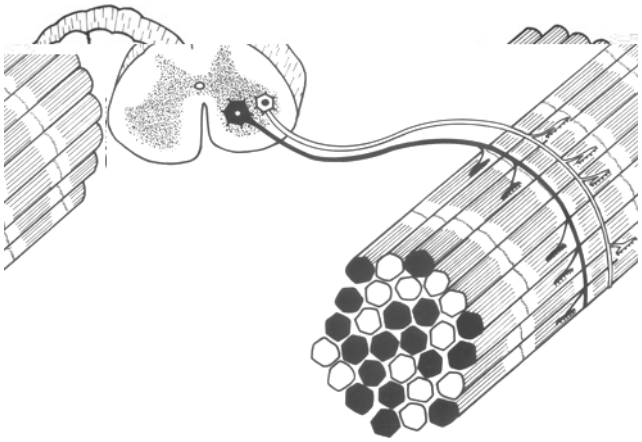

FIGURE 15-5 Schematic representation of the homogeneity of skeletal muscle motor units. Motor units have a homogeneous myofiber-type composition whereby slow-twitch motor units are composed of only type 1 myofibers (light staining for myosin ATPase), whereas fast-twitch units are composed of only type 2a (fast-twitch, fatigue resistant) myofibers, or only type 2b (fast-twitch, fatigable) myofibers (dark staining for myosin ATPase).

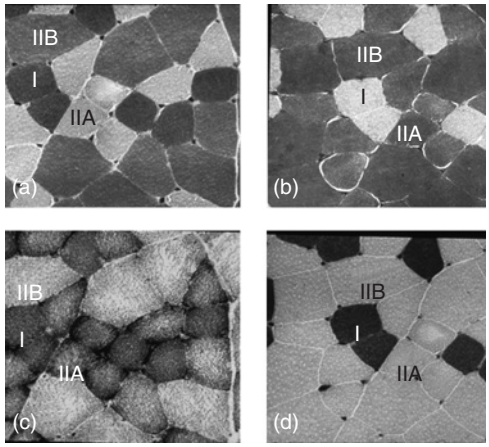

FIGURE 15-6 Serial sections of cat medial gastrocnemius muscle incubated for the histochemical demonstration of (a) myofibrillar ATPase, incubated at pH 9.4; (b) myofibrillar ATPase, preincubated at pH 4.5; (c) NADH-tetrazolium reductase. Type 1 myofibers comprise slow-twitch motor units that are resistant to fatigue. Type IIA myofibers comprise fast-twitch motor units that are resistant to fatigue, whereas type IIB myofibers comprise fast-twitch motor units that fatigue rapidly. Dark NADH staining indicates high mitochondrial content; and (d) myofibrillar ATPase, preincubated at pH 4.2.

of (1) the motor neuron, consisting of its cell body located within the central nervous system (selected cranial nerve nuclei or the ventral horn of the spinal cord), and its axon, which extends along the ventral root and peripheral nerve; (2) the neuromuscular junctions; and (3) the myofibers innervated by the motor neuron.

Motor neurons may differ based on their rates of discharge: (1) phasic motor neurons with a fast discharge rate and (2) tonic motor neurons with a slow discharge rate. In addition, the phasic motor neurons are characterized by shorter after hyperpolarization potentials, faster conduction velocities, and larger axons than the tonic motor neurons. Investigations of these parameters in motor neurons of slow-contracting and fast-contracting muscles indicate that tonic motor neurons, which discharge at rates of 10 to 20 per second, innervate slow-contracting muscles, and phasic motor neurons, which discharge at rates of 30 to 60 per second, innervate fast-contracting muscle. Thus, there are at least two types of motor units, which differ in their physiological properties and type of motor neuron innervation (Eccles *et al.*, 1958).

Physiological measurements performed on isolated motor units in the cat have revealed two types of fast-twitch motor units and one type of slow-twitch unit (Burke, 1975). Some fast-twitch motor units are resistant to fatigue and designated FR units (i.e., fast-twitch, resistant to fatigue); others fatigue rapidly and are designated FF units (i.e., fast-twitch, fatigable). All of the slow-twitch units are resistant to fatigue and are therefore designated as S units (i.e., slow-twitch). The average number of muscle fibers per motor unit in cats ranges from 550 to 650. Subsequent immunohistochemical studies (discussed later) reveal that slow-twitch motor units contain type I myosin isoforms, and most FR motor units contain type IIa or IIa/x myosin isoforms and most FF motor units contain type IIx (mammals) or IIb (rodent) myosin isoforms.

D. Histology and Histochemistry

1. Histochemical Properties of Myofibers

a. Histoenzymic Properties Associated with Myosin-ATPase

Myofibers have been differentiated histochemically into type I and type II myofibers based on their staining reaction for myosin ATPase (Fig. 15-6) (Dubowitz and Brooke, 1973). Furthermore, type II myofibers, classified by the myosin ATPase staining reaction, may be further subdivided into type IIA, type IIB, and type IIC myofibers based on the lability of their ATPase activity following preincubation in acid and alkaline media (Fig. 15-6) (Brooke and Kaiser, 1970). If the actin-activated myosin ATPase activity is rate limiting in the speed of contraction, it follows that the histochemical method for myosin ATPase would be a specific method for the differentiation of myofiber types based on their speed of contraction. This classification scheme is generally applicable to all mammalian species except for canine muscles, which do not contain classical type IIB myofibers (Braund *et al.*, 1978; Orvis and Cardinet, 1981).

b. Immunocytochemical Identification of Myosin Isoforms

More recently, immunohistochemical differentiation of fiber types based on antibodies directed against myosin heavy chain isoforms have been used to identify contractile muscle fiber types (Gorza, 1990). To henceforth distinguish between the two methods for fiber-type identification roman numerals will be used for histochemical fiber types

and Arabic numbers will be used for myosin isoforms. Immunohistochemical staining for myosin isoforms reveals that the true number of distinctly identified muscle fiber types supersedes the number recognized by histochemistry alone. Myosin isoforms include neonatal and slow-twitch myosin isoforms as well as five distinct fast-twitch isoforms (Rubenstein and Kelly, 2004). Type 2a, type 2b, and type 2x are the most widely expressed skeletal muscle isoforms in the body with 2m fibers found in the jaw muscles of carnivores and 2eom in extraocular muscles. Unfortunately, type IIB fibers distinguished histochemically by myosin ATPase activity do not correspond to type 2b fibers distinguished by immunhistochemical staining for myosin heavy chains. Rather type IIB fibers correspond more closely with type 2x fibers (also called 2d) found in many mammalian species whereas 2b fibers correspond to myosin found in rapidly contracting muscle fibers found in rodents and camelids (Gorza, 1990). Moreover patterns of contractile protein isoforms and enzyme activities recognized in developing or pathological muscles do not correlate with standard histochemically derived fiber types (Linnane *et al.*, 1999). Hence, though useful as a screening tool for pathologists and physiologists, histochemical techniques have limitations.

Most limb muscles are "mixed" and contain variable proportions of type 1, type 2a, and type 2x myofibers. Intermediate fiber types called type IIC by myosin ATPase histochemistry or neonatal by immunohistochemistry are normally rare in mature muscle. These fibers presumably represent fibers capable of transitioning between type 1 and type 2 myofibers (Brooke and Kaiser, 1970).

c. Histoenzymic Properties Associated with Aerobic and Anaerobic Energy Metabolism

Histochemical studies show that type 1 myofibers have higher activities of oxidative enzymes such as succinate dehydrogenase (SDH), reduced nicotinamide adenine dinucleotide tetrazolium reductase (NADH-TR) (Fig. 15-6), and reduced nicotinamide adenine dinucleotide phosphate-tetrazolium reductase (NADPH-TR) than type 2 fibers (Dubowitz and Brooke, 1973). In conjunction with electron microscopic observations, the activities of these enzymes have been localized to mitochondria, which are present in abundance in type I fibers. Associated with the large mitochondrial volume of type 1 myofibers are lipid inclusions. Type II fibers in general stain darkly with glyco(geno)lytic stains such as phosphorylase or phosphofructokinase activity. Because various intermediate histochemical reactions of myofibers also exist, a classification system that describes type 1, type 2 oxidative, and type 2 glycolytic is often used.

d. Relationships with Functional Properties

Each motor unit is homogeneous with respect to its myofiber-type composition. Motor units with slow-twitch fibers are fatigue resistant and corresponded to type 1 fibers in histochemical stains. Two types of fast-contracting motor units exist; fast-twitch fatigue resistant, corresponding to type 2a fibers, and fast-twitch rapidly fatigable corresponding to type 2x fibers identified histochemically (Burke, 1975).

The physiological and histochemical properties and classifications of myofibers are summarized in (Table 15-1) and illustrated in Figure 15-6 and Figure 15-7.

TABLE 15-1 Metabolic Properties of Muscle Fiber Types in an Untrained Animal

	Type 1	Type 2a	Type 2x
Speed of Contraction	Slow	Intermediate	Fast
Myoglobin Content	High	Intermediate	Low
Fatigue Resistance	High	Intermediate	Low
Oxidative Capacity	High	Intermediate	Low
Fat Content	High	Intermediate	Low
Glycolytic Capacity	Low	High	High
Glycogen Content	Low	High	High

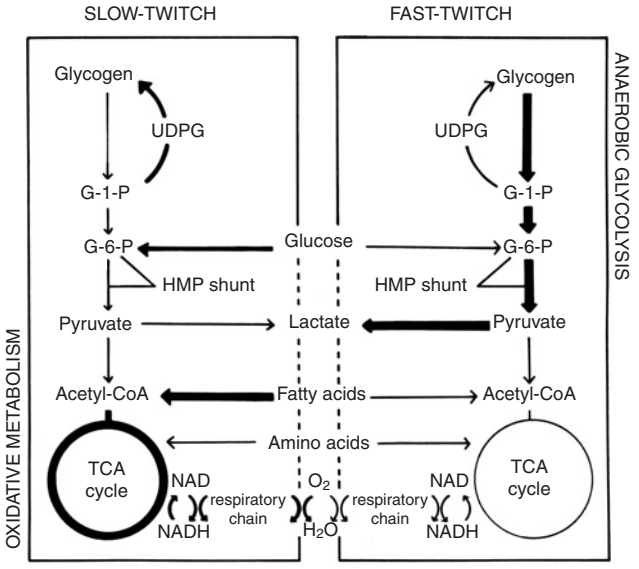

FIGURE 15-7 Schematic representation of some differences in energy-yielding metabolic pathways of slow-twitch and fast-twitch muscles. In slow-twitch muscles, energy for contraction is derived primarily by oxidative phosphorylation resulting from the oxidation of fatty acids, carbohydrates, and perhaps amino acids via the tricarboxylic acid cycle (TCA). Fast-twitch muscles derive their energy primarily via anaerobic glycogenolysis and glycolysis through the degradation of glycogen and glucose to lactate. Aerobic glycolysis via the HMP (hexose monophosphate) shunt is a minor pathway in both types of muscle.

E. Quantitative Biochemistry

1. Metabolic Pathway for Utilization of Energy (ATP) for Contraction

As previously discussed, the actin-activated myosin ATPase activity catalyzes the cyclical physiochemical interactions of actin and myosin during contraction (Fig. 15-4). Furthermore, the intrinsic speed of contraction (sarcomere shortening) has been demonstrated to be proportional to the activity of actin-activated myosin-ATPase, and differences exist between the myosin-ATPase activities of type I and type II muscle fibers. From those observations it is postulated that the rate-limiting step of sarcomere shortening during contraction is the hydrolysis of ATP. The ATPase activity of type I fibers is lower than in type II fibers, and their pH dependency and liability in acid and alkaline conditions also differ (Barany, 1967; Seidel, 1967).

2. Metabolic Pathways That Generate Energy (ATP) for Contraction

Quantitative differences in enzyme activities and various substrate concentrations have been reported between slow-twitch type 1 and fast-twitch muscle fibers type 2 as well as between fibers expressing myosin isoforms type 2a and 2x. Those biochemical differences between fiber types reflect differences in their principal metabolic pathways active in the generation of energy (ATP) for muscular contraction (Fig. 15-7).

The ATP required for contraction is not stored in significant quantities. Therefore, ATP must be readily produced through the metabolism of fats, carbohydrates, and creatine phosphate stores to support the energy requirements for contraction. Aerobically, ATP is produced in muscle mitochondria by oxidative phosphorylation coupled to electron transport. Anaerobically, ATP is produced in the aqueous sarcoplasm through substrate phosphorylation of ADP by (1) creatine kinase, utilizing creatine phosphate stores; (2) glyco-(geno)lysis, utilizing muscle glycogen stores, and (3) myokinase kinase, utilizing ADP produced by the ATP hydrolysis.

a. Aerobic and Anaerobic Energy Metabolism

In general, fast-twitch muscle fibers in the untrained state are biochemically suited to derive energy for contraction by anaerobic glyco(geno)lysis. Fast-twitch fibers, particularly type IIx, tend to have higher concentrations of glycogen and creatine phosphate as well as higher activities of enzymes associated with glycogenolysis and glycolysis (Table 15-1). Slow-twitch type I fibers, on the other hand, generally have higher concentrations of triglycerides and myoglobin and are better suited to derive their energy by oxidative phosphorylation via the electron transport system following the oxidation of fatty acids and glucose via the Krebs cycle (Table 15-1). Type IIa fibers are intermediate in their glycolytic and oxidative capacity between type IIx and type I fibers (Adhihetty *et al.*, 2003; Rubenstein and Kelly, 2004).

Triglycerides and glycogen serve as primary substrates for muscle metabolism. In general, the rate of glycogen utilization is greatest with high-intensity anaerobic exercise, whereas low-intensity submaximal exercise results in a lower rate of glycogen utilization and reliance on oxidation of fatty acids as fuel (Kiens, 2006). Under conditions of restricted energy intake or prolonged exercise, amino acids may also serve as energy substrates within skeletal muscle (Rennie *et al.*, 2006).

b. Purine Nucleotide Cycle

With strenuous exercise when the regeneration of ATP fails to meet energy demands, the myokinase reaction can be used to generate ATP from accumulated ADP. The accumulation of the additional product of this reaction, AMP, stimulates the purine nucleotide cycle, which removes AMP thereby preventing product inhibition of the myokinase reaction. The deamination of AMP by AMP deaminase in the purine nucleotide cycle results in the production of ammonia and inosine monophosphate (IMP) (Lowenstein, 1972). The cycle further involves the regeneration of AMP through deamination of aspartate and the hydrolysis of guanosine triphosphate to form adenylosuccinate, and the cleavage of adenylosuccinate to form fumarate and AMP. The activity of AMP deaminase is greater in type II compared to type I muscle fibers.

The purine nucleotide cycle regulates energy requirements for muscular contraction through (1) maintenance of a high ATP:ADP ratio by regulating the relative AMP, ADP, and ATP levels; (2) regulation of phosphofructokinase (PFK) activity through activation of this enzyme by ammonia; (3) regulation of phosphorylase activity through activation by IMP; (4) replenishment of citric acid cycle intermediates by the production of fumarate; and (5) deamination of amino acids for oxidative metabolism through the formation of aspartate (Tullson and Terjung, 1991).

From the foregoing, it is evident that the deamination of AMP can promote ATP synthesis by (1) stimulating anaerobic glyco(geno)lysis through the activation of phosphorylase b by IMP, and the activation of PFK by ammonia, and (2) supporting oxidative metabolism through the production of intermediates into the TCA cycle. The degradation of adenine nucleotides in equine muscle appears to occur mainly through deamination of AMP. Reported AMP deaminase activities are greatest for equine middle gluteal muscles, which were approximately double reported values for muscles of the rat and rabbit (Cutmore *et al.*, 1986).

c. AMP Kinase

Another emerging key sensor and regulator of energy metabolism in skeletal muscle is AMP-activated protein

kinase (AMPK), which monitors astonishingly small shifts in the cellular AMP:ATP ratio (Hardie, 2004). The activation of AMPK—either by allosteric interactions of AMP, phosphorylation by AMPK kinase, or both—triggers a shift from energy-consuming pathways, such as glycogen, fatty acid, and cholesterol synthesis, to ATP-generating pathways via the phosphorylation of key regulatory enzymes (Carling, 2004). AMPK activity may be necessary for contraction-stimulated glucose transport. AMPK has also been implicated in regulating gene transcription and, therefore, may function in some of the cellular adaptations to training.

F. Muscle Fiber Composition

Most muscles in domestic animals contain a mixture of muscle fiber types (Fig. 15-6). The muscle fiber composition, the percentage of type 1, 2a, and 2x fibers, and muscle fiber cross-sectional areas vary greatly among species, muscle groups, individuals, and breeds. When comparing the fiber-type composition of different individuals, a standardized site must be used as fiber-type proportions vary along the length and depth of a muscle. Locomotor muscles in most domestic animals have a combination of type 1, 2a, and 2x fibers (or I, IIA, and IIB depending on the technique used for fiber typing). Locomotor muscles in dogs contain type I and type IIA fibers and no type 2B fibers using ATPase stains for fiber typing; however, histochemical type IIA fiber types appear to correspond to both type 2a and hybrid type 2a/x MHC isoforms (Strbenc *et al.*, 2004). Camelid muscles contain an unusual mixture of 1, 2a, 2b, and 2x fibers (Graziotti *et al.*, 2001). Horses have a high proportion of type 2a and 2x fibers relative to type 1 fibers in their locomotor muscles. Breed differences have been extensively studied in horses (Snow and Valberg, 1994). In general, quarter horses and Thoroughbreds have the highest percentage of fast-twitch muscle fibers, 80% to 90%; standardbreds have an intermediate number, 75%; and donkeys have the lowest percentage of fast-twitch fibers in locomotor muscles (Snow and Valberg, 1994).

Fiber-type composition is not constant, as growth and training can alter the fiber-type composition and fiber size in the same muscle over time. With growth and training, there is a change in the length and breadth of a fiber as well as a change in the proportion of fiber types rather than an increase in the number of muscle fibers. Growth and training at speed results in an increase in the proportion of type IIA (2a) fibers and a concomitant decrease in type IIB (2x) fibers (Eto *et al.*, 2003, 2004).

G. Muscle Fiber Recruitment

When a muscle contracts during exercise, it does so in response to a predetermined recruitment of particular muscle fibers. This orderly recruitment of muscle fibers leads to smooth, coordinated movement. As exercise begins, a select number of motor units are recruited to provide the power to advance the limb. Motor units are recruited with respect to their contractile speed and oxidative capacities (Burke, 1975; Valberg, 1986). At slow exercise intensities, type I and a small number of type II fatigue-resistant muscle fibers are stimulated. The force produced by any muscle is proportional to the cross-sectional area that is active. As the speed or duration of exercise increases, more muscle fibers are recruited, and this occurs in the order of their contractile speed from type I to type IIA and type IIB (Lindholm *et al.*, 1974; Valberg, 1986). With moderate intensity, type I and type IIA myofibers are preferentially recruited, whereas moderate intensity of long duration or maximal exercise intensity is required for recruitment of type IIB myofibers.

More recent studies suggest that muscle fiber recruitment may be regulated by the central nervous system, with the subconscious brain producing an anticipated regulated response governed by peripheral feedback mechanisms and predetermined patterns of recruitment acquired from training and modulated by conscious motivation (Noakes *et al.*, 2004).

IV. ORIGINS OF FIBER DIVERSITY

The origins of muscle fiber-type composition appear to lie in lineage directives that developing embryonic myoblasts obtain from their progenitors, which limit to some extent the plasticity of the adult myofibers (Rubenstein and Kelly, 2004). Specification to become slow- or fast-twitch fibers appears to exist already in the myoblast stage and manifests when myotubes express one or the other MHC isoform. Subtypes of fast-twitch fibers become established following the commitment to the fast-twitch phenotype and occur in concert with the development of thyroid function (Russell *et al.*, 1988). In the embryo, the primordial myoblasts migrate to their position in the limb of the embryo where their fiber type is further influenced by temporal and positional factors, synaptogenesis, imposed neuronal activity, and activation of specific signal transduction pathways. At least two signal transduction pathways may contribute to fiber-specific synthesis of slow myosin. These include calcineurin, a calcium-regulated serine/threonine phosphatase, and Ras (Rubenstein and Kelly, 2004). A mosaic of fiber types subsequently forms with fiber-type predominance programmed in certain muscles or portions of muscles.

In mature muscle, the nerve has important trophic influences on the innervated muscle, which regulate its structural and metabolic properties. Motor units contain fibers of the same type. When motor neurons that normally innervate slow muscles are cross-innervated to supply muscles that are normally fast, and motor neurons that normally innervate fast muscles come to innervate muscles that are normally

slow, a reversal of contractile properties occurs—that is, fast-twitch muscles become slow, and slow-twitch muscles become fast. Accompanying this is a corresponding change in the enzyme histochemical profiles of the myofibers. Therefore, the motor neuron influences (1) the type of energy metabolism employed by a myofiber and all the structural changes in fiber organelles that this implies and (2) the myofiber's physiological properties of contraction. More recent cross-innervation studies, however, demonstrate that the embryogenic determination of muscle fiber types provides an inherent bias toward an original phenotype. Transplantation of myoblasts from cat jaw muscles (type 2m fibers) into the fast-twitch extensor digitorum limb muscle results in expression of their 2m myosin isoform even when enervated by the extensor digitorum nerve (Hoh and Hughes, 1988). Conversely, when jaw muscle myoblasts are transplanted into the slow-twitch soleus muscle, the soleus nerve can override type 2m expression and switch fibers to myosin heavy chain type 1 expression. Taken together, these studies suggest that muscle fiber type is determined by competitive interactions between endogenous programming and exogenous cues from motor neurons that require continual reinforcement (Rubenstein and Kelly, 2004).

V. EXERCISE AND ADAPTATIONS TO TRAINING

A. Exercise Intensity and Sources of Energy

The rate of energy utilization during intense exercise can be as much as 200 times greater than at rest and the rate of ATP utilization is closely associated with the rate of ATP synthesis (Holloszy, 1982a). Hence, the availability of ATP is a central requirement for sustaining the rate and duration of exercise. Because the stores of creatine phosphate and ATP available for immediate use within myofibers are small, the metabolic pathways for ATP synthesis serve a vital function in the maintenance of exercise. A number of interdependent factors appear to influence the metabolic pathways used for energy production during exercise. These include the speed and duration of exercise, the muscle fiber composition, the metabolic properties of the muscle fibers recruited, and the availability of oxygen and different energy substrates.

Aerobic pathways such as the Krebs cycle, β oxidation of free fatty acids (FFA) and the electron transport chain are located within mitochondria and provide the bulk of ATP for the cell as long as oxygen is plentiful. The efficiency of mitochondrial pathways is demonstrated by the ability to generate 38 molecules of ATP from oxidation of one molecule of glucose or the generation of up to 146 molecules of ATP from β oxidation of an FFA. Anaerobic pathways such as glycolysis, creatine phosphate, and the purine nucleotide cycle are found within the cell cytoplasm. Anaerobic glycolysis converts glucose to pyruvate, and then lactate provides only two molecules of ATP for each molecule of glucose metabolized. Anaerobic glycolysis, although less efficient, rapidly supplies ATP even when oxygen is not available.

The main fuels for aerobic muscular contraction are FFA and glucose, which are supplied by intramuscular (lipid droplets, β glycogen particles) and extramuscular (liver and adipose tissue) depots during exercise. The rate-limiting factor in the supply of plasma free fatty acid (FFA) to muscle appears to be the rate of FFA release from adipose tissues (Bennard *et al.*, 2005). The rate-limiting factor in the extramuscular supply of glucose to working muscle is glucose uptake by the myofibers. It is estimated that 65% or more of the oxygen utilization during moderate to heavy exercise is accounted for by the oxidation of carbohydrates (Holloszy, 1982a; Sahlin, 1986). Glycogen is the primary fuel metabolized to synthesize ATP during anaerobic metabolism (Holloszy, 1982a).

At rest, oxidation of FFA and stored triglycerides contributes the bulk of the fuel used for maintaining muscle tone, whereas the oxidation of glucose accounts for only 10% to 20% of the CO_2 produced (Havel *et al.*, 1967). At the onset of exercise, energy is initially derived from creatine phosphate and anaerobic glyco(geno)lysis. However, as the duration of exercise is increased and blood flow increases, there is a shift to aerobic metabolism in which glucose, FFA, and triglycerides are oxidized. At low to moderate exercise intensities, the oxidation of fatty acids provides the major source of energy. At moderate to high aerobic exercise intensities, the oxidation of fatty acids decreases and carbohydrates account for 50% or more of the amount of substrate utilized (Wahren, 1977). At moderately high aerobic exercise intensities, muscle glycogen accounts for the majority of the glucose oxidized, and oxidized FFA are primarily derived from muscle triglyceride depots. By using FFA, intramuscular glycogen stores are spared. Metabolic events within skeletal muscle, which are believed to contribute to fatigue during prolonged submaximal exercise, involve a combination of the following: intramuscular glycogen concentrations become depleted, muscle temperatures become markedly elevated, electrolyte concentrations are altered, or neuromuscular fatigue occurs. Very little lactic acid accumulates at fatigue during submaximal exercise.

At maximal exercise speeds, oxygen consumption peaks, oxidative energy metabolism is maximal, and further energy must be generated by anaerobic glycolysis or deamination of ATP. Glycogen serves as the major fuel utilized at maximal speeds and exponential accumulation of lactate results. Depletion of glycogen stores normally does not appear to limit maximal exercise because marked depletion is not observed before the onset of fatigue. Conventional theories regarding muscle fatigue with maximal exercise have hypothesized that an acidosis, arising from accumulation of lactic acid, is the primary determinant of muscle fatigue. Lactic acid was said to inhibit the activity of phosphofructokinase,

the rate-limiting step in glycolysis, and possibly impair muscle contractile mechanisms (Sahlin *et al.*, 1981). Muscle pH can fall as low as 6.4 following maximal exercise. However, more recent studies show that PKF activity is not inhibited at pH 6.4 (Spriet, 1991), and hydrolysis of ATP, which generates ADP, free phosphate, and hydrogen ion, is a more likely source of acidosis than lactic acidosis (Lindinger *et al.*, 2005; Robergs *et al.*, 2004). When ATP demands of muscle are met by mitochondrial respiration, hydrogen ions are used by the mitochondria for oxidative phosphorylation. With maximal exercise, when ATP is largely generated by glycolysis, hydrogen ions accumulate creating an acidosis. Under more current thinking, lactate is generated to prevent pyruvate accumulation and generate NAD^+ to facilitate glycolysis and serves as an anion to actually buffer hydrogen ion accumulation (Lindinger *et al.*, 2005). Thus, lactate serves as a marker for acidosis but is not directly involved in acidotic conditions within muscle cells (Lindinger *et al.*, 2005). The ability to buffer or remove hydrogen ions remains very important for muscle function during maximal exercise.

Further metabolic limitations to maximal high intensity exercise may relate to the demand for ATP outstripping the myofiber's innate ability to produce ATP at maximal speeds. Under these circumstances, the cell turns to its last venue of energy production, the purine nucleotide cycle (Harris *et al.*, 1991). Short term, this produces ATP for muscle contraction from the accumulated ADP. However, the total nucleotide pool becomes depleted from deamination of AMP to IMP. For intracellular stores of ADP and ATP to be replenished, at least 30 to 60 min is required for reamination of IMP. Whole muscle concentrations of ATP rarely decline by more than 50% with maximal exercise; however, ATP in individual fibers during maximal exercise can be minimal, and concentrations in individual fibers may be more important for the onset of fatigue than the measured concentrations in whole muscle samples (Essen-Gustavsson *et al.*, 1997).

A more complex model of fatigue has recently been developed that refutes the classic model of peripheral fatigue of muscle contraction arising from inadequate oxygen delivery or substrate depletion. In this newly proposed model, fatigue is not a physical limit within muscle but rather a sensation that arises from conscious perception of subconscious regulatory processes in the brain that control muscle fiber recruitment. Termination of exercise occurs when a conscious desire to continue exercising is overridden by the summation of negative sensations arising from afferent feedback from physiological systems that would include sensors of substrate availability and muscle pain (Noakes *et al.*, 2004).

B. Adaptations to Exercise Training

Exercise induces major biochemical adaptations in skeletal muscle. The nutritional state, intensity and duration of exercise, and degree of physical fitness are all factors that qualitatively and quantitatively affect the metabolic pathways used in the generation of energy for muscular contraction.

The principal metabolic adaptation of skeletal muscles to training is an increase in the oxidative capacity to utilize fat, carbohydrate, and ketones (Grobler *et al.*, 2004; Hurley *et al.*, 1986). Muscle glycogen content often increases with training (Gollnick *et al.*, 1972), whereas glycogenolytic and glycolytic enzyme activities are largely unchanged (Baldwin *et al.*, 1973; Holloszy, 1982b). In contrast, the mitochondrial protein content increases approximately 60% with training (Holloszy, 1982b). The activities of enzymes that transport FFA into the mitochondria, the capacity for oxidation of FFA, as well as the activities of oxidative enzymes in the citric acid cycle increase in response to a training program (Gollnick *et al.*, 1972; Holloszy, 1982b; Mole *et al.*, 1973; Saltin *et al.*, 1977). In horses, training studies most frequently show increased activities of oxidative enzyme markers such as citrate synthase and variable to no measurable increase in markers for fat oxidation such as 3-OH-acyl-CoA dehydrogenase and glycolysis (Cutmore *et al.*, 1986; Golland *et al.*, 2003; Hodgson, 1985).

Histochemical studies show that the increase in oxidative capacity that occurs with training occurs most notably in type 2 and particularly type 2x (IIB) fibers of horses and the capillarization of all fiber types increases (Henckel, 1983; Serrano *et al.*, 2000; Yamano *et al.*, 2005). Most studies indicate that over time the cross-sectional area of type 2x (IIB) muscle fibers decreases with training and type 1 and type 2a fibers increase in size (Rivero *et al.*, 1993). These metabolic adaptations favor the delivery of oxygen and blood-borne substrates, the early activation of oxidative metabolism, and the utilization of FFA in muscle fibers. By sparing muscle glycogen, endurance is enhanced, and fatigue is delayed. At high exercise intensities, improved oxidative capacity decreases the rate of hydrogen and lactate ion accumulation in trained versus untrained subjects performing the same exercise. Although an increase in oxidative capacity may be metabolically advantageous, a decrease in the percentage of type 2x fibers and a decrease in their cross-sectional areas may also deleteriously affect their speed and force of contraction. Obviously a balance is required between skeletal muscle fiber metabolic and contractile properties for optimum speed and endurance. Because the muscle fiber composition and fiber properties vary so greatly among individuals, achievement of this balance may be different for each horse and each type of equestrian competition.

In summary, the major metabolic consequences of the adaptations of muscle to endurance exercise are a slower utilization of muscle glycogen and blood glucose, a greater reliance on fat oxidation, and less lactate production during a given intensity. At workloads below maximal O_2 utilization, aerobic pathways are the principal sources of energy through the oxidation of FFA and glucose. This

correlates with the evidence that type 1 and type 2a myofibers are activated first and their metabolic orientation is toward aerobic pathways. With workloads approaching maximal O_2 utilization and beyond, the sources of energy are derived principally from anaerobic pathways through glyco(geno)lysis. Type 2x (IIB) myofibers are recruited with increased workload intensities, and their metabolic energy derivation is mainly by anaerobic pathways.

VI. DIAGNOSTIC LABORATORY METHODS FOR THE EVALUATION OF NEUROMUSCULAR DISORDERS

Neuromuscular diseases are classified, whenever possible, as to the origin or site of the primary lesion. Myopathies are those diseases in which the primary defect or disease process is considered to be limited to the myofibers, and neuropathies are those diseases of muscle that are secondary changes resulting from defects or diseases of the neuron (e.g., denervation).

Muscular weakness, abnormal muscle contraction, and stiffness or muscular pain are principal clinical signs of neuromuscular disorders. Manifestations of muscular weakness may be functional (e.g., paresis, paralysis, gait abnormalities, exercise-related weakness, dysphagia, regurgitation, dyspnea, and dysphonia) or physical (e.g., gross atrophy, hypotrophy, hypertrophy, and skeletal deformities). Abnormal muscle contraction may be a functional disturbance of neuronal or muscular excitation/conduction. Muscle pain is often the result of physical disruption of muscle cells or sustained muscle contractions.

Instituting measures of prevention or therapy for neuromuscular disorders depend on an accurate definition of the functional and physical manifestations of muscle weakness/contraction/pain and the identification of the specific pathoanatomic motor unit component(s) involved (i.e., neurons in neuropathies, neuromuscular junctions in disorders of neuromuscular transmission, or myofibers in myopathies) and, when possible, identification of the specific cellular dysfunctions underlying the muscular dysfunction.

The evaluation of neuromuscular disorders requires a coordinated approach and special examinations, some of which fall outside the scope of this chapter. This approach involves the neurological examination and includes the signalment (e.g., species, breed, age, sex), history (e.g., congenital or acquired, course of the disease, exposures, and responses to treatment), clinical findings (e.g., presence and distribution of signs, neurological deficits, and abnormal reflexes) and electrodiagnostic tests that involve electromyography (EMG), and the evaluation of sensory and motor nerve conduction velocity measurements and evoked MAPs.

Standard hematological and clinical chemistry panels are indicated to provide general screening that would suggest possible infectious, immune, or metabolic abnormalities. Exercise testing may be revealing in cases of exertional myopathies or exercise intolerance. In addition to these evaluations, there are some more specific tests that provide insight into the pathoanatomic involvement and in some instances specific identification of the etiology and pathogenesis of the muscular weakness.

A. Muscle-Specific Serum Enzyme Determinations Used in the Diagnosis of Neuromuscular Disorders

A valuable adjunct to the clinical diagnosis of neuromuscular diseases has been the utilization of serum enzyme determinations. The activities or concentrations of the enzymes are usually low in serum or plasma because they are normally located within healthy myofibers. Necrosis of myofibers is a primary example of a process by which serum activities of intracellular enzymes are elevated, and the elevations are roughly proportional to the mass of tissue involved. Elevations in serum enzyme activities may also occur in association with increased cell permeability (leakage), increased enzyme production by the parenchymal cells, obstructions to normal enzyme excretory routes, increased amount of enzyme-forming tissue, delayed removal, or inactivation of enzyme (Cornelius *et al.*, 1959; Dawson and Fine, 1967).

The initial examination of a patient with muscle disorders should always include the measurement of muscle-specific enzyme activities. This provides immediate information concerning the possible presence of muscle necrosis and provides a course-grain analysis for distinguishing between myopathies and neuropathies.

1. *Creatine Kinase*

The most widely used serum enzyme determination in neuromuscular diseases of domestic animals is creatine kinase (CK), previously designated creatine phosphokinase (CPK). In muscle, this enzyme provides ATP for contraction by phosphorylation of ADP from creatine phosphate (Fig. 15-2). Analysis of tissues from humans indicates that significant CK activities are present in skeletal muscle, myocardium, and brain, with lesser amounts in the gastrointestinal tract, uterus, urinary bladder, kidney, and thyroid (Dawson and Fine, 1967). The diversity of organs tested in other animals is not as broad, but those tested correlate well with these findings. The liver has negligible amounts of CK (Dawson and Fine, 1967). Normal values for CK activity vary with physical activity, restraint, age, and sex (Anderson, 1975; Blackmore and Elton, 1975; Heffron *et al.*, 1976; Tarrant and McVeigh, 1979). Intramuscular injections may also increase CK activities because of local areas of muscle necrosis (Steiness *et al.*, 1978). The amount of CK liberated following intramuscular injection of a drug depends on

the properties of the injected solution and on such muscle factors as species differences in muscle CK activity, local blood flow, susceptibility of the muscles, and local muscle binding of the drug (Steiness *et al.*, 1978). Therefore, an accurate history is important in evaluating CK activities. A three- to five-fold increase in serum CK from normal values is believed to represent necrosis of approximately 20g of muscle tissue (Volfinger *et al.*, 1994).

There are three principal isoenzymic forms of CK. Creatine kinase has a dimeric structure consisting of M (muscle) subunits and B (brain) subunits, which combine to form the three heterogeneous MM (or CK3), MB (or CK2), and BB (or CK1) isoenzymes (Dawson *et al.*, 1968; Dawson and Fine, 1967). A fourth variant form, CK-Mt, is found in mitochondrial membranes and may account for up to 15% of the total cardiac CK activity. The isoenzymes can be separated by three methods: (1) electrophoresis, (2) immunological techniques, and (3) ion-exchange chromatography (Fiolet *et al.*, 1977). The pattern of isoenzyme distribution varies among the organs of different species. Thus, identification of the isoenzymes present can be used to help determine the tissue source of elevations in CK (Bulcke and Sherwin, 1969). Ontogenic studies in the rat revealed that all organs investigated contained only BB-CK in early stages of fetal development. In skeletal muscle, BB-CK forms slowly disappear and are initially replaced by MB-CK forms followed by CK-MM forms. Mixtures of isoenzymes occur during the transition. In the adult pattern, MB-CK forms have been variously reported to be present or absent in skeletal muscle. The inconsistency in noting the presence of MB-CK forms in skeletal muscle of animals may be due to the source of skeletal muscle sampled, because all skeletal muscles may not contain the MB-CK isoenzyme (Bulcke and Sherwin, 1969; Thorstensson *et al.*, 1976). However, other studies indicate that, although there is more MM-CK in white muscle of the rat than in red, there is no MB-CK fraction in either (Dawson and Fine, 1967). Reasons for the discrepancies in the detection of MB-CK forms in mammalian skeletal muscles are not evident. The adult isoenzyme pattern in muscles of the rat appears at 90 days after birth, whereas in cardiac muscle, the shift occurs earlier and the adult pattern has both MB-CK and MM-CK forms. In the brain, BB-CK is the major isoenzyme throughout life (Eppenberger *et al.*, 1964). Determinations of serum isoenzyme patterns have found clinical application in human medicine. The determination of MB forms has been used as a biochemical diagnostic tool for acute myocardial infarction (Hamdan *et al.*, 2006). However, studies of the isoenzyme composition in cardiac muscle of the horse reveal that less than 1.5% to 3.9% of the total CK activity is attributable to the MB-CK form. Hence, its determination cannot be used for detection of myocardial disorders in the horse (Argiroudis *et al.*, 1982).

Elevations in total CK activities have been reported in a wide variety of species with muscle disorders typified by myofibers necrosis. Pre- and 4 h postexercise CK determinations have been useful when combined with exercise testing to identify patients with exertional rhabdomyolysis (Valberg *et al.*, 1999). Peak serum CK activity occurs about 4 to 6 h after muscle damage and declines fairly rapidly with a half-life in serum of approximately 108 min in horses (Fig. 15-8) (Cardinet *et al.*, 1967; Valberg *et al.*, 1993a). CK activity in itself, however, does not provide information relative to the etiology of the disease process. More precise information regarding the etiology of muscle diseases can be obtained by the use of histological and histochemical examination of muscle biopsies.

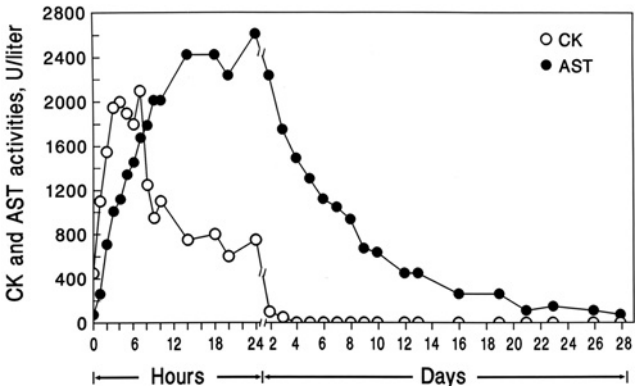

FIGURE 15-8 The difference in the time course of elevations in AST and CK activities as a result of muscle necrosis (equine exertional rhabdomyolysis). The AST activity remained elevated for much longer periods than CK activity. Adapted from Cardinet *et al.* 1967).

2. *Aspartate Transaminase*

Another enzyme that has been used as a diagnostic aid in neuromuscular disorders of domestic animals is serum aspartate transaminase (AST), formerly called serum glutamic oxaloacetic transaminase (SGOT). Normal values do not appear to differ greatly between sexes, although reported values for cows are somewhat higher than values for bulls (Cornelius *et al.*, 1959; Roussel and Stallcup, 1966). Differences associated with age have been reported in sheep (Lagace *et al.*, 1961), and there are seasonal differences in bulls (Lagace*et al.*, 1961; Roussel and Stallcup, 1966). Also, physical activity is associated with higher values in horses (Blackmore and Elton, 1975; Cardinet *et al.*, 1963, 1967; Cornelius *et al.*, 1963).

Elevations of AST activities have been reported in numerous muscle disorders characterized by myofiber necrosis. Although the use of AST determinations has proven valuable as a diagnostic aid, the enzyme lacks organ specificity because in addition to high concentrations in skeletal and cardiac muscle, AST activities are also high in the liver as well as other organs and tissues, including the red blood cells (RBCs) (Cardinet *et al.*, 1967; Cornelius *et al.*, 1959; Loeb *et al.*, 1966).

Combined determination of CK and AST can be of value in assessing the course of rhabdomyolysis (Fig. 15-8). Elevations in AST activities are present for weeks after the onset of clinical disease, whereas CK activities remain elevated for only a few days after myonecrosis. The course of elevations of these enzymes in this disease can be directly attributed to different half-lives and disappearance rates of their activity in the plasma. Although CK is more specific for myonecrosis than AST, the simultaneous determinations of AST and CK in the horse are potentially valuable diagnostic and prognostic aids owing to the different disappearance rates of their serum or plasma activities: (1) elevated CK activities indicate that myonecrosis is active or has recently occurred; (2) persistent elevations of CK indicate that myonecrosis continues to be active; and (3) elevated AST resulting from myonecrosis accompanied by decreasing or normal CK activities indicates that myonecrosis is no longer active.

3. *Lactate Dehydrogenase*

Lactate dehydrogenase (LDH) activities are high in various tissues of the body. Therefore, measurements of LDH are not organ specific. Molecules of LDH are tetrameric, made up of four subunits of the two parent molecules, M (muscle) and H (heart). Various combinations of those subunits result in five isoenzymes of LDH, which can be separated by electrophoresis. The M monomer is found in purest form in skeletal muscle as the isoenzyme M4 (or LDH5), whereas the H monomer is found predominantly in the heart muscle as the isoenzyme H4 (or LDH1). The other three forms are molecular hybrids forming the isoenzymes M3H (or LDH4), M2H2 (or LDH3), and MH3 (or LDH2), and they are found in various amounts in different organs. The H4 isoenzyme is maximally active at low concentrations of pyruvate and strongly inhibited by excess pyruvate, which favors the oxidation of lactate (Dawson and Romanul, 1964). The M form, on the other hand, maintains activity at relatively high pyruvate concentrations, which favors anaerobic reduction of pyruvate (Dawson and Fine, 1967). Thus, tissues with essentially aerobic metabolism, such as heart muscle, contain mostly heart-specific isoenzymes, whereas tissues with more viable or flexible metabolic properties, such as skeletal muscle, contain predominantly the muscle-specific isoenzyme. Elevated LDH activities have been reported in numerous muscle disorders characterized by myonecrosis as well as a variety of hepatic disorders. Therefore, unless isoenzyme analysis is utilized, the measurements of LDH elevations are not organ specific.

B. Muscle-Specific Serum Proteins and Antibodies

With the advent of immunochemical procedures such as enzyme-linked immunosorbent assay (ELISA), radial immunodiffusion assays, radioimmunoassays, and immunocytochemical assays, sensitive tests for the detection of tissue-specific proteins and antibodies in serum are being applied to the diagnosis of neuromuscular disorders.

1. *Myoglobin*

Myoglobin is a 17, 500-Da heme protein that stores and transports oxygen in myofibers. Elevated levels of myoglobin have been found in myopathies of humans (Sieb and Penn, 2004). The specificity of myoglobin for skeletal and cardiac muscle and its plasma clearance make myoglobin determinations a potentially effective method for monitoring myonecrosis (Holmgren and Valberg, 1992). In horses, myoglobin concentrations peak shortly after myonecrosis occurs, and clearance from the blood stream is more rapid than CK activity (Valberg *et al.*, 1993b).

2. *Troponin*

Troponin I assays have been used to identify myocardial degeneration in several species (Burgener *et al.*, 2006; Fuchs *et al.*, 1999; Slack *et al.*, 2005). These assays offer improved specificity and sensitivity for differentiating myocardial versus skeletal myofiber necrosis. However, a false-positive rate of 17% may still occur when using troponin I to assess myocardial necrosis in patients with marked rhabdomyolysis (Li *et al.*, 2005).

3. *Carbonic Anhydrase* III

Serum carbonic anhydrase III has been proposed as a marker for rhabdomyolysis. It increases and decreases in concentration more rapidly than creatine kinase (Nishita *et al.*, 1995).

4. *Acetylcholine Receptor Antibodies*

Detection of circulating autoantibodies to acetylcholine receptors (AChR) is a valuable adjunct to the diagnosis of immune-mediated myasthenia gravis (MG) in humans (Engel and Hohfield, 2004) and dogs (Dewey *et al.*, 1997; Palmer, 1977; Pflugfelder *et al.*, 1981). It has been estimated that approximately 80% of human patients with MG have detectable AChR antibodies (Engel and Hohfield, 2004). Positive serum antibody titers to acetylcholine receptors measured by immunoprecipitation radioimmunoassay are normally less than 0.6 nmol/l (Shelton *et al.*, 1990). A valuable immunocytochemical screening test for circulating AChR antibodies in canine MG employs staphylococcal protein A conjugated to horseradish peroxidase (SPA-HRP), a reagent that localizes IgG. Control sections of muscle containing neuromuscular junctions when incubated with canine MG patient sera and subsequently with SPA-HRP localizes IgG at neuromuscular junctions (Pflugfelder *et al.*, 1981). This immunoreagent has also served to detect antinuclear antibodies, antistrial antibodies, and sarcolemmal-associated antibodies in immune-mediated myasthenia gravis and

inflammatory muscle disorders in the dog (Shelton and Cardinet, 1987).

VII. MUSCLE BIOPSY AND HISTOCHEMISTRY IN THE DIAGNOSIS OF NEUROMUSCULAR DISORDERS

Muscle biopsies provide an excellent opportunity to evaluate the integrity of myofibers, neuromuscular junctions, intramuscular nerve branches, connective tissues, and blood vessels in various neuromuscular disorders. As discussed previously, histochemical examination of skeletal muscle provides information relative to the morphological, biochemical, and metabolic properties of myofibers. Therefore, the application of histochemical techniques in conjunction with routine light and electron microscopic examination of muscle biopsies offers the potential to evaluate and integrate the pathoanatomical, biochemical, and physiological manifestations of neuromuscular disorders. Further, the advent of immunocytochemistry has extended our ability to recognize immunopathological mechanisms and disorders as well.

The application of histochemical techniques has become an essential diagnostic procedure for the evaluation of neuromuscular disorders in humans, dogs, cats, and horses (Cardinet and Holliday, 1979; Dubowitz and Brooke, 1973; Engel and Franzini-Armstrong, 2004; Schatzberg and Shelton, 2004; Valberg, 1999). Their application has been most helpful in determining which portion of the motor unit (neuron, myofiber, or both) is involved in the disease process or providing profiles specific for selected neuromuscular disorders (Dubowitz and Brooke, 1973). Neuropathic disorders frequently produce angular atrophy of type 1 and type 2 muscle fibers. In contrast, myopathic disorders may be characterized by angular atrophy of type 2 fibers, muscle fiber necrosis, inflammatory infiltrates, or abnormal storage products. Common histochemical stains used with frozen sections include myosin ATPase stains for fiber typing, trichrome and NADH staining of mitochondria, oil-red-O and periodic-acid Schiff's staining for lipid and glycogen, respectively, acid phosphatase stains for lysosomal storage products, and a variety of stains for enzymatic activity of phosphorylase, PFK, and cytochrome oxidase. Appropriate immunostains can be used to identify deficiencies in interstitial components such as dystrophin, to adherent immunoglobulin to end plates or myofibers, as well as to subtype lymphocytic infiltrates. A detailed consideration of muscle biopsy techniques in the evaluation of neuromuscular diseases is beyond the scope of this chapter. For details, refer to Dubowitz and Brooke (1973) and Engel and Franzini-Armstrong (2004).

VIII. MOLECULAR DIAGNOSTIC TESTING

Advances in the understanding of the genetic basis for a number of myopathies in dogs, horses, swine, and cattle have led to the development of new molecular diagnostic tests. These tests are often performed on hair roots or blood samples and distinguish the presence of a mutation (homozygous or heterozygous) in a specific portion of a gene that has previously been shown to be associated with a disease. A selection of these genetic diseases is reviewed in Section IX.

IX. SELECTED NEUROMUSCULAR DISORDERS OF DOMESTIC ANIMALS

Neuromuscular disorders in animals are associated with spontaneous and inherited endocrine, immune-mediated, infectious, toxic, metabolic, and neoplastic diseases. This section presents a selection of neuromuscular disorders to highlight the spectrum of acquired and genetic myopathies found in domestic animals. With continued application of advanced histochemical, biochemical, and molecular techniques and sequencing of animal genomes, undoubtedly many heretofore unrecognized neuromuscular disorders in animals will be recognized.

A. Ion Channelopathies

1. *Acetylcholine Receptor Ion Channels and Myasthenia Gravis*

Myasthenia gravis is a disorder of neuromuscular transmission in which there is a reduction in the number of ligand-gated AChR ion channels on the postsynaptic sarcolemmal membrane (PSM). This condition results in weakness because of the reduced sensitivity of the PSM to the transmitter, ACh. Two basic forms of MG exist: (1) acquired autoimmune MG and (2) congenital MG. Different mechanisms are responsible for the reduction of AChRs in these two disorders.

a. Acquired Autoimmune Myasthenia Gravis

Acquired MG is an immune-mediated disorder of humans (Engel and Hohfield, 2004), dogs, and cats (Dewey *et al.*, 1997; Shelton, 2002; Shelton *et al.*, 2000) in which autoantibodies are produced against AChRs. The density of AChRs is reduced by the complement-mediated destruction, accelerated internalization, and degradation of AChRs by cross-linking of the receptors by antibody. In humans and dogs, the autoantibody response is heterogeneous. Most antibodies are IgG and directed against the main immunogenic region (MIR), a specific external portion of the α-subunit that is distinct from the ACh-binding site; however, autoantibodies are also produced against all of the other subunits (Engel and Hohfield, 2004; Shelton, 1999). Only a small percentage of antibodies is directed against the ACh-binding sites on the α-subunits.

Dogs with MG usually exhibit some form of muscular weakness; however, this can be quite variable and may

include the following presentations: acute quadriplegia, degrees of exercise-related weakness, gait abnormalities, no apparent limb muscle weakness with dysphagia, or regurgitation associated with a megaesophagus. There appears to be a bimodal distribution in the onset of this disease in dogs (early and late onset). Dogs are rarely affected before 1 year of age and peak frequencies were found at 3 and 10 years of age; the prevalence did not appear to be gender related (Dewey *et al.*, 1997; Shelton *et al.*, 1988). Frequently, overt signs may be limited to esophageal dysfunction. In a study of 152 dogs afflicted with idiopathic megaesophagus, 40 to 57 dogs (26% to 38%) had MG (Shelton *et al.*, 1990).

A definitive diagnosis of MG is provided by detection of circulating antibodies to the AChR. Additional diagnostic tests that provide for a presumptive diagnosis include clinical, pharmacological, electrodiagnostic, and immunocytochemical methods of evaluation (Dewey *et al.*, 1997; Shelton, 2002). When clinical signs permit the objective assessment of strength, pharmacological testing can be employed through the intravenous administration of 1 to 10 mg of edrophonium chloride, an ultra-short-acting anticholinesterase agent. Improved strength with edrophonium provides a presumptive diagnosis of MG. A presumptive diagnosis of MG is also suggested when the application of low-frequency (2 to 10 Hz), repetitive nerve stimulation results in the reduced amplitude of the first few evoked compound MAPs (decrementing response). Immunocytochemical procedures provide presumptive tests for MG. In muscle biopsies of human and canine MG patients that contain neuromuscular junctions, it is possible to localize the IgG bound to the PSM using the immunoreagent (Engel and Hohfield, 2004; Pflugfelder *et al.*, 1981). A more specific diagnosis can be established by measuring acetylcholine receptor antibody titer in serum samples from affected animals (Dewey *et al.*, 1997; Shelton, 2002).

b. Congenital Myasthenia Gravis

Congenital MG is a developmental disorder of humans and dogs (Dickinson *et al.*, 2005; Engel *et al.*, 2004; Shelton, 2002). In the dog, the synthesis of AChRs appears to be normal, and degradation does not appear to be accelerated. The reduced AChR density is believed to be due to a low insertion rate of AChRs into the PSM (Engel *et al.*, 2004). In humans, several congenital myasthenic syndromes are recognized, which result from a number of inherited defects that may be presynaptic (7% of cases), synaptic basal lamina-associated (14%), or postsynaptic (79%) defects (Engel *et al.*, 2004). Because congenital MG is not immune mediated, the immunodiagnostic tests used in acquired MG are of no value in establishing the diagnosis of congenital MG.

2. *Sodium Ion Channels and Periodic Paralysis*

Hyperkalemic periodic paralysis (HyPP) is a dominantly inherited disorder of muscle in quarter horses, American paint horses, Appaloosas, and quarter horse crossbred animals that causes episodes of tremors, myotonia, weakness, or paralysis in association with elevated serum potassium (Naylor, 1997; Spier *et al.*, 1990). Weakness or paralysis can be induced by the ingestion of potassium. HyPP is caused by a single base pair sequence defect within the gene encoding the voltage-dependent equine skeletal muscle sodium channel α-subunit (Rudolph *et al.*, 1992). The point mutation produces a Phe to Leu substitution in the transmembrane domain IVS3. Patients are usually heterozygous and express both normal and mutant α-subunits, although homozygous HyPP horses have been identified. The primary physiological defect in the mutant sodium channels is impaired inactivation (Cannon *et al.*, 1995). This results in a resting membrane potential that is closer to firing than in normal horses. Sodium channels are normally briefly activated during the initial phase of the muscle action potential. The HyPP mutation results in a failure of a subpopulation of sodium channels to inactivate when serum potassium concentrations are increased. As a result, an excessive inward flux of sodium and outward flux of potassium ensues, resulting in persistent depolarization of muscle cells and temporary weakness. It appears likely that the clinical variability and severity of signs are associated with the ratio of mutant-to-normal sodium ion channels expressed in the skeletal muscles of heterozygous horses (Zhou *et al.*, 1994). This disorder in horses is similar to HyPP in humans in which there are also a number of mutations involving the gene encoding the sodium ion channel α-subunit (Lehmann-Horn *et al.*, 2002). A definitive diagnosis is possible by base-pair analysis of the DNA sequence responsible for encoding of the α-subunit (Rudolph *et al.*, 1992).

3. *Chloride Ion Channels and Myotonia*

Myotonia is a clinical sign in which uncontrolled, prolonged, and painless contraction of skeletal muscles occurs. The condition is due to hyperexcitability of the sarcolemma and the abnormal production of repetitive depolarizations of the sarcolemma followed by delayed repolarization and relaxation. Affected patients exhibit varying degrees of muscle stiffness with the onset of exercise. The stiffness will often subside with continued exercise or repeated movements and is not aggravated by cold. Muscles may be grossly hypertrophied with well-defined muscle groups. Percussion of muscles results in local contractions that create dimpling of the surface overlying the contracting muscles.

Two principal myotonic disorders occur in humans: (1) myotonia congenita and (2) myotonic dystrophy (Harper and Monckton, 2004). Myotonia congenita is a nonprogressive childhood disorder in which there is a diminished chloride conductance across the sarcolemma caused by mutations of the skeletal muscle chloride ion channel (Heine *et al.*, 1994). A similar form of myotonia congenita occurs as a recessive trait in miniature schnauzers

and goats (Bryant and Conte-Camerino, 1991; Vite *et al.*, 1998). Histopathological changes in skeletal muscle are usually minimal and nonspecific. The canine mutation results in a threonine residue in the D5 transmembrane segment with methionine (Bhalerao *et al.*, 2002; Rhodes *et al.*, 1999). Functional characterization of the mutation demonstrates a profound effect on the voltage dependence of activation such that mutant channels have a greatly reduced open probability at voltages near the resting membrane potential of skeletal muscle.

Myotonic dystrophy differs from congenital myotonia in that it is progressive and variably involves a variety of other systems (e.g., smooth muscle of hollow organs, heart, brain and peripheral nerves, endocrine glands, eyes, skeletal system, and integument) (Harper and Monckton, 2004). In humans, this disorder results from repeat expansion in the untranslated region of the DMPK (dystrophic myotonia protein kinase) gene (Davis *et al.*, 1997) or a specific zinc-finger gene (Liquori *et al.*, 2001). Part of the unique molecular pathogenesis of these repeat expansions appears to involve production of toxic RNA repeats, which lead to aberrant splicing of many other proteins. The systemic features are most helpful in differentiating between myotonia congenita and myotonic dystrophy in addition to consistent histopathological features, which include increased central nuclei, ringed fibers, sarcoplasmic masses, and type 1 fiber atrophy. Myotonic disorders have been described in horses that have similar histopathological and electromyographic abnormalities (Hegreberg and Reed, 1990; Montagna *et al.*, 2001; Reed *et al.*, 1988). The precise molecular mechanism for myotonic dystrophy in horses is unknown.

4. *Calcium Release Channels of the Sarcoplasmic Reticulum and Malignant Hyperthermia*

Malignant hyperthermia (MH) is an inherited pharmacogenetic disorder of humans, swine, dogs, and horses. When exposed to halogenated anesthetics or succinylcholine, genetically MH susceptible (MHS) individuals exhibit tachycardia, hyperthermia, elevated carbon dioxide production, and death if the anesthetic is not discontinued. Metabolic acidosis and muscle rigidity are severe in both swine and humans, whereas in dogs metabolic acidosis is usually moderate and muscle rigidity is minimal (Nelson, 1991). In swine, stresses such as fighting, transport, and exercise also trigger its onset. During an attack, serum CK and AST enzyme activities are markedly elevated because of extensive myonecrosis. MH is inherited as an autosomal recessive gene in swine (Fujii *et al.*, 1991) but as an autosomal dominant gene in humans, horses, and dogs (Monnier *et al.*, 2005; Roberts *et al.*, 2001; Aleman *et al.*, 2004). Genetic mapping of the MH locus in pigs and humans placed it in the vicinity of the RYR1 gene, which encodes the sarcoplasmic reticulum ryanodine receptor (calcium release channel). In addition, many biochemical and physiological measurements implicated this very large protein as the site of the defect in both pigs and humans (Mickelson and Louis, 1996). Base pair sequence defects in the RYR1 have now been identified for pigs (Fujii *et al.*, 1991), humans (Treves *et al.*, 2005), dogs (Roberts *et al.*, 2001), and horses (Aleman *et al.*, 2004).

The clinical signs of increased muscle metabolism and muscle contracture are likely due to the effects of the RYR1 mutation on the gating properties of this channel. Many studies have shown that calcium release channels in MHS have a greater open probability, allowing greater rates of calcium efflux from the SR terminal cisternae into the myoplasm, which is exacerbated by the MH triggering agents (Mickelson and Louis, 1996). The SR calcium ATPase is unable to resequester the calcium back into the SR lumen fast enough, and the myoplasmic calcium concentration rises. The resulting MH episode is due to calcium stimulation of phosphorylase, myofilament contractile activity, and the resultant activation of aerobic and anaerobic metabolism to fuel the contraction.

No specific histopathological features are present in most susceptible individuals apart from nonspecific findings of central nuclei. One specific form of MH seen in children with muscle weakness produces central core disease. Biopsies in these cases are characterized by lack of mitochondrial and myofibrillar staining in discrete areas of type I fibers (Treves *et al.*, 2005).

Molecular genetic testing for the specific mutations in RYR1 provides the most specific means of testing swine, dogs, and horses and has largely replaced standardized *in vitro* contracture tests.

B. Cytoskeletal Dystrophin Deficiency and Muscular Dystrophy

Duchenne muscular dystrophy is an X-linked recessive disorder of skeletal muscle in humans, dogs, and cats (Kornegay *et al.*, 1988; Shelton, 2004; Shelton and Engvall, 2002, 2005). The disorder is due to a deficiency of a subsarcolemmal cytoskeletal protein dystrophin that participates in the attachment of myofibrils to the sarcolemma (Hoffman *et al.*, 1987). Dystrophin in concert with a transmembrane protein complex (dystrophin-associated protein) is believed to provide stability to the sarcolemma. The deficiency of dystrophin presumably creates structural instability of the sarcolemma allowing uncontrolled focal ingress of extracellular fluid components such as calcium.

A number of mutations of the dystrophin gene have been identified. Golden retrievers have a splice site mutation in the dystrophin gene, which causes a premature termination codon in exon 8 and a peptide that is 5% the size of normal dystrophin (Sharp *et al.*, 1992). The mutation in the cat has not been identified.

The expression of the disease varies among species but may be characterized as a progressive degenerative disorder

of muscle in which there is a marked increase in serum CK and AST enzyme activities, gross hypertrophy of some muscle groups, and weakness and atrophy of other muscles in dogs and cats. Affected individuals may also have a cardiomyopathy, as the dystrophin deficiency also involves cardiac myofibers (Moise *et al.*, 1991). In dogs, the onset of clinical signs is usually evident by 2 to 4 months of age and somewhat later in cats. In dogs, this disorder was first observed in golden retrievers and has subsequently been identified in other breeds, including Irish terriers, rottweilers, German short-haired pointers, and Samoyeds.

Histological sections reveal focal lesions consisting of myofiber clusters undergoing the spectrum of change from myonecrosis through macrophage infiltration and phagocytosis to regeneration. Individual fibers may be atrophic or hypertrophic, calcified, and hypercontracted, and may possess central nuclei. Beyond clinical signs and biopsy features, immunoblotting and immunocytochemical staining for dystrophin within muscle biopsies and genetic screening are valuable diagnostic methods for detecting dystrophin deficiency.

C. Immune-Mediated Canine Masticatory Muscle Myositis

The muscles of mastication are selectively affected in an inflammatory muscle disorder in dogs known as masticatory muscle myositis (Evans *et al.*, 2004). Limb muscles are essentially spared. The muscles of mastication in the dog are principally composed of type 2m myofibers, fast-twitch fibers that possess a unique isoform of myosin, heavy and light chains (Shelton *et al.*, 1985). This disorder appears to be an MHC-1-restricted CD8(+) T-cell-mediated autoimmune disease (Shelton and Paciello, 2006). Dogs afflicted with this disorder produce autoantibodies directed against type 2m fibers LC2-M (myosin light chain 2-masticatory), which has little cross-reaction with type 2a fibers of limb muscles. Diagnosis of the disorder includes muscle biopsy demonstration of lymphocytic and plasmocytic cellular infiltrates around muscle fibers and in perivascular locations. Occasionally eosinophils are present as the predominant infiltrate. In chronic cases, muscle atrophy and fibrosis are apparent. Localization of immunoglobulins fixed to type 2m fibers within the biopsy and demonstration of circulating antibodies against type 2m fibers employing SPA-HRP are more specific diagnostic tests (Shelton *et al.*, 1987).

D. Disorders of Glyco(geno)lysis Affecting Skeletal Muscle

Disorders of glyco(geno)lysis affecting skeletal muscles variably involve some excess storage of glycogen within affected myofibers, resulting in the presence of glycogen-containing vacuoles. In humans, glycogen storage diseases (GSD) affecting muscle include deficiencies of] -l, 4-glucosidase (GSD-II), debranching enzyme (GSD-III), branching enzyme (GSD-IV), myophosphorylase (GSD-V), phosphofructokinase (GSDVII), phosphorylase b kinase (VIII), phosphoglycerate kinase (GSD-IX), phosphoglycerate mutase (GSD-X), and lactate dehydrogenase (XI) (Tsujino *et al.*, 2000). Though variably documented, some of these disorders also occur in domestic animals.

1.] -1,4-*Glucosidase Deficiency* (GSD II)

Lysosomal α-1,4-glucosidase deficiency, also known as Pompe's disease, generalized type II glycogenosis, and acid maltase deficiency, occurs in humans with childhood (infantile and juvenile) and adult forms, which are variations of the same disorder based on the age of onset and tissue and organ involvement (Reuser *et al.*, 1995). This disorder is inherited as an autosomal recessive trait. This disorder has also been reported in shorthorn and Brahman cattle (Dennis *et al.*, 2000). Both infantile and late-onset equivalent variations have been described (Dorling *et al.*, 1981; Howell *et al.*, 1981). Clinical signs in Brahman calves become evident at 2 to 3 months of age with a loss of condition, poor growth, and lethargy followed by incoordination and muscle tremors with death by 9 months of age. Although the onset of clinical signs may also occur within the first 2 to 3 months of age, some affected shorthorn calves appear clinically normal until 5 to 9 months of age when weight gains are not maintained and progressive muscular weakness develops with death by 12 to 16 months of age. Excessive accumulation of glycogen occurs in skeletal and cardiac muscle, brain, and spinal cord (Howell *et al.*, 1981). The disorder in cattle is also inherited as an autosomal recessive trait. Two mutations have been identified in Brahmans, and one in shorthorns, that lead to generalized glycogenosis. All three mutations result in premature termination of translation (Dennis *et al.*, 2000). In other species, single cases of generalized glycogenoses in which α-glucosidase deficiency was demonstrated include the Lapland dog (Walvoort *et al.*, 1982) and Japanese quail (Murakami *et al.*, 1980).

2. *Debranching Enzyme Deficiency* (GSD III)

Debranching enzyme possesses two activities, α-l,4glucan transferase and α-l,6-glucosidase. In the hydrolysis of glycogen, myophosphorylase acts on the α-l,4 linkages of the terminal glucose residues up to the last four glucose residues preceding the α-1,4 linkages. The α-l,4-glucan transferase transfers the last three residues to another branch and the α-1,6-glucosidase hydrolyses the α-l,6 branch point. Several presumed cases of debranching enzyme deficiency have been described in the dog (Ceh *et al.*, 1976; Otani and Mochizuki, 1977; Rafiquzzaman *et al.*, 1976). Biochemical demonstration of debranching enzyme deficiency is limited to a single case (Ceh *et al.*, 1976). There is diffuse organ involvement with glycogen storage. Onset of signs appears

at 2 months of age, and the disorder is progressive with death by 10 to 15 months.

3. Branching Enzyme Deficiency (GSD IV)

Glycogen storage associated with branching enzyme deficiency has been reported in a family of Norwegian forest cats (Fyfe, 1995; Fyfe *et al.*, 1992) and in quarter horses (Render *et al.*, 1999; Valberg *et al.*, 2001). Clinical signs and involved organs include skeletal muscle, heart, and the central nervous system. Abnormal glycogen is evident in tissues at birth and abortion or stillbirths are common. GSD-IV is an autosomal recessive disorder in both species. Eight percent of quarter horses are carriers of the mutation, and at least 3% of abortions can be attributed to the disease (Wagner *et al.*, 2006). Diagnosis in foals is made by identifying characteristic amylase-resistant PAS-positive globular inclusions in tissues and, in horses, was confirmed by DNA testing for the point mutation in exon 1 (Ward *et al.*, 2004).

4. Myophosphorylase Deficiency (GSD V)

Myophosphorylase deficiency (McArdle's disease) is an inherited, autosomal recessive, glycogenosis in humans (DiMauro *et al.*, 1995; Tsujino *et al.*, 2000), Charolais cattle (Angelos *et al.*, 1995), and sheep (Tan *et al.*, 1997). In cattle, clinical signs include recumbency and fatigue with forced exercise and elevated serum CK and AST activity. Muscle glycogen concentrations are elevated 1.6 times higher than controls, and histopathological changes are modest with some vacuolated myofibers that do not appear to contain glycogen. A rapid diagnosis is possible by genetic testing for the autosomal recessive point mutation in the myophosphorylase gene (Bilstrom *et al.*, 1998).

5. Phosphofructokinase Deficiency (GSD VII)

Phosphofructokinase (PFK) is a key enzyme of the Embden-Meyerhof pathway in all tissues, and inherited deficiencies of this enzyme in humans are expressed primarily as a myopathy in which it is designated as type VII glycogen storage disease (GSD-VII). There is a partial expression of hemolysis, and the deficiency is otherwise quite heterogeneous (Giger *et al.*, 1988a; Harvey and Reddy, 1989). Deficiency of PFK was reported in springer spaniel dogs that presented a clinical picture remarkably similar to that seen in humans. The dogs presented with a history of intermittent severe hemolytic episodes, and total erythrocyte PFK activity was 10% of normal controls (Giger *et al.*, 1985). The disorder is inherited as an autosomal recessive trait (Giger *et al.*, 1986).

Mammalian PFK is present in different tissues as tetramers of three subunits: PFK-M (muscle), PFK-L (liver), and PFK-P (platelets). Human muscle and liver contain homogeneous tetrameric PFK-M4 and PFK-L4, respectively. The erythrocytes contain an admixture of PFK-M and PFK-L tetramers. In normal dogs, a similar isoenzymic distribution pattern exists except in the erythrocytes where the PFK tetramers consist of an admixture of PFK-M and PFK-P subunits. As in humans, PFK deficiency was found to be a deficiency of the PFK-M subunits, and the erythrocytic hybrids consisted of the PFK-L and PFK-P subunits. Giger *et al.* (1985) speculated that exertional stresses inducing hyperventilation and respiratory alkalosis in turn directly or indirectly enhance the alkaline fragility of their erythrocytes and subsequent hemolysis.

Early reports suggested that affected dogs did not manifest severe muscle-related signs, which were possibly masked by signs referable to hemolysis. However, biochemical studies have revealed reduced glycolysis in muscle (Giger *et al.*, 1988a, 1988b), and pathological studies have established the presence of a myopathy that included the presence of PAS-positive polysaccharide storage vacuoles in up to 10% of the myofibers (Harvey *et al.*, 1990). Lack of M-PFK enzyme activity is caused by a nonsense mutation in the penultimate exon of the M-PFK gene, leading to rapid degradation of a truncated (40 amino acids) and therefore unstable M-PFK protein. A genetic test can identify M-PFK-deficient and carrier animals (Smith *et al.*, 1996).

6. Polysaccharide Storage Myopathy

An inherited polysaccharide storage myopathy (PSSM) has been described in quarter horses, quarter horse crossbreeds, American paints, and Appaloosa horses (Valberg *et al.*, 1992). The horses have chronic episodes of exertional rhabdomyolysis and myoglobinuria. In addition, draft horse breeds and their derivatives also have polysaccharide storage myopathy (Firshman *et al.*, 2005). Up to 30% of the type 2 muscle fibers have subsarcolemmal vacuoles as well as cytoplasmic vacuoles that contained acid mucopolysaccharide inclusions that are brilliantly stained with the periodic-acid Schiff's (PAS) stain and resistant to amylase digestion. These inclusions consisted of β-g1ycogen particles and filamentous material. Glycogen concentrations are approximately 1.5 times higher in the muscles of horses with these polysaccharide inclusions (Annandale *et al.*, 2004). Glycogen accumulation in PSSM quarter horses appears to have a novel basis related to enhanced insulin sensitivity, muscle glucose uptake, and glycogen synthesis (Annandale *et al.*, 2004; De La Corte *et al.*, 1999). An arginine to histidine mutation in the gene encoding glycogen synthase (GYS1) was recently identified (McCue *et al.*, 2008). The connection between increased synthesis of glycogen and rhabdomyolysis has yet to be fully explained but appears to be related to decreased energy generation in individual muscle fibers (Annandale *et al.*, 2005). A genetic test can identify this disease.

E. Mitochondrial Myopathies

A large number of complex mitochondrial myopathies have been described in humans (DiMauro and Bonilla, 2004),

and, recently, there have been reports of mitochondrial muscle disorders in animals (Breitschwerdt *et al.*, 1992; Houlton and Herrtage, 1980; Paciello *et al.*, 2003; Valberg *et al.*, 1994; Vijayasarathy *et al.*, 1994). When the utilization of oxygen is reduced, lactate formation is favored and results in elevated blood lactate even with low-intensity exercise. Disorders of the respiratory chain often result in increased numbers of abnormal mitochondria and aggregates of mitochondria under the sarcolemma. In sections, these mitochondrial aggregates impart a "ragged-red" appearance to the periphery of myofibers when stained with the modified trichrome stain. The presence of ragged red myofibers and elevated lactate concentrations with exercise warrant investigation of metabolic abnormalities involving mitochondria.

1. *Respiratory Chain Complex* I (NADH U*biquinone* O*xidoreductase*) D*eficiency*

A deficiency of complex I was observed in an Arabian mare with severe limitations to even mild exercise in which there was an elevated venous pO_2, low oxygen consumption and lactic acidosis (Valberg *et al.*, 1994). Complex I of the respiratory chain is one of four complexes involved in oxidative phosphorylation and transfers electrons from NADH to CoQ in the conversion of oxygen to water.

2. *Cytochrome c Oxidase* D*eficiency*

An episodic weakness reported in Old English sheepdog littermates is accompanied by elevated serum enzymes, lactic acidosis, and increased pO_2 (Breitschwerdt *et al.*, 1992). This disorder may involve a reduction in cytochrome c oxidase (Vijayasarathy *et al.*, 1994).

3. *Lipid Storage* D*isorders*

Abnormal accumulation of lipid droplets has been observed in type 1 fibers of dogs with generalized myalgia, weakness, and muscle atrophy (Platt *et al.*, 1999; Shelton *et al.*, 1998). In human beings, lipid storage myopathies have been attributed to several different deficiencies of enzymes involved with lipid transport into mitochondria (carnitine palmityl transferase deficiency) or beta oxidation of free fatty acids. Clinical features include muscle necrosis and myoglobinuria without painful contractures. A specific enzyme deficiency remains to be defined for the lipid storage myopathies in dogs.

F. Endocrine Myopathies

Signs referable to muscle weakness are frequently observed as part of the clinical presentations of endocrine disorders.

1. *Corticosteroid Myopathy*

Hyperadrenocorticism causes muscle wasting (atrophy) and weakness in dogs and horses with Cushing's disease and following corticosteroid administration (Braund *et al.*, 1980a, 1980b; Duncan *et al.*, 1977); (Aleman *et al.*, 2006). The muscle wasting is due to a rather selective anguloid to angular atrophy of type 2 myofibers; however, quantitative studies reveal atrophy of type 1 fibers as well. Myotonia is a variable accompanying sign of this disorder (Duncan *et al.*, 1977). Muscle wasting appears to be due to catabolism with decreased protein synthesis and increased protein degradation mediated by altered transcription in protein metabolism.

2. H*ypothyroid Myopathy*

Thyroid status has a profound affect on skeletal muscle, and hypothyroid states are often accompanied by manifestations of neuromuscular disease. However, descriptions of muscle disorders in clinical veterinary medicine are limited (Braund *et al.*, 1981). Selective type 2 myofiber atrophy and type 1 myofiber predominance (or type 2 myofiber paucity) are common findings in canine hypothyroidism. Experimental studies reveal that the proportion of myofiber types is influenced by thyroid status in which thyroidectomy results in type 1 myofiber predominance and thyroid excess results in type 2 myofiber predominance (Li *et al.*, 1996; Li and Larsson, 1997).

I. INTRODUCTION

Clinical biochemistry in nephrology is mainly used to diagnose and monitor renal dysfunction or damage. This is of special importance in human medicine, because of the frequent observation of renal failure in elderly people, and in canine and feline medicine, especially for the early detection of chronic renal failure (CRF), which is frequent. In U.S. private practice, however, renal disease was not reported as one of the 29 most common disorders in dogs and was ranked 17th in cats (Lund *et al.*, 1999), and in a survey of Australian practices, the expected frequency of renal failure ranged from one case per week to one case every 2 weeks (Watson *et al.*, 2001). A British survey indicated that 0.2% of dogs were presented with suspected renal disease, which was confirmed in 25% of the cases with no evidence of breed or sex predisposition (MacDougall *et al.*, 1986). The reported prevalence of CRF in a U.S. university hospital was three times higher in cats than in dogs (Polzin *et al.*, 1992). However, the frequency of renal disease increases with age, especially in dogs and cats, as in humans (Cowgill and Spangler, 1981; Gobar *et al.*, 1998; McCall Kaufman, 1984). In U.S. veterinary university hospitals, renal disease was observed in 15% of dogs more than 10 years old, in 33% of cats more than 15 years old (Polzin *et al.*, 1989), in 3% of cats aged 7 to 10 years, and in 30% of cats more than 15 years old (Krawiec and Gelberg, 1989).

Kidney diseases are uncommon in equids and cattle (Fetcher, 1985). The latter show better resistance to a loss of kidney function than monogastric animals because of the filtration function of the rumen epithelium as shown by bilateral nephrectomy (Fetcher, 1986).

II. KIDNEY MORPHOLOGY AND FUNCTION

A. General Structure of the Kidneys

The mammalian kidney consists of tens of thousands to millions of nephrons that function as parallel units. The larger the species, the greater the number of nephrons per kidney (Kunkel, 1930; Rytand, 1937–1938; Vimtrup, 1928). This ranges from about 10,000 in mice (Cullen-McEwen *et al.*, 2003), 175,000 in cats (Brown *et al.*, 1993), 300 to 700,000 in dogs (Finco and Duncan, 1972), and 7 million in elephants, as compared to about 1 million in humans. The number of nephrons progressively increases during fetal development and is complete at birth (e.g., in sheep or humans) or during the few days following birth (e.g., in rat) (Gimonet *et al.*, 1998). The number of nephrons in the dog decreases slightly (5%) during the 2 first months of life, whereas the glomerular volume increases by 33% (Horster *et al.*, 1971). However, great interindividual variability is observed within species. In dogs, the size or the weight has little influence on the number of glomeruli, but the size of these latter is larger in larger breeds (Finco and Duncan, 1972; Kunkel, 1930). In sheep, the number of nephrons in twins was about 30% lower than in single lambs (Mitchell *et al.*, 2004) or showed no difference (Bains *et al.*, 1996).

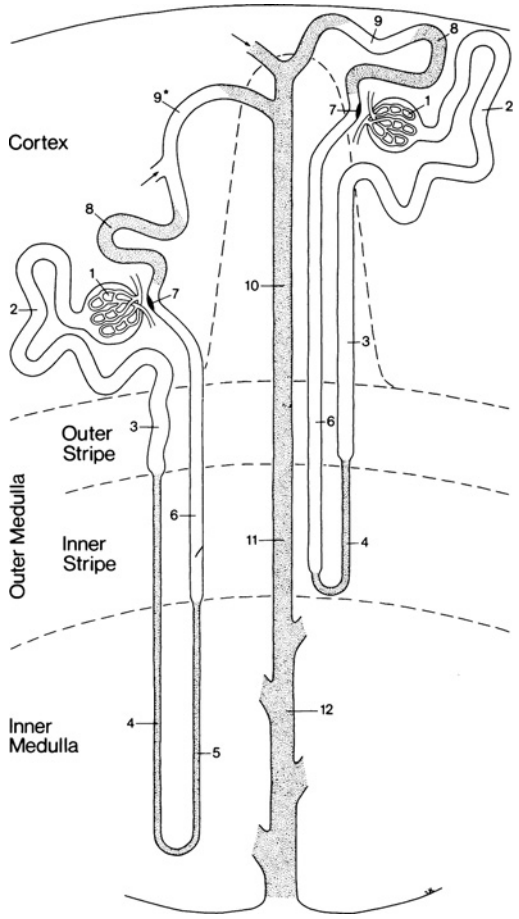

FIGURE 16-1 Schematic representation and international nomenclature of the parts of the nephron. 1: Renal corpuscle including Bowman's capsule and the glomerulus (glomerular tuft). 2: Proximal convoluted tubule. 3: Proximal straight tubule. 4: Descending thin limb. 5: Ascending thin limb. 6: Distal straight tubule (thick ascending limb). 7: Macula densa located within the final portion of the thick ascending limb. 8: Distal convoluted tubule. 9: Connecting tubule; 9*: Connecting tubule of the juxtamedullary nephron that forms an arcade. 10: Cortical collecting duct. 11: Outer medullary collecting duct. 12: Inner medullary collecting duct. Reproduced with permission of the publisher from Kriz and Bankir (1988).

The general architecture of the nephrons is identical in all species (Fig. 16-1) (Kriz and Bankir, 1988), but their disposition within the kidney differs between species (Bankir and de Rouffignac, 1985).

Blood is supplied to the kidneys by the renal arteries. These divide into interlobar and arcuate arteries located at the corticomedullary junction. Branches of the latter supply blood to the afferent arterioles of the tuft of capillaries in the glomerulus, from which it is collected by the efferent arterioles. Depending on the location of the glomeruli, blood is then supplied to a network perfusing the cortical tubules or to the vasa recta vessels, which penetrate deep into the medulla in "hairpins" parallel to the loops of Henle. See the review in Pallone *et al.* (1998). The total blood supply to the kidneys (renal blood flow, RBF) is very high, about 20% of the cardiac output, and most of it goes to the cortex. Only a fraction of the plasma flow (renal plasma flow, RPF) is

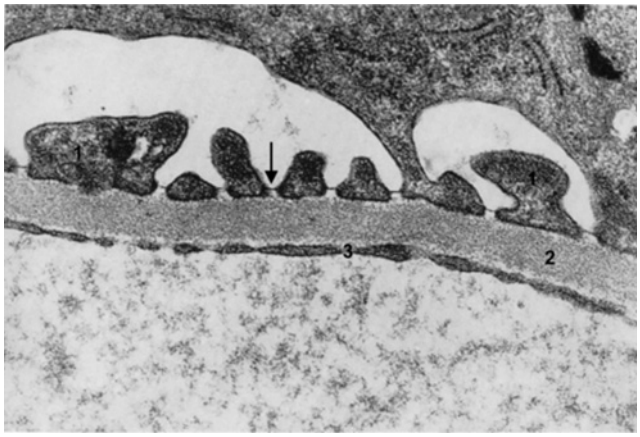

FIGURE 16-2 Electron micrograph of the glomerular filtration barrier. 1: Footlike processes of the podocytes; arrow shows the slit diaphragm of a filtration slit. 2: glomerular basement membrane. 3: fenestrated endothelium of the glomerular capillaries. Reproduced with permission of the publisher from Poirier *et al.* (1999).

filtered resulting in the glomerular filtration rate (GFR). This is the filtration fraction (FF), which generally amounts to 20% to 30% of RPF: GFR = RPF × FF.

The RBF remains quite stable, because of autoregulation, even with variations in systemic blood pressure. The precise mechanism of autoregulation is unknown but results from vasoconstriction/dilation of the afferent and efferent glomerular arterioles, which maintains an almost constant hydrostatic pressure within the glomerulus. Autoregulation is efficient in healthy dogs between 70 to 180 mmHg and may be altered in disease, especially during CRF (Brown *et al.*, 1995).

B. Glomerulus and Filtration

Each glomerulus consists of a tuft of anastomosed capillaries within the Bowman's capsule, which collects the primitive urine formed by plasma filtration and opens into the tubule conducting urine to the renal pelvis. The filter between the plasma and urine consists of three layers (Fig. 16-2) (see reviews in Deen *et al.* [2001], and Rennke and Venkatachalam [1977]):

- The fenestrated endothelium of the capillaries, allowing direct contact between the plasma and the basal membrane via large pores and fenestrae (~50 to 100 nm); the luminal face is coated with sulfated glycosaminoglycans and glycoproteins.
- The basement membrane made of a gel containing approximately 90% water and negatively charged sulfated glycosaminoglycans.
- The filtration slits (~25 nm) between the footlike processes of the podocytes (i.e., the visceral epithelial cells covering the external surface of the capillaries) (Gubler, 2003). The slits are made porous by the slit diaphragm in which proteins, consisting mainly of the extracellular part of the nephrin molecule anchored in the membrane of the

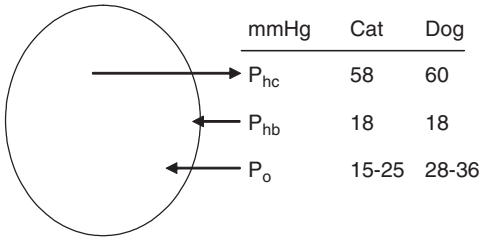

FIGURE 16-3 Pressures involved in glomerular filtration within a glomerular capillary. The driving force is the hydrostatic pressure in the capillary (Phc), which is opposed by hydrostatic pressure within Bowman's space (Phb) and oncotic pressure in the capillary (Po). Values are pressures in dogs and cats.

podocytes, are arranged in zipper-like fashion (Wartiovaara *et al.*, 2004). This slit diaphragm seems to be the basis of filter selectivity, although this has long been considered a function of the basement membrane; it may also act as a signaling system to modulate filtration (Benzing, 2004).

The driving force of filtration is hydrostatic pressure of cardiac origin (Fig. 16-3). This is opposed by plasma colloidal (oncotic) pressure produced by plasma proteins and urine hydrostatic pressure within the Bowman's capsule. The colloidal pressure in the Bowman's capsule is negligible because of the almost total absence of proteins. As a result, the effective filtration pressure is 10 to 15mmHg (Navar *et al.*, 1977).

The limits of filtration (see the review in Tryggvason, 1999) are as follows:

- Size and shape: Neutral molecules with a diameter $<$2.5nm diffuse freely. Then as diameter increases, filtration decreases to approximately 0 when the diameter is $>$3.5nm (i.e., the approximate diameter of the albumin molecule).
- Charge: Because of the high concentration of sulfated glycosaminoglycans at the surface of endothelial cells and in the GBM, the filtration slit tends to repel negatively charged molecules (i.e., most plasma proteins at blood pH).

As a result of glomerular filtration, all small hydrosoluble plasma molecules, including water and ions, are freely filtered but high molecular weight proteins are not. Albumin, which has an MW ~67,000 and a pI = 4.9 (Purtell *et al.*, 1979), is very close to the limit of filtration so that only a minimal amount is filtered by "normal" kidneys. The albumin concentration in primitive urine is ~20 to 30mg/l and many smaller proteins are also present, most of which are reabsorbed in the tubule.

C. Tubule: Reabsorption and Secretion

1. *Parts of the Tubule*

The tubule is divided into different segments (Fig. 16-2) (see standard nomenclature in Kriz and Bankir, 1988):

- The proximal tubule begins with a convoluted portion followed by a straight section dipping toward the medulla; the epithelium of the proximal tubule consists of thick cuboidal cells with a very dense brush border on the luminal side, which provides an immense surface of exchange with the glomerular urine; this is the portion of the nephron where most solutes and water are reabsorbed.
- The loop of Henle produces a "hairpin" bend within the medulla, ending close to the glomerulus at the juxtaglomerular apparatus. Long and short loops descend only into the inner or outer medulla, respectively. The loop of Henle is essential to urine concentration mechanism and it is often stated that long loops are mostly observed in species living in desert areas, and thus related to higher concentrating ability. Almost all the nephrons in dogs and cats are long looped (Bulger *et al.*, 1986), whereas those in humans and pigs are mostly short looped (Bankir and de Rouffignac, 1985), and the average urines are more concentrated in dogs and cats than in humans or swine. The two main points regarding function are that (1) the water and urea permeability of the descending thin limb is high, because of the presence of the aquaporin 1 water channel and (2) the ascending thin limb shows very low water and high sodium chloride permeability.
- The juxtaglomerular apparatus is a morphological entity at the confluence of the afferent and efferent arterioles of the glomerulus and a differentiated part of the loop called the macula densa (Spangler, 1979a, 1979b). The cells in the macula densa respond to decreases in blood pressure or hyponatremia by secreting renin stored in the granules, thus activating the angiotensin-aldosterone response.
- The distal convoluted tubule stretches from the macula densa to the confluence into a collecting tubule within the cortex. The reabsorption capacity is lower than in the proximal nephron (e.g., only ~5% to 10% of sodium and chloride), and secretion of potassium may occur. See the review in Reilly and Ellison (2000).
- The collecting tubules leading to the renal pelvis. The final regulation of urine volume and solute excretion occurs in the final segment of the distal tubule and the collecting tubule, and it is partly regulated by hormones.

2. *Functions of the Tubule*

The main tubule functions are the reabsorption of water, electrolytes, and small molecules and, to a lesser extent, the secretion of ions and small molecules. Reabsorption is dominant in healthy animals and mainly occurs in the proximal tubule by active and passive transport. Further adjustment of urine excretion occurs in the distal tubule and is controlled by hormones, so that the final urine is usually more concentrated than the ultrafiltrate. See the review in Reilly and Ellison (2000). Reabsorption and secretion continually adapt to maintain an almost constant plasma composition, whereas the intake and utilization of ions and small molecules vary with food and water supply,

proximity of meals, environment, physical effort, and so on. This is why the following occurs:

- Urine composition can show large variations in the same healthy or diseased subject.
- A notable overlap of urinary analyte concentrations is observed in healthy and diseased animals.
- The reference intervals for urine analytes are of little relevance when determining spot urine compositions.

a. Small Hydrophilic Molecules

Glucose, amino acids, and low-molecular-weight proteins are mostly reabsorbed in the proximal tubule. Almost 100% of the glucose, amino acids, and proteins are reabsorbed. The former return to the plasma, whereas small proteins are degraded in the tubular cells. Other small hydrophilic molecules are not or only poorly reabsorbed (e.g., creatinine) (see Section II.A.1.a).

Glucose reabsorption is permitted by the SGLT1 (sodium glucose transporter) in the apical membrane, which couples glucose reabsorption with sodium transport down a gradient produced by an Na/K-ATPase in the basolateral membrane, across which glucose diffuses in a concentration gradient by means of GLUT-2 transporters. This glucose reabsorption capacity is limited by the finite number of transporters: maximal tubular reabsorption (Tm) is attained when plasma glucose concentration (P-Glucose) is about 12 mmol/l in dogs, 15 to 18 mmol/l in cats, and 8 to 10 mmol/l in cows.

No urea reabsorption occurs before the medullary part of the collecting duct because of the presence of urea transporters activated by antidiuretic hormone (ADH). This is part of the mechanism creating a high inner medullary osmolality. A small amount of urea is even secreted into the medullary part of the ascending branch of the loop of Henle. Urea reabsorption is increased when urine flow is low (e.g., during dehydration or volume depletion). Urea is central to the concentrating mechanism in the kidney and is ensured by the presence of urea transporters at the thin extremity of the descending loop of Henle and corresponding segments of the vasa recta, which enable urea diffusing from the medullary part of the collecting tubule to enter the nephron and to a lesser degree the blood. See the review on urea transporters in Smith and Rousselet (2001).

b. Electrolytes

Electrolytes are mostly reabsorbed in the proximal tubule. The rate of reabsorption differs considerably according to the internal balance of each ion. Under "normal" conditions it is almost 100% for sodium, chloride, calcium, and phosphates, but much lower for potassium, especially in ruminants owing to their high dietary intake.

The extent of reabsorption can be estimated from the fractional excretion (FE) of solutes (i.e., the fraction of the filtered load of an electrolyte that is finally excreted in urine) (see Section II.C.3):

- Sodium concentration is kept low in tubule cells, as in other cells, by an Na/K-ATPase in the basolateral membrane. See the review in Feraille and Doucet (2001). This active transport of sodium ions from the urine accounts for most sodium reabsorption. It also creates a sodium concentration gradient that allows cotransport of amino acids, glucose and other ions, and so on. See the review in De Weer (1992). Further reabsorption of sodium and chloride occurs in the ascending branch of the loop of Henle via an Na-K-2Cl cotransporter in the luminal membrane. See the review in Russell (2000). Final adjustment in the distal part of the nephron is hormonally controlled by aldosterone and natriuretic peptides.
- Chloride is the most abundant anion in the extracellular compartment. The plasma concentration and elimination of chloride are usually concomitant with those of sodium, except in the case of acid-base disorders. In metabolic acidosis, bicarbonate ions secreted by the kidney cells are exchanged with chloride by an Na-independent Cl/HCO_3 exchanger, thus increasing urine chloride elimination and the plasma anion gap.
- Potassium is reabsorbed in the proximal tubule (~70%) and in the ascending part of the loop of Henle, the distal tubule, and the medullary collecting duct. Potassium is also secreted by the distal tubule and cortical collecting duct, mainly during hyperkalemia (Berliner and Kennedy, 1948). See the review in Hebert *et al.* (2005). Part of this process is based on aldosterone secretion, which induces the synthesis of Na/K-ATPases, thereby favoring potassium excretion and sodium reabsorption.
- The inorganic phosphates (P_i) in plasma comprise about 80% HPO_4^{2-} and 20% $H_2PO_4^-$. They are reabsorbed in the proximal tubule by a sodium cotransporter, which is inhibited by PTH, thus increasing phosphodiuresis. Some newly identified peptides may also decrease tubular phosphate reabsorption without any alteration of glucose and amino acid reabsorption and thus lead to renal loss of phosphates. See the reviews in Laroche and Boyer (2005) and Ritz *et al.* (2003). The Tm for phosphate reabsorption is higher in ruminants than in other species (Summerill and Lee, 1985; Symonds and Manston, 1974).
- Calcium: Free and complexed calcium ions are freely filtered by the glomerulus. Calcium is mostly reabsorbed in the proximal tubule and in the ascending branch of the loop of Henle, except in horse and rabbit, which excrete significant amounts of this ion when supply is sufficient. Reabsorption occurs by paracellular route. Epithelial channels in the distal part of the nephron permit the transcellular transport of about 15% of filtered calcium. See the

reviews in Hoenderop and Bindels (2005) and Hoenderop *et al.* (2005). This final reabsorption is mainly under the hormonal control of PTH.

• Magnesium: Non-protein-bound magnesium is filtered by the glomerulus. Only about 25% are reabsorbed in the proximal tubule. Most reabsorption occurs in the ascending branch of the loop of Henle (50% to 60%) (Rosol and Capen, 1996).

c. Water

Most water (~75%) is reabsorbed passively in the proximal tubule along with ions and small hydrophilic molecules, so that the fluid entering the descending branch is isotonic. Water is reabsorbed in the descending branch of Henle's loop as a result of the corticopapillary osmolar gradient, whereas the ascending branch is impermeable to water. Final reabsorption occurs in the collecting tubule, mainly under the hormonal control of the antidiuretic hormone (ADH). This hypothalamic nonapeptide is secreted by the posthypophysis when osmolality increases and during hypovolemia or decreased blood pressure. Receptors in the collecting tubule cells trigger the AMPc-dependent synthesis and shuttling of aquaporins, mainly the AQP2 water channel, into the apical and basolateral membrane, thereby permitting water reabsorption and the final adjustment of urine concentration. See the review in Nielsen *et al.* (2002). The final urine concentration is usually much greater than that of the glomerular filtrate (Fig. 16-4).

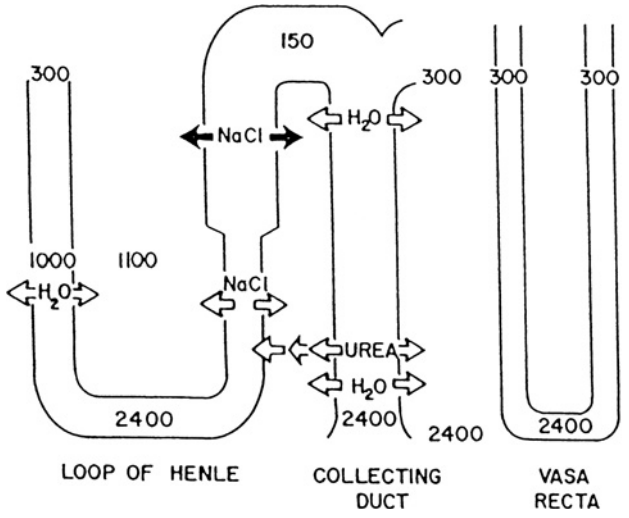

FIGURE 16-4 Water reabsorption in the kidney tubule (values are osmolalities). The corticomedullary osmotic gradient results from reabsorption of sodium and chloride without concomitant reabsorption of water in the ascending limb of the loop of Henle and from urea reabsorption in the medullary part of the collecting ducts. Owing to water permeability of the descending limb of the loop of Henle plasma isoosmotic urine flowing from the proximal tubule is first concentrated in the descending branch of the loop of Henle, then is diluted by escape of NaCl and water retention in the ascending branch, and finally is concentrated along the collecting ducts. Reproduced with permission of the publisher from Finco (1995b).

d. Acid-Base Regulation

The main organs involved in acid-base regulation are the kidneys and lungs. The lungs modulate the elimination of CO_2 and the kidneys the elimination of protons and generation of bicarbonate ions.

The carbonic acid (H_2CO_3)-bicarbonate (HCO_3^-) buffer system is the most efficient extracellular buffer system. It is based on the low dissociation of carbonic acid (pKa ~6.1) at the pH of the extracellular/intravascular compartment and the fact that it is an open system eliminating CO_2 in the lungs. Its efficiency is enhanced by the action of carbonic anhydrase, which accelerates the hydration of carbonic anhydride (CO_2) into carbonic acid. High concentrations of carbonic anhydrase occur in many tissues including the kidney tubule. The relationship between CO_2, H_2CO_3, and HCO_3 is expressed in the following equation:

$$H_2O + CO_2 \leftrightarrows H_2CO_3 \leftrightarrows HCO_3^- + H^+$$

Bicarbonate ions filtered by the glomerulus are mainly reabsorbed in the proximal tubule (~80%) as CO_2, which is lipophilic and able to diffuse across the membrane. Within the cell, CO_2 is hydrated by carbonic anhydrase into carbonic acid, which dissociates into bicarbonate ions and protons. The secretion of protons into the tubule lumen ensures the conservation of bicarbonate and its transfer to the plasma. This occurs principally in the distal tubule, where protons are excreted and buffered in urine with filtered organic anions, phosphate, and ammonia generated from glutamine in the tubule cells by the action of glutaminase and glutamate dehydrogenase. This process is enhanced during acidosis, when distal tubule and collecting tubule cells excrete protons against a concentration gradient by the action of an H^+-ATPase in the basolateral membrane.

e. Endocrine Functions

Two major hormones, erythropoietin (EPO) and 1α, 25-dihydroxycholecalciferol (calcitriol), are synthesized by the kidneys and released into the blood.

EPO is a cytokine that regulates erythrocyte production synthesized in the peritubular cells in response to hypoxia. Minor amounts are also produced in the liver, mainly in the newborn. EPO binds to receptors of bone marrow progenitor cells and acts synergistically with other growth factors to proliferate and mature the erythroid progenitor cells. In advanced chronic renal disease, the synthesis of EPO decreases and is insufficient to meet the demands for new red cell production, resulting in anemia. See the review in Fisher (2003).

Calcitriol is a secoBsteroid hormone derived from vitamin D_3. It is produced in the proximal tubule cells by the

action of 1α-hydroxylase on 25-hydroxyvitamin D_3 produced by liver hydroxylation of vitamin D_3. Calcitriol is a major antihypocalcemic hormone acting at the transcriptional level to induce active intestinal absorption of calcium. It acts in synergy with PTH to activate calcium release from bone. PTH increases the expression and activity of 1α-hydroxylase activity during calcium and vitamin D_3 deficiency. The direct modulating effects of calcium and phosphates are weaker. 1α-Hydroxylase activity was recently shown to be down-regulated by phosphaturic peptides called phosphatonins. See the reviews in Ebert *et al.* (2006), Jones *et al.* (1998), and Kumar (1984). Calcitriol synthesis is decreased in CRF, and its administration is recommended for the treatment of animals with CRF and concomitant hyperparathyroidism. See the review in Nagode *et al.* (1996).

III. TESTS OF KIDNEY FUNCTION

Kidney function can be evaluated from the concentrations of plasma or urine analytes, which are mainly dependent on their elimination (e.g., P-Creatinine). These indirect markers can be easily and rapidly measured, but their sensitivity is poor and generally remains unaltered until 75% of renal function has been lost and their concentrations may be modified by extrarenal factors. Direct tests of kidney function are based on the elimination kinetics of markers of glomerular filtration, blood flow, or tubule reabsorption/secretion and are based on the clearance concept. These tests are more difficult and take longer to perform but allow earlier detection of reduced function.

A. Indirect Tests of Glomerular Function

P-Creatinine is the test most often used to diagnose and monitor kidney disease in human and animal clinical pathology. P-Urea is also used frequently but is subject to more numerous extrarenal factors of variation. These molecules are almost totally eliminated by glomerular filtration, so that in the case of kidney failure their plasma concentration increases. However, neither test is sensitive in the early diagnosis of kidney disease because of the large functional reserve of the kidneys. Moreover, variations of P-Urea and P-Creatinine are not proportional to the number of functional nephrons (e.g., a mean increase of 85% in P-Creatinine and of 140% in P-Urea was observed after a two-fold reduction of GFR, with values close to the upper limit of the reference interval) (Lefebvre *et al.*, 1999).

1. *Creatinine*

a. Creatinine Metabolism

Creatinine is a small molecule (MW 113) produced by degradation of creatine and creatine-phosphate, an energy-storing molecule mainly present in skeletal muscles. See the reviews in Braun *et al.* (2003), Perrone *et al.* (1992), and Wyss and Kaddurah-Daouk (2000). Creatine is synthesized from the amino acids glycine, arginine, and methionine, the final step occurring in the liver (Fig. 16-5). It is then taken up by the muscles where it is reversibly phosphorylated by creatine-kinase into creatine-phosphate. Skeletal muscles contain about 95% of the total body creatine and creatine-phosphate pool. The estimated turnover of creatine-phosphate (about 2%) is fairly constant in a given individual. The resulting estimated daily input of endogenous creatinine into plasma was 380 $\pm$ 45μmol/kg BW in healthy beagles and 10% to 20% lower in animals with reduced kidney mass (Watson *et al.*, 2002a). In carnivores and omnivores, creatinine can also originate from the creatine and creatinine in food (Harris and Lowe, 1995; Harris *et al.*, 1997).

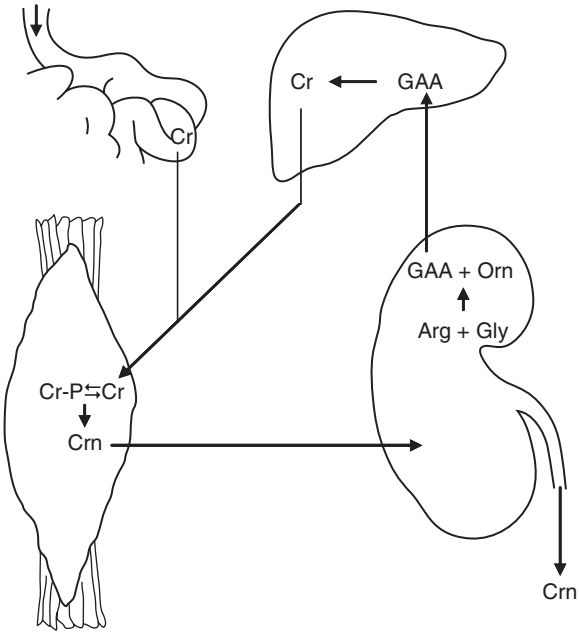

FIGURE 16-5 Schematic representation of creatinine metabolism. The first step is the transamidination of arginine and glycine yielding guanidinoacetic acid (GAA) by the kidney enzyme arginine:glycine amidinotransferase. In the liver, N-methylation of guanidinoacetate into creatine is catalyzed by guanidinoacetate methyltransferase, using methyl groups donated by S-adenosylmethionine. Creatine is distributed to muscle cells where it is reversibly phosphorylated to creatine phosphate by creatine kinase. Creatinine is the product of the spontaneous, irreversible, nonenzymatic, internal dehydration of creatine, and dephosphorylation of creatine phosphate.

Creatinine mainly circulates in a free form in the plasma and is distributed into the whole body water compartment (Schloerb, 1960; Watson *et al.*, 2002a). It was reported that, in dog plasma, 6% were bound to plasma proteins (Kennedy *et al.*, 1952). Creatinine is freely filtered by the glomerulus and is not reabsorbed or secreted in cats (Finco and Barsanti, 1982) and ponies (Finco and Groves, 1985), but it may be strongly secreted in horses

(Bickhardt *et al.*, 1996). In dogs, either no secretion has been observed (Finco *et al.*, 1993; Watson *et al.*, 2002a) or very weak proximal tubule secretion has been reported in males but not in females (O'Connell *et al.*, 1962; Swanson and Hakim, 1962). This secretion is slightly increased following reduction of the renal mass (Robinson *et al.*, 1974). Secretion of creatinine by active transport in the proximal tubule has been reported in humans, in whom it is nonuniformly increased in renal failure (Walser *et al.*, 1988), also in sheep (Bickhardt and Dungelhoef, 1994), rabbit (Matos *et al.*, 1998), pig (Wendt *et al.*, 1990), and goat (Ladd *et al.*, 1957). Creatinine is reabsorbed by the tubules in newborn rabbits and humans, probably by back-leak through the immature tubules (Matos *et al.*, 1998).

As observed in humans and rats, extrarenal intestinal catabolism may be suspected in cases of renal failure. This may involve the bacterial flora, as demonstrated in the rat by accumulation creatine bacterial catabolites including methylguanidine (Jones and Burnett, 1972; Mitch *et al.*, 1980). This hypothesis is supported by the observed increase in cats with ARF (Ohashi *et al.*, 1995). Finally, creatinine is rapidly cleared from plasma (half-life of 3 h in dogs; Watson *et al.*, 2002a) and eliminated in urine, where its total excretion depends on body weight (Gartner *et al.*, 1987).

b. Preanalytical Factors of Variation

- Specimen: Serum and plasma creatinine concentrations are identical, although a slightly higher serum value has been reported in dogs (Thoresen *et al.*, 1992). Differences between jugular and cephalic vein may be overlooked (5 μmol/l in dogs) (Jensen *et al.*, 1994). Canine P-Creatinine is not changed by storage at -20°C or -70°C for up to 8 months (Thoresen *et al.*, 1995) or by three freeze-thaw cycles (Reynolds *et al.*, 2006).

In human urines, the creatinine concentration decreased by about 20% to 30% in 1 week at any temperature between 4°C and -80°C, and was not altered by five freeze-thaw cycles (Schneider *et al.*, 2002), whereas others found that it was stable up to 30 days when stored at 4°C and minimally decreased at 25°C (Spierto *et al.*, 1997).

- Diet and meals: P-Creatinine in dogs and cats was increased by meals containing meat, especially when this was cooked (Epstein *et al.*, 1984; Evans, 1987; Harris and Lowe, 1995; Lowe *et al.*, 1998; Sagawa *et al.*, 1995; Watson and Church, 1980; Watson *et al.*, 1981) or after oral loading with creatine (Lowe *et al.*, 1998), although large interindividual differences were observed. P-Creatinine was higher in dogs fed chicken-based diets than egg- or casein-based diets (Bartges *et al.*, 1995a). No differences in P-Creatinine were observed between cats receiving high- or low-protein diets (Adams *et al.*, 1993). P-Creatinine was moderately higher in young dogs on a low-salt diet (Bagby and Fuchs, 1989) and about 50% higher in goats fed on a low-protein diet (Valtonen *et al.*, 1982).

- Hydration status: P-Creatinine was only moderately increased in dogs deprived of water for 4 days, even when the weight loss was $\geq$10% (English *et al.*, 1980; Hardy and Osborne, 1979).
- Physical exercise: P-Creatinine was decreased (by about 40%) by physical training in sled dogs (Kronfeld *et al.*, 1977; Querengaesser *et al.*, 1994). It was not significantly changed after strenuous physical exercise in untrained dogs (Chanoit *et al.*, 2002). It was increased by about 20 μmol/l after a 400m sprint in greyhounds (Rose and Bloomberg, 1989; Snow *et al.*, 1988) and by approximately 50% after strenuous sprint efforts in sled dogs (Hammel *et al.*, 1997; Querengaesser *et al.*, 1994), but not after very long races (up to 415 miles) (Hinchcliff *et al.*, 1993; Querengaesser *et al.*, 1994).
- Housing: P-Creatinine was slightly higher (10 to 20 μmol/l) in dogs kept indoors than outdoors (Kuhn and Hardegg, 1988; Rautenbach, 1988), whereas others found no difference (Spangenberg *et al.*, 2006).
- Drugs: P-Creatinine was decreased in dogs receiving glucocorticoids (Braun *et al.*, 1981), whereas U-Creatinine was increased (Iversen *et al.*, 1997). P-Creatinine was unchanged or little affected by a single dose of nonsteroidal anti-inflammatory drugs (NSAID) (Lobetti and Joubert, 2000; Mathews *et al.*, 2001) or by halothane anesthesia (Lobetti and Lambrechts, 2000), and moderately increased by furosemide administration (Adin *et al.*, 2003) and high-dose trimethoprim-sulfadiazine in dogs (Lording and Bellamy, 1978). P-Creatinine could increase (Kitagawa *et al.*, 1997), remain unchanged (Atkins *et al.*, 2002), or decrease (Pouchelon *et al.*, 2004) in dogs treated with ACE inhibitors for heart failure.

c. Analytical Factors of Variation

HPLC is considered to be the reference method (Blijenberg *et al.*, 1994; Hanser *et al.*, 2001), but routine analyses are based on the nonspecific Jaffé reaction (alkaline picrate) and enzymatic procedures (Guder *et al.*, 1986). See the reviews on creatinine measurement in Spencer (1986) and recommendations for improvement in Myers *et al.*, (2006). The enzymatic methods give slightly lower results than HPLC and Jaffé reaction, $\sim$5 and 20 μmol/l, respectively, in dog plasma (Evans, 1987; Palm and Lundblad, 2005). The main interferents in the Jaffé reaction are glucose, ketones, and hemoglobin, but canine plasma was unaffected by hemolysis up to 25 g/l (Jacobs *et al.*, 1991, 1992; O'Neill and Feldman, 1989). Interference in the kinetic Jaffé technique is limited in normal dog plasma as the other chromogens react more slowly than creatinine (Palm and Lundblad, 2005). There is less interference in urine because of the lower proportion of Jaffé chromogens, so that calculated creatinine clearances may differ greatly according to the technique used, as shown in rats (Jung *et al.*, 1987).

The accuracy of plasma creatinine measurement is far from satisfactory in human medicine and cannot be

expected to be better in veterinary medicine (Miller *et al.*, 2005; Myers *et al.*, 2006). The measurement of urine creatinine has not been validated in animals, but a poor correlation between different techniques was shown in dogs, especially in concentrated urines (Trumel *et al.*, 2004).

d. Reference Intervals and Physiological Factors of Variation

$$100\mu\text{mol/l} = 1.13\text{mg/dl}$$

Reference intervals for P-Creatinine have been poorly defined in most species because of animal selection and the chosen analytical method. The reference intervals for dogs were shown to differ considerably from one textbook to another (Lefebvre *et al.*, 1998b), so that any interchanging of reference limits or decision levels would be risky:

- Breed: P-Creatinine is higher in large breeds of dogs (Braun *et al.*, 2002; Feeman *et al.*, 2003; Hilppo, 1986; Medaille *et al.*, 2004), even in puppies (Kühl *et al.*, 2000).
- Gender: No differences related to gender were observed in dogs (Broulet *et al.*, 1986; Passing, 1981), although moderately higher concentrations (~+10%) were observed in 1- to 3-year-old and 9- to 11-year-old male beagles (Fukuda *et al.*, 1989).
- Age: A high P-Creatinine concentration was reported in newborn calves, puppies, and foals, probably because of the accumulation of creatinine ingested from the allantoic fluid (9 to 23 mmol/l in bovines) (Edwards *et al.*, 1990; Klee *et al.*, 1985; Kühl *et al.*, 2000; Lupke *et al.*, 1967). This decreased during the following weeks and then showed a moderate increase again. In dogs and cats, P-Creatinine almost doubled from the first weeks to 1 year of age, then remained stable up to 10 years (Kraft *et al.*, 1996; Passing and Brunk, 1981; Strasser *et al.*, 1993, 1997; Swanson *et al.*, 2004; Vajdovich *et al.*, 1997; Wolford *et al.*, 1988), although other authors reported a regular decrease with age in dogs (Fukuda *et al.*, 1989; Lowseth *et al.*, 1990). In piglets, P-Creatinine almost doubled between 2 and 6 months of age (Krogh *et al.*, 1979).
- Biological rhythms: Both a circadian and a seasonal rhythm were observed in dogs, but they were of limited significance (Singer and Kraft, 1988; Sothern *et al.*, 1993; Strasser *et al.*, 2001), whereas no such rhythms were reported in bulls (Boehnke, 1980). In healthy sheep, creatinine was 25% higher in summer than in winter (Nawaz and Shah, 1984).

e. Variations of P-Creatinine in Disease

An inverse curvilinear relationship was observed between P-Creatinine and GFR in dogs (Fig. 16-6) (Finco *et al.*, 1995, 1993; Miyamoto, 2001a; Westhoff *et al.*, 1993). This was the same in both sexes (Finco *et al.*, 1995). The assessment of GFR from creatinine is hazardous because of interindividual variability (e.g., P-Creatinine = 200 μmol/l could be observed in dogs with GFR ranging from 0.4 to 1.4 ml/min/kg) (Finco *et al.*, 1995). In cats the relationship is almost linear (Haller *et al.*, 2003).

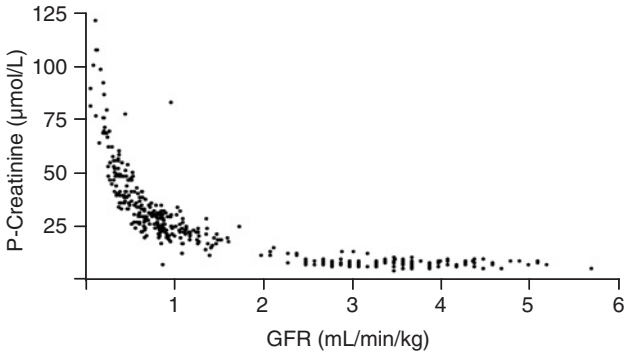

FIGURE 16-6 Relationship between P-Creatinine and GFR in dogs. Observe that (1) on the right-hand part of the graph, GFR can be decreased from about 6 to 2 ml/min/kg without any significant change of P-Creatinine; (2) on the left-hand part of the graph, dramatic reductions of P-Creatinine, as observed during animal rehydration in clinics, do not imply a significant increase in GFR. Reproduced with permission of the publisher from Finco (1995a).

The sensitivity and specificity of P-Creatinine for the diagnosis of CRF are not very high in dogs and neither are the predictive values (Braun and Lefebvre, 2005; Gleadhill, 1994). The critical difference for P-Creatinine in dogs is 35 μmol/l (Jensen and Aaes, 1993). These criteria have not been reported for other species.

It was suggested that the evolution of renal disease in dogs could be monitored by repeated creatinine measurement and that the time of death could be predicted from the 1/P-Creatinine versus the time curve (Allen *et al.*, 1987); however, this approach gave false estimates in humans (Walser *et al.*, 1988).

P-Creatinine is the most efficient indirect marker of GFR in mammals. It is increased in chronic and acute renal failure, and also in some conditions not directly involving the kidney. For example, see the review as it pertains to dogs in Table 16-1 and in Braun *et al.* (2003). Similar variations were also observed in cats, equines, and bovines.

2. Urea

a. Urea Metabolism

Urea is a small hydrosoluble molecule (MW 60) synthesized in the liver from bicarbonate and ammonium in the Krebs-Henseleit cycle. Urea is the main form in which nitrogen is eliminated in mammals. After synthesis, it is distributed into the total body water compartment (Dunegan *et al.*, 1978; Schloerb, 1960). It is freely filtered by the kidney glomeruli and reabsorbed from the collecting tubule. Its passive reabsorption is increased when urine flow in the tubule is reduced (Park and Rabinowitz, 1969),

TABLE 16-1 Main Causes of Variations of P-Creatinine in the Dog

↗ P-Creatinine	
Primary renal disease	Intoxication by arsenate
amyloidosis	fluoride
glomerulosclerosis	citrinin
polycystic disease	ochratoxin
uremic crisis	vitamin D
kidney graft rejection	
congenital renal diseases	
Secondary renal disease	
babesiosis	leishmaniasis
leptospirosis	borreliosis
trypanosomiasis	encephalitozoonosis
histiocytosis	heartworm disease
Extrarenal disease	
ureteral obstruction	uroperitoneum
↘ P-Creatinine	
portosystemic shunts	cachexia
early babesiosis	kidney graft
hyperthyroidism	

For references, see Braun et al. (2003).

which can lead to increased P-Urea in dehydrated patients or in patients with hemorrhage or to decreased P-Urea in overhydrated patients. Some urea also filters into the intestine, where it is degraded by bacteria into ammonium, which is absorbed and provides a notable proportion of the ammonium supply to the liver. Another important source of ammonium is the catabolism of amino acids. Proteins are thus a major source of ammonium for urea synthesis. Intense recycling of urea occurs in ruminants by transfer to the gastrointestinal tract and to saliva. Urea can also be added to ruminant food (Cirio *et al.*, 2000; Marini and Van Amburgh, 2003), whence it is incorporated into bacterial proteins. The dietary supply of urea is low in other species.

b. Preanalytical Factors of Variation

- Specimen: No difference between canine serum and heparin plasma was observed and only minor changes were noted when specimens were stored frozen for up to 8 months (Thoresen *et al.*, 1995). P-Urea is little affected by hemolysis (up to 25 g hemoglobin/l) and icterus in cattle, horses, cats, or dogs; it is decreased by lipemia in dogs (Jacobs *et al.*, 1992; O'Neill and Feldman, 1989). P-Urea is stable in plasma and whole blood stored for up to 3 days at 20°C (Thoresen *et al.*, 1992) and in serum or plasma stored frozen at −20°C and at −70°C up to 8 months (Thoresen *et al.*, 1995).
- Diet and meals: P-Urea is increased in dogs after meals. Peak postprandial increase can be as high as 7 mmol/l about 6 h after the meal and last for more than 18 h; it is greater with high-protein diets or in animals fed large amounts (Anderson and Edney, 1969; Epstein *et al.*, 1984; Evans, 1987; Vogin *et al.*, 1967). In most species, basal P-Urea reflects the balance between nitrogen utilization and excretion and can be greatly influenced by nutrition (Kohn *et al.*, 2005). The fasting concentration of P-Urea was lower in dogs on low-protein diets with normal or reduced renal function (Polzin *et al.*, 1983, 1991; Reynolds *et al.*, 1999), in horses (Doreau and Martin-Rosset, 1985), in sheep (Rabinowitz *et al.*, 1973), in goats (Valtonen *et al.*, 1982), and in cats (Hesta *et al.*, 2005). P-Urea was also increased by prolonged fasting, because of catabolism of body proteins (Rabinowitz *et al.*, 1973).
- Hydration status: Dehydration had little effect on P-Urea in dogs (≤12.5 mmol/l in 4 days, with weight loss up to 16%) (Hardy and Osborne, 1979), but it produced a twofold increase in calves within 4 days (Bianca *et al.*, 1965).
- Drugs: P-Urea was unchanged by halothane anesthesia in dogs (Lobetti and Lambrechts, 2000) and was increased at high doses of trimethoprim-sulfadiazine (Lording and Bellamy, 1978).
- Physical exercise: P-Urea in sled dogs was higher after 12 weeks of training, probably as a result of increased protein intake (Reynolds *et al.*, 1999). In greyhounds, P-Urea was unchanged by a 235 m sprint and moderately increased 30 min after a 420 m run (Snow *et al.*, 1988).

c. Analytical Factors of Variation

Most techniques are based on the specific action of a bacterial urease. The accuracy of P-Urea measurements is not usually reported.

d. Reference Intervals and Physiological Factors of Variation

1 mmol/l = 6 mg/dl. There is no good reason to continue using BUN, as the analytical procedure was abandoned long ago and is merely a source of confusion. If required, the factors are BUN (mg/dl) × 0.356 = Urea (mmol/l), and BUN (mg/dl) × 21.4 = Urea (mg/l).

- Gender: No significant effect of gender was observed in young beagles (Passing and Brunk, 1981) or in adult dogs (Broulet *et al.*, 1986).
- Age: P-Urea decreases in dogs (by about 50%) between birth and 1 to 2 months (Kühl *et al.*, 2000; Wolford *et al.*, 1988), after which irregular but moderate variations have been reported (Broulet *et al.*, 1986; Cowgill and Spangler, 1981; Lowseth *et al.*, 1990; Passing and Brunk, 1981; Strasser *et al.*, 1993, 1997; Vajdovich *et al.*, 1997). P-Urea increased from birth to 6 months in Great Danes, except those fed on low-protein diets (Nap *et al.*, 1991). P-Urea was similar in adult horses and newborn foals, decreasing by about 50% in foals on the first day and remaining low for at least 2 months (Edwards *et al.*, 1990). P-Urea decreased during the first week in calves (Hartmann *et al.*, 1987), although others did not report any change during this time (Klee *et al.*, 1985).
- Individuals: Intraindividual variations in horses were more important than the variations observed before and after foaling (Doreau and Martin-Rosset, 1985).
- Biological rhythms: P-Urea in sheep was 30% higher in summer than in winter (Nawaz and Shah, 1984), but other authors found no seasonal difference in dogs (Strasser *et al.,* 2001).

e. Pathological Factors of Variation

The efficiency of P-Urea in renal failure diagnosis has not been reported. The critical difference in dogs was 2.4 mmol/l around a mean value of 5 mmol/l (Jensen and Aaes, 1993). A threshold of decision of 10 mmol/l has been suggested for cattle with suspected renal disease (Campbell and Watts, 1970).

The relationship between P-Urea and P-Creatinine in dogs was reported to be low (Gabrisch, 1973) or high and linear (Toutain *et al.,* 2000), except for frequent increases in P-Urea concentration, with normal P-Creatinine likely the result of poor preanalytical conditions (Medaille *et al.,* 2004). Because of great interindividual variations, differences in the urea/creatinine ratio cannot be related to specific diseases (Finco and Duncan, 1976).

The variations in P-Urea with disease are similar to those of P-Creatinine, but numerous extrarenal factors may contribute to increased P-Urea, such as gastrointestinal hemorrhage, fasting, or sepsis, which increase protein catabolism; thyrotoxicosis, which lowers P-Urea by increasing GFR; and decreased renal perfusion, which increases renal reabsorption (DiBartola *et al.*, 1996; Prause and Grauer, 1998). Other factors of decreased P-Urea include portosystemic shunts, malnutrition (Davenport *et al.*, 1994), liver insufficiency, and Krebs-Henseleit cycle enzyme defects. See the reviews in Dial (1995) and Sutherland (1989). These extrarenal factors of variation explain why P-Urea is less specific than P-Creatinine for the diagnosis and management of CRF and should not be recommended as a test of renal function. However, as P-Urea greatly depends on protein supply, it is a useful tool for monitoring the effects of dietary protein restriction (Devaux *et al.*, 1996).

P-Urea is less effective in cattle than P-Creatinine to evaluate decreased GFR in diarrheic calves (Brooks *et al.*, 1997), and only 30% of cattle with P-Urea above the upper limit of the reference interval had renal disease (Campbell and Watts, 1970).

f. Effects of Prolonged Increases of P-Urea: Carbamylated Hemoglobin

The carbamylation of proteins is an irreversible nonenzymatic reaction occurring between amino groups of proteins and isocyanate, the active form resulting from cyanate isomerization. This latter is derived from the spontaneous dissociation of urea in solution into ammonium and cyanate ions. Thus, the higher and longer the concentration of P-Urea, the higher the concentration of carbamylated proteins, for instance, of hemoglobin (a process analogous to protein glycation in diabetes mellitus). As proposed in human medicine (Stim *et al.*, 1995; Wynckel *et al.*, 2000), carbamylated hemoglobin may be useful for assessing canine CRF and distinguishing it from ARF (Heiene *et al.*, 2001b), whereas others found a significant overlap with specificity and sensitivity equal to 96% and 84%, respectively, at a 100 μg/g Hb threshold (Vaden *et al.*, 1997a).

3. *Cystatin* C

Cystatin C is a small constitutive protein (MW ~14,000) synthesized by all nucleated cells and only cleared by glomerular filtration. The plasma concentration is thus increased in cases of renal failure. Cystatin C is considered the most sensitive marker of renal failure in humans. See the reviews in Filler *et al.* (2005), Laterza *et al.* (2002), and Price (2000). It can be measured with reagents used in humans in plasma from dogs (Almy *et al.*, 2002; Jensen *et al.*, 2001; Martin *et al.*, 2002) but not cats (Martin *et al.*, 2002). A 50% decrease of P-Cystatin C was reported in dogs following a meal, so sampling should be done after a 12-hour fast (Braun *et al.*, 2002). The upper limit of the reference interval in dogs is 1.3 mg/l (Braun *et al.*, 2002) and similar to the human threshold. P-Cystatin C is well correlated with P-Creatinine and GFR in normal dogs and in dogs with reduced GFR (Almy *et al.*, 2002; Braun *et al.*, 2002). At present, no diagnostic advantage of P-Cystatin C over P-Creatinine has been demonstrated in dogs.

B. Direct Tests of Glomerular Function

The determination of glomerular filtration rate (GFR)—that is, the volume of ultrafiltrate produced per unit of time (e.g., ml/min) by glomerular filtration—is considered the best way to evaluate kidney function. This is based on the hypothesis of the "intact nephron": as "the surviving nephrons of the diseased kidney largely retain their essential functional integrity" and "retain a remarkably uniform relationship between glomerular and tubular function" (Bricker *et al.*, 1997).

GFR depends on the size of the animal, so different modes of expression have been proposed. One of the most frequently used is to relate GFR to body weight (ml/min/kg) or better still to lean body mass in humans (Swaminathan *et al.*, 2000). Another approach is to use the body area (ml/min/m^2), but as the equations used to calculate this from BW have not been validated in all species, this may introduce further inaccuracy (Price and Frazier, 1998). Another mode of expression consists of relating GFR to the volume of the extracellular compartment, as one kidney function is the regulation of body water content. This indexing is rarely adopted but has been used in humans (Peters *et al.*, 2000) and dogs (Gleadhill, 1994; Gleadhill and Michell, 1996).

1. *Determination of* GFR

There is no easy method for determining GFR from a single blood or urine specimen. In human clinical pathology, there are equations to estimate GFR from P-Creatinine, gender, weight, and age. The most frequently used are the Cockroft-Gault's equations, but these are imprecise and the results depend on the techniques used for P-Creatinine (Grubb and Nordin, 2006; Wuyts *et al.*, 2003). No such equations are available for use in animals. To our knowledge, the only study relating GFR to P-Creatinine showed that the estimation of canine GFR from P-Creatinine was imprecise, and the authors did not recommend using the equation to estimate GFR (Finco *et al.*, 1995).

The measurement of GFR is based on the clearance of markers freely filtered by the glomerulus and having no or minor secretion and reabsorption. See the review in Heiene and Moe (1998). The accepted reference for GFR determination is the urinary clearance of inulin, a low-molecular-weight polysaccharide (Shannon, 1935). The total amount of this marker eliminated in urine over a period of time is equal to the filtered load:

Total amount eliminated during time t = (U-Inulin) × (U-Volume) = GFR × (P-Inulin)

$$GFR = (U\text{-}Volume) \times (U\text{-}Inulin)/(P\text{-}Inulin) \times t$$

in which U-Inulin and P-Inulin are in the same units, volume is in ml, and time in min, thus GFR is in ml/min.

However, such determinations are labor intensive: they necessitate the maintenance of a constant plasma concentration by constant infusion of the marker, the accurate determination of urine volume, and precise and accurate measurement of the marker. Urine collection is often impractical as the total urine is required, which implies careful washing of metabolic cages (Watson *et al.*, 2002a) or the use of indwelling catheters. See the review on urine collection and preservation in cats and dogs in Osborne (1995).

Easier procedures have been proposed, based on the following:

- The use of other markers: Some markers; such as ferrocyanide (Ladd *et al.*, 1956), thiosulphate (Bing and Effersoe, 1948; Dalton, 1968), and sulfanilate (Maddison *et al.*, 1984; Ross and Finco, 1981) have been abandoned. The endogenous or exogenous clearance of creatinine is the most frequently used technique, whatever the species. Iodinated radiocontrast media (e.g., iohexol) provide a good alternative to inulin, but most laboratories are not equipped to measure iodine (Westhoff *et al.*, 1993, 1994). The metabolism of these various markers has not been documented in domestic animals. In some cases extrarenal metabolism can be significant, as shown in cats for diethylenetriaminepentaacetic acid (DTPA), which first concentrates in the heart and lung, then accumulates moderately in the liver before being concentrated in the kidneys (Drost *et al.*, 2000; Uribe *et al.*, 1992). Radiolabeled markers (see the review in Daniel *et al.* [1999]) allow easier and more accurate measurement of concentrations, but their use is restricted to specially equipped centers: ^{131}I-Inulin, ^{51}Cr-EDTA (Biewenga and van den Brom, 1981; van den Brom and Biewenga, 1981), and ^{99m}Tc-DTPA (Gleadhill *et al.*, 1999). They have also been used in large species such as horses (Matthews *et al.*, 1992; Walsh and Royal, 1992).
- The technique of administration: Single injection instead of continuous infusion and determination of plasma clearance of the marker, with calculations based on the decreased plasma concentration of the marker (Pihl and Nosslin, 1974; Summerville and Treves, 1986).
- The use of nuclear imaging techniques and ^{99m}Tc-labeled tracers such as DTPA. These permit the functions of each kidney to be evaluated separately (Assailly *et al.*, 1977; Drost *et al.*, 2000; Krawiec *et al.*, 1988), as these may be similar in healthy but not always in diseased dogs (Cowgill and Hornhof, 1986; Lourens *et al.*, 1982). Determination of GFR by imaging is not as precise as clearance methods (Barthez *et al.*, 1998; Kampa *et al.*, 2002).

2. *Variations of Results of* GFR *Determination According to Procedure*

a. Preanalytical Factors of Variation

- Anesthesia: In most cases, anesthesia/sedation was reported to have little or no effect on GFR determination in the dog (Bostrom *et al.*, 2006; Gagnon *et al.*, 1982; Lourens

et al., 1982; Newell *et al.*, 1997), but a decrease was reported after acepromazine alone (Lourens *et al.*, 1982) and others found that GFR was slightly higher in anesthetized than in nonanesthetized dogs (Balint and Forgacs, 1967), maybe as a consequence of the intravenous fluids. Anesthesia could lead to reduction of GFR in dogs with reduced renal mass (Stone *et al.*, 1981). Thiopental anesthesia had no effect on GFR in sheep (Cirio *et al.*, 1990).

- Hydration status: GFR was higher in dogs that were hyperhydrated, so hydration status should be standardized (Kerr, 1958; Kunze *et al.*, 2006; Tabaru *et al.*, 1993). In cats, infusion of Ringer lactate at 1 to 2ml/min produced on average a 40% increase of GFR (Rasmussen *et al.*, 1985). In sheep, GFR was lower in summer than in winter because of hemoconcentration (Nawaz and Shah, 1984).
- Diet: GFR was higher in dogs fed animal proteins rather than other proteins (Bartges *et al.*, 1995a, 1995b, 1995d; Kerr, 1958). It was higher with high levels of proteins in the diet in normal dogs and cats and after renal mass reduction (Adams *et al.*, 1994; Bartges *et al.*, 1995c; Bovee, 1992; Bovee and Kronfeld, 1981; Robertson *et al.*, 1986). In partially nephrectomized dogs, low- or high-sodium diets had little influence on GFR (Greco *et al.*, 1994). In cats, GFR was moderately reduced by low-sodium diets (Buranakarl *et al.*, 2004), unchanged in cats receiving potassium-depleted food, but lowered when the same food was acidified with ammonium chloride (Dow *et al.*, 1990). In cows, GFR was unchanged by mineral supply (Hartmann *et al.*, 2001). GFR was higher in sheep fed a normal or high rather than a low protein diet (Cirio and Boivin, 1990a, 1990b; Cirio *et al.*, 1990; Eriksson and Valtonen, 1982; Rabinowitz *et al.*, 1973; Valtonen *et al.*, 1982).
- Meals: GFR increases ranging from 10% to 45% were observed after a meal of proteins in normal dogs and in dogs with renal mass reduction (Bourgoignie *et al.*, 1987; Brown, 1992; Ewald, 1967; Jolliffe and Smith, 1932; Moustgaard, 1947; O'Connor and Summerill, 1976; Reinhardt *et al.*, 1975). This postprandial increase of GFR was not observed in dogs with experimental Fanconi's syndrome (Woods and Young, 1991). It was not reduced by fasting for more than 1 day (Moustgaard, 1947). No difference in GFR was observed when ponies were fed twice a day or received the same amount of food every 2h (Clarke *et al.*, 1990).
- Exercise: GFR was unchanged by training in horses and dogs (McKeever *et al.*, 1985, 2002) or by submaximal exercise for 20 or 60min despite hemoconcentration (Hinchcliff *et al.*, 1990; McKeever *et al.*, 1991). During effort under anaerobic conditions in horses, GFR decreased sharply then returned to prerun values within 15min (Schott *et al.*, 1991).
- Drugs: In dogs and sheep, GFR was increased by glucocorticoids, probably by an increase of plasma flow rate as in rats (Baylis and Brenner, 1978; Gans, 1975). GFR was decreased by furosemide in dogs and cats (Bostrom *et al.*, 2003; Hanna *et al.*, 1988). Controversial effects of NSAIDs were reported in dogs: either no change of GFR with meloxicam, carprofen, and ketoprofen (Crandell *et al.*, 2004; Ko *et al.*, 2000; Narita *et al.*, 2005) or a moderate decrease with carprofen or ketoprofen (Forsyth *et al.,* 2000). GFR was moderately decreased after repeated excretory urograms in dogs (Feeney *et al.*, 1980a). In cats with experimental CRF, the ACE inhibitor benazepril increased GFR up to 30% (Brown *et al.*, 2001), whereas ACE inhibitors could decrease GFR in sodium-restricted dogs (Hall *et al.*, 1979).
- Biopsy: GFR was not affected after repeated renal biopsies in dogs (Drost *et al.*, 2000; Groman *et al.*, 2004).

b. Techniques of GFR Measurement

The procedures used to calculate plasma clearances may also influence the results as they depend on the mathematical model chosen (Heiene and Moe, 1999; Powers *et al.*, 1977; Watson *et al.*, 2002a) and on the proposed limited sampling strategies (Barthez *et al.*, 2001; Blavier *et al.*, 2001; Finco, 2005; Watson *et al.*, 2002a). Others have suggested measuring the concentration of an exogenous marker at a given time after injection (e.g., P-Creatinine after I.V. load in dogs) (Labato and Ross, 1991; Watson *et al.*, 2002a).

The measurement of creatinine concentrations by Jaffé technique (discussed earlier) led to erroneously high values for creatinine clearance in early studies. Because of the larger proportion of interfering substances in plasma than in urine with the Jaffé technique, P-Creatinine was overestimated in comparison to U-Creatinine (e.g., in dog urine) (Shannon *et al.*, 1932). This discrepancy between creatinine and inulin clearances does not exist when the measurements are based on the more accurate enzymatic techniques (Finco *et al.*, 1993).

The results of GFR determination may vary according to the technique so their transferability is limited (Driehuys *et al.*, 1998; Finco, 2005; Gagnon *et al.*, 1971; Izzat and Rosborough, 1989; Oester *et al.*, 1968; Rogers *et al.*, 1991), and caution is required when using decision limits from other laboratories or from the literature. Correcting factors have been proposed in some cases, for instance, for iohexol plasma clearance and exogenous creatinine urinary clearance in dogs (Finco *et al.*, 2001; Gleadhill and Michell, 1996). However, such results remain controversial. The estimation of GFR based on iohexol clearance, for example, was considered reliable in dogs and cats (Brown *et al.*, 1996), whereas others showed differences of up to 0.95ml/min/kg with creatinine clearance (Miyamoto, 2001b). The urine clearance of endogenous creatinine and the urine and plasma clearance of exogenous creatinine gave similar results (Finco *et al.*, 1981, 1991; Lee *et al.*, 1983; Watson *et al.*, 2002a), but plasma DTPA clearance was 1.15 time higher than plasma iohexol clearance in dogs (Moe and Heiene, 1995).

2000) and almost the same in both kidneys of dogs (Groman *et al.,* 2004).

- Biological rhythms: Creatinine clearance remained almost stable over 1 day in dogs (Hartenbower *et al.*, 1974; Uechi *et al.*, 1994b), horses (Morris *et al.*, 1984), cats (Uechi *et al.*, 1998), and sheep (Garry *et al.*, 1990c).

d. Variations with Disease

Decreased GFR is the gold standard of renal failure, whatever its cause or subsequent evolution (discussed later). A critical approach should always be applied in the clinical evaluation of renal function (Finco and Barsanti, 1989), especially as the results obtained differ according to the method used (discussed earlier).

Alterations of GFR may be secondary to many extrarenal diseases. GFR is decreased in hypothyroidism (Adams *et al.*, 1997) and hypoxia (Lobetti *et al.*, 1996). It may be decreased or not in experimental or spontaneous diabetes mellitus (Kaneko *et al.*, 1978, 1979). GFR evaluation is also useful for monitoring the toxicity of drugs eliminated by renal filtration (e.g., carboplatin) (Bailey *et al.*, 2004; Shapiro *et al.*, 1988) and as an indicator of the effects of renal dysfunction on the pharmacokinetics of drugs (e.g., oxytetracyclin in dogs) (Duffee *et al.*, 1990).

C. Tests of Tubule Function

1. *Concentrating Ability*

a. Urine Osmolality versus Urine-Specific Gravity

One of the most important functions of the kidney in mammals is to reabsorb more than 99% of the filtered water, so that the final urine is more concentrated than the glomerular ultrafiltrate.

Urine concentration is best evaluated by osmolality (Bovee, 1969)—that is, the concentration of particles in a solution, independently of their chemical characteristics (1 sodium ion has the same osmotic effect as 1 molecule of urea or as 1 molecule of albumin). The main determinant of specific gravity in dog urine is urea (Meyer *et al.*, 1997). The laws of osmolality are only valid for dilute solutions in which the different particles are completely independent and this is not verified in urine or plasma. See the review in Sweeney and Beuchat (1993).

The urine concentration is determined in routine tests from the specific gravity (U-SG)—that is, the ratio of the weight of 1l of solution to 1l of water, which depends on the relative proportions and the molecular weight of all the compounds in solution (for instance, 300mOsm/kg solutions of NaCl, urea, and glucose would have SGs of approximately 1.009, 1.014, and 1.054, respectively; the latter would correspond to ~1mOsm/kg solution of albumin).

Urine osmolality and specific gravity were highly correlated in dogs (Bovee, 1969; Dossin *et al.*, 2003; Harvey, 1973; Hendriks *et al.*, 1978; Meyer *et al.*, 1997), sheep (English and Hogan, 1979), and cats (Lees and Osborne, 1979). The correlation was weaker in calves (Thornton and English, 1976). Maximum concentrations could be as high as 1400mOsm/l in rabbits, 2400mOsm/l in dogs, and 3200mOsm/l in cat and sheep (Anderson, 1982).

b. Preanalytical Factors of Variation

- Specimen: In cats, U-SG was not changed by freezing (Lees and Osborne, 1979). Spot urines could give very different U-SG results in the same animal depending on the time of sampling.
- Diet: U-SG was lower in cats supplied with moist food than with dry food (Palmore *et al.*, 1978). In cows, U-osmolality was little changed when the mineral supply was reduced by 50% or increased to 200%, but the urine volume was greatly increased during the high mineral supply period (Hartmann *et al.*, 2001).
- Physical exercise: In greyhounds, U-Osmolality was decreased (~8%) by training because of increased diuresis resulting from plasma volume expansion (McKeever *et al.*, 1985). U-SG was transiently decreased for 1 to 2h after an effort under anaerobic conditions in horses (Schott *et al.*, 1991). The 25% to 75% interval for U-SG in postrace Thoroughbred horses was 1.021 to 1.033 (Cohen *et al.*, 2002).
- Environment: Water intake, urine volume, and osmolality differed significantly in sheep depending on whether the environment was cool or hot, dry or humid (Guerrini *et al.*, 1980).
- Drugs: U-SG was increased in dogs after the administration of radiographic contrast media (Feeney *et al.*, 1980b). In dogs, urine volume was increased and osmolality decreased after medetomidine (Burton *et al.*, 1998) and after glucocorticoids administration, which interferes with the action of vasopressin on the kidney (Joles *et al.*, 1980; Sirek and Best, 1952; Waters *et al.*, 1997). In horses, U-Osmolality was increased after oral sodium bicarbonate loading (Rivas *et al.*, 1997) and was low after treatment with furosemide (median 1.018) (Cohen *et al.*, 2002).
- Anesthesia: U-SG was not changed by halothane anesthesia in dogs (Lobetti and Lambrechts, 2000) but was decreased by isoflurane anesthesia in horses because of increased diuresis, maybe from the fluid support (Watson *et al.*, 2002b). In horses, U-Volume was increased, and U-SG and U-Osmolality were decreased by xylazine and detomidine (Gasthuys *et al.*, 1986, 1987; Nunez *et al.*, 2004; Steffey and Pascoe, 2002; Thurmon *et al.*, 1984; Trim and Hanson, 1986).

c. Analytical Factors of Variation

Measuring osmolality requires expensive equipment, thus is not easy to do in most veterinary clinics. Freeze-point osmometers are usually unsuitable for the direct measurement of highly concentrated urines, especially in cats (Lees and Osborne, 1979).

U-SG must be measured by refractometry. See the review in George (2001). The reagent strips available for U-SG

determination in humans should not be used for animal urine. The measurement is based on changes in ionic strength and gave satisfactory results with 80% to 90% of human urines (Burkhardt *et al.*, 1982), but it was less accurate than refractometry (Dorizzi *et al.*, 1987). Results with these test strips did not correlate with osmolality or refractometry in dogs (Allchin *et al.*, 1987; Dossin *et al.*, 2003; Paquignon *et al.*, 1993; van Vonderen *et al.*, 1995). To the authors' knowledge this test strip has not been validated in other domestic species.

d. Reference Values and Physiological Factors of Variation

The range of variations of U-SG or U-Osmolality in healthy animals is large in all species, so that reference intervals are devoid of any relevance for spot urines.

- Breed: U-SG was higher in miniature schnauzers than in labradors and might be a factor in oxalate stone formation (Stevenson and Markwell, 2001).
- Gender: Sex had no effect on canine U-SG (van Vonderen *et al.*, 1997).
- Age: U-SG was lower in aged dogs than in young adults (van Vonderen *et al.*, 1997). U-SG was low at birth in puppies, then increased over the first 2 months to values higher than those of mature dogs (Faulks and Lane, 2003; Laroute *et al.*, 2005). U-SG/osmolality in newborn foals was similar to or moderately lower than that of adults, then it decreased to a state of hyposthenuria during the first day of life and remained so for at least 2 months (Edwards *et al.*, 1990).
- Inter- and intraindividual variability: U-SG high in canine urine, CVs were in the range of 30% to 40% (van Vonderen *et al.*, 1997).
- Biological rhythms: U-SG in dogs was slightly lower in evening than in morning samples (van Vonderen *et al.*, 1997).

e. Pathological Factors of Variation

As variations in healthy animals can be large, hypo- or isosthenuria must either be confirmed on repeated samples or observed in moderately dehydrated or azotemic animals to be interpreted as an indicator of kidney dysfunction.

A concentrating ability below the commonly accepted limits of 1.030 and 1.035, in dogs and cats, respectively, is considered inadequate. See the review as this pertains to dogs in Watson (1998).

2. *Tests of Water Deprivation*

When plasma osmolality increases, osmoreceptors in the hypothalamus stimulate the release of ADH in blood, thus increasing water reabsorption and equilibrating plasma osmolality. Diabetes insipidus is an uncommon condition characterized by polyuria and polydipsia without glucosuria. It can be congenital or acquired (Harb *et al.*, 1996) and results from decreased secretion of ADH by the hypothalamus (central diabetes insipidus) or from insensitivity of kidney cells to the effects of ADH. See the reviews in Cohen and Post (2002) and Neiger and Hagemoser (1985).

Tests of water deprivation are based on the fact that sudden or progressive withholding of water produces progressive dehydration. The resulting increase in extracellular fluid osmolality triggers the release of ADH, thus an increase of U-Osmolality and U-SG in healthy subjects. The concentrating ability after exogenous ADH administration can be measured to test whether the absence of urine concentration results from a central defect of ADH secretion or from peripheral resistance to ADH. See the review in Finco (1995a). Protocols for test combination have been proposed (Mulnix *et al.*, 1976), as well as for ADH measurement, but they have not gained wide acceptance (Biewenga *et al.*, 1987). In dogs as in humans, urinary excretion of aquaporin-2 occurs in parallel to ADH action and can be used as a marker of collecting duct responsiveness (van Vonderen *et al.*, 2004).

Water deprivation tests may be hazardous, so should only be used to investigate polydipsia-polyuria once significant kidney damage has been ruled out (MacDougall, 1981). They are contraindicated in dehydrated, azotemic, or hypercalcemic dogs or cats (Barsanti *et al.*, 2000).

Water restriction in 10-month-old beagles produced maximum U-SG = 1.070 after up to 23h of water deprivation (Balazs *et al.*, 1971). In adult dogs, maximum U-Osmolality was 2738mOsm/kg with corresponding U-SG of 1.076 after 72h and a weight loss of 16% (Hardy and Osborne, 1979). In horses, water deprivation for 72h led to an average loss of weight of 8%, and an increase in U-SG (mean ~1.050), the hematocrit, and P-Proteins (Genetzky *et al.*, 1987; Rumbaugh *et al.*, 1982).

3. *Urine Excretion of Ions*

a. Fractional Excretion

Many electrolytes are intensely reabsorbed after filtration, mainly in the proximal tubule; their excretion is thus increased when tubule dysfunction occurs. Urine electrolyte concentrations also depend on the alimentary supply as the homeostatic mechanisms aimed to stabilize plasma concentration modulate tubule reabsorption. They can thus greatly differ as a function of the diet in all species and on the proximity of meals in monogastric animals.

The most meaningful information would be obtained from daily urine excretion, which is often impossible to obtain because of the difficulties associated with urine collection. Expressing the urinary elimination of a solute (X) as the ratio of the filtered load that is found in urine has been proposed, whence the name fractional excretion (FE):

$$\begin{aligned} FE_X &= \text{amount in urine/amount filtered} \\ &= (\text{U-X} \times \text{U-Volume})/(\text{P-X} \times \text{GFR}) \end{aligned}$$

in which U-X and P-X are the urine and plasma concentration of X respectively.

If creatinine clearance is used as a measurement of GFR, it can be demonstrated that FE is equal to the ratio of the solute clearance to creatinine clearance, thus the synonym fractional clearance may be preferred (Constable, 1991). FEs can easily be determined in "spot" samples of plasma and urine according to the following equation:

$$FE_X = (U\text{-}X/P\text{-}X) \times (P\text{-Creatinine}/U\text{-Creatinine})$$

Such spot measurements are often well correlated with daily elimination. See the reviews in Coffman (1980) and King (1994). However, spot determinations in cats are highly variable compared with 72-h values, and should thus be interpreted with caution (Finco *et al.*, 1997). FE_{Na} and FE_K are poor indicators of the daily excretion of these ions in animals with renal failure (Adams *et al.*, 1991). FEs and standard clearances are highly correlated in horses for sodium, potassium, and phosphates (Traver *et al.*, 1977) (e.g., spot measurements of FE_{Pi} are within 0.1% of the calculated 24h value) (Lane and Merritt, 1983). In sheep FE_{Na}, FE_K, FE_{Cl}, and FE_{Pi} are highly correlated with the respective daily urine excretion of these ions (Garry *et al.*, 1990c).

b. Preanalytical Factors of Variation of Ion Excretion

- Diet: Daily elimination and FE_{Na}, FE_K, FE_{Ca}, and FE_{Mg} are higher in fed than in nonfed healthy dogs, whereas the excretion of phosphate is unchanged (Lulich *et al.*, 1991). Diuresis and urine mineral composition differ according to food composition and intake in dogs (Zentek *et al.*, 1994) and cats (Sauer *et al.*, 1985a, 1985b) (e.g., cats fed a low K diet had lower FE_K and higher FE_{Cl}) (Dow *et al.* 1990); cats supplemented with magnesium showed a four-fold increase of FE_{Mg} (Norris *et al.*, 1999a), and FE_{Ca} was increased in phosphate-depleted dogs (Goldfarb *et al.*, 1977). FE_{Pi} is lower in dogs fed low-phosphate diets (Polzin *et al.*, 1991) and low-protein diets (Polzin and Osborne, 1988). In cattle (see a review in Lunn and McGuirk [1990]), the composition of the diet greatly influences electrolyte balance, especially for calcium and magnesium (Gray *et al.*, 1988): FE_{Mg} was about three times higher in cows receiving oral magnesium hydroxide than in controls (Kasari *et al.*, 1990) and is mainly used to test magnesium status (Sutherland *et al.*, 1986). In cows receiving a high mineral diet, FE_{Ca}, FE_{Mg}, and FE_{Pi} were increased (Hartmann *et al.*, 2001). In sheep artificially loaded with NaCl by oral or intraruminal route, GFR, FE_{Na}, and FE_K increased, whereas P-Sodium remained stable (Meintjes and Engelbrecht, 1993). In cattle, sodium bicarbonate loading increased FE_{Na} and FE_{HCO3}, decreased FE_{Mg} and FECa, but had no effect on FE_K, FE_{Cl}, and FE_{Pi} (Roby *et al.*, 1987). In mares, FE_{Ca} and FE_{Pi} are dependent on the diet (e.g., FE_{Pi} ranged from almost 0% to 20% when mares fed on pasture alone or with a high-P mineral supplement) (Caple *et al.*, 1982a, 1982b). FE_{Ca}, FE_{Mg}, and FE_{Pi} were increased in cows receiving a high-mineral diet (Hartmann *et al.*, 2001).
- Meals: In cats, urine excretion of phosphates and magnesium is moderately higher in the postprandial period (Finco *et al.*, 1986). Postprandial variations of FE_{Na} and FE_{Pi} were observed in cats fed a high-phosphate high-sodium diet (Finco *et al.*, 1989). FEs were altered after large meals in ponies (Clarke *et al.*, 1990)
- Physical exercise: In horses, FE_K, FE_{Na}, and FE_{Cl} were decreased by training (McKeever *et al.*, 2002). FE_{Na} was increased, whereas FE_{Cl} was decreased, and FE_K remained unchanged during submaximal exercise (McKeever *et al.*, 1991) or transiently decreased immediately after effort under anaerobic conditions (Schott *et al.*, 1991).
- Drugs and fluid therapy: In dogs, FE_K is increased in volume expansion by NaCl infusion (Massry *et al.*, 1969). FE_K and FE_{Cl} but not FE_{Na} are increased after medetomidine administration in dogs (Burton *et al.*, 1998). In horses, I.V. infusions of glucose or saline solutions increased FE_{Na}, FE_{Cl}, and FE_{Pi}, and FE_K was also increased after glucose infusion (Roussel *et al.*, 1993). In ponies, administration of xylazine increased FE_K, FE_{Na}, and FE_{Cl} (Trim and Hanson, 1986).

c. Analytical Factors of Variation

Ion concentrations in urine are usually measured with the same techniques as in plasma with ad hoc dilutions when necessary, but techniques have not been validated in animal species. An interfering substance in the urine of sheep, cattle, horses, and cats, but not dogs, causes falsely low results for potassium but not sodium with ion-selective electrodes (Brooks *et al.*, 1988).

d. Reference Intervals and Physiological Factors of Variation

Mean values of FEs collected from the literature are summarized in Figure 16-8. It should be remembered, as emphasized in horses (Morris *et al.*, 1984), that interindividual variations are large and the values observed in individuals may be outside the limits of each group.

- Age: In puppies, FE_{Na} increased during the first 6 months of life, whereas FE_K peaked at about 4 months, and FE_{Cl}, FE_{Ca}, and FE_{Pi} were little changed (Lane *et al.*, 2000).
- Pregnancy-lactation: In cows, significant changes in FE_{Na}, FE_K, FE_{Cl} , FE_{Ca}, and FE_{Pi} were observed prepartum and during lactation (Ulutas *et al.*, 2003). FE_{Na}, FE_K, and FE_{Cl} were unchanged with the stage of lactation, whereas FE_{Pi}, FE_{Ca}, and FE_{Mg} differed (Fleming *et al.*, 1992).
- Biological rhythms: In fasted dogs, FE_{Na} and FE_{Ca} were higher in the morning and FE_{Pi} in early afternoon (Hartenbower *et al.*, 1974). In cows, FE_{Na}, FE_K, FE_{Cl}, FE_{Ca}, FE_{Pi}, and FE_{Mg} did not vary significantly over 24h

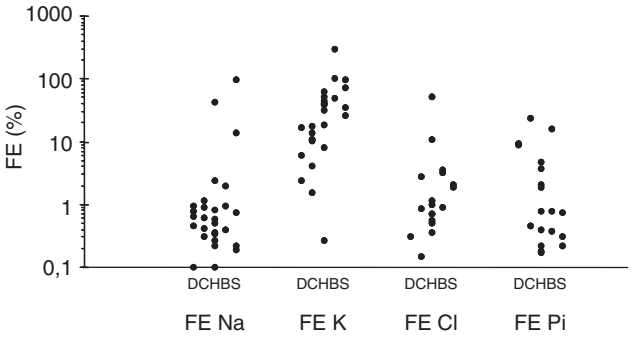

FIGURE 16-8 Mean values of FE of sodium, potassium, chloride, and inorganic phosphates. Each point is the result of an original study in dogs (D), cats (C), horse (H), bovine (B), and sheep (S). The y-axis has a logarithmic scale.

FE_{Cl} *Cattle: Buranakarl *et al.*, 2004; Burton *et al.*, 1998; Dow *et al.*, 1990. *Dog: Edwards, 1989. *Cat: Fleming *et al.*, 1991; Garry *et al.*, 1990a, 1990b. *Horse: Gelsa, 1979; Kohn and Strasser, 1986; McKeever *et al.*, 1991; Morris *et al.*, 1984; Neiger and Hagemoser, 1985; Roussel *et al.*, 1993; Russo *et al.*, 1986. *Sheep: Toribio *et al.*, 2005; Ulutas *et al.*, 2003.

FE_{Pi} *Cattle: Bickhardt and Dungelhoef, 1994; Caple *et al.*, 1982. *Dog: Caple *et al.*, 1982; Edwards, 1989. *Cat: Finco *et al.*, 1997. *Horse: Fleming *et al.*, 1991; Garry *et al.*, 1990a, 1990b; Gelsa, 1979; Kohn and Strasser, 1986; Lane and Merritt, 1983; Lulich *et al.*, 1991; Neiger and Hagemoser, 1985; Roussel *et al.*, 1993; Russo *et al.*, 1986. *Sheep: Toribio *et al.*, 2005; Traver *et al.*, 1977; Ulutas *et al.*, 2003.

but most showed great interindividual variability (Fleming *et al.*, 1991). Other authors have observed significant changes in Pi, Na, and K total excretion and FEs with maximal values at the middle of the day, which did not depend on age or production category (high or low) (Fleming *et al.*, 1992).

e. Pathological Factors of Variation

The main difficulty when interpreting FEs in the diagnosis of renal disease is that they are greatly influenced by all extrarenal factors involved in the regulation of plasma electrolyte balance, mainly by dietary supply (Finco and Barsanti, 1989; Finco *et al.*, 1992a). As a result, the interpretation of increased FEs in terms of tubular dysfunction is often hypothetical. Only repeated measurements under well-controlled conditions (e.g., experimental settings) may offer some relevance.

In cats with severe CRF, the FEs of ions were normal in most animals, and their measurement did not seem to improve diagnosis (Filippich, 1992). In dogs, it was shown that FE_{Pi} was a less accurate indicator of CRF than P-Creatinine (Gleadhill, 1994).

FEs are also changed in nonrenal diseases. In diabetic cats, FE_{Mg} was about 20 times higher than in controls and could be responsible for the frequent hypomagnesemia observed in diabetes mellitus (Norris *et al.*, 1999b). In the cat, a case of increased FE_{Pi} with normal P-Phosphates is described, probably because of deficient reabsorption and resulting in rickets-like symptoms (Henik *et al.*, 1999). In horses, FE_K is moderately but insignificantly lower during rhabdomyolysis (Beech *et al.*, 1993)

IV. TESTS OF KIDNEY DAMAGE

A. Glomerular Damage

1. *Proteinuria*

Proteinuria is one of the most frequent abnormalities in routine urinalysis and was observed in about 43% and 50% of canine and feline samples submitted to a university hospital (Barlough *et al.*, 1981). See the review on human proteinuria in Waller *et al.* (1989). Although glomerular damage is the cause of the most intense proteinurias, it is not the only one: these can also originate from the tubules and their cause may be pre- or postrenal (Table 16-2). See the consensus statement on canine proteinuria in Lees *et al.* (2005).

The following systematic approach is required in cases of confirmed proteinuria: (1) check that it is persistent, (2) evaluate the magnitude, and (3) localize the origin. See the reviews in Hurley and Vaden (1995), Kunze *et al.* (2006), and Lees *et al.* (2005).

a. Origin of Urinary Proteins

The characteristics of the glomerular filtration slit (see Section I.B) are such that almost no or very little plasma protein is filtered. The MW of albumin is closest to the filtration threshold, so this is the first plasma protein to

TABLE 16-2 Categories of Causes of Proteinuria Based on the Site or Mechanism of the Underlying Abnormality

Prerenal (Definition: due to abnormal plasma content of proteins that traverse glomerular capillary walls having normal permselectivity properties.) Normal proteins that are not normally present free in the plasma (e.g., hemoglobin or myoglobin). Abnormal proteins (e.g., immunoglobulin light chains) (Bence-Jones proteins).
Renal (Definition: due to abnormal renal handling of normal plasma proteins.) **Functional** (Definition: proteinuria that is due to altered renal physiology during or in response to certain transient phenomena [e.g., strenuous exercise, fever, and so on].) The key distinction here is that the proteinuria is not attributable to presence of renal lesions. The hallmarks of this type of proteinuria are that it is mild and transient—that is, it promptly resolves when the condition that is generating it resolves. **Pathological** (Definition: proteinuria that is attributable to structural or functional lesions within the kidneys, regardless of their magnitude or duration.) **Glomerular** (Definition: due to lesions altering the permselectivity properties of the glomerular capillary wall.) **Tubular** (Definition: due to lesions that impair the tubular recovery of plasma proteins that ordinarily traverse glomerular capillary walls having normal permselectivity properties.) These plasma proteins traffic into the urine from glomerular capillaries. They consist mainly of low-molecular-weight proteins but may also include small amounts of moderate molecular weight proteins (e.g., albumin). **Interstitial** (Definition: due to inflammatory lesions or disease processes [i.e., acute interstitial nephritis] causing exudation of proteins into the urinary space.) These proteins traffic into the urine from peritubular capillaries.
Postrenal (Definition: due to entry of protein into the urine after it enters the renal pelvis.) **Urinary** (Definition: due to entry of proteins derived from hemorrhagic or exudative processes affecting the walls of the urine excretory pathway, renal pelvis, ureter, urinary bladder, and urethra [including into the urethra from the prostate gland in males].) **Extraurinary** (Definition: due to entry of proteins derived from secretions or from hemorrhagic and/or exudative processes affecting the genital tract and/or external genitalia during voiding or in the process of collecting urine for analysis.)

escape into urine in the case of glomerular disturbance. See the review in Mathieson (2004). Filtered proteins are almost totally reabsorbed in the tubule, and the remaining molecules are substantially degraded before excretion in human or rat urine; this may lead to underestimation of U-Proteins with certain techniques but has not been documented in domestic animals (Greive *et al.*, 2001).

A mixture of serum-derived proteins can be identified in normal dog urine (Porter, 1964, 1966), but their concentrations are very low, except for albumin, and undetected by routine techniques. Other "normal" urinary proteins (i.e., Tamm-Horsfall protein secreted by the distal tubule) (see the review in Pressac [2000]), urokinase, and secretory immunoglobulins A are added in the tubule. Tamm-Horsfall protein is the major constituent of proteinaceous casts (Sanders *et al.*, 1990) and may be involved in vitamin A excretion in dogs (Schweigert *et al.*, 2002) and in urine stone formation as its excretion is about 10 times lower in stone formers (Raila *et al.*, 2003).

b. Protein Concentration versus Daily Protein Output versus U-(Protein/Creatinine) Ratio

Spot urine protein concentration can differ considerably within a given animal, depending mainly on the urine concentration. Better estimates of proteinuria would be obtained by measuring total daily excretion, but this is difficult due to the need to collect urine for 24h. The concentration of creatinine, which is inversely related to urine dilution, is used as a correction in spot samples as its excretion in a given animal is supposed to be fairly constant. Urine protein excretion is thus expressed as the U-(Protein/Creatinine) ratio (U-P/C), in which the concentrations of the two analytes are expressed in mg/l. This ratio has gained general acceptance in clinical pathology. See the reviews in Lulich and Osborne (1990) and Price *et al.* (2005).

The U-P/C ratio in spot urines is well correlated with 24-h urine excretion in healthy and CRF dogs and cats (Adams *et al.*, 1992; Barsanti and Finco, 1979; Grauer *et al.*, 1985; Monroe *et al.*, 1989; White *et al.*, 1984).

c. Preanalytical Factors of Variation

- Specimen: The method of urine collection (natural voiding, catheterization, cystocentesis) was not found to have a significant effect on U-Proteins in dogs (Barsanti and Finco, 1979). U-P/C could be increased in cases of cystitis and blood contamination of urine (Bagley *et al.*, 1991).
- Diet and meals: U-Protein was higher in dogs with CRF, fed high-protein diets (Polzin *et al.*, 1983, 1984). U-P/C is moderately decreased 4 to 8h after a meal (Jergens *et al.*, 1987).
- Housing: U-P/C was higher in hospitalized non-proteinuric dogs than in nonhospitalized ones and was generally lower than 0.5 (McCaw *et al.*, 1985).
- Drugs: In dogs, long-term glucocorticoid therapy produced a regular increase of U-P/C $>$ 0.5 at 2 weeks

and peaked slightly above 1.0 after 4 weeks (Waters *et al.*, 1997). Nephroangiography often produces transient proteinuria (Holtas *et al.*, 1981).

d. Techniques

• Detection: The different screening techniques do not provide the same results. See the review in human medicine (Thysell, 1969). Proteinuria detection is most often based on the use of test strips, the detection limit being 0.25 to 0.30g/l for albumin but much higher for globulins (Behr *et al.*, 2003). Moreover, as the reagent patch is based on a pH indicator, falsely positive results are often observed in alkaline urines. Hemoglobin interference remains negligible as long as the urine is not colored, even if the "blood" patch is strongly positive (Jansen and Lumsden, 1985; Vaden *et al.*, 2004). False positives are not encountered with denaturation tests such as the sulfosalicylic acid and nitric acid ring tests, which give identical reactions with globulins and albumin. Caution should be taken in the interpretation of dipstick results for the effects of urine dilution/concentration, and readings must be interpreted with U-SG as a possible correction factor.

• Quantification: The quantification and fractionation of proteins should preferably be performed in nonconcentrated urines, although the U-Protein content is usually low, necessitating special procedures. Concentration techniques may alter the relative composition of urine proteins in human urines (Ala-Houahala *et al.*, 1984). The biuret reaction cannot be used unmodified as its quantification limit is too high (a few g/l). Older methods based on heat denaturation, turbidimetry (Hendriks *et al.*, 1976), and more recent ones using special stains such as Ponceau S and Coomassie Blue have mostly been abandoned. The main stain currently used is pyrogallol red, which gives slightly higher results with albumin than with globulins (Behr *et al.*, 2003). Calibrations are performed with different specimens (albumin, dilution of serum, concentrated urines, etc.), thus urine protein measurements can greatly differ from one laboratory to another, as with older techniques (Barsanti and Finco, 1979). U-Protein and U-P/C can be measured in canine but not feline urine with special dipsticks used for human urine (Welles *et al.*, 2006).

e. Reference Values and Physiological Factors of Variation

Proteinuria is not detected by routine techniques in urines of healthy animals, except for possible "traces" or "+" readings in highly concentrated urines. In most species, the upper limit of U-Proteins is about 0.3 to 0.4g/l as observed in piglets (Ruhrmann *et al.*, 1986) and horses (Edwards *et al.*, 1989). In normal dogs, the urinary loss of proteins is very low and the median is 6mg/kg BW/day. The value in 80% of dogs was ≤10mg/kg/day (Biewenga *et al.*, 1982), whereas others reported 14mg/kg/day (DiBartola *et al.*, 1980a). The upper limits of U-Proteins in cats were <21/mg/kg/d and 27mg/kg/d in females and males, respectively (Monroe *et al.*, 1989). The commonly accepted reference limits for U-P/C are 0.5 and 0.4 in dogs and cats, respectively (Lees *et al.*, 2005; Elliot, 2007).

• Age: In puppies, total proteinuria and U-P/C decreased in the first 6 months of life (Lane *et al.*, 2000). Total daily excretion of proteins was lower in 2-month-old puppies than in adults (Laroute *et al.*, 2005), but others detected proteins in urines of almost all dogs aged less than 3 months (Faulks and Lane, 2003). In newborn piglets there was a transient increase of U-Proteins between 6 and 24h (Parker and Aherne, 1980) because of absorption of fragments of colostral IgGs during the first day of life, and after 3 days proteins become almost undetectable (Martinsson, 1972).

• Gender: U-Protein is higher in naturally voided urine of male than female dogs; the difference is not observed in urines obtained by cystocentesis (Barsanti and Finco, 1979).

• Intra- and interindividual variations: Interindividual variations in proteinuria are much greater in adult dogs than in 2-month-old puppies (Laroute *et al.*, 2005) and are very large in cats (Russo *et al.*, 1986). In sheep, total protein excreted per 4h and U-P/C were stable for 2 days (Garry *et al.*, 1990c).

• Biological rhythms: In dogs, no differences in protein output and U-P/C were observed between night and day samples (McCaw *et al.*, 1985).

f. Pathological Factors of Variation

In human medicine, U-PC is considered a safe method to rule out the possibility of significant excessive 24-hour protein excretion (Price *et al.*, 2005). One-quarter of a colony of beagles 4 to 6 years old with no clinical signs and normal U-SG showed transient or permanent proteinuria (Stuart *et al.*, 1975).

Glomerulopathies are the cause of the most severe urine protein losses. See the review in Lulich *et al.* (1996). Dramatic increases in protein excretion are observed in canine and feline amyloidosis and membranous glomerulonephritis with values attaining 900mg/kg/day and U-P/C >10 (Biewenga and Gruys, 1986; Center *et al.*, 1985, 1987; DiBartola *et al.*, 1980b; Minkus *et al.*, 1994). Proteinuria is the earliest sign of glomerular disease in experimental glomerulonephritis of the cat (Bishop *et al.*, 1991).

Proteinuria is also observed in extrarenal conditions: exercise in the dog (Epstein and Zambraski, 1979) as in humans, plasma protein overload in dogs when P-Proteins exceed 95 to 100g/l (Terry *et al.*, 1948), and urinary infections in 90% to 95% of cases when leukocytes or bacteria are identified (Fettman, 1987, 1989). About half of the dogs

with pituitary-dependent hyperadrenocorticism show moderate increases of U-P/C (Hurley and Vaden, 1998; Ortega *et al.*, 1996).

2. *Albuminuria-Microalbuminuria*

More than 99% of filtered albumin is reabsorbed in the proximal tubule. See the review in Gekle (1998). Maximal reabsorption capacity is lower in rodents, so that a minimal increase in plasma concentration results in urine excretion, which is not observed in dogs (Gartner, 1981). The word *microalbuminuria* is used to qualify the urinary elimination of traces of albumin, below the detection limit of urine total proteins (i.e., below ~300mg/l) but above 20 to 30mg/l. These thresholds correspond to those used in human medicine for the early diagnosis of renal complications of diabetes mellitus.

Microalbuminuria cannot be detected in canine or feline urine with tests used for human microalbuminuria (Pressler *et al.*, 2002). Special tests are commercialized for the semiquantitative evaluation of microalbuminuria in canine urines (Pressler *et al.*, 2002). Preliminary studies showed that microalbuminuria was observed in a large proportion of dogs without any clinical sign of renal disease, but the upper limit of "normal" urine elimination of albumin and the effects of possible factors of variation have not been determined in dogs. Moreover, the detection of microalbuminuria does not provide any information about the existence of a possible evolutive disease of the kidney. More basic studies will be required before any use of this new test.

U-albumin in human urine is stable for up to 5 months when stored at −20°C and correctly homogenized after thawing (Brinkman *et al.*, 2005). An ELISA test with a limit of quantification of 10mg/l has been set up for use in dog urine (Vaden *et al.*, 2004). Albuminuria is unchanged in dogs after exercise for 20 min at 8km/h (Gary *et al.*, 2004).

3. *Urine Protein Electrophoresis*

The diagnostic use of electrophoresis of urinary proteins is based on the identification of selective proteinuria versus unselective proteinuria. The latter results from severe glomerular damage allowing massive transfer of all plasma proteins (unselective) including high MW immunoglobulins. The former is observed during the first stages of glomerular damage, when only low MW plasma proteins are eliminated or when tubular damage impairs the reabsorption of filtered low MW proteins, thus producing selective proteinuria. Protein identifications are most frequently performed in SDS-agarose gels where the proteins are separated according to their MW (Meyer-Lindenberg *et al.*, 1997; Muller-Peddinghaus and Trautwein, 1977; Schultze and Jensen, 1998). Protein electrophoresis permits the identification of severe glomerulo- and tubulointerstitial nephropathies but not their differentiation (Zini, 2004). The technique is 100% sensitive for glomerular damage but only 40% specific in dogs (Zini *et al.*, 2004). A more selective identification of urine proteins can be obtained by mass spectrometry; for instance, retinol-binding protein is only present in the urine of dogs with kidney damage and Tamm-Horsfall protein excretion is reduced in kidney disease (Forterre *et al.*, 2004).

In normal dogs and cats, electrophoresis shows only traces of albumin and rarely of proteins migrating in the globulin zone—that is, mainly transferrin and α1-microglobulin (Groulade *et al.*, 1977, 1978; Harvey and Hoe, 1966; Meyer-Lindenberg *et al.*, 1997; Pages and Trouillet, 1990; Yalcin and Cetin, 2004) and sometimes low-molecular-weight proteins (Muller-Peddinghaus and Trautwein, 1977; Zaragoza *et al.*, 2003).

Monoclonal or polyclonal immunoglobulin light chains (Bence-Jones proteins) are identified in ~40% of cases of monoclonal gammopathy (Leifer and Matus, 1986; Matus *et al.*, 1986), in spontaneous ehrlichiosis (Varela *et al.*, 1997), and in plasma cell malignancy (Hurvitz *et al.*, 1971).

B. Tubule Damage

1. *Urine Enzyme Activities*

a. Pathopathology

The enzymes found in urine have two origins. See the reviews in Dubach and Schmidt (1979) and Jung *et al.* (1992). Low MW plasma enzymes are filtered by the glomerulus (e.g., lysozyme or amylase) and are almost totally or partially reabsorbed by the tubule. High MW plasma enzymes cannot be filtered by the glomerulus, but they can be released by the tubule cell. The release of enzymes by other parts of the urinary tract seems negligible.

Most of the enzyme markers used in routine analysis occur mainly in the proximal tubule cell. Renal damage causes their excretion into urine to increase, but there are no increases in plasma enzyme activity, except in severe cases (Shaw, 1976). The kidney specificity of enzymes used as markers of tubule damage is not an issue as long as the MW of the enzymes is large enough to preclude glomerular filtration of the corresponding plasma circulating enzyme.

The localization of enzymes along the nephron is not homogeneous. In rats, proximal and distal tubule damage can be distinguished by measuring the respective glutathione-S-transferase and lactate dehydrogenase (Bomhard *et al.*, 1990) but this has not been used in domestic species. The intracellular localization of enzymes differs considerably, for example, alkaline phosphatase (ALP), alanine aminopeptidase (AAP), GPDAP (glycyl-prolyl-dipeptidyl aminopeptidase), and gamma-glutamyl transferase (GGT) occur in the brush borders, β-glucuronidase, N-acetyl-β-glucosaminidase (NAG) in the lysosomes, lactate dehydrogenase (LDH) and glutathione-S-transferase (GST) in the cytoplasm, and glutamate dehydrogenase (GLD) in the mitochondria. This has been used in experimental toxicology to study the progression of cell damage (Bret *et al.*, 1993), but it has not been used in clinical cases.

Enzymes cannot accumulate in urine, as they do in plasma because of their elimination with each urination. Thus, the amount of enzyme eliminated in a urine sample reflects the amount of kidney damage that has occurred since the preceding urination. However, the urine concentration of enzymes not only depends on the release of these latter from the kidneys but also on urine concentration/dilution, hence the frequent use of the U-(Enzyme/Creatinine) ratio as a correction factor in the determination in spot urines (Gossett *et al.*, 1987).

b. Preanalytical Factors of Variation

- Specimen: Many enzymes are unstable in refrigerated canine urine and are almost totally inactivated by freezing (e.g., GGT, LDH, and amylase) (Keller and Freudiger, 1984), whereas NAG and AAP are stable for one month at 4°C and −18°C after gel filtration (Reusch *et al.*, 1991). GGT is stable for 3 days at +4°C (Adams *et al.*, 1985; Gossett *et al.*, 1987).
- Anesthesia: U-GGT and U-(GGT/Cr) were increased after prolonged sevoflurane anesthesia in horses (Driessen *et al.*, 2002).

c. Analytical Factors of Variation

No technique has been validated for the measurement of urine enzyme activities, so results may differ greatly from one laboratory to another.

Better measurements of AAP and NAG enzyme activities in dog urine are obtained after the elimination of small-molecular-weight inhibitors by dialysis or gel filtration (Reusch *et al.*, 1991). Others have reported that GGT and NAG in urine from dogs (Sato *et al.*, 2002a), cattle (Sato *et al.*, 1997), horses (Adams *et al.*, 1985; Gossett *et al.*, 1987), and cats (Sato *et al.*, 2002b) can be measured without prior preparation.

d. Reference Intervals and Physiological Factors of Variation

As with plasma enzyme activity measurements, no validly transferable reference intervals are available for urine enzymes because of the lack of standard techniques and primary control material to ensure interlaboratory controls of accuracy. It is thus unwise to take such information from the literature without checking values of the laboratory.

- Gender: U-NAG was approximately two times higher in male dogs than in females (Nakamura *et al.*, 1983; Reusch *et al.*, 1991; Sato *et al.*, 1997), and was reduced by castration and by vasectomy (Higashiyama *et al.*, 1983). U-NAG was also higher in steers than in cows, but the U-(NAG/Creatinine) ratio was not influenced by sex in cattle (Sato *et al.*, 1997) and cats (Sato *et al.*, 2002b). U-GPDAP activity was higher in males than in females (Uechi *et al.*, 1997).
- Age: Neither age nor gender affected U-GGT and U-ALP activities in horses (Brobst *et al.*, 1986).
- Individuals: Inter- and intraindividual variations were large in dogs and cats (Ogura, 1986; Reusch *et al.*, 1991).
- Biological rhythms: No circadian rhythm of U-GGT or U-NAG was observed in cats (Uechi *et al.*, 1998), but the excretion of both enzymes in dogs was higher between 12:00 and 16:00 (Uechi *et al.*, 1994b) and that of GPDAP was higher between 8:00 and 12:00 (Uechi *et al.*, 1997). U-GGT and U-ALP were moderately higher in morning urines in horses (Brobst *et al.*, 1986).

e. Pathological Factors of Variation

Increased urine enzyme excretion is a sign of acute kidney damage, whatever its cause, but does not imply organ dysfunction (Ellis *et al.*, 1973b, 1973c). In many cases, significant increases of urine enzyme excretion are observed without or earlier than any alteration of the function markers (Rivers *et al.*, 1996). Urine enzyme excretion shows little or no modification in chronic renal diseases (e.g., canine CRF) (Heiene *et al.*, 1991).

Although NAG is largely used in toxicology, GGT is often preferred in routine clinical practice because of its easy measurement without urine predialysis and use of readily available reagents. Only urine NAG was increased initially when primary damage was located in the papillary zone of dogs (e.g., ethyleneimine) (Ellis *et al.*, 1973a).

Enzymuria is probably the most sensitive test for monitoring kidney damage induced by treatments with potentially nephrotoxic drugs such as gentamicin in dogs (Adelman *et al.*, 1979; Davies *et al.*, 1998; Grauer *et al.*, 1994, 1995; Greco *et al.*, 1985; Lora-Michiels *et al.*, 2001; Martinez *et al.*, 1996; Spangler *et al.*, 1980), sheep (Brown and Garry, 1988; Garry *et al.*, 1990a), and horses (Rossier *et al.*, 1995). Similar changes were observed in horses treated with neomycin: enzyme excretion was increased whereas creatinine clearance and plasma creatinine concentration were unaltered (Edwards *et al.*, 1989).

Urine enzyme excretion was also increased in renal damage secondary to extrarenal disease, such as canine leishmaniasis (Palacio *et al.*, 1997), approximately 40% of cases of pyometra (de Schepper *et al.*, 1989a, 1989b; Heiene *et al.*, 2001a), and in heartworm disease (Uechi *et al.*, 1994a). The U-NAG and U-(NAG/Creatinine) ratios were increased in cows with interstitial nephritis and amyloidosis (Sato *et al.*, 1999).

2. *Blood*

Hematuria can originate from any part of the kidney or the urinary tract. See the review in Forrester (2004). It is detected by the color of the urine, ranging from light pink to red in macrohematuria, or more frequently by routine urinalysis for invisible microhematuria. This latter is detected by the peroxidase activity of hemoproteins and can therefore give false positives with other proteins such as myoglobin or catalase. The limit of detection of hemoproteins is low, so that occult blood can be detected in the absence of a positive reaction for proteins. See the review on techniques of blood detection in Syed *et al.* (2002).

Idiopathic kidney bleeding has been reported in Weimaraners (Hitt *et al.*, 1985). See the review in Hitt (1986). Occult blood could be detected in approximately 25% of cases in 2-month-old dogs (Faulks and Lane, 2003). Blood in urine can result from sample collection, especially catheterization, as in large animals when indwelling systems are used (Godeau *et al.*, 1990). Macroscopic and microscopic hematuria could result from kidney biopsy in cats (Nash *et al.*, 1983) but only rarely (Osborne, 1971).

V. BIOCHEMICAL CHANGES IN KIDNEY DISEASE

Renal or kidney disease is a pathological process affecting any part of the kidney and may or may not be associated with alterations in kidney function. Kidney or renal failure (insufficiency) is characterized by a decrease in one or several kidney functions, first the urine concentrating ability, then the elimination of small-molecular-weight molecules from the plasma, characterizing azotemia (i.e., increases of P-Urea and/or P-Creatinine). Uremia is the syndrome resulting from renal failure. Cases of azotemia are not always primary renal azotemia caused by parenchymal damage but may be prerenal or postrenal azotemia resulting from reduced kidney perfusion and interferences with urine excretion, respectively. See the reviews in DiBartola (2005b) and Osborne and Polzin (1983).

Although the etiology of renal diseases and associated lesions may differ markedly, the differential diagnosis, prognosis, and monitoring of disease evolution or therapy is mainly based on clinical biochemistry. However, clinical biochemistry cannot identify the cause of the renal dysfunction/lesion, which requires other tools, such as renal biopsy, imaging, genetic testing, urine culture, cytology, and so on. Most of the literature available is concerned with dogs and cats and, to a much lesser degree, horses. The major renal syndromes of interest to the clinical pathologist are chronic renal failure, acute renal failure, nephrotic syndrome, and Fanconi-like syndromes because of their specific pattern of alterations in biochemical variables and the time course of these changes.

A. Chronic Renal Failure

Chronic renal failure is a slow irreversible deterioration of kidney function, which, on account of the very large functional reserve of the kidneys, occurs without clinical or biological signs over a long period. Chronic renal failure in dogs and cats is highly prevalent in old animals and is a frequent cause of death: it usually evolves more or less rapidly from early renal disease by a largely unknown process. See the reviews in Brown *et al.* (1997) and Finco *et al.* (1999). As renal disease does not necessarily imply CRF, the main challenge is to detect any kidney disease as early as possible to limit its progression by appropriate dietary and therapeutic renoprotective maneuvers. See the reviews in Braun and Lefebvre (2005), Grauer (1985, 2005), Greco (2005), and Lees *et al.* (1998).

1. *Development and Progression of Renal Failure*

Experimental models of chronic renal failure have helped to extend our knowledge of CRF progression and of the concomitant changes in biochemical variables. However, some results obtained in rodents seem not to be applicable to cats and dogs. The most commonly used model is the remnant kidney model, based on nephrectomy of the right kidney and reduction of the left kidney mass by selective ligatures of the renal arteries or by electrocoagulation of the left renal cortex. The intensity of left kidney mass reduction determines the postoperative decrease in renal function quantified by the decrease of GFR between the control and postoperative periods.

In dogs, a 5/6 renal mass reduction led to a 65% decrease in GFR and only moderate increases of P-Creatinine and P-Urea, which remained within the reference limits (Brown *et al.,* 2000). One month after the renal mass had been reduced to $^1/_{16}$ in dogs, GFR was approximately 0.75ml/min/kg and P-Creatinine approximately 300μmol/l (Finco *et al.*, 1992b). In cats, ¾ and $^5/_6$ reductions of renal mass led to reductions in renal function of one-half and two-thirds, respectively (Adams *et al.*, 1994; Miyamoto, 1998).

The only compensatory mechanism observed was hypertrophy of the remaining tissue except after subtotal kidney mass reduction, when hyperplasia occurred (Filippich *et al.*, 1985). For example, the removal of one kidney in dogs was followed by a 40% increase in weight of the remaining kidney (Carriere, 1978). Compensation was progressive, being rapid for the first 2 to 12 weeks, then slower (Churchill *et al.*, 1999). This explains why the immediate postoperative GFR value is not indicative of the GFR measured several weeks later (Lefebvre *et al.*, 1998a). The GFR decrease was generally less than expected from the reduction of renal mass, and hypermetabolism was observed in the remaining kidney tissue (Fine, 1991). It is thus recommended to wait at least 6 to 8 weeks after surgery to obtain stationary conditions before testing renal function.

Compensation is dependent on many factors, especially nutrition. It was less effective in dogs fed a low-protein (White *et al.*, 1991) or a high-phosphorus diet (Finco *et al.*, 1992b) and in the case of hypertension (Finco, 2004), whereas dietary sodium supply had no effect, except when very low (Greco *et al.*, 1994). Cats with experimental CRF fed a low-sodium diet had lower GFR values than cats fed a normal diet (Buranakarl *et al.*, 2004).

The progression of renal disease is poorly understood (Terzi *et al.*, 1998) and leads to clinical disturbances of increasing severity. This has led experts to propose dividing canine and feline CRF into four stages based on P-Creatinine

TABLE 16-3 Staging of Chronic Renal Failure in Dogs and Cats According to the IRIS Group of Experts

Stage	Creatinine (μmol/L)	Comments
I	<125 dogs <140 cats	Nonazotemic Some other renal abnormality present (e.g., inadequate urinary concentrating ability without identifiable nonrenal cause); abnormal renal palpation or abnormal renal imaging findings; proteinuria of renal origin; abnormal renal biopsy results; increasing plasma creatinine concentration noted when serial samples have been collected
II	125–179 dogs	Mild renal azotemia (lower end of the range lies within the reference range for many laboratories, but the insensitivity of creatinine as a screening test means that animals with creatinine values close to the upper reference limit often have excretory failure)
	140–249 cats	Clinical signs usually mild or absent
III	180–440 dogs 250–440 cats	Moderate renal azotemia Many extrarenal clinical signs may be present
IV	>440 dogs and cats	Severe renal azotemia Many extrarenal clinical signs are usually present

Reproduced from Elliott (2007).

at presentation (Table 16-3) and substagings based on proteinuria and blood pressure (Elliott, 2007). Experimental CRF does not necessarily lead to self-perpetuating renal disease (i.e., a spontaneous decline of GFR over time). Kidney function in dogs with a 75% reduction of renal mass was stable up to 4 years, except in some animals fed low-protein diets (Bovee *et al.*, 1979), but not in others (Robertson *et al.*, 1986). Following uninephrectomy in 7- to 8-year-old dogs, $^{23}/_{31}$ animals survived 4 years, and the GFR remained stable at ~3.5ml/min/kg, irrespective of dietary protein content (18% and 24%) (Finco *et al.*, 1994). GFR was stable for 1 year, and U-P/C was moderately increased but remained below 0.3 after uninephrectomy in young cats (Finco *et al.*, 1998). After 15/16 nephrectomy, renal function decreased rapidly in dogs fed a high-Ca, high-P diet (Brown *et al.*, 1991).

Spontaneous CRF results mainly from tubular-interstitial disease, amyloidosis, and glomerulonephritis, which progress to the uremic syndrome (multiple organ dysfunctions) when end-stage renal failure is reached (Polzin *et al.*, 2000). These dysfunctions probably result from the accumulation of solutes normally excreted by the kidney, the so-called uremic toxins. Ninety molecules, most of them nonidentified, are considered to be potential uremic toxins. See the reviews in Boure and Vanholder (2004), Vanholder and De Smet (1999), Vanholder and Glorieux (2003), and Yavuz *et al.* (2005), but urea and creatinine have little or no toxicity.

Familial renal diseases in dogs and cats provide unique models for human medicine, as most of them lead to the development of CRF. See the reviews in DiBartola (2005a) and Lees (1996). The biochemical findings in such patients when clinical signs are present are the same as in dogs with CRF (see the review in DiBartola, 2000). Proteinuria and hypercholesterolemia are present in primary glomerular disease, as observed in Bernese mountain dogs. Glucosuria may be observed in primary renal tubular defects in Norwegian elkhounds and basenjis (see later Fanconi-like syndromes). The major laboratory finding in Welsh corgis with renal telangiectasia is marked hematuria.

2. Biochemical Changes in Animals with Spontaneous CRF

The most frequent biochemical findings in CRF are isosthenuria, proteinuria, azotemia, hyperphosphatemia, and metabolic hyperchloremic acidosis. When the CRF diagnosis cannot be confirmed, GFR should be measured. Although it is relatively rare in horses, CRF produces biochemical alterations similar to those observed in dogs and cats. See the review in Schott (2004).

- Azotemia is a common finding in dogs and cats with CRF and is sometimes the only biochemical criterion used to diagnose CRF. However, it was absent or mild at presentation in about 50% of dogs with glomerulonephritis or renal amyloidosis (Cook and Cowgill, 1996; DiBartola *et al.*, 1989). It was commonly observed in cats and sharpei dogs with amyloidosis (Grauer and DiBartola, 2000). Survival was inversely correlated to P-Creatinine in cats and dogs with CRF (Allen *et al.*, 1987; Elliott *et al.*, 2000). The variations of P-Urea in dogs and cats with CRF are usually similar to those of P-Creatinine, except in cases when P-Urea synthesis is decreased (e.g., in animals with liver insufficiency). Serial P-Urea measurements to determine the need to adapt dietary protein level in dogs with CRF have been recommended (Devaux *et al.*, 1996).
- Isosthenuria is a frequent finding in dogs with CRF and is the earliest observable urine alteration. It probably results from the increased filtration by remaining nephrons leading to a high urinary volume that overwhelms reabsorptive capacity, thereby producing urine dilution, polyuria, and polydipsia. See the review in Hughes (1992). Isosthenuria in azotemic or dehydrated animals is a good

indicator of the inability of the kidney to concentrate urine. U-SG and P-Creatinine are inversely related in cats (Elliott *et al.*, 2000), but cats with CRF retained concentrating ability longer than dogs (Ross and Finco, 1981), although decreased U-SG was frequently observed in cases of severe CRF (Deguchi and Akuzawa, 1997; Elliott and Barber, 1998). As U-SG is higher in puppies than in adult dogs (noted earlier), the cutoff value for abnormally low U-SG should therefore be higher.

- Proteinuria may or may not be present in CRF. The identification of proteinuria does not mean that its cause is renal and this needs to be ascertained by rational diagnosis. When proteinuria is observed in dogs and cats with CRF, it is generally mild to moderate. However, there is some evidence that the presence of proteinuria in CRF dogs or cats aggravates prognosis (Brown *et al.*, 1998a, Grauer, 2005). The persistence of proteinuria should be confirmed by repeated measurement over time (Lees *et al.*, 2005). Although U-P/C is usually higher in dogs with amyloidosis than in dogs with glomerulonephritis, and higher in the latter than in dogs with interstitial nephritis, proteinuria cannot be relied on for differential diagnosis of the underlying renal disease, which requires a renal biopsy (Grauer and DiBartola, 2000). When renal proteinuria is present in dogs or cats, the current recommendation is to treat it to avoid complications, when the U-P/C in nonazotemic animals is higher than 1, and in azotemic patients, higher than 2. See reviews in Lees *et al.* (2005) and Lulich *et al.* (1996). Angiotensin-converting enzyme inhibitors are the currently used antiproteinuric agents. The administration of such agents was shown to decrease U-P/C in dogs (Grauer *et al.*, 2000) and cats (Brown *et al.*, 2001). The magnitude of proteinuria may decrease in end-stage renal disease, when GFR decrease is severe (Jaenke and Allen, 1986).
- Hypoalbuminemia occurs in many dogs and cats with glomerular disease as a consequence of increased urinary loss of proteins. Severe hypoalbuminemia ($<$21g/l) was observed in 70% of dogs with amyloidosis (DiBartola *et al.*, 1989).
- Hyperphosphatemia is a frequent finding in clinical CRF, but it is uncommon in patients with subclinical renal disease. It is currently considered that hyperphosphatemia per se does not directly contribute to clinical signs but is the main cause of renal secondary hyperparathyroidism, which is observed in models of CRF (Grunbaum *et al.*, 1984) and in spontaneous cases (e.g., in about 84% of cats with CRF) (Barber and Elliott, 1998). The precise pathophysiology of secondary hyperparathyroidism in dogs remains unclear. See reviews in Nagode *et al.* (1996) and Yaphé and Forrester (1994). Phosphate retention is increased as renal failure progresses. As a result of phosphate binding and decreased formation of calcitriol in the kidney, the ionized calcium concentration progressively decreases, thus inducing a progressive increase of PTH secretion, which enhances calcium mobilization from bone and absorption from the intestine and phosphate elimination by the kidney. Finally at the ESRF stage, PTH secretion becomes resistant to calcium suppression, leading to tertiary hyperparathyroidism. In rare cases, hyperphosphatemia may lead to renal osteodystrophy (Nagode and Chew, 1992), but PTH probably contributes to the pathophysiology of the uremic syndrome and may be a uremic toxin. The parathyroid concentration therefore needs to be measured in uremic animals for hyperparathyroidism diagnosis (Polzin *et al.*, 2000), and results should be interpreted with regard to serum calcium concentration, especially that of ionized calcium. In small animal nephrology, minimizing hyperphosphatemia and hyperparathyroidism by dietary phosphorus restriction, the use of intestinal phosphate binding agents, and the possible administration of calcitriol is a therapeutic goal (Nagode *et al.*, 1996). Careful monitoring of phosphatemia is therefore recommended in dogs and cats with CRF.
- Hyperphosphatemia is frequently associated with moderate hypocalcemia, which may be masked when hypercalcemia is the cause of renal disease. See the reviews in Kruger and Osborne (1994a, 1994b) and Kruger *et al.* (1996). In horses, CRF usually produced hypercalcemia and hypophosphatemia (Brobst *et al.*, 1977, 1978a; Roberts and Seiler, 1979) but hyperphosphatemia was also observed in a few cases (Brobst *et al.*, 1977). This hypercalcemia may result from the fact that calcium is more strongly excreted by the horse kidney than in other species (see excretion of crystals of calcium carbonates) (Kruger *et al.*, 1996). Hypocalcemia and hyperphosphatemia were observed in 70% of azotemic cattle but did not permit differentiation of prerenal from renal or postrenal causes (Brobst *et al.*, 1978b).
- Electrolyte and water disturbances are frequent, especially in advanced stages of CRF. Dehydration is highly prevalent in cats ($\sim$70%) (Lulich *et al.*, 1992) and should be regularly determined during renal disease from repeated measurements of PCV, total proteins, and body weight. Metabolic hyperchloremic acidosis is due to the decreased excretion of hydrogen ions, bicarbonate wasting, and chloride retention. The estimated overall prevalence in cats was 63% to 80% (DiBartola *et al.*, 1987; Lulich *et al.*, 1992), or 0% in nonuremic cats to about 50% in cats with end-stage CRF (Elliott and Barber, 1998). Thus, the acid-base status should be investigated in all uremic patients. Acidosis may have several adverse effects on cardiovascular physiology, promote protein malnutrition, and induce bone demineralization. Hypokalemia has been reported in cats with CRF (Lulich *et al.*, 1992) but is apparently uncommon in dogs. The muscle potassium content decreased in normokalemic cats with CRF (Theisen *et al.*, 1997). The cause-effect relationship between kalemia and CRF remains unclear, but hypokalemia may be

responsible for general weakness, anorexia, and decreased renal function.

- Hyperlipidemia and hypercholesterolemia have been reported in dogs with glomerular diseases and nephrotic syndrome (Cook and Cowgill, 1996; DiBartola *et al.*, 1989). For example, the estimated prevalence of hypercholesterolemia in dogs with glomerular amyloidosis was 86% (DiBartola *et al.*, 1989). These changes probably result from a combination of increased hepatic synthesis and decreased catabolism of proteins and lipoproteins. Hypercholesterolemia and hyperlipidemia may contribute to further renal damage.
- Hematological alterations: CRF is associated with the development of progressive nonregenerating anemia. The main cause in dogs and cats (Oishi *et al.*, 1993) is the decreased synthesis of erythropoietin (EPO). See the review in Cowgill (1992). However, an overlap of EPO concentrations was observed in anemic dogs or cats with and without CRF (Oishi *et al.*, 1995; Pechereau *et al.*, 1997). A loss of antithrombin III by increased filtration and platelet hypersensitivity resulting from hypoalbuminemia was reported in canine nephrotic syndrome and other forms of glomerulonephritis (Greco and Green, 1987; Green *et al.*, 1985), resulting in the thrombus formation reported in cases of amyloidosis (Slauson and Gribble, 1971).

B. Acute Renal Failure

1. *Definition, Etiology, and Pathophysiology*

Acute renal failure (ARF) is "a clinical syndrome characterized by the sudden onset of hemodynamic, filtration and excretory failure of the kidneys with subsequent accumulation of metabolic (uremic) toxins and dysregulation of fluid, electrolyte and acid-balance" (Cowgill and Elliott, 2000). ARF is generally reversible (unlike CRF) if diagnosed early and given adequate therapy. Whereas CRF results from a progressive decline of GFR, the cause of which most often remains unknown, ARF is associated with an acute decline in GFR frequently caused by an ischemic or toxic insult. Probably, one of the most difficult challenges in nephrology is to differentiate ARF from end-stage CRF as the clinical signs (depression, vomiting, diarrhea, anorexia, and dehydration) and laboratory findings (azotemia, hyperphosphatemia, hyperkalemia, metabolic acidosis, and isosthenuria) are identical.

The etiology of ARF is generally classified as prerenal, intrinsic renal parenchymal, and postrenal (Narins *et al.*, 1992). Prerenal ARF is a functional decline in glomerular filtration resulting from a decrease in renal blood flow or perfusion pressure. Azotemia and increased U-SG are hallmarks of this condition. However, increased urine concentration may be masked by concomitant diseases (e.g., CRF, hepatic insufficiency) that impair the kidney's ability to concentrate urine. Renal parenchymal ARF is produced by intrinsic damage to the kidney caused by toxic insults, CRF, systemic diseases affecting renal function, or by prerenal ARF. Postrenal ARF is the consequence of obstruction or diversion of urine outflow, and accumulation of excretory products in the body. See the review in Cowgill and Elliott (2000). Three consecutive phases of ARF have been described: the initiation phase (subclinical lasting from hours to days) in which the kidneys are subjected to the renal insult; the maintenance phase (lasting from a few days to 2 to 3 weeks), which develops when lesions of the renal tubules have been established; and the recovery phase associated with an improvement of renal function. The initiation phase is difficult to identify from a pathological point of view unless the onset of ARF is relatively slow. In such conditions, GFR decreases progressively, P-Creatinine and P-Urea increase but may remain within the reference intervals, urine-concentrating ability may change, and urine abnormalities (proteinuria, cylindruria, enzymuria) may be present. The maintenance phase is characterized by the most severe clinical signs and by plasma and urine biochemical alterations. The clinical signs and biochemical findings are generally resolved during the recovery phase unless the lesions are irreversible. Polyuria is usually observed. See the reviews in (Grauer and Lane, 1995; Lane *et al.*, 1994a, 1994b; Lulich *et al.*, 1992).

Experimental models of ARF in various domestic animal species were first based on binephrectomy in ponies (Tennant *et al.*, 1981), sheep (Simesen *et al.*, 1979), and bulls (Watts and Campbell, 1970, 1971). Ruminants survived longer than monogastric animals (about 7 days) and showed almost linear increases of P-Urea and P-Creatinine, whereas P-Phosphates and P-Potassium were little changed and P-Calcium was decreased. Many other models based on nephrotoxic agents such as mercuric chloride, uranyl acetate, and so on, surgery, radiation have been used, but the resulting alterations in urine/plasma biochemistry tend to differ as the various agents do not produce the same initial events and subsequent cascade (Stein *et al.*, 1975). Moreover, the biochemical alterations may differ considerably, according to the renal status of the animal. For example, in gentamicin-induced nephrotoxicity, polyuric hypokalemic ARF is observed in dogs with normal renal function or renal impairment at the onset of treatment, and this can lead respectively to reversible polyuric hypokalemic ARF or to fatal oligoanuric hyperkalemic ARF (Frazier *et al.*, 1986).

2. *Urine and Plasma Biochemical Findings in* ARF

Urine and plasma biochemical findings are essential to distinguish between types of ARF. Generally, in prerenal ARF, hypersthenuric urine is produced as the ability of the kidney

to concentrate urine is not impaired. If azotemia is present and the U-SG decreased, then renal parenchymal ARF should be considered. Distinction from CRF may be difficult. Nonregenerative anemia, normo- or hypokalemia, is more common in CRF (Grauer and Lane, 1995). Metabolic acidosis is generally more severe in ARF. For a similar degree of azotemia, animals with ARF exhibited more severe electrolyte disturbances than animals with prerenal azotemia or CRF (Cowgill and Elliott, 2000). The commonest life-threatening electrolyte disturbance in ARF is hyperkalemia, which may cause weakness, cardiac arrhythmia, and possible death of the animal. However, hypokalemia may also develop during the diuretic stage of ARF. Moreover, abnormally low plasma concentrations of sodium, calcium, magnesium, and potassium may exacerbate the development of ARF, especially in case of nephrotoxicity (e.g., caused by gentamicin) (Grauer, 1996). GFR measurements are not indicated in ARF as hydration status and renal function may vary considerably from one hour to another. Once the animal has recovered, GFR determination may permit quantification of the residual renal function, as ARF events may predispose to CRF development. In spontaneous ARF of dogs, P-Urea, P-Creatinine, or P-Phosphates were ineffective predictors of outcome, whereas oliguria was the best indicator of poor prognosis (Behrend *et al.*, 1996).

Diagnosis of postrenal ARF is based on history, clinical signs, and imaging. Hematuria and peritoneal fluid with a higher creatinine concentration than that of plasma and similar to the urine creatinine concentrations are observed when rupture of the urinary tract occurs. Casts were detected in about 30% of dogs with ARF (Vaden *et al.*, 1997b).

Urine enzyme activities are useful early markers of cell damage in ARF principally in nephrotoxicity studies, as they are more sensitive than other markers. In dogs treated with gentamicin, urine excretion of GGT increased by day 2 of administration, P-Creatinine remained below 180μmol/l until day 9, and endogenous creatinine clearance remained within normal values until day 8 (Greco *et al.*, 1985). The intensity of total enzyme excretion may help to quantify the extent of renal damage. The use of enzymuria in routine nephrology remains questionable except in toxicological settings and to monitor the effects of potentially nephrotoxic drugs.

Proteinuria is often detected in uremic animals because of frequent evidence of inflammation and hemorrhage in the urine sediment. However, its relevance in the differential diagnosis, prognosis, and follow-up of ARF patients, in contrast to CRF, remains unknown.

Unusual causes of ARF in dogs and cats have been reviewed recently (Stokes and Forrester, 2004). Many cases of spontaneous acute renal failure result from intoxications. A common example is the ingestion of ethylene-glycol (antifreeze) by dogs and cats, which is oxidized by alcohol dehydrogenase in the liver to glycolaldehyde and acids, with oxalic acid the terminal metabolite. These metabolites are responsible for severe metabolic acidosis and ARF with dramatic increases of P-Urea and P-Creatinine, proteinuria, and calcium oxalate crystalluria. In the initial phase, affected animals are polyuric with decreased U-SG and U-pH (Connally *et al.*, 1996; Fox *et al.*, 1987; Grauer *et al.*, 1984; Hamlin, 1986; Thrall *et al.*, 1984). In ruminants, equids, and swine, ARF is more frequently caused by nephrotoxic plants or mycotoxins than by infections; for example, ochratoxin A and citrinin produced increases in urinary enzyme excretion, proteinuria, and decreased U-SG in pigs (Szczech *et al.,* 1973, 1974). Diagnosis is based on increases of P-Urea and P-Creatinine and a decrease of U-SG (Divers *et al.*, 1982; Gouda *et al.*, 1986).

Treatments with nephrotoxic drugs can also cause ARF. Cisplatin toxicosis is mainly due to damage of the lower segment of the proximal tubule. This produces a decrease of GFR in dogs and no change or increases of P-Urea or P-Creatinine and increases of FE_{Mg} and FE_{Pi}, and of U-GGT and U-GGT/Creatinine (Forrester *et al.*, 1993; Hardie *et al.*, 1991). A decrease of GFR, U-SG, and P-Potassium was observed with amphotericin B, as was an increase of P-Urea and P-Creatinine (Randall *et al.*, 1996).

Gentamicin nephrotoxicity determines progressive renal failure characterized by increases of urinary enzyme excretion, proteinuria, hematuria and cylindruria, azotemia, hyperphosphatemia, hypoalbuminemia, hyper- or hypokalemia, reduction of GFR, and an increase of FE_{Na} and FE_K in dogs (Daugaard *et al.*, 1987; Riviere *et al.*, 1984), cats (Hardy *et al.*, 1985; Mealey and Boothe, 1994), and sheep (Garry *et al.*, 1990b).

C. Nephrotic Syndrome

Nephrotic syndrome is characterized by the presence of proteinuria, hypoalbuminemia, hypercholesterolemia, and edema or ascites. It is mainly a consequence of diabetic nephropathy in humans. See the review in Orth and Ritz (1998). In dogs and cats, it is caused by glomerular renal disease, mainly by immune-mediated glomerulonephritis and amyloidosis. See the reviews in Osborne and Jeraj (1980) and Relford and Lees (1996). A model has been obtained in dogs by repeated administration of cationized bovine albumin after endotoxin sensitization (Choi and Lee, 2004). The hallmark of nephrotic syndrome is severe proteinuria in the absence of active sediment. The prevalence of hypoalbuminemia and hypercholesterolemia in dogs ranged from 61% (Center *et al.*, 1987) to 100% (Jeraj *et al.*, 1984; Kurtz *et al.*, 1972). Edema was usually less prevalent (from 0% to 15%) (Center *et al.*, 1987; Kurtz *et al.*, 1972). When the GFR decrease is substantial, animals with nephrotic syndrome become azotemic and present the clinical signs and biological findings characteristic of CRF and ARF. The prevalence of azotemia in dogs with glomerular disease varied from 20% (Wright *et al.*, 1981) to 100% (Jeraj *et al.*, 1984; Kurtz *et al.*, 1972). In cats, azotemia, hypercholesteremia, hypoalbuminemia, anemia, and edema/ascites

were reported to occur in 67%, 77%, 96%, 63%, and 75% of cases, respectively (Arthur *et al.*, 1986).

D. Fanconi-Like Syndromes

Fanconi-like syndromes are observed in some breeds of dogs, mainly basenjis (Noonan and Kay, 1990). They are characterized by multiple defects in the reabsorption of glucose, sodium, potassium, calcium, phosphate, amino acids, and water by the tubule (Bovee *et al.*, 1979; Settles and Schmidt, 1994) producing decreased U-SG, proteinuria, and glucosuria (Darrigrand-Haag *et al.*, 1996; Easley and Breitschwerdt, 1976). They may also be acquired as a result of gentamicin toxicity (Brown *et al.*, 1986) or calcitriol deficiency (Freeman *et al.*, 1994), they may be experimentally produced by maleic acid (Al-Bander *et al.*, 1985) or 4-pentaenoate administration (Gougoux *et al.*, 1989), or they may be transient and of unknown etiology (Hostutler *et al.*, 2004; Jamieson and Chandler, 2001).

GFR in dogs with Fanconi-like syndrome may be decreased or remained unchanged (Bovee *et al.*, 1979; Breitschwerdt *et al.*, 1983). Glucosuria, which is one of the major findings in Fanconi-like syndromes, was not correlated with a reduction in GFR or with defective reabsorption of phosphate and sodium (Bovee *et al.*, 1978a,b). The cause of death is apparently not progressive nonspecific renal failure, as the final events are papillary necrosis and pyelonephritis (Bovee *et al.*, 1978b, 1979).

I. INTRODUCTION

The body fluids are arranged in dynamic, but orderly, functional compartments. Maintenance of these compartments in terms of volume and composition is essential for sustaining normal physiological and biochemical events. The electrolytes dissolved in body fluids fulfill vital roles in virtually all of life's processes. Transmembrane movements of electrolytes are responsible for the electrical events that result in nerve conduction and muscular contraction, and the electrical stability of membranes is highly dependent on the concentration of electrolytes on both sides. Electrolytes also serve as essential cofactors in many enzymatically mediated metabolic reactions. The pH of body fluids is maintained within narrow limits. This fine control is necessary to maintain the structure and function of proteins essential for normal progression of metabolic events. Virtually every organ system participates in the maintenance of fluid and electrolyte balance or is adversely affected by imbalances. In many disease states, impaired fluid intake, excessive fluid losses, or organ damage and dysfunction will lead to a state of altered fluid and electrolyte balance. Regardless of whether fluid and electrolyte alterations are the primary problem or simply represent secondary manifestations of some other disease process, successful patient management depends on correct evaluation and appropriate therapy. To achieve this goal, one must have a clear understanding of the anatomy

and physiology of the body fluids, the pathological mechanisms by which normal processes become deranged, the means by which these disturbances can be identified accurately, and finally the procedures that can be used to correct such disturbances in a prompt, safe, and effective manner (Tasker, 1980).

II. PHYSIOLOGY OF FLUID AND ELECTROLYTE BALANCE

A variety of units have been used in the quantitative evaluation of biological specimens. To avoid confusion, this chapter describes the units of measure that apply directly to the body fluids and electrolytes. An international standard for clinical chemistry units, the "Systeme Internationale d'Unites" (SI units), was developed to provide consistent terminology and usage. Although SI units are the international standard, they may not be familiar to all students or clinicians. All solute concentrations are expressed in moles or millimoles per l, blood gas partial pressure in kilopascals, and osmolality in millikelvins of freezing point depression.

Electrolytes are substances that exist as positive or negative charged particles in aqueous solution. The positively charged particles are "cations," and the negatively charged particles are "anions." For univalent ions such as sodium, potassium, chloride, and bicarbonate, 1 mole equals 1 equivalent. For multivalent ions, 1 equivalent is equal to the molecular weight in grams (i.e., 1 mole) divided by the charge on the particle. To maintain electrical neutrality in biological fluids, there must be an equal number of equivalents or milliequivalents of anions and cations in solution. Electrolytes in solution combine equivalent for equivalent, not on a gram for gram or mole for mole basis.

The osmotic properties of a solute in solution are related to the number of particles in solution and not to its weight or its charge. One osmole of a nondissociable substance is equal to its molecular weight in grams. One osmole of any substance that dissociates in solution into two or more particles is equal to the molecular weight in grams divided by the number of particles into which each molecule dissociates. Osmolarity is defined as the number of osmoles per l of final solution, whereas osmolality is the number of osmoles per kilogram of water. Although the expressions are similar, osmolality more correctly describes the osmotic properties as measured in the clinical laboratory.

Most solutes in biological fluids are present in relatively dilute concentrations, and it is more convenient to express these concentrations as millimoles, milliequivalents, or milliosmoles. These simply represent one-thousandth of the standard unit. Conventional terms are milligrams per deciliter (mg/dl), millimoles per l (mmol/l), milliequivalent/l (mEq/l), and milliosmole per kg water (mOsm/kg). The concentrations of the principal anions and cations in plasma are presented in Table 17-1 as expressed in these conventional terms.

III. BODY FLUID COMPARTMENTS

Before discussing the assessment of fluid deficits or imbalances, it is necessary to consider the organization and composition of the fluid compartments from which these losses occur. An understanding of the forces that govern the relative volume and composition of the body fluid compartments is central to understanding both the clinical and clinicopathological manifestations of altered fluid balance.

A. Total Body Water

Water is the most abundant compound in the body, and most of life's essential processes take place in this aqueous environment. Although there is substantial variation, the total body water (TBW) of most domestic animals is approximately 60% of body weight (0.60 l/kg). In a 500-kg horse, this amounts to approximately 300 l (Carlson, 1983c), whereas in a 20-kg dog, it amounts to just over 12 l (Kohn and DiBartola, 1992).

Adipose tissue contains little water, and the amount of body fat has a major impact on the relative TBW. The average body water content of women is 0.45 to 0.50 l/kg as compared to 0.55 to 0.60 l/kg for men (Edelman *et al*., 1958; Elkinton and Danowski, 1955). This difference is largely the result of the larger fat deposits in the adult woman and the larger muscle mass of the adult man (Elkinton and Danowski, 1955). Clear sex-associated differences in body fat are not appreciated in domestic animals. However, certain species of domestic animals such as fattened swine or sheep have a large amount of body fat. Although lighter sheep had a TBW of near 0.65 l/kg (Wade and Sasser, 1970), the TBW of these fattened animals may be less than 0.50 l/kg (English, 1966b; Hansard, 1964), whereas the TBW of the athletic horse is generally greater than 0.65 l/kg (Dieterich and Holleman, 1973; Judson and Mooney, 1983; Robb *et al*., 1972). The relative water content of newborn animals is much higher than adults. Data in human infants, calves, foals, and lambs suggest a water content in excess of 75% of body weight at birth (Bennett, 1975; Dalton, 1964; Edelman and Leibman, 1959; Phillips *et al*., 1971; Pownall and Dalton, 1973). The large TBW is primarily the result of the very large extracellular fluid (ECF) volume, which exceeds 0.40 l/kg at birth in most species (Bennett, 1975; Kami *et al*., 1984; Spensley *et al*., 1987; Tollertz, 1964). There is an initial rapid decline during the first few days to weeks of life with TBW, and ECF volumes approach adult levels by 6 months of age (Spensley *et al*., 1987).

The TBW consists of two major compartments, the intracellular fluid (ICF) volume and the ECF volume. The distribution of body water is illustrated in Figure 17-1 indicating the normal fluid balance of a 450-kg horse. The ICF accounts for approximately one-half to two-thirds of the TBW, and the ECF accounts for the remainder. Although these two compartments differ markedly in electrolyte

TABLE 17-1 Plasma Electrolyte Concentrations Expressed in Different Units[a]

Plasma Electrolyte	Normal Concentration			
	mOsmol/kg	mg/dl	mmol/l	mEq/l
Cations				
Sodium (Na^+)	326.6	142.0	142.0	142.0
Potassium (K^+)	16.8	4.3	4.3	4.3
Calcium (Ca^{2+})[b]	5.0	1.25	2.5	1.25
Magnesium (Mg^{3+})[b]	1.3	0.55	1.1	0.55
Total cations	349.7	148.1	149.9	148.1
Anions				
Chloride (Cl^-)	369.2	104.0	104.0	104.0
Bicarbonate (HCO_3^-)	146.4	24.0	24.0	24.0
Phosphate ($H2PO_4^-$, HPO_4^{-2})[c]	3.4	1.1	2.0	1.1
Proteins[b]	7000.0	2.5	14.0	2.5
Others (sulfate lactate, etc.)	—	5.5	5.9	5.5
Total anions	7519.0	135.5	149.9	137.0
Total milliosmoles from electrolytes				285.1

[a] *From Tasker* (1980).
[b] *Only ionized calcium and magnesium have been considered here.*
[c] *Phosphate concentration is that of organic phosphorus. Because a variable equilibrium exists between* $H_2PO_4^-$ *and* HPO_4^{-2}*, the actual valence and milliequivalents must be estimated. The same variability is true of protein anions as well.*

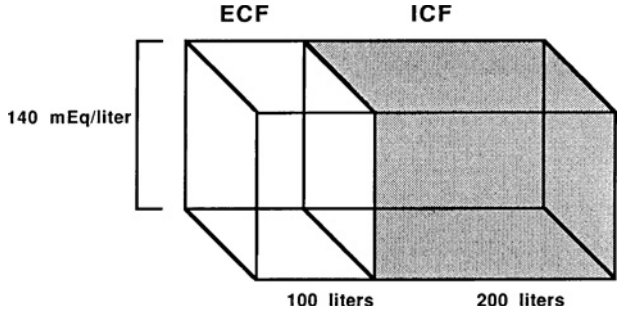

FIGURE 17-1 Body fluid compartments in a normal 450-kg horse. Serum sodium concentration is 140 mEq/l (140 mmol/l). Extracellular fluid (ECF) volume is 100 l and intracellular fluid (ICF) volume is 200 l.

composition, they are in osmotic equilibrium, and water is freely diffusible between them. The relative volume distribution of water between these two compartments is largely governed by the number of osmotically active particles in each compartment. The ECF sodium content determines the ECF volume, whereas ICF volume is a function of ICF potassium content. The relationship between the exchangeable cation content (sodium in the ECF, potassium in the ICF) and the total body water was defined by Edelman *et al.* (1958):

$$\text{serum sodium mEq/l } H_2O \approx (\text{exchangeable sodium} + \text{potassium}) \text{ total body water} \quad (17\text{-}1)$$

Because most cell membranes are very permeable to water, there are no major osmotic gradients between the ECF and the ICF, and serum sodium concentration and osmolality reflect the osmolality of the ICF compartment as well as that of the ECF compartment (Edelman *et al.*, 1958; Saxton and Seldin, 1986; Scribner, 1969).

B. Extracellular Fluid Volume

The ECF should be viewed as a physiological rather than a strictly definable anatomical space (Carlson *et al.*, 1979a). The ECF volume of adult animals ranges from 0.15 to 0.30 l/kg body weight (Carlson *et al.*, 1979a; English, 1966b; Evans, 1971; Hankes *et al.*, 1973; Hix *et al.*, 1953; Kohn, 1979; Spurlock *et al.*, 1985; Thornton and English, 1977; Zweens *et al.*, 1975), depending on the species and

the volume dilution procedure used. Regulation of ECF volume is a complex process in which a variety of factors interact. The ECF consists of all the fluids located outside the cells and includes the plasma (0.05 l/kg), interstitial fluid and lymph (0.15 l/kg), and the transcellular fluids (Edelman and Leibman, 1959; Rose, 1984; Saxton and Seldin, 1986). The transcellular fluids, which include the fluid content of the gastrointestinal tract, are generally considered a subcomponent of the ECF. In small animal species, the fluid content of the gastrointestinal tract is relatively small (Strombeck, 1979). In the large animal herbivore species, a substantial volume of fluid is normally present within the gastrointestinal tract. In the horse, this may amount to 30 to 45 l (Carlson, 1979a), and in cattle, the forestomach may contain as much as 30 to 60 l of fluid (Phillipson, 1977). During periods of water restriction and certain other forms of dehydration, this gastrointestinal fluid reservoir can be called on to help maintain effective circulating volume (McDougall *et al*., 1974). All of the fluids of the ECF contain sodium in approximate concentrations of 130 to 150 mEq/l H_2O. Sodium provides the osmotic skeleton for the ECF, and the sodium content is the single most important determinant of ECF volume (Rose, 1984). Sodium deficits result in decreases in ECF volume, whereas sodium excess is most often associated with water retention and results in edema (McKeown, 1986; Rose, 1984).

C. Intracellular Fluid Volume

The ICF volume represents the fluid content within the body's cells. This volume cannot be measured directly but is calculated as the difference between the measured TBW and the measured ECF volume. Potassium provides the osmotic skeleton for the ICF in much the same way that sodium provides the osmotic skeleton for the ECF. Because water is freely diffusible into and out of the cell, changes in the tonicity of the ECF are rapidly reflected by similar changes in ICF tonicity (Saxton and Seldin, 1986). This is largely the result of the movement of water across the cell membrane with resultant changes of ICF volume. Thus, whereas plasma sodium concentration decreases in response to water retention, ICF volume increases (Humes, 1986). On the other hand, with water depletion resulting in hypernatremia, ICF volume decreases (Humes, 1986). Relatively little is known about the organization of intracellular water into the various subcellular compartments and organelles.

IV. REGULATION OF BODY FLUIDS AND ELECTROLYTES

A. Effective Circulating Volume

The effective circulating volume refers to that part of the ECF that is within the vascular space and is effectively perfusing the tissues (Rose, 1984). Effective circulating volume tends to vary with ECF volume, and both parameters vary with the total body sodium stores (Rose, 1984). Sodium loading produces volume expansion, whereas sodium depletion leads to volume depletion.

Effective circulating volume is not a quantitatively measurable entity but refers to the rate of perfusion of the capillary circulation. Effective circulating volume is maintained by varying vascular resistance, cardiac output, as well as renal sodium and water excretion (Rose, 1984). Decreases in effective circulating volume result in decreased venous return, decreased cardiac output, and decreased blood pressure. Decreased volume and pressure are recognized by special volume receptors in the cardiopulmonary circulation and kidney, which trigger increased sympathetic tone resulting in increased arterial and venous constriction as well as increased cardiac contractility and heart rate. These responses tend to correct for the volume deficit by increasing cardiac output and systemic blood pressure. Volume and pressure changes associated with decreases in effective circulating volume also result in activation of the renin-angiotensin system with subsequent enhancement of aldosterone secretion by the adrenal cortex (Brobst, 1984). Aldosterone acts to enhance renal sodium resorption, which is a critical factor for maintaining and eventually restoring effective circulating volume. Additional factors that influence sodium resorption in response to changes in fluid volume include alterations in glomerular filtration rate, renal hemodynamics, atrial natriuretic factor, and plasma sodium concentration.

B. Antidiuretic Hormone

Antidiuretic hormone (ADH) plays a primary role in the regulation of the osmolality of the body fluids. Antidiuretic hormone is synthesized in the hypothalamus, stored in the neurohypophysis, and released in response to changes in plasma osmolality. Because sodium concentration is the primary determinant of plasma osmolality, ADH-release is closely correlated to plasma sodium concentration. Special sensors in the hypothalamus recognize increases in plasma osmolality, and the normal response is increased thirst to enhance water intake and the release of ADH, which increases water reabsorption by the renal collecting tubules. Antidiuretic hormone exerts its activity on the collecting tubules by activating adenyl cyclase; this results in the generation of cyclic adenosine monophosphate (cyclic AMP) and protein kinases, which in turn alter the permeability of the tubules to water (Rose, 1984). Antidiuretic hormone also is released in response to decreases in effective circulating fluid volume, although the renin-angiotensin system exerts primary control over volume changes. Antidiuretic hormone acts extrarenally as an arterial vasoconstrictor, thus increasing blood pressure. Plasma osmolality decreases in response to a water load, and ADH release is inhibited. The resultant reduction in ADH-mediated reabsorption of water in the collecting tubules allows for appropriate renal excretion of the water load and a return of plasma osmolality toward normal.

This highly sensitive system responds rapidly to small changes in osmolality, and as a result, plasma osmolality is normally maintained within a relatively narrow range.

C. Renin-Angiotensin

The renin-angiotensin system plays an important role in the maintenance of effective circulating fluid volume. Renin is a proteolytic enzyme produced by special juxtaglomerular cells of the glomerular afferent arteriole. Renin is released in response to reduced renal perfusion produced by hypotension, volume depletion, or increased sympathetic activity. Renin converts the circulating globulin angiotensinogen to angiotensin I, which is subsequently converted by an enzyme in the lung and vascular endothelial cells to the biologically active form, angiotensin II. Angiotensin II exerts a variety of systemic effects that tend to correct hypovolemia and hypotension. Angiotensin II increases renal retention of sodium and water by enhancing secretion of aldosterone from the adrenal cortex as well as having direct effects on the renal tubule. Angiotensin II exerts hemodynamic effects, which tend to increase blood pressure by inducing arteriolar vasoconstriction.

D. Aldosterone

Aldosterone plays a central role in the maintenance of effective circulating fluid volume and potassium balance largely through its effects on renal resorption of sodium in exchange for potassium and hydrogen ion. Aldosterone is produced in the adrenal cortex and exerts its effects on sensitive cells, such as the renal collecting tubules, by interacting with specific cytoplasmic receptors. The aldosterone receptor complexes subsequently enhance RNA-mediated production of specific proteins, which actually mediate the physiological effects of the hormone. There is evidence for aldosterone-mediated effects on gastrointestinal sodium and potassium absorption as well as effects on sweat glands to alter the electrolyte composition of sweat in response to sodium depletion (Michell, 1974). Aldosterone secretion is enhanced by the renin-angiotensin system in response to changes in effective circulating fluid volume.

E. Atrial Natriuretic Factor

Atrial natriuretic factor (ANF), also known as atrial natriuretic peptide (ANP), exists as a group of diverse peptide hormones produced in the heart and released into the circulation in response to processes that increase central venous pressure and thereby stretch the atrial wall (Inagami, 1994). The actions of ANF that tend to reduce cardiac output and systemic blood pressure are mediated by transmembrane receptors, which result in the production of cyclic guanidine monophosphate generated by guanylyl cyclase (Inagami, 1994). ANF results in natriuresis and diuresis by the kidneys. ANF also causes vasodilatation and reduces fluid volume by acting directly on vascular smooth muscle and inhibiting the release of aldosterone from the adrenal cortex and norepinephrine from peripheral adrenergic neurons. Additionally, ANF has been found in the brain, and centrally medicated effects on fluid volume regulation may be important. Elevated plasma ANF has been noted in humans with a variety of diseases ranging from congestive heart failure to obstructive lung disease to chronic renal failure. However, the physiological importance of ANF in these disease processes is not completely resolved. In humans, Bartter's syndrome and Gordon's syndrome are thought to be due to an excess or deficiency of ANF, respectively (Christensen, 1993). In horses, the elevation of plasma ANF has been associated with treadmill exercise (McKeever *et al.*, 1991).

V. PHYSIOLOGY OF ACID-BASE BALANCE

The hydrogen ion concentration of the ECF is maintained within remarkably narrow limits and is normally approximately 40 nmol/l. This concentration is roughly one-millionth the concentration of other common electrolytes. Even at these extremely low concentrations, hydrogen ions have profound effects on metabolic events largely through interaction with cellular proteins. These interactions alter protein configuration and thus alter protein function. Most enzymatic reactions have a narrowly defined range of pH optimum, and changes in hydrogen ion concentration have direct effects on the rates of reaction and, thus, many basic biological processes.

A. Definition of pH

Although the hydrogen ion concentration can be expressed in nmol/l a more useful expression is that of pH. The pH of a solution is equal to the negative logarithm of the hydrogen ion concentration.

$$\mathrm{pH} = -\log[\mathrm{H}^+] \qquad (17\text{-}2)$$

It is important to remember that the pH varies inversely with hydrogen ion concentration. When hydrogen concentration in the blood increases, pH decreases, and the animal develops an acidosis. When the hydrogen ion concentration in the blood decreases, the pH rises, and the animal develops an alkalosis. The traditional view of acid-base balance involves the following:

1. Extracellular and intracellular buffering
2. Regulation of the rate of alveolar ventilation to control carbon dioxide concentration
3. Regulation of renal hydrogen excretion

B. Buffers

A buffer system consists of a weakly dissociated acid and the salt of that acid. The body buffers are able to take up

or release hydrogen ions so that changes in hydrogen ion concentration are minimized. According to the law of mass action, the dissociation of a weak acid, HA, into H^+ and A^- can be written

$$K_a = \frac{[H^+][A^-]}{[HA]} \quad (17\text{-}3)$$

where K_a is the dissociation constant for the reaction. The equation can be rewritten

$$[H^+] = K_a \frac{[HA]}{[A^-]} \text{ or } [H^+] = K_a \frac{[Acid]}{[Salt]} \quad (17\text{-}4)$$

Taking the negative logarithm of both sides of the equation yields

$$-\log\ [H^+] = -\log K_a - \log \frac{[HA]}{[A^-]} \quad (17\text{-}5)$$

Substituting pH for $-\log\ [H^+]$, $\log\ [A^-]/[HA]$ for $-\log\ [HA]/[A^-]$ and defining pK_a as $-\log\ K_a$, the formula now reads

$$pH = pK_a - \log \frac{[A^-]}{[HA]} \quad (17\text{-}6)$$

This formula is the familiar Henderson-Hasselbalch equation for the dissociation of a weak acid. The buffering capacity of the body includes the extracellular buffers, intracellular buffers, and bone. The extracellular buffers include the bicarbonate (HCO_3/H_2CO_3) and phosphate ($HPO_4/H_2PO_4^-$) buffer pairs as well as the plasma proteins. The intracellular buffers include protein; organic and inorganic phosphates; and in the red cell, hemoglobin. Cation exchange involving the intracellular movement of hydrogen ion in exchange for potassium and (to a much lesser extent) sodium is an additional and important means whereby cellular mechanisms buffer an acid load. The carbonate in bone provides a large and often overlooked buffer store. Although difficult to accurately measure, it has been estimated that bone carbonate may contribute up to 40% of the buffering capacity of an acute acid load. It is important to remember that a change in hydrogen ion concentration will affect all the body's buffer pairs. Thus, evaluation of any one buffer pair reflects the changes that occur in all of the buffer pairs.

1. Bicarbonate/Carbonic Acid Buffer System

Large amounts of carbon dioxide are produced by oxidative metabolism each day. Although carbon dioxide is not an acid, it combines with water as it is added to the bloodstream resulting in the formation of carbonic acid. The enzyme carbonic anhydrase in red blood cells and other cells facilitates this reaction:

$$CO_2 + H_2O \rightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (17\text{-}7)$$

The ensuing elevation in the hydrogen concentration is minimized because most of the excess H^+ ions combine with the intracellular buffers, particularly hemoglobin (Hb):

$$H_2CO_3 + Hb^- \leftrightarrow HHb + HCO_3^- \quad (17\text{-}8)$$

The bicarbonate generated by this reaction then leaves the erythrocyte and enters the extracellular fluid in exchange for extracellular chloride ion. The net effect is that CO_2 is primarily carried in the venous circulation as HCO_3^- with little change in the extracellular pH. These processes are reversed in the alveoli. As HHb is oxygenated, H^+ is released and combines with HCO_3^- to form H_2CO_3, which dissociates to CO_2 and H_2O. Carbon dioxide then is excreted by alveolar ventilation.

From a clinical and physiological standpoint, the bicarbonate-carbonic acid buffer pair is clearly the most important. Bicarbonate is present in relatively high concentrations, it is relatively easy to measure, and it is the buffer system over which the body has the greatest control. The Henderson-Hasselbalch equation applied to this buffer pair becomes

$$pH = 6.1 - \log \frac{[HCO_3^-]}{[H_2CO_3]} \quad (17\text{-}9)$$

where $6.1 = pK_a$ for the HCO_3^-/H_2CO_3 buffer pair.

Plasma pH is determined by the concentration of bicarbonate and carbonic acid or, more importantly, the ratio between bicarbonate and carbonic acid. An equilibrium exists between the partial pressure of CO_2 in the alveolar air, the partial pressure of gaseous CO_2 dissolved in the blood, and the carbonic acid concentration of the blood. The conventional method of evaluating carbonic acid is the determination of the partial pressure of carbon dioxide (pCO_2) in the blood. The carbonic acid concentration can be calculated by multiplying pCO_2 by 0.03 (0.03 is the solubility constant for carbon dioxide in plasma). The Henderson-Hasselbalch equation for this buffer pair then becomes

$$pH = 6.1 - \log \frac{[HCO_3^-]}{0.03\ (pCO_2)} \quad (17\text{-}10)$$

The four primary acid-base imbalances and their compensating responses are presented in Table 17-2. Acidosis is associated with a decrease in pH resulting from an increase in hydrogen ion concentration. Alkalosis is due to a decrease in hydrogen ion concentration, which is reflected by an increase in pH. In the metabolic disorders, the primary imbalance is due to changes in bicarbonate concentration.

The compensating response is mediated by the respiratory system, which, within limits, alters the pCO_2 so as to counterbalance the primary imbalance and to partially restore the pH toward normal. As the name implies, the primary imbalances of the respiratory disorders are related to alterations in alveolar ventilation, which result in increases in pCO_2 in respiratory acidosis and decreases in pCO_2 with

TABLE 17-2 Acid-Base Imbalances and Compensating Responses

Disorder	pH	$[H^+]$	Primary Imbalance	Compensating Response
Metabolic acidosis	↓	↑	↓$[HCO_3^-]$	↓ pCO_2
Metabolic alkalosis	↑	↑	↑$[HCO_3^-]$	↑ pCO_2
Respiratory acidosis	↓	↑	↑ pCO_2	↑$[HCO_3^-]$
Respiratory alkalosis	↑	↓	↓ pCO_2	↓$[HCO_3^-]$

respiratory alkalosis. The compensating responses for these primary respiratory imbalances are mediated by the kidney through alterations in the excretion or retention of hydrogen ions or bicarbonate.

Blood samples drawn for acid-base evaluation must be drawn anaerobically and sealed so as to avoid alteration in the blood gas tension. Heparin is the anticoagulant of choice. The rectal temperature of the patient should be taken so that appropriate temperature corrections can be made. For evaluation of blood gases during intense exercise, central blood temperature should be used for this correction because rectal temperature may not accurately reflect blood temperature under these non-steady-state conditions. The temperature correction usually has a greater impact on the pO_2 and pCO_2 than bicarbonate or base balance. Arterial blood samples are generally preferred and are essential for the evaluation of primary respiratory disorders or the patient's status under general anesthesia. Venous blood samples provide reliable data on metabolic acid-base abnormalities, and because they are easier to obtain, they are routinely used. Acid-base parameters of venous blood are significantly influenced by the acid-base status of the tissues from which the blood is draining. Central veins (e.g., vena cava) provide blood that better reflects the acid-base status of the body as a whole. As a general rule, blood gas determination should be made as soon after collection as possible. However, appropriately collected blood samples can be held in ice water for as long as 4 h and still yield reliable results.

The effects of various sampling sites (arterial, venous, and capillary blood) on blood gas determination have been evaluated in dogs (Ilkiw *et al*., 1991; van Sluijs *et al*., 1982), horses (Littlejohn and Mitchell, 1969; Speirs, 1980), and swine (Hannon *et al*., 1990). Consistent differences were demonstrated between arterial and venous blood. Arterial blood samples yield higher values for pH and lower values for pCO_2 and bicarbonate than venous blood, but calculated base balances tend to be similar for both arterial and venous blood samples. In horses, venous-arterial differences in bicarbonate can exceed 10 mEq/l during intense exercise. The higher venous bicarbonate reflects the important role of bicarbonate as a means of CO_2 transport in the venous circulation (Carlson, 1995). At rest and during exercise, more than 70% of the CO_2 produced in the tissues is transported in the venous circulation to the lungs as bicarbonate. This process is greatly facilitated by erythrocyte carbonic anhydrase and the mechanism of the "chloride shift." The effects of temperature on oxygen content of dog blood have been studied (Hedey-Whyte and Laver, 1964), as has the oxygen affinity and Bohr coefficient of dog blood (Reeves *et al*., 1982). Recumbency in neonatal patients and body position during general anesthesia may have a significant impact on both arterial and mixed venous blood gas data (Madigan *et al*., 1992; Mason *et al*., 1987; Steffey *et al*., 1977). Nomograms have been developed relating the effects of temperature, CO_2 content, and hemoglobin saturation for dog blood (Rossing and Cain, 1966). The use of blood gas data for the evaluation of acid-base imbalances for clinical problems has been reviewed (DiBartola, 1992a, 1992b, 1992c; George, 1994; de Morais, 1992a, 1992b).

C. Acidosis

1. *Metabolic*

Metabolic acidosis is characterized by a decrease in pH and bicarbonate. Metabolic acidosis, as traditionally viewed, can be produced by the addition of hydrogen ions or a loss of bicarbonate ions. The initial buffering of an acid load is by the ECF buffers, primarily the bicarbonate-carbonic acid buffer pair (Rose, 1984). Intracellular buffers, particularly protein and phosphate, assist in the buffering process. The intracellular movement of hydrogen in exchange for potassium helps to prevent an excessive increase of the ECF hydrogen ion concentration in the face of an acid load. This exchange is called the "cation shift" and can result in hyperkalemia even though the total body potassium stores have been depleted due to renal or gastrointestinal losses.

a. Causes of Metabolic Acidosis

The most common causes include lactic acidosis; ketoacidosis; gastrointestinal problems, such as indigestion colic or diarrhea; and renal failure, which may result in a decreased ability to excrete hydrogen and thus to retain bicarbonate (Emmett and Nairns, 1977). It has long been held that

the acidosis in calves associated with diarrhea was largely due to the loss of bicarbonate into the bowel. This view has been challenged in an elegant paper utilizing a quantitative strong ion approach to assess the mechanism of the acid-base abnormality (Constable *et al.*, 2005). A profound metabolic acidosis without dehydration leading to depression, recumbency, and death has been described in goat kids (Tremblay *et al*., 1991), which appears to be similar to reports in calves (Kasari and Naylor, 1984, 1986). The cause was undetermined, but the acidosis was usually associated with an increased anion gap. Sodium bicarbonate therapy, if initiated early in the course of the disease, was often curative. The acidosis observed in these calves may have been associated with increases in both D and L isomers of lactate generated by bacterial fermentation as described in several recent clinical and research studies of calves with indigestion associated with milk ingestion (Ewaschuk *et al*., 2003, 2004; Lopez *et al*., 2004; Lorenz *et al*., 2005; Omole *et al*., 2001; Stampfli, 2005). Additional causes of a metabolic acidosis include ingestion of certain medications or toxic compounds such as salicylate, methanol, ethylene glycol, or paraldehyde, which result in the accumulation of exogenous anions (DiBartola, 1992b).

b. Compensation

A metabolic acidosis is recognized quickly, and the compensating respiratory response of increased ventilation will begin reduction of the pCO_2 within minutes. In dogs, the anticipated respiratory response is a reduction of pCO_2 by 0.7 mmHg for each mEq/l decrease in bicarbonate (de Morais, 1992a, 1992b). This minimizes the fall in pH, but the protective effects of the respiratory response are relatively short lived, lasting only a few days. Long-term correction of a metabolic acidosis requires renal bicarbonate retention and enhanced renal acid excretion, primarily as ammonium ion because there is little ability to increase the titratable acidity, which consists primarily of phosphate buffers (Rose, 1984). Complete correction of a metabolic acidosis may be difficult in patients with intrinsic renal disease or diseases that would impair the kidney's ability to excrete acid or retain bicarbonate such as renal tubular acidosis.

2. *Respiratory*

A respiratory acidosis is characterized by a decrease in pH and an increase in pCO_2. Respiratory acidosis develops because of decreased effective alveolar ventilation or breathing an atmosphere with elevated CO_2. The initial buffering of the acid load produced by a respiratory acidosis is almost exclusively by the intracellular buffers. The principal ECF buffer, the bicarbonate-carbonic acid buffer pair, cannot buffer a respiratory acidosis. Carbon dioxide diffuses through the lung much more readily than O_2; thus, diseases that compromise ventilation normally result in decreases in pO_2 before significant increases in pCO_2 develop. The respiratory center is extremely sensitive to minor changes in pCO_2, and increased pCO_2 normally provides the major stimulus to ventilation (Rose, 1984). In contrast, hypoxemia does not begin to promote enhanced ventilation until the arterial pO_2 is substantially decreased. If, however, the arterial pCO_2 is held at normal values or is elevated because of intrinsic lung disease, then ventilation begins to be enhanced as the arterial pO_2 falls below 70 to 80 mmHg (Rose, 1984).

a. Causes of Respiratory Acidosis

Any disorder that interferes with normal effective ventilation may produce a respiratory acidosis. The most common causes are primary pulmonary diseases ranging from acute upper respiratory obstruction, to pneumonia, to pneumothorax, and chronic obstructive lung disease. Diseases or drugs that affect the central nervous system may inhibit the medullary respiratory center and can produce a profound respiratory acidosis. An additional cause of special importance in veterinary medicine is general anesthesia with volatile agents using a closed system. Under these conditions, ventilation may be seriously reduced without producing hypoxia. The high oxygen content of the gas mixture maintains high pO_2 in the blood, but depression of the respiratory center may result in insufficient alveolar ventilation so that CO_2 accumulates. This problem can be overcome through the use of a positive pressure ventilatory apparatus and careful monitoring of arterial blood gases during general anesthesia.

b. Compensation

The compensating response for a respiratory acidosis is renal retention of bicarbonate and increased excretion of hydrogen ion. This response requires several days, and thus the response is seen only in a chronic respiratory acidosis. In dogs with chronic respiratory acidosis, a compensating increase of 0.35 mEq/l of bicarbonate is anticipated for each mmHg increase in pCO_2 (de Morais, 1992a, 1992b). The extent of the rise in the plasma bicarbonate concentration in chronic respiratory acidosis is determined by increased renal hydrogen secretion (Rose, 1984). Exogenous bicarbonate is unnecessary, and should bicarbonate be administered to patients with a respiratory acidosis, it would be excreted without affecting the final plasma bicarbonate concentration.

D. Alkalosis

1. *Metabolic Alkalosis*

Metabolic alkalosis is characterized by an increase in pH and bicarbonate. Metabolic alkalosis occurs with some frequency in domestic animals and is commonly observed in association with digestive disturbances in ruminants. The development of a metabolic alkalosis requires an initiating process capable of generating an alkalosis and the additional factors that are necessary for maintaining the alkalosis (Rose, 1984). Generation of a metabolic alkalosis can be due to excessive

hydrogen loss, bicarbonate retention, or as a contraction alkalosis. A contraction alkalosis occurs with reduction of ECF fluid volume resulting from a loss or sequestration of sodium and chloride containing fluid without commensurate loss of bicarbonate (Garella *et al*., 1975). Excessive hydrogen ion losses can result in a metabolic alkalosis.

a. Causes of Metabolic Alkalosis

The most common causes of increased hydrogen loss are gastrointestinal losses of chloride-rich fluids associated with vomiting in small animals (Strombeck, 1979) or sequestration of chloride-rich fluid in the abomasum and forestomach of ruminants (Gingerich and Murdick, 1975b; McGuirk and Butler, 1980). Excessive renal hydrogen loss associated with mineralocorticoid excess, diuretic usage (particularly the loop diuretics such as furosemide), and low chloride intake may cause or contribute to the generation of a metabolic alkalosis (Rose, 1984). Most of these disorders are also associated with the development of significant sodium and chloride deficits and resultant decreases in effective circulating volume. These deficits and the responses that decreased effective circulating volume induce are central features of the processes that maintain and perpetuate a metabolic alkalosis. Hydrogen loss from the ECF can also occur with hydrogen movement into the cells in response to potassium depletion (Irvine and Dow, 1968). Excessive bicarbonate administration is an additional potential cause of metabolic alkalosis. Most normal animals can tolerate large doses of bicarbonate, and excesses are rapidly eliminated by renal excretion (Rumbaugh *et al*., 1981). However, patients with decreases in effective circulating blood volume or with potassium or chloride deficits may not tolerate a bicarbonate load because renal clearance of excess bicarbonate is likely to be impaired.

The factors that are responsible for the maintenance of a metabolic alkalosis all impair renal bicarbonate excretion. These factors may include decreased glomerular filtration of bicarbonate seen in some types of renal failure. However, the most common factor is increased renal tubular bicarbonate resorption, which is associated with the renal response to decreases in the effective circulating fluid volume, potassium depletion, or chloride depletion (Rose, 1984). Sodium resorption is enhanced in response to hypovolemia to help restore normal effective circulating fluid volume. The maintenance of electroneutrality requires that sodium resorption in the proximal tubule must be accompanied by a resorbable anion such as chloride, whereas in the distal tubule, sodium resorption is associated with the secretion of a cation, usually hydrogen or, to a lesser extent, potassium. The only resorbable anion normally present in appreciable quantities in the proximal tubular fluid is chloride. In a metabolic alkalosis, plasma bicarbonate is increased and chloride concentration is generally decreased as the result of disproportionately high chloride losses that result from vomiting, sequestration of gastric fluid (Whitlock *et al*., 1975b), diuretic usage, or heavy sweat losses in exercising horses (Carlson, 1975, 1979b). The relative lack of the resorbable anion, chloride, in the proximal tubule thus allows a larger amount of sodium to reach the distal tubule where the action of aldosterone enhances hydrogen loss into the tubular lumen in exchange for sodium. The maintenance of effective circulating volume is so critical that the body chooses to maintain circulating volume by enhanced sodium resorption by whatever means necessary, even at the expense of extracellular pH. Renal hydrogen excretion is directly linked with bicarbonate resorption. Thus, it is not possible to eliminate the excess bicarbonate, and the metabolic alkalosis is maintained (Rose, 1984). This mechanism is the reason for the paradoxic acid urine seen in some patients with metabolic alkalosis (Gingerich and Murdick, 1975a, 1975b; McGuirk and Butler, 1980). Hypokalemia is another factor that contributes to the maintenance of a metabolic alkalosis. Hypokalemia is associated with an increase in intracellular hydrogen ion concentration. Increased renal tubular cell hydrogen ion concentration may enhance hydrogen secretion and thus bicarbonate reabsorption by the tubular cells.

b. Compensation

Chemoreceptors in the respiratory center sense the alkalosis, and the respiratory response to a metabolic alkalosis is hypoventilation resulting in an increase in pCO_2. In dogs, the expected compensating response is an increase of pCO_2 of 0.7 mmHg for each mEq/l increase in bicarbonate.

2. *Respiratory Alkalosis*

Respiratory alkalosis is associated with an increase in pH and a decrease in pCO_2.

a. Causes of Respiratory Alkalosis

Respiratory alkalosis is due to hyperventilation, which may be stimulated by hypoxemia associated with pulmonary disease, congestive heart failure, or severe anemia. Hyperventilation may also be associated with psychogenic disturbances or neurological disorders that stimulate the medullary respiratory center such as salicylate intoxication or Gram-negative sepsis. Respiratory alkalosis may be seen in animals in pain or under psychological stress. Hyperventilation may occur in dogs and other nonsweating animals as they employ respiratory evaporative processes for heat loss to prevent overheating (Tasker, 1980).

b. Compensation

The initial compensating response to an acute respiratory alkalosis is a modest decline in ECF bicarbonate concentration as the result of cellular buffering. Subsequent renal responses result in decreased ECF bicarbonate concentration through reduced renal bicarbonate reabsorption. These responses require 2 to 3 days for completion. The decline in bicarbonate is partially offset by chloride retention in order to retain electroneutrality. Thus, hyperchloremia

and decreased pCO_2 may be associated with compensated respiratory alkalosis as well as compensated metabolic acidosis. Compensating responses for chronic respiratory alkalosis lasting several weeks may actually be sufficient to return pH to normal. In dogs, anticipated renal compensation for a chronic respiratory alkalosis results in a decrease of bicarbonate of 0.55 mEq/l for each mmHg decrease in pCO_2 (de Morais, 1992a, 1992b).

E. Mixed Acid-Base Imbalances

Mixed acid-base disorders occur when several primary acid-base imbalances coexist (de Morais, 1992a). Metabolic acidosis and alkalosis can coexist and either or sometimes both of these metabolic abnormalities may occur with either respiratory acidosis or alkalosis (Nairns and Emmett, 1980; Wilson and Green, 1985). Evaluation of mixed acid-base abnormalities requires an understanding of the anion gap, the relationship between the change in serum sodium and chloride concentration, and the limits of compensation for the primary acid-base imbalances (Saxton and Seldin, 1986; Wilson and Green, 1985). Clinical findings and history are also necessary to define the factors that may contribute to the development of mixed acid-base disorders. The following are important considerations in evaluating possible mixed acid-base disorders:

1. Compensating responses to primary acid-base disturbances do not result in overcompensation.
2. With the possible exception of chronic respiratory acidosis, compensating responses for primary acid-base disturbances rarely correct pH to normal. In patients with acid-base imbalances, a normal pH indicates a mixed acid-base disturbance.
3. A change in pH in the opposite direction to that predicted for a known primary disorder indicates a mixed disturbance.
4. With primary acid-base disturbances, bicarbonate and pCO_2 always deviate in the same direction. If these parameters deviate in opposite directions, a mixed abnormality exists.

Although mixed acid-base abnormalities undoubtedly occur in animals and have been documented in the veterinary literature, they are often overlooked (Wilson and Green, 1985). An appreciation of the potential for the development of mixed abnormalities is essential for the correct interpretation of clinical and clinicopathological data, which would otherwise be quite confusing. Care should be taken when evaluating suspected mixed acid-base abnormalities that sufficient time has elapsed so that anticipated compensating responses could have occurred (de Morais, 1992a).

F. Anion Gap

The anion gap can be calculated as the difference between the major cation (sodium) and the measured anions (chloride + bicarbonate) (Emmett and Narins, 1977). Some investigators prefer to use the following formula:

$$\text{anion gap} = (\text{sodium} + \text{potassium}) - (\text{chloride} + \text{bicarbonate}) \quad (17\text{-}11)$$

The addition of potassium to the equation, however, adds little to the diagnostic utility of this calculation (Emmett and Narins, 1977; Epstein, 1984; Oh and Carroll, 1977); the anion gap calculated with the inclusion of potassium concentration will be about 4 mEq/l higher. Because most of the published data on the anion gap in animal species are the result of calculations using the second equation (Eq. 17-11), this form will be used in Table 17-3. Provided the component determinations are valid, the calculated anion gap provides an approximation of the so-called "unmeasured anions." Normally, these unmeasured anions consist primarily of negatively charged plasma proteins because the charges of the unmeasured cations (potassium, calcium, and magnesium) tend to balance out the charges of the unmeasured anions (phosphate, sulfate, and organic ions). The anion gap is most useful in situations where the concentrations of phosphate and plasma proteins, particularly albumin, are within the normal range (see Section V.I). The anion gap for most species of domestic animals appears to be similar to that defined for human subjects (i.e., approximately 10 to 20 mEq/l) (10 to 20 mmol/l). However, there

TABLE 17-3 Causes of Alterations in Anion Gap

Decreased anion gap:
Increased cationic protein
Polyclonal gammopathy (IgG)
Hypoalbuminemia
Hyperchloremic acidosis
Altered protein anionic equivalents
Laboratory error
Increased anion gap:
Metabolic acidosis
Organic acids (lactic, keto acids)
Hypovolemic shock
Anaerobic exercise
Diabetes
Grain overload
Ketosis
Nonmetabolizable acids
Inorganic acids (sulfate, phosphate)
Uremic acidosis
Intoxication or poisoning
Salicylate
Paraldehyde
Metaldehyde
Methanol
Ethylene glycol
Laboratory error

do appear to be significant differences in the normal range of the anion gap of different species as indicated in Table 17-4 (Adrogue *et al*., 1978; Bristol, 1982; Feldman and Rosenberg, 1981; Gossett and French, 1983; Polzin *et al*., 1982; Shull, 1978, 1981). Age-related changes in anion gap have been reported in horses (Gossett and French, 1983), with young foals having a significantly larger anion gap than adults. Further experimental data will be necessary to more clearly establish the normal range for the anion gap of animals under varying conditions.

The simple calculation of anion gap can be employed in the categorization of acid-base disorders with regard to potential causal factors and may serve as a prognostic guide in a variety of circumstances (Bristol, 1982; Garry and Rings, 1987; Shull, 1978). Decreases in anion gap can be seen with increases in cationic proteins associated with polyclonal gammopathy or multiple myeloma. Decreases in anion gap resulting from decreases in unmeasured anions occur most commonly with hypoalbuminemia and hyperchloremic metabolic acidosis, but they also may be noted with overhydration. The causal factors associated with a hyperchloremic metabolic acidosis with a normal to low anion gap can often be differentiated based on the serum potassium concentration. Hyperchloremic metabolic acidosis associated with gastrointestinal fluid losses from diarrhea or renal causes such as renal tubular acidosis most often manifests a hypokalemia (Saxton and Seldin, 1986; Ziemer *et al*., 1987a, 1987b). Hyperchloremic metabolic acidosis associated with decreased mineralocorticoid secretion or activity such as seen in Addison's disease or renal failure generally presents with a hyperkalemia (Saxton and Seldin, 1986). There are indications that changes in hydrogen ion concentration may alter protein equivalency and thus alter the anion gap in either an acidosis or alkalosis (Adrogue *et al*., 1978; Madias *et al*., 1979).

Dehydration and alkalosis are potential, but minor, causes of increased anion gap. Most commonly, elevations of anion gap are associated with the development of a metabolic acidosis in which there is an increase in anions, which are not routinely measured in the clinical laboratory. This is called a high anion gap acidosis and may be associated with an accumulation of metabolizable acids as in a lactic acidosis associated with anaerobic exercise, grain overload, or hypovolemic shock or ketoacidosis resulting from diabetes or ketosis or with the accumulation of nonmetabolizable acids as in uremic acidosis or various intoxications (see Table 17-3). The presence of a metabolic acidosis with a high anion gap thus provides grounds to undertake a thorough investigation of disease processes capable of producing an accumulation of these unmeasured anions. The anion gap also may be useful in the identification of mixed acid-base imbalances. When the change in the anion gap does not approximate the change in bicarbonate, a mixed metabolic acid-base imbalance should be suspected. In cases of grain overload in herbivores, a large ion gap may be due to increased ECF levels of D-lactic acid, which is not detected by the usual assays for lactic acid because they detect only the L-isomer produced in mammalian metabolism. Either a special assay for D-lactate must be performed, or an increased level of D-lactate may be assumed based on history and other clinical data.

G. Bicarbonate and Total CO_2

If respiratory disturbances can be eliminated, the metabolic component of acid-base balance is indicated by the bicarbonate concentration. Bicarbonate is usually estimated by determination of the "CO_2 content" or "total CO_2" of plasma or serum samples.

Bicarbonate actually accounts for approximately 95% of the measured total CO_2, and thus the total CO_2 provides a measure of metabolic changes in acid-base balance. The bicarbonate determined in this fashion will be decreased in a metabolic acidosis and increased in a metabolic alkalosis. Estimates of bicarbonate are often provided in automated chemistry profiles. These determinations may indicate the metabolic acid-base status. However, if acid-base abnormalities are suspected, a proper blood gas evaluation should be undertaken.

H. Buffer Base, Standard Bicarbonate, and Base Excess or Base Deficit

These values are mathematically derived from the measurements of blood pH and pCO_2 and provide an indication of the metabolic component of acid-base balance. It should be noted that the metabolic changes indicated by these parameters do not always reflect the primary acid-base imbalances but may represent compensating responses for primary respiratory disorders.

The buffer base indicates the sum of all the buffer anions in blood under standardized conditions. The standard bicarbonate is the plasma bicarbonate concentration that would be found under specific conditions, which eliminate respiratory influences on the values obtained. The base excess, which is sometimes considered as the base deficit when the value is negative, indicates the deviation of the buffer base from normal. This derived value is often supplied in routine assessment of acid-base balance and is generally taken as an indication of the deviation of bicarbonate from normal. In an animal with a metabolic acidosis, the calculated base deficit provides a means of estimating the amount of bicarbonate required to correct acid-base balance to normal. This estimate is calculated by multiplying the base deficit by the probable bicarbonate space (which is variably estimated from 0.25 to 0.55 l/kg body weight). In newborn animals, the bicarbonate may be even higher, 0.40 to 0.65 l/kg body weight. The usual figure used is 0.3 to 0.4 l/kg. For a 20-kg

animal with a base deficit of 10 mEq/l (10 mmol/l), the bicarbonate required would be calculated as follows:

$$\text{bicarbonate required} = 20\text{kg} \times 0.3\text{l/kg} \times 10\text{mEq/l} = 60\text{mEq} \quad (17\text{-}12)$$

This calculation provides only a crude guide to bicarbonate requirements, but it can be a useful step in the quantitative approach for correcting a serious primary metabolic acidosis.

I. Nontraditional or Strong Ion Approach to Acid-Base Balance

Peter Stewart (Stewart 1981, 1983) was the first to describe a quantitative physiochemical approach to acid-base balance. In this approach, the acid-base status of the aqueous solutions of the body is determined not only by the Henderson-Hasselbalch equation but also by a series of seven other relationships, all of which could be represented by equations which must be satisfied simultaneously. Acid-base balance is determined by three independent variables: (1) strong ion difference [SID], (2) the partial pressure of CO_2, and (3) the total concentration of nonvolatile weak acids [Atot], the principal component of which is the plasma proteins but also includes inorganic phosphate. Bicarbonate and hydrogen ion concentration, and thus pH, are dependent variables determined by the independent variables listed here. The appeal of Stewart's approach is the focus on factors that are causally related to acid-base balance, the independent variables. The interested reader is referred to Stewart's original work. A number of authors have attempted to adapt Stewart's approach for practical application in human and veterinary medicine (de Morais, 1992b; Fencl and Leith, 1993; Fencl and Rossing, 1989; Frischmeyer and Moon 1994; Gilfix *et al.*, 1993; Jones, 1990; Kowalchuck and Scheuermann, 1994; Whitehair *et al.*, 1995). Many of these early papers directed to animal species used the human values for Atot and *K*a, which may not be appropriate. Species-specific data are now available.

In a landmark paper, Peter Constable (1997) refined Stewart's model and developed an approach that he called the simplified strong ion model of acid-base equilibrium. The simplified strong ion model was developed from the assumption that plasma ions act as strong ions, volatile buffer ions (HCO_3^-), or nonvolatile buffer ions. Plasma pH is determined by five independent variables: pCO_2, strong ion difference, concentration of individual nonvolatile plasma buffers (albumin, globulin, and phosphate), ionic strength, and temperature. The simplified strong ion model conveys, on a fundamental level, the mechanism for change in acid-base status, explains many of the anomalies when the Henderson-Hasselbalch equation is applied to plasma, and is conceptually and algebraically simpler than Stewart's strong ion model. The model has provided an *in vitro* method for determination of species-specific values for [Atot] and *K*a, which has been applied to the plasma of horses, dogs, cattle, pigeons, and humans (Constable, 1997; Constable and Stampfli, 2005; Stampfli *et al.*, 1999, 2006; Stampfli and Constable, 2003).

Strong electrolytes are completely dissociated in aqueous solution and chemically nonreactive. The [SID] is simply the difference between the total concentration of strong cations (sodium, potassium, and magnesium) and the total concentration of strong anions (chloride, sulfate, lactate, acetoacetate, and 3-OH-hydroxybutyrate). Because they are present in higher concentrations in the body fluids, sodium, potassium, and chloride are normally the principal determinants of [SID]. The [SID] is synonymous with buffer base as described by Singer and Hastings (1948) and, as such, can be considered as roughly equivalent to the metabolic component of the traditional approach to acid-base balance. In fluids such as the CSF, which are normally devoid of protein, bicarbonate concentration is the same as the [SID]. Abnormalities in pCO_2 are viewed in essentially the same manner in both the traditional and nontraditional approach to acid-base balance as described earlier. The contribution of plasma proteins to acid-base balance is not considered in the traditional approach to acid-base balance. The plasma proteins, or, perhaps more correctly, plasma albumin, make up the majority of [Atot], whereas inorganic phosphate normally accounts for less than 5% of [Atot]. The [Atot] in body fluids exists in both dissociated [A^-] and undissociated [HA] forms. A decrease in [Atot] because of hypoalbuminemia causes an alkalosis with an increase in bicarbonate, whereas hyperalbuminemia has the opposite effect. Hypoalbuminemia is one of the most common causes of alkalosis in older human patients (McAuliffe *et al.*, 1986). Changes in A^- associated with changes in albumin concentration also have a direct and frequently overlooked effect on anion gap. Increases in A^- result in an increase in anion gap, whereas decreases in A^- cause a decrease in anion gap (McAuliffe *et al.*, 1986). Change in protein concentration may potentiate or ameliorate the effects of alterations in SID on acid-base balance. As an example, in a vomiting dog, the elevated plasma protein associated with dehydration may reduce the bicarbonate increase anticipated for a given change in chloride concentration and SID.

Protein and inorganic phosphate remain within the normal range in many clinical situations, and acid-base balance is then largely controlled by changes in pCO_2 mediated by the respiratory system, whereas changes in [SID] are largely under the control of the kidneys. Renal compensation for primary respiratory disorders and respiratory compensation for primary metabolic acid-base disturbances are thought to be similar in both the traditional and nontraditional approach. Precise quantification of the anticipated compensating responses to primary acid-base disturbances based on change in SID has not yet been determined.

Vomiting in a dog; heavy sweat loss in an endurance horse; displaced abomasum in a cow; and the administration of the loop diuretic, furosemide, in a cat result in similar acid-base disturbances. In each circumstance, a disproportionate loss of chloride relative to sodium results in a hypochloremia and an increase in [SID]. Correction of the alkalosis is brought about by the provision of chloride, generally as sodium chloride or potassium chloride, which results in a decrease in [SID] and thus a return of the dependent variables, bicarbonate and pH (hydrogen ion), toward normal. A metabolic acidosis with a large base deficit is generally treated with sodium bicarbonate. In the traditional approach, the calculated bicarbonate requirement is administered as sodium bicarbonate to replace the bicarbonate deficit, whereas in the strong ion approach, the sodium bicarbonate is administered to provide the strong cation, sodium, without a strong anion. Other metabolizable anions could be substituted for bicarbonate and achieve a similar effect. In practice, both approaches work, but the rationale is substantially different.

Calculation of SID is simple and provides useful insight in patients with metabolic acid-base disturbances. Factors that influence SID range from changes in free water, to sodium-chloride imbalances that result from excessive losses or disproportionate retention of sodium or chloride, to the accumulation of strong organic anions. Organic acidosis can be produced by the accumulation of exogenous as well as endogenous organic anions. Examples of exogenous anions include salicylate, glycolate and formate associated with the ingestion of aspirin, ethylene glycol, and methanol, respectively. Many of these endogenous and exogenous organic anions are not routinely monitored in the diagnostic laboratory. This situation can create problems when calculating the SID because the presence of these unmeasured strong anions may not be appreciated. Although the anion gap can be helpful, it does not always accurately predict the presence of these compounds. More sophisticated mathematical methods have been suggested as a means for the detection of unmeasured anions the strong ion gap (Constable *et al*., 1998; Stewart, 1981) and, more recently, the simplified strong ion gap (Constable and Stampfli, 2005). In animals with major changes in protein or albumin concentration, the primary concern must be a thorough investigation of the cause of the increase or decrease in protein. The acid-base consequences of change in protein and albumin concentration tend to be modest but are a potential source of confusion when evaluating acid-base data.

The traditional approach and the nontraditional or strong ion approach to acid-base balance each has its supporters, and discussion over the benefits and limitations of either approach has at times been strident. However, this need not be an either-or situation. Both approaches have proven useful to address practical problems in both research and medical settings. The traditional approach based on the Henderson-Hasselbalch equation is simpler, more user friendly, and more widely accepted. Bicarbonate concentration estimates the severity of the acid-base disorder, but the strong ion approach may provide a better understanding as to why the bicarbonate is changing because it integrates acid-base and electrolyte disorders (de Morais, 2005). The strong ion approach has been gaining acceptance from the critical care community, which finds it useful in the analysis of the complex fluid, electrolyte, and acid-base problems presented to intensive care units. A number of computer programs adaptable to hand-held electronic devices have been developed and take some of the mathematical fear out of using the strong ion approach.

J. Dietary Factors in Acid-Base Balance

Dietary factors, particularly the dietary cation-anion balance (DCAB), have been extensively studied in cattle, swine, poultry, and horses. The calculation of DCAB of a dry feed ration is remarkably similar to the calculation SID of body fluids. The DCAB in mEq is generally represented as (sodium + potassium) − (chloride + sulfate) per kg of dry matter of the diet. Diets with a high DCAB, such as alfalfa hay, have an alkalinizing effect and are an important factor in the alkaline urine of most herbivores. High grain rations tend to have a lower DCAB. Manipulation of the DCAB has been employed to enhance milk yield in dairy cattle, to reduce the incidence and severity of gastric ulceration in swine, to decrease the incidence of milk fever in cattle, and to alter the urine pH and calcium balance in horses. The addition of sodium bicarbonate to the ration of lactating dairy cattle to raise the DCAB from −100 to +200 mEq/kg diet DM resulted in an increase of milk production of over 8%, which was due, in part, to more effective ruminal digestion (Block, 1984). On the other hand, supplementation of the diet of late-term cattle with calcium chloride or ammonium chloride so as to lower the DCAB and have an acidifying effect has been shown to reduce the incidence of milk fever by enhancing the mobilization of calcium from the bone (Block, 1984). As the application of these dietary practices becomes more widespread, it is essential that we appreciate the implications of dietary factors and electrolyte supplementation on mineral metabolism and acid-base balance (Fredeen *et al*., 1988).

Sodium bicarbonate supplementation has been used as a prerace ergogenic aid in racehorses. Relatively large doses, 500 g or more of sodium bicarbonate, often mixed with sugar and water and referred to as “milk shakes,” have been given via nasogastric tube and result in a marked metabolic alkalosis. Although experimental studies have often failed to detect a measurable performance benefit from sodium bicarbonate supplementation, practical experience suggests that some horses, particularly standardbreds, show marked improvement in race times. Administration of any substance with intent to alter the performance is illegal in most racing jurisdictions. In many racing states,

horses must meet specific guidelines for venous blood pH and bicarbonate or risk disqualification.

VI. EVALUATION OF IMBALANCES

It is important to understand the difference between volume regulation and osmoregulation. Osmoregulation is governed by osmoreceptors influencing ADH and thirst, whereas volume disturbances are sensed by multiple volume receptors that activate effectors such as aldosterone. Antidiuretic hormone increases water resorption (and therefore urine osmolality), but it does not affect sodium transport directly. Aldosterone enhances sodium reabsorption but not directly that of water. Thus, osmoregulation is achieved by changes in water balance and volume regulation mostly by changes in sodium balance.

Water balance is achieved when water intake from all sources is equal to water output by all routes. Water is available as drinking water, as water content of feedstuffs, and as metabolic water derived by oxidative metabolism. Oxidation of 1g of fat, carbohydrate, or protein results in the production of 1.07, 0.06, or 0.41g of water, respectively. Water is normally lost from the body by four basic routes: urine, feces, insensible loss (respiratory and cutaneous evaporation), and sensible perspiration (sweat) in some animal species. Water intake and output may vary considerably from day to day, but normal animals are able to maintain water balance within remarkably narrow limits and, at the same time, maintain the critical interrelationship between water balance and electrolyte balance.

For human subjects, there are well-established normal values for water intake and output via various routes. Although there is a substantial amount of data on water balance for many domestic animals (English, 1966a; Fonnesbeck, 1968; Hinton, 1978; Kamal *et al*., 1972; Leitch and Thomson, 1944; Sufit *et al*., 1985; Tasker, 1967a; Yoshida *et al*., 1967), these data vary markedly from species to species and are valid only for the specific experimental conditions under which they were collected. Animals eat to meet their caloric requirements. The nursing or grazing animal may have a feed intake that is greater than 90% water as compared to animals on dry hay or dried prepared pet food, which may contain less than 10% water. Some desert rodents are so well adapted that they are able to maintain water balance without water intake and rely on the water content of feedstuffs and metabolic water derived from oxidative metabolism. The koala in its native state in Australia obtains virtually all its water from the leaves of specific species of eucalyptus trees, which constitute its entire diet. Dehydration because of water restriction with and without heat stress has been studied widely in a variety of animal species (Bianca *et al*., 1965; Brobst and Bayly, 1982; Carlson *et al*., 1979a; Elkinton and Taffel, 1942; Genetzky *et al*., 1987; Hix *et al*., 1953; Kamal *et al*., 1972; Rumbaugh *et al*., 1982; Rumsey and Bond, 1976; Schultze *et al*., 1972; Tasker, 1967b).

Quantitative assessment of the compartmental distribution of TBW between the ECF and the ICF has largely been based on the volume dilution of certain compounds or isotopic tracers. These studies require steady-state conditions and take a substantial period of time; as such, they are not well suited to the dynamic and often rapidly changing fluid balance characteristic of many clinical situations. Bioelectrical impedance analysis (BIA) may prove a useful tool in this regard. Bioelectrical impedance has been used for the assessment of body fat and fluid balance in humans and many animal species. Multifrequency bioelectrical impedance analysis has been successfully employed to monitor the rapid fluid changes in small animal patients undergoing dialysis. Algorithms for multifrequency BIA have been developed for use in the horse (Fielding *et al*., 2004).

A. Water

1. *Depletion-Dehydration*

Dehydration is a relatively common problem in domestic animals. Dehydration results from inadequate fluid intake in the face of normal to increased fluid losses. When water losses occur with little or no electrolyte losses (i.e., panting or feed and water restriction), serum sodium concentration and osmolality increase. This situation is called a hypertonic dehydration and occurs when water losses exceed losses of the exchangeable cations sodium and potassium (Carlson, 1987). This imbalance between total body water and exchangeable cations is best characterized as a relative water deficit (Scribner, 1969). The effects of a pure water loss of 30l in a 450-kg horse are illustrated in Figure 17-2. In this theoretical example, there has been a 10% loss of body water but no change in electrolyte balance. Plasma

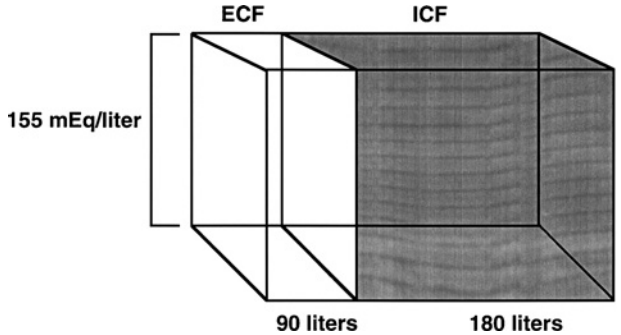

FIGURE 17-2 Body fluid compartments in a 450-kg horse with a pure water loss of 30l. Hypertonic fluid volume contraction is indicated by the increase in serum sodium concentration from 140 mEq/l (140 mmol/l) to 155mEq/l (155mmol/l). Fluid losses are shared by the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume.

sodium concentration has increased from a normal of 140 mEq/l (140 mmol/l) to 155 mEq/l (155 mmol/l). Fluid losses are shared proportionately by the ICF and ECF, and few other clinical or clinicopathological abnormalities will be noted until the fluid losses become more severe. Hypernatremia is associated with contraction of the ICF volume and shrinkage of the cells.

When water losses are associated with proportionate losses of exchangeable cations (i.e., 130 to 150 mEq [130 to 150 mmol] of sodium plus potassium per l of water lost), an isotonic fluid volume contraction develops. Despite what at times may be large water and electrolyte losses, plasma sodium concentration and osmolality remain unchanged. The ECF and ICF share the fluid losses in a distribution that reflects the relative losses of sodium and potassium as proportional of the initial content in their respective fluid compartments. In many instances, isotonic dehydration may occur in which sodium loss exceeds potassium loss. This type of dehydration is observed with heavy sweat loss in horses, with acute diarrhea in most species, and with inappropriate diuretic administration. The effects of an isotonic fluid loss of 30 l of water, 3800 mEq (3800 mmol) of sodium, and 400 mEq (400 mmol) of potassium in a 450-kg horse are illustrated in Figure 17-3. With this type of isotonic fluid loss, plasma sodium concentration remains within normal limits despite the development of large sodium deficits. These animals manifest clinical signs of inadequate circulating fluid volume reflecting the sodium deficit and the associated decrease in plasma and ECF volume as has been shown in human subjects (McCance, 1937, 1938). When a substantial portion of the water deficit is replaced by water consumption or free water administration in these animals, the serum sodium concentration and osmolality decline, and a hypotonic, hypovolemic dehydration can develop (Sufit *et al.*, 1985). The hyponatremia noted in this circumstance is best considered as an indication of a relative water excess (Scribner, 1969).

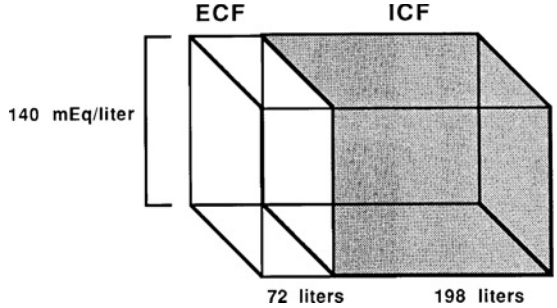

FIGURE 17-3 Body fluid compartments in a 450-kg horse with an isotonic fluid loss of 30 l of water, 3800 mEq (3800 mmol) sodium, and 400 mEq (400 mmol) potassium. Serum sodium remains unchanged at 140 mEq/l (140 mmol/l) despite the development of the substantial sodium deficit. Fluid losses are borne primarily by the extracellular fluid (ECF) volume.

2. *Water Excess-Overhydration*

The effects of the administration and retention of 30 l of water in a 450-kg horse are illustrated in Figure 17-4. In this example, total body water has been increased by 30 l, and there is an absolute as well as relative water excess. The primary effect of this water load is to dilute the electrolytes in the body fluids producing a substantial decline in plasma sodium concentration and osmolality. These changes occur despite the fact that there has been no change in sodium or potassium balance. In this example, the ECF and ICF share the water excess proportionately. The hyponatremia is associated with expansion of ICF and thus swelling of the cells.

Overhydration rarely occurs in normal individuals. The large water load described in Figure 17-4, if administered to a normal animal, would produce only transient changes, and the excess water would be eliminated by renal excretion. Even animals with psychogenic polydipsia ordinarily are able to maintain normal water balance through appropriate renal water excretion unless sodium depletion and renal medullary washout occur. However, overhydration can occur iatrogenically as the result of excessive fluid administration to patients with compromised renal function. If these fluids provide free water, as with 5% dextrose, plasma sodium concentration will decrease reflecting the change in relative water balance. If these fluids consist of isotonic sodium-containing replacement fluids such as saline or lactated Ringer's solution, there will be little or no change in plasma sodium concentration (Carlson and Rumbaugh, 1983; Cornelius *et al.*, 1978), but there will be an increase in plasma and ECF volume with the potential for cardiovascular overload, pulmonary edema, or generalized edema formation. In this instance, the primary problem is sodium retention, and the changes in water balance are secondary.

B. Sodium

The ECF volume contains approximately one-half to one-third of the body's sodium. Most of the remaining sodium is bound in skeletal bone, relatively little of which is rapidly

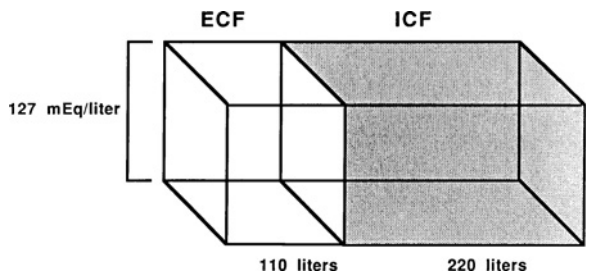

FIGURE 17-4 Body fluid compartments in a 450-kg horse after administration and retention of 30 l of water. Although no sodium or potassium losses have occurred, serum sodium concentration has declined from 140 mEq/l (140 mmol/l) to 127 mEq/l (127 mmol/l) reflecting a relative water excess. Water retention results in proportionate expansion of extracellular fluid (ECF) volume and intracellular fluid (ICF) volume.

exchangeable (McKeown, 1986). The ECF volume thus contains essentially all of the body's readily available and exchangeable sodium. The exchangeable sodium content is the principal determinant of ECF volume, and sodium deficits are the principal causes of decreased ECF volume (Saxton and Seldin, 1986). Increases in sodium content result in expansion of ECF volume, which may lead to the development of hypertension or edema formation (Dow *et al*., 1987b; McKeown, 1986). In either instance, the observed plasma sodium concentration will primarily depend on relative water balance. Because monitoring daily electrolyte balance is difficult in most animal species, urinary fractional excretion or creatinine clearance ratios have been useful to provide an index of daily intake or potential deficits of sodium, potassium, chloride, and other electrolytes. Normal values have been established for dogs, cats, horses (Morris *et al.*, 1984), and cattle (Fleming *et al.*, 1992).

1. *Sodium Depletion*

Sodium depletion is rarely the result of dietary sodium deficiency (Aitken, 1976). This is true even for herbivores whose feedstuffs are normally very low in sodium. Chronic sodium depletion has been reported in lactating dairy cows on a low salt diet (Whitlock *et al*., 1975a), but the sodium deficit was most probably the result of sodium losses in milk (Michell, 1985). Mastitis markedly enhances sodium loss in milk and could play a role in sodium depletion in lactating cows maintained on a low-salt diet (Michell, 1985). Sodium depletion almost invariably is associated with excessive losses of sodium-containing fluid (McKeown, 1986; Rose, 1984), most often occurring as the result of gastrointestinal losses through vomiting or diarrhea (Fisher and Martinez, 1976; Lakritz *et al.*, 1992). Excessive renal sodium losses can occur with intrinsic renal disease or as the result of diuretic therapy (Rose, 1984; Rose and Carter, 1979; Rose *et al*., 1986). Cutaneous losses via sweating are important in the exercising horse and may occur in any animal with extensive exfoliative dermatitis or burns. Salivary losses as the result of esophagostomy have been reported as a cause of sodium depletion in horses (Stick *et al*., 1981). A history suggestive of excessive loss of sodium-containing fluid is thus an extremely important criterion for the diagnosis of sodium depletion in domestic animals. The foregoing discussion applies indirectly to the so-called third space problems associated with a sequestration or compartmentalization of a portion of the ECF volume (Rose, 1984). This situation can occur with obstructive bowel disease or with the sudden accumulation of fluid within the abdomen or thorax resulting from peritonitis, ruptured bladder, ascites, or pleural effusion. These fluids have an electrolyte composition similar to the ECF and initially are drawn from the plasma volume and interstitial fluids. The resultant change in plasma volume and effective circulating fluid volume produce the same clinical and clinicopathological changes as those observed with excessive external losses of sodium containing fluid (Billig and Jordan, 1969). In these cases, fluids have not been lost from the body, but there has been an internal sequestration of fluid which can be mobilized if treatment is effective.

2. *Sodium Excess*

Sodium excess occurs most often in association with an increase in body water leading to an isotonic expansion of ECF volume and the development of hypertension or generalized edema (Saxton and Seldin, 1986). Congestive heart failure, hypoalbuminemia, and hepatic fibrosis may lead to a failure to maintain effective circulating volume, which then, in turn, results in compensating renal sodium retention (Rose, 1984). In these cases, expanded ECF volume represents an attempt to restore effective circulating fluid volume, and, at least initially, plasma volume may decrease whereas ECF volume expands. An expansion of ECF volume of 20% to 30% may be necessary before edema is first evident (Scribner, 1969). Sodium excess and edema can develop iatrogenically as the result of the excessive administration of sodium-containing fluid to patients with severely compromised renal function.

Most domestic animals can tolerate a large sodium intake provided they have adequate drinking water (Aitken, 1976; Buck *et al*., 1976; Pierce, 1957). Excessive salt intake may occur when animals that had been on salt-restricted diets are first allowed free access to salt (Michell, 1985). Salt intoxication can occur in cattle that are feeding in reclaimed salt water marshes or on pastures contaminated by oil field wastes when they are deprived of fresh water (Aitken, 1976; McCoy and Edwards, 1979; Michell, 1985; Pierce, 1957; Sandals, 1978). Salt poisoning in swine also occurs in association with water restriction followed by access to water (Aitken, 1976; Buck *et al*., 1976). Salt intoxication is generally associated with increases in plasma or cerebrospinal fluid sodium concentrations. Neurological signs associated with excessive salt consumption coupled with water restriction are related to development of cortical edema and, in swine, a characteristic eosinophilic meningoencephalitis (Aitken, 1976).

C. Potassium

Potassium is largely an intracellular ion with over 98% of the exchangeable potassium located intracellularly (Brobst, 1986; Strombeck, 1979). This distribution of potassium is coupled with the active extrusion of sodium from the cells, which is maintained by an energy-dependent sodium:potassium pump at the cell membrane (Brobst, 1986; Tannen, 1986). Potassium distribution across the cell membrane plays a critical role in the maintenance of cardiac and neuromuscular excitability. Changes in potassium concentration that alter the ratio of intracellular to extracellular potassium alter membrane potential (Tannen, 1986). In general, hypokalemia increases membrane potential, producing a

hyperpolarization block resulting in weakness or paralysis, whereas hyperkalemia decreases membrane potential causing hyperexcitability (Patrick, 1977). These features depend on the state of total body potassium content but also depend on the speed with which hypokalemia or hyperkalemia develops (Saxton and Seldin, 1986). As an example, acute potassium depletion may result in hypokalemia before the development of marked change in intracellular potassium, producing a substantial alteration in the ratio of intracellular-to-extracellular potassium. Acute hypokalemia can produce a much greater alteration in membrane potential and thus more marked clinical signs than a gradually developing hypokalemia of the same magnitude (Saxton and Seldin, 1986). Potassium homeostasis involves regulation of internal balance (i.e., the distribution of potassium between the ECF and ICF) as well as external balance (i.e., the relation of potassium input to output) (Brobst, 1986; Rose, 1984). Internal potassium balance is influenced by changes in acid-base status, glucose and insulin administration, exercise, and catecholamine release and will be discussed in greater detail in the section on factors that influence plasma potassium concentration.

1. *Potassium Depletion*

Potassium depletion is the result of altered external balance in which potassium losses by all routes exceed intake. Potassium is present in relatively high concentrations in most animal feeds. Therefore, dietary deficiency alone is not a common cause for potassium depletion (Tasker, 1980). However, dietary factors were associated with hypokalemia in hospitalized cats, particularly when associated with diseases linked to increased potassium loss (Dow *et al.*, 1987a). Herbivores, such as the horse, fed an all-hay diet may have a daily potassium intake of 3000 to 4000 mEq (3000 to 4000 mmol) per day (Hintz and Schryver, 1976; Tasker, 1967a). Most of this potassium is absorbed in the small intestine and colon with subsequent renal excretion of more than 90% of the daily potassium intake (Hintz and Schryver, 1976). These animals are thus highly adept at excretion of a large daily potassium intake. However, renal compensation for deficient potassium intake is not efficient, and renal conservation of potassium may be delayed for several days when animals normally fed a high-potassium diet are suddenly taken off feed or develop anorexia (Tasker, 1967b).

Potassium depletion most commonly develops as the result of gastrointestinal losses from vomiting or diarrhea. Excessive renal losses can occur as the result of diuretic usage, mineralocorticoid excess, renal tubular acidosis, and in the diuresis state that follows relief of urinary obstruction (Saxton and Seldin, 1986). Potassium depletion may result in decreased ICF volume, altered membrane potential, altered intracellular pH, and alterations of potassium-dependent enzymatically mediated reactions (Elkinton and Winkler, 1944). Clinical features include muscle weakness, ileus, cardiac arrhythmias, rhabdomyolysis, and renal dysfunction (Dow *et al.*, 1987a, 1987b; Earley and Daugharty, 1969; Tannen, 1986).

2. *Potassium Excess*

Potassium excess occurs relatively rarely and is generally a consequence of some alteration of renal excretion of potassium. Potassium excess may be associated with Addison's disease, some forms of renal disease, and clinical situations associated with hypovolemia and renal shutdown (Rose, 1984; Weldon *et al.*, 1992). Care should be taken to avoid the rapid administration of large amounts of potassium salts orally or intravenously to patients with severely compromised renal function. Even normal animals can develop significant electrocardiographic abnormalities with potassium (Dhein and Wardrop, 1995; Epstein, 1984; Glazier *et al.*, 1982) or calcium infusions (Glazier *et al.*, 1979).

D. Chloride

Modest changes in hydration tend to produce roughly proportional changes in plasma sodium and chloride relative to sodium concentration. Acid-base alterations are associated with disproportionate changes in plasma chloride concentration (Saxton and Seldin, 1986). A disproportionate hyperchloremia is seen in association with a low to normal anion gap metabolic acidosis. Chloride concentration increases in this type of acidosis as the result of proportionately smaller losses of chloride than bicarbonate and enhanced renal chloride resorption in response to decreased bicarbonate (Saxton and Seldin, 1986). Disproportionate hypochloremia is a consistent feature of metabolic alkalosis (Rose, 1984). Chloride depletion develops in these animals as a result of excessive loss or sequestration of fluids with high chloride content. Changes in water balance can result in modest alterations in the relative concentrations of plasma sodium and chloride. A pure water deficit produces increased sodium concentration, which exceeds the increases in chloride. This contributes to the development of a contraction alkalosis with an increase in bicarbonate. A pure water excess has the opposite effect and can result in an expansion acidosis.

VII. CLINICAL FEATURES OF FLUID AND ELECTROLYTE BALANCE

It is convenient to discuss the theoretical ramifications of pure water loss or specific electrolyte deficits. However, in practical clinical situations, the issue is almost never so clearly defined, and most often, there is a combination of fluid, electrolyte, and acid-base alterations. Many medical problems result in a consistent pattern of fluid and electrolyte loss with predictable changes in fluid volume, electrolyte concentration, and acid-base balance.

A clear understanding of the interrelationships between specific deficits and their clinicopathological consequences is essential if an appropriate initial diagnosis is to be made. Once treatment has been initiated, all clinical and clinicopathological data will be influenced not only by the primary medical problem and compensating responses but also by the effects of chemotherapeutic agents and fluid therapy as well. Therapeutic intervention may not always be appropriate, organ function may be impaired, and thus the anticipated clinicopathological responses become less predictable. These situations represent the bulk of clinical case material and laboratory data evaluated by clinicians and clinical pathologists. Under these circumstances, it is essential to understand the basic mechanisms that underlie changes in clinicopathological data and how these changes relate to specific imbalances.

Rational fluid therapy depends on accurate evaluation of the fluid and electrolyte deficits, the associated acid-base alterations, and the primary disease processes that underlie these imbalances. Evaluation must include an accurate history, a complete physical examination, and, of course, laboratory evaluation of appropriate parameters.

A. History

An accurate history is absolutely essential for the evaluation and management of the patient with fluid and electrolyte imbalances. Basic signalment factors of age, sex, breed, pregnancy, and stage of lactation are important because these factors influence the incidence and severity of many disorders. The presence of a preexisting or coexisting disease process and an accurate drug history can be exceedingly important not only in the evaluation of fluid and electrolyte disorders but also in fluid selection and patient management. Of particular importance is the history of prior renal disease, diuretic usage, or exposure to potentially nephrotoxic drugs. Status of feed and water intake is exceedingly useful. Most animals that continue to eat and drink normally are able to maintain fluid balance even in the face of excessive fluid losses. However, reduced or restricted fluid intake in the face of normal to enhanced fluid losses can quickly result in dehydration. Inadequate fluid intake may result from neurological disorders or traumatic injuries to the head or neck, whereas painful or obstructive lesions in the mouth, pharynx, or gastrointestinal tract may restrict feed and water intake. Inadequate water intake is often the result of management errors, broken or frozen water lines, and other factors. A history of polydipsia suggests that excessive fluid losses have occurred. Vomiting and diarrhea are obvious causes of fluid and electrolyte loss, but these findings also reflect gastrointestinal disorders, which may contribute to inadequate fluid and electrolyte intake or absorption.

Excessive fluid losses may be associated with vomiting, diarrhea, polyuria, excessive salivation, copious drainage from cutaneous wounds or burns, and as the result of heavy sweat losses in exercising horses. The water losses that occur in these situations are generally associated with significant sodium depletion and subsequent decreases in the effective circulating fluid volume. Vomiting in small animals (Clark, 1980), gastrointestinal stasis in ruminants (Gingerich and Murdick, 1975b), and excessive sweat losses in endurance horses (Carlson, 1983b) are associated with large losses or compartmentalization of chloride-rich fluids, which contribute to the metabolic alkalosis that frequently accompanies these disorders.

B. Clinical Signs

Dehydration is defined as a loss of body water. Clinical signs of dehydration are said to be first apparent with fluid losses equivalent to 4% to 6% of body weight. Moderate dehydration is said to be present with fluid losses of 8% to 10%, and severe dehydration is present when fluid losses exceed 12% of body weight. It is important to realize that although these guidelines have been clinically useful, there is relatively little documentation of this precise quantitative relationship in most animal species. Accurate measurement of fluid intake from all sources and output by all routes is not possible in most clinical situations. In acute situations, changes in body weight provide the most accurate guide to change in net water balance. Repeated measurement of body weight is a key component of the monitoring of patients on fluid therapy. The clinical signs of dehydration include weight loss, altered skin turgor, sunken eyes, and dry mucous membranes. If control of renal function is normal, urine volume is generally markedly reduced. The clinical consequences of dehydration depend much more on the pattern of electrolyte loss than the absolute water deficit.

Clinical signs associated with acute sodium deficits are largely related to hypovolemia and decreases in the effective circulating volume. These signs include increased pulse rate, decreased pulse pressure, delayed jugular distensibility, increased capillary refill time, and decreased blood pressure. Urine output is generally decreased and urine sodium and chloride concentrations are normally reduced. Decreases in ECF volume are always reflected by decreases in plasma volume, but the reverse is not always true. In the absence of blood or protein loss, the PCV and TPP concentrations increase, reflecting the decrease in plasma and ECF volume as will be discussed more fully in Section VIII.A.

VIII. CLINICOPATHOLOGICAL INDICATORS OF FLUID AND ELECTROLYTE IMBALANCE

A. Packed Cell Volume and Total Plasma Protein

The packed cell volume (PCV) and total plasma protein (TPP) concentration are simple, convenient, and useful tools

for the evaluation of acute fluid and electrolyte alterations. If one assumes that there has been no gain or loss of erythrocytes or protein from the vascular compartment, changes in PCV and TPP reflect changes in plasma volume (Boyd, 1981). For the estimation of alterations in plasma volume in human subjects, the change in PCV or hemoglobin concentration is preferred over change in protein concentration (van Beaumont *et al*., 1973). This preference exists because fluxes of protein both into and out of the plasma volume may occur in certain rapidly changing clinical circumstances (Landis and Pappenheimer, 1963; Senay, 1970). There is a substantial extravascular protein pool, and the volume distribution of both albumin and globulins is approximately two to three times that of the plasma volume (Landis and Pappenheimer, 1963; Matteeuws *et al*., 1966). This situation is one of the reasons that plasma transfusions have limited effects on the plasma protein concentration of hypoproteinemic patients. In most animal species, there is a much wider range of normal for PCV than for TPP. In some of these species, most notably the horse, mobilization of erythrocytes from splenic reserves in response to excitement, pain, or catecholamine release can result in marked variability in PCV, erythrocyte count, or hemoglobin concentration (Carlson, 1987; Persson, 1967; Persson *et al*., 1973). For these reasons, it has proven most useful to utilize the change in both PCV and TPP as a crude index of change in plasma volume in domestic animals. For these estimations to be valid, initial values for PCV and TPP must be known, and there must have been no loss of blood or protein. The most common causes for decreases in plasma volume are the sequestration or loss of sodium-containing fluid as in obstructive bowel disease, diarrhea, vomiting, renal disease, or in heavily sweating horses. In these circumstances, both PCV and TPP increase in relation to the change in plasma volume, but not necessarily by the same proportion (Boyd, 1981).

If it is assumed that the quantity of plasma proteins within the plasma volume remains constant (this assumption is not always correct), it is possible to calculate the percentage change in plasma volume based on protein concentration (Boyd, 1981):

$$\%\mathrm{PV} = [(\mathrm{PP}_1/\mathrm{PP}_2) - 1]\ 100 \qquad (17\text{-}13)$$

When sodium-containing fluids are administered to dehydrated volume-depleted subjects, plasma volume reexpansion is reflected by the return of PCV and TPP toward the normal range (Hayter *et al*., 1962). Declining PCV and TPP in response to fluid therapy are the two most useful laboratory indicators of return of effective circulating fluid volume and should be correlated with clinical evidence such as return of normal pulse pressure, capillary refill time, and jugular distensibility.

B. Serum Sodium

Serum sodium concentration varies within relatively narrow limits in the normal individual, but there is substantial interspecies variation in the normal range of sodium, chloride, and osmolality as indicated in Table 17-4. A serum sodium concentration of 134 mEq/l (134 mmol/l), although quite normal for a horse or cow, represents a significant hyponatremia in a dog or cat. Before proceeding with a discussion of the significance of alterations of sodium concentration, some comment on the methods used for electrolyte determination is appropriate. In the past, flame photometry was the standard method for the determination of both sodium and potassium concentrations. Presently, electrolyte concentrations in biological fluids are generally determined utilizing ion-specific electrode technology. Although consistent differences might have been expected, ion-specific electrode instruments, which dilute samples, tend to yield values that are similar to values reported from the flame photometer. This situation may be a function of the mathematical algorithm employed in these devices to convert changes in electric potential to electrolyte concentration. Interfering substances in the urine of some animal species render urine potassium determinations inaccurate when assessed by ion-specific potentiometry (Brooks *et al.*, 1988).

1. H*yponatremia*

The common causes of hyponatremia are listed in Table 17-5. A falsely low sodium concentration may be noted when there is marked hyperlipemia or hyperproteinemia. Large quantities of lipid or protein occupy a significant volume in a serum or plasma sample, and because electrolytes are dissolved only in the aqueous phase, the measured concentrations will be falsely low. The presence of obvious lipemia or markedly elevated serum protein concentration should alert the clinician to the probable cause of an accompanying hyponatremia. Should this information not be available, the presence of a false hyponatremia can be determined by comparison of the measured serum osmolality and the calculated osmolality based on sodium, glucose, and urea concentration as explained in Section VIII.E. This potential cause for confusion in interpretation of hyponatremia can be avoided if ion-specific electrodes are used for electrolyte determination.

Marked hyperglycemia associated with diabetes mellitus or the administration of glucose at an excessive rate generally produces a hyponatremia. As glucose concentration increases in the ECF, osmotic forces are generated, which result in the movement of cellular water into the ECF, diluting serum sodium concentration. The actual

Inappropriate ADH secretion

mechanics of this process are complicated by the fact that cells and tissues are variably permeable to glucose, and thus the glucose space clearly exceeds the ECF volume. For practical purposes, it can be anticipated that serum sodium concentration will decline 1.6 mEq/l (1.6 mmol/l) for each 100 mg/dl (5.55 mmol/l) increase in glucose concentration (Saxton and Seldin, 1986). Serum osmolality may be increased by hyperglycemia, but this should not cause a large disparity between the measured and calculated serum osmolality.

Changes in water balance are principally responsible for changes in serum sodium concentration (Leaf, 1962). Hyponatremia should be considered as an indication of a relative water excess (Scribner, 1969). Hyponatremia is often, but not invariably, associated with conditions that cause sodium depletion and resultant decreases in effective circulating volume. These conditions include vomiting, diarrhea, excessive sweat losses, and adrenal insufficiency. Dehydration and volume depletion induce neurohormonal responses that result in increased water consumption via increased thirst and enhanced renal conservation of water as well as sodium (Rose, 1984). Fluid losses in these forms of dehydration are most often hypotonic or isotonic, and initial fluid and electrolyte deficits do not result in hyponatremia until water intake or renal water retention disturbs the balance between the remaining exchangeable cations and the total body water. Thus, whereas substantial sodium and potassium deficits are associated with these conditions, plasma sodium concentration does not always reflect these deficits, and a diagnosis of sodium depletion should be based on other grounds (Scribner, 1969).

The accumulation of sodium-containing fluid within body cavities as a result of ascites, peritonitis, or a ruptured bladder is referred to as a "third space problem" (Rose, 1984). The fluid that accumulates in the "third space" has a composition similar to the ECF. When this accumulation of fluid occurs rapidly, plasma volume is reduced, and serum sodium concentration then may decrease as the compensating responses result in water retention. A classic example of this situation is the marked hyponatremia associated with ruptured bladder in neonatal foals. As the dilute urine of the neonate accumulates in the abdomen, osmotic equilibrium is established first with the ECF and then with all of the body fluid compartments. Sodium and chloride as well as other ions are drawn from the rest of the ECF into this progressively expanding fluid compartment, and hyponatremia develops despite the fact that there has been no appreciable loss of sodium from the body. The severe neurological signs associated with ruptured bladder in foals are related in large part to the effects of the sudden and marked hypotonic hyponatremia on the central nervous system. Hyponatremia associated with excessive retention of water also can occur without the development of significant sodium depletion or decreases in effective circulating fluid volume. Hyponatremia may be observed with psychogenic polydipsia if the rate of water consumption exceeds renal capacity for free water clearance because of intrinsic renal disease or renal medullary washout (Tyler *et al*., 1987). This condition also may occur in patients with impaired free water clearance resulting from renal disease or when under the influence of inappropriate release of ADH (McKeown, 1986). Hyponatremia and associated neurological disturbances can develop with naturally occurring disease (Lakritz *et al*., 1992) or iatrogenically if excessive amounts of free water are administered to patients with altered renal function (Arieff, 1986; Sterns *et al*., 1986).

Urine sodium concentration can be useful in the differentiation of the causes of hyponatremia as indicated in Figure 17-6. Renal adaptive responses normally result in sodium retention and production of urine with very low sodium concentration in patients with sodium depletion resulting from vomiting, diarrhea, excessive sweat loss, or third space problems (Rose, 1984). Hyponatremia and hypokalemia of adrenal insufficiency are generally associated with a relatively high urine sodium concentration (Rose, 1984). With the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), urine sodium tends to be high in the presence of hyponatremia, whereas urine sodium concentration tends to be low in animals with psychogenic polydipsia. Urine sodium concentration in animals with renal failure can be quite variable.

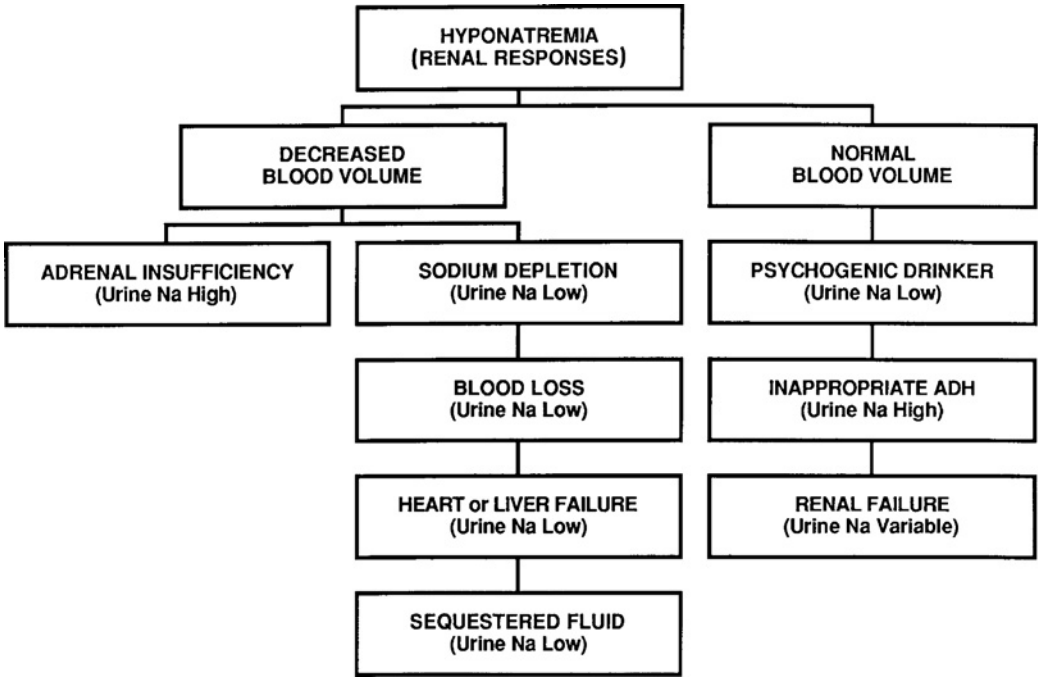

FIGURE 17-6 The urinary sodium concentration as an aid in the differentiation of possible causes of hyponatremia. Urinary electrolyte concentration is also influenced by dietary intake.

A form of moderate to pronounced hyponatremia associated with elevated levels of ADH, which develops in the absence of an appropriate osmotic or volume stimuli, has been well recognized in human subjects. This syndrome has been associated with several systemic disorders including malignant neoplasms that produce an ADH-like material, with a variety of brain diseases that apparently stimulate synthesis and release of ADH, or in association with certain pulmonary diseases that may result in abnormal neural inputs from the lung that trigger the inappropriate ADH release from the pituitary.

The diagnosis of SAIDH in the absence of readily available procedures for ADH determination depends on ruling out a number of other potential causes for persistent hyponatremia. The diagnostic criteria for SIADH for human subjects include the following (McKeown, 1986):

1. Demonstration of a hypotonic hyponatremia without hypovolemia or edema
2. Normal renal, adrenal, and thyroid function
3. Inappropriately elevated urine osmolality relative to plasma osmolality
4. Relatively high urine sodium concentration
5. Correction of the hyponatremia by strict fluid restriction

The SIADH has been reported in the dog (Breitschwerdt and Root, 1979; Brofman *et al*., 2003; Crow and Stockham, 1985; Fleeman *et al*., 2000; Giger and Gorman, 1984; Houston *et al*., 1989), but the incidence and importance of this problem in other animal species are uncertain. A variant of SIADH has been described in certain chronically ill and malnourished human subjects that maintain a mild but persistent hyponatremia. In these individuals, ADH secretion remains under osmotic control, but it would appear that the osmoreceptor threshold functions at a lower value than normal (McKeown, 1986). Thus, it is the resetting of the osmostat that results in persistent chronic hyponatremia. Resolution of the underlying medical problem usually results in correction of this variant form of SIADH.

2. H*ypernatremia*

Hypernatremia almost always is associated with elevation of serum osmolality. Hypernatremia occurs in dehydrated subjects when water losses exceed losses of sodium and potassium and should be considered as an indication of a relative water deficit (Scribner, 1969). This situation can occur in the initial stages of diarrhea, vomiting, or renal disease if losses of water exceed the electrolytes lost (see Table 17-6) (Saxton and Seldin, 1986). As water losses are replaced by increased water consumption or enhanced renal water retention, serum sodium concentration tends to decline into or below the normal range. Hypernatremia also develops as the result of an essentially pure water loss, such as the evaporative respiratory water loss in panting animals (Tasker, 1980). Hypernatremia is associated with excessive renal free water loss with either central or nephrogenic diabetes insipidus if water intake is restricted (Breukink *et al*., 1983). Food and water deprivation in normal individuals is associated with substantial reduction of

renal and fecal output (Brobst and Bayly, 1982; Carlson *et al*., 1979b; Genetzky *et al*., 1987; Tasker, 1967b). However, continued cutaneous and respiratory insensible water loss may result in hypernatremia (Carlson *et al*., 1979b; Elkinton and Taffel, 1942; Genetzky *et al*., 1987; Rumsey and Bond, 1976). Abnormal thirst mechanisms with resultant hypernatremia have been reported in young dogs (Crawford *et al*., 1984; Hoskins and Rothschmidt, 1984). Hypernatremia may occur transiently following administration of hypertonic saline or sodium bicarbonate if water intake is restricted or impaired. The hypernatremia observed with salt poisoning in cattle and swine is, in fact, triggered by water restriction in animals with a high salt intake (Padovan, 1980; Pearson and Kallfelz, 1982). So long as adequate water is available, salt poisoning does not occur. In human subjects, hypernatremia is reported with mineralocorticoid excess (McKeown, 1986).

C. Serum Potassium

Serum potassium concentration does not always reflect potassium balance but is influenced by factors that alter internal balance (i.e., the distribution of potassium across the cell membrane between the ECF and ICF) as well as factors that change external balance (i.e., potassium intake and output) (Brobst, 1986; Patrick, 1977; Rose, 1984). The effective adjustment of external and internal balance in normal individuals in response to either large potassium loads or excessive potassium losses usually maintains serum potassium concentration within normal limits. However, changes in potassium concentration occur in a wide variety of clinical circumstances and have profound neuromuscular effects largely because of changes in cell membrane potential (Brobst, 1986). The compensating responses to change in circulating fluid volume distribution and acid-base balance can result in confusing and contradictory findings. As an example, calves with acute diarrhea may develop significant depletion of body potassium stores because of excessive losses and inadequate intake (Phillips and Knox, 1969). However, the serum potassium concentration in these calves may actually be normal to increased as the result of renal shutdown and the metabolic acidosis induced by dehydration and sodium depletion with resultant decreases in the effective circulating fluid volume. Electrolyte replacement fluids given to these calves should include potassium (Fettman *et al.*, 1986). Correct interpretation of serum potassium concentration thus requires a knowledge of probable intake and sources of excessive loss as well as the status of renal function and acid-base balance. Measurement of erythrocyte potassium concentration has been suggested as an aid in the assessment of the potassium status of horses with exercise-related myopathy (Bain and Merritt, 1990; Muylle *et al*., 1984a, 1984b). However, experimental studies have failed to demonstrate a close correlation between erythrocyte potassium concentration and potassium depletion.

1. H*ypokalemia*

Hypokalemia occurs relatively frequently in domestic animals and may result from depletion of the body's potassium stores or from a redistribution of potassium from the ECF into the ICF space (Brobst, 1986), as indicated in Table 17-7. Hypokalemia most often is associated with excessive potassium losses from the gastrointestinal tract as the result of vomiting or diarrhea (Tasker, 1967c). Excessive renal loss of potassium results from the action of mineralocorticoid excess, the action of certain diuretics, and as the result of altered renal tubular function in animals with renal tubular acidosis or postobstructive states. Chronic dietary potassium deficiency eventually can lead to modest hypokalemia even in normal individuals (Aitken, 1976; Dow *et al*., 1987a). A rapidly developing and profound hypokalemia can occur in animals with reduced dietary intake as a result of anorexia when coupled with other causes of excessive potassium loss (Tasker, 1980).

Hypokalemia may develop without potassium depletion as the result of intracellular movement of potassium from the ECF space. This situation occurs with an acute alkalosis (Burnell *et al*., 1966) and in patients treated with insulin and glucose infusions (Tannen, 1986). In fact, medical management of severe life-threatening hyperkalemia often involves the administration of glucose, insulin, and,

in some circumstances, bicarbonate in an effort to shift potassium intracellularly. Catecholamines exert a biphasic effect on potassium concentration (Tannen, 1986). The initial response to catecholamine administration is a modest transient increase in potassium as the result of α-adrenergic stimulation followed by hypokalemia as the result of α-adrenergic receptor responses (Bendheim *et al*., 1985; Clausen *et al*., 1980; Williams *et al*., 1985). α-Adrenergic agents have been used for the treatment of hyperkalemic periodic paralysis (Bendheim *et al*., 1985). The relationship between catecholamine release, receptor stimulation, and potassium balance may play a significant role in the development of exertional fatigue in human and equine athletes (Carlson, 1987; Sjogaard *et al*., 1985).

2. H*yperkalemia*

Hyperkalemia can be produced iatrogenically by the excessive administration of potassium salts but does not usually result from high dietary intake in individuals with normal renal function (Aitken, 1976). There are three major causes of hyperkalemia as indicated in Table 17-8. Hyperkalemia may develop *in vitro* in blood sample containers because of hemolysis or prolonged storage of blood samples before the serum or plasma has been separated from erythrocytes in the sample. This leakage of erythrocyte potassium can result in significant errors in those species (horse, pig, most cattle) with a high potassium content in their erythrocytes (Tasker, 1980). The erythrocytes of cats and most dogs have a high sodium content and relatively low potassium. Slight hemolysis will have little effect on serum or plasma potassium concentration in these species. There are, however, polymorphisms in intracellular cation content of certain breeds of sheep, cattle, and dogs, which relate to sodium-potassium ATPase activity of mature erythrocytes. Release of potassium from leukocytes or platelets into the serum following clot formation in the sample collection vial is a potential cause of hyperkalemia in subjects with a marked leukocytosis or thrombocytosis (Degan, 1986; Mandell *et al*., 1988).

Hyperkalemia may be associated with excessive renal potassium retention in conditions such as Addison's disease, acute renal failure, and renal shutdown secondary to inadequate effective circulatory fluid volume. Hyperkalemia results, in a number of circumstances, from the movement of intracellular potassium into the ECF without change in external potassium balance. Hyperkalemia develops in association with a metabolic acidosis, particularly when the acidosis results from volume depletion complicated by renal shutdown. Hyperkalemia may be noted in patients with diabetes or transiently in animals with massive muscle necrosis. Interestingly, most horses with exertional rhabdomyolysis do not develop hyperkalemia or a metabolic acidosis (Koterba and Carlson, 1982). Vigorous short-term exercise at high intensity results in a profound hyperkalemia in horses. Serum potassium as high as 9 to 10 mEq/l (9 to 10 mmol/l) has been observed transiently in horses exercising at maximal intensity on a high performance treadmill (Harris and Snow, 1986). Muscular exhaustion in these horses appeared to be related to the hyperkalemia and the profound lactic acidosis seen in the immediate postexercise state (Carlson, 1987; Krzywanek, 1974; Krzywanek *et al*., 1976; Milne *et al*., 1976). An interesting and unusual condition of episodic hyperkalemia and muscular weakness has been recognized in the

dog (Jezyk, 1982) and certain quarter horses (Cox, 1985; Pickar *et al.*, 1991; Spier *et al.*, 1990, 1993; Steiss and Naylor, 1986). In the horse, the condition closely resembles the heritable disease hyperkalemic periodic paralysis, which has been reported in human subjects and is due to an alteration in the voltage-regulated sodium chemical (Rudolph *et al.*, 1992a, 1992b). Sudden marked increases in serum potassium concentration result from the transcellular movement of potassium. Serum potassium concentration can reach 8 to 9 mEq/l (8 to 9 mmol/l) and is associated with profound electrocardiographic abnormalities and fluid shifts, which result in marked increases in PCV and protein concentration. The disease is inherited as an autosomal dominant, and all affected horses can be traced back to a common ancestor. A DNA test that can detect the single base pair substitution responsible for this disease has been developed (Rudolph *et al.*, 1992ba). Using this procedure, it is possible to identify individuals that are heterozygous or homozygous for this trait.

D. Serum Chloride

It long has been assumed that the anion, chloride, which combines with sodium to form common salt, simply follows sodium in the physiological processes that regulate body fluid and electrolyte balance. It is becoming increasingly apparent that this may not always be true and that some of the problems ascribed to sodium retention do not occur unless chloride is present in excess as well (Kurtz *et al.*, 1987). Causes of alterations in chloride concentration are given in Table 17-9. The hyperchloremia and hypochloremia, which are normally seen in association with roughly proportional changes in sodium concentration, are due to changes in body water balance.

Changes in chloride concentration that are not associated with a similar change in sodium concentration are usually associated with acid-base imbalances (Divers *et al.*, 1986). Chloride concentration tends to vary inversely with bicarbonate concentration. A disproportionate increase in chloride most commonly is associated with a normal to low anion gap hyperchloremic metabolic acidosis such as renal tubular acidosis and may be seen as a compensating response for a primary respiratory alkalosis (Saxton and Seldin, 1986). Disproportionate decreases in chloride characteristically are seen in a metabolic alkalosis but also may be seen as part of the compensating response for a chronic primary respiratory acidosis (Saxton and Seldin, 1986).

E. Osmolality

It has been demonstrated that the concentration of sodium in serum water is closely correlated with the serum osmolality over an extremely wide range of physiological and pathological states provided appropriate corrections are made for the contributions made by variations in glucose and urea concentrations (Edelman *et al.*, 1958). The measurement of serum osmolality has two specific and very useful purposes (Gennari, 1984): first, to determine whether serum water content deviates widely from normal and, second, to screen for the presence of foreign low-molecular-weight substances in the blood. Interpretation of serum osmolality for these purposes requires simultaneous comparison of the measured osmolality and the calculated osmolality as determined from the measured concentrations of the major solutes in serum (sodium, glucose, and urea). The difference between the measured and the calculated osmolality is sometimes referred to as the "osmolal gap" (Feldman and Rosenberg, 1981; Shull, 1978, 1981).

Sodium is the principal cation in serum, and sodium is balanced by a number of different anions (chloride, bicarbonate, protein, sulfate, and phosphate). Sodium concentration thus provides a reasonable estimate of the total electrolyte concentration (anions and cations) in the sample and, in this calculation, is usually multiplied by a factor of 2. As mentioned earlier, the water content of serum samples is approximately 94%. Correction for the water content of serum is not necessary because, fortuitously, it is counterbalanced by the fact that sodium chloride does not dissociate completely and has an osmotic coefficient of 0.93 in serum (Dahms *et al.*, 1968; Rose, 1984; Wolf, 1966). The osmolality can thus be calculated using the measured sodium concentration, and the concentration of the two nonelectrolyte components of serum that are normally present in amounts sufficient to influence osmolality:

$$\text{mOsm/kg } H_2O = 2 \times \text{sodium} + \text{glucose} + \text{urea} \quad (17\text{-}15)$$

This calculation is valid if concentrations of sodium, glucose, and urea are expressed in mmol/l. Conversion of glucose concentration from mg/dl to mmol/l requires division by 18, and urea concentration in mg/dl can be converted to mmol/l by dividing by 2.8.

Decreases in osmolar gap indicate laboratory error. Increases in osmolar gap (>10 mOsm/kg) could also represent laboratory error but generally result from one of two circumstances: either a decrease in serum water content or the addition of low-molecular-weight substances in serum. Decreases in serum water content occur with marked hyperlipidemia or hyperproteinemia, and the calculated osmolality will exceed the measured osmolality. This is the cause of the false hyponatremia discussed in Section VI.B. The presence of a similar disparity between the measured and calculated osmolality in the absence of hyperlipidemia or hyperproteinemia should prompt an alert for the presence of exogenous substances in abnormally high concentrations in the serum. These substances could include a variety of exogenous and potentially toxic compounds, such as mannitol, ethanol, methanol, ethylene glycol, isopropanol, ethyl ether, acetone, trichloroethane, and paraldehyde (Saxton and Seldin, 1986).

I. HYPOTHALAMUS-PITUITARY SYSTEM

The hypothalamic-pituitary system is a preeminent example of the integration of neural and endocrine control. It consists of three major systems: (1) a neuroendocrine system connected to an endocrine system by a portal circulation, (2) a neurosecretory pathway, and (3) a direct neural regulation of endocrine secretion (Fig. 18-1).

The neuroendocrine system involves clusters of peptide- and monoamine-secreting cells in the anterior and midportion of the ventral hypothalamus. Their products reach the median eminence by axonal transport. From there they are released into the capillary vessels of the hypothalamic-pituitary portal system and transported to the pituitary to regulate the secretion of hormones from the anterior lobe (AL) of the adenohypophysis (Amar and Weiss, 2003).

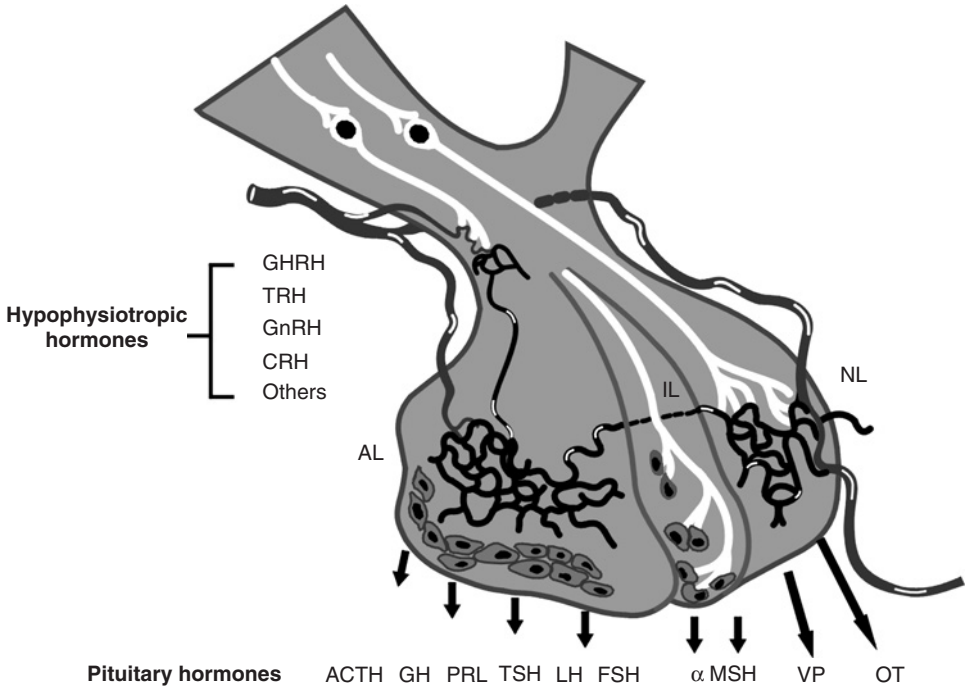

FIGURE 18-1 Schematic representation of the relationship between the hypothalamus and the pituitary in a generalized mammal. The hypothalamus exerts control over the anterior lobe (AL) by releasing and inhibiting factors. These hormones reach the AL cells via capillaries of the pituitary portal system. The neural lobe (NL) of the pituitary is a downward projection of the hypothalamus. The intermediate lobe (IL) is under direct neurotransmitter control.

The neurosecretory pathway runs from the anterior hypothalamus, traverses the floor of the ventral hypothalamus, and terminates in the neural lobe (NL) of the neurohypophysis on fenestrated blood vessels (Page, 1986). The system is involved in osmoregulation through the production and release of vasopressin, and in parturition and nursing through the secretion of oxytocin.

In the intermediate lobe (IL) the secretory activity is regulated via direct neuronal inhibitory and stimulatory influences (Saland, 2001). In amphibians (Vazquez-Martinez *et al.*, 2003) and reptiles (Dores *et al.*, 1987), the IL plays an important role in adaptation to background color. The function of IL cells in mammals has not been fully established, but they may play a role in opioid-regulated functions.

A. Anatomical Considerations

The hypothalamus and pituitary control vital functions such as growth, reproduction, lactation, basal metabolism, stress response, parameters of immune function, and the state of hydration. Understanding of the complicated functional relationship of the hypothalamus to the pituitary requires an appreciation of the anatomical relationships.

1. *Hypothalamus*

Hypophysiotropic neurohormones are produced in several areas of the hypothalamus. For example, in an immunofluorescence study of hypothalami of dogs, the majority of cell bodies with immunoreactivity to corticotropin-releasing hormone (CRH) was found in the region of the periventricular and paraventricular nuclei, but they were also found in the supraoptic and suprachiasmatic area as well as craniodorsal to the mammillary bodies (Stolp *et al.*, 1987).

The cell bodies of the neurohormone-producing neurons that project to the median eminence are in part intermingled with cell bodies that also synthesize these neurohormones but project to other brain areas. The majority of the neurons that project to the median eminence are found in the preoptic and suprachiasmatic region of the hypothalamus. Axons containing the same neurohormone may have synaptic contacts that enable regulation of cellular function between these neurons.

The neurohormone-producing cells receive a complex neural input from a variety of chemical messengers, such as neurotransmitters and other neurohormones. Not only the neurohormones CRH and arginine vasopressin (AVP), but in general the combination of a neurohormone and another chemical messenger, may colocalize within a single neuron.

The neurons of the neurohypophyseal system represent a more anatomically distinct entity, with cell bodies located in the paraventricular and supraoptic hypothalamic nuclei (Sawchenko and Swanson, 1983). However, within these areas there are also neurons producing a variety of other neuropeptides.

2. *Neurotransmitter Systems*

The major neurotransmitter systems for intercellular communication within the central nervous system consist of monoamines and peptides. These chemical messengers regulate the biosynthesis and release of the hypophysiotropic neurohormones. Through a network of axodendritic and axoaxonic contacts, these neurons are connected to the neurohormone-producing cells. In addition, many monoamines and peptides are found within the hypophysiotropic hormone-producing cells, where they are released together with the neurohormones into the portal system and modify the effect of hypothalamic hormones on the pituitary.

The biogenic amine neurotransmitters, known to play a regulating/modulating role in the hypothalamic-pituitary system, include catecholamines (dopamine, noradrenalin, and adrenalin), indolamines (serotonin, melatonin), acetylcholine, γ-aminobutyric acid (GABA), and histamine. Neuropharmacological agents can be used to alter neurotransmitter effects and, as a consequence, hypothalamic and pituitary hormone release.

Many of the peptides with potential effects on hypophysiotropic hormone release are widely distributed in hypothalamic and extrahypothalamic areas of the brain. They include, among many others, peptides common to the gastrointestinal tract, such as gastrin, cholecystokinin, and pancreatic polypeptide as well as bombesin, angiotensin II, galanin, substance P, neurotensin, enkephalins, neuropeptide Y, natriuretic peptide, the vasoactive intestinal peptide (VIP), and the peptide histidine isoleucine (PHI). The last three peptides may, through vasoconstriction and vasodilatation activities, play an important role in the control of the portal blood flow.

3. *Vascular System*

The releasing and inhibiting hormones are stored in nerve terminals in the median eminence, where their concentrations are 10 to 100 times as great as elsewhere in the hypothalamus. The uniquely organized capillary plexus (Halasz, 1994; Page, 1986) of the median eminence is in close proximity to nerve terminals of the hypophysiotropic neurons. In contrast to other brain regions, the blood-brain barrier in the area of the median eminence is incomplete, permitting protein and peptide hormones as well as other charged particles to move to the intercapillary spaces and the nerve terminals contained therein. These terminals respond to humoral and neuronal stimuli by secreting releasing and inhibiting factors into the portal system.

The portal capillaries coalesce into a series of vessels that descend through the pituitary stalk and form a second capillary plexus that surrounds the AL cells (Fig. 18-1).

Inferior hypophyseal arteries supply the neurohypophysis. From the primary plexus of the neural lobe (NL), blood flows not only to the systemic circulation but also to the AL and the hypothalamus. There is evidence for some degree of

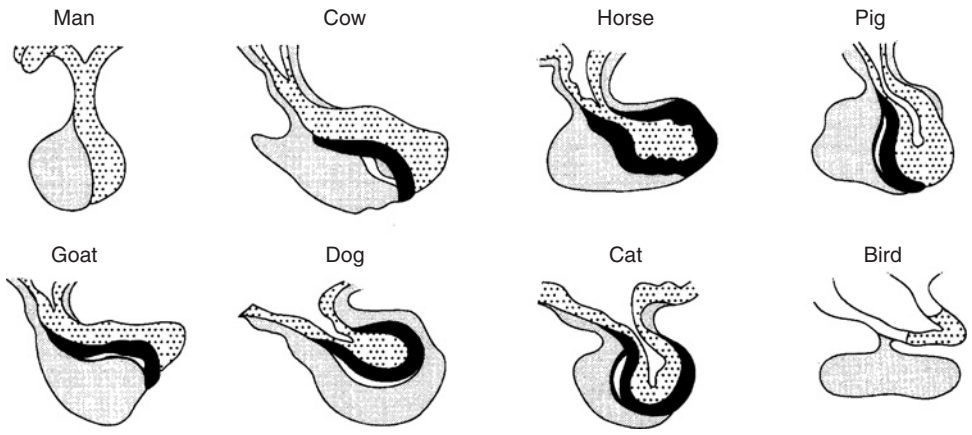

FIGURE 18-2 Schematic illustration of median sections through mammalian and avian pituitaries. Key ▨, anterior lobe; ■, intermediate lobe; ▩, neural lobe. Redrawn from Batten and Ingleton (1987).

circulatory flow within the pituitary, that is, from the AL to the NL, from there to the infundibulum, and then back to the AL. The primary capillary plexus of the NL appears to be well positioned in the minicirculatory system, controlling all of the afferent vascular events and many of the efferent vascular events in the pituitary (Page, 1986).

The vascularization of the intermediate lobe is closely linked to that of the neurohypophyis. In spite of the rich blood supply of the NL, the IL is a poorly vascularized structure. In horses the IL is supplied by a vast capillary or sinusoidal plexus, which connects that in the AL with that in the NL (Okada *et al.* 1997).

4. *Pituitary Organogenesis and Ontogenesis*

During embryogenesis the adenohypophysis develops from Rathke's pouch, which arises from the primitive roof of the mouth in contact with the base of the brain. Rathke's pouch subsequently separates by constriction from the oral cavity. The anterior wall thickens and forms the anterior lobe of the adenohypophysis. This largest portion of the adenohypophysis remains separated from the intermediate lobe by the hypophyseal cleft, which is the residual lumen of Rathke's pouch. In several species (Fig. 18-2), the adenohypophysis also extends into a pars tuberalis that forms a cuff or collar around the proximal neurohypophysis and may even envelop part of the median eminence (Batten and Ingleton, 1987; Hullinger, 1993).

In the embryonic development, the anterior lobe undergoes major cellular proliferation and differentiation (Dubois *et al.* 1997). Totipotent pituitary stem cells give rise to two main cell lineages, the acidophilic (mammasomatotropic, somatotropic, lactotropic) and the basophilic (corticotropic, thyrotropic, and gonadotropic) differentiated pituitary cell types. Determination of AL cell-type lineages results from a temporally regulated cascade of homeodomain transcription factors that are being dissected by genetic and molecular approaches at a rapid pace (Treier *et al.* 1998). Although most pituitary developmental information has been acquired from murine models, histological and pathogenetic observations in others mammals and human subjects have corroborated these developmental mechanisms. The transcription factor Rpx (Rathke's pouch homeobox) is the earliest known specific marker for the adenohypophyseal primordium. Rathke's pouch expresses several transcription factors of the LIM homeodomain family, including Lhx3 and Lhx4 (Sheng *et al.* 1997). Lhx3 is one of the earliest markers for cells that are destined to form the AL and the IL and is required for Pit-1 expression (Sheng *et al.* 1996). The homeodomain transcription factor Ptx1 behaves as a universal pituitary regulator and activates transcription of α-GSU (the α-subunit of gonadotroph hormones) and POMC (Drouin *et al.* 1998; Lamonerie *et al.*, 1996). Transcription factors Tpit (T box transcription factor) (Lamolet *et al.*, 2001) and NeuroD1 (Lamolet *et al.*, 2004) appear to be a prerequisite for POMC expression and determine the development of the corticomelanotrope cell lineage. TSH and gonadotropin (LH and FSH)-expressing cells share the common α-GSU expression under developmental control of GATA-2. Prop-1, the prophet of Pit-1, stimulates the Pit-1 gene. Pit-1 (or POU1F1), a POU-homeodomain transcription factor, determines the development and appropriate temporal and spatial expression of cells committed to GH, PRL, and TSH. Corticotroph cell commitment, although occurring earliest during fetal development, is independent of Pit-1-determined cell lineages. Mutations arising within these transcription factors may result in isolated or combined pituitary hormone failure syndromes. German shepherd dogs with pituitary dwarfism have a combined deficiency of GH, TSH, and PRL together with impaired release of gonadotropins, whereas ACTH secretion is intact (Kooistra *et al.*, 2000c). The transcription factors Lhx4 (van Oost *et al.*, 2002), Prop-1 (Lantinga-van Leeuwen *et al.*, 2000a), Pit-1 (Lantinga-van Leeuwen *et al.*, 2000b), and the LIF receptor gene (Hanson *et al.*, 2006b) have been excluded as candidates for pituitary dwarfism in German shepherds and the cause remains to be elucidated.

The posterior wall of Rathke's pouch is closely apposed to the neural tissue of the NL, thereby forming the intermediate lobe (IL), which is well developed in most mammals,

TABLE 18-1 Molecular Weights of Adenohypophyseal Hormones and Staining Properties of Adenohypophyseal Cells

Cell Type	Hormone	MW[a]	Subunits	Staining	Orange G	PAS[b]	Color[c]
Somatotrope	GH	22,000	—	Acidophil	+	−	Yellow
Lactotrope	PRL	22,500	—	Acidophil	+	−	Yellow
Gonadotrope	LH	30,000	α/β	Basophil	−	+	Blue

but not in humans and birds (Fig. 18-2). In humans only during fetal life is a distinct IL found (Amar and Weiss, 2003), whereas there is some debate about the view that in adults "invading" cells of the posterior lobe are homologous with the IL cells of lower vertebrates (McNicol, 1986). Unlike reptiles and mammals, birds have no IL (Batten and Ingleton, 1987). Nevertheless the typical "IL hormone" MSH is present in birds, having been found in the adenohypophysis, where it coexists with ACTH in cells named corticomelanotrophs (Iturriza *et al.*, 1986).

The pituitary stalk (infundibulum) and the neurohypophysis (posterior lobe, neural lobe) develop from the basal outgrowth of the diencephalon in connection with the development of Rathke's pouch. The cells of the diencephalic outgrowth later develop into glial cells (pituicytes), whereas nerve fibers from the supraoptic and paraventricular nuclei grow into the NL.

5. *Cells of the* Anterior Lobe (AL)

The peptide hormones secreted by the AL can be divided into three categories: (1) the somatomammotropic hormones growth hormone (GH) and prolactin (PRL); (2) the glycoprotein hormones thyrotropin (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH); and (3) the corticomelanotropins, which are all derived from the precursor molecule proopiomelanocortin (POMC), and the corticomelanotropins include adrenocorticotropin (ACTH), α-melanotropin (α-MSH), β-endorphin (β-END), and β-lipotropin (β-LPH).

Identification of the adenohypophyseal cells has been developed by histochemical staining techniques, immunohistochemical methods, and ultrastructural studies. Staining and immune reactions depend on the chemical nature of the hormones that are stored in granules within the cytoplasm. A general identification of adenohypophyseal cells (Batten and Ingleton, 1987) is given in Table 18-1, although it must be realized that the various cell types do not always give exactly the same reaction in different animal species. Having undergone a number of modifications over the years to improve sensitivity and specificity, immunohistochemistry remains the single most often used method in the identification of normal and diseased AL cell types. Apart from staining for the full spectrum of hormones (GH, PRL, ACTH, FSH, LH, TSH, and α-subunit), special stains investigate the diseased AL cell, such as staining with MIB-1, a cell proliferation marker that recognizes the KI-67 antigen, or demonstration of the protein p53, the product of a tumor suppressor gene, as parameters for aggressive behavior of cells. Development of sophisticated tools of molecular biology during the 1990s has enabled researchers to study chromosomal defects, genetic abnormalities such as specific mutations, the presence of oncogenes or of tumor suppressor genes, cell membrane receptors, signal transductions mechanisms, and intracellular changes that affect hormone synthesis and release. Pituitary cell cultures (normal and diseased, e.g., murine AtT-20 corticotrope cell line) allow various *in vitro* studies to be undertaken. *In situ* hybridization demonstrates specific messenger RNAs (mRNAs) at the subcellular level, which allows the reliable assessment of gene expression. *In situ* hybridization can be used to demonstrate the mRNA of receptors, growth factors, transcription factors, genes, and other regulatory peptides. Whereas immunocytochemistry provides information regarding cell hormone content, *in situ* hybridization confirms the presence of ongoing hormone synthesis.

Transmission electron microscopy allows the study of AL cells at the ultrastructural level. Applications of immunohistochemical methods at the ultrastructural level have also contributed to the rapid progress in the field. Ultrastructural studies of AL cells demonstrate the presence of distinct varieties of secretory granules and typical

organization of cytoplasmic organelles for peptide synthesis and release. Characteristics such as the form, size, and location of the various organelles and the size and shape of the cells and their nuclei allow identification of adenohypophyseal cells at the ultrastructural level (Batten and Ingleton, 1987; Mikami, 1986).

The distribution of the various secretory cells of the AL is not random, different hormone-secreting cells preferentially accumulate at different sites in the AL. This topological organization of the AL is well known in the human and may also be true for domestic animals. The gland comprises a central "mucoid" wedge containing thyrotropes and corticotropes and lateral wings containing somatotropes and lactotropes. The gonadotropes are distributed diffusely throughout the gland. Also, the numerical contribution of each AL cell type is not the same. In the pituitary anterior lobe of humans the distribution is corticotrope (10% to 15%), thyrotrope (5%), somatotrope (50%), lactotrope (10% to 30%), and gonadotrope (15% to 20%).

The concept of one pituitary cell making one hormone is an oversimplification. Immunoelectron microscopy has shown that one hormone can be produced by the same or different cell populations. In some instances, multiple hormones are produced by the same cell population and have even been visualized within the same secretory granule. The majority of gonadotropes and somatomammotropes is multihormonal cells that contain LH and FSH or GH and PRL, respectively. Also, other combinations such as gonadotroph hormones and ACTH or TSH and ACTH have been described.

In addition to the functionally distinctive AL cell types noted above, cells termed "stellate" or "folliculostellate" also occur within the normal pituitary. Folliculostellate cells lack secretory granules as well as hormone secretion and are characterized by processes that insinuate themselves between the AL cells. The physiological role of folliculostellate cells is uncertain. They are thought to be supportive in nature and synthesize a variety of chemical messengers, intrapituitary growth factors, and cytokines that exert local paracrine effects on cell function and proliferation (Denef, 1994).

6. *Cells of the Intermediate Lobe* (IL)

The predominant IL cell in mammals is the melanotrope, a cell with immunoreactivity for α-MSH, which is sparse in the AL (Halmi and Krieger, 1983). In some species, including the dog (Halmi *et al.*, 1981) and the horse (Amann *et al.*, 1987), the IL is cytologically heterogeneous. ACTH-containing cells (B cells) have been found to be dispersed among the predominant melanotropes (A cells). In the dog, the immunoreactive ACTH content of the IL even exceeds that in the AL (Halmi *et al.*, 1981). In ferrets, as in dogs and cats, the melanotropic cell was the most abundant cell type of the IL (Schoemaker *et al.*, 2004). In agreement with the previously mentioned direct neural regulation of IL secretory activity, the presence of neural elements was demonstrated in the bovine IL (Boyd, 1987). Evidence is accumulating that the cells of the pars intermedia are also involved in the biosynthesis and release of a yet unknown prolactin-releasing factor. The blood supply of the IL is poor, and therefore the peptides released from the IL are thought to mainly act by diffusion in a paracrine manner.

7. *Cells of the Neural Lobe* (NL)

The NL contains axonal nerve fibers, often swollen by being packed with neurosecretory granules. These nerve fibers and the glial cells (pituicytes) have synaptoid contacts. The pituicytes play an intermediary role in the regulation of the release of vasopressin and oxytocin (Rosso *et al.*, 2004).

B. Regulation of Pituitary Functions

For the regulation of each of the five major adenohypophyseal hormone systems (ACTH, LH and FSH, TSH, GH, and PRL), there is a feedback (closed-loop) system. AL hormone and hypophysiotropic hormone secretions are suppressed by the products of target endocrine glands such as the thyroid, adrenals, and gonads. Apart from this long-loop feedback, some hormones (e.g., PRL) regulate their own secretion directly by acting on the hypothalamus (short-loop feedback). On this powerful feedback control with primarily blood-borne signals, other signals are superimposed. These may originate within the central nervous system (open loop) and can be mediated through neurotransmitters and hypophysiotropic hormones. Thus, influences are exerted that represent the environment (temperature, light-dark), stress (pain, fear), and intrinsic rhythmicity.

These regulatory factors influence peptide synthesis or release in adenohypophyseal cells, where each of the steps in hormone synthesis and ultimate secretion represents a potential control point in the regulation of circulating hormone concentrations.

1. *Hypophysiotropic Hormones*

The main hypothalamic neurohormones may stimulate or inhibit the release of a single hormone, or it may affect several hormone-producing cells (Fig. 18-3). The predominant influence of the hypothalamic hormones on the pituitary is stimulatory, and these peptides are known as releasing hormones (Guillemin, 2005). Interference with the integrity of the hypothalamic-pituitary connections results in decreased secretion of pituitary hormones. The exception is PRL, the secretion of which is increased when hypothalamic influence is removed.

As the complexity of the peptide structures of the hypophysiotropic hormones increases, species variation in

sequence may occur. Whereas the structures of TRH, GnRH, and somatostatin (SS) (3, 10, and 14 amino acids, respectively) are identical for mammals, those of GHRH and CRH (44 and 41 amino acids) exhibit species specificity. The one nonpeptide hypophysiotropic hormone is dopamine. In addition to its major role as a neurotransmitter, dopamine is the most important inhibitor of PRL release.

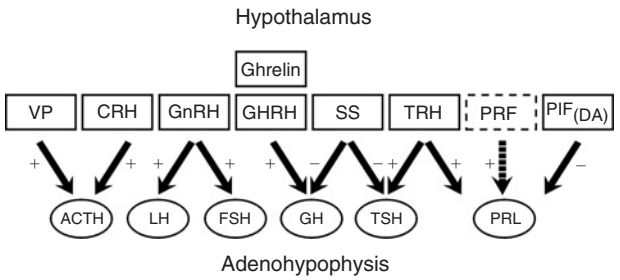

FIGURE 18-3 Hypophysiotropic regulation of the secretion of pituitary hormones. Solid lines denote hormones whose structures have been determined. Dashed lines indicate a factor whose identity is still unknown.

2. *Regulation of Gene Expression*

The developments in recombinant DNA technology have enabled an increased knowledge on the genes encoding pituitary hormones and the regulatory elements involved in gene transcription. In short, the main elements regulating the gene transcription will be mentioned (Fig. 18-4). Eukaryotic genes encoding peptide hormones consist of a promoter (regulatory) unit and a transcription unit encoding the primary transcript that after appropriate processing will form the messenger RNA (mRNA).

The promoter unit is the upstream part (5′) of the gene. The promoter has specific DNA sequences (response elements) permitting the binding of transcription factors that enhance or inhibit gene expression by changes in the stability of the RNA polymerase-TATA box complex at the constitutive promoter. Also, with a higher distance to the gene-specific enhancer elements, or locus control regions as seen with GH expression (Ho *et al.*, 2006), may regulate gene transcription. Tissue-specific silencers and enhancers that are mandatory for gene expression regulate the highly

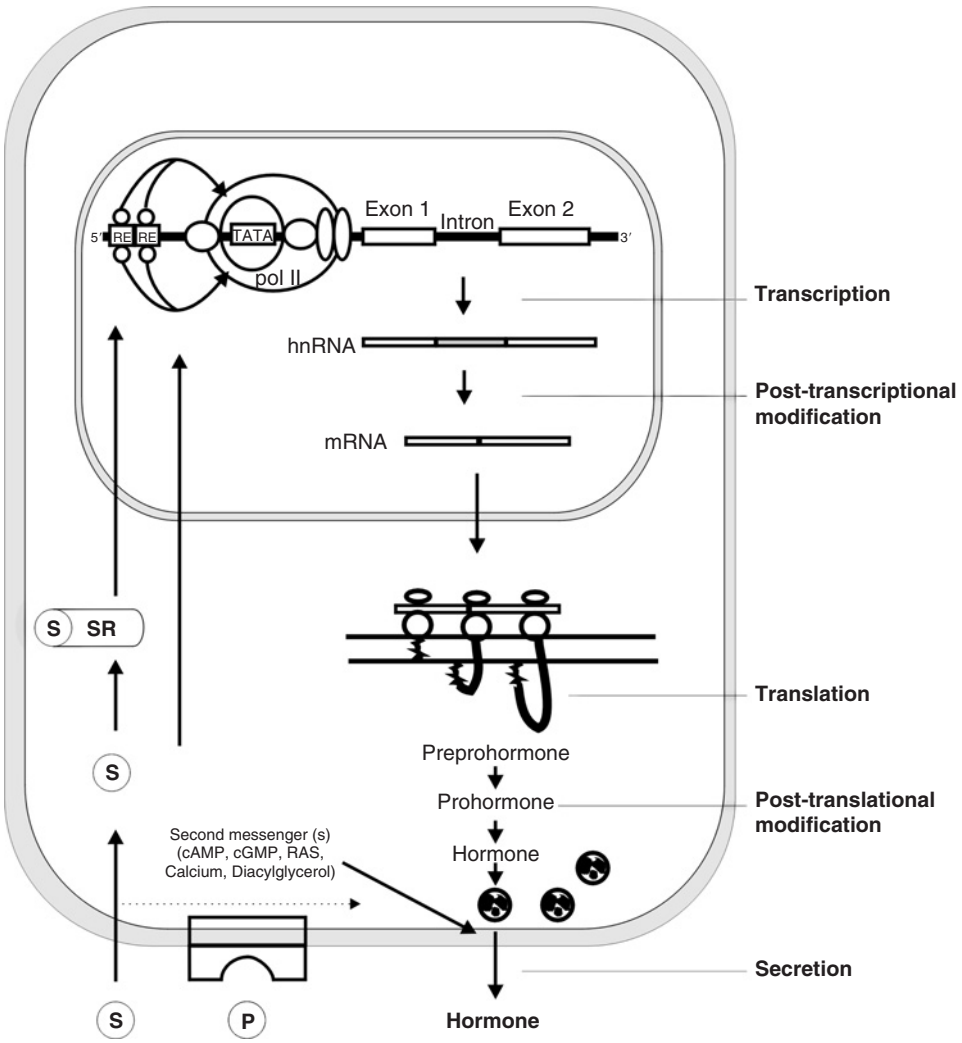

FIGURE 18-4 Schematic representation of potential control points in pituitary hormone synthesis and secretion.

specialized hormone production. Methylation patterns of the promoter may also strongly influence the overall expression level (Newell-Price, 2003).

Tissue-specific intracellular transcription factors play a crucial role in the regulation, whether a gene comes to expression. Specific binding of neurohormones from the hypothalamus to membrane receptors of individual AL cells will result in changes in intracellular second messenger concentrations or activity, a process called signal transduction. Using microarray technology important signaling pathways for pituitary hormone expression can be revealed (Ma *et al.*, 2005). Activation of these pathways results in differences in phosphorylation of transcription factors that may bind to a response element (RE) in the promoter unit. Steroid hormones, thyroid hormone, and retinoids will, after binding to specific cytoplasmic or nuclear localized receptors, induce receptor binding to specific areas of the promoter. For example, a glucocorticoid response element (GRE) in the promoter of the gene encoding proopiomelanocortin binds the glucocorticoid-receptor complex resulting in inhibition of gene transcription (negative GRE). Transcription is thus regulated by responses to extracellular signals, which may also be derived by components of the extracellular matrix (ECM) (Paez-Pereda *et al.*, 2005).

After transcription has been initiated, a primary transcript is made containing an RNA copy of the entire transcription unit, the heteronuclear RNA (hnRNA). After excision of the intron areas, a process called splicing, a cap formation at the 5′ end and the addition of a poly(A) tail at the 3′ end a mature mRNA is formed. Through alternative splicing reactions, length variants of the mRNA may ultimately result in variation of the coding sequence (see Section II.C.1), changes in mRNA stability as found for the insulin-like growth factors (IGFs), or by differences in exon coupling even completely different peptides can be obtained from a single gene as for instance in the gene encoding calcitonin.

3. *Prohormone Biosynthesis, Processing, and Release*

The process of peptide synthesis occurs principally on the rough endoplasmic reticulum (RER). Messenger RNA (mRNA), encoded by nuclear DNA, passes to cytosolic ribosomes, whereby sequential processing of transfer RNAs (tRNA), with their attached amino acids, the translation process of mRNA to a peptide starts (Fig. 18-4). The beginning of the growing peptide forms a specific signal peptide that facilitates the attachment of the translation complex to the RER and enables the passage into the lumen of the RER. The signal sequence of the preprohormone is cleaved, and the remaining prohormone undergoes several modifications as disulfide formation and glycosylation. The peptide passes along the RER lumen into the Golgi complex, where peptides are packaged and released into the cytoplasm as membrane-bound granules. During storage of these granules, the prohormone is further processed by specific proteolytic cleavage, C-terminal amidation, or N-terminal carboxylation. Characteristic for proteolytic cleavage sites are pairs of the basic amino acids arginine and lysine. The granules are stored until the hormone is released by exocytosis. This process involves fusion of the granule membrane with the cell membrane.

II. ANTERIOR LOBE AND INTERMEDIATE LOBE

A. Proopiomelanocortin-Derived Peptides

The corticotropic cells of the AL and the melanotropic cells of the IL are both able to synthesize proopiomelanocortin (POMC), the common prohormone for ACTH, α-MSH, β-lipotropin, and a family of β-endorphin-related peptides (Fig. 18-5).

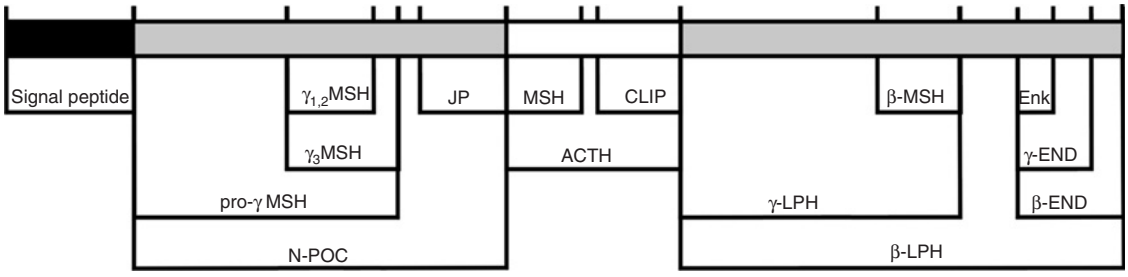

FIGURE 18-5 Schematic representation of preproopiomelanocortin (horizontal bar), with four domains: the signal peptide, which is cleaved after entrance to the lumen of the RER; the N-terminal peptide (N-POC), containing the (pro) γ-MSH sequences and the joining peptide (JP); the ACTH domain from which MSH and corticotropin-like intermediate lobe peptide (CLIP) is generated; and the β-lipotropin (β-LPH) domain, including the endorphin (END) family of peptides and a metenkephalin sequence (Enk). Pairs of basic amino acid residues are indicated with vertical lines, representing potential sites of proteolytic cleavage. In the AL major cleavage products are N-POC, ACTH, and β-LPH. In the IL the major products are N-POC, γ-MSH, α-MSH, and β-endorphin.

The asterisk (*) means an identical sequence for all species. The shaded box indicates the two pairs of basic amino acids prone to proteolytic cleavage. The insert shows a dendrogram indicating the mutual relationship.

1. ACTH/α-MSH

a. Gene Expression

The gene encoding POMC contains three exon areas. Exon 1 encodes a 5′ untranslated region (5′-UTR), and exon 2 encodes the signal peptide and the N-terminal part of the POMC prohormone. The majority of the prohormone, including γ-MSH, is encoded by exon 3. After the splicing process, an mRNA of approximately 1150 nucleotides is formed in the pituitary of most species, including the dog (Mol *et al.*, 1991). In many peripheral tissues, very low expression of shorter POMC mRNA sequences are found, whereas in nonpituitary tumors, an mRNA of 1350 nucleotides can be found (Newell-Price, 2003).

The presence of an unmethylated CpG island in the POMC promoter is a prerequisite for gene expression, whereas methylation completely blocks gene expression (Newell-Price, 2003). These methylation patterns are set during early development. Synergistic stimulation of gene expression requires binding of yet partially characterized transcription factors in the distal and central part of the POMC promoter. The expression of the POMC gene in corticotropes and melanotropes is regulated by the same promoter elements as shown by experiments with transgenic mice (Tremblay *et al.*, 1988). Three important response elements act within the central promoter region. The pituitary homeobox 1 (Ptx1) protein, which is widely expressed in the pituitary, acts in synergy with the corticotrope/melanotrope-specific factors NeuroD1 (Newell-Price, 2003) or Tpit (Quentien *et al.*, 2006) to stimulate POMC gene expression.

Binding of corticotropin-releasing hormone (CRH) stimulates POMC expression in the PD through stimulation of cAMP within the cell (Jacobson and Drouin, 1994). CRH acts synergistically with the leukemia-inhibitory factor (LIF) through binding of the cAMP response element binding protein (CREB) at the response element sites for NUR77 and STAT1-3 (Mynard *et al.*, 2004). Nur77 is an orphan nuclear receptor that antagonizes the negative feedback of glucocorticoids on POMC expression (Martens *et al.*, 2005).

POMC expression in the IL melanotrope is also stimulated by cAMP. *In vitro* experiments in various species point to a possibility that CRH activates this signal transduction system. However, chronic infusion of CRH stimulates the POMC mRNA concentrations in the AL but inhibits mRNA concentration in the IL (Hollt and Haarmann, 1984). IL POMC expression is also regulated by stimulation with serotonin and norepinephrine or GABAergic and dopaminergic inhibition (Saland, 2001). Glucocorticoids inhibit AL POMC expression but have no effect on the IL expression of POMC.

Extrapituitary POMC expression is found in many tissues (DeBold *et al.*, 1988), also in skin tissue of various species including the dog (Kidney *et al.*, 2004).

b. (Pro)hormone

POMC prohormone sequences are known for a variety of species and share a common structure (Fig. 18-5). Among species a high sequence homology is found between the N-terminal site (N-POC) of the prohormone (including γ-MSH), the ACTH region, and the β-endorphin region. In contrast, the regions between γ-MSH and ACTH and the first part of β-lipotropin are rather heterogeneous (Mol *et al.*, 1991; Numa and Imura, 1985). Species differences in the sequence of ACTH occur only in the N-terminal part (Fig. 18-6), whereas the ACTH(1-24) sequence, necessary for full biological activity, is identical among mammals. The specificity of immunoassays to measure ACTH concentrations is achieved by directing antibodies toward the ACTH (13-18) epitope, which is absent in MSH and corticotropin-like intermediate lobe peptide (CLIP). These antibodies do, however, cross-react with intact POMC and may result in apparent elevated ACTH concentrations (Goossens *et al.*, 1995). Two-sided assays are more sensitive to variation in the carboxy-terminal part and show insufficient cross-reactivity among the species.

The proteolytic enzymes PC1/PC3 and PC2 are involved in the processing of prohormones in neuroendocrine cells. They cleave the precursor at pairs of basic amino acids, resulting in the formation of biologically active hormones. The PC1/PC3 enzyme present in the AL cleaves POMC to ACTH and β-LPH. PC2 generates the ACTH(1-13) fragment in both the AL and IL. The combination of both enzymes is present in the melanotropes of the IL. In the hypothalamus, these enzymes determine also the availability of POMC-derived melanocortins, which play an essential role in the regulation of energy balance (Bertile and Raclot, 2006; Helwig *et al.*, 2006).

In the melanotrope α-MSH is formed by C-terminal amidation and N-terminal acetylation of ACTH(1-13). Various degrees of acetylation of MSH result in the storage

TABLE 18-2 Factors Modulating ACTH Release from the Adenohypophysis

	Stimulating	Inhibiting
Hormones	CRH Vasopressin	Glucocorticoids Enkephalin

Biogenic amines	Norepinephrine Serotonin GABA	Dopamine
Otherwise	Hypoglycemia Hypoxia Stress (physical, emotional)	

of desacetyl-, monoacetyl-, and diacetyl-αMSH in secretory granules. The canine IL contains predominantly the monoacetyl-αMSH (Young *et al.*, 1992).

c. Secretion by the AL

ACTH is released in frequent pulses, as demonstrated in the pituitary venous effluent of the horse (Alexander *et al.*,1994; Redekopp *et al.*, 1986a, 1986b). By measurements in peripheral blood (Kemppainen and Sartin, 1984), the episodic secretion of ACTH in dogs was documented, with an average of nine peaks per 24-hour period.

Many factors influence the secretion of ACTH by the AL (Table 18-2). A number of these factors modulate the release of CRH and AVP, which are considered to be the predominant stimulating neurohormones *in vivo* (Antoni, 1986; Keller-Wood and Dallman, 1984). The relative contribution of CRH and AVP to ACTH release varies among species and circumstances. In dogs (van Wijk *et al.*, 1994) and pigs (Minton and Parsons, 1993), both exogenously administered CRH and LVP induce comparably high plasma ACTH concentrations. In sheep, AVP is the predominant ACTH-releasing factor. In horses, AVP is the immediate stimulus for ACTH release, and even ACTH micropulses appear to be regulated by AVP set point (Alexander *et al.*, 1996). On the other hand, CRH secretion and pituitary responsiveness to CRH rise when cortisol falls, suggesting that in horses a major role for CRH is to fix the cortisol set point (Alexander *et al.*, 1996). In the rat, the stimulation of ACTH release by CRH and AVP is synergistic, meaning that the response to CRH + AVP is greater than the sum of the reactions to CRH and AVP separately (Buckingham, 1987).

The basal release of ACTH is regulated by the occupancy of type I or mineralocorticoid receptors (MR) in the hippocampus (Jacobson and Sapolsky, 1991). Decreases in brain MR binding capacity of the dog during aging results in enhanced basal activity of the hypothalamus-pituitary-adrenal axis (Rothuizen *et al.*, 1993). In sheep, basal ACTH release is inhibited by active immunization against AVP (Guillaume *et al.*, 1992a) but not by immunization against AVP (Guillaume *et al.*, 1992b).

Exercise and insulin-induced hypoglycemia stimulate ACTH release. In the horse, exercise-induced ACTH release and mild insulin-induced hypoglycemia are accompanied by increased AVP concentration in pituitary venous blood without changes in CRH concentrations (Alexander *et al.*, 1991). However, when hypoglycemia becomes severe, CRH is released, which augments the ACTH response (Alexander *et al.*, 1996, 1997). In sheep, mild hypoglycemia is accompanied by increases in AVP and CRH concentrations in portal blood, but in severe hypoglycemia the AVP secretion is relatively much higher than the CRH release (Caraty *et al.*, 1990). AVP also regulates the ACTH response on hypoglycemia in the neonatal rat (Muret *et al.*, 1992).

Hypotension induced by nitroprusside (Kemppainen and Sartin, 1987) or by hemorrhage (Lilly *et al.*, 1983) causes ACTH release in the dog, together with large increases in plasma AVP derived from the NL (Raff *et al.*, 1989). Selective neurohypophysectomy results in greatly attenuated ACTH and AVP responses to hypotension and angiotensin II, whereas the ACTH response to CRH injection remains unchanged. By substitution with adequate AVP infusion, the ACTH response to hypotension can be restored (Raff *et al.*, 1992). In sheep, chronic absence of ovarian hormones after ovariectomy reduces the ACTH response to hypotension also, but not to CRH, AVP, or hypoglycemia (Pecins-Thompson and Keller-Wood, 1994).

In the dog, the release of ACTH is stimulated by β-adrenergic agonists (isoproterenol), dopaminergic antagonists (haloperidol), and serotoninergic agonists (quipazine maleate). TRH and GnRH stimulate the release of cortisol, probably by stimulating ACTH release (Stolp *et al.*, 1982). In the horse, the α2-adrenergic agonist clonidine lowers ACTH secretion primarily by reducing the secretion of AVP and possibly CRH (Alexander and Irvine, 2000). Although direct stimulatory effects of catecholamine on the *in vitro* release of ACTH from ovine pituitary cells have been found, central stimulation of predominantly noradrenergic, but also adrenergic, pathways evokes the highest ACTH response (Liu *et al.*, 1991).

Endogenous opiates (metenkephalin, dynorphin, and β-endorphin) inhibit the release of ACTH in humans (Besser *et al.*, 1987). Conflicting results have been reported on the effect of metenkephalin in the rat, but β-endorphin and dynorphin may exert tonic inhibition of CRH release (Plotsky, 1986). The metenkephalin agonist DAMME stimulates the release of ACTH in the dog (Meij *et al.*, 1990).

Activation of the immune system by infections results in the enhanced production of the cytokine interleukin-1 (IL-1β), which has the ability to stimulate CRH secretion from the hypothalamus and thus activates the hypothalamus-pituitary-adrenal axis. The biosynthesis and release of IL-6 has been found in the folliculostellate cells of the AL. IL-6 also stimulates the HPA-axis, at both the hypothalamic and the pituitary level (Sweep *et al.*, 1991).

Endogenous corticosteroids inhibit ACTH release predominantly at hypothalamic sites. Synthetic steroids such as dexamethasone may act primarily at the pituitary level (de Kloet *et al.*, 1974). In a review on corticosteroid-mediated feedback, Keller-Wood and Dallman (1984) suggested three different time schedules: a fast feedback that acts on the corticotropic cell but may not be related to nuclear receptor binding, an intermediate feedback that probably acts by inhibition of CRH release, and a slow feedback that acts by a decrease in mRNA encoding POMC in the pituitary gland. The delay in inhibiting ACTH production may be caused by the high stability of the mRNA encoding POMC and not by the absence of direct inhibition of the transcription. Dexamethasone inhibits gene transcription *in vivo* within 30 min in the rat (Fremeau *et al.*, 1986). In the dog, the intermediate-delayed feedback is determined by the mean change in corticosteroid concentration over time (Keller-Wood, 1989). Acute lowering of plasma cortisol in the horse by inhibition of synthesis in the adrenal gland resulted in an increased ratio of ACTH:CRH in pituitary venous blood before CRH concentrations started to rise (Alexander *et al.*, 1993, 1996), indicating that the first effect is the opposite of the fast feedback and is mediated by increased sensitivity of the corticotrope.

d. Secretion by the IL

The release of POMC-derived peptides by the IL is under direct neural control. The rat and the mouse have been the mammals in which most studies on the regulation and processing of POMC in the IL have been carried out thus far. In the rat, the release of POMC-derived peptides is regulated predominantly via tonic dopaminergic inhibition and β-adrenergic stimulation (Berkenbosch *et al.*, 1981; Tilders *et al.*, 1985), although GABAergic innervation of the IL has also been demonstrated (Oertel *et al.*, 1982). In addition, Proulx-Ferland *et al.*, (1982) demonstrated that CRH is a potent stimulator of α-MSH secretion by the IL. In line with the absence of a glucocorticoid receptor in the IL (Antakly *et al.*, 1985), the α-MSH response to CRH could not be suppressed by dexamethasone administration. The expression of the glucocorticoid receptor in the IL is suppressed by dopamine (Antakly *et al.*, 1987), whereas the CRH receptor content of the rat IL is stimulated by dopamine (Shiver *et al.*, 1992).

In the dog, *in vitro* studies (Mol *et al.*, 1987) and *in vivo* and immunohistochemical observations (Middleton *et al.*, 1987b) have revealed the IL to be resistant to glucocorticoid suppression. There is also evidence from *in vivo* studies that dopaminergic pathways play a regulatory role in canine IL function (Kemppainen and Sartin, 1986). However, in other respects the situation in the dog is different from that in the rat with regard not only to the heterogeneous cytology (see Section I.A.5) but also to some of the regulation characteristics. Despite the fact that CRH-immunoreactive fibers have been identified in the canine neurointermediate lobe (Stolp *et al.*, 1987) and although *in vitro* CRH stimulates ACTH release from the neurointermediate lobe (Mol *et al.*, 1987), there is no convincing evidence that CRH can stimulate release of ACTH from the IL *in vivo* (Kemppainen and Sartin, 1986, 1987; Middleton *et al.*, 1987a), whereas no (Kemppainen and Sartin, 1986) or a very small (Rijnberk *et al.*, 1987) α-MSH response to CRH stimulation has been observed. Kooistra *et al.*, (1997a) showed that α-MSH is secreted in a pulsatile manner in the dog. In contrast, with a significant increase of plasma α-MSH concentrations after administration of the dopamine antagonist haloperidol, even after pretreatment with dexamethasone to inhibit the contribution of the AL, there were small increases in the plasma concentrations of ACTH and cortisol, which suggests that the canine IL contributes to circulating ACTH concentrations (Kooistra *et al.*, 1997a).

The cat has an actively secreting IL, which is reflected in high plasma concentrations of α-MSH and β-endorphin, POMC-derived peptides secreted predominantly by melanotropes (Peterson *et al.*, 1994). In the cat as well as in the dog, no stimulation of α-MSH occurs after CRH administration (Willemse and Mol, 1994). However, cats undergoing handling and skin testing without anesthesia show significant increases in plasma α-MSH concentrations (Willemse *et al.*, 1993). *In vitro* experiments revealed the sensitivity of feline IL MSH release to dopaminergic inhibition (Willemse and Mol, 1994).

In fetal and newborn lamb and in adult sheep (Newman *et al.*, 1987), the administration of a dopamine-receptor antagonist results in α-MSH release. Elimination of the inhibitory hypothalamic control in sheep by hypothalamus-pituitary disconnection results in increased α-MSH release (Clarke *et al.*, 1986). The dopamine inhibition of ACTH secretion in the hyperadrenocorticoid horse (Wilson *et al.*, 1982) suggests that in the normal horse the IL is under dopaminergic control. In the rabbit the dopaminergic control of the IL is absent (Schimchowitsch *et al.*, 1986).

e. Action

The predominant action of ACTH is stimulation of steroidogenesis and corticosteroid release from the adrenals (see Chapter 19 on adrenal function). ACTH also exerts a growth-stimulating effect on the adrenal cortex. Moreover, non-ACTH portions of POMC—that is, N-terminal POMC peptides—are involved in adrenocortical growth (Lowry *et al.*, 1987). In pharmacological dosages, ACTH may promote lipolysis in fat cells and amino acid uptake in muscle. The role of intact ACTH produced in hypothalamic neurons

projecting to higher brain centers remains to be elucidated. Distribution patterns have been reported for the cat (Rao *et al.*, 1986). The C-terminal fragment of ACTH (18-39), called corticotropin-like intermediate lobe peptide (CLIP), has been found a potent stimulator of *in vitro* adrenal DNA synthesis (Wulffraat *et al.*, 1987).

Nowadays five different receptors for the melanocortins have been cloned with variable affinities for ACTH(1-39), α-MSH, and γ-MSH and related peptides. The MC2 receptor is unique because only ACTH(1-39) activates this receptor. The receptor is present in the adrenal cortex of many species and is also shown in adipocytes of mice. The other receptors, MC1R and MC3R, have been found to be expressed throughout the body, whereas MC4R is only found within many brain regions and MC5R only in peripheral tissues. Through these five receptors, the melanocortins play a role in many biological functions such as skin physiology, pain and nerve regeneration, behavior, obesity and energy metabolism, and inflammatory and immune processes (Getting, 2006). The melanocortin system plays a role in regulating feeding behavior and energy balance (Bertile and Raclot, 2006).

In the dog a single mutation in the MC1R gene results in a premature stop codon and is associated with the yellow coat color in Labrador retrievers (Everts *et al.*, 2000).

f. Disease

Lesions at the hypothalamic and pituitary level may result in altered synthesis and release of POMC-derived peptides. There have been no reports of the occurrence of isolated ACTH deficiency in domestic animals. There are a few reports of dogs with tumorous (supra)hypophyseal lesions, with indirect evidence for multiple adenohypophyseal and neurohypophyseal deficits (Eigenmann *et al.*, 1983b; Rijnberk, 1971), and one dog reported to have secondary hypoadrenocorticism without information about other pituitary functions (Peterson *et al.*, 1992).

In contrast to the few descriptions of ACTH deficiency, pituitary-dependent hyperadrenocorticism is a common disorder in the dog (Hanson *et al.*, 2005; Meij *et al.*, 2002; Peterson, 1987) and rare in the cat (Meij *et al.*, 2001). The adenomas producing the ACTH excess may originate in the AL or IL (Peterson *et al.*, 1986). Cats with pituitary-dependent hyperadrenocorticism usually have concurrent insulin-resistant diabetes mellitus. Various pituitary neoplasm's have been described in cats such as AL and IL corticotropic adenomas (Meij *et al.*, 2001), corticotropic and somatotropic adenoma (double adenoma) (Meij *et al.* 2004), and melanotropic adenoma (Meij *et al.*, 2005). Dogs with pituitary-dependent hyperadrenocorticism had significantly lower CRH concentrations in cerebrospinal fluid compared to control dogs indicating that the excessive ACTH secretion is not caused by chronic hyperstimulation with CRH (Van Wijk *et al.*, 1992). The ACTH secretion appeared also to be less sensitive to stimulation with CRH than with LVP (van Wijk *et al.*, 1994). The expansion of pituitary corticotroph adenomas in dogs is correlated with insensitivity to glucocorticoid feedback (Kooistra *et al.*, 1997b) and plasma concentrations of ACTH precursors (Bosje *et al.*, 2002). Evidence for a genetic involvement in tumorigenesis was found in a family of Dandie Dinmont terriers (Scholten-Sloof *et al.*, 1992). In the horse, the disease originates primarily in the IL (Heinrichs *et al.*, 1990; Orth *et al.*, 1982; van der Kolk *et al.*, 2004; Wilson *et al.*, 1982). In agreement with the characteristics described earlier for the secretion of POMC-derived peptides by the IL, ACTH release by tumors of IL origin in both the dog and the horse tends to be strongly resistant to suppression by dexamethasone (Orth *et al.*, 1982; Peterson *et al.*, 1986). In dogs, the highest plasma α-MSH concentrations are found in individuals with dexamethasone-resistant ACTH secretion (Meij *et al.*, 1997b). This suggests an IL origin of the disease, although there is evidence that the pituitary lesions do not always maintain the characteristics of the lobe of origin (Rijnberk *et al.*, 1988b). A dog with diabetes insipidus has been described, in which the pituitary tumor released primarily biologically inactive POMC-derived peptides (Goossens *et al.*, 1995). In contrast with the equine IL tumors, these tumors in dogs respond poorly to administration of dopamine agonists in terms of diminished ACTH secretion (Rijnberk *et al.*, 1988b). A dog has been described that had dexamethasone-resistant hyperadrenocorticism and elevated ACTH secretion resulting from multiple endocrine neoplasia—that is, a pituitary corticotropic tumor, bilateral adrenocortical tumors, and pheochromocytoma (Thuroczy *et al.*, 1998).

For details on clinical manifestations, laboratory findings, diagnostics, and treatment of these diseases, including iatrogenic hypoadrenocorticism resulting from corticosteroid therapy, refer to textbooks by Feldman and Nelson (2004) and Rijnberk (1996) and Chapter 19 on adrenocortical function in this volume.

g. Tests

Basal levels of circulating POMC-derived peptides are measured for diagnostic purposes in situations of suspected hypo- as well as hypersecretion. ACTH values below or just within the reference range (Table 18-3) may be found in cases of hypothalamus-pituitary disease, as well as in situations where endogenous or exogenous glucocorticoid excess suppresses hormone synthesis in the corticotropic cells. This makes the measurement of basal ACTH levels a useful tool in the differentiation between pituitary-dependent hyperadrenocorticism and hyperadrenocorticism resulting from adrenocortical tumor (Feldman, 1983; Peterson, 1986). In pituitary-dependent hyperadrenocorticism, ACTH values exceeding the reference range may be found, but there is considerable overlap (Meij *et al.*, 1997a). Basal MSH concentrations have been found to be elevated in horses (Orth *et al.*, 1982) and dogs (Meij

et al., 1997b; Peterson *et al.*, 1986; Rijnberk *et al.*, 1987) with pituitary-dependent hyperadrenocorticism of IL origin. In the horse, basal plasma ACTH concentration predicts a pituitary adenoma of the IL with 100% sensitivity (van der Kolk *et al.*, 1995).

Of the dynamic tests, the dexamethasone suppression tests (see Chapter 19 on adrenocortical function) are still the best for the diagnosis and differential diagnosis of excessive ACTH and glucocorticoid secretion. In animals suspected of having pituitary-adrenocortical insufficiency, the secretory capacity for POMC-derived peptides can be measured by provocative testing.

CRH and AVP are also used in the differentiation between pituitary-dependent hyperadrenocorticism and hyperadrenocorticism resulting from adrenocortical tumor. The chronically suppressed corticotropic cells are presumed to be unresponsive to these stimuli. However, Meijer *et al.*, (1978) found considerable overlap in plasma cortisol value in the AVP test, whereas much less is claimed to occur in the CRH test (Peterson, 1986). It has been demonstrated that LVP stimulates cortisol release by adrenal tumors in a direct way (van Wijk *et al.*, 1994).

It has been shown that dogs with pituitary-dependent hyperadrenocorticism usually remain responsive to single CRH administration (Rijnberk *et al.*, 1987) or combined hypophysiotropic stimulation in spite of persisting hypercortisolism and neoplastic transformation of the corticotropes (Meij *et al.*, 1997a). The cells of the pituitary lesions were found to be less responsive to CRH *in vitro* than were normal corticotropes (Mol *et al.*, 1987) and less sensitive to inhibition by glucocorticoids (van Wijk *et al.*, 1998).

As far as the possibility for manipulation of canine IL function is concerned, of the substances tested only the dopamine agonist haloperidol (Kemppainen and Sartin,

1986; Rijnberk *et al.*, 1987) caused significant increases in circulating α-MSH. More detailed information pertaining to some of these tests is presented in Section IV and in Table 18-4.

2. β-Endorphin/β-Lipotropin

a. Gene Expression and Biosynthesis

Both β-lipotropin and β-endorphin are derived from the precursor protein POMC. The gene expression of POMC has been described in Section II.A.1. β-Lipotropin (β-LPH) consists of the 91 C-terminal amino acids of the POMC precursor. It is synthesized in the corticotropic cells of both the AL and IL. The C-terminal sequence (36-91) is remarkably similar in human, porcine, and ovine pituitaries, whereas the N-terminal sequence (1-36) is rather heterogeneous. β-MSH (sequence 37-58) appears to be an extraction artifact and plays no physiological role.

By proteolytic cleavage at amino acid 61, γ-LPH (β-LPH[1-61]) and a family of endorphins are formed. Through specific deletion of C-terminal amino acids and N-terminal acetylation, a variety of β-END-related peptides are formed. The three main compounds are β-END(61-91), γ-END(61-77), and α-END(61-76). The corticotropic cells of the AL synthesize approximately equal or higher concentrations of β-LPH than of β-END(1-31) in most species. The equine AL, however, contains primarily β-END(1-31) and N-acetyl-β-END(1-27) (Millington *et al.*, 1992).

The corticotropic/melanotropic cells of the IL produce relatively more β-END and related peptides. In the IL of the normal dog, the ratio β-LPH/β-END is less than 0.1 (Krieger, 1983). In the dog, β-END(1-27) is the most abundant form in the IL (Young and Kemppainen, 1994).

b. Secretion

The stimuli that induce ACTH or α-MSH release from either the AL or IL cells cause also a release of the β-LPH-related peptides from the same cell. The cellular subset of specific proteolytic, amidating, and acetylating enzymes present in the secretory vesicles defines the ultimate composition of POMC-derived peptides that are secreted into the blood. The secretion of the IL is mainly under control of multiple neurotransmitters (Saland, 2001). In fearful dogs, only marginal increases in plasma β-END were measured after a gunshot test (Hydbring-Sandberg *et al.*, 2004). In horses, a critical exercise threshold exists before plasma β-END concentrations increase (Mehl *et al.*, 2000).

c. Action

The main action of β-LPH is to mobilize fat from adipose tissues, as demonstrated in the rabbit. Its biological function in humans and other species has not been fully elucidated. Brain tissue can break down β-LPH to form β-END-related peptides. However, it is questionable whether these pituitary peptides are involved in brain function; in conscious sheep, hemorrhagic stress elevates β-END concentrations in plasma but not in cerebrospinal fluid (Smith *et al.*, 1986).

β-END is an endogenous opiate with a potent morphinomimetic action. It is also produced in the hypothalamus where the entire POMC precursor is present. Brain and pituitary endorphin are probably part of separate systems. The role of β-END and other opioid peptides in the secretion of pituitary hormones has been studied with long-acting analogues, opiates, and opioid receptor antagonists (Estienne and Barb, 2005; Molina, 2006).

d. Disease/Tests

Hypersecretion of β-END is associated with the ACTH hypersecretion of IL tumors in both equine and canine pituitary-dependent hyperadrenocorticism (Orth *et al.*, 1982; Peterson *et al.*, 1986; Rijnberk *et al.*, 1987). As the regulation of the secretion of β-END is similar to that of other POMC-derived peptides from the AL and IL, testing procedures can be applied as mentioned in the section on ACTH and α-MSH. Elevation of plasma β-END has been documented in horses following running and shipping (Li and Chen, 1987) and in sheep during electroimmobilization and shearing procedures (Jephcott *et al.*, 1987). Treadmill exercise of Thoroughbred horses induces a variable response in plasma β-END concentrations (Art *et al.*, 1994). Elevated plasma β-END concentrations are found in dogs with congestive heart failure (Himura *et al.*, 1994) and are further elevated after naloxone treatment.

B. Glycoprotein Hormones

The gonadotropes and thyrotropes synthesize the hormones LH, FSH, and TSH, each of which consists of two different peptide chains, termed the α- and β-subunits. The amino acid sequence of the α-subunit is identical for LH, FSH, and TSH within a species, as it is for placental chorionic gonadotropin. The β-subunits have unique structures and determine the hormone specificity. Carbohydrate substituents account for 10% to 20% of the molecular weights of these hormones.

1. α-Subunit

a. Gene Expression

The gene encoding the α-glycoprotein subunit (αGSU) varies between 8 and 16.5 kb among the species and contains four exons. The α-subunit comes to expression in a variety of cells such as thyrotropes, gonadotropes, and syncytiotrophoblasts. The expression in gonadotropes and thyrotropes is in part differently regulated. In the developing pituitary αGSU is one of the first hormones to be detected and regulated by the transcription factors Pitx1, Lhx3, SF-1, Otx1 (Brown and McNeilly, 1999; Cohen and Radovick,

2002; Jorgensen *et al.*, 2004), and FOXL2 (Ellsworth *et al.*, 2006). In thyrotropes, however, expression of the TSHβ subunit precedes the expression of the αGSU. Apart from commonly used elements the promoter of the αGSU also contains response elements specifically used by gonadotropes, thyrotropes, or throphoblasts (Jorgensen *et al.*, 2004). Also in the horse, this tissue-specific regulation of αGSU expression is documented (Farmerie *et al.*, 1997). The canine αGSU has been coexpressed in a baculovirus expression system together with the canine TSHβ gene (Yang *et al.*, 2000). The steroidogenic factor-1 (SF-1) has been shown in sheep to be essential for αGSU expression (Baratta *et al.*, 2003).

b. (Pro)hormone

Translation of the mRNA results in the formation of a precursor peptide with a molecular weight of approximately 13,500. The α-subunit has a high degree of homology among species (Fig. 18-7). The human sequence contains 92 amino acids, rather than the 96 as found in all other species studied so far. The shorter human sequence is due to a deletion of 12 nucleotides at the beginning of exon 3. After cleavage of the signal peptide, five disulfide bridges are formed. Two asparagine residues are prone to N-glycosylation, but there is also a putative O-glycosylation site (Fig. 18-7). The α-subunit is produced in excess of the β-subunit that determines the hormone specificity. The β-subunit formation is rate limiting in the formation of hetero $\alpha\beta$ dimer.

2. TSH

The thyrotropic cells of the anterior pituitary produce thyroid-stimulating hormone (TSH), which stimulates both the synthesis and secretion of thyroid hormone.

a. Gene Expression

The rat, human, and canine TSH gene consists of three exons, whereas the mouse gene has five exons. Its expression is restricted to pituitary thyrotropes. For the development of thyrotropes, and also gonadotropes, the same transcription factors are necessary as described for αGSU expressing cells. For the development of specific thyrotropes, the transcription factor Pit-1 is essential (Dasen and Rosenfeld, 2001). Expression of the TSHβ gene is stimulated by the transcription factors Pit-1 and GATA2, whereas TSHβ gene expression is suppressed by the active thyroid hormone T_3 (Nakano *et al.*, 2004; Shupnik, 2000). In contrast with the suppression of TSHβ synthesis by T_3, which is produced within the pituitary by selective deiodination of T_4 by type 2 deiodinase (D2), TRH plays a dominant role in the stimulation of TSH synthesis (Nikrodhanond *et al.*, 2006).

The feline TSH has also been cloned and brought to expression (Rayalam *et al.*, 2006).

b. (Pro)hormone

The TSHβ chain consists of 118 amino acids and forms six intrachain disulfide bonds (Fig. 18-8). There are no free cysteine residues, consistent with the fact that beta subunits form a heterodimer with the αGSU noncovalently. The TSHβ subunit has an N-glycosylation site at asparagine 23 and has a molecular weight of 18,000 after appropriate glycosylation.

The α-subunit is produced in excess of the β-subunit, which determines the hormone specificity, and its formation is rate limiting in the formation of the α-β dimer.

c. Secretion

The release of TSH is mainly regulated by stimulation by the hypothalamic thyrotropin-releasing hormone (TRH) and a strong negative feedback by thyroid hormone (Pazos-Moura

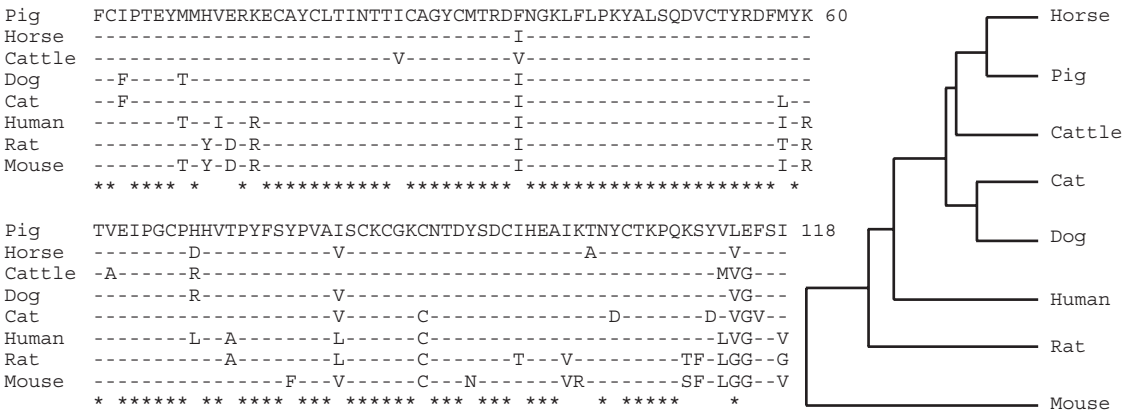

FIGURE 18-8 Sequence comparison of the β-subunit of TSH. See the legend for Figure 18-6.

et al., 2003) at the pituitary and hypothalamic level. The prohormone thyroxine (T_4) must therefore be converted locally to the active 3,3′,5-triiodothyronine (T_3) by type 2 iodothyronine deiodinase (D2) before binding to the nuclear thyroid hormone receptor of the thyrotrope (Christoffolete *et al.*, 2006). Superimposed on this regulatory system, hypothalamic factors (somatostatin, dopamine) may inhibit TSH synthesis and release. Intrapituitary growth factors can also stimulate (EGF) or inhibit (Neuromedin B) TSH release (Pazos-Moura *et al.*, 2003). Evidence has been presented on an ultra-short-loop feedback control by TSH through pituitary folliculostellate cells (Prummel *et al.*, 2004).

In the dog, TRH stimulates plasma TSH concentrations. Single administration of TRH results in slightly higher plasma TSH concentrations than measured after combined stimulation with four releasing hormones (Meij *et al.*, 1996b). In euthyroid dogs, cTSH release is relatively stable with hardly any pulses as measured during a 6-h pulse study, whereas in hypothyroid dogs, an increased basal concentration coincides with higher pulse frequencies (Kooistra *et al.*, 2000b).

d. Action

TSH stimulates both synthesis and secretion of thyroid hormones from the thyroid gland. After receptor binding, TSH stimulates via the Gs alpha protein the production of cAMP, which acts as an intracellular second messenger. In addition, intracellular Ca^{2+} may modulate the biological effect of TSH via the phosphoinositol pathway. As a result of receptor activation T_4, and to a much lesser extent T_3, is secreted into the blood. Prolonged stimulation of the thyroid with TSH results not only in hypersecretion of thyroid hormone but also in enlargement of the thyroid gland. Genetic analysis of DNA from hyperplastic or adenomatous thyroid nodules in cats has revealed that somatic mutations in the TSH-receptor or in the Gs alpha protein are the cause of feline thyroid hyperplasia (Peeters *et al.*, 2002; Watson *et al.*, 2005). Apart from the thyroid, TSH receptors have been found in brain and pituitary where they may have a function in feedback mechanisms, and in lymphocytes, thymus, testis, kidney, adipose tissue, and bone (Davies *et al.*, 2005).

e. Disease/Tests

Since 1995, sensitive TSH assays have become available for the dog (Williams *et al.*, 1996). Since then numerous reports have been published on the usefulness of cTSH measurements in the diagnosis of canine hypothyroidism. Low total plasma T_4 concentrations may be caused by decreased binding to plasma TBG—such as seen after long-term glucocorticoid excess in Cushing's syndrome or interference of T_4 binding to TBG by, for instance, NSAIDs or antiepileptic drugs—and they are therefore not conclusive for the diagnosis of hypothyroidism. Unfortunately some 25% to 40% of dogs with proven hypothyroidism will have plasma cTSH concentrations within the reference range for healthy dogs (Boretti and Reusch, 2004; Peterson *et al.*, 1997). In dogs with nonthyroidal disease also low serum concentrations of total T_4 are seen with serum TSH concentrations that remain within the reference range (Kantrowitz *et al.*, 2001). In a recent study, quantitative measurement of thyroidal $^{99m}TcO_4^-$ showed no overlap between dogs with primary hypothyroidism and nonthyroidal illness (Diaz Espineira *et al.*, 2007) and may together with a thyroid biopsy be the ultimate proof of primary hypothyroidism.

Secondary hypothyroidism caused by a pituitary tumor (Rijnberk, 1971) or panhypopituitarism caused by a suprasellar tumor (Eigenmann *et al.*, 1983b) is rare. German shepherd dogs with dwarfism have a secondary hypothyroidism, which can be demonstrated by a blunted TSH response on TRH in a combined pituitary function test (Kooistra *et al.*, 2000c). For further details, refer to Chapter 20 on thyroid function.

Chemical induction of hypothyroidism in horses using the antithyroid drug PTU results in a steady increase of plasma TSH concentration and an exaggerated response to TRH administration (Breuhaus, 2002).

FIGURE 18-9 Sequence comparison of the β-subunit of LH. See the legend for Figure 18-6.

3. LH *and* FSH

Luteinizing hormone (LH), which is identical to the interstitial-cell-stimulating hormone, and follicle-stimulating hormone (FSH) are produced by the gonadotropic cells of the AL.

a. Gene Expression

In the gonadotropes αGSU appears to be the lead protein before the expression of the β-subunits, which determine the hormone specificity (Pope *et al.*, 2006). Next the β-subunits arise in the bihormonal gonadotropes. During development of the pituitary, transcription factors Pitx, Hesx1, Lhx3, SF-1, and Otx1 regulate gonadotropin subunit expression (Brown and McNeilly, 1999). Although LH and FSH are produced within the same gonadotrope, its gene expression and secretion pattern are different.

In primates, multiple copies of LHβ-related genes have been identified, the chorionic gonadotropins (CG), which are expressed in the placenta for the maintenance of early pregnancy. Apart from primates, only in equids has this placental production of CG been well described (Jorgensen *et al.*, 2004). In the horse, placental eCGβ is derived from the same gene that encodes pituitary LHβ (Saneyoshi *et al.*, 2001). For pituitary LHβ expression, three highly conserved response elements have been found in the promoter region that bind the early growth response protein (Egr-1), the orphan nuclear factor SF-1, and the homeodomain protein Pitx1 (Jorgensen *et al.*, 2004; Melamed *et al.*, 2006).

For the regulation of basal FSHβ gene expression Lhx3 plays a prominent role, whereas a direct effect of SF-1 on FSHβ expression is not demonstrated in the ovine pituitary gland (Baratta *et al.*, 2003).

The LHβ promoter is sensitive to stimulation by GnRH via Egr-1 and inhibition by androgens. The activated androgen receptor (AR) binds SF-1 to block communication via Pitx1 (Jorgensen *et al.*, 2004). The AR, however, increases FSHβ gene promoter activity, as also documented for the progesterone receptor (PR) and glucocorticoid receptor (GR) (Thackray *et al.*, 2006). Estrogens activate the LHβ promoter (Melamed *et al.*, 2006). Inhibin, activin, and follistatin, originally found as hormones from the gonads but they may also be produced within the pituitary, are important regulators of LH and FSH synthesis and release. Activin stimulates FSHβ gene expression and mRNA stability, whereas inhibin and follistatin inhibit FSHβ gene expression and accelerate the degradation of FSHβ mRNA (Gregory and Kaiser, 2004). As activin stimulates and inhibin inhibits expression of GnRH receptors, an indirect effect on LHβ expression and release also can be found.

b. (Pro)hormone

After cleavage of the signal peptide, LHβ proteins are formed of 121 amino acids (Fig. 18-9). Exception is the horse sequence, which shows a highly variant C-terminal part that is also some 14 to 28 amino acids longer. The β-subunit contains six intrachain disulfide bridges. In humans, LHβ has one unique N-linked glycosylation at asparagine 30. In the horse, asparagine 13 is glycosylated and in addition 12 O-glycosylation sites have been found (Bousfield *et al.*, 2001). The percentage glycosylation is related to increased plasma half-life and thus bioavailability of the hormones.

The FSHβ chain consists of 111 amino acids, six intrachain disulfide bridges, and two N-linked glycosylation sites at asparagine 7 and 24. The N-linked oligosaccharide chains are critical for bioactivity. Deglycosylated FSH may act as a potent FSH antagonist (Fares, 2006). The sequence of canine FSH shows the lowest homology (approximately 80%) with the sequences of other species (Fig. 18-10), which may cause limitations to the use of heterologous immunoassays for proper FSH measurements in the dog.

FIGURE 18-10 Sequence comparison of the β-subunit of FSH. See the legend for Figure 18-6.

c. Secretion

As with other pituitary hormones, the gonadotropins are released in a pulsatile fashion, stimulated by pulses of the hypothalamic gonadotropin-releasing hormone GnRH. The release of GnRH in seasonal breeders is tightly regulated by the length of the photoperiod and the subsequent release of melatonin by the pineal gland (Thiery *et al.*, 2002). Pulsatile GnRH secretion has been demonstrated in sheep (Clarke and Cummins, 1982) and the horse (Irvine and Alexander, 1994). GnRH can be used for estrus induction and prevention in the dog (Gobello, 2007). In contrast to single administration of GnRH, continuous administration of GnRH agonists reversibly suppresses gonadotropin secretion because of down-regulation/desensitization of GnRH receptors. Effect of dose and duration of treatment with a GnRH-agonist resulting in a switch from stimulated LH and FSH release toward down-regulation has been reported recently for the dog (Concannon *et al.*, 2006).

In the dog, LH and FSH pulses coincide during different phases of the estrus cycle although the longer duration of FSH pulses may be due to the difference in plasma half-life. During progression from early to late anestrus basal plasma FSH increase without a concomitant increase in basal LH concentrations (Kooistra and Okkens, 2001a; Okkens and Kooistra, 2006). During the early follicular phase, the LH secretion has frequent increases of short duration (Kooistra *et al.*, 1999). The preovulatory FSH in female dogs may start a few hours earlier or may coincide with the LH surge, which is associated with the highest plasma estradiol-17β concentrations and the start of increasing plasma progesterone concentrations (de Gier *et al.*, 2006). During the mid- to late-luteal phase, basal LH concentrations in pregnant bitches were higher with lower peak frequency and height in comparison to nonpregnant bitches. Plasma FSH concentrations were higher during pregnancy (Onclin *et al.,* 2002). Chronic administration of the synthetic progestin MPA has no effect on plasma LH concentrations, but, like in pregnancy, increased plasma FSH concentrations are found (Beijerink *et al.*, 2007).

Administration of dopamine-agonists to shorten the anestrus interval results in a rapid rise in basal FSH concentration (Okkens and Kooistra, 2006), whereas the serotonin antagonist metergoline, which lowers also plasma prolactin concentrations, does not affect the LH and FSH secretion patterns in the dog (Beijerink *et al.*, 2004).

Low plasma estrogen concentrations inhibit the GnRH and LH release through a negative feedback system, whereas high concentrations of estrogens may exert a positive feedback by stimulating GnRH release. Kiss1 neurons in the periventricular nucleus are thought to be involved in the estrogen and progesterone-induced LH surge (Smith *et al.*, 2006). In the male, LH stimulates the synthesis and release of testosterone in the Leydig cells of the testis, which may in turn exert a negative feedback on LH secretion. This feedback may depend on aromatization of testosterone to estradiol in the brain. In the male dog, both testosterone and estradiol are the major inhibitors of LH and FSH release (Winter *et al.*, 1982).

Finally, FSH can also be regulated by more specific stimulation through activin or by prevention of activin binding and thus inhibition of downstream signaling by inhibin and follistatin (Gregory and Kaiser, 2004; Gregory *et al.*, 2005). Other members of the TGFβ family such as the bone morphogenic protein-6, BMP-7, and BMP-15 can also exert an effect on FSH secretion.

d. Action

FSH stimulates in the female ovary the folliculogenesis and ripening of the ovaries to the antral follicle stage. LH stimulates changes in the ovarian follicle resulting in ovulation and maintenance of the corpus luteum (Hunter *et al.*, 2004). LH stimulates the production of the androgen precursor androstenedione that is converted, by FSH stimulation, to estradiol-17β and during the luteal phase

progesterone secretion. The LH effects are mediated by LHR containing granulosa cells through the release of EGF-like growth factors (Conti *et al.*, 2006).

FSH is essential for Sertoli cell proliferation and maintenance of sperm quality in the male testis. LH interacts predominantly with Leydig cells and stimulates the production of testosterone.

e. Disease/Tests

LH and the LHR are also involved in the pathogenesis of adrenal tumors in ferrets, which develop after castration-induced high plasma LH concentrations (Schoemaker *et al.*, 2002b). In the adrenal carcinomas that secrete predominantly adrenal androgens, the presence of LHR mRNA and protein has been demonstrated.

The LHR is expressed constitutively in urogenital tissues and adrenal glands in rodents, but they need functional maturation at a posttranslational level (Apaja *et al.*, 2005). Dogs have also LHR and FSHR in the lower urinary tract (Ponglowhapan *et al.*, 2006). In long-term spayed bitches, relative lower plasma LH and FSH concentrations were found in dogs with urinary incontinence in comparison with continent dogs (Reichler *et al.*, 2005).

C. Somatomammotropic Hormones

Growth hormone (GH) and prolactin (PRL) together with the placental lactogen show homology in amino acid composition and some biological activities. Therefore, they may group together as a family of somatolactotropic hormones. There is increasing evidence that these hormones evolved from a single ancestral gene (Seo, 1985; Wallis, 1984).

1. GH

The somatotropic cells, producing GH, are the most abundant cells of the anterior lobe.

a. Gene Expression

In primates, multiplication of the GH gene has resulted in a cluster of five GH-related genes. The GH-N gene is expressed in the pituitary and the other four, consisting of the chorionic somatomammotropins (so-called placental lactogens) and a variant gene (GH-V), are expressed in the placenta during pregnancy. In most nonprimates, a single gene encodes GH, but a family of PRL-like genes (also including placental lactogens) is present. In sheep and goats in some individuals, there are two GH-like genes from which one may be expressed in the placenta. In red deer, two gene sequences encoding GH were found, but this is shown to be related to allelic polymorphism (Wallis *et al.*, 2006).

The GH-producing cells arise from a lineage of TSH-, GH-, and PRL-producing pituitary cells by the action of transcription factor Pit-1 that is under the control of the prophet of Pit-1 (Prop1). The final maturation of GH-producing cells is under the control of transcription factors Pitx1, Zn-15, Lhx3, and Pit1 (Mullis, 2005). Pit1 and GH expression are already found at the 8- to 16-cell stage in bovine embryos (Joudrey *et al.*, 2003). For the activation of the pituitary GH gene, a 5′-remote locus control region in humans 14.5 kb upstream of the GH-N promoter plays an important role (Ho *et al.*, 2006). This site contains also three Pit1 binding sites (Shewchuk *et al.*, 2002). The pituitary somatotroph differentiation is further stimulated by glucocorticoids and thyroid hormone (Porter, 2005).

GH mRNA expression is stimulated by GHRH and ghrelin by inducing cAMP production and subsequently Pit1 mRNA expression (Garcia *et al.*, 2001; Theill and Karin, g993; Yan *et al.*, 2004). Somatostatin (SS) inhibits in general GH release although in porcine somatotropes SS can also stimulate GH release depending on the dose used. It appeared that SS receptors SST1 and SST2 mediate the inhibitory effects whereas SST5 mediates a stimulatory effect of somatostatin (Luque *et al.*, 2006). The rat GH promoter contains a positive thyroid hormone response element (TRE) and a negative TRE (nTRE) (Sanchez-Pacheco and Aranda, 2003). GH expression is stimulated by the positive TRE. In the absence of T_3 binding the unliganded thyroid hormone receptor (TR) may induce GH expression in nonpituitary cells. In severely hypothyroid dogs elevated plasma GH concentrations have been found, which may be related to this mechanism (Lee *et al.*, 2001). Gonadal steroids modulate also GH production. 17β-Estradiol may reduce the inhibitory effect of SS on GH production, whereas testosterone treatment increases GH mRNA concentrations in adulthood (Chowen *et al.*, 2004).

b. Extrapituitary GH Expression

In dogs, endogenous progesterone and exogenous progestins may induce considerable rises in plasma GH concentrations, resulting in acromegalic changes and insulin resistance with the possibility of development of frank diabetes mellitus (Eigenmann *et al.*, 1983a; Selman *et al.*, 1994a). GH excess has only been found to occur in intact female dogs during the progesterone-dominated phase of the sexual cycle or in dogs treated with progestins (Eigenmann and Rijnberk, 1981).

Selman *et al.*, showed the autonomous character of progestin-induced GH secretion (Selman *et al.*, 1991) and found the canine mammary gland to be the source of plasma GH after progestin treatment (Selman *et al.*, 1994b). The mammary origin was confirmed by an arterial-venous gradient across the mammary gland, a rapid decrease and normalization of plasma GH concentrations after complete mammectomy (Selman *et al.*, 1994b), and the presence of GH mRNA in the canine mammary gland as measured by RT-PCR (Mol *et al.*, 1995b). From the 100% sequence identity it is concluded that a single gene encodes pituitary and mammary GH in the dog, in agreement with the fact that only one canine GH gene is found in the published canine genome sequence. The dog is not unique in expressing GH

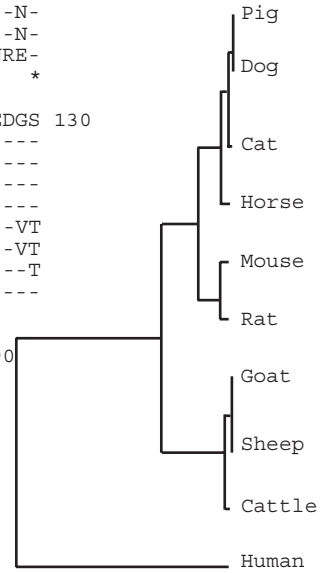

FIGURE 18-11 Sequence comparison of GH. See the legend for Figure 18-6.

in the mammary gland as it is demonstrated also in cats with progestin-induced fibroadenomatous changes of the mammary gland (Mol *et al.*, 1995b), and GH mRNA has been demonstrated in the normal and neoplastic human mammary gland as well (Mol *et al.*, 1995a; Mol *et al.*, 1996). The presence of a putative binding site for the progesterone receptor in the GH promoter of human, rat, mouse, and dog makes it likely that progestin-induced GH expression is a direct effect of activated PRs on the GH gene promoter (Lantinga-van Leeuwen *et al.*, 2002).

Apart from the mammary gland, extrapituitary GH expression seems to be widespread throughout the body. GH functions already as an early local embryonic growth, and differentiation factor, including the neural tube, before pituitary GH expression is detectable (Sanders and Harvey, 2004). Furthermore, GH expression is found in the postnatal rat lung (Beyea *et al.*, 2005), chicken testis (Harvey *et al.*, 2004) and canine lymphomas (Lantinga van Leeuwen *et al.*, 2000), insulinomas (Robben *et al.*, 2002), and growth plate or osteosarcomas (Kirpensteijn *et al.*, 2002).

c. (Pro)hormone

GH is a single-chain polypeptide. It contains two intrachain disulfide bridges and has an apparent molecular weight of 22,000. In humans, a small fraction of circulating GH has a molecular weight of 20 kDa because of alternative splicing of the pituitary GH gene. The metabolic effects are comparable to the normal 22 kDa form (Hayakawa *et al.*, 2004). The amino acid sequence of GH belongs to the best-known sequences of pituitary hormones among species (Fig. 18-11). The sequences of canine and porcine GH are identical and very similar to the horse. The canine and porcine sequence is suggested to be identical to the GH sequence for the ancestral placental mammal (Forsyth and Wallis, 2002).

In cattle, a polymorphism in the GH gene exists, resulting in four GH variants that can arise from two possible N-terminal amino acids (phenylalanine or alanine) and two amino acids in position 127 (leucine or valine). The transmission of the trait of high milk production was greater for homozygous leucine-127 in Holstein cows and valine-127 in Jersey cows (Lucy *et al.*, 1993). GH exhibits also heterogeneity because of posttranscriptional processing that may vary in binding to the plasma GH binding protein (GHBP) or biological effects (De Palo *et al.*, 2006). The glycine in the third α-helix of bovine GH (G118) and human GH (G120) is crucial for biological functioning of GH. Substitution of this glycine results in a molecule without growth-promoting activity that inhibits the actions of GH *in vitro* and *in vivo* (Kopchick, 2003).

d. Secretion

The release of GH by the pituitary is regulated by a variety of factors (Fig. 18-12 and Table 18-5). The integration of all these factors results in a pulsatile release of GH. In the female dog, plasma GH pulse patterns are dependent on the estrus cycle. In the early luteal phase, elevated basal GH concentrations are associated with a low pulse frequency of 2 peaks/12 h, whereas at anestrus lower basal GH concentrations are found with an enhanced pulse frequency of

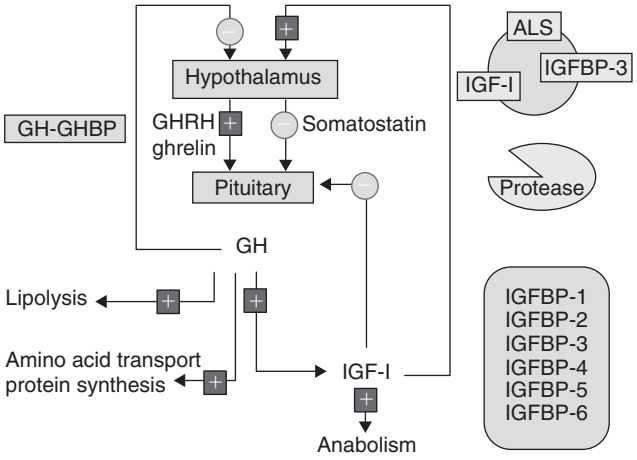

FIGURE 18-12 Regulation of pituitary GH release, peripheral actions, and feedback.

5 peaks/12 h (Kooistra *et al.*, 2000a). The higher basal concentration and diminished pulsatility in early luteal phase may be caused by a direct or indirect inhibition of pituitary GH release by GH secretion from the mammary glands stimulated by progesterone.

Pituitary somatotropes are not only stimulated by the GH-releasing hormone (GHRH), which was first isolated from human pancreas islet tumors in 1982 and next found in the hypothalamus, but also by the more recently discovered GH-releasing hormone ghrelin, which was originally isolated from rat and human gut. In the pituitary, two GHRH-R isoforms exist generated by alternative splicing. The predominant short form activates somatotropes through the adenylate cyclase/cAMP/PKA pathway. The pituitary contains also two splice variants of a distinct seven-transmembrane helix, G protein coupled receptor for ghrelin, called the GH secretagogue receptor (GHS-R). Only the long type 1a isoform activates pituitary somatotropes via the phospholipase C/IP_3/PKC pathway. The expression of both receptors is down-regulated by exposure to GHRH as well as ghrelin in porcine pituitary cell cultures (Luque *et al.*, 2004). The release of GH is generally inhibited by somatostatin (SS). In the pituitary all five SS receptors (SST1-5) are expressed. In porcine pituitary cells low SS concentrations may, however, also stimulate GH release. It has been found that the inhibitory effects are mediated by SST1 and SST2 receptors, whereas SST5 mediates the stimulatory effect of SS on GH release *in vitro* (Luque *et al.*, 2006).

In young beagle dogs, 13 to 17 months of age, ghrelin was shown to a more potent GH secretagogue in comparison to GHRH. With aging, 7 to 12 year of age, the GH response to ghrelin was significantly lower, whereas only a moderate decrease in the sensitivity toward GHRH was noticed and GHRH appeared to be at higher age a more potent stimulator of GH release (Bhatti *et al.*, 2006b). In contrast to humans, in the dog ghrelin has hardly any stimulatory effect on ACTH and prolactin release (Bhatti *et al.*, 2006b; van der Lely *et al.*, 2004). Plasma concentrations of acylated ghrelin, which is the biologically active form, are higher after fasting and lower after food intake, suggesting a role in feeding control and energy homeostasis also in the dog (Bhatti *et al.*, 2006c, 2006d). No clear relation was found of plasma GH and ghrelin in the study by Bhatti *et al.*, in agreement with a previous study in which also no close relation was found between plasma GH and ghrelin concentrations during the juvenile period in dogs (Yokoyama *et al.*, 2005).

Next to the direct and selective effects of the hypophysiotropic hormones on GH secretion at the pituitary level, there are indirect neuronal influences that modulate GH secretion (see also Table 18-3) (McMahon *et al.*, 2001). In general, the main physiological stimuli of GH secretion are sleep, physical exercise, stress, fasting, catecholamines, hypoglycemia, and certain amino acids. However, this does not apply in every respect to all species. For example, GH secretion in dogs is not related to sleep or day-night cycles, although GH peaks may occur after forced wakefulness at the onset of sleep (Takahashi *et al.*, 1981). Insulin-induced hypoglycemia and arginine administration do not consistently result in GH release in the dog (Eigenmann and Eigenmann, 1981). Of the neurotransmitter systems involved, adrenergic systems seem to play a major role. α-Adrenergic agonists promote GH secretion, whereas β-adrenergic agonists are inhibitory. Thus, clonidine, a central α_2-adrenergic agonist, is an effective stimulator of GH secretion in the dog (Eigenmann and Eigenmann, 1981; Selman *et al.*, 1994a). The dopaminergic D2 receptor is important for stimulating GH release, as can be concluded from the dwarfism in the D2 KO mouse (Garcia-Tornadu *et al.*, 2006).

Plasma IGF-I exerts a negative feedback of GH release both at the hypothalamic level where it stimulates SS release and inhibits GHRH release, as well as at the pituitary level. As the majority of plasma IGF-I is bound to specific binding proteins, in plasma predominantly IGFBP3, the free rather than the protein-bound IGF-I determines these feedback regulations (Chen *et al.*, 2005). The elevated GH concentrations in fasting dogs have also been explained as the result of impaired feedback inhibition caused by low IGF-I plasma levels (Eigenmann *et al.*, 1985).

Finally thyroid hormone, sex steroids, and glucocorticoids modulate GH synthesis and release. In contrast to humans and rats where low plasma thyroid hormone concentrations result in attenuated GH secretion, hypothyroidism in the dog is associated with enhanced basal plasma GH concentrations and reduced pulsatility (Lee *et al.*, 2001). In dogs with pituitary-dependent hyperadrenocorticism, no differences exist in the basal plasma GH secretion, but less GH is secreted in pulses in comparison to control dogs (Hanson *et al.*, 2006a; Lee *et al.*, 2003). In dogs, endogenous and exogenous progestins may induce considerable rises in plasma growth hormone concentrations, resulting in acromegalic changes and insulin resistance (Rijnberk *et al.*, 2003; Selman *et al.*, 1994a; Selman *et al.*, 1994b).

e. Action

The effects of GH can be divided into two main categories: rapid or metabolic actions and slow or hypertrophic actions. The (acute) metabolic responses are due to direct interaction of growth hormone with the target cell, whereas the slow hypertrophic effects or those on cartilage, bone, and other tissues are indirect. The direct effects of GH result in differentiation of prechondrocytes, enhanced lipolysis in adipose tissue, increased gluconeogenesis, and restricted glucose transport caused by insulin resistance (Eigenmann, 1984; Renaville *et al.*, 2002; Veldhuis *et al.*, 2006). The GH responsiveness of adipose tissue is less dependent on nutrition than that of the liver, which may explain the reduced adiposity in the absence of growth enhancement in GH-treated ruminants (Breier *et al.*, 1986). *In vitro* GH has also a direct positive effect on the maturation of bovine oocytes (Bevers and Izadyar, 2002) and human hematolymphopoiesis (Hanley *et al.*, 2005).

In contrast to these direct catabolic effects, the indirect actions are anabolic and mediated by the insulin-like growth factors IGF-I and IGF-II (Daughaday *et al.*, 1987). In their chemical structure the IGFs have approximately 50% homology with insulin/proinsulin, suggesting they have evolved from a common ancestral molecule. The IGFs are bound to a family of six different high-affinity IGF-binding proteins (Firth and Baxter, 2002). The main IGFBP in plasma is IGFBP3, which forms together with an acid-labile subunit a ternary complex of 150 kDa. As a consequence, IGFs have a long plasma half-life, which is consistent with their long-term growth promoting action. Specific proteolysis may increase free IGF concentration locally and modulates the IGF receptor signaling (Bunn and Fowlkes, 2003).

Dogs have an extreme variation of body size between breeds. It has been shown that a large body size is associated with GH excess at a young age (Favier *et al.*, 2001). In adult dogs, circulating IGF-I concentrations were found to correlate with body size in different dog breeds (Eigenmann *et al.*, 1988). By studying genetic subgroups within one breed (i.e., standard, miniature, and toy poodles), plasma IGF-I concentrations, and not GH secretory reserve, did parallel body size (Eigenmann *et al.*, 1984a).

f. Disease

Inadequate growth hormone secretion at a young age retards growth. Apart from occasional reports on dwarfism in dogs and cats, GH-deficiency dwarfism seems to occur primarily as a genetically transmitted condition in the German Shepherd (Andresen *et al.*, 1974) and in the Carelian bear dog (Andresen and Willeberg, 1977). In the German shepherd, the GH deficiency is associated with TSH and prolactin deficiency and impaired LH and FSH release without disturbances in ACTH secretion (Kooistra *et al.*, 2000c). This indicates that at a defect in the organogenesis of the pituitary resulting from mutation in an essential transcription factor may have occurred. So far the involvement of mutations in Pit-1 (Lantinga-van Leeuwen *et al.*, 2000b), Prop1 (Lantinga-van Leeuwen *et al.*, 2000a), LHX4 (van Oost *et al.*, 2002), and the LIF receptor (Hanson *et al.*, 2006b) has been excluded as candidate genes for pituitary dwarfism.

In adults, growth hormone deficiency causes much less impressive changes. The clinical features remain confined to the skin and coat. Affected dogs are presented with alopecia and hyperpigmentation of the skin. In contrast to dogs with congenital hyposomatotropism, these dogs may have low but detectable plasma GH concentrations, a blunted response to a clonidine or GHRH stimulation test, but plasma IGF-I concentrations within the reference range. This may be caused by a mild and fluctuating hyperadrenocorticism (Rijnberk *et al.*, 1993). In some dogs the alopecia was explained by an adrenal androgen imbalance. Among other treatments, administration of GH has been associated with hair regrowth (Frank, 2005).

Syndromes resulting from GH excess are known to occur in the dog and the cat. In both species, the GH excess gives rise to outgrowth of bone and soft tissues (acromegaly), as well as to insulin resistance with the possibility of development of frank diabetes mellitus. However, the pathogenesis of the excessive GH secretion in these species is completely different. GH-producing canine pituitary adenomas are extremely rare and only reported once (Fracassi, 2007). A physiological, reversible form of extrapituitary GH secretion is found to be stimulated during

pregnancy in the dog. Synthetic progestins or endogenous progesterone may induce hyperplastic ductular changes in the canine mammary gland with foci of immunoreactive GH-producing cells (Selman *et al.*, 1994b). The MPA-induced elevated plasma GH concentrations can be effectively lowered by treatment with the progesterone receptor antagonist aglepristone (Bhatti *et al.*, 2006a). Also canine, feline, and human mammary carcinomas may express GH mRNA within tumor tissue (Mol *et al.*, 1995b, 1999). The GH excess is, next to the acromegalic features and insulin resistance, associated with the development of cystic endometrial hyperplasia (CEH), which does not necessarily have to originate within the mammary gland (Bhatti *et al.*, 2007). Local production of GH has also been documented in canine insulinomas (Robben *et al.*, 2002), in normal growth plates, and in spontaneous osteosarcoma (Kirpensteijn *et al.*, 2002). Enhanced expression of GHR mRNA in duodenal and colonic biopsies of dogs with chronic enteropathies (Spichiger *et al.*, 2005) and distraction-induced osteogenesis (Theyse *et al.*, 2006) points to a role for GH in gastrointestinal and bone repair processes.

In cats, excessive amounts of GH may be secreted by a pituitary tumor resulting in acromegalic features and insulin resistance (Hurty and Flatland, 2005). In untreated diabetic cats without concurrent hypersomatotropism, plasma IGF-I concentrations are lower in comparison to control animals, whereas in case of underlying excessive GH secretion, plasma IGF-I concentrations are elevated (Reusch *et al.*, 2006).

g. Tests

As GH secretion is pulsatile, single values are of no great diagnostic value. In healthy individuals, basal plasma GH concentrations (Table 18-6) may be very low. Hence, when GH deficiency is suspected, a stimulation test is needed. In the dog stimulation with clonidine, xylazine, GHRH, or ghrelin has proved to be reliable for this purpose, whereas in calves and lambs GHRH stimulation has been used.

Elevated GH values are not definitive proof of acromegaly, not only because of the pulsatile nature of the GH secretion but also because environmental factors may cause sharp increases. Although hypersecretion should be checked by an inhibition test, in case of progestin-induced GH secretion, a blunted stimulation of high basal GH concentrations may support the diagnosis, together with elevated plasma IGF-I concentrations (Selman *et al.*, 1991).

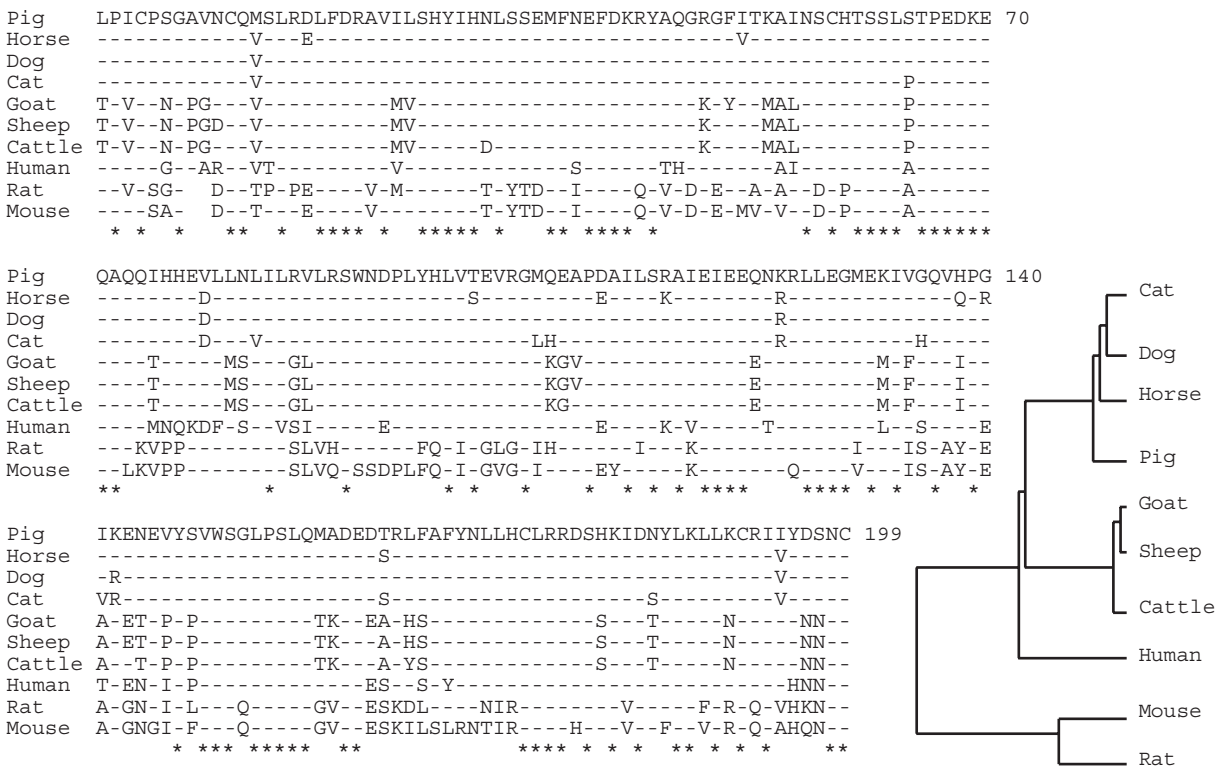

FIGURE 18-13 Sequence comparison of PRL. See the legend for Figure 18-6.

It should be kept in mind that the reference values for plasma IGF-I concentrations in the dog are breed (=body size) dependent.

2. *Prolactin*

a. Gene Expression

Prolactin (PRL) is encoded by a single gene in humans. In nonprimates, a family of PRL-related genes is found and only one gene encoding GH. In the rat, a PRL family of at least 24 related genes can be found including the placental lactogens, proliferans, and PRL-like proteins (PLPs) (Alam *et al.*, 2006). In the cow, an expanded PRL family also has been found; however, its members are not orthologous with members of the mouse and rat PRL family genes (Soares, 2004). Expansion of the PRL family does not exist in the dog.

The appearance of specific PRL-producing lactotropes is one of the latest events in pituitary development. It has been proposed that lactotropes arise from somatotropes or at least a common progenitor cell, the somatomammotrope (Burrows *et al.*, 1999). In chicken, however, evidence is presented that lactotropes do not differentiate from somatotropes during embryonic development (Fu *et al.*, 2004). In mouse pituitaries, mammosomatotropes represent only 5% to 6% of somatotropes (Villalobos *et al.*, 2004).

The Pit-1 transcription factor is a prerequisite factor for PRL expression, as it is for GH and TSH. In the PRL gene Pit-1 acts in synergy with an estrogen nuclear receptor (ER) at a distal enhancer site, with two ETS-domain-containing factors (Ets-1 and ERF) and the Pitx1 and Pitx2 transcription factors (Dasen and Rosenfeld, 2001). The expression and release of PRL are under tonic dopaminergic inhibitory control. No consensus exists on the identity of physiologically relevant PRL releasing factors. In extracts of the bovine posterior pituitary, a PRL-releasing factor was found (Hashizume *et al.*, 2005). The melanocortin peptide γ3-MSH also stimulates PRL expression (Langouche *et al.*, 2004), whereas a variety of factors are found that stimulate PRL release, such as PRL-releasing peptide (PrRP), TRH, oxytocin, VIP, angiotensin II, PACAP, and intermedin and may also stimulate PRL gene expression.

The PRL gene, like the GH gene, has five exon areas. In the pituitary, a promoter upstream of the Cap site in exon 1b is used, outside the pituitary expression of PRL is regulated by a second promoter upstream of exon 1a initially described for PRL expression in decidua and lymphocytes (Gerlo *et al.*, 2006; Goffin *et al.*, 2002).

b. (Pro)hormone

Prolactin (PRL) is synthesized as a single polypeptide, which, after cleavage of the signal peptide, has a molecular weight of approximately 23,000 daltons and three intrachain disulfide bridges. There is a good deal of variability in the sequences of PRL from different species. The rat and mouse PRL are most distinct and differ from the other sequences at about 40% of all amino acid residues (Fig. 18-13).

By proteolytic cleavage a variety of N-terminal prolactin variants have been found. These fragments act on endothelial cells to suppress vasodilatation and angiogenesis and promote vascular regression (Clapp *et al.*, 2006). It has been suggested that these fragments should be called "vasoinhibins." In cartilage, the 16kDa N-terminal fragment is produced from full-length PRL by matrix metalloproteases. The 16kDa fragment is a potent antiangiogenic factor (Macotela *et al.*, 2006).

Prolactin can be phosphorylated at several serine and threonine residues, which may constitute as much as 80% of total pituitary PRL in cattle. The degree of glycosylation may vary from 1% to 60% among species. Finally, dimerization and polymerization may result in high-molecular weight forms that in general have reduced biological activity (Freeman *et al.*, 2000).

c. Secretion

For two reasons, PRL has a unique place among the AL hormones. First, it is the only hormone that is under tonic inhibition by the hypothalamus. After transplantation of the pituitary under the kidney capsule, PRL synthesis is remarkably enhanced. Second, PRL lacks a specific target organ that produces factors exerting negative feedback.

The main hypothalamic prolactin-inhibiting factor (PIF) is dopamine, released primarily from the tuberoinfundibular dopaminergic neurons located in the arcuate nucleus, with nerve terminals in the median eminence. Dopamine released from these neurones is transported to the pituitary lactotropes via the hypophyseal portal vessels. In addition, dopamine released from the periventricular hypophyseal and tuberohypophyseal dopaminergic neurons is released in the intermediate and neural lobes of the pituitary, respectively, and reaches the anterior pituitary by means of short portal vessels. Dopamine activates D2 receptors on lactotropes to tonically inhibit the release of PRL. In turn, PRL enters the brain through a receptor-mediated process in the choroid plexus and stimulates the activity of all three populations of dopaminergic neurons in the hypothalamus acting through PRL receptors directly on these dopamine neurons. In this manner, PRL can regulate its own release via a short-loop negative feedback (Andrews, 2005).

Apart from this short-loop negative feedback, PRL secretion from the anterior pituitary gland is controlled by neuroendocrine factors originating in the hypothalamus and the posterior pituitary gland, and paracrine factors originating in the anterior pituitary gland. At the hypothalamic level, PRL-inhibiting factors are dopamine and GABA- and PRL-releasing factors are vasoactive intestinal peptide (VIP) and TRH. At the level of the posterior pituitary gland, oxytocin and vasopressin, transported to the lactotropes through the short portal vessels, stimulate PRL release. Tachykinins, paracrine factors present in the pituitary gland and brain, can stimulate PRL release through an indirect (hypothalamus, PRF) or direct stimulatory effect on lactotropes in the anterior pituitary, or, under some circumstances, they may inhibit PRL secretion by enhancing dopamine release from the hypothalamus (Debeljuk and Lasaga, 2006).

The suckling-, stress-, or estrogen-induced PRL surge cannot be explained by changes in dopaminergic inhibition alone. Therefore, the presence of a prolactin-releasing factor (PRF) has been suggested. Several candidates for the PRF have been proposed. One of the components of hypothalamic extracts known to have a stimulatory effect on PRL release is TRH. This was demonstrated in several mammalian species, including the pig (Bevers and Willemse, 1982). However, TRH is probably neither the sole nor the major physiological PRF. Another strong candidate for PRF is vasoactive intestinal peptide (VIP) (Shimatsu *et al.*, 1985).

The rat posterior pituitary was found to contain a potent PRF (Hyde *et al.*, 1987). Further analysis demonstrated that two compounds, oxytocin from the NL and an unidentified peptide from the IL, could function as PRF. The low potency of oxytocin made it a less likely candidate for the physiological regulation of PRL release. The PRF from the IL appeared to be a small peptide that is present in the posterior pituitary of many species. Its chemical nature remains to be determined.

Prolactin-releasing peptide (PrRP) was first isolated from bovine hypothalamus as an orphan G-protein-coupled receptor (Hinuma *et al.*, 1998). PrRP was shown to stimulate PRL secretion *in vitro* and *in vivo* (Matsumoto *et al.*, 1999). However the effect of PrRP on PRL is less than that of TRH, and the idea that PrRP was a real hypophysiotropic PRL-secreting factor has been challenged. Morphological and physiological studies indicate that PrRP may play a wide range of roles in neuroendocrinology other than PRL release, among which the most important are energy metabolism, metabolic homeostasis, and stress responses (Sun *et al.*, 2005).

Like other pituitary hormones, PRL is released in a pulsatile manner, with fluctuations during different stages of the reproductive cycle. Apart from an increase around the time of ovulation (McNeilly *et al.*, 1982), plasma PRL concentrations increase during the luteal phase of the sexual cycle in dogs and cows (Dieleman *et al.*, 1986) but not in cats (Banks *et al.*, 1983). During lactation, very high PRL concentrations have been found in the sow (Bevers *et al.*, 1978) and in the dog (Concannon *et al.*, 1978). In addition, distinct increases in PRL concentration have been found in relation to pregnancy and parturition (Taverne *et al.*, 1982).

Progesterone induces GH production from the mammary gland but also modulates the secretion of PRL in the bitch. In pregnant and overtly pseudopregnant bitches, the plasma PRL concentration starts to rise about 1 month after ovulation, which is when the plasma progesterone concentrations begin to decline. Also in healthy bitches, most PRL is released during the second half of the luteal phase. The changes in GH and PRL release during the luteal phase may promote the physiological proliferation

and differentiation of mammary gland tissue in the bitch (De Coster *et al.*, 1983; Kooistra and Okkens, 2001b, 2002; Okkens *et al.*, 1985). In goats with pseudopregnancy, characterized by hydrometra and the presence of a persistent corpus luteum, no correlation was found with the plasma PRL concentration. PRL does not play a crucial role in the etiology of pseudopregnancy in the goat (Hesselink *et al.*, 1995; Kornalijnslijper *et al.*, 1997).

The effect of the lighting regime on PRL secretion in rams is thought to be a direct effect of melatonin on the pituitary gland (Lincoln and Clarke, 1994). In dogs, PRL secretion has a circannual rhythmicity (i.e., the months with longer daylight had significantly higher PRL concentrations than the months with the shortest) (Corrada *et al.*, 2003, 2006). There are also ultradian gender-related differences (i.e., higher basal levels were found in females compared with males) (Corrada *et al.*, 2003, 2006). In male dogs, PRL secretion has been reported relatively constant (Koch *et al.*, 2006) or pulsatile in nature (Corrada *et al.*, 2003, 2006) with a distinct breed difference (i.e., serum PRL concentrations in beagles were significantly higher than in crossbreeds and German shepherds) (Corrada *et al.*, 2003, 2006).

Important modulating factors in the control of PRL secretion are estrogens, especially 17-β-estradiol. Estrogens modulate the TRH receptor levels in the pituitary (Lean *et al.*, 1977) and cause a biphasic increase in transcription of the prolactin gene (Gorski *et al.*, 1985). From experiments in rats, it is concluded that progesterone may also stimulate the release of PRL (Deis and Alonso, 1985). Estradiol rapidly induces an enhanced PRL response to TRH in dogs, without changing basal PRL levels (Rutteman *et al.*, 1987). Subsequent administration of medroxyprogesterone acetate did not further affect these findings.

Neurogenic factors also influence PRL secretion. Milking and suckling are almost immediately followed by PRL release. Removal of litters from their dams, for example, piglets from sows (Bevers *et al.*, 1978), results in a rapid decline in PRL levels in plasma. Following return of the litters, PRL concentrations rise again.

d. Action

PRL is produced mainly by the lactotrope cells of the anterior pituitary and, in mammals, its most apparent function is the regulation of lactation. In addition, PRL has been attributed an important role in reproduction, as was illustrated by the observation that $PRL^{-/-}$ mice not only have defects in mammopoiesis but are also sterile (Horseman *et al.*, 1997). Although the bulk of PRL circulating in serum is produced by the lactotrope cells of the pituitary, PRL is also expressed extrapituitary by various tissues including uterine decidualized endometrial cells and leukocytes (Ben-Jonathan *et al.*, 1996). The most familiar role of PRL in mammals is stimulation of mammary gland growth and lactation. PRL increases mitosis of mammary gland epithelial cells not only during development but also during pregnancy and lactation. It has been relatively difficult to demonstrate *in vitro* effects of PRL on cell proliferation in mammary glands (Friesen *et al.*, 1985). This can be explained by the increasing evidence that the growth-promoting effect of PRL has much in common with that of GH (i.e., intermediate factors comparable to IGF are required for effects on cell proliferation) (Nicoll *et al.*, 1985).

PRL has a wide variety of other physiological actions among vertebrates. It may affect water and electrolyte balance, metabolism, gonadal function, and behavior. Of these, the effect on the ovary has received much attention. PRL has a luteotrophic effect in some animals, such as rodents, sheep, and ferrets (McNeilly *et al.*, 1982), but not in the cow (Bevers and Dieleman, 1987). Bovine follicles do not bind (ovine) PRL (Bevers *et al.*, 1987).

The reciprocal relationship between PRL and LH has been well established in several species, including the sow (Bevers *et al.*, 1983) and the cow (Dieleman *et al.*, 1986). This can explain the reduced fertility during lactation that is known in many species. It has been suggested that PRL may also interfere directly at the ovarian level (McNeilly *et al.*, 1982). These effects of PRL also appear to play a role in the maintenance of the long interestrous interval in the bitch. Treatment of bitches with the dopamine agonist bromocriptine results in considerable shortening of the interestrous interval (Okkens *et al.*, 1985).

Mammalian maternal behavior in several species consists of nest building and caring for offspring. Prolactin-induced maternal behavior has been established in some animals. However, the primary role of PRL in inducing mammalian maternal behavior has recently been questioned (Scapagini *et al.*, 1985). There appears to be diversity in the hormonal basis of maternal behavior, and in some species estrogens and progesterone play a crucial role (Rosenblatt, 1984).

e. Disease

Prolactinomas are the most common hormonally active pituitary tumors in humans. There is a marked female preponderance, and prolactinoma is relatively rare in men. Mixed GH-PRL adenomas are known to occur in a substantial number of patients with acromegaly, and the concomitant production and secretion of PRL by corticotroph adenomas is not unusual (Ishibashi and Yamaji, 1985). Pituitary PRL production is under tonic inhibitory control by hypothalamic dopamine, such that in humans' pituitary macroadenomas other than prolactinomas cause pituitary stalk interruption and also produce hyperprolactinemia. There have been no well-documented reports on the occurrence of prolactinomas in animals, although in dogs with pituitary-dependent hyperadrenocorticism (PDH), plasma PRL concentrations and the PRL response to stimulation were higher than those in healthy control dogs, probably as a result of cosecretion with ACTH by the transformed corticotropic cells (Meij *et al.*, 1997a).

Thus, there do not seem to be pathological hyperprolactinemical states in domestic animals that require treatment

TABLE 18-7 Concentrations of PRL in Plasma of Healthy Animals

Species (n)	Condition	Mean ± SEM (μg/liter)	Reference
Dog (6)	1.5 weeks of lactation	86 ± 19	(Concannon *et al.*, 1978)
Dog (6)	8–32 h prepartum	117 ± 24	(Concannon *et al.*, 1978)
Dog (5)	Ovariectomized females	7.9–11.5	(Rutteman *et al.*, 1987)
Dog (6)	Females, early luteal phase	2.5 ± 0.4	(Kooistra and Okkens, 2002)
Dog (6)	Females, anestrous	2.0 ± 0.1	(Kooistra and Okkens, 2002)
Dog (7)	Females, anestrous	7.0 ± 1.2[c]	(Corrada *et al.*, 2003)
Dog (6)	Females in estrous cycle	3.9 ± 1.6[a]	(de Gier *et al.*, 2006)
Dog (6)	Females in midluteal phase	3.2 ± 0.2[b]	(Lee *et al.*, 2006)
Dog (65)	Males	2.7 ± 0.2	(Corrada *et al.*,2006)
Dog (8)	Males	3.0 ± 0.3[b]	(Koch *et al.*, 2006)
Cat (8)	Early gestation	7.0 ± 0.3	(Banks *et al.*, 1983)
Cat (8)	End of gestation	43.5 ± 4.5	(Banks *et al.*, 1983)
Cat (8)	4 Weeks post partum	40.6 ± 7.2	(Banks *et al.*, 1983)
Cow (5)	Luteal phase	23.3 ± 4.8	(Dieleman *et al.*, 1986)
Cow (5)	Follicular phase	15.8 ± 2.7	(Dieleman *et al.*, 1986)
Sow (3)	2nd Week of lactation	9.1 ± 1.4–26.1 ± 5.0[c]	(Bevers *et al.*, 1978; Matthews and Parrott, 1992)
Sow (3)	Piglets removed	1.4 ± 0.3–1.9 ± 0.1[c]	(Bevers *et al.*, 1978; Matthews and Parrott, 1992)
Sheep (8)	Males	68 ± 15.3	(Matthews and Parrott, 1992)

[a] *Mean of 3 measurements/24 h during early follicular phase, six measurements/24 h during late follicular phase, and 6 measurements/24h during early luteal phase.*
[b] *Mean of 24 measurements at 15-min intervals.*
[c] *Mean of 8 measurements at 15-min intervals.*

with dopaminergic drugs. These drugs are nevertheless often used, the main application being in a physiological condition in the bitch called pseudopregnancy (Janssens, 1981). Administration of the dopamine agonist bromocriptine results in rapid disappearance of the signs, suggesting impending parturition. As treatment with bromocriptine lowers PRL concentrations in plasma (Okkens *et al.*, 1985; Stolp *et al.*, 1986), it is likely that the lactation and maternal behavior of the diestrual bitch is PRL dependent.

Isolated PRL deficiency has been reported in few case reports in women that became apparent because these women suffered from galactogenesis after normal pregnancies (Douchi *et al.*, 2001). However, the involvement of a genetic defect in the observed PRL deficiency was not addressed. Isolated PRL deficiency in domestic animals has not been reported.

f. Tests

Despite the variations in amino acid sequences of PRLs from different species, plasma concentrations can be measured in heterologous assays, for example, employing labeled porcine PRL with an antibody against ovine PRL in an assay for canine PRL (Stolp *et al.*, 1986). PRL levels in the blood may vary during the reproductive cycle, but the basal levels in both male (Meij *et al.*, 1996a) and anestrous female dogs are within similar narrow limits (Stolp *et al.* 1986). Reference values are presented in Table 18-7.

When there is a suspicion of prolactin deficiency, the secretory capacity can be tested with TRH. In healthy dogs intravenous administration of 10 μg TRH per kg body weight resulted in a mean plasma PRL peak level of 19.7 ± 5.8 μg/liter at 5 min following single TRH administration and of 28.5 ± 6.8 μg/liter at 5 min following combined administration of four hypothalamic-releasing hormones (Meij *et al.*, 1996a). In cats, 75 μg TRH caused PRL elevation to seven times the basal levels (Banks *et al.*, 1983). Prolactin concentrations can be suppressed with the dopamine agonist bromocriptine. Both 20 μg/kg intravenously (Stolp *et al.*, 1986) and 10 μg/kg orally (Rijnberk *et al.*, 1987) resulted in protracted decreases lasting at least 8 h after administration.

III. NEUROHYPOPHYSIS

A. Vasopressin

1. *Gene Expression*

Although there is considerable homology between the genes for vasopressin (VP) and oxytocin (OT), each of the relevant

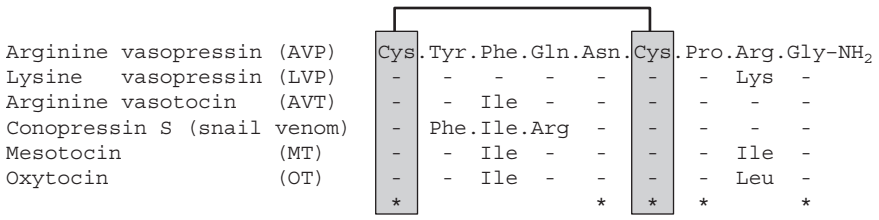

FIGURE 18-14 Sequence comparison of vasopressin (VP) and oxytocin (OT)-like peptides. Lines between shaded boxes represent intrachain disulfide bridges. See the legend for Figure 18-6.

hypothalamic neurons produces only one hormone, either VP or OT. The VP and OT genes are located within the same chromosomal locus at a very short distance from each other in a head-to-head orientation organization (Burbach *et al.*, 2001). Regulatory domains in this intergenic region control their hypothalamus-specific expression (Fields *et al.*, 2003).

The VP gene consists of three exons that encode for different functional parts of the VP precursor peptide, the propressophysin. Exon 1 encodes the signal peptide, the nonapeptide VP, and the N-terminal part of neurophysin II (NP-II). Exon 2 encodes the central part of NP-II, and exon 3 encodes the C-terminal part of NP-II and a glycoprotein (GP). The major factors that regulate VP expression are osmotic and hypovolemic stimuli. Water deprivation stimulates hypothalamic VP mRNA most probably through two cAMP response elements (CRE) and an AP2 site within the promoter. Glucocorticoids suppress VP gene expression through a GRE in the VP promoter (Kim *et al.*, 2001).

2. (Pro)hormone

After cleavage of the signal peptide, the GP moiety of the VP prohormone is glycosylated, disulfide bonds are generated, and then the prohormone is packaged into a secretory vesicle. The correct sorting of the prohormone into the secretory pathway requires the formation of aggregates. Specific association of VP and NP-II results in dimeric and tetrameric units that are essential for sorting (Burbach *et al.*, 2001). The secretory vesicles are axonally transported to the axon endings in the posterior pituitary. Studies in the dog suggest that approximately 1.5 h are required from the time of synthesis to possible release of the nonapeptide (Ivell *et al.*, 1986). During this transport the neurophysin II, VP, and the GP moiety are liberated by proteolytic cleavage. The C-terminal glycine residue of the VP-molecule is finally amidated.

In most mammals, VP contains an arginine residue at position 8 (arginine vasopressin, AVP) and a five-membered ring formed by a disulfide bridge between the cysteine residues at position 1 and 6 (Fig. 18-14). In the members of the pig family, VP contains a lysine residue at position 8. The lysine vasopressin (LVP) is the only form present in the domestic pig. Heterozygotic peccaries, warthogs, and hippopotami may possess both AVP and LVP. Substitution of the phenylalanine residue at position 3 by isoleucine leads to arginine vasotocin (AVT). This peptide has been identified as a uniquely nonmammalian substance and is probably the most primitive and certainly the most commonly occurring neurohypophyseal peptide.

3. Secretion

The major determinant in the release of vasopressin is plasma osmolality. Below a certain plasma osmolality threshold, which may vary considerably between individuals, plasma VP concentration is suppressed to levels that allow maximal free water clearance (Wade *et al.*, 1982). Once plasma osmolality rises to the threshold, the pituitary secretes VP. Although the concentration of plasma VP causing maximal antidiuresis is about 5 to 10 pmol/liter, the release of VP is related to plasma osmolality over a much broader range (Robertson, 1983). Biewenga *et al.*, developed a nomogram for this relationship in the dog, which allows analysis of the osmoregulation of VP secretion in terms of sensitivity and threshold (Biewenga *et al.*, 1987). In healthy dogs, VP is secreted in a pulsatile fashion with a wide variation in number of pulses, VP pulse duration, and VP pulse amplitude and height (van Vonderen *et al.*, 2004b). After water deprivation, total and basal VP secretion, the number of significant VP pulses, as well as the pulse characteristics, is not different from basal values. However, during osmotic stimulation with hypertonic saline, there is a large increase in both basal and pulsatile VP secretion, and the number of VP pulses and VP pulse height and amplitude increase significantly (van Vonderen *et al.*, 2004b).

Apart from the influence of osmolality, a significant decrease in circulating blood volume may also cause enhanced VP secretion. The decrease in left atrial pressure triggers receptors. Denervation of these receptors prevents the hypovolemia-mediated VP release. The functional properties of this regulatory system differ from those of the osmoregulatory system. Although the relationship between plasma osmolality and VP appears to be linear, the relationship between blood volume and plasma VP is best described by an exponential function (Vokes and Robertson, 1985a).

Under ordinary circumstances, changes in VP levels are not observed until blood volume decreases by 5% to 10%. With further decreases, plasma VP rises exponentially. The relative insensitivity of VP to modest changes in blood volume means that this regulatory mechanism plays little or no role in the physiological control of water balance. Under ordinary circumstances, total body water rarely changes by more than 1% to 2%, an amount far too small to affect

VP secretion through hemodynamic influences (Wang and Goetz, 1985). In dogs, 24 h of fluid deprivation increases plasma VP because of changes in both extracellular volume and tonicity, but the increase in tonicity plays a greater role than the reduction in volume (Wade *et al.*, 1983).

It has been proposed that hemodynamic influences modulate VP secretion by raising or lowering the osmostat (Robertson, 1978). According to this concept, a decrease in plasma volume or pressure will permit normal osmoregulation of VP, but the threshold for release will be lowered by an amount proportional to the degree of hypovolemia or hypotension, associated with increased sensitivity of the VP response to rising plasma osmolality. Conversely, hypervolemia or hypertension increases the threshold and decreases the sensitivity of release (Quillen and Cowley, 1983).

There are numerous other factors that may influence VP secretion. Of these, nausea/vomiting (Rascher *et al.*, 1986), insulin-induced hypoglycemia (Vokes and Robertson, 1985b), and stress (Jorgensen *et al.*, 2002) are the most potent. The effects of opiates and opioid peptides on VP secretion have been studied for many years and have been the subject of some controversy. Both stimulatory and inhibitory effects have been reported. Apart from the substances, doses, and routes of administration used, the animal species is an important factor (Van Wimersma Greidanus, 1987). Intracerebroventricular administration of β-END in conscious rats decreases basal and stimulated VP release (ten Haaf *et al.*, 1986). An opioid inhibition of dehydration-induced VP release has been reported in dogs (Wade, 1985). However, Hellebrekers *et al.*, (1988) could not confirm this endogenous opioid modulation of osmolality-regulated VP release in conscious dogs subjected to hypertonic saline infusion. In contrast, sharp increases in plasma VP have been found in conscious dogs after intravenous administration of the μ-type opiate receptor agonist methadone (Hellebrekers *et al.*, 1987).

In addition, a large number of drugs and hormones, among which are glucocorticoids (inhibitory effect), angiotensin II, and corticotropin-releasing factor (stimulatory effect), influence VP secretion (Berl and Robertson, 2000).

4. VP *Action and Aquaporin*-2

The biological effects of VP are mediated by three receptor subtypes: V1 receptors on blood vessels, V2 receptors on renal collecting duct epithelia, and V3 receptors (also termed V1b) responsible for the stimulation of adrenocorticotropin from the AL (Birnbaumer, 2000; Robinson and Verbalis, 2003).

The major role of VP is to regulate body fluid homeostasis by affecting water resorption. An increase in plasma VP results in increased water retention, which maintains plasma osmolality between narrow limits. The antidiuretic effect is achieved by promoting the reabsorption of solute-free water in the distal and collecting tubules of the kidney. In the absence of VP, this portion of the nephron is not permeable to water and the hypotonic filtrate of the ascending limb of Henle's loop passes unmodified through the distal tubule and collecting duct. In this condition urine osmolality decreases to around 80 mOsm/kg. Binding of VP to its V2 receptor in collecting duct cell membranes initiates a signal transduction cascade leading to an intracellular increase in cAMP (Jard, 1983), activation of protein kinase A (Deen *et al.*, 2000), and subsequent phosphorylation of the water channel protein, the so-called aquaporin-2. In the plasma membranes of highly water-permeable cells, aquaporins (AQPs), a family of integral membrane proteins, function as water-selective channels (Agre *et al.*, 2002; Deen *et al.*, 2000; Nielsen *et al.*, 1995). Seven different renal AQPs (AQP 1-4, 6-8) have been defined thus far, correlating with well-defined segmental permeabilities in the nephron (King and Yasui, 2002). Aquaporin-2 has been characterized as the major VP-regulated water channel and is predominantly localized in the apical membrane and the intracellular vesicles of collecting duct principal cells (Nielsen *et al.*, 1993). In the presence of these water-selective channels, water can move passively along an osmotic gradient—that is, from the distal and collecting duct tubules to the hypertonic renal medulla. After VP withdrawal, aquaporin-2 is redistributed into the cell and water permeability decreases (Nielsen *et al.*, 1995). Urinary excretion of AQP2 closely parallels changes in VP exposure and has been proposed as a reliable marker for collecting duct responsiveness to VP in various physiological states of water homeostasis as well as disorders of water homeostasis. As in humans, urinary AQP2 excretion in dogs closely reflects changes in VP exposure, elicited by water loading, hypertonic saline infusion, and intravenous desmopressin administration and is proposed as a marker for collecting duct responsiveness to VP (van Vonderen *et al.*, 2004c).

Besides this well-known role in the regulation of fluid homeostasis, VP exerts a large variety of effects. Among these is the vasopressor effect, which is mediated by V1 receptors (Liard, 1986). In addition, VP increases glucogenolysis by liver cells, increases ACTH release by adenohypophysis (Lowry *et al.*, 1987), and has several effects on animal behavior (de Wied and Versteeg, 1979). The extrarenal effects on hepatocytes and vascular smooth muscle are exerted through cAMP-independent, calcium-dependent V1 receptors (Jard, 1983).

There is some evidence that in birds AVT, apart from its established antidiuretic action, also has oxytocic properties and participates in normal oviposition (Shimada *et al.*, 1986, 1987). MT does not seem to function in oviposition and its release was found to be negatively correlated with plasma osmolality (Koike *et al.*, 1986).

5. *Disease*

Disorders of the hypothalamic-neurohypophyseal system resulting in deficiency or excess of VP are known to occur

in domestic animals. Deficient VP release causes the syndrome of diabetes insipidus, which is characterized by insatiable polydipsia and persistent inappropriately dilute urine in the presence of strong osmotic stimuli for VP release. The disease is not uncommon in the dog and cat (Feldman and Nelson, 2004; Rijnberk, 1996) and rare in other species.

VP excess is known as the syndrome of inappropriate ADH (SIADH) secretion or the Schwartz-Bartter syndrome. The VP release is inappropriately high in relation to the plasma osmolality. The resulting defect in water excretion causes hyponatremia, which is the hallmark of SIADH. This condition has been documented as a disease of the dog and at the same time studies of the threshold and sensitivity of VP secretion revealed that it occurred in two forms (Houston *et al.*, 1989; Rijnberk *et al.*, 1988a). The polyuria can be explained by down-regulation of V2 renal receptors resulting from chronic exposure of the kidney to increased VP levels (Rijnberk, 1996; Rijnberk *et al.*, 1988a).

In dogs with primary polydipsia, described as a psychological problem, evidence indicates a primary disturbance in the regulation of VP secretion (van Vonderen *et al.*, 1999) and a wide variation in VP responses to hypertonic stimulation can be found, including a hyperresponse, a hyporesponse, and a nonlinear response (van Vonderen *et al.*, 2004a).

The glucocorticoid excess in Cushing's syndrome is accompanied by (mild) polyuria in the dog. A marked impairment of the osmolality-regulated VP release at the pituitary level may, in concert with a partial VP resistance at the kidney level, be the cause of the corticosteroid-induced polyuria (Biewenga *et al.*, 1991). Chronic liver disease is accompanied by both enhanced activity of the pituitary-adrenocortical axis and disturbances in sodium and water homeostasis. Also in these cases, a profoundly impaired osmoregulation of VP release was found (Rothuizen *et al.*, 1995). Besides hyperadrenocorticism and hepatic failure, other conditions in the dog also lead to secondary or acquired nephrogenic diabetes insipidus. Hypercalcemia (Rijnberk, 1996), pyometra (Heiene *et al.*, 2004), and hyperaldosteronism (Rijnberk *et al.*, 2001) that are marked by polyuria and polydipsia are associated with impaired renal response to VP, either by VP receptor resistance or down-regulation of AQP2.

In dogs with secondary polycythemia, blood hyperviscosity and increased blood volume result in impaired VP release and polyuria (van Vonderen *et al.*, 1997b). In dogs with spontaneous pericardial effusion, moderately elevated plasma VP levels declined rapidly after pericardiocentesis (Stokhof *et al.*, 1994).

6. Tests

The diagnosis of VP deficiency requires that it be differentiated from other causes of water diuresis. Following exclusion of conditions such as hyperadrenocorticism, hyperthyroidism, and hypercalcemia, both nephrogenic diabetes insipidus and primary polydipsia remain as the main differential diagnoses. Urine-specific gravity (Usg) and urine osmolality (Uosm) are used routinely in the dog to assess renal concentrating ability. However, intra- and interindividual variations of these parameters in healthy dogs are much larger than previously thought (van Vonderen *et al.*, 1997a), which complicates the interpretation of findings in pathological conditions. Slightly elevated plasma osmolality may suggest neurogenic or nephrogenic diabetes insipidus, whereas low plasma osmolality may be observed in primary polydipsia. However, in many cases this parameter is not conclusive.

The procedure that is widely used to differentiate these disorders is the modified water-deprivation test, as introduced for the dog by Mulnix *et al.* (1976). In this test maximal urine concentration is induced by several hours of dehydration. Once a plateau in urine osmolality is reached, the effect of an injection with VP is investigated. A further increase in urine osmolality by 50% or more is regarded as diagnostic for VP deficiency.

Although these indirect criteria for VP secretion can usually differentiate between complete neurogenic and complete nephrogenic diabetes insipidus, they cannot differentiate among partial neurogenic, partial nephrogenic, and dipsogenic polyurias. In these situations, direct measurements of plasma VP during hypertonic saline infusion are required (Biewenga *et al.*, 1989). However, the significance of the VP response to hypertonic saline infusion as the gold standard for diagnosis of canine polyuria is complicated by the occurrence in healthy dogs of spontaneous VP pulses and increased VP pulses (to the magnitude of "erratic bursts") during hypertonic saline infusion (van Vonderen *et al.*, 2004b).

Hypersecretion of VP can only be diagnosed by measurements of the circulating concentrations of the hormone (Table 18-8). The basic criterion is the presence of "inappropriately" high VP concentrations in relation to the hypoosmolality of the extracellular fluid. The type of the osmoregulatory defect can best be judged by repeatedly measuring plasma osmolality and VP during administration of hypertonic saline (Rijnberk *et al.*, 1988a). Details of this test are given in Section IV.

Measurement of urinary excretion of AQP2 may become a diagnostic tool in dogs for differentiation of polyuric conditions such as (partial) central or nephrogenic diabetes insipidus, primary polydipsia, and inappropriate VP release (van Vonderen *et al.*, 2004c).

B. Oxytocin

1. Gene Expression

The oxytocin (OT) gene expression is predominantly found in the hypothalamic supraoptic nucleus and paraventricular nucleus (Burbach *et al.*, 1986). The neurons project

TABLE 18-8 Concentrations of Neurohypophyseal Hormones in Plasma of Healthy Animals[a]

Hormone (Unit)	Species (n)	Condition	Mean ± SEM (Range)	Reference
VP	Dog (8)	basal	3.2 ± 0.3	(van Vonderen *et al.*, 2004b)
(pmol/liter)	Dog (8)	hypertonic saline	15.3 ± 3.4	(van Vonderen *et al.*, 2004b)
	Goat	basal	1.3 ± 0.2	(Thornton *et al.*, 1986)
	Calf (16)	basal	1.3 ± 0.2[b]	(Doris and Bell, 1984)
	Calf (16)	4 days dehydration	16.9 ± 1.9[b]	(Doris and Bell, 1984)
OT	Dog (10)	1st week lactation	(15–66)	(Eriksson *et al.*, 1987)
(pmol/liter)	Cow (334)	before milking	1.6 ± 0.6	(Schams *et al.*, 1983)
	Sow (9)	6–12 days postpartum	<10	(Porter *et al.*, 1992)
	Sow (9)	idem, suckling	(24.9–74.6)	(Porter *et al.*, 1992)
	Goat	basal	4.5 ± 1.0	(Thornton *et al.*, 1986)

[a] 1 *ng/liter* VP = 0.932 *pmol/liter*; 1 *ng/liter* OT = 0.994 *pmol/liter*.

[b] In μU/ml.

mainly to the posterior pituitary, where OT is secreted for endocrine stimulation of parturition and lactation, while other neurons project to higher brain centers, where OT may be converted by brain peptidases and exert an effect as a neurotransmitter or neuromodulator (van Wimersma Greidanus *et al.*, 1986). Together with VP, the neuropeptide OT is a critical mediator of partner preference, and plays a central role in monogamy in prairie voles (Young and Wang, 2004). Oxytocin seems to be more important in females and may regulate mother-infant bonding in sheep.

The organization of the OT gene closely resembles that of the VP gene. The exon-intron organization is similar, with the exception that exon 3 lacks a glycoprotein domain. In the cow, among 194 bases of the 3′ part of exon 2, no single base is different from the corresponding one in the VP exon 2. Exon 3 shows the least homology between the VP and OT genes (Ivell and Richter, 1985).

The expression of OT mRNA is regulated by the same intergenic region that regulates VP expression (Fields *et al.*, 2003). Estrogens greatly induce bovine OT mRNA expression although the OT promoter has response elements for estrogen receptors. The estrogenic stimulation appeared to be dependent on the nuclear orphan receptor ERRα through the MAP kinase pathway (Koohi *et al.*, 2005).

In bovine granulosa cells, LH has been found to stimulate OT gene transcription. Also, estrogens can stimulate bovine OT expression in heterologous transfection systems in contrast to human and rat OT promoters. Other transcription factors are related to induced (steroidogenic factor-1 [SF-1]) or inhibited (COUP-TF) OT mRNA expression (Stormshak, 2003).

2. (Pro)hormone

After translation of the mRNA, proteolytic enzymes cleave OT from neurophysin I, and a C-terminal amidation of OT occurs. This posttranslational processing is time dependent, as for the biotransformation of the AVP prohormone. Through modification of the first three amino acids a potent OT antagonist is developed, from which newer analogues are designed with even higher OT antioxytocic properties (Flouret *et al.*, 2006).

3. Secretion

The release of OT is most abundant during parturition and the lactation period. The main stimuli for the release of OT from the posterior pituitary therefore arise from either the nipples during milking (Lupoli *et al.*, 2001) or suckling, or from vaginal and cervical distension. The suckling-related release of OT has been documented in the dog (Eriksson *et al.*, 1987). The neural regulation of OT release is complex. Both dopamine and opioid peptides (enkephalin and β-endorphin) modulate OT release at the nerve terminals in the NL (Forsling, 1986). Opioid effects on posterior pituitary pituicytes may mediate this interaction. There is some evidence that OT is released in response to osmotic challenge in the rat and some carnivores but not in primates or ungulates (Thornton *et al.*, 1987).

Plasma OT levels may also vary during the reproductive cycle. Generally, a similar secretion pattern is found among domestic animals. Plasma levels increase after the preovulatory LH surge and decrease at the time of luteal regression, in the cow, goat, and sheep (Schams, 1983). In the mare, plasma OT levels are lower in the midluteal phase than on day 2 of estrus and day 5 after ovulation (Burns *et al.*, 1981). The latter is more closely to the pattern of OT release in humans. The high OT content of the corpus luteum of the sheep and the cow may mean that the majority of the circulating OT is derived from the ovary in these species.

Ovarian estrogen may enhance pituitary OT release, whereas progesterone inhibits it. In male animals, mating may be a stimulatory factor. Nonreproductive factors such as stress and plasma osmolality may also influence the OT release (Forsling, 1986).

4. Action

OT causes contraction of the myoepithelial elements of the excretory ducts of the mammary glands, resulting in milk ejection. In addition, it exerts a constricting effect on the uterine muscle. Estrogens increase the response of the uterus to OT, whereas progesterone inhibits it. During pregnancy, the sensitivity of the uterus to OT is greatly reduced. However, during delivery and immediately thereafter, the uterus is particularly sensitive to OT. In birds, AVT is far more active in stimulating the contraction of the oviduct than is OT (Bentley, 1971).

5. Disease/Tests

To our knowledge no pituitary dysfunction concerning OT release in domestic animals has been reported. Basal plasma levels of OT are in approximately the same range as plasma VP concentrations (Table 18-8). In the human and the goat (Thornton *et al.*, 1986), OT release cannot be stimulated by hypertonic saline infusion but does increase in response to insulin-induced hypoglycemia (Nussey *et al.*, 1986). In the rat, nausea-producing chemical agents and cholecystokinin cause a dose-dependent increase in OT (Verbalis *et al.*, 1986).

IV. ASSESSMENT OF PITUITARY FUNCTION

Endocrine studies in animals with suspected hypothalamus-pituitary disease may be carried out for three reasons: (1) documentation of specific endocrine deficits; (2) insight into the type, size, and progression of the lesion; and (3) characterization of hyperfunction. Specific diagnostic tests for several of the pituitary hormones have been described in the previous sections. Here the discussion will concentrate on a more general approach in an attempt to determine the extent of involvement of AL, IL, or NL.

A. Adenohypophysis

1. Anterior Lobe

The species specificity of some of the AL hormones precludes their measurement in several animal species with the assays available. For many other hormones, however, homologous or heterologous assays are available, allowing assessment of AL function.

Although baseline hormone levels can provide much information, the pulsatile nature of AL hormone secretion often makes interpretation difficult. It is particularly difficult to distinguish between normal and low levels of these hormones. For this reason, provocative tests should be used to examine hypothalamus-pituitary adequacy. Now that hypothalamic-releasing hormones have become available and are applicable in most species, appropriate testing of AL function is possible.

In all instances blood samples are collected at −15, 0, 10, 20, 30, and 45 min (for the short test), and 60, 90, and 120 min (for the long test) for measurement of the pituitary hormones. At time zero the test substance is injected intravenously. It may be one of the following:

1. 1 μg GHRH/kg, 2 μg ghrelin/kg, or 10 μg clonidine/kg to test GH and IGF-1 secretion.
2. 1 μg CRH/kg or 0.6 μg lysine vasopressin/kg to test ACTH (+cortisol) secretion.
3. 10 μg TRH/kg to test PRL or TSH secretion (see Section II.C.2).
4. 10 μg GnRH/kg to test FSH or LH secretion.

Because of the rapid proteolytic degradation of some pituitary hormones, blood samples should always be chilled on ice as soon as possible and stored at ≤20°C (see also Section V.E of Chapter 19 on adrenocortical function).

Combined function tests are coming into use in humans. The anterior pituitary is stimulated with four hypothalamic-releasing hormones in a single procedure. Despite the fact that there is some interaction of the different releasing hormones, combined administration of releasing hormones seems to be a useful test for the assessment of pituitary function (Schopohl *et al.*, 1986). Such a combined function test has been introduced for the dog. In this test, the anterior pituitary is stimulated with four hypothalamic-releasing hormones (CRH, GHRH, TRH, and GnRH) with measurements of ACTH (+cortisol), GH, PRL, TSH, and LH (Meij *et al.*, 1996a, 1996b). Compared with the single administration of these secretagogues, there is little interference in this test, except for the LH response, which is lower in the combined test than following single GnRH administration. The test has been used successfully to document combined pituitary hormone deficiency in German shepherd dogs with dwarfism (Kooistra *et al.*, 2000c) and to document AL function in bitches treated with medroxyprogesterone acetate (Beijerink *et al.*, 2007).

2. Intermediate Lobe

α-MSH is secreted specifically by the IL. Its release can be stimulated with dopamine agonists such as haloperidol in a dose of 0.2 mg/kg (Table). The times of sampling for α-MSH can be as for the tests of adenohypophyseal function (see Section IV.A), and the test has been used to document IL function before and after hypophysectomy in dogs (Meij *et al.*, 1997c).

B. Neurohypophysis

As explained in Section III.A, VP secretion can be examined indirectly by means of a modified water-deprivation

test and directly by measuring plasma VP during hypertonic saline infusion. Both procedures are described here in detail, as they have been developed for use in the dog (Biewenga *et al.*, 1987; Mulnix *et al.*, 1976). It should be noted that because of interference of plasma proteins, the radioimmunoassay for VP requires prior extraction of the peptide with ethanol and validation of the assay for the dog (Biewenga *et al.*, 1991; Hellebrekers *et al.*, 1987). Antisera against AVP may possess 100% cross-reactivity with AVT (Choy and Watkins, 1986; Hellebrekers *et al.*, 1987).

1. *Modified Water-Deprivation Test*

a. Indication

Differentiation between neurogenic and nephrogenic diabetes insipidus, when the administration of DDAVP (Minirin) has not resolved the diagnosis.

b. Procedure

Following 12 h of fasting, water is withheld and plasma and urine are collected every hour or 2 h, depending on the severity of the polyuria. Osmolality is measured in both samples. At each collection the animal is weighed. When the weight loss approaches 5% of initial body weight, the test should be stopped.

When, in the presence of an adequate osmotic stimulus (Posm $>$ 305 mOsm/kg), urine concentration is maximal (less than 5% increase in Uosm between consecutive collections), 2IU of lysine vasopressin are administered subcutaneously. Uosm is measured again 1h later.

c. Interpretation

In both nephrogenic diabetes insipidus and neurogenic diabetes insipidus, Uosm will remain low during water deprivation. In neurogenic diabetes insipidus, Uosm will rise by 50% or more following the injection of vasopressin, whereas in nephrogenic diabetes insipidus, there will be little or no rise in Uosm.

However, as mentioned earlier, in some cases the outcome may not be conclusive and erroneous results may also occur.

2. VP *Measurements during Hypertonic Saline Infusion*

a. Indications

Differential diagnosis of polyuric conditions and suspicion of inappropriate VP secretion.

b. Procedure

The euhydrated animal is infused for 2 h via the jugular vein with 20% NaCl solution at a rate of 0.03 ml/kg body weight per minute. Samples for plasma VP and Posm are obtained at 20-minute intervals. Especially in the severely polyuric animal, there is a risk of inducing critical hypertonicity. In these cases the samples collected at 0, 40, and 80 min should be checked for Posm immediately.

c. Interpretation

The slope of the regression line for Posm and plasma VP concentration is used as a measure of the sensitivity of the osmoregulatory system. In the nomogram developed by Biewenga *et al.*, (1987), the 90% range for sensitivity was 0.24 to 2.47 (pg/ml)/(mOsm/kg). The 90% range for the threshold of the system was 276 to 309 mOsm/kg. After hypophysectomy in the dog, there is no VP response to hypertonic saline infusion (Meij *et al.*, 1997c).

However, as mentioned earlier, the occurrence of spontaneous VP pulses makes it difficult to differentiate these from VP pulses (to the magnitude of "erratic bursts") during hypertonic saline infusion (van Vonderen *et al.*, 2004b).

I. ANATOMICAL CONSIDERATIONS

In mammals, the adrenal glands are bilateral structures located craniomedial to the kidneys. The adrenal is, in fact, made up of two glands of different embryological origin. The center of the gland, the medulla, comprises coalesced chromaffin cells of neuroectodermal origin that secrete epinephrine or norepinephrine. The surrounding adrenal cortex arises from mesoderm and can be divided histologically into three zones: (1) zona glomerulosa (or arcuata), (2) zona fasciculata, and (3) zona reticularis. The cells of the zona glomerulosa are arranged in ovoid groups immediately inside the connective tissue capsule. The region may be particularly obvious (e.g., sheep) or difficult to discern (e.g., small rodents). The zona fasciculata accounts for most of the adrenal cortex (>60%) and appears histologically in radial lines. The inner zona reticularis comprises networks of cell cords surrounding the large blood sinuses. A notable feature of the ferret adrenal gland is that islands of cortical cells can be found among cells of the medulla. These cells resemble those of the inner part of the zona fasciculata (Holmes, 1961).

In birds, the adrenal glands are also separate, encapsulated organs. The glands lie cranial to the kidney, often wholly or partly covered by the gonads. The adrenocortical and chromaffin tissues are intermingled to varying degrees, depending on the species. The basic unit of avian adrenocortical tissue is a cord of a double row of parenchymal cells, with their long axes in the transverse plane of the strand. The cords radiate from the center of the gland, branch, and anastomose frequently. Groups of chromaffin cells lie between the cords and are also ensheathed within the connective tissue reticulum (Chester-Jones, 1987).

Blood flow of the adrenals is centripetal. In species with separated medulla and cortex, this results in high medullary corticoid concentrations that induce an enzyme in the chromaffin cells, converting norepinephrine to epinephrine. Therefore, species with anatomically separated medulla and cortex predominantly secrete epinephrine and species with intermingled chromaffin and adrenocortical tissue secrete predominantly norepinephrine (Marks, 1983).

II. PHYSIOLOGY OF ADRENOCORTICAL HORMONES

The secretion of the mammalian adrenal cortex comprises three main categories of hormones, which can be related to some extent to the above-described anatomical zonation. The zona glomerulosa produces mineralocorticoids (aldosterone and deoxycorticosterone), which maintain salt balance. The cells of the zona fasciculata secrete glucocorticoids (cortisol and corticosterone), which are primarily involved in carbohydrate metabolism. The third category of adrenocortical hormones, the androgens (e.g., androstenedione), is produced in the zona reticularis. This zone to a minor degree also secretes glucocorticoids and other hormones such as progesterone and estrogens.

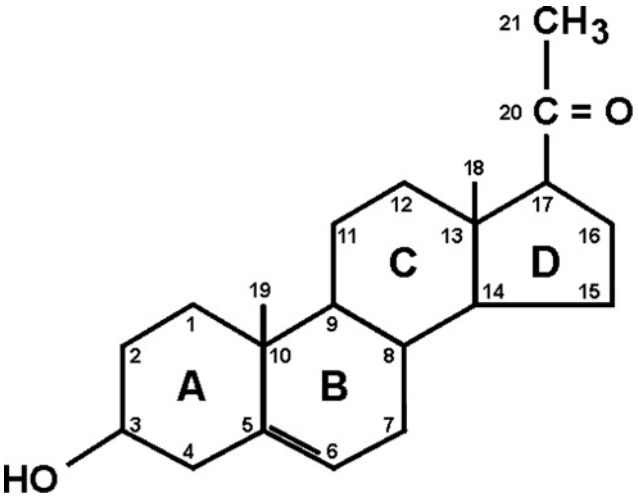

FIGURE 19-1 Numbers of the carbon atoms and letters designating the rings of the pregnenolone molecule (IUPAC-IUB, 1989).

In birds aldosterone and corticosterone are the main corticosteroids secreted. Zonation of the avian adrenal is less clear than in the mammalian adrenal. However, the outer subcapsular cells, looping in a manner similar to the zona glomerulosa, appear to be the predominant aldosterone secretors. The cells reaching toward the central part of the gland form corticosterone (Kime, 1987).

A. Steroid Nomenclature

The adrenal steroids contain as their basic structure a cyclopentanoperhydrophenanthrene nucleus consisting of three six-carbon rings (A, B, and C) and a single five-carbon ring (D). The letter designations for the carbon rings, and the numbers of the carbon atoms are shown for pregnenolone (Fig. 19-1), a key biosynthetic intermediate. The Greek letter Δ indicates a double bond, as does the suffix -ene. The position of a substituent below or above the plane of the steroid ring is indicated by α and β, respectively. The α substituent is drawn with a broken line (e.g.--OH) and the β substituent with a solid line (e.g.-OH). The C_{18} steroids, which are devoid of a side chain at C-17 and have a substituent at C-18, are estrogens. The C_{19} steroids, which have substituent methyl groups at positions C-18 and C-19, are androgens (see also Fig. 19-1) (IUPAC-IUB, 1989).

Steroids that have a ketone group at C-17 are termed 17-ketosteroids. The C_{21} steroids, the corticosteroids and progestagens, are those that have a two-carbon side chain (C-20 and C-21) attached at C-17 and in addition have substituent methyl groups at C-18 and C-19. The C_{21} steroids that also possess a hydroxyl group at position 17 are termed 17-hydroxy-corticosteroids and may have predominantly glucocorticoid properties.

B. Biosynthesis

Cholesterol, derived from food and from endogenous synthesis via acetate (Fig. 19-2), is the principal starting compound in steroidogenesis. The adrenal gland is enriched in receptors that internalize low- and high-density lipoproteins. This uptake mechanism increases when the adrenal is stimulated and provides the major cholesterol source. Subsequent steps occur in the mitochondrion or at the endoplasmic reticulum. Two classes of enzymes are involved in the synthesis of steroids, the cytochrome P450 (CYP) heme-containing proteins that catalyze mainly hydroxylation reactions and the hydroxysteroid dehydrogenases (HSD) that are involved in oxidation and reduction reactions (Payne and Hales, 2004). The human CYP enzymes are written with capitals, whereas in mice lowercase is used. For other species no rules are given, but we will use here the abbreviations as used for human.

The precursor cholesterol has a side chain that is cleaved by CYP11A1 resulting in formation of pregnenolone (Fig. 19-2). Mice defective in the Cyp11a1 gene produce no steroids, survive during embryogenesis, but die after birth (Hsu *et al*., 2006). The zonal difference in adrenocortical hormone production is due to two steroidogenic enzymes. The mitochondrial CYP11B2 (aldosterone synthase), which converts 11-deoxycorticosterone by 11β-hydroxylation and the formation of a carbon 18 aldehyde group toward aldosterone, is found only in the zona glomerulosa. The characteristic enzymes of the inner zones are the microsomal CYP17 (17α-hydroxylase/17,20 lyase) and the mitochondrial CYP11B1 (11β-hydroxylase). CYP17 catalyzes the 17α-hydroxylation of pregnenolone and progesterone as well as the side chain fission of 17α-hydroxy C21 steroids resulting in the formation of dehydroepiandrosterone (DHEA) or androstenedione (Fig. 19-2). CYP11B1 catalyzes the 11β-hydroxylation in the zona fasciculata and reticularis (Payne and Hales, 2004). The other steroidogenic enzymes are present in all three zones of the adrenal cortex (Müller, 1986).

In rat, mouse, guinea pig, baboon, and hamster two distinct CYP11B forms are found, in contrast with cow, pig, sheep, and frogs where the formation of glucocorticoids and mineralocorticoids is catalyzed by a single 11β-hydroxylase (CYP11B1) (Lisurek and Bernhardt, 2004).

The characteristic microsomal 21-hydroxylating (CYP21) and mitochondrial 11β-hydroxylating (CYP11B1) enzymes appear to have developed at an early stage of evolution and are present in all vertebrates. Also, the 18-oxygenated corticosteroids (CYP11B2) retain their importance as mineralocorticoids in all vertebrates. For the 17α hydroxylation (CYP17) potential, the situation is different. Most mammals secrete cortisol as the predominant glucocorticoid. However, rodents and birds secrete predominantly 17-deoxycorticosteroids such as corticosterone.

In line with this, steroid determinations in adrenal venous blood of dogs (Hirose *et al*., 1977) have revealed cortisol/

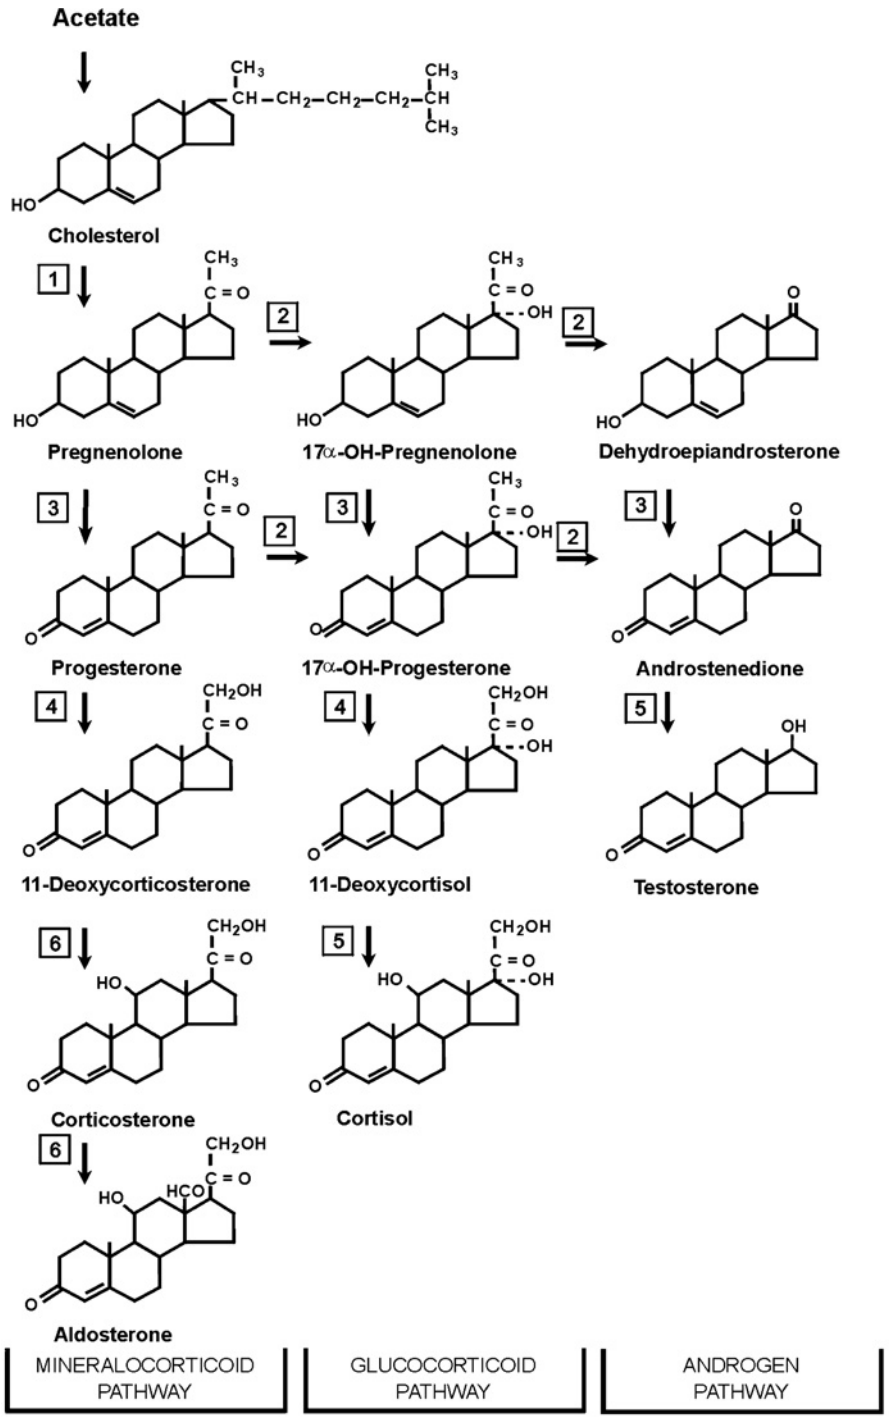

FIGURE 19-2 Biosynthetic pathways for adrenal steroid production. Numbers by arrows denote specific enzymes: 1 = CYP11A1; 2 = CYP17; 3 = 3β-HSD; 4 = CYP21; 5 = CYP11B1; 6 = CYP11B2.

corticosterone ratios to range from about 3 to 7. In another study, ratios of secretion rates were found ranging from 1.2 to 2.7 and corticosterone/aldosterone secretion ratios between 7 and 25 (Dor *et al*., 1973). With HPLC analysis in peripheral blood of ACTH-stimulated dogs, the cortisol/corticosterone ratios ranged from 2.4 to 9.7 with a mean of 5.0 (Lothrop and Oliver, 1984). In addition to glucocorticoids and aldosterone, the adrenal vein blood of dogs and pigs contains androstenedione, 11-hydroxyandrostenedione, androsterone, pregnenolone, progesterone, and 11-hydroxyprogesterone (Heap *et al*., 1966; Holzbauer and Newport, 1969), as well as very small amounts of estradiol and estrone (Dor *et al*., 1973).

In cats, the cortisol/corticosterone ratio has been estimated to range from 1.6 to 12.4, whereas in kittens the ratio is less than unity (Ilett and Lockett, 1969). In the

peripheral blood of horses, higher cortisol/corticosterone ratios (16.0:0.5 and 7.0:0.5) have been reported (James *et al*., 1970; Zolovick *et al*., 1966).

In birds, corticosterone, a glucocorticoid with minor mineralocorticoid properties, is by far the main adrenal secretory product. In the peripheral blood of adult birds, no cortisol could be demonstrated with radioimmunoassay (Walsh *et al*., 1985; Zenoble *et al*., 1985) or HPLC analysis (Lumeij *et al*., 1987). In chickens, the 17α-hydrolyase activity is present in embryonic life but decreases after hatching (Carsia *et al*., 1987; Nakamura *et al*., 1978).

C. Regulation of Secretion

The steroidogenic activity of the two inner zones of the adrenal cortex is predominantly controlled by the pituitary hormone ACTH. The production of aldosterone in the zona glomerulosa is adapted to the sodium and potassium status of the organism by a complex, multifactorial, and mainly extrapituitary control system. For details on the secretion of ACTH by the pituitary and its regulation, refer to Chapter 18. In puppies, the feedback control of the hypothalamic-pituitary-adrenal axis is already operative at the time of birth (Muelheims *et al*., 1969), although up to the age of 8 weeks basal plasma cortisol concentrations are lower than in mature dogs. There is indirect evidence that this is related to low binding to transport proteins (Randolph *et al*., 1995).

The action of ACTH on the adrenal gland is rapid; within minutes of its release, the concentration of steroids in the adrenal venous blood increases. The most likely mechanism by which ACTH stimulates steroidogenesis is via activation of membrane-bound adenylate cyclase. This increases the level of cyclic adenosine 3′,5′-monophosphate (cAMP), which activates adrenocortical protein kinases. This results in the phosphorylation of enzymes that enhance the rate of conversion of cholesterol to pregnenolone. Within the adrenal gland, a crosstalk exists with the adrenal medulla (Schinner and Bornstein, 2005). *In vitro* coculture of adrenocortical cells with chromaffin cells results in a 10-fold increase of steroidogenic activity (Haidan *et al*., 1998). Also, many intra-adrenal produced cytokines and growth factors play an important role in the regulation of steroidogenesis (Ehrhart-Bornstein *et al*., 1998). In adrenal tumors, a variety of ectopic and abnormal hormone receptors may stimulate adrenal corticoid release (Lacroix *et al*., 2001) (see also the section on adrenocortical diseases).

In the regulation of aldosterone secretion, the two most important effectors are the peptide hormone angiotensin II (ANG II) and the extracellular potassium concentrations. Regulation of aldosterone secretion by the potassium status is direct and rather simple (Fig. 19-3). The second loop, which adapts aldosterone secretion to the sodium balance, is much more complex. These two systems are regulated by negative feedback loops. In contrast, ACTH is a representative of other factors that may stimulate aldosterone release

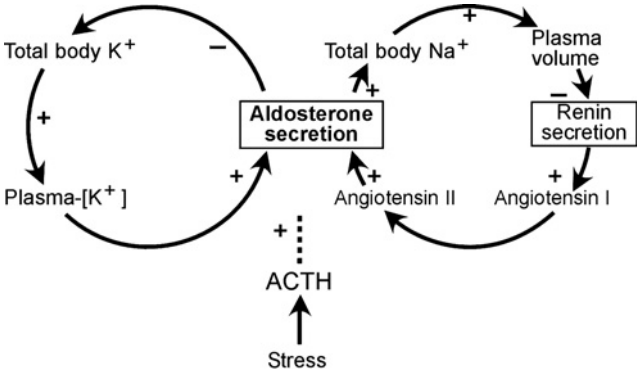

FIGURE 19-3 Physiological control of aldosterone secretion (Müller, 1986).

without a link to negative feedback (Williams, 2005). From all factors known to regulate aldosterone production *in vitro*, the stimulation is probably confined under physiological conditions to stimulation by ANG II, K^+, and ACTH and inhibition by the atrial natriuretic hormone (ANP) (Spat and Hunyady, 2004).

Apart from these factors, other intra-adrenal factors (Ehrhart-Bornstein *et al*., 1998) and environmental factors may regulate aldosterone production not only at the level of conversion of cholesterol to pregnenolone but also at the level of aldosterone synthase (CYP11B2) (Williams, 2005).

D. Transport

At normal concentrations, only about 10% of the total blood cortisol and corticosterone is in the free form (i.e., susceptible to ultrafiltration). At body temperature, 70% of the plasma cortisol is bound to a globulin called transcortin or corticosteroid-binding globulin (CBG). Transcortin has a high affinity for cortisol and corticosterone, but its binding capacity is limited. Another 20% of plasma cortisol is bound to albumin although its affinity for cortisol is much less than that of transcortin. In line with these percentages, in the dog the free fraction has been estimated to range from 5% to 12% (Kemppainen *et al*., 1991; Meyer and Rothuizen, 1993).

Transcortin is ubiquitous in mammals, but plasma concentrations vary considerably, resulting in species differences in total cortisol concentration. Most domestic animals have little corticosteroid-binding activity compared to humans (Rosner, 1969). As the free rather than the protein-bound steroid is biologically active, methods have been developed to measure free cortisol. By employing the combination of ultrafiltration and equilibrium dialysis, it was demonstrated that in dogs with portosystemic encephalopathy the associated hyperadrenocorticism is not only characterized by an increased total cortisol concentration in plasma but also by an increase in the free fraction of plasma cortisol (Meyer and Rothuizen, 1994). Between various pig breeds, a two-fold difference in plasma CBG binding capacity was found and related to increased drip loss in the Meishan breed (Geverink *et al*., 2006).

Unbound steroids readily diffuse into the salivary glands. Because of the close relationship between free cortisol in blood and saliva (Riad-Fahmy *et al*., 1982), techniques have been developed for the collection of saliva from cattle (Murphy and Connell, 1970), sheep (Fell *et al*., 1985), and dogs (Phillips *et al*., 1983). Saliva cortisol concentrations correlated significantly with plasma cortisol concentrations after an insulin-induced hypoglycemia and varied from 7% to 12% of total plasma concentrations, in line with other reports of free plasma cortisol concentrations in dogs (Beerda *et al*., 1996). In cow's milk, about 60% of the cortisol is present in the ultrafiltrate. Following parturition, the percentage of unbound cortisol (in colostrum) decreases to 40% (Shutt and Fell, 1985) owing to the higher concentrations of CBG-like protein.

The physiological significance of protein binding probably lies in a buffering effect, which prevents rapid variations of the plasma cortisol level. Transcortin restrains the active cortisol from reaching the target organ and also protects it from rapid inactivation by the liver and excretion through the kidneys.

Plasma aldosterone is predominantly bound to albumin, which has a low affinity. The relatively low degree of protein binding of plasma aldosterone partially explains the very low plasma concentration and the short biological half-life of this hormone.

E. Metabolic Breakdown and Excretion

Only unbound cortisol and its metabolites are filterable at the glomerulus. Most of this filtered cortisol is reabsorbed, whereby a tubular maximum is only achieved at very high filtered loads of free cortisol (Boonayathap and Marotta, 1974). Less than 20% of the filtered cortisol is excreted unchanged in the urine. Nevertheless, in most mammals the kidneys account for 50% to 80% of the excretion of the metabolized steroids. The remainder is lost via the gut. To render them suitable for renal elimination, the steroids are inactivated and made more water soluble through enzymatic modifications. The liver is the major organ responsible for steroid inactivation and conjugation to form water-soluble compounds, although in the dog—contrary to humans—the kidney and the gastrointestinal tract also contribute to the metabolic clearance of cortisol (McCormick *et al*., 1974). In the canine, kidney cortisol glucuronide is both secreted and reabsorbed, without a tubular maximum or a plasma threshold (Boonayathap and Marotta, 1974).

Cortisol is cleared from the plasma with a half-life of 60 min or less. For pigs, the metabolic clearance rate of cortisol was calculated to be about $11 h^{-1}.kg^{-1}$ (Hennesy *et al*., 1986). In dogs, about 60% of infused cortisol is eliminated within 24 h in the urine (Rijnberk *et al*., 1968a). The 11β-hydroxyl group of cortisol can be oxidized to the ketone, forming cortisone (Fig. 19-4). The reaction is reversible, and in general the equilibrium is shifted to favor the 11β-hydroxyl

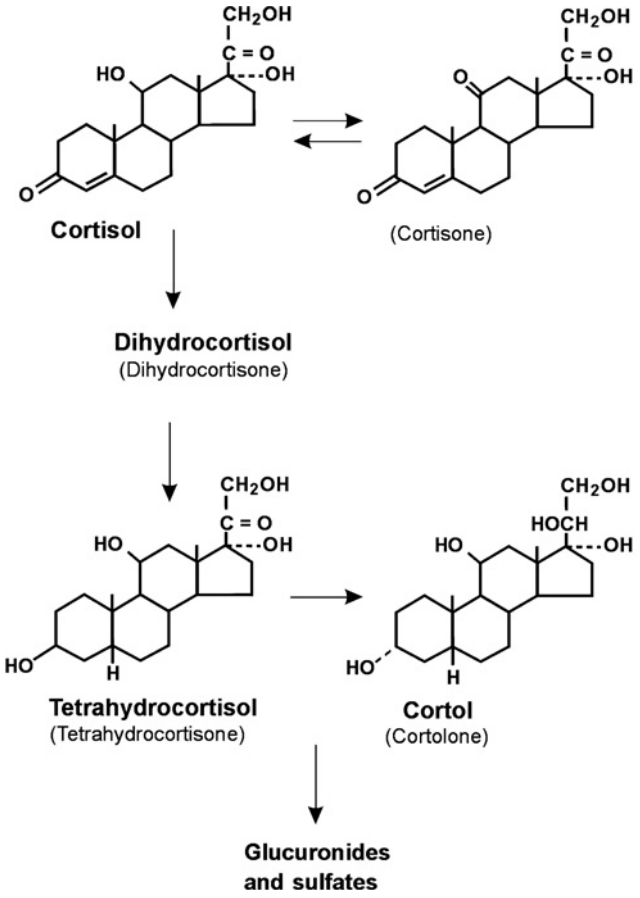

FIGURE 19-4 Metabolism of cortisol in the dog (simplified).

group. However, because the adrenal cortex produces much more cortisol than cortisone (if any), there is substantial cortisol-to-cortisone conversion. These two steroids have similar subsequent metabolic fates.

Apart from this 11β-hydroxylation, cortisol metabolism in the dog involves the following: (1) reduction of ring A to tetrahydro derivatives, (2) reduction of the 20-keto group to a hydroxyl, and (3) conjugation with glucuronic acid to form glucuronides (Gold, 1961). In addition, unconjugated 20-hydroxycortisol/cortisone has been found in canine urine.

In total glucuronide fraction of urinary corticoids in dogs, at least steroids reduced at C-20 represent 60%. This is of prime importance when it comes to assessing adrenocortical function by measuring urinary cortisol metabolites. Measurements directed at steroids containing a 17α,21-dihydroxy, 20-keto arrangement (i.e., the Porter-Silber reaction) will detect only a small part of the cortisol metabolites and therefore have limited value (Siegel, 1965). Instead, preferably, measurements are preformed involving reduction of the urine metabolites at C-20, followed by oxidation to 17-ketosteroids, which are then quantitated. Further details on this measurement of total 17-hydroxycorticosteroids are given in Section IV.B.3.

Aldosterone is converted not only to tetrahydroaldosterone-3-glucuronide but also to aldosterone-18-glucuronide. Most of aldosterone metabolism takes place in liver and

TABLE 19-1 Relative Potencies of Corticosteroids

Corticosteroid	Mineralocorticoid Activity	Glucocorticoid Activity
Cortisol	1	1
Cortisone	0.7	0.7
Corticosterone	0.2	2
11-Deoxycorticosterone	0.0	20
Aldosterone	0.1	400
9α-Fluorocortisone	10	400
Prednisone	4	0.7
Prednisolone	4	0.7
Dexamethasone	30	2
Triamcinolone	3	0
6α-Methylprednisolone	5	0.5

kidney, but the intestine and spleen might also contribute to a minor degree (Balikian, 1971).

In domestic animals, the catabolism of androgens has not been studied in any detail. For the dog, it is known that little of the secreted androgens can be measured as 17-ketosteroids in urine (Rijnberk *et al*., 1968b; Siegel, 1967). Probably most of the excretion occurs via the bile.

In the cat, glucocorticoid excretion is also largely biliary (Rivas and Borrell, 1971; Taylor, 1971). Feline liver function has several specific features, including a relatively low glucuronyl-transferase activity. Hence, formation of glucuronide conjugates is low, and the conjugates are mainly sulphates, which are mostly excreted via the biliary route. Despite this low urinary excretion of metabolites and conjugates, it was shown that renal excretion of free cortisol is sufficient for diagnostic purposes (Goossens *et al*., 1995) (see also Section IV.B).

Apart from the use of urinary excretion to examine the glucocorticoid status, fecal glucocorticoid metabolite measures are increasingly being used, especially for zoo and wildlife animals. Interpretation of fecal glucocorticoids may be confounded by a large variety of factors that should be taken into account (Millspaugh and Washburn, 2004).

F. Steroid Receptors and Actions

1. *Glucocorticoids*

Of the naturally occurring glucocorticoids (cortisol, cortisone, and corticosterone), cortisol is the most potent. Several of the synthetic analogues of cortisol are more potent than cortisol itself (Table 19-1). Figure 19-5 illustrates the structural features that determine glucocorticoid potency.

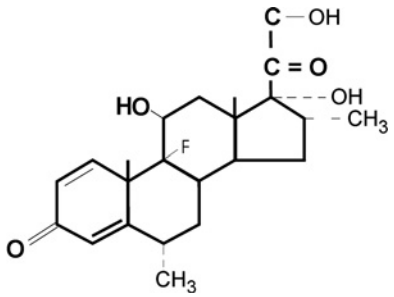

FIGURE 19-5 Structure-function relationships of corticosteroids. The bold lines and letters indicate the structure common to all glucocorticoids. Substituents that may enhance glucocorticoid activity are presented by light lines and letters.

In their target organ cells, glucocorticoids act in the same manner as other steroid hormones: diffusion through the cell membrane; binding to the cytoplasmic, glucocorticoid (GR), and mineralocorticoid (MR) receptors; translocation of the hormone receptor complex to the nucleus; and subsequent stimulation of the synthesis of specific RNAs leading to synthesis of specific enzymes. The latter include key enzymes in gluconeogenesis such as fructose-1,6-disphosphatase, glucose-6-phosphatase, and pyruvate carboxylase. In the dog, corticosteroid excess also results in induction of an isoenzyme of alkaline phosphatase. This corticosteroid-induced form of alkaline phosphatase has not yet been found in other species. The marked stability at 65°C allows easy quantitation in plasma as a diagnostic screening tool for cases of suspected hyperadrenocorticism (Teske *et al*., 1986, 1989).

The traditional view is that the ligand activated GR binds as a homodimer to response elements in promoter

regions of genes. However, apart from this direct interaction, the GR may also bind to other transcription factors and thus regulate gene expression of genes devoid of a classical glucocorticoid responsive element (GRE). Next osmolytes, small molecules that promote protein folding during metabolic extremes, may also contribute to protein:protein interactions at the genomic level (Kumar and Thompson, 2005). A splicing variant of the classical GRα is called GRβ and may act as a dominant-negative inhibitor of GRα (Charmandari *et al*., 2005). Glucocorticoids may also act in a way that does not directly and initially influence gene expression, referred to as "nongenomic." These pathways involve the production of second messengers and activation of signal transduction pathways by either the classical GR or by a membrane glucocorticoid receptor. Apart from "nongenomic" effects, glucocorticoids may also predominantly inhibit the synthesis of a variety of proteins by decreasing their mRNA stability (Dallman, 2005; Stellato, 2004).

The overall effect of glucocorticoids on metabolism is to supply glucose to the organism by the transformation of proteins. This occurs via the above-mentioned induction of gluconeogenic enzymes in the liver. Thus, glucocorticoids divert metabolism from a phase of growth and storage toward increased physical activity and energy consumption, whereas chronic excess leads to catabolic effects such as muscle wasting, skin atrophy, and osteoporosis. The tendency to hyperglycemia is opposed by increased secretion of insulin, which in turn tends to enhance fat synthesis. This along with the increased food intake owing to central appetite stimulation (Debons *et al*., 1986) explains the (centripetal) fat deposition, manifested by abdominal enlargement.

In situations of glucocorticoid deficiency, water excretion is impaired, whereas glucocorticoid excess may result in polyuria, being most pronounced in the dog. This is in part due to antagonism of cortisol to the action of vasopressin. In addition, glucocorticoid excess causes loss of the sensitivity of the osmoregulation of vasopressin release (Biewenga *et al*., 1991). Even physiological increases in cortisol may inhibit basal vasopressin release in dogs (Papanek and Raff, 1994).

Glucocorticoids have long been known to have effects on blood cells, including a reduction in the numbers of eosinophils and lymphocytes and an increase in the number of neutrophils and hence in the total number of leukocytes. Glucocorticoid deficiency leads to normochromic, normocytic anemia.

As far as effects on other endocrine glands are concerned, it is shown that canine hyperadrenocorticism results in reversible suppression of growth hormone secretion (Peterson and Altszuler, 1981). The frequently observed lowering of circulating thyroxine concentrations has been ascribed to changes in the thyroid hormone binding capacity of the plasma and to inhibition of lysosomal hydrolysis of colloid in the thyroid follicular cell (Kemppainen *et al*., 1983; Woltz *et al*., 1983). Glucocorticoids have multiple effects on peripheral transfer, distribution, and metabolism (Kaptein *et al*., 1992), but thyroid function does not seem to be affected (Rijnberk, 1996). The glucocorticoid prednisone was found to inhibit LH secretion in male dogs, leading to reduced testosterone concentrations (Kemppainen *et al*., 1983).

2. *Adrenal Androgens*

In health, adrenocortical production of androgens is trivial in comparison with the production of these hormones by the gonads. However, a pathological excess of adrenal androgens might induce virilization (i.e., the development of masculine secondary sex characteristics), which would be most noticeable in the female or immature male. So far, no virilization as a consequence of enzyme deficiency has been reported in domestic animals, but in equine hyperadrenocorticism, hirsutism is a common feature (Pauli *et al*., 1974; Van der Kolk *et al*., 1993).

3. *Mineralocorticoids*

The widespread MR has equal affinity for aldosterone and the glucocorticoids cortisol and corticosterone, whereas the latter two hormones circulate at much higher concentrations than aldosterone. However, in the classical aldosterone targets (kidney, colon, and salivary gland), the enzyme 11β-hydroxysteroid dehydrogenase (11βHSD) converts cortisol and corticosterone (but not aldosterone!) to the 11-keto analogues. These analogues cannot bind to MR, thereby enabling aldosterone to occupy this receptor (Funder, 2005). Thus, not the receptor but a prereceptor modification provides the tissue specificity.

The synthetic steroid 9α-fluorocortisone (Table 19-1) binds tightly to mineralocorticoid receptors and is used for mineralocorticoid replacement therapy because it is more stable than aldosterone after oral administration. Mineralocorticoid antagonists such as spironolactone bind to these receptors and in this way block aldosterone action.

Aldosterone controls the volume and the cationic composition of the extracellular fluid by regulating sodium and potassium balance. Its main action is on the tubular apparatus of the kidneys, but aldosterone receptors are also found in the gut, the salivary glands, and the sweat glands. In the kidney, the effect of aldosterone on the distal tubule consists almost entirely of an exchange of sodium with potassium and hydrogen ions. Aldosterone also promotes the excretion of magnesium and ammonium ions.

G. Physiological Variation, Stress, and the Immune System

In the absence of extraordinary stress, the plasma cortisol concentration of healthy animals varies within certain limits, although adrenocortical secretion does not occur evenly throughout the day but rather in bursts. In humans, most of the secretory bursts occur between midnight and early

morning, leading to a diurnal rhythm of circulating cortisol levels. The temporal coincidence between secretory bursts and plasma ACTH concentrations indicates neuroendocrine control.

In domestic animals and certainly in the dog, initially there has been some controversy as to the occurrence of circadian variation in cortisol concentrations. Later definite evidence for episodic but not circadian fluctuations in plasma cortisol concentrations in dogs was presented (Kemppainen and Sartin, 1984a). In the horse (Dybdal *et al*., 1994) and the pig (Benson *et al*., 1986; Bottoms *et al*., 1972; Janssens *et al*., 1995b; Larsson *et al*., 1979) as well as in sheep (Fulkerson and Tang, 1979), bulls (Thun *et al*., 1981), pigeons (Joseph and Meier, 1973; Westerhof *et al*., 1994), and chickens (Lauber *et al*., 1987), the occurrence of circadian variations is generally acknowledged. Also in the cat, there have been reports on the occurrence of an (opposite) diurnal rhythm. However, in later reports this was not confirmed (Johnston and Mather, 1979; Leyva *et al*., 1984). As in the dog, the secretion is episodic without evidence for a diurnal rhythm (Peterson and Randolph, 1989). Apart from relatively short-term changes such as episodic secretion and diurnal variation, plasma cortisol concentration may change with age and during the estrus cycle, during pregnancy, and around the time of parturition. For example, basal cortisol concentrations in puppies 8 weeks of age or younger are lower than in mature dogs, most probably because of reduced binding to plasma proteins rather than to altered secretion patterns (Randolph *et al*., 1995). In gilts a discrete cortisol peak occurs during the early follicular phase of the sexual cycle, coinciding with the decline in plasma progesterone levels (i.e., at 4 days before the plasma LH surge) (Janssens *et al*., 1995c). Plasma cortisol concentrations of pregnant cows decrease significantly during the fourth month of pregnancy. Thereafter they remain fairly constant until the fifth and sixth day before parturition, when a sharp rise is seen, and also at around 24 h before parturition plasma corticoids increase again (Eissa and El-Belely, 1990).

A highly significant increase in basal plasma cortisol concentrations occurs with aging in dogs (Goy-Thollot *et al*., 2006) with no differences in ACTH-stimulated plasma cortisol concentrations. This confirms earlier studies (Rothuizen *et al*., 1993) where the increased basal activity of the hypothalamo-pituitary-adrenal axis is attributed to a decrease in limbic type-I MR concentrations, whereby no differences were found for the type II GR in canine brain structures. The increase in pituitary type II GR with aging explains the intact feedback in the aging dog (Rothuizen *et al*., 1993). The ACTH-stimulated increase in plasma aldosterone concentrations was found to be significantly reduced with aging (Goy-Thollot *et al*., 2006).

Independent of these physiological variations, it is clear that stress may activate the pituitary-adrenocortical system. Factors such as housing (Carlstead *et al*., 1993; Cockram *et al*., 1994; Koelkebeck and Cain, 1984), lactation (Gwazdauskas *et al*., 1986), exercise (Dybdal *et al*., 1980; Foss *et al*., 1971; Rossdale *et al*., 1982; Sloet van Oldruitenborgh-Oosterbaan *et al*., 2006), surgery (Robertson *et al*., 1994), anaesthesia, heat (Gould and Siegel, 1985), emotional strain (Bobek *et al*., 1986; James *et al*., 1970; Kirkpatrick *et al*., 1977), food deprivation (Messer *et al*., 1995), and anticipation of feeding (Murayama *et al*., 1986) all lead to increased corticosteroid secretion. In dogs, a visit to a veterinary practice, orthopedic examination, and hospitalization increased the urinary corticoid:creatinine ratio, which is a measure for adrenocortical function (Van Vonderen *et al*., 1998). In the horse, during exercise increased plasma renin activity results in a considerable rise in aldosterone secretion (Guthrie *et al*., 1980, 1982). From the lack of any increase in plasma corticosterone in homing pigeons during flight, it was concluded that the animals were not under serious stress (Viswanathan *et al*., 1987).

With chronic stress, such as during prolonged tethered housing of pigs, an increased responsiveness of the adrenal cortex to ACTH is induced, whereas the sensitivity of the pituitary to stimulation with corticotrophin releasing hormone (CRH) or vasopressin remains unaltered, and the challenge (nose sling)-induced ACTH response is lower than in loosely housed pigs. This indicates that during chronic stress, mitigating mechanisms become operational, most probably mediated by endogenous opioids (Janssens *et al*., 1995a).

According to Selye's theory of general adaptation, corticosteroids are needed for the (metabolic and circulatory) defense reaction. Administration of cortisol to improve nonspecific resistance is indicated in established pituitary or adrenal insufficiency. From an immunological point of view, stress suppresses defense reactions. Stress-induced glucocorticoid secretion prevents the overshooting of the animal's reactions to stress. The glucocorticoids modulate the mediators of the immune system such as the different lymphokines and mediators of the inflammatory reactions: prostaglandins, leukotrienes, kinins, serotonin, and histamine (Munck *et al*., 1984).

It is now well established that the interaction of the neuroendocrine system and the immune system is not a one-way but a bidirectional communication. Tissue injury or inflammation elicits production of immunoregulatory cytokines (lymphokines and monokines) by macrophages and monocytes. These cytokines also activate the pituitary-adrenal axis and increase glucocorticoid concentrations, whereas the production and action of these immune mediators are inhibited by glucocorticoids. Thus, there is strong evidence for the existence of a feedback circuit, in which immunoregulatory cytokines act as afferent and ACTH and glucocorticoids as efferent hormonal signals (Besedovsky *et al*., 1986; Woloski *et al*., 1985). The regulatory actions of the cytokines are exerted at the level of the hypothalamus, where CRH is the major mediator of the response (Berkenbosch *et al*., 1987), although cytokines also exert

an influence at the level of the pituitary and the adrenals (Gaillard, 1994).

III. ADRENOCORTICAL DISEASES

As this chapter is not meant to cope with clinical and pathological details, discussion of adrenocortical diseases is confined to definitions, short statements on occurrence in species, and referral to key references. In textbooks on endocrine diseases of companion animals (Drazner, 1994; Feldman and Nelson, 2004; Rijnberk, 1996), the adrenocortical diseases of the dog and the cat are described in detail.

A. Hypoadrenocorticism

Adrenocortical hypofunction includes all conditions in which the secretion of adrenal steroid hormones falls below the requirements of the animal. It may be divided into two categories:

1. Primary hypoadrenocorticism or Addison's disease is the result of deficiency of both glucocorticoid and mineralocorticoid secretion from the adrenal cortices (primary adrenocortical failure). "Idiopathic" or immune-mediated atrophy (Schaer *et al*., 1986) of all zones is the most frequently observed histopathological lesion, although the lymphocytic adrenalitis may be confined to the zona fasciculata and zona reticularis (Kooistra *et al*., 1995). It is well known in the dog and rare in the cat (Peterson and Randolph, 1989).

2. Secondary hypoadrenocorticism is the result of pituitary ACTH deficiency, causing decreased glucocorticoid secretion. Because of the almost unaltered aldosterone secretion, it will usually remain unnoticed. It is observed occasionally in dogs with pituitary insufficiency resulting from pituitary cystic lesions leading to an empty sella or as a result of a compressive nonfunctioning (endocrine inactive) pituitary macroadenoma.

Animals receiving long-term corticosteroid treatment, despite physical and biochemical hyperadrenocorticoid changes, develop secondary adrenocortical insufficiency because of prolonged hypothalamo-pituitary suppression. Atrophy of the two inner zones of the adrenal cortex results from the loss of endogenous ACTH stimulation. This is observed in the species in which corticosteroid therapy is common practice such as the dog (Greco and Behrend, 1995; Rijnberk, 1996) and the horse (Hoffsis and Murdock, 1970; Toutain and Brandon, 1983). It has also been observed in dogs and cats treated with progestagens, owing to the glucocorticoid activity that is intrinsic to these drugs (Chastain *et al*., 1981; Mansfield *et al*., 1986; Middleton *et al*., 1987; Selman *et al*., 1994).

B. Hyperadrenocorticism

In principle, the adrenal cortex of animals might, as in humans, give rise to three distinct clinical syndromes of hyperfunction: mineralocorticoid excess or hyperaldosteronism (Conn's syndrome), glucocorticoid excess or hypercortisolism (Cushing's syndrome), and androgen excess (adrenogenital syndrome).

Hypercortisolism is common in the dog though rare in the cat and the horse. In about 15% of hyperadrenocorticoid dogs, the disease is due to a primary adrenocortical tumor (ACTH independent). The excessive secretion of cortisol by these tumors may either be autonomous or associated with aberrant expression of ectopic or overexpression of eutopic adrenocortical receptors (Lacroix *et al*., 2001). For example, the expression of ectopic receptors for gastric inhibitory polypeptide may result in "food-dependent hypercortisolism." In the other 85% of cases, the (ACTH-dependent) hypercortisolism is associated with a pituitary lesion, producing excess ACTH. The pituitary corticotroph adenomas may reside in either the anterior lobe or the intermediate lobe (Kemppainen and Peterson, 1994; Peterson *et al*., 1982). In rare cases, Cushing's syndrome may also be due to ectopic secretion of ACTH by a neuroendocrine tumor outside the pituitary gland (Galac *et al*., 2005). In cats, hypercortisolism (Cushing's syndrome) is usually concurrent with diabetes mellitus and may be either primary adrenocortical or pituitary dependent (Meij *et al*., 2001, 2004; Meijer *et al*., 1978b; Peterson and Randolph, 1989).

Primary hyperaldosteronism in cats may be due to an adrenocortical tumor (Ash *et al*., 2005; Flood *et al*., 1999; Mackay *et al*., 1999; Moore *et al*., 2000; Rijnberk *et al*., 2001) or to bilateral hyperplasia of zona glomerulosa tissue (Javadi *et al*., 2005). Prominent clinical features in cats with hyperaldosteronism are hypokalemia, episodic weakness, cervical ventroflexion, arterial hypertension, and vision loss resulting from retinal detachment. The nontumorous form of primary hyperaldosteronism in cats is associated with progressive renal disease (Javadi *et al*., 2005).

In the horse, hypercortisolism (Cushing's syndrome) originates almost invariably in the intermediate lobe of the pituitary (Orth *et al*., 1982). In domestic ferrets, hyperadrenocorticism is quite common and it is primarily associated with adrenocortical tumor or nodular adrenocortical hyperplasia (Rosenthal *et al*., 1993). Domestic ferrets with hyperadrenocorticism have no detectable abnormalities in plasma concentrations of ACTH or α-MSH (Schoemaker *et al*., 2002a) and increased urinary corticoid/creatinine ratios resistant to dexamethasone suppression (Schoemaker *et al*., 2004), both indicating ACTH-independent hyperadrenocorticism. Positive staining was found with the LH receptor antibody in hyperplastic or neoplastic adrenal glands of hyperadrenocorticoid ferrets supporting the hypothesis that gonadotropic hormones play a role in the pathogenesis of hyperadrenocorticism in ferrets (Schoemaker *et al*., 2002b).

IV. ASSESSMENT OF ADRENOCORTICAL FUNCTION

A. Routine Laboratory Diagnostics

In both hypoadrenocorticism and hyperadrenocorticism, there are a number of abnormal laboratory findings that are more common than in other diseases. Many of these abnormalities can be derived from the above-described action of glucocorticoids and mineralocorticoids (Section II.F). The essentials are summarized here.

In primary hypoadrenocorticism, the decreased aldosterone production results in hyponatremia and hyperkalemia. The associated hypovolemia leads to prerenal uremia. In hyperadrenocorticism, the classic hematological abnormality is eosinopenia, which may be associated with lymphopenia and occasionally with leukocytosis and erythrocytosis. A common biochemical abnormality is the elevated plasma concentration of alkaline phosphatase (Eckersall and Nash, 1983) that may occur in conjunction with mild elevation of alanine aminotransferase (ALT). In addition, hyperglycemia, hyperlipidemia, and low thyroxine concentrations may be observed. Urine-specific gravity is usually low, and in 5% to 10% of cases glucosuria is found.

Of these abnormalities, the elevated alkaline phosphatase (AP) concentration is the most common laboratory abnormality in dogs with corticosteroid excess (either exogenous or endogenous). This increase is due to the induction of a specific isoenzyme, which has greater heat stability at 65°C than other AP-isoenzymes (Teske *et al*., 1986) and is therefore easily measured by a routine laboratory procedure. An abnormally elevated AP-65°C value may point to hyperadrenocorticism, but it is unsuitable as a diagnostic test because of its low specificity (Teske *et al*., 1989). The low thyroxine (T4) concentrations in plasma, which may be observed in hyperadrenocorticism, seem to be a consequence of altered transport, distribution, and metabolism of T_4 rather than the result of hyposecretion (Rijnberk, 1996).

There may be other conditions causing these abnormalities, however, and some cases do not present with typical routine laboratory characteristics. Therefore, a detailed understanding of the specific laboratory tests commonly used to investigate adrenocortical function is essential. In addition, the spontaneous forms of hyperadrenocorticism may arise from pituitary ACTH overproduction or from autonomously hypersecreting adrenocortical tumors. Each of these requires a different mode of treatment, and therefore insight into the tests used in the differential diagnosis is of prime importance.

B. Tests of Basal Adrenocortical Function

The availability of highly specific radioimmunoassays has greatly enhanced and simplified assessment of adrenocortical function. Some of the older (chemical) methods, which are now seldom used, are mentioned briefly. Methods in common use are described in more detail, which applies especially to the dynamic tests, part of which is used in the differential diagnosis (Section IV.C).

1. *Cortisol Production Rate*

In the radionuclide dilution method, the rate of cortisol production is determined through administration of radiolabeled cortisol and isolation of cortisol metabolites from urine that is collected over at least 24h. The specific activities of labeled cortisol and tetrahydrocortisol (THF) or tetrahydrocortisone (THE) are compared. Some preliminary work (Rijnberk *et al*., 1968b) indicated that this test worked for the dog and might potentially be very useful. However, the laborious character of the procedure rules out general availability.

2. *Plasma Corticoids*

Plasma corticoid concentrations are subject to considerable variation owing to the pulsatile nature of the secretion, physiological variation (see Section II.G), and alterations in transport proteins (Meyer and Rothuizen, 1994). Therefore, single determinations are regarded of little diagnostic value in assessing hypo- or hyperadrenocorticism. Nevertheless, in a considerable percentage of cases, resting values outside the reference ranges may be found. It has been demonstrated recently that calculation of the ratio of plasma cortisol:ACTH concentrations in hypoadrenocorticism did not show an overlap with values of healthy control dogs (Javadi *et al*., 2006). There are few data on sex and breed differences, and they are not dealt with in Table 19-2. Nevertheless there is evidence that they should be taken into account (Frank *et al*., 2003a). In dogs, circulating cortisol concentrations do not differ between males and females, but in small dogs higher values are found than in large breed dogs (Reimers *et al*., 1990), and neutered males may have lower plasma cortisol concentrations in comparison to intact males (Frank *et al*., 2003b). Also in pigs, breed-specific basal plasma cortisol concentrations exist (Sutherland *et al*., 2006).

3. *Urinary Corticoids*

With measurements of urinary corticoids or their metabolites, an integrated reflection of corticoid production over a period of time is obtained, thereby adjusting for the fluctuations in the plasma levels. Indeed, in dogs measurements of 17-hydroxycorticosteroids in 24-hour urine samples were found to have a high discriminatory power (Table 19-3; Rijnberk *et al*., 1968a). However, the method has been abandoned because of the complicated and time-consuming chemical analysis, in combination with the difficulty of accurate collection of 24-hour urine samples.

TABLE 19-2 Basal Corticosteroid Concentrations in Healthy Animals

Hormone (Unit)	Species (n)	Fluid	Sampling Time	Mean ± SD (Range)	Reference
Cortisol (nmol/l)	Dog (14)	Plasma	After overnight fast	46.0 ± 1.3	(Beerda *et al.*, 1996)
		Saliva	After overnight fast	4.7 ± 0.4	(Beerda *et al.*, 1996)
	Cat (130)	Plasma	After overnight fast	79 ± 79	(Javadi *et al.*, 2004)
	Horse (7)	Plasma	06.00h	251 ± 115	(van der Kolk *et al.*, 2001)
		Saliva	06.00h	3.2 ± 1.9	(van der Kolk *et al.*, 2001)
		Plasma	18.00h	142.0 ± 52.9	(van der Kolk *et al.*, 2001)
		Saliva	18.00h	2.1 ± 1.4	(van der Kolk *et al.*, 2001)
	Cattle (39)	Plasma	08.00–14.00	17.1 ± 1.1	(Beerda *et al.*, 2004)
	Cattle	Milk	Morning	1.24 ± 0.13	(Gygax *et al.*, 2006)
	Pig (6)	Plasma	—	(27–355)	(Cook *et al.*, 1997)
		Saliva	—	(3.1–21.3)	(Cook *et al.*, 1997)
	Sheep (4)	Plasma	—	19.0 ± 4.9	(Turner *et al.*, 2002)
	Ferret (29)	Plasma	—	(3–27)	(Schoemaker *et al.*, 2003)
Aldosterone (pmol/l)	Dog (12)	Plasma	After overnight fast	118 ± 14	(Javadi *et al.*, 2003)
	Cat (130)	Plasma	After overnight fast	267 ± 135	(Javadi *et al.*, 2004)
	Horse (6)	Plasma	—	63.0 ± 12.8	(McKeever and Malinowski, 1999)
PRA (fmol/l/s)	Dog (12)	Plasma	After overnight fast	201 ± 25	(Javadi *et al.*, 2003)
	Cat (130)	Plasma	After overnight fast	240 ± 165	(Javadi *et al.*, 2004)

TABLE 19-3 Molar Urinary Corticoid Creatinine Ratios

Species (n)	Season	Range (Mean ± SD)	Reference
Dog (28)		$1.2–6.9 \times 10^{-6}$	(Stolp *et al.*, 1983)
Dog (12)		$(9 \pm 4 \times 10^{-6})$	(Jones *et al.*, 1990)
Dog (20)		$0.5–17.7 \times 10^{-6}$	(Feldman and Mack, 1992)
Dog (31)		$0.1–31.2 \times 10^{-6}$	(Smiley and Peterson, 1993)
Cat (42)		$2–36 \times 10^{-6}$	(Goossens *et al.*, 1995)
Ferret—intact	Breeding	$(6.0 \pm 0.5 \times 10^{-6})$	(Schoemaker *et al.*, 2004)
Ferret—intact	Nonbreeding	$(1.5 \pm 0.2 \times 10^{-6})$	(Schoemaker *et al.*, 2004)
Ferret—castrated	Nonbreeding	$(1.3 \pm 0.1 \times 10^{-6})$	(Schoemaker *et al.*, 2004)

Meanwhile, for the dog, Stolp *et al*. (1983) have introduced another measurement reflecting cortisol secretion over a period of time. In this approach, the 24-hour urine collection has been replaced by morning samples. The urinary corticoids (largely cortisol) are measured by radioimmunoassay and related to the creatinine concentration. In an assessment (Rijnberk *et al*., 1988), the corticoid/creatinine ratios were found to have a higher diagnostic accuracy in the diagnosis of hyperadrenocorticism than the commonly used dexamethasone screening test (see Section IV.C.3).

The method has also been introduced for diagnostic use in the cat (de Lange *et al*., 2004; Goossens *et al*., 1995) and the ferret (Gould *et al*., 1995; Schoemaker *et al*., 2004). Also for these species the determination of the urinary corticoid/creatinine ratio appears to be valuable for the diagnosis of hyperadrenocorticism.

4. *Salivary Cortisol*

In saliva, the "free" (biologically active) fraction rather than the "total" cortisol is measured. So far in animals, salivary collection devices have been used primarily for research purposes. In the past, a disadvantage has been the anesthesia involved, although it does not inhibit salivary flow (Phillips *et al*., 1983). In recent years there has been renewed interest in the approach, especially now that a technique has been introduced for saliva collection in unrestrained animals. Cortisol measurements in saliva may serve as a noninvasive indicator of stress in animals. By allowing the animals to chew on large wads of cotton for up to 30sec, adequate saliva samples can be obtained from dogs (Vincent and Michell, 1992). The same method has been used successfully in pigs (Parrott and Misson, 1989) and sheep (Cooper *et al*.,

TABLE 19-4 Plasma Corticoids (nmol/l) Following ACTH Stimulation

Species	ACTH Dose and Route	Sampling Time	Hormone	Range (Mean ± SEM)	Reference
Dog	250μg I.V.	90min	Cortisol	120–620	(Meijer *et al.*, 1978c)
Dog	5μg/kg I.V.	60min	Cortisol Corticosterone	220–560 18–102	(Behrend *et al.*, 2005) (Behrend *et al.*, 2005)
Cat	125μg I.V.	60min	Cortisol	(274 ± 19)	(Peterson and Kemppainen, 1993)
Horse	250μg I.V.	120min	Cortisol	308–602	(van der Kolk *et al.*, 2001)
Cattle	2IU/kg $BW^{0.75}$	60min	Cortisol	(145 ± 27)	(Beerda *et al.*, 2004)

1989). It does not seem to be advisable to increase saliva flow by pilocarpine (Blackshaw and Blackshaw, 1989). It has also been reported that in calves (Fell and Shutt, 1986) and goats (Greenwood and Shutt, 1992), saliva can be aspirated from the side of the mouth with minimum restraint.

5. *Cortisol in Milk*

Monitoring adrenocortical activity by measurements in milk may be of value in searching for stressors in the livestock industry (Gygax *et al.*, 2006; Stephens, 1980). In a comparison of different milking systems, no differences in milk cortisol concentrations were found (Gygax *et al.*, 2006). The low concentrations indicate that in milk also the biologically active free fraction instead of the total cortisol fraction is measured.

6. *Plasma* ACTH

Determinations of resting plasma ACTH concentrations are not useful in the diagnosis of hyperadrenocorticism because of the overlapping values for normal dogs and dogs with hyperadrenocorticism. Its value lies mainly in the differential diagnosis of hyperadrenocorticism (discussed later). In animals with primary adrenocortical failure, plasma ACTH concentrations are usually extremely high. However, in most cases such a determination is primarily of academic interest as the diagnosis can be made with the more practical ACTH stimulation test (see Section IV.C.1). Plasma ACTH measurements are useful when in doubt about a primary or secondary adrenocortical insufficiency (Kooistra *et al.*, 1995).

C. Dynamic Tests

Apart from the above-described measurements of reflections of basal adrenocortical secretions, various maneuvers have been introduced to test the physiology of the hypothalamo-pituitary-adrenocortical axis. As in other areas of endocrinology, stimulation tests are used when hypofunction is suspected, and suppression tests are used when hyperfunction is suspected.

1. *Tests of Adrenocortical Reserve*

The critical feature of the test is that a substantial increase in plasma (or urinary) corticoids must occur in response to ACTH if one is to prove the existence of adrenal reserve (Table 19-4). One method is described in detail in Section IV.F.

In veterinary medicine, ACTH stimulation has also been used to confirm adrenocortical hyperfunction. This is based on the assumption that hyperplastic adrenal cortices have abnormally large cortisol reserves. Indeed, hyperresponsiveness to ACTH or lysine-vasopressin (Meijer *et al.*, 1978a) stimulation is found in pituitary-dependent hyperadrenocorticism, but there is considerable overlap with normal dogs. Over the years, several modifications/combinations of the ACTH stimulation test (Eiler and Oliver, 1980; Eiler *et al.*, 1984; Feldman, 1986) for the diagnosis of hyperadrenocorticism have been used, but it still appears to be a dynamic test with less diagnostic accuracy than the low-dose dexamethasone suppression test (LDDST) (Behrend *et al.*, 2005; Feldman, 1986; Peterson, 1986). This seems to hold true for the horse as well (Dybdal *et al.*, 1994), although the ACTH stimulation test is recommended for the diagnosis of equine hyperadrenocorticism (Van der Kolk *et al.*, 1993). The value of the ACTH stimulation test lies in the diagnosis of hypoadrenocorticism (see Section IV.F). When used for the diagnosis of hyperadrenocorticism, the modification of a combination with a dexamethasone suppression test seems the least desirable, as doses of $\geq$0.1 mg of dexamethasone/kg can alter the results of the ACTH stimulation test for at least 3 days (Kemppainen *et al.*, 1989). Measurement of plasma corticosterone or 17α-hydroxyprogesterone after ACTH stimulation is of little additive value as the changes measured are proportionate with changes in cortisol and may be high in dogs with nonadrenal neoplasia as well (Behrend *et al.*, 2005).

2. *Tests of Pituitary* (ACTH) *Reserve*

In animals with adrenals responsive to ACTH, administration of the 11β-hydroxylase inhibitor metyrapone decreases cortisol secretion and consequently increases ACTH secretion. As a result, cortisol precursor synthesis increases, which can

TABLE 19-5 Upper Reference Values for Plasma Cortisol Concentrations (nmol/l) after Low-Dose Dexamethasone Suppression Test

Species	Dose and Route	Sampling Time	Cortisol	Reference
Dog	10μg/kg I.V.	8h	<40	(Meijer *et al.*, 1979)
Dog	15μg/kg im	2, 4, 6, 8h	<28	(Peterson, 1986)
Cat	10μg/kg I.V.	8h	<36	(Smith and Feldman, 1987)
Cat	15μg/kg im	8h	<14	(Peterson and Graves, 1988)
Horse	40μg/kg I.V.	15h	<30	(Dybdal *et al.*, 1994)

be measured as urinary 17-hydroxycorticosteroids. Although effective in the dog (Siegel, 1968), the cumbersome procedure has prohibited wider use in veterinary medicine. At present, pituitary ACTH reserve is tested by use of physiological suprapituitary stimuli (i.e., vasopressin or CRH) (see Chapter 18). Such tests are mainly useful in the differential diagnosis, whereby it should be noted that vasopressin is the least useful for this purpose, as it can exert a direct stimulatory effect on cortisol release by adrenocortical tumors (Van Wijk *et al.*, 1994).

3. *Tests of Pituitary-Adrenocortical Suppressibility*

The integrity of the feedback system can be tested by giving a potent glucocorticoid and judging suppression of ACTH secretion by measuring either steroids excreted in urine or plasma cortisol levels. A potent glucocorticoid such as dexamethasone is used so that the administered compound may be given in such small amounts as not to contribute significantly to the steroids to be analyzed. In pituitary-dependent hyperadrenocorticism, there is loss of normal sensitivity to suppression, and as a result higher values are found than in normal individuals following dexamethasone administration (Table 19-5).

In the dog, the most frequently used test is still the low-dose dexamethasone suppression test (LDDST) (Meijer *et al.*, 1978a). In this test, 0.01 mg of dexamethasone/kg of body weight is administered intravenously, and a plasma sample for cortisol determination is taken after 8 h. In healthy dogs at this time the plasma cortisol concentrations are still depressed (Kemppainen and Sartin, 1984b). This test is described in detail in Section IV.F. Others recommend intramuscular administration of 0.015 mg of dexamethasone/kg and the collection of plasma samples for cortisol determination 2, 4, 6, and 8 h after injection (Peterson, 1984). Although not necessary for the diagnosis, the results of a 3- or 4-h sample may be informative for differential diagnosis (see Sections IV.D and IV.F).

D. Tests for Differential Diagnosis

In animals with primary hypoadrenocorticism, the physical and biochemical features are very much determined by the electrolyte disturbances caused by the insufficient mineralocorticoid secretion. In secondary hypoadrenocorticism, mineralocorticoid secretion is practically unchanged, and the presenting signs are usually completely different. Thus, only rarely is there a need for additional tests to distinguish between these two forms of hypoadrenocorticism. However, when doubt exists about the background of the hyporesponsiveness to exogenous ACTH, plasma ACTH concentrations should be measured (see also Section IV.B.6) or the pituitary should be tested for ACTH reserve (see Section IV.C).

For hyperadrenocorticism, the situation is completely different. Once the diagnosis of hyperadrenocorticism has been made by either a basal test or a dynamic test, it is necessary to distinguish between pituitary-dependent hyperadrenocorticism and hyperadrenocorticism arising from an adrenocortical tumor. In principle, these forms of the disease require different modes of treatment. Probably owing to the additional secretion of steroids with mineralocorticoid activity by adrenocortical tumors, a higher incidence of hypokalemia is found than in animals with pituitary-dependent hyperadrenocorticism (Meijer, 1980). However, this sign is not specific enough to allow differentiation between the two forms. As there are no further signs that may be helpful to distinguish the two entities, specific tests are needed. The two most helpful procedures are the measurement of basal plasma ACTH levels and the high-dose dexamethasone suppression test (HDDST). A test of pituitary ACTH reserve may also be helpful.

Normal to high plasma ACTH concentrations ($\geq$40 pg/ml) in hyperadrenocorticoid dogs usually indicate ACTH excess of pituitary origin. Low to undetectable concentrations of ACTH are found in dogs with hyperadrenocorticism arising from an adrenocortical tumor in which the feedback control of pituitary ACTH secretion is undisturbed. ACTH concentration may not be low when both disease entities

occur simultaneously (Nothelfer and Weinhold, 1992; Van Sluijs *et al*., 1995). However useful this measurement may be, in practice it is not the first choice when it comes to the differential diagnosis of hyperadrenocorticism because of the requirements for collecting and handling the samples and the technically difficult assay (see also Section IV.E).

In contrast to the determination of endogenous ACTH, the HDDST is readily available. Despite a decreased sensitivity to the suppression by glucocorticoids, the ACTH secretion of most animals with pituitary-dependent hyperadrenocorticism can be suppressed with a 10-fold dose of 0.1 mg dexamethasone/kg body weight, resulting in a decrease of the adrenocortical secretion. The autonomous hypersecretion by adrenocortical tumors will not be influenced by the high dose of dexamethasone.

Two procedures are used in the dog, one employing plasma cortisol as a reflection of adrenocortical secretion (Meijer *et al*., 1979) and the other urinary corticoid/creatinine ratios (Rijnberk *et al*., 1988). In both, a greater than 50% decline from baseline values is regarded as diagnostic for pituitary-dependent hyperadrenocorticism (see Section IV.F). When suppression is less than 50%, the hyperadrenocorticism may be due to either an adrenocortical tumor or a pituitary ACTH excess that is extremely resistant to dexamethasone suppression. For the differentiation between these two forms, the above-mentioned measurement of endogenous ACTH may be necessary, or a CRH test may be performed. In dogs with pituitary-dependent hyperadrenocorticism, CRH administration (1 μg/kg I.V.) elevates both plasma ACTH and cortisol, whereas no such rise is seen in dogs with hyperadrenocorticism caused by adrenocortical tumors (Van Wijk *et al*., 1994). The high cost of the commercially available powder preparation and the necessary pharmaceutical preparation prohibit general use of CRH.

E. Collection and Handling of Samples

It has become common practice for clinicians to perform endocrine function studies and to mail samples to a laboratory for measurement of cortisol. It is therefore important to rule out nonpathological factors that can alter hormone concentrations. Apart from stress (see Section IV.B), the nutritional state of the animal may also play a role. In a study by Reimers *et al*. (1986), the researchers found that mean serum concentrations of cortisol in dogs fasted 12 or 24 h were lower than those in dogs that were not fasted. The concentrations were not further affected by continued fasting for 36 h.

Olson *et al*. (1981) have studied several aspects of sample handling, such as uncentrifuged storage and storage time. They concluded that either serum or plasma of dogs is suitable for radioimmunoassay of cortisol, and samples (with and without added anticoagulants) may be left uncentrifuged at 4°C for up to 40 h without cortisol degradation. However, prolonged storage of serum at room temperature is detrimental, particularly for samples that have large concentrations of cortisol. Samples allowed to defrost and sit for more than 3 days en route to a laboratory may have a lower cortisol concentration than they did at the time of collection.

The peptide ACTH is readily inactivated at room temperature. Therefore, blood for ACTH measurements should be collected in EDTA-coated tubes placed in ice, and the blood should be centrifuged at 4°C. The plasma should then be placed in polypropylene tubes and kept frozen until assayed. These requirements are most easily fulfilled when the samples are collected in a clinic with the necessary facilities. If the samples have to be transformed, it is imperative that they be kept frozen with dry ice in a Styrofoam container. These strict rules can be alleviated to some extent by adding a protease inhibitor (aprotinin) to the collection tubes (Kemppainen *et al*., 1994).

F. Protocols

The protocols presented next are applicable to the dog. With the data presented in some of the tables, extrapolation to other species may be possible.

1. ACTH *Stimulation Test*

a. Indications

The ACTH stimulation test is performed when there is suspicion of decreased adrenocortical reserve capacity: (1) primary adrenocortical insufficiency (Addison's disease) and (2) (iatrogenic) secondary adrenocortical insufficiency.

b. Performance

Blood for cortisol measurements is collected immediately before and 90 min after intravenous administration of 0.25 mg synthetic ACTH (Cortrosyn [Organon]). In cases in which treatment for adrenocortical insufficiency was already started, on the morning of the test, the cortisone administration is postponed until after completion of the test. When the treatment is already longer than 3 to 4 days, iatrogenic suppression of the adrenals should be taken into consideration.

c. Interpretation

In healthy dogs, the cortisol concentrations rise to 270 to 690 nmol/liter (Rijnberk, 1996). In Addison's disease, the control value is usually low and does not increase following ACTH administration. In animals with secondary adrenocortical insufficiency, the basal cortisol values may be low as well, and, depending on the severity (duration) of the ACTH deficiency, the cortisol rise is subnormal or absent.

2. *Low-Dose Dexamethasone Suppression Test*

a. Indication

The low-dose dexamethasone suppression test is used when hyperadrenocorticism (Cushing's syndrome) is suspected.

b. Performance

In the morning, 0.01 mg dexamethasone per kg body weight is administered intravenously. Blood for cortisol measurements is collected immediately before and at 3 and 8 h after dexamethasone administration.

c. Interpretation

A plasma cortisol concentration exceeding 40nmol/liter at 8 h after dexamethasone administration can be regarded as diagnostic for hyperadrenocorticism with a diagnostic accuracy of 0.83 (95% confidence limits 0.76 to 0.88) (Rijnberk *et al*., 1988). The measurements at 0 and 3 h are not needed for the diagnosis of hyperadrenocorticism but may be informative in the differential diagnosis. Quite commonly the high value at 8 h is preceded by a lower value at 3 h. Thus, at 8 h the pituitary-adrenocortical system escapes from the suppression by dexamethasone. If the value at 3 or 8 h is at least 50% lower than the basal value, the disease may be regarded as pituitary dependent.

3. *High-Dose Dexamethasone Suppression Test*

a. Indication

Differentiation between pituitary-dependent hyperadrenocorticism and hypercorticism arising from adrenocortical tumors is possible with the high-dose dexamethasone suppression test.

b. Performance

Blood for cortisol determination is collected immediately before and 3 to 4 h after administration of 0.1 mg dexamethasone per kg body weight.

c. Interpretation

If the plasma cortisol declines by more than 50%, the diagnosis of pituitary-dependent hyperadrenocorticism is justified. A decrease of less than 50% can be due either to an adrenocortical tumor or to dexamethasone-resistant pituitary-dependent hyperadrenocorticism. Differentiation between these two forms requires additional tests (see Section IV.D).

4. *Urinary Corticoid/Creatinine Ratios (with High-Dose Dexamethasone Test)*

a. Indication

Determination of corticoid/creatinine ratios can be performed when hyperadrenocorticism is suspected.

b. Performance

The owner is asked to collect morning urine samples at set times (e.g., 7 A.M.) on 3 consecutive days. On the preceding evenings, the animal should have its last walk at identical times (e.g., 11 P.M.). After collection of the second urine sample, dexamethasone is administered orally. At 8-h intervals, the owner administers 0.1mg dexamethasone per kg body weight.

c. Interpretation

Corticoid/creatinine ratios exceeding 10×10^{-6} can be regarded as compatible with hyperadrenocorticism with a diagnostic accuracy of 0.91 (95% confidence limits 0.85 to 0.95) (Rijnberk *et al*., 1988). When the ratio of the third urine sample is 50% lower than the mean of the first two ratios, the diagnosis of a pituitary-dependent hyperadrenocorticism is justified. A lesser decrease may be due to either adrenocortical tumors or dexamethasone-resistant pituitary-dependent hyperadrenocorticism (for differentiation, see Section IV.D).

d. Comment

This test is now generally regarded as a sensitive screening test for the diagnosis of hyperadrenocorticism (Feldman, 1995). There has been some debate on its specificity (Feldman, 1992; Rijnberk and Teske, 1992), and recently it was stated that the test lacks specificity (Feldman, 1995). Indeed as with other screening tests the specificity is not 100% (Kaplan *et al*., 1995; Smiley and Peterson, 1993), and in conditions that are associated with increased adrenocortical function, such as hepatic encephalopathy (Rothuizen *et al*., 1995), elevated ratios can be found.

In this discussion, two points remain somewhat underexposed. First, a high sensitivity and not a high specificity is essential for a screening test. The predictive value of a positive test result depends on the sensitivity of the test and also on the prevalence of the disease in the population studied. When the testing is limited to dogs suspected of the disease, the population under study will have a high prevalence of disease, and as a result the predictive value of a positive test result will be high. Second, as always, the diagnostic accuracy of a test depends also on the quality of the test procedure. In this respect, it should be mentioned that easily elevated C/C ratios can be obtained when the urines are collected under stressful conditions, such as in the hospital. This will increase the number of false-positive test results (i.e., lower the specificity).

When C/C ratios are measured in a population suspected of hyperadrenocorticism, with urine collections at home, not only is the sensitivity of the test high, but also the specificity (0.77) is comparable to that of the low-dose dexamethasone suppression test (0.73) (Rijnberk *et al*., 1988).

Chapter 20

Thyroid Function

J. Jerry Kaneko
Department of Pathology, Microbiology, and Immunology
School of Veterinary Medicine
University of California, Davis
Davis, California

I. INTRODUCTION

Disorders of the thyroid gland are the most common endocrine disorders in humans, and extensive historical and scientific literature is available. Among the domestic animals, thyroid function and its diseases are well known in companion animals but less so in other animals, domestic or wild. In livestock, nutritional iodine deficiencies have been of greater importance than thyroid gland diseases, particularly in the iodine-deficient areas of the world. The importance of thyroid function and its diseases has also become progressively more important as the longevity of companion animals such as the dog and the cat has increased.

Advances in thyroid physiology, pathogenesis of its diseases, and the continued development and refinement of methods of testing thyroid function have added impetus to the study of thyroid disease in all animals. This chapter reviews the anatomy and physiology of the thyroid gland and its diseases as a corollary to the understanding of the pathophysiology of the thyroid gland in disease. Emphasis is placed on the physiological bases of a variety of thyroid function tests, most of which are now readily available to the veterinary clinician.

II. ANATOMICAL CONSIDERATIONS

The thyroid gland of animals is a bilobed structure that overlays the trachea at a point just below the larynx. Anatomical variations of the gland are marked between species and, to some extent, within a given species. The isthmus connecting the two lobes of the thyroid is the region that varies most markedly between species. Humans and pig have a large discrete isthmus, which forms a pyramidal lobe connecting the two lateral lobes. The cow has

a fairly wide band of glandular tissue, which forms the connecting isthmus. In the horse, sheep, goat, cat, and dog, the isthmus is a narrow remnant of tissue and may be nonexistent. The size of the gland relative to body weight is extremely small in all animals, approximating 0.20% of body weight. The size of the gland varies and may be enlarged when iodine deficiency, ingestion of goitrogenic toxins, tumors, or hyperactivity is present. In primary hypothyroidism, the gland may be reduced to fibrotic and inactive remnants of thyroid tissue.

Accessory or extrathyroidal tissue is commonly observed in the dog, particularly near the thoracic inlet though they may be found anywhere along the esophagus. This accessory tissue is fully functional physiologically, synthesizes hormone, and can be located by its uptake of radionuclides. This is a particularly important consideration for the dog when thinking about surgical intervention for treatment of hyperthyroidism resulting from a thyroid tumor.

The thyroid gland is a highly vascularized tissue with a large blood flow. The functional unit of the thyroid gland is the thyroid follicle, which can be envisioned as a spherical structure composed of an outer monolayer of follicular cells surrounding an inner core of colloid. Colloid is a thyroglobulin-hormone complex that is the storage reservoir of thyroid hormone in the thyroid gland. The colloid stored in the lumen is a clear, viscus fluid. The individual follicular cells vary from 5 to 10 μm in height, and the entire follicle may vary from 25 to 250 μm in diameter. The size of the follicles and the height of their follicular cells vary according to the functional state of the gland. The cells may vary from an inactive squamous cell to the highly active, tall columnar cell. Interspersed between the follicles are the thyroid "C" cells, the source of calcitonin, the hypocalcemic hormone associated with calcium metabolism. A third type of hormonal tissue, the parathyroid, is imbedded within the thyroid or located in close proximity to it. The parathyroids are the source of parathormone, the hypercalcemic hormone. Removal of the parathyroids is virtually unavoidable during surgical thyroidectomies so that postsurgical hypocalcemias are important consequences to be considered.

III. NUTRITIONAL REQUIREMENTS

The thyroid gland is unique among the endocrine glands in that an integral part of its hormone, L-thyroxine (T_4), is a trace mineral, iodine, which is available to the animal in only limited amounts. Marine plants are known to be good sources of iodine, but on land, iodine is limited and many regions of the world are known to be iodine deficient. The recommended daily requirement is 35μg/kg bw (276nmol/kg bw) for the adult dog and 70μg/kg bw (551.6nmol/kg bw) for the growing puppy. For most animals, nutrient requirements are given in mg/Kg dry diet or ppm and range from 0.1 to 1.0 mg, including cats and horses. Milk is a poor source of hormonal iodide contributing only about 4% to 7% of the maintenance requirements for hormone (Akasha and Anderson, 1984).

The small requirements are compensated for by an efficient intestinal absorption mechanism and conservation and recycling of internal iodine. Little iodine is lost from the body by the various excretory routes such as urine, saliva, tears, milk, sweat, and feces. Also, whereas most endocrine glands store little of their hormones, the thyroid manages to store large quantities of hormone sufficient for 1 to 3 weeks depending on the species. The thyroid gland contains about 20% of the total body iodine. Its iodine content and size vary with iodine intake and the state of thyroid function, but it usually contains 10 to 40mg (78.8 to 315.2μmol) iodine/100 gm tissue or 4 to 16mg (31.5 to 126.1μmol) iodine in a 20-kg dog.

IV. IODINE METABOLISM

Iodine can be absorbed in any of its soluble chemical forms, but in the intestines it is usually absorbed in the form of iodides (I^-), iodates (IO_4^-), or as the hormonal forms. Iodides may be absorbed from any moist body surface, including the mucus membranes, and it is absorbed easily through broken epithelia. Normally, the chief route of entry into the general circulation is by absorption through the mucosal cells of the small intestine. The I^- in the circulation is trapped almost exclusively by the thyroid gland, with small amounts being trapped by the salivary gland and minimal amounts by the gastric mucosa, placenta, and mammary gland. In the ruminant, 70% to 80% of an oral dose is absorbed in the rumen and 10% in the omasum.

The main route of excretion of I^- is by the kidneys through which almost all the I^- that was not trapped by the thyroid is lost in the urine. A small but significant amount is lost in the saliva, and minimal amounts are lost in tears, feces, sweat, and milk. A minute amount of free hormone, that fraction not bound to serum proteins, is also lost in the urine. These routes of excretion are especially important considerations when patients are being treated with radioiodine.

V. FUNCTIONS OF THE THYROID GLAND

The main functions of the thyroid gland are the trapping of I^- and the synthesis, storage, and release of thyroid hormones (Fig. 20-1), and these activities are under the control of the thyrotropin or the thyroid-stimulating hormone (TSH). Although TSH stimulates all steps in hormonogenesis, the trapping of I^- and the release of hormone are the two major sites of its action.

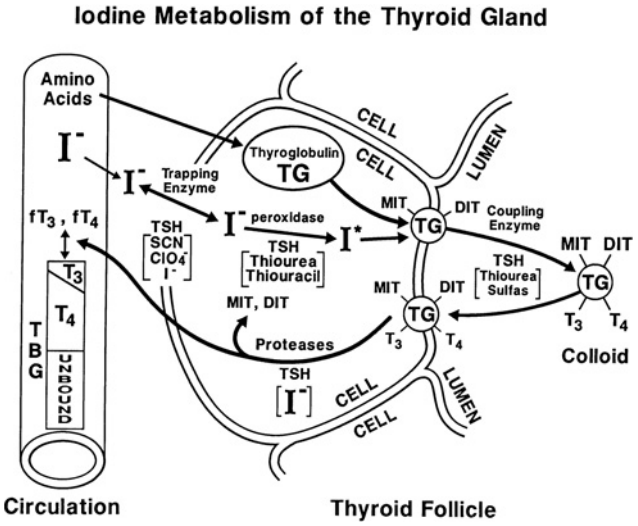

FIGURE 20-1 Pathways of iodine metabolism and thyroid hormone synthesis. Goitrogenic blocking agents are shown in brackets.

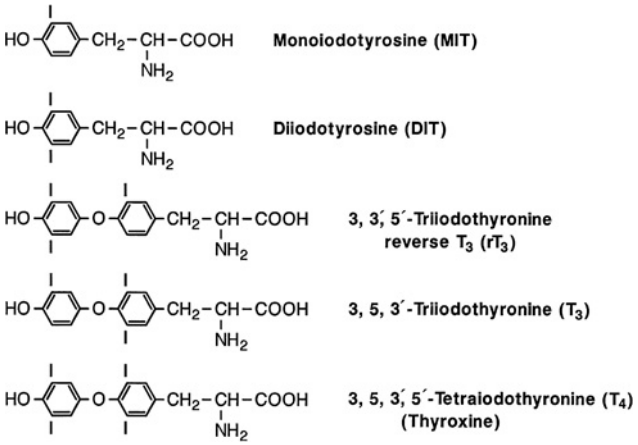

FIGURE 20-2 Chemical structures of the major iodinated compounds of the thyroid gland.

A. Thyroid Hormones

The principal thyroid hormones elaborated by the thyroid are the two active hormones, 3,5,3′,5′-tetraiodothyronine (T_4) and 3,5,3′-triiodothyronine (T_3), and the inactive hormone, 3,3′,5′-triiodothyronine (reverse T_3 or rT_3). The rT_3 is the inner deiodination product of the T_4. The structures of the individual hormones are given in Figure 20-2. The T_4 molecule contains 65.3% iodine, and the T_3 molecule contains 58.5% iodine. The T_3 is the active hormone in the target cell. The T_4 functions as the transport form and as the feedback regulator of the thyroid gland.

B. Hormonogenesis and Release

1. *Trapping of Iodide*

The I^- in the general circulation is taken up by the thyroid follicular cells by a highly efficient trapping and concentrating mechanism. It does this against a large concentration gradient, which can be from 1:20- to 1:500-fold across the thyroid cell membrane and is stimulated by TSH. The trapping process is catalyzed by a trapping enzyme, requires oxygen, and is an active transport or "pump" mechanism catalyzed by a Na^+K^+-ATPase and dependent on ATP. The transport process is mediated by a sodium iodide symporter (NIS) protein located on the plasma membrane (Riesco-Eizaguirre and Santisteban, 2006). It is the high efficiency of this trapping system that concentrates virtually all of the body iodine in the thyroid gland. It also accounts for the microgram nutrient requirement for iodine. In addition, the thyroid follicular cells have a high capability for compensatory hypertrophy when there is a scarcity of iodine, hence the development of iodine deficiency goiters. The efficiency of I^- trapping is also the basis for the radioactive iodine uptake (^{131}I Uptake) test of thyroid function, ^{131}I thyroid imaging, and ^{131}I thyroid therapy. The trapping of I^- is stimulated by TSH and blocked by the goitrogenic agents such as thiocyanate (SCN^-), perchlorate (CLO_4^-) and by large amounts of I^-. Figure 20-1 also shows the sites of these and other blocks in the thyroxine biosynthetic pathway. Other compounds are trapped by the thyroid gland, and the most widely clinically used one is ^{99m}Tc-pertechnetate, which is used for thyroid tissue imaging.

2. *Synthesis of Thyroid Hormones*

After trapping, there is an oxidation of I^- catalyzed by a peroxidase and the product is a highly active form of iodine, most likely a free radical, I^*. This reaction is inhibited by thyrotoxic agents such as the thiouracils or thioureas and stimulated by TSH. Propylthiouracil is commonly used in the treatment of hyperthyroidism. The I^* almost instantaneously binds to the phenyl groups of the tyrosine moieties of thyroglobulin at the 3 or 5 position to form a monoiodotyrosine (MIT) or a diiodotyrosine (DIT). This iodination occurs while the tyrosines remain in polypeptide linkage within the thyroglobulin molecule. Next, the iodinated phenyl groups of the tyrosines are coupled by the oxidative condensation of an iodinated phenyl group of one DIT to another DIT to form T_4 or of an MIT group to a DIT to form T_3. These iodination reactions occur mainly at the follicular cell membrane-colloid interface. These iodination reactions are energy requiring and sensitive to blocking by sulfa drugs, thioureas, and paraaminobenzoic acid (PABA).

3. *Storage of Hormone*

Thyroglobulin is the thyroidal glycoprotein of high molecular weight (660,000 daltons) synthesized exclusively by

the thyroidal follicular cells. After synthesis, it moves to the cell membrane where the iodinations occur and the iodinated thyroglobulin, or colloid, is released into the lumen of the follicle where it is stored. The amount stored can be quite large as evidenced by the mass of protein contained within a normal follicle.

4. *Release of* Hormone

TSH stimulation of the release of hormones is the second of its two principal sites of action. Within a few minutes after giving TSH, small packets of colloid are taken up by the follicular cell membrane, and vesicles are formed and taken into the follicular cell by endocytosis. The vesicles merge with lysosomes within the cell, and the lysosomal proteases hydrolyze the colloid and release their MIT, DIT, T_3, and T_4. The released MIT and DIT are enzymatically degraded by microsomal tyrosine deiodinases, and their iodine is recycled within the follicular cell. The T_4 and T_3 are released into the circulation by a simple diffusion process. Of the total hormone released, about 90% is T_4 and 10% is T_3. Within the gland, there is also some deiodination of the T_4 of the inner phenyl group to form rT_3, but most of this deiodination occurs in the peripheral tissues. This rT_3 is the inactive form of thyroid hormone and is on a degradation pathway.

VI. TRANSPORT OF HORMONE: PROTEIN BINDING

The thyroid hormones in the circulation are T_4, T_3, and rT_3. Immediately upon entering the circulation, these hormones are bound to transport proteins, mainly to thyroxine-binding globulin (TBG), and with lesser amounts to thyroxine binding prealbumin (TBPA) and to albumin. There is a wide spectrum of species variation in hormone binding by serum proteins (Table 20-1). TBPA is present in all the species in contrast to earlier reports indicating that TBPA was present only in humans, rhesus monkey, horse, cat, rabbit, pigeon, and chicken. The early work was based on electrophoretic migration, but later work based on chemical properties identified TBPA or its analogues at different migration sites (Larsson *et al.*, 1985). The differences in migration are likely due to differences in the amino acid composition of these proteins among the various species. Using chemical criteria, all species have TBPA.

TABLE 20-1 Thyroxine-Binding Proteins of Various Species, Their Electrophoretic Migration, and Their Relative Thyroxine Binding[a]

	Electrophoretic Migration Position		
Species	Alpha-Globulin	Albumin	Prealbumin
Human	TBG (73)	ALB (10)	TBPA (17)
Rhesus monkey	TBG (59)	ALB (8)	TBPA (33)
Cattle*	TBG (60)	TBPA (20)	ALB (20)
Sheep	TBG (86)	TBPA (14)	
Goat	TBG (63)	TBPA (37)	
Water buffalo	TBG (78)	TBPA (22)	
Horse	TBG (61)	ALB (17)	TBPA (22)
Pig	TBPA (0)	TBG (93)	ALB (7)
Dog	TBG (60)	TBPA (17) α-G (11)	ALB (12)
Cat*	TBPA (39)	ALB (61)	
Rabbit*	TBPA (73)	ALB (27)	
Rat*		ALB (80)	TBPA (20)
Mouse*		ALB (80)	TBPA (20)
Guinea pig*		ALB (81)	TBPA (19)
Chicken	TBPA (10)	ALB (75)	TBPA (15)
Pigeon*		ALB (50)	TBPA (50)

[a] TBG, *thyroxine-binding globulin*; ALB, *albumin*; TBPA, *thyroxine-binding prealbumin*; α-G, α-*globulin*: *positioned as shown relative to the albumin position in each species. Numbers in parentheses specify the percentage of thyroxine binding. Constructed from the data of Tanabe* et al. (1969), *Refetoff* et al. (1970), *and Larsson* et al. (1985). *The * indicates approximations.*

TBG is the major binding protein for hormone, but not all species have TBG. In those species without TBG, albumin serves as the major binding protein. The binding constant of TBG for T_4 is about 10^{10} liter/mole so that some 99.97% of the plasma T_4 is bound to TBG and only 0.03% is free or unbound (fT_4). The binding constant for T_3 is about 10^9 liter/mole so that about 99.7% of the plasma T_3 is bound to TBG and 0.3% is free. Therefore, TBG or albumin transports most of the hormones.

In the cat, rabbit, rat, mouse, guinea pig, pigeon, or chicken, TBG is absent and most of the hormone is transported by albumin. The albumin binding constant is about 10^5 liter/mole for T_4 or T_3 but with an unlimited binding capacity. In these species without TBG, albumin transports between 50% and 80% of the hormones. T_3 (and likely rT_3) appears to bind to these transport proteins in parallel with T_4 binding.

Protein binding has several functions. Protein binding solubilizes these lipid soluble hormones for transport in the aqueous plasma. The bound forms also do not readily pass through the renal glomerular membrane, so they minimize urinary loss of hormones, whereas the free hormones pass and are lost. The bound forms also serve as a large and readily accessible reservoir of the active hormones for delivery to the target organs and cells. Finally, the protein binding equilibrium is the fundamental basis for protein or immunoprotein binding assays of hormone and the indirect assay of TBG.

VII. MECHANISM OF THYROID HORMONE ACTION

A. General Effects of Thyroid Hormones

After the administration of thyroid extracts or T_4, its first physiological effects are noted in 24 to 28 h and its maximal effects are noted in 7 to 10 days (Table 20-2). The T_4 requirements for these effects vary. The requirement for T_3 also varies, and less is required for equivalent activity and it acts more quickly. T_3 is now recognized as the active form of the thyroid hormone within the target cell. The T_4 that is transported into the target cell is rapidly deiodinated to the active T_3. However, rT_3, which is also produced in the cell in the deiodination process, is an inactive form of thyroid hormone and is simply degraded.

B. Molecular Basis of Thyroid Hormone Action

The molecular basis of thyroid hormone action at the cellular level has been frequently reviewed, and a multifaceted concept of its action has evolved. For many years, the mitochondrion was considered to be the site of thyroid hormone action. Uncoupling of oxidative phosphorylation (ox-phos) in the mitochondria was a viable hypothesis for many years. Under normal conditions, 3 moles of ATP (P) are synthesized per atom of oxygen (½ 0_2 = 0) used in the cytochrome oxidase system; hence, P:0 ratio equals 3. If less than 3 moles of ATP are formed per unit 0 in a system in the presence of a compound such as the thyroid hormone, the system is said to be uncoupled (i.e., P:0 ratio is less than 3). In this event, more O_2 would be needed to generate an equivalent amount of ATP, and O_2 consumption would increase. T_4 has repeatedly been shown to uncouple oxidative phosphorylation in *in vitro* systems, but it does so only in large, unphysiological amounts. These findings were extended to the whole animal to explain the increased oxygen consumption by T_4. The large amounts of oxidative energy not incorporated into ATP increased body temperature and were dissipated as heat. Thus, T_4 action was theorized to be the result of the uncoupling of oxidative phosphorylation.

Another now well-known effect of thyroid hormone is the stimulation of cellular protein synthesis (Tapley, 1964; Tata *et al.*, 1963), and this occurs during the latent period when the calorigenic effect of thyroid hormone occurs. T_3 is now known to stimulate messenger RNA (mRNA) transcription, increasing translation and protein synthesis and accounting for the anabolic effects of thyroid hormones. This also means that the site of action is at the cell nucleus.

Another action of thyroid hormone is to stimulate the "sodium pump" (Na-K-ATPase) at the cell membrane, an action that would increase O_2 consumption (Edelman, 1974). Ouabain, an inhibitor of Na-K-ATPase, also inhibits the increased O_2 consumption induced by T_4 or T_3. Thus, stimulation of the sodium pump is an important way in which thyroid hormones stimulate increased oxygen consumption and accounts for almost half of the increase.

TABLE 20-2 Effects of Thyroid Hormone

Category	Effect
Clinical	Tremors, nervousness, exophthalmos, hyperactivity, weight loss
Physiological	Increased temperature, heart function
Calorigenic	Increased basal metabolic rate (O_2 consumption)
Carbohydrate metabolism	Increased glucose turnover, absorption
Protein metabolism	Anabolic, positive N balance
Lipid metabolism	Decrease in blood cholesterol
Development	Stimulation of growth and maturation
Reproductive	Fertility, pregnancy, ovulation
Hematological	Erythropoiesis

A direct effect of thyroid hormones on cell membrane transport has also been suggested from studies on 2-deoxyglucose uptake (Segal *et al.*, 1977). Pliam and Goldfine (1977) proposed that T_3 binds to receptors on the cell membrane and is transported by carriers into the cell.

A combination of the aforementioned mechanisms is the most likely explanation of the mechanism of action of thyroid hormone. A viable model patterned after the generalized steroid hormone model is one in which (1) T_3 is bound to a receptor site on the plasma membrane, (2) T_3 is transported across the membrane into the cell by the carrier protein, (3) T_3 in the cell is again bound to a carrier protein, (4) T_3 rapidly exchanges between receptor sites on the mitochondrion or nucleus, and (5) T_3 interacts in metabolic processes and protein synthesis.

VIII. CATABOLISM AND EXCRETION OF THYROID HORMONES

The thyroid hormones undergo deiodination, conjugation, or oxidative reactions. The deiodination reaction occurs widely in peripheral tissues and is catalyzed by deiodinases specific for each iodine position, and the released iodine is returned to the iodine pool. The details of the specific reactions, however, are not yet known. The deiodinase that catalyzes the deiodination of T_4 to T_3 in target cells is actually participating in an activation reaction. Deiodination at the 3 position of T_4 gives rT_3, the inactive form on the degradation pathway. Within a cell, therefore, some of the T_4 is converted to its active form, and some is converted to its inactive form for degradation. Some of the thyroid hormones are conjugated in the liver and excreted in the bile either as glucuronides or as sulfates. Also, the thyroid hormones, being amino acids, are deaminated and decarboxylated in the liver to form corresponding tetraiodoacetic acid and tri-iodoacetic acid, which are excreted by the kidney. Finally, the kidney also excretes the small amounts of free hormones in the blood.

IX. REGULATION OF THE THYROID GLAND

A. Production and Regulation of Thyroid-Stimulating Hormone

The thyroid gland is under the control of the thyroid-stimulating hormone (TSH), which is secreted by the anterior pituitary gland, which in turn is mediated through the hypothalamus and its thyrotropin-releasing hormone (TRH). The TRH is synthesized in the anterior hypothalamus by neurosecretory cells and then transported down axonic processes to the anterior pituitary. There, TRH stimulates the thyrotrophic cells to synthesize TSH. The secretion of TSH is regulated by a classic negative feedback control system based on the product of the target gland, thyroxine. A high plasma concentration of free hormone, fT_4, depresses TSH secretion by the pituitary and, to some extent, the TRH from the hypothalamus. The direct inhibition of the pituitary by increased fT_4 is the faster responding of the two tissues. At low concentrations of fT_4, however, the hypothalamus responds quickly by increasing its synthesis and release of TRH, which in turn increases the synthesis and release of pituitary TSH. In consequence, this regulatory mechanism, which is sensitive to either high or low concentrations of fT_4, maintains the circulatory hormone concentrations at the normal homeostatic level for that species.

B. Action of the Thyroid-Stimulating Hormone on the Thyroid Gland

TSH has a number of direct effects on the thyroid gland: the gland increases in size, the height of the follicular cell increases, and there is a loss of colloid. The response of the thyroid gland to TSH is modified by the intake of stable iodine. When iodine intake is high, the action of TSH is suppressed and the height, size, and activity of the follicular cells decrease. When iodine intake is low, there is a compensatory hypertrophy of the gland with an increase in number, height, and size of the follicular cells. This is characteristic of the iodine deficiency goiters or the nontoxic goiters.

C. Action of the Thyroid-Stimulating Hormone on Hormonogenesis

The effects of TSH on hormone synthesis by the thyroid follicle are outlined in Figure 20-1 and discussed in Section V. TSH affects every reaction in the hormone synthetic pathway beginning with the uptake of iodine, its activation, tyrosine iodination, coupling of the iodinated phenyls, and hydrolysis of colloid. The two most important sites of TSH action are the initial uptake of iodine and the final hydrolysis of colloid to release hormones into the circulation.

D. Long-Acting Thyroid Stimulators

A second thyroid stimulatory factor has been identified in the serum of human patients with Graves' disease and appears to be closely involved in the mechanism of thyrotoxicosis (Adams, 1958). It differs from TSH in that it is cleared from the blood more slowly and produces its thyroid-stimulating effects many hours (8 to 24) after that of TSH. It is therefore referred to as long-acting thyroid stimulator, or LATS. Studies of LATS have been largely in humans where it has been closely correlated with hyperthyroidism (Lipman *et al.*, 1967). Since the initial observations, many other forms of delayed-acting thyroid stimulators have been found, and all, including LATS, are now known to be immunoglobulins of the IgG class. These

thyroid-stimulating immunoglobulins or thyroid-stimulating antibodies (TSAb) do not appear to have a role in normal thyroid physiology, nor have corresponding stimulators been found in animals.

X. THYROID FUNCTION TESTS

The diagnosis of thyroid disease is usually obscured by the nonspecific nature and variety of clinical signs. A thorough physical examination is essential for the detection of a potential thyroid disease and as a rationale for laboratory tests of thyroid function. Initial routine laboratory tests such as hematology or urinalysis are of limited value except for a moderate to slight normocytic normochromic anemia, which may sometimes be observed. The initial biochemical screen is also limited except for a hypercholesterolemia, which may be observed. In consequence, the specific tests of thyroid function are of great importance in the diagnosis of thyroid disease. Fortunately, improvements of standard tests and the development of new tests have made several specific and direct tests of thyroid function readily available to the veterinary clinician.

A. Indirect Tests of Thyroid Function

1. *Hematology*

A moderate normocytic normochromic anemia is sometimes associated with clinical hypothyroidism in the dog. This anemia has also been observed in human hypothyroidism and in experimental animals and is known to be of a depression type or the anemia of chronic disease. The stained blood smear characteristically has little or no evidence of active erythrogenesis such as anisocytosis, polychromasia, or nucleated red cells. Leptocytosis may be prominent in some cases. The hemogram, therefore, is characteristic of the nonresponsive anemia of chronic diseases such as neoplasia, chronic infection, and so on. This anemia is not diagnostic for hypothyroidism, but conversely, in cases of unexplained hypoplastic or nonresponsive anemia, hypothyroidism is an important differential diagnosis that should be pursued.

2. *Cholesterol*

The serum cholesterol generally varies inversely with thyroid activity. The net effect of thyroid hormone on cholesterol metabolism is to increase the rate of its catabolism by the liver (Koppers and Palumbo, 1972), thereby lowering the cholesterol. In hypothyroidism, the net effect is a decrease in cholesterol catabolism and an increase in cholesterol.

The cholesterol is carried in dog plasma equally by the low-density lipoproteins (LDL-Chol) and the high-density lipoproteins (HDL-Chol) (Mahley and Weisgrober, 1974). In humans, cholesterol is carried mainly by the LDL-Chol and only about 20% by the HDL-Chol. This partitioning of cholesterol is important because increased LDL-Chol is associated with atherosclerosis, whereas increased HDL-Chol is associated with a reduced risk for heart disease, hence it is commonly known as "good" cholesterol.

Total cholesterol alone is of limited value because hypercholesterolemia is seen in a variety of conditions unrelated to thyroid activity. These include the diet, nephrotic syndrome, hepatic function, biliary obstruction, and diabetes mellitus. The diagnostic accuracy of serum cholesterol for hypothyroidism in the dog is about 66%. However, when the concentrations are very high, >500 mg/dl (>12.9 mmol/l), and diabetes mellitus is eliminated, its diagnostic accuracy increases greatly. Therefore, increased cholesterol again is simply a signal to further investigate thyroid disease.

Similarly, hypocholesterolemia has little value as an index of hyperthyroidism. On the other hand, cholesterol decreases consistently in response to thyroxine replacement therapy, so it has value as a guide to therapeutic response. In thyroidectomized horses with clinical evidence of hypothyroidism, Lowe *et al.* (1974) found a 50% decrease in serum cholesterol shortly after feeding iodinated casein. Feeding of iodinated casein to these horses also resulted in a rapid rise of T_4 to above normal. Iodinated casein contains about 2.5μg (3.85 nmol) T_4 and 1.25μg (1.61 nmol) T_3 per gram.

B. Direct Tests of Thyroid Function

Direct approaches to thyroid evaluation are (1) to measure the amount of the hormones in the blood, (2) to assess the response of the thyroid to stimulation by the thyroid-stimulating hormone (TSH), or (3) to assess the response of the pituitary gland to stimulation by the thyrotropin-releasing hormone (TRH). Because there are thyroid inhibitory effects among a wide variety of iodine containing compounds, it is critical that any form of iodine-containing medication, including thyroid hormones, be ascertained in the history of the patient. As a general rule, any iodine-containing medication or thyroid hormones being given to the patient should be withdrawn for at least 2 weeks before any thyroid function tests are undertaken.

1. *Thyroxine by Radioimmunoassay*

The principle of competitive protein binding (T_4-CPB) is the basis for the now standard radioimmunoassay for all hormones including T_4 and T_3. The method is based on the competitive binding of TBG for patient T_4 and ^{131}I-labeled T_4. The $^{131}T_4$ and patient T_4 bind to the TBG in proportion to their concentrations so that labeled T_4 binding is inversely proportional to patient T_4 concentration.

Specific antibodies have replaced the use of TBG so that there is high specificity for the assay of proteins, polypeptides, haptens, and most of the hormones. Polyclonal antibodies give accurate results and are usually used for these hormone assays. The mean normal T_4-RIA in dogs is 2.3 ± 0.8 μg/dl (29.6 ± 10.3 nmol/l) with an observed range of 0.6 to 3.6 μg/dl (7.7 to 46.3 nmol/l), which is comparable to the 1.5 to 3.6 μg/dl (19.3 to 46.3 nmol/l) of Sims *et al.* (1977). T_4-RIA is also widely used in cats because of the high prevalence of hyperthyroidism in this species. The reference range for cats is 0.1 to 2.5 μg/dl (1.3 to 32.3 nmol/l). In the horse, T_4-RIA is also quite low, 0.9 to 2.8 μg/dl (11.6 to 36.0 nmol/l). Messer *et al.* (1995) reported a mean T_4-RIA of 21.42 ± 3.46 nmol/l in 12 adult horses.

2. Thyroxine by Enzyme-Labeled Immunoassay

An important advance in hormone assay is the development of an enzyme-labeled immunoassay (EIA) test comparable in every way to radioimmunoassay except that the labeling is by an enzyme rather than radioiodine. This method has some obvious advantages in that there is no need to use radioactivity and the enzyme can be assayed in any laboratory. One system labels T_4 with malate dehydrogenase (MD), which in competition with unlabeled T_4, binds to antibody. This method has the acronym EMIT for enzyme multiplied immunosorbent test. This method has another advantage in that the labeled and unlabeled fractions need not be separated. The MD when bound to T_4 is inactive, and when it binds to the immunoglobulin, it is activated. The activity of malate dehydrogenase is assayed by standard enzyme methodology, and the T_4 is read from a standard curve as in a radioimmunoassay.

Another system uses two separate recombinant fragments of the enzyme β-galactosidase (Horn *et al.,* 1991). The individual fragments, enzyme donor (ED) and enzyme acceptor (EA), are inactive but when they recombine, they form the active enzyme. Thyroxine is bound to ED. In the presence of thyroxine antibody, the thyroxine-ED-antibody complex inhibits recombination with EA, and no active β-galactosidase is formed. When sample thyroxine and a standard amount of thyroxine-ED are mixed, they compete for a standard amount of antibodies. Thus, unbound thyroxine-ED accumulates in direct proportion to the amount of sample thyroxine. The unbound thyroxine-ED is free to bind with EA to form the active β-galactosidase. In this case, enzyme activity is directly proportional to the amount of thyroxine. This method had a very high correlation coefficient when compared to an RIA ($r = 0.969$), EIA ($r = 0.966$) and a fluorescence polarization immunoassay (FPIA, $r = 0.939$).

Another variation of the nonisotopic immunoassay is the fluorescence immunoassay in which a fluorochrome is tagged to the T_4. The T_4 concentration is inversely proportional to the fluorescence as in the RIA. This is also a sensitive test, but it requires a sensitive spectrofluorometer for the assay.

Chemiluminescence is another nonisotopic method with comparable accuracy (Wilkinson *et al.,* 1993). Enzyme immunoassays have not replaced radioimmunoassays for hormones, but the principle is now widely used for antigen or antibody assays using horseradish peroxidase (HRP) as the enzyme label. The procedure is popularly known as the enzyme-linked immunosorbent assay or by its acronym, ELISA. This procedure has been adapted for T_4 by labeling T_4 with HRP, coupling the HRP to a dye that indicates enzyme activity and hence T_4 concentration.

3. Triiodothyronine by Radioimmunoassay

Triiodothyronine is also commonly assayed by radioimmunoassay (T_3-RIA). In the dog, the mean normal T_3-RIA is 107 ± 18 ng/dl (1.6 ± 0.3 nmol/l) with an observed range of 82 to 138 ng/dl (1.26 to 2.12 nmol/l) (Kaneko, 1997). It closely parallels T_4-RIA in the dog so that the simultaneous determination of T_4-RIA and T_3-RIA will increase the diagnostic accuracy of either one alone. In cats, T_3-RIA is less widely used in comparison to T_4-RIA. The reference range for cats is 15 to 50 ng/dl (0.23 to 0.77 nmol/l). In the horse, Messer *et al.* (1995) reported a mean T_3-RIA of 0.85 ± 0.52 nmol/l.

4. "Free" Thyroxine and "Free" Triiodothyronine

"Free" thyroxine (fT_4) is the unbound fraction of the total circulating T_4, and its concentration is controlled by the equilibrium between TBG and TBG-T_4 (Section III). Equilibrium dialysis is now considered the best method for determining the free hormones, but it is often too labor-intensive for use in many clinical laboratories. An equilibrium dialysis method for free thyroxine is commercially available so that this method is now widely used.

The fT_4 concentration for dogs is 0.52 to 2.7 ng/dl (6.7 to 34.7 pmol/l). In the hyperthyroid cat, Hays *et al.* (1988) found no differences in dialyzable T_4 from the normal. They inferred that the total T_4 is sufficient for diagnosis and that the free hormone is not needed in the cat. In the horse, Messer *et al.* (1995) reported a mean fT_4-RIA of 14.0 ± 1.16 pmol/l.

The fT_3-RIA parallels fT_4-RIA in its binding characteristics. Because fT_3 is the physiologically active form of the hormone, it is potentially the single most reliable test of thyroid function. In the horse, Messer *et al.* (1995) reported a mean fT_3-RIA of 0.89 ± 0.53 pmol/l.

5. Thyroid-Binding Globulin, Thyroglobulin, and Thyroid Autoantibodies

Thyroid-binding globulin (TBG) and thyroglobulin (Tg) or colloid are measured by RIA. The standard technique for

thyroglobulin antibodies (TgAA) is the ELISA method. Haines *et al.* (1984), using ELISA, detected TgAA in a high percentage of dogs with hypothyroidism, in dogs with other endocrine diseases, and in those dogs that were closely related to the TgAA-positive dogs but found a low percentage in healthy unrelated dogs. They concluded that thyroid autoimmunity is strongly genetically influenced in the dog. An enzyme immunoassay (EIA) method has also been developed for the detection of autoantibodies to thyroxine and triiodothyronine (Patzi and Mostl, 2003).

6. *Thyroid-Stimulating Hormone*

Serum TSH is measured by radioimmunoassay (TSH-RIA) using an anticanine TSH antibody, which is commercially available for use in dogs. The human assay method, which is not suitable for dogs (Larsson, 1981), has been used in monkeys (*M. mulatta*) with 0.2 to 2.6 μU/ml (1.53 μU/ml) (Belchetz *et al.*, 1978). Marca *et al.* (2001) compared three assay methods for canine serum: RIA, EIA, and chemiluminescent. They found that the chemiluminescent assay had the best within- and between-run precision, and that all three had satisfactory correlations to serum TSH concentrations.

7. *Thyrotrophin-Releasing Hormone*

Although as yet no reliable thyrotrophin-releasing factor (TRH) assay has been developed for use in domestic animals, a highly purified TRH is available and is used in the TRH response test.

C. Radionuclide Uptake Tests

1. *Radionuclide Scintigraphy*

Radioiodine is taken up by the thyroid gland in exactly the same manner as the nonradioactive isotope, and its uptake remains as one of the most definitive tests for thyroid function. Radioactive ^{99m}Tc-pertechnetate is also taken up in the same manner and is now widely used for scintigraphy. Pertechnetate scintigraphy is used for detecting asymmetry of the thyroids, for localizing of active thyroid nodules and "hot spots" (Scriviani *et al.*, 2007). Quantitative pertechnetate uptake was found to have the highest discriminatory power between primary hypothyroidism and nonthyroidal illness when compared to other methods of evaluating thyroid function (Diaz-Espineira *et al.*, 2007).

D. Thyroid Ultrasonography

Ultrasonographic evaluation of the thyroid gland has been proposed as a means to differentiate between hypothyroid and euthyroid dogs. Two studies have reached essentially the same conclusion that the estimated thyroid volume by ultrasound has a highly specific predictive value for canine hypothyroidism (Bromel *et al.,* 2005; Reese *et al.,* 2005).

E. Trophic Hormone Response Tests

1. *Thyroid-Stimulating Hormone Response Test*

The response of the thyroid to TSH injection is a means of evaluating thyroid activity as well as to differentiate a primary hypothyroidism because of a thyroid lesion from a hypothyroidism secondary to a pituitary lesion. The responsiveness of the thyroid to the TSH injection is evaluated by an increase (or failure to increase) as evidence of thyroid activity (or inactivity). In the general procedure, thyroidal activity (or lack of activity) is first established by the measurement of serum hormones, and this is followed by the injection of TSH. In a primary hypothyroidism where the lesion is localized in the thyroid, there is no response to the exogenous TSH. If the hypothyroidism is due to a pituitary hypofunction with a deficiency of TSH or a hypothalamic lesion with a lack of TRH, there will be a response of the thyroid to the exogenous TSH as seen by a significant increase in serum hormone concentrations. Glucocorticoids and phenylbutazone are also well known to depress thyroid activity so that the TSH response test is useful in detecting low hormone concentrations due to thyroid disease. Useful procedure for the TSH response test is to first to obtain a serum sample for baseline T_4 or T_3, then inject 10IU of bovine TSH intravenously. Held and Oliver (1984) and Oliver and Waldrop (1983) have recommended a minimum of 5IU for the dog and horse, respectively. After 4 h, a second serum sample is taken and hormone again measured. The normal response in dogs is a doubling or more of the hormone above baseline level. In the primary hypothyroid individual, there is a virtual absence of a response. In the drug-induced or Cushing's patient with low hormone, there will be a response to well within the normal hormone concentrations. The secondary (TSH) or tertiary (TRH) hypothyroid patient will have a response similar to the drug-induced or Cushing's patient. In cats, Peterson *et al.* (1983) found T_4 to increase almost threefold above the baseline at 4 h post TSH. In the baboon, the TSH response test had peaks of more than double the baseline at 8 and 12 h for T_3 and T_4, respectively (Maul *et al.,* 1982). In horses, Messer *et al.* (1995), at 6 h after TSH administration, found significant increases in T_4, T_3, and fT_4 but not in fT_3. They suggested that the TSH response test may not be as valuable for thyroid disease diagnostics in the horse as it is in the dog and cat.

2. *Thyrotrophin-Releasing Hormone Response*

The response to thyrotrophin-releasing hormone (TRH) has been used in dogs and cats. Lothrop *et al.* (1984) found

a doubling of T_4-RIA at 6 h postinjection in dogs and cats. Scott-Montcrieff and Nelson (1998) measured TSH at 30min after TRH injection and found a small increase in TSH in hypothyroid as compared to euthyroid dogs. They concluded that the test had little advantage over using the baseline TSH, total T_4, or fT_4.

XI. DISEASES OF THE THYROID

Thyroid disease has been most extensively studied in the dog, whereas in the cat, the number of studies is increasing as the incidence of hyperthyroidism has increased. Hyperthyroidism is now the most frequently encountered endocrinopathy in this species. In the horse, Lowe *et al.* (1974) described the clinical effects of experimental thyroidectomy in mares and stallions, and hypothyroidism remains as a frequent consideration in breeding problems. In ruminants, a congenital goiter has been described in Merino sheep and in Afrikander cattle. Local enlargements or nodules are also observed in all animals, and these are usually benign tumors.

A. Goiter

Goiter may be defined as an enlargement of the thyroid gland, which is not due to inflammation or malignancy. There are two general types of goiters: (1) nontoxic goiters, which produce either (a) normal amounts of hormone (simple goiter) or (b) below normal amounts of hormone (hypothyroid), and (2) the toxic goiters, which produce excess amounts of hormone (hypertrophy). Furthermore, a defect or deficiency at any trophic step can also result in thyroid disease. Iodine deficiency (endemic goiter) is well known in iodine-deficient areas of the world. Goitrogenic materials, either natural substances or drugs, induce goiters by their blocking effects on steps in the hormonogenic pathways. There are also rare types of familial goiters associated with defects in hormone synthesis (dyshormonogenesis) in humans, which find their counterparts in Merino sheep (Rac *et al.*, 1968) and in Afrikander cattle (Van Zyl *et al.*, 1965). The congenital goiter in the Merino sheep is fundamentally a failure of thyroglobulin synthesis. The goiter is inherited as an autosomal recessive and is frequently seen in Australia. The similar congenital goiter in the Afrikander cattle (Ricketts *et al.*, 1985) is also inherited as an autosomal recessive. These cattle have a thyroglobulin synthesis defect involving defective gene splicing of the thyroglobulin gene transcript. In Bongo antelopes, goiter was observed in a group of adults, which was associated with synthesis of an abnormal 19S thyroglobulin (Schiller *et al.*, 1995). The goitrous antelopes were hormonally euthyroid but had other manifestations of hypothyroidism (e.g., reproductive difficulties). Iodine deficiency goiter was observed in seven Thoroughbred foals in the northern island of Hokkaido, Japan (Osame and Ichijo, 1994), which was attributed to iodine deficiency in the soil of the region. All foals had readily detectable thyroid enlargements, and four of the seven had clinical signs of thyroid deficiency as well. The goiters receded after iodine supplementation of the feed.

Simple goiter is a compensatory increase in thyroid glandular mass (hyperplasia and hypertrophy) so that the gland maximizes iodine uptake and is able to synthesize and release a normal amount of T_4. At this time, the patient is physiologically normal, but the gland can become quite large. Ultimately in iodine deficiency, the goitrous gland fails to synthesize sufficient T_4 and hypothyroidism occurs.

B. Hypothyroidism

Hypothyroidism may be the result of a variety of causative factors. Thyroiditis, with similarities to Hashimoto's thyroiditis in humans, has been reported in about 12% of beagle dogs (Beierwaltes and Nishiyama, 1968). Antithyroglobulin antibodies were found in these dogs. In the adult dog, follicular atrophy is probably the most common cause of hypothyroidism. Finally, hypothyroidism may be secondary to a pituitary insufficiency.

The hypothyroid dog is typically obese, lethargic, has myxedema, a dry skin, and a sparse hair coat. Hypothyroidism is therefore an important differential in the diagnoses of dermatoses. The requirement of T_4 for normal reproduction, growth, and development is well known, so hypothyroidism is an important differential in reproductive failures. Experimentally, thyroidectomized mares and stallions failed to grow; were lethargic, had coarse, dull hair coats; and had increased serum cholesterol (Lowe *et al.,* 1974). Hypothyroid horses tend toward obesity and crestiness.

In the initial screen, an increased cholesterol is often the first clue to hypothyroidism. Definitive laboratory findings in the hypothyroidism of animals are a low T_4 or T_3 with little or no response to the TSH response test. Therefore, the recommended algorithm is to first obtain the total T_4 and T_3 (and the fT_4 and fT_3 if available). If the results are equivocal, this is followed by the TSH response test. Other definitive studies such as the ^{99m}Tc-pertchnetate scans can be used in specialized hospital settings for the identification of isolated thyroid nodules.

In human thyroid disease diagnostics, TSH is now considered to be the single best test of thyroid status and more cost effective than T_4. TSH can now be readily assayed with a functional sensitivity of 0.01 to 0.02 mU/l. Because of this sensitivity, human thyroidologists now recommend that TSH be used as the initial test and that T_4 or preferably fT_4 be used only on a selected basis. In the dog, however, Kooistra *et al.* (2000) found that TSH in hypothyroid dogs was secreted in a pulsatile pattern. This may explain

the variations in TSH found in hypothyroid dogs, which detract from its usefulness canine hypothyroidism.

C. Hyperthyroidism

Hyperthyroidism or toxic goiter is characterized by weight loss, hyperactivity, a voracious appetite, and increased thyroid hormones. Hyperthyroidism is rarely observed in dogs, but in the cat, the high incidence of hyperthyroidism has been recognized as a common endocrinopathy (Peterson *et al.*, 1983). The most common form of hyperthyroidism in the cat is a functional thyroid adenoma.

Increases in T_4 or T_3 are virtually pathognomonic signs of hyperthyroidism in the cat. In 131 cases, T_4 was increased to between 4.0 and 54.1 μg/dl (51.5 to 696.3 nmol/l) in all cats, and T_3 was between 54 and 1000 ng/dl (0.83 to 15.36 nmol/l) in 97% of the cats (Peterson *et al.,* 1983). Hays *et al.* (1988) suggested that T_4 and T_3 are sufficient for diagnosis and that the free hormones are not needed for the diagnosis. In the 131 cases, the mean 24-h ^{131}I uptake was 39.1% as compared to 9.2% in normal cats. There was no increment of response above the baseline value to the TSH response test in these cats as would be expected of a tumor. ^{99}Tm-pertechnetate scans demonstrated increased uptake and size in one or both lobes of the thyroid.

D. Tumors of the Thyroid Gland

Except for the dog and cat, tumors of the thyroid occur infrequently in animals. About 20% of canine thyroid tumors are functional. Scintigraphic imaging is now used to identify functional thyroid tumors and their metastases. In feline hyperthyroidism, a functional thyroid adenoma is the most common finding.

Chapter 21

Clinical Reproductive Endocrinology

Håkan Andersson[1]
Department of Integrative Biology
Umea University
Umea, Sweden

I. INTRODUCTION

Clinical reproductive endocrinology includes the study of diseases and secretory status of the endocrine glands involved in reproduction and their secretory products, the reproductive hormones. To obtain a satisfactory understanding of the complex endocrinological events that occur during normal and abnormal reproductive function, it is necessary to quantify specific hormones.

Major progress in hormone analytical techniques occurred as the result of the development of immunoassay and related systems. The first of the assays, radioimmunoassay, was developed in the late 1950s (Berson and Yalow, 1959) with the competitive protein binding assay following a few years later (Murphy, 1964). Nonradiometric assays (e.g., enzyme immunoassay) were developed in the 1970s (Engvall and Perlmann, 1971; van Weemen and Schuurs, 1971). These assay systems have the characteristics of being sensitive, specific, relatively inexpensive, and requiring small amounts of assay material. They have been of special value for studying endocrinological reproductive function in domestic animals in that they have made possible the study of dynamic endocrine changes through the assay of serial blood samples from the same animal. The immunoassay systems have also been useful as diagnostic aids for identifying and elucidating clinical reproductive problems. In clinical practice, these methods are important from both a diagnostic and therapy-monitoring point of view.

Because this book deals with clinical biochemistry in domestic animals, this chapter emphasizes the determination of hormones and the use of the data as diagnostic aids. General reproductive endocrinology in domestic species is broadly covered. Readers specifically interested in this subject are referred to specialized books dealing with this matter.

A. Definition of Hormones

The best understood humoral control system in the body is the endocrine system. This system uses specific messengers, termed *hormones*, to regulate important body functions. By the classical definition, hormones are chemical substances synthesized and secreted by ductless endocrine glands in minute quantities directly into the blood vascular system and are transported to a remote target organ where they regulate the rates of specific biochemical processes. The classic endocrine glands include the pituitary, thyroid, parathyroid, adrenal, pancreas, ovary, testis, placenta, and pineal gland.

In the case of reproduction, the pituitary and pineal glands, the gonads, and the placenta play a primary role in controlling the system. Other endocrine glands such as the adrenal and thyroid glands also have some influence

[1]Revised and updated by Lars-Erik Edqvist and Mats Forsberg

on reproductive function. It has also been shown that other organs like the uterus and the hypothalamus, although they may not fulfill the strict requirement of being defined as endocrine glands, can synthesize and secrete hormones that have a profound influence on reproductive function.

B. Chemical Classes of Reproductive Hormones

1. *Peptide and Protein* Hormones

a. Releasing Hormones

Several types of hormones are involved in the regulation of reproduction. Releasing hormones are peptide hormones, which are produced within the hypothalamus and transferred via the hypothalamo-hypophyseal portal veins to the adenohypophysis, where they regulate the synthesis or release of adenohypophyseal hormones. Gonadotropin-releasing hormone I (GnRH), a decapeptide with the sequence pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2, regulates the release of two important reproductive hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). A conserved second GnRH (GnRH-II) form exists in some mammals but appears not to have importance for gonadotropin release (Millar, 2005). Thyrotropin-releasing hormone, a tripeptide (pGlu-His-Pro-NH_2), which regulates the synthesis and release of thyroid-stimulating hormone (TSH), also causes the release of prolactin in several species.

GnRH is released in a pulsatile fashion, where the frequency of peaks varies according to reproductive status (see Clarke and Pompolo, 2005). Recently discovered neuropeptides have shed some light on the central regulation of GnRH release. Kisspeptin (or mestatin) and its receptor (G protein-coupled receptor 54) are expressed in the hypothalamus in close connection with GnRH-neurons. Kisspeptin is regulated by sex steroids and can directly activate GnRH neurons and induce GnRH secretion; thus it may be an important regulator of the reproductive axis and puberty (Seminara, 2005). First discovered in birds (Tsutsui *et al.*, 2000), gonadotropin-inhibiting hormone (GnIH) has also been demonstrated in mammals, where its hypothalamic localization, association with steroid receptors, and inhibiting effect on gonadotropin secretion suggest an important role in the reproductive axis (Kriegsfeld *et al.*, 2006).

b. Hypophyseal Hormones

Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are glycoproteins containing 13% to 25% carbohydrate. The molecular weight of LH in domestic animals (bovine, ovine, porcine, equine) is about 30,000. Ovine and equine FSH have molecular weights of about 32,000. Prolactin is a protein with a molecular weight of approximately 23,000 (bovine, ovine, porcine). Luteinizing hormone and FSH, as well as TSH, consist of two nonidentical subunits designated α and β. Within a species, the α-subunit is identical for these glycoprotein hormones, whereas the β-subunit is unique for each hormone and determines the biological activity. Individual subunits by themselves possess little or no biological activity and are probably not released into the circulatory system under normal physiological conditions.

The cells of the adenohypophysis can be divided into basophiles (affinity for basic stains) and acidophiles (affinity for acid stains). Luteinizing hormone and FSH are produced within basophilic cells; it has been demonstrated that LH and FSH can be present within the same cell (the gonadotrope). Prolactin, on the other hand, has been localized in acidophilic cells. Gonadotropes have G protein-coupled GnRH-receptors on their surface, and the secretion of LH and FSH during the ovarian cycle is controlled by changes in the frequency of GnRH pulses. Except during the preovulatory LH surge in the estrus cycle, there is a clear difference in the patterns of FSH and LH secretion, as measured in the peripheral circulation, and only LH is released in a clear pulsatile manner reflecting GnRH secretion (see Pawson and McNeilly, 2005).

c. Neurohypophyseal Hormones

The posterior pituitary is responsible for storage and release of oxytocin, an important reproductive hormone, and antidiuretic hormone (vasopressin). These two hormones are synthesized primarily in the regions of the paraventricular nucleus and supraoptic nucleus of the hypothalamus. The hormones are transported to the posterior pituitary by axoplasmic fluid. Release of these hormones occurs as a result of stimulation of the nerve cell bodies in the nuclei. Oxytocin is an octapeptide with a molecular weight of 1000.

d. Gonadal Activins and Inhibins

Activins and inhibins are structurally related proteins belonging to the transforming growth-factor-β (TGF-β) superfamily and have impact on the endocrine reproductive axis. Inhibins and activins are made up of two peptide chains. Inhibins form α-β dimers and activins β-β dimers. There are two varieties of the β-unit (called A and B) producing two forms of inhibin, inhibin A (α-βA), and inhibin B (α-βB), and three forms of activin, activin A (βA-βA), activin B (βB-βB), and activin C (βA-βB). Activins and inhibins secreted from the gonads act antagonistically on the gonadotropes to regulate FSH release. In the female, activins have several autocrine/paracrine functions in reproductive tissues and ovary activin A has been indicated as an endocrine stimulator of FSH release. In the male, inhibin is produced by Sertoli cells and function as a negative feedback regulator of pituitary FSH, probably in synergy with testosterone. In most species (e.g., bull, boar, and stallion), the dominant testicular form is inhibin B, whereas in the ram, inhibin A appears to be the dominant inhibin of the testicles of adult males (McNeilly *et al.*, 2002).

e. Placental Gonadotropin

A gonadotropin, renamed equine chorionic gonadotropin (eCG) because of its close relationship with human chorionic gonadotropin (hCG) (Farmer and Papkoff, 1979), was formerly called pregnant mares' serum gonadotropin (PMSG) and is produced by mares during early pregnancy (day 40 to 140) by fetal trophoblastic cells of the chorionic girdle, which attach to, invade, and phagocytose the maternal epithelium and become embedded within the uterus as specialized endometrial cups. This process begins on day 36 of pregnancy. No specific placental gonadotropins have been demonstrated in other domestic species.

2. *Steroid Hormones*

Steroid hormones are derived from a common precursor molecule, cholesterol, via the metabolic pathway schematically outlined in Figure 21-1. More than 1500 biologically active steroids have been isolated from biological material or have been produced synthetically. The molecular weight of steroid hormones is low, usually below 500 (Table 21-1). Examples of steroids that play an important role in reproductive processes are estrogens, androgens, and progestagens, with the main source being the gonads. The structure of the most important sex steroids is presented in Figure 21-2. The most common steroid hormones are usually designated by a trivial name (e.g., estradiol, testosterone, or progesterone). The International Union of Pure and Applied Chemistry (IUPAC; www.iupac.org) has recommended systemic names for steroid hormones. These systemic names describe the chemical and stereoisomeric characteristics of the particular steroid hormone (Table 21-1).

3. *Prostaglandins*

Prostaglandins constitute a group of 20-carbon unsaturated fatty acids with molecular weights usually between 300 and 400 (Table 21-1). Prostaglandins are not hormones

TABLE 21-1 Nomenclature and Molecular Weights of Some Biologically Important Steroids and Prostaglandins

Trivial Name	Systematic Name	Molecular Weight
Androstenedione	4-Androstene-3, 17-dione	286
17β-Estradiol	1,3,5(10)-Estratriene-3, 17β-diol	272
Estrone	3-Hydroxy-1,3,5(10)-estatrien-17-one	270
17α-Hydroxyprogesterone	17α-Hydroxy-4-pregnene-3,20-dione	331
Pregnenolone	3β-Hydroxy-5-pregnen-20-one	317
Progesterone	4-Pregnene-3,20-dione	315
Testosterone	17β-Hydroxy-4-androsten-3-one	288
$PGF_{2\alpha}$	9α,11α,15-Trihydroxyprosta-5, 13-dienoic acid	354
15-Keto-13, 14-dihydro-$PGF_{2\alpha}$	9α,11α,Dihydroxy-15-ketoprost-5-enoic acid	354

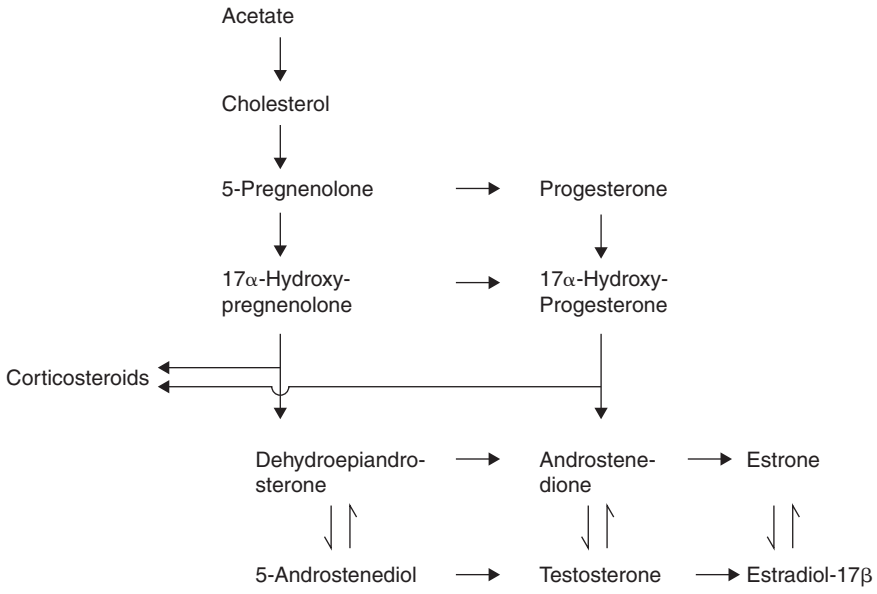

FIGURE 21-1 Pathway for the synthesis of biologically active steroids from acetate. The steroids secreted from the gonads and the adrenals are formed from acetate and cholesterol.

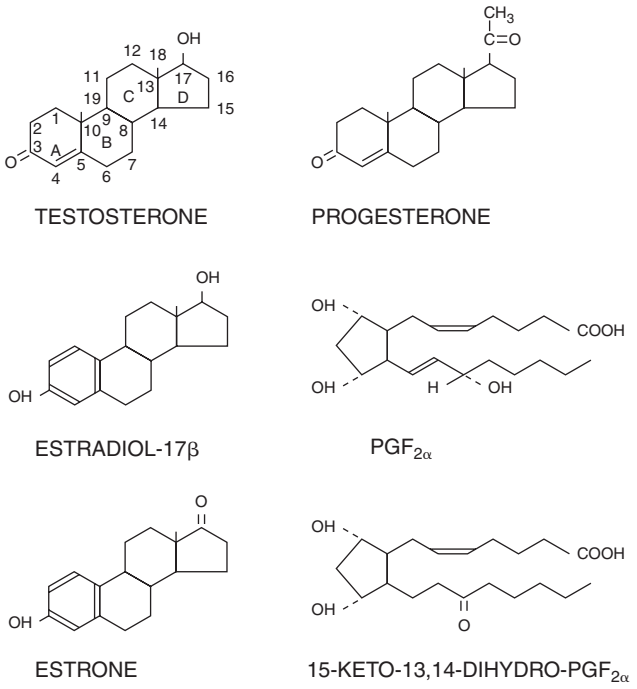

FIGURE 21-2 The number of sequence for the carbon atoms of the steroid skeleton and lettering sequence for the four rings are shown for testosterone. The structures of three other important sex steroid hormones, estrone, estradiol-17β, and progesterone, as well as the structure of prostaglandin $F_{2\alpha}$ and its blood plasma metabolite 15-keto-13,14-dihydro-prostaglandin $F_{2\alpha}$ are also depicted.

in the strictest sense, and the expressions "paracrine factor" or "local hormones" have been used to describe these substances. This is because prostaglandins are not secreted from any particular gland and the biological half-life of prostaglandins is usually extremely short, allowing, in most cases, only a local action. Several different prostaglandins are found in a number of types of mammalian tissues. One prostaglandin released from the uterus, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), plays an important role in regulating reproductive cycles in domestic species through the control of luteal activity in nonpregnant animals and the initiation of delivery in pregnant animals. The structures of prostaglandin $F_{2\alpha}$ and its main metabolite, 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$, are presented in Figure 21-2.

C. Hormone Receptors

Because steroid hormones are fat soluble, they are able to enter all cells of the body as the lipid cellular boundaries present no barrier. Steroid hormone concentrations in plasma are very low as compared to many compounds including their important precursor, cholesterol. For example, plasma estrogens in nonpregnant domestic animals range from as low as 10 pmol/l to as high as 150 pmol/l. In this situation, most cells within the body have very low concentrations of estrogen. The specificity of tissue response occurs because cells of tissues that have need of estrogen stimulation should have receptors that enable those particular cells to concentrate the hormone within the cell and, more important, to elicit particular cellular responses. This explains the important generalization that specific tissue response requires specific receptors to be present within the cell, in this case for a particular steroid hormone.

Binding of a hormone to a receptor in a target cell can be considered to be the primary event and the hormone receptor interaction will cause a measurable biological response that differs for different hormones. Receptors have a limited binding capacity (receptors are saturable thus limiting number of hormone molecules that can enter a target cell), they bind specific hormones (e.g., estrogen receptors are specific for estrogenic compounds), and upon binding a biological response will be created.

Steroid hormones enter cells by passive diffusion and bind to receptors inside the cell. It is assumed that only nonprotein bound or free hormone can enter target cells. Traditionally, the steroid bound irreversible to the carrier protein have been considered to be virtually biologically inactive and only the minute quantity of free (nonprotein bound) steroid can enter the cell. However, studies suggest that sex steroids bound to the sex hormone-binding globulin can be internalized and as the carrier is degraded by lysosomes, the steroids are released to induce steroid-responsive genes (Hammes *et al.*, 2005). When the steroid interacts with its receptor, a steroid-receptor complex is formed. The hormone-receptor complex is then activated and alters gene expression. The target cell responds by increased RNA synthesis with the transcription of specific mRNAs, which enters cytoplasm and stimulates protein synthesis. The specific effect of steroid hormones on target cells is an altered cell function related to a change in the pattern of protein synthesis. In addition to this classical genomic steroid action, rapid effects (within minutes) of steroid have also been described (see Bramely 2003; Kelly and Wagner, 1999).

Protein hormones like GnRH, LH, and FSH do not enter the target cell to exert their effects but interact with their receptors, which are located on the plasma membranes of the cell, s.c. G protein-coupled receptors. The binding of the hormone to the cell surface receptor activates second messenger(s), for example, cyclic AMP (3′,5′-AMP). The second messenger(s) is the intracellular mediator of many actions of LH and FSH in the ovary and the testis. The second messenger(s) is thought to activate another intracellular enzyme, protein kinase, which will influence the transport of cholesterol into the mitochondrion and the conversion of cholesterol to pregnenolone, which is the rate-limiting step in the biosynthetic pathway for the steroids that play a significant role in reproductive processes.

D. Local Conversion of Steroids in Target Tissues

The effects of steroid hormones on cells can be accentuated or modulated by the conversion of the entering hormone

to another form. For example, many of the tissues that are particularly responsive to androgens have the enzyme 5α-reductase that converts testosterone to 5α-dihydrotestosterone (5α-DHT); 5α-DHT has a much higher affinity for the androgen receptor within the target cell, which makes 5α-DHT more biologically active than testosterone as to its androgenic effects. The androgenic potency of 5α-DHT is twice that of testosterone.

Another important interconversion of steroid hormones is the one resulting from the increase in circulating cortisol concentrations that occur in the fetal lamb before parturition. The elevated fetal cortisol concentrations stimulate 17α-hydroxylase, C17-C20 lyase activity, and probably aromatase activity in the plaxcenta. This makes it possible for progesterone to be converted to estrogen synthesis in the placenta. Estrogens then affect the synthesis of prostaglandin $F_{2\alpha}$, which precipitates delivery. The interconversion of progesterone to estrogen is well documented in the sheep and probably also occurs in a similar way in the goat and the cow.

E. Synthesis and Clearance of Hormones

The determination of concentrations of hormones in biological fluids including plasma, urine, saliva, milk, and feces has been useful in determining the reproductive status of animals. Although a number of factors can influence hormone concentrations, the overriding factors are synthesis and clearance. We are usually concerned about the rate of synthesis of a hormone from a particular endocrine gland because factors that govern clearance are usually stable, and the concentration of the hormone usually reflects the rate of synthesis or secretion.

The synthesis of steroid hormones of the reproductive system is under the control of gonadotropins, which are released in pulsatile fashion. This has a profound influence on the secretion of testosterone in the male in that changes in pulsatile rate can occur a number of times a day with increases in pulse rate resulting in greatly increased concentrations of testosterone. For example, in males of many domestic species, testosterone values can range from 3.5 to 20 nmol/l within a period of a few hours with the extremes still representing normal production of testosterone by the testes. The usual judgment as to normalcy is based on an animal having at least the minimal or basal concentration. In the female, estrogen and progesterone synthesis by the ovary is also under the control of a pulsatile mode of gonadotropin secretion. The pulse rate usually remains relatively stable over certain periods of time so that fluctuations in concentration of these hormones are not as acute as for androgens.

In the female, synthesis rates for ovarian steroid hormones are obviously related to ovarian function. Progesterone concentrations, relatively stable during the luteal phase of the estrus cycle, decline rapidly over a 24- to 36-h period during luteolysis. Estrogen values continually increase during the follicular phase of the cycle, declining with the onset of the gonadotropin preovulatory surge as the granulosa is converted from estrogen to progesterone production. Even though secretion rates can change for both progesterone and estrogen, analysis of these hormones usually brings useful information as to luteal or follicular activity, respectively. One other factor must be considered if one wishes to use hormone values (in blood, for example) as an indication for secretory activity of an endocrine organ (i.e., the conversion of steroid hormones by peripheral tissues). For example, in primates, estrone concentrations are derived mainly from the conversion of ovarian estradiol-17β and adrenal androstenedione by tissues such as the liver.

Steroids are eliminated via conjugation with glucuronic acid or sulfates to form inactive mono- or diglucosiduronates or sulfates. These conjugates are all water soluble with excretion occurring via urine or bile (feces). The conjugation occurs mainly in the liver, and the conjugates formed lack steroidal activity. Steroids are also rendered inactive by their metabolism to compounds that have greatly reduced biological activity. In this way, steroids are rapidly cleared from the bloodstream. Clearance is defined as the volume of blood that would be totally cleared of a particular steroid per unit time. Clearance can thus be expressed as liters/minute, and the clearance for most steroid hormones is around 1 liter/minute. In most situations, the clearance rate of steroids is relatively constant, so that blood concentrations are a fairly good measure of fluctuations in production rates.

Placental gonadotropic hormones like hCG and eCG are produced in high concentrations and have much longer half-lives than the pituitary gonadotropins and prolactin. The latter have half-lives that are around 10 to 30 min, whereas the corresponding figures for the placental hormones are from 1.5 days for hCG to 6 days for eCG. One exception is equine LH, which shows structural similarities to eCG and also has a much longer half-life (days) than LH from other species. The increased half-lives are due to the fact that the molecules are composed of a larger portion of carbohydrate moiety as compared to FSH and LH of most species.

In the blood circulation, prostaglandins are rapidly metabolized to their respective 15-keto-13,14-dihydro compounds (Fig. 21-2). Primary prostaglandins like $PGF_{2\alpha}$ have a half-life in the peripheral circulation that is less than 20sec, whereas the 15-keto-13,14-dihydro-$PGF_{2\alpha}$ have a somewhat longer half-life of about 8 min; 90% or more of $PGF_{2\alpha}$ is metabolized by one passage through the lungs. The 15-keto metabolites are biologically inactive, and before being excreted into urine they are degraded into short dicarboxylic acids (Neff *et al.*, 1981).

II. ASSAY METHODS

The radioimmunoassay (RIA) technique was originally introduced for the measurement of plasma insulin (Berson and Yalow, 1959) and the enzyme immunoassay (EIA)

techniques for the quantitative determination of immunoglobulin G (Engvall and Perlmann, 1971). The techniques are competitive and utilize the same basic principle, which is based on the ability of nonlabeled hormone to compete with a fixed amount of labeled (radioactive isotope or enzyme) hormone for the binding sites on a fixed amount of protein. The nonlabeled hormone reduces the number of free binding sites on the protein, thus decreasing the availability of the binding sites to the labeled hormone. At equilibrium, the free hormone is separated from the protein-bound hormone, and the reaction is quantified by the determination of the amount of labeled hormone that is antibody bound or free (Fig. 21-3). The degree of inhibition of binding of the labeled hormone to the binding protein is a function of the concentration of nonlabeled hormone present in the solution. As a basis for the quantification, a standard curve is developed with fixed amounts of labeled hormone and binding protein incubated together in the presence of a known and graded concentration of unlabelled hormone (Fig. 21-3).

Certain disadvantages exist to the use of radioisotopes as labels in immunoassays. Among those are limited shelf life and stability of radiolabel compounds, need for relatively expensive counting equipment (especially for tritium-labeled

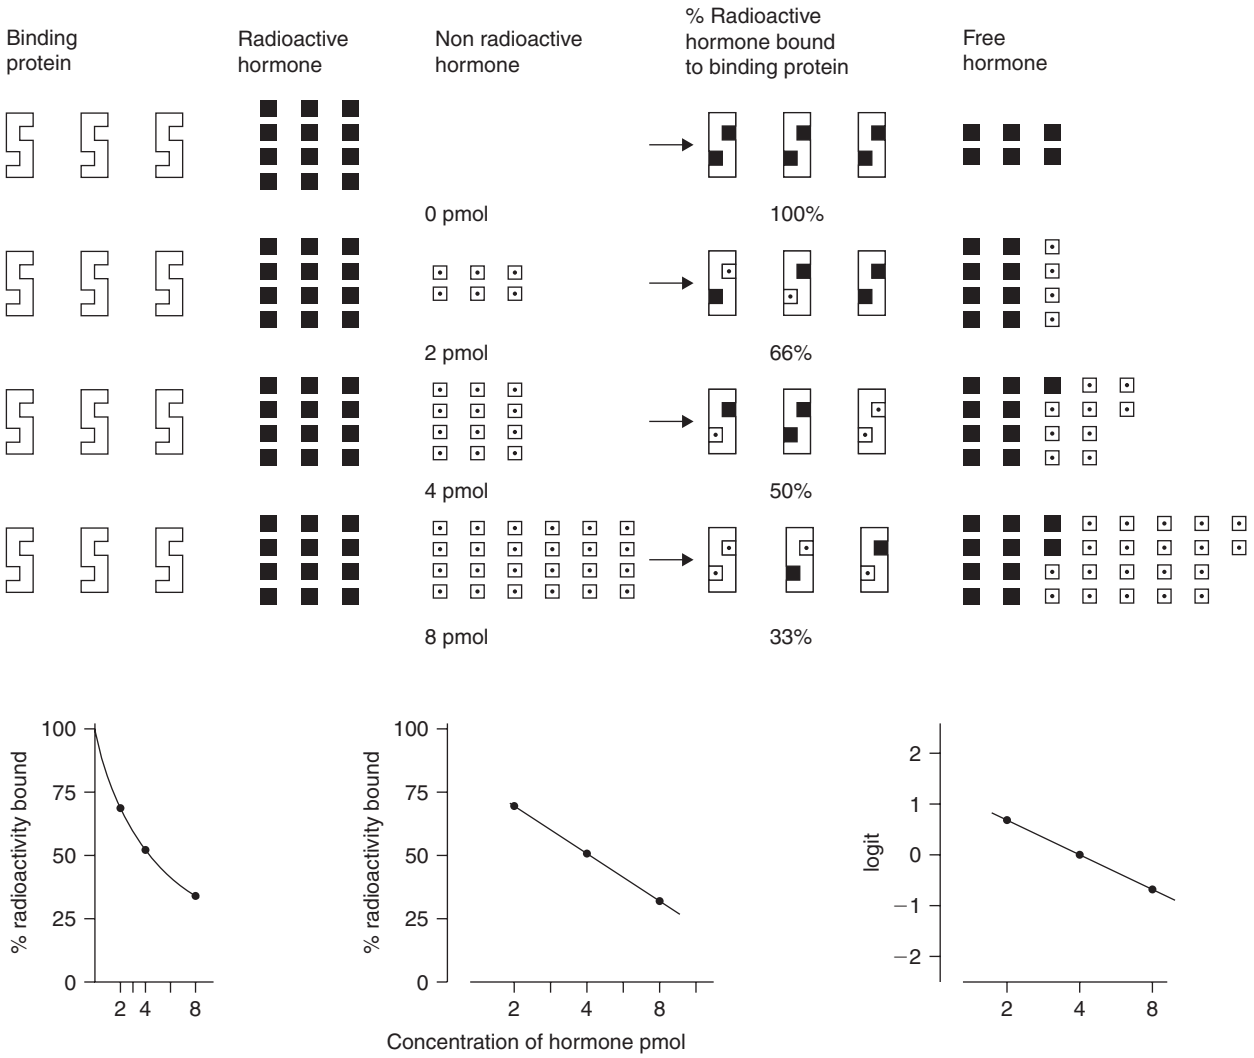

FIGURE 21-3 The principle of an immunoassay technique is based on the ability of the binding protein to bind the labeled hormone. Excess-labeled hormone as added to ensure saturation of the hormone-binding sites on the binding protein. The addition of increasing amounts of nonlabeled hormone (2,4, and 8 pmol) results in a proportional decrease in the quantity of labeled hormone bound to the binding protein. Separation of labeled hormone bound to the binding protein from free hormone must be achieved before quantification can be done. In the lower part of the figure, this reaction is depicted in three different ways. In the panel to the left and in the middle, the percentage-labeled hormone bound to the binding protein is on the ordinate, and the amount of hormone on a linear scale (left) and log scale (middle) is on the abscissa. In the panel to the right, the logit of the response variable is on the ordinate, and the amount of hormone is plotted on a log scale. The method depicted in the middle and to the right can be used for determination of parallelism. The logit/log transformation (right) is frequently used when computers analyze immunoassay data.

compounds), need for well-trained personnel and specialized laboratory, and problems in disposal of radioactive waste. Consequently, great progress has been made to develop assays that use nonisotopic labels such as enzymes, fluorogens, and chemiluminescent precursors. Enzyme immunoassays can be as sensitive, accurate, and precise as radioimmunoassays; the specificity depends on the quality of the antibody as is true for radioimmunoassay systems (Munro and Stabenfeldt, 1984). Of particular interest in domestic animals has been their use in the determination of progesterone in blood (Lopate and Threlfall, 1991; Meyers *et al.*, 1988; Munro and Stabenfeldt, 1984) and in milk (Allen and Foote, 1988; Arnstadt and Cleere, 1981; Etherington *et al.*, 1991; Sauer *et al.*, 1981). Enzyme immunoassay in the laboratory setting is very efficient, particularly as concerns the time required for the assay reaction (2h or less), ease of separation of bound from free hormone when using microtiter plate system (30 sec to wash 96 wells on a microtiter plate), and speed of end point analysis (optical densities can be determined in 1min for a 96 well microtiter plate).

Among the various approaches to enzyme immunoassay, the double antibody sandwich method for determination of larger hormones is frequently used. In this assay system, the plastic wells are coated with antibody. The sample to be processed is then added, and its hormone binds to the antibody-coated plastic well. A second enzyme-labeled antibody directed against another epitope of the hormone is then added. The amount of enzyme-labeled antibody bound is directly proportional to the amount of hormone in the sample. There are two advantages with this methodology: (1) the hormone does not need to be isolated for labeling, and (2) the same general technique can be used to label different antibodies. The method can only be used to assay hormones with at least two binding sites, and it is thus unsuitable for measurement of low-molecular-weight hormones like steroid hormones.

The analytical equipment used for enzyme immunoassay can be used for a variety of determinations including those involved in disease surveillance and drug analysis. This allows for the sharing of one specialized spectrophotometer among several disciplines at a great reduction in cost. Another benefit is that the analytical equipment needs little maintenance. The elimination of the problems engendered by use of radioisotopes is a major advantage for enzyme immunoassay. This and the fact that color change is fundamental to enzyme immunoassay means that the assay can be used visually to determine the presence or absence of a corpus luteum (CL) in domestic and other species. Enzyme immunoassay-based analytical systems for progesterone in blood or milk can be used on the farm beside the animal to directly assess the functional ovarian status of an animal (Herrler *et al.*, 1990; Matsas *et al.*, 1992; Nebel *et al.*, 1989; Romagnolo and Nebel, 1991).

Automatized immunoassay instrumentation has been developed mainly for the human medical market, but some systems have specific veterinary applications (e.g., chemiluminescent-labeled immunoassays by DPC), and as some hormones (e.g., steroids) cross-react between species, these automatized immunoassay instruments can be useful in a veterinary diagnostic lab with high throughput.

A. Immunoassay

1. *Production of Antibodies*

Immunoassay techniques utilize antibodies as binding proteins. Hormones such as LH and FSH, which are glycoproteins with molecular weights of around 30,000, are antigenic because of their size and chemical composition. In general, a lower level of purity is required of the polypeptide hormones for antibody production as compared to the hormone used in the labeling procedure.

If an assay for bovine LH utilizes an antibody to bovine LH, radio- or enzyme-labeled bovine LH as tracer, and bovine LH as the standard, the assay system is completely species specific and is said to be of the homologous type. Such a system represents the ideal immunoassay system for measuring a polypeptide hormone. Because of the limited availability or lack of suitable purity of polypeptide hormone preparations, heterologous assay systems have been developed. In these cases, an antiserum to a polypeptide hormone of one species has been used to determine the same polypeptide hormone in another species. The standard hormone used for quantification of the assay should, however, originate from the same species for which the measurements are performed.

Polypeptide hormone antisera are available that show a high degree of cross-reactivity. One such antiserum of special interest in the field of reproductive hormones in domestic species is a polyclonal LH antiserum raised against ovine LH (Niswender *et al.*, 1969). This antiserum reacts specifically with LH from other species and has been used to determine LH in approximately 45 species including the cow, sheep, pig, cat, and dog (Madej and Linde-Forsberg, 1991; Millar and Aehnelt, 1977). A monoclonal antibody generated against bovine LH has been reported to have high cross-reactivity between species (Bravo *et al.*, 1992; Forsberg *et al.*, 1993b; Matteri *et al.*, 1987).

Steroid hormones and prostaglandins have considerably lower molecular weights and thus are not immunogenic per se. However, these structures can be rendered immunogenic if covalently linked to large carrier molecules such as bovine serum albumin, and specific antibodies can be elicited. For such a hormone-protein conjugate to be immunogenic, approximately 10 to 20 hormone molecules should be present per molecule of protein. In the case of bovine serum albumin, about 30% of the sites available for conjugation should be occupied.

Most naturally occurring steroid hormones and prostaglandins contain hydroxyl or ketone groups, which are used

to prepare derivatives containing active groups such as carboxyl or amino groups. These groups are then activated so that they react with amino or carboxyl groups of the protein molecule. The specificity of the antisera obtained by immunization with a steroid-protein conjugate depends on the site used for conjugating the steroid to the protein. More specific antisera are obtained if the hapten (steroid) is attached to the protein at a site remote from the characteristic functional groups of the hormone (Lindner *et al.*, 1972).

The species most frequently used to produce polyclonal antibodies are sheep and rabbits. One of the most popular and efficient schedules for immunization involves multiple injections in the back and neck of the animal of the antigen emulsified in complete Freund's adjuvant (Vaitakaitus *et al.*, 1971). During immunization, the developing antibody titer is monitored, and a relatively large number of milliliters of serum can be obtained when a suitable titer has been achieved. A few milliliters of a high titer antiserum are usually sufficient for millions of immunoassay determinations. Antisera seem to be stable when stored at −20°C, although the usual preferred temperature is −70°C.

The discovery that hybridomas could be used to produce an endless supply of antibodies with certain specificity (Köhler and Milstein, 1975) led to a new development in the technology of antibody production. The procedure involves the fusion of two cell lines: B lymphocytes selected for the production of a specific antibody and myeloma cells that have the capacity for permanent growth. Antibody production occurs by injection of the cell lines into mice; permanency is assured by maintaining a supply of cells in the frozen state. Monoclonal antibodies are useful for the quantitative immunoassay of hormones. They have the advantages of specificity, unlimited supply over time, and the possibility to standardize assay methods between laboratories; disadvantages are that they have lower affinities as compared to polyclonal antibodies and they do not always form precipitates with antigens. Mixing of monoclonal antibodies may increase affinity (Ehrlich *et al.*, 1982).

2. *Labeled Hormone*

In radioimmunoassay techniques for polypeptide hormones, the antigen (hormone) is most commonly used for preparing the radioactive tracer. Usually, radioactive iodine, ^{125}I, is used for radioiodination of the antigen. The two most frequently used techniques for iodination are the chloramine-T (Hunter and Greenwood, 1962), immobilized chloramine-T (Iodobeads; Markwell, 1982), and the lactoperoxidase procedures (Thorell and Johansson, 1971). Peptide hormones containing tyrosyl or histidyl residues can also be iodinated with these techniques.

Many RIA systems for steroid hormones and prostaglandins utilize tritiated forms of these molecules, which are available commercially. Because tritium has a considerably longer half-life than iodine, tritium tracers can be used in many cases over several years, whereas the iodinated tracers often have to be prepared monthly. There are, however, certain advantages in using iodinated tracers for steroid hormones and prostaglandins in that simpler and cheaper counting systems can be used (i.e., gamma counting as opposed to liquid scintillation counting). Another advantage of radioiodine over tritium is its higher specific activity, which increases the sensitivity of the assay. Direct incorporation of iodine in the skeleton of steroid hormones results in a loss of the immunoreactivity. Thus, the approach taken for radioiodination of steroid hormones has been to link a tyrosyl or histidyl molecule to the steroid molecule, making direct radioiodination possible (Niswender, 1973), or to iodinate a compound such as tyramine and conjugate the iodinated compound to the steroid molecule (Lindberg and Edqvist, 1974).

Most EIA systems for steroid hormones use horseradish peroxidase, alkaline phosphatase, or β-galactosidase as labels. The enzyme-labeled steroid is produced the same way as has been described for the synthesis of steroid protein conjugates for the production of antibodies.

3. *Separation of Antibody-Bound and Free Hormone*

An essential part of any immunoassay system is an efficient procedure for the separation of antibody-bound and free hormone. Several different approaches have been taken to achieve a rapid and efficient separation. Frequently used separation procedures are based on antibodies coupled to an insoluble polymer, precipitation of antibodybound hormone, or adsorption of free hormone.

Antibodies coupled to an insoluble polymer can be used for separating antibody-bound and free hormone in RIA procedures (Abraham, 1969). One procedure involves the decanting of polystyrene tubes in which antibodies have been adsorbed to the surface of the tube, which is followed by determination of radioactivity in the antibody-bound (contained in the tube) or free (contained in the eluent) form. In most EIA systems designed for low-molecular-weight hormones, antibody-bound hormone is measured after free hormone has been removed by washing the wells of the microtiter plate that have been previously coated with antibody.

Another common procedure for RIA utilizes antibodies covalently coupled to an insoluble polymer granule. In this case, free and antibody-bound hormones are separated through centrifugation. After removal of the supernatant containing the free hormone, the antibody-bound radioactivity can be determined. Antibody-coated glass beads have been used in both RIA and EIA (Schmidt *et al.*, 1993). Separation is achieved by washing the bead and then the radio or enzyme activity is determined.

Precipitation of the antibody-bound hormone has been achieved through the addition of ammonium sulfate (Mayes

and Nugent, 1970) or polyethylene glycol (Desbuqois and Aurbach, 1971), leaving the free hormone in the solution. The latter precipitation procedure has been found advantageous for the precipitation of prostaglandin antibody complexes (Van Orden and Farley, 1973). Precipitation of the antibody-bound hormone complexes can also be achieved through the addition of a second antibody prepared against the first antibody. Thus, in an RIA technique for bovine LH that utilizes an antiserum to bovine LH raised in a rabbit (first antibody), the second antibody will be an antibody prepared against rabbit gammaglobulin. The addition of the second antibody will result in a precipitate containing the antibody-bound LH, which can be separated from the supernatant by centrifugation. The time required for the separation can be decreased by the addition of polyethylene glycol (Eisenman and Chew, 1983). Systems using a second antibody coupled to insoluble particles are efficient and commonly used (Dericks-Tan and Taubert, 1975; Forsberg *et al.*, 1993b).

For steroid hormones, a traditional separation procedure is the adsorption of free hormone to dextran-coated charcoal. After the addition of the charcoal, the separation of free and antibody-bound steroids is achieved through centrifugation. This method is rapid and efficient in separating free and bound steroid hormones. However, the charcoal can also adsorb some of the antibody-bound steroid, which is called "stripping." To control this, timing of the reaction is important.

4. *Reliability Criteria*

The reliability of immunoassay analyses depends on its specificity, sensitivity, accuracy, and precision.

a. Specificity

The specificity of an immunoassay, or freedom from interference by substances other than the one to be measured, depends on several different factors, the most important being the specificity of the antiserum used. Demonstration of specificity for the immunoassay of hormones that cannot easily be synthesized is relatively difficult and relies on indirect criteria because these molecules have to be isolated and purified from biological material with variable purity.

A relatively common finding is the cross-reaction of TSH with antibodies to LH, and vice versa. Antibody specificity is usually demonstrated by testing the binding of hormones, other than the one intended to be measured, to the antibody. If, for example, bovine TSH significantly inhibits the binding of bovine LH to an antibody to bovine LH, this indicates that the antiserum used is nonspecific or that the TSH preparation contains LH. If the inhibition curves are parallel, the latter explanation is likely because the parallelism indicates the same binding kinetics. It should be noted that parallelism, in itself, is not adequate proof of specificity. As indicated previously, both LH and TSH are composed of two subunits, an α-subunit that is identical for the two hormones and a β-subunit that is unique for each hormone. It is possible that an antiserum could contain binding sites, which will react only with the α-subunit. In such a case, the dose-response curve of LH and TSH utilizing such an antisera will be parallel, the assay system will not be hormone specific, and thus the system will be invalid for the measurement of LH. Double antibody sandwich methods utilizing monoclonal or polyclonal antisera can partly reduce the problem.

In the case of immunoassay techniques for steroid hormones and prostaglandins, the same proof of specificity has to be undertaken. Here the situation is simpler, because small-molecular-weight hormones can easily be purified and, in most cases, produced synthetically more easily.

Some idea as to the specificity of an antiserum to a steroid hormone can be gained from the position of the steroid molecule that is used as the anchoring point to the protein (Fig. 21-2). If an antiserum to estradiol-17β is produced through the use of an antigen conjugated via the hydroxyl group at carbon 17 of the steroid, the resulting antiserum will react almost equally well with estrone and thus would have relatively poor specificity. This is because the only structural difference between the estradiol-17β and estrone molecules is the configuration at position 17 (Fig. 21-2). In general, steroid antibodies are more specific for the portion of the steroid molecule that protrudes from the carrier protein and less specific for the portion of the steroid used for linkage to the protein. Thus, in the case of estradiol-17β, highly specific antibodies have been developed after immunization with conjugates when carbon 6 of the B ring has been used as the site of attachment to the protein (Exley *et al.*, 1971).

Protein hormone determination by immunoassay is often performed in blood serum or plasma. The influence of serum or plasma on the binding of the tracer to the antibody must be investigated. The assay of different amounts of serum or plasma should result in curves parallel to those obtained with protein hormone standard. In some steroid hormone immunoassays, an organic solvent from a blood plasma sample extracts the hormone. Organic solvents can also be used as a means to selectively remove steroids from biological fluids. For example, many immunoassay procedures designed to measure progesterone utilize antisera developed against a progesterone-11 protein conjugate, which results in a minor cross-reaction with corticosteroids (Thorneycroft and Stone, 1972). By using a nonpolar solvent such as petroleum ether for the extraction of progesterone from serum or plasma samples, about 80% to 90% of progesterone is extracted leaving the more polar corticosteroids in the plasma (Johansson, 1969). The use of such a selective extraction system increases the overall assay specificity. Direct analytical systems for steroid hormones omitting the extraction step are also employed. Because steroid hormones in a blood sample to be analyzed are bound to carrier proteins, direct assay systems have to secure that all steroid molecules, both free and protein-bound

steroids in the sample, are given equal opportunities to interact with the antibody used in the assay. The synthetic steroid danazol (17α,2,4-pregnandien-20-yno(2,3-d)isoxazol-17ol) can be used to displace progesterone from the binding proteins (Carrière and Lee, 1994).

Certain immunoassay systems may require purification of the plasma extract to achieve an acceptable specificity.

The main problem in the immunoassay of primary prostaglandins is that they can continue to be formed in large amounts by platelets after the blood sample has been obtained (Samuelsson *et al.*, 1975), thus the concentrations of $PGF_{2\alpha}$ reported in blood serum or plasma can appear much higher than the actual values. The primary prostaglandins have a very short half-life in the circulation (Hamberg and Samuelsson, 1971) and are rapidly converted to their corresponding 15-keto-13,14-dihydro derivatives. The latter have considerably longer half-lives and occur in higher concentrations than the parent compounds (Beguin *et al.*, 1972). Analysis of metabolites of prostaglandin $F_{2\alpha}$ avoids the problem of the overestimation observed for the parent compound in that the metabolites are formed only within the body and values thus remain stable once a blood sample has been obtained. Radioimmunoassay systems utilizing antibodies to 9α,11α-dihydroxy-15-ketoprost-5-enoic acid and 5α,7α-dihydroxy-11-ketotetranorprosta-1,16-dioic acid have been developed (Granström and Samuelsson, 1972). Most problems involved in the determination of the primary prostaglandins are avoided if their main metabolites, the 15-keto-13, 14-dihydro compounds, are measured.

b. Sensitivity

The sensitivity of immunoassays is defined as the smallest quantity of hormone that the assay can reliably distinguish from a zero amount of the hormone. Usually two kinds of sensitivity are evaluated. The sensitivity of the standard curve is defined as the smallest amount of hormone that is significantly different from zero at the 95% confidence limit. However, the most meaningful sensitivity to establish is the smallest amount of hormone that can be measured per unit of biological fluid (e.g., per milliliter of blood plasma).

c. Accuracy

The accuracy of an assay is defined as the extent to which the measurement of a hormone agrees with the exact amount of the hormone. Accuracy is often determined by comparing immunoassay data with values determined by other procedures such as gravimetry, gas liquid chromatography, and mass spectrometry. For steroid hormones and prostaglandins, accuracy is also often determined by recovery experiments in which different amounts of hormones are added to a biological fluid (e.g., blood plasma), which contains low concentrations of the hormone; the amount of hormone measured in the assay is then compared with the amount of hormone added.

d. Precision

Two types of precision are usually evaluated. The within-assay precision is determined from duplicate measurements of the same sample within the same assay. The between-assay precision is determined from replicate analyses of the same sample in different assays. Usually the between-assay variance is greater than the within-assay variance. Assay variance should be checked continuously with each assay of a certain hormone by use of plasma pools containing set amounts of the hormone. Usually three different plasma sets containing low, medium, and high hormone concentrations are used. Within- and between-assay variations in immunoassay procedures are usually greater than for ordinary routine procedures used in clinical chemistry.

III. PHYSIOLOGY OF REPRODUCTIVE HORMONES IN THE FEMALE

This presentation is relatively brief as to its coverage of endocrinological events during the reproductive cycle. Readers interested in a more complete presentation of hormonal events involved in reproduction are referred to texts dealing specifically with the subject. Also, some hormones with some influence on reproductive processes, such as those of the thyroid, adrenal, and pineal glands, are not covered in this presentation.

A. Estrus Cycle

The major endocrine events that precede ovulation have been well documented in the cow (Chenault *et al.*, 1975), ewe (Nett *et al.*, 1974), sow (Shearer *et al.*, 1972), mare (Evans and Irvine, 1975; Palmer and Jousset, 1975; Stabenfeldt *et al.*, 1975), dog (Concannon *et al.*, 1975), and cat (Shille *et al.*, 1979b). In large domestic animals (cattle, horse, pig, sheep, and goat), follicle growth occurs during the luteal phase in spite of the inhibitory nature of progesterone, the main secretory product of the CL. Although follicles are usually not ovulated during the luteal phase in most species, the mare occasionally ovulates during the luteal phase.

With regression of the CL, follicles grow rapidly before ovulation because of gonadotropin stimulation. The follicles secrete increasing amounts of estrogen during development, which is important for the onset of sexual receptivity as well as for the initiation of the surge release of gonadotropins that is essential for the ovulatory process (Fig. 21-4). Estrogens initiate the surge of LH and FSH through the release of GnRH (Moenter *et al.*, 1990). In most species, the preovulatory surge of gonadotropins begins approximately 24 h before ovulation and is usually of short duration, (e.g., 8 to 10 h in the cow). The mare is an exception in that large amounts of LH are released during an 8- to 9-day period with ovulation occurring on the third day (Geschwind *et al.*, 1975). Another important

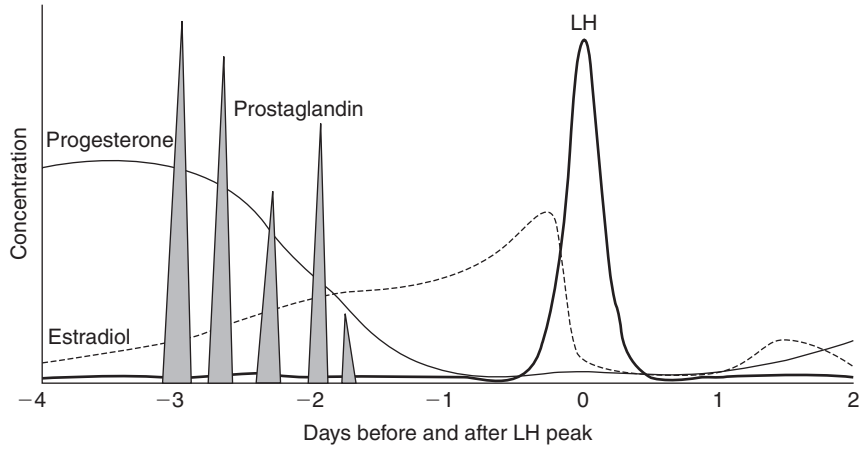

FIGURE 21-4 Schematic presentation of the preovulatory events in general applicable to the cow, doe, ewe, and sow. These endocrine events also occur in the mare, but in this species, the release of LH occurs over a considerably longer time period.

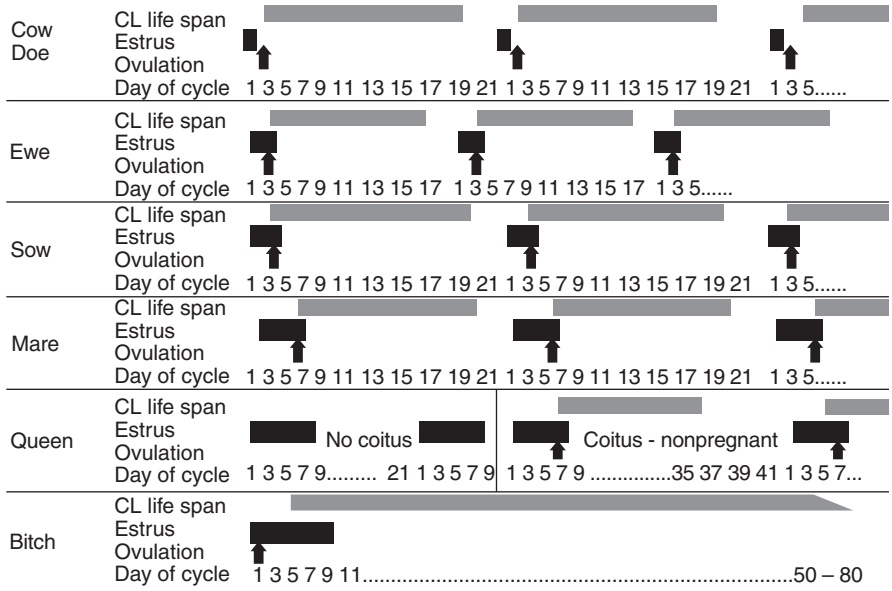

FIGURE 21-5 Comparative data on the duration of estrus, time of ovulation, and duration of corpus luteum function in the cow, ewe, sow, mare, queen, and bitch. Modified from Stabenfeldt (1974).

function of GnRH is to elicit sexual receptivity. Thus, the onset of the preovulatory LH surge and sexual receptivity is coordinated via GnRH synthesis and release.

Following ovulation, a CL is formed under the influence of pituitary gonadotropins. In most species, LH is the major luteotropin, though prolactin is thought to play a role in sheep and in rodents. If pregnancy does not ensue, the CL regresses, which permits the estrus cycle to be repeated. This well-timed sequence occurs repetitively at set intervals if not interrupted by pregnancy.

A summary of estrus cycle activity in common domestic animal species is given in Figure 21-5. Most of the domestic species have evolved from seasonally breeding ancestors. In mammals, photoperiod, via the circadian melatonin profile, synchronizes endogenous circannual rhythms (Lincoln *et al.*, 2003). The mare, ewe, doe, and queen undergo cyclic ovarian activity only during the breeding season in response to seasonal changes in photoperiod. In contrast, cattle, pigs, and dogs can reproduce the entire year, although vestiges of seasonality have been demonstrated (e.g., Andersson *et al.*, 1998).

Estrus cycle length is approximately 21 days in the cow, doe, mare, and sow and 17 days in the ewe. The bitch has a much longer estrus cycle, the luteal phase often being between 50 to 80 days in duration. The interval between cyclic ovarian activities in the bitch is extended even further by the occurrence of a 4- to 5-month anestrus period following regression of the CL. The cat is an induced ovulator requiring coital stimulation for ovulation and thus for CL formation. In the absence of coitus, follicles develop every 15 to 20 days, with follicular growth and regression occupying 5 to 7 days of each period. An ovulatory, nonfertile mating results in the formation of CL that persists for approximately 35 days and a syndrome termed pseudopregnancy in the cat.

B. Control of the Corpus Luteum

The regression of the CL (luteolysis) is a key event that is responsible for the well-timed estrus cyclicity seen in most domestic species. The importance of the uterus in the control of the life span of the CL has been documented

through hysterectomy (Stabenfeldt *et al.*, 1974b). Removal of the uterus from these species during the luteal phase prolongs luteal activity. It is well established that the uterus in these species synthesizes and releases $PGF_{2\alpha}$, which causes the CL to regress (McCracken *et al.*, 1972).

The temporal release patterns of $PGF_{2\alpha}$ (Fig. 21-4), usually in a pulsatile mode lasting a few hours, have been described in the ewe (Barcikowski *et al.*, 1974; Harrison *et al.*, 1972), sow (Gleeson *et al.*, 1974), doe (Fredriksson *et al.*, 1984), and cow (Nancarrow *et al.*, 1973). Some of the problems involved in determining $PGF_{2\alpha}$ (e.g., a short half-life and formation by platelets at collection) can be avoided if the main blood plasma metabolite, 15-keto-13,14-dihydro-$PGF_{2\alpha}$, is determined. Data are available on the patterns of the metabolite during luteolysis in the cow (Kindahl *et al.*, 1976), ewe (Peterson *et al.*, 1976), mare (Neely *et al.*, 1979), doe (Fredriksson *et al.*, 1984), and sow (Shille *et al.*, 1979a).

Regression of CL is usually accomplished within 48h following the onset of the prostaglandin release. It is likely that estrogens, presumably of ovarian follicle origin, initiate $PGF_{2\alpha}$ release. Estrogen also initiates the formation of endometrial oxytocin receptors (McCracken *et al.*, 1984), which in sheep are important for pulsatile synthesis and release of $PGF_{2\alpha}$ in that oxytocin can initiate the release of $PGF_{2\alpha}$ (Sharma and Fitzpatrick, 1974). In ruminants, the CL is able to synthesize oxytocin and oxytocin release from the CL in response to $PGF_{2\alpha}$, which, in turn, initiates the synthesis and release of $PGF_{2\alpha}$ by the uterus; this is the basis for the pulsatile secretion of $PGF_{2\alpha}$ (for a review, see Flint *et al.* [1992], and Whates and Denning-Kendall [1992]). In the dog and cat, $PGF_{2\alpha}$ does not appear to be involved in luteolysis, although its precise role is still uncertain.

C. Early Pregnancy

Modification of $PGF_{2\alpha}$ release is essential for the establishment of pregnancy in the species (cow, ewe, mare, and sow) in which this compound serves as the luteolysin (Kindahl *et al.*, 1976; Nett *et al.*, 1976; Shille *et al.*, 1979a). The rapid elongation of fetal membranes, which precedes the critical time of the initiation of luteal regression by about 3 days in the nonpregnant animal, appears to be important for modifying prostaglandin release. Fredriksson *et al.* (1984) in goats and Zarco *et al.* (1988) in sheep have shown that the main change in $PGF_{2\alpha}$ synthesis and release, nonpregnant versus pregnant animal, involves a continuous mode of secretion, not pulsatile. In fact, $PGF_{2\alpha}$ concentrations increase at the onset of pregnancy, but the release is continuous, which prolongs luteal activity.

Maternal recognition of pregnancy in the cow, ewe, doe, and sow involves mechanisms that alter the prostaglandin release to protect the CL from luteolysis. In the cow, ewe, and doe, embryonic interferon tau (IFN-τ), which is secreted between days 10 and 21 to 24 of pregnancy

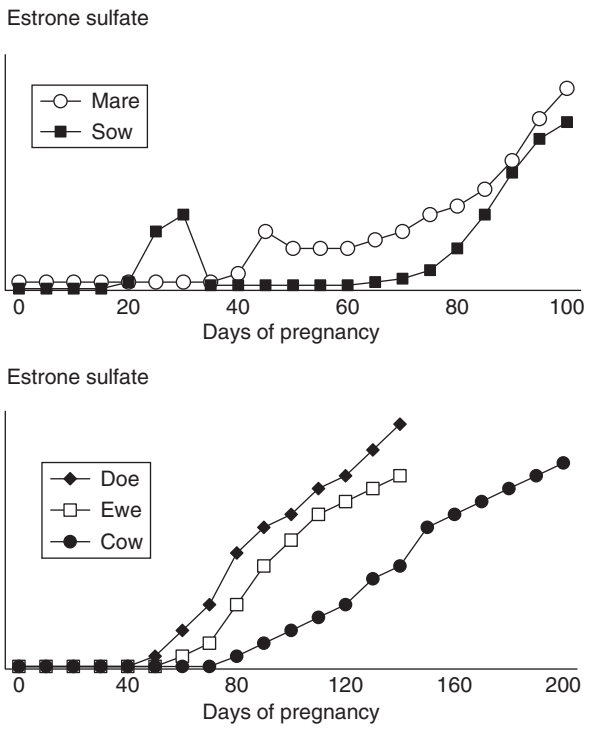

FIGURE 21-6 Blood levels of conjugated estrogens (mainly estrone sulfate) during early pregnancy in the mare, sow, doe, ewe, and cow. Data derived from Kindahl *et al.* (1982) (mare); Robertson and King (1974) (sow); Chaplin and Holdsworth (1982) (doe); Tsang (1978) (ewe); and Gaiani *et al.* (1982) (cow).

by trophectoderm cells of the blastocysts (Roberts *et al.*, 1990), inhibits uterine $PGF_{2\alpha}$ pulses (Spencer *et al.*, 1999; Thatcher *et al.*, 2001). IFN-τ is secreted into the uterine lumen and inhibits the expression of estrogen and oxytocin receptors, thus blocking the episodic uterine $PGF_{2\alpha}$ secretion and luteolysis (for a review, see Spencer *et al.* [2004]). In the sow, the maternal recognition of pregnancy is controlled by conceptus-derived estrogens (Geisert *et al.*, 1982; Perry *et al.*, 1976) (Fig. 21-6).

Modification of the release pattern of $PGF_{2\alpha}$ (pulsatile to continuous) by the luteotropic products from the conceptus and uterus is probably the most important factor that allows luteal activity to continue. The net result is that luteal activity is extended in the cow, ewe, mare, and sow beginning at about 14 days following ovulation. Modification of $PGF_{2\alpha}$ release appears not to be important for the establishment of pregnancy in the dog and cat.

D. Pregnancy and Parturition

The presence of a CL is necessary for the maintenance of pregnancy in a vast majority of cows (Estergreen *et al.*, 1967). The pig also requires luteal support throughout gestation (see Bazer *et al.*, 1979). In the ewe, the presence of CL is required for the first 50 to 60 days of gestation

(Linzell and Heap, 1968). After this time period, the fetoplacental unit secretes significant amounts of progesterone. The dog requires the presence of CL for all of gestation. Sokolowski (1971) found that ovariectomy even as late as day 56 postbreeding resulted in premature delivery.

The necessity of secondary CL, which are formed in the mare between days 40 and 60 of gestation, has been discussed over the years. The secondary CL are the result of eCG secretion by the endometrial cups, which are formed from a circular band of cells of placental origin (chorionic girdle cells) that invade the endometrium and form isolated endocrine organs of temporary function (Allen, 1969). Although secondary CL are not essential for the maintenance of pregnancy in the mare in that the primary CL continues to function for up to 150 days, they do add extra progestational support for the pregnancy during the time placental production of progesterone is being established. Progesterone support of pregnancy in the mare begins to be taken over by the placenta as early as day 50 of gestation but is not complete for all mares until approximately 100 days or later, a time that coincides with the beginning demise of both primary and secondary CL (Holtan *et al.*, 1979).

It has been demonstrated that eCG has a close immunological relationship with equine LH (Farmer and Papkoff, 1979); further, incubation studies of CL have shown a luteotropic effect of eCG (Squires *et al.*, 1979). If fetal loss occurs after the formation of endometrial cups, continuing eCG production supports luteal activity, even to the point of making lysis of these CL difficult in conjunction with the pharmacological administration of prostaglandin $F_{2\alpha}$.

The endocrine activity of the fetoplacental unit can be monitored through the measurement of conjugated estrogens, especially estrone sulfate in peripheral blood plasma or urine (Fig. 21-6). In the pregnant sow, concentrations of estrone sulfate become detectable at day 17 of pregnancy, increase until about day 28, then decline to low or undetectable values and then increase again beginning around day 75 to 80 of pregnancy and remain high until parturition (Robertson and King, 1974). In the mare, estrone sulfate values begin to increase around day 35 to 40 of pregnancy with accentuated production at 80 to 90 days and with highest values obtained from day 150 to parturition (Kindahl *et al.*, 1982; Terqui and Palmer, 1979). In the ewe (Tsang, 1978), estrone sulfate levels can be detected from around day 70 to 80 after conception and in the goat concentrations start to increase around day 50 of pregnancy (Chaplin and Holdsworth, 1982). In the pregnant cow, estrone sulfate concentrations in milk start to increase between days 100 to 120 (Hatzidakis *et al.*, 1993; Henderson *et al.*, 1994). In all species, high values of estrone sulfate in the peripheral blood, milk, or urine are strong evidence for the presence of a viable fetus.

The mare produces two estrogens during pregnancy that are unique to equids, equilin, and equilenin, both of which have unsaturated B rings. Pashen and Allen (1979) have shown through fetal gonadectomy in the horse the importance of fetal gonads in the production of estrogen in cooperation with the placenta. Little evidence of estrogen production during pregnancy has been reported for the dog (Hadley, 1975). Estrogen production by the fetoplacental unit in the cat also appears to be minimal during gestation (Verhage *et al.*, 1976).

An important endocrine change, which occurs before parturition in the cow, ewe, and sow, involves an increase in the synthesis and release of unconjugated estrogens by the fetoplacental unit. This increased estrogen synthesis is reflected in elevated plasma estrone concentrations in the pregnant cow beginning between 30 and 20 days prepartum (Edqvist *et al.*, 1973), in the ewe about 2 days before parturition (Challis *et al.*, 1971), and in the pig about 1 week before delivery (Robertson and King, 1974). In the cow (Edqvist *et al.*, 1973; Stabenfeldt *et al.*, 1970) and bitch (Smith and McDonald, 1974), parturition is preceded by an abrupt fall in progesterone concentrations between 48 and 24 h before delivery. In the ewe (Stabenfeldt *et al.*, 1972), mare (Noden *et al.*, 1978), and sow (Baldwin and Stabenfeldt, 1975), partial withdrawal of progesterone occurs before delivery. In the cow (Edqvist *et al.*, 1978; Fairclough *et al.*, 1975), ewe (Liggins *et al.*, 1972), and bitch (Concannon *et al.*, 1988), it has been demonstrated that prostaglandin release initiates regression of the CL and thus is responsible for the withdrawal of progesterone.

High estrogen and prostaglandin concentrations combined with low progesterone concentrations increase the contractile state of the uterus. Prostaglandins may also initiate cellular changes within the cervix, in addition to the effect of relaxin, which result in cervical softening and dilation. Cervical stimulation, the result of the initial entry of the fetus into the pelvic canal, causes the reflex release of oxytocin from the posterior pituitary. This increases the intensity of uterine contractions and thus aids the final delivery process.

IV. CLINICAL ASPECTS OF REPRODUCTIVE ENDOCRINOLOGY

Important differences exist between humans and animals as concerns endocrine analysis. For example, steroid hormone concentrations are much lower (10-fold less as concerns estrogens) in animals, which produces a requirement for more rigorous assay systems for animals. In animals, the most useful information comes from assessing gonadal or fetoplacental activity (versus pituitary activity) and thus emphasizes the determination of steroid hormones. Besides the fact that gonadotropin values are less useful for the assessment of clinical situations, variations in amino acid composition among species as concern specific hormones mean that multiple systems have to be developed to determine the content of one protein hormone

across species lines. Antibodies such as the one developed for LH by Professor Gordon Niswender (Niswender *et al.*, 1969), which are able to detect LH in many species, are the exception.

For hormone analyses to be useful as a diagnostic tool, certain criteria have to be fulfilled. The concentration of the hormone at the sampling site (usually a peripheral vein) should closely correlate with the amount of the hormone being released from the endocrine gland. It is preferable that the release pattern of the hormone be steady, which allows valid information to be obtained on the secretory status of the endocrine gland from one sample. Several reproductive hormones do not fulfill the latter criteria, and thus their determination is not useful from a routine diagnostic view. For example, the duration of the LH surge observed in conjunction with ovulation is short in most domestic species except the horse. In the cow, the preovulatory LH peak has a duration of 8 to 10h, requiring samples to be obtained every 4h in order to detect the peak. In the mare, the duration of the peak is considerably longer, 8 to 9 days, which allows a less frequent sampling interval (Geschwind *et al.*, 1975). However, the long duration of LH peak in the mare prevents the determination from being useful in predicting ovulation.

One reproductive hormone, progesterone, has been found to be of significant clinical value in females of most domestic species and, in fact, overall its analysis gives the most useful information as to the reproductive status of animals. Other hormones with established or potential clinical use will be discussed further for each species. As a percentage of total number of clinical assays, the highest number has been utilized as pregnancy diagnostic tests. It is worth keeping in mind that the analysis of hormones as a diagnostic aid in solving clinical problems only supplements, but does not replace, the information gained by a careful clinical examination.

Although blood has been the usual medium for hormone analysis, milk, urine, saliva, and even feces are also sources for gaining useful endocrine information. The latter tissues have the advantage in certain situations of being easier to collect and, at the very least, they allow one to avoid the use of venipuncture. It has been shown that the determination of estrogens conjugates in urine is much more effective in revealing ovarian follicle production of estrogens as compared to the analysis of either free or conjugated estrogen in plasma.

A. Cattle

1. *Progesterone*

Several reports are available on progesterone concentrations in blood during early pregnancy in cattle (Pope *et al.*, 1969). A finding of importance is that progesterone can be measured in the milk of lactating cows and, further, that its concentration accurately reflects the concurrent blood plasma concentration of progesterone (Laing and Heap, 1971).

The difference that exists in both blood plasma and milk progesterone concentrations 19 to 24 days after a fertile breeding as compared to a nonfertile breeding has been used as an early pregnancy test (Robertson and Sarda, 1971; Shemesh *et al.*, 1968) (Fig. 21-7). The plasma progesterone concentration in blood of pregnant cows at 21 days postbreeding is almost always at least 2 ng/ml (6 nmol/liter) and usually 4 to 8 ng/ml (13 to 26 nmol/liter), as compared to less than 0.5 ng/ml (1.6 nmol/liter) in the nonpregnant animal at the same time. Elevated progesterone concentrations, however, only reflect the presence of luteal tissue and do not directly indicate the presence of a fetus *in utero*. Furthermore, a slight prolongation of luteal activity in a nonpregnant animal can occur, which results in elevated progesterone concentrations at day 21, a situation in which the analytical progesterone result would be positive and the animal would be falsely considered pregnant. The accuracy of the forecast for pregnancy (positive forecast) thus is often lower than desirable, in most cases ranging between 75% and 90%. The negative forecast, however, is more accurate because cows having low progesterone concentrations in milk or blood 21 days postbreeding will almost always not be pregnant. The accuracy of the positive forecast increases if progesterone analyses are also carried out on samples obtained at the time of insemination in order to eliminate animals inseminated during the luteal phase of the estrus cycle. Cows inseminated during the luteal phase will be in the luteal phase 21 days later with the animal being falsely considered pregnant.

It should be recognized that the main focus of early pregnancy diagnosis is for the more efficient management of breeding. In most cases involving early pregnancy

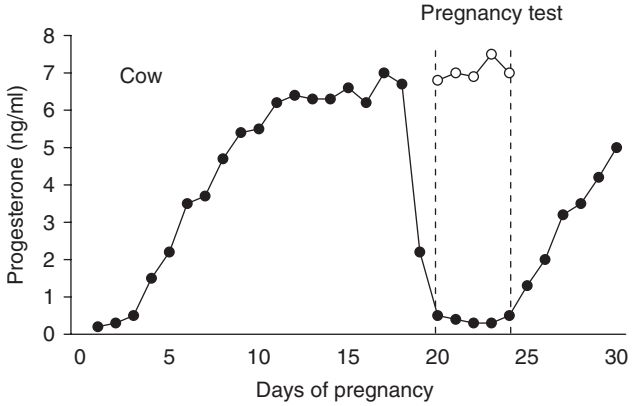

FIGURE 21-7 Time after breeding for utilizing progesterone analysis as a means of pregnancy diagnosis. Progesterone content in nonpregnant (•) cows compared with progesterone content of pregnant animals (◦) (Stabenfeldt *et al.,* 1969b).

diagnosis, pregnancy status needs to be verified again at about 40 days postbreeding. In spite of the limitations of progesterone analysis as concerns pregnancy diagnosis, this is the most common clinical use of any of the reproductive hormones. Progesterone analysis can also be used for the retrospective confirmation of the absence (or presence) of a CL at the time of insemination in cattle. Because inadequate detection of estrus is the most common cause of low fertility in herds utilizing artificial insemination, the determination of progesterone concentrations at the time of insemination can be a useful tool when herds with fertility problems are encountered. The use of progesterone determinations in milk obtained at the time of insemination in cows with questionable heat signs and inconclusive genital tract findings can serve as a valuable tool for educating the staff responsible for insemination (Garcia and Edqvist, 1990).

A potential important area for the diagnostic use of progesterone analysis concerns the elucidation of clinical syndromes in the postpartum period in which cows fail to show sexual receptivity for extended periods of time. Animals that have reestablished ovarian activity can often be distinguished from those that have ovarian inactivity; elevated progesterone values indicate that significant ovarian activity is present. Cows that have luteal activity can be manipulated through $PGF_{2\alpha}$ treatment with a reasonable expectation of response as concerns the initiation of a new cycle. Progesterone determinations could also be used to verify the presence of luteal tissue in conjunction with endometritis/pyometra (Pepper and Dobson, 1987) and ovarian cysts (Booth, 1988; Sprecher *et al.*, 1990). Both conditions should respond to prostaglandin therapy. As concerns ovarian cysts in cattle, differentiation of luteal versus follicular cysts is usually not done because it is technically difficult by palpation *per rectum* and because the same gonadotropin treatment can be used in both situations; luteinization of the structure with a luteotropin is followed in 10 to 14 days with prostaglandin treatment. In both cases though, the use of progesterone analysis would be useful in establishing the therapeutic response.

2. Estrone Sulfate

High concentrations of estrone sulfate are found in blood beginning at about day 80 of pregnancy and in milk from about day 100 (Fig. 21-6). In a study measuring estrone sulfate concentrations in milk samples as an indicator for pregnancy status, an overall accuracy rate of 95% in milk samples collected at 120 days or later was found (Henderson *et al.*, 1994). When comparing peripheral blood concentrations of estrone sulfate between three breeds of cattle, it was found that the breed giving birth to the lightest calves had lower estrone sulfate concentrations in the interval 101 to 200 days of gestation (Abdo *et al.*, 1991). Estrone sulfate measurements cannot be used to predict time of calving (Shah *et al.*, 2006).

3. Other Substances

Proteins of placental origin, bovine pregnancy-specific protein B (bPSBP), and bovine pregnancy-associated glyco-protein 1(bPAG-1) have been observed in the blood of pregnant cows beginning between days 16 and 21 of gestation (Sasser and Ruder, 1987). The existence of proteins that are present only if an embryo is present opens the way for an early and definitive pregnancy diagnosis in cattle by blood analysis. Humblot *et al.* (1988) compared diagnosis of pregnancy in Frisian cattle by determination of progesterone and bPSBP in blood. The study revealed the accuracy (number positive and pregnant/number of positive diagnoses) of the positive forecast to be 67% (82/122) for progesterone on day 24 after insemination. The accuracy of the negative forecast for progesterone was 98% (52/53). The accuracy of the positive forecast for bPSPB increased with gestation age from 86% (50/58) on day 24 to 99% (83/84) on day 70. The accuracy of the negative diagnoses by bPSPB increased from 72% (84/117) on day 24 to 100% (83/83) on days 30 to 35. The authors concluded measurement of bPSPB 30 days after insemination to be an efficient test both for the positive and the negative pregnancy diagnoses. A cardinal principle of pregnancy detection is that the test should be effective by the time the estrus cycle would end if the animal was not pregnant. This reemphasizes the main point of early pregnancy detection (i.e., it is done so the animal can be rebred if not pregnant). The test fulfilling this criterion has yet to be found.

A comparison of ultrasonography with bPSBP and bPAG-1 RIA assays showed no difference in accuracy diagnosis of pregnant cows compared to calving results. However, the accuracy of detection of nonpregnant cows by the bPSBP and bPAG-1 measurements was limited by the relatively long half-life of these proteins after calving and early embryonic death (Szenci *et al.*, 1998). On-farm tests to detect bPAG-1 (early conception factor) have been developed to be used within 48 h of conception. Although the test appears to function well, it also has been criticized for not being reliable for determine nonpregnancy in cattle (Cordoba *et al.*, 2001).

B. Sheep

1. Progesterone

Progesterone analysis as an early test for pregnancy has been used in sheep (Robertson and Sarda, 1971). In the ewe, the progesterone analysis has to be carried out on blood samples, as most breeds of sheep are not lactating at the time of breeding. Maximal luteal phase progesterone concentrations in the ewe are approximately 2 to 4 ng/ml (6 to 13 nmol/liter), whereas the concentrations at estrus range from 0.15 to 0.25 ng/ml (0.5 to 0.8 nmol/liter) (Stabenfeldt *et al.*, 1969c). Using an amplified enzyme

immunoassay technique for plasma progesterone an accuracy of 100% to diagnose pregnancy in samples taken between days 15 to 16 from a flock of 130 ewes (107 diagnosed pregnant and 24 diagnosed nonpregnant) was reported (McPhee and Tiberghen, 1987).

A relatively marked increase in progesterone values from 2 to 4 ng/ml (6 to 13 nmol/liter) to 12 to 20 ng/ml (38 to 64 nmol/liter) occurs between days 60 and 125 of pregnancy (Stabenfeldt *et al.*, 1972). This increase is due to increased progesterone production from the fetoplacental unit. The contribution of the CL to progesterone concentrations remains constant throughout pregnancy, thus the relatively large difference in progesterone concentrations between nonpregnant ewes with a CL present and ewes with fetus(es) present could be used to minimize the relatively high false-positive forecasts observed for sheep at 17 days postbreeding. The limitations are the same for the use of progesterone analysis as a pregnancy test in sheep as discussed for cattle.

2. Estrone Sulfate

In the pregnant ewe estrone sulfate produced from the fetoplacental unit is detected in elevated concentrations beginning at around day 70 after conception (Tsang, 1978) (Fig. 21-6). Worsfold *et al.* (1986) determined estrone sulfate concentrations in blood from ewes bred 85 days previously and found the accuracy of the nonpregnant versus pregnant interpretations was 44% and 88%, respectively. A considerable overlap in estrone sulfate values between ewes with single and multiple fetuses was found and even at day 116 of pregnancy, estrone sulfate concentrations overlapped between groups of ewes with single and multiple fetuses. Because of this the authors conclude that estrone sulfate concentrations could not be used as a predictive tool for litter size (Fletcher and Worsfold, 1988).

3. Other Substances

Circulating pregnancy-associated glycoprotein 1 (ovPAG-1) has been reported in sheep. A heat labile protein with a molecular weight of around 8000 was found in sera of sheep as early as day 6 of gestation (Cerini *et al.*, 1976). It has been demonstrated that the bovine pregnancy-specific protein B (bPSPB) assay can be used for early detection of pregnancy also in the ewe, as pregnant ewes have a blood antigen that cross-reacts with antibodies to bPSPB (ovPSPB, Ruder *et al.*, 1988). In a study comparing the accuracy of detecting pregnancy with an ultrasonic device, a real-time scanning instrument and a RIA for bPSPB in ewes, it was concluded that the RIA for bPSPB detected pregnancy earlier and more accurately than the ultrasonic device and equally accurate as the real-time scanning instrument (Ruder *et al.*, 1988).

Ovine placental lactogen (oPL) has been demonstrated in the peripheral blood of pregnant ewes (Kelly *et al.*, 1974). Increase in maternal oPL concentrations occurs between 40 and 50 days of pregnancy, reaches maximum concentrations between days 120 and 140, and declines as parturition approaches (Chan *et al.*, 1978). The determination of oPL concentrations might be used as a basis for a specific pregnancy test in the ewe.

C. Pig

1. Progesterone

Luteal phase progesterone concentrations in the pig are considerably higher than in cattle and sheep, namely, 20 to 50 ng/ml (64 to 159 nmol/liter), whereas concentrations at estrus are below 0.5 ng/ml ($<$1.6 nmol/liter) (Stabenfeldt *et al.*, 1969a). The difference in progesterone values between nonpregnant and pregnant animals 19 to 24 days after service has been used as an early pregnancy test (Robertson and Sarda, 1971). In the pig, progesterone determination is usually performed on blood. Because of the sensitivity of the assay systems and the concentration of progesterone in blood in pigs during the luteal phase, analyses can be performed on a small volume of blood (about 10 drops), allowing the sample to be obtained through a small incision in an ear vein. The limitations associated with using progesterone determinations as a pregnancy test in the pig are similar to those previously discussed for cattle. Progesterone analyses can be used to determine ovarian activity in clinically anestrus gilts as well as to establish the stage of the estrus cycle in gilts and subsequent response to treatment. It is also possible to monitor luteal phase activity in the sow through measurement of fecal gestagens (Hultén *et al.*, 1995; Moriyoshi *et al.*, 1997).

2. Estrone Sulfate

Previous studies of estrogen concentrations in urine revealed a marked increase in estrogen between day 20 and 30 of pregnancy in pigs (Velle, 1958). Studies of blood concentrations of estrone sulfate in pigs during pregnancy showed patterns similar to those determined in urine (Robertson and King, 1974) (Fig. 21-6). In early pregnancy in the pig, it has been hypothesized that estrogen synthesized by the early preimplantation embryo may be the messenger for the maternal recognition of pregnancy (Perry *et al.*, 1976) and that the elevated estrone sulfate concentrations in the maternal circulation during early pregnancy reflect fetal synthesis. The determination of estrone sulfate in early pregnancy in the pig is thus a specific pregnancy test (Cunningham *et al.*, 1983). The index of discrimination between estrone sulfate concentrations in blood of pregnant versus nonpregnant pigs around 25 days after breeding is very high as concerns pregnancy diagnosis. Sugiyama *et al.* (1986) reported an accuracy rate of 98% in pigs between

days 20 and 26 of pregnancy. Horne *et al.* (1983) found litter size on days 20 to 26 of pregnancy to be positively correlated with estrone sulfate values but such a relationship was not found later in pregnancy. During the latter part of pregnancy, the maternal blood concentrations of estrogens (estrone sulfate, estrone, and estradiol-17β) are very high and can thus be used to confirm pregnancy at this stage of gestation (Fig. 21-6).

In the pregnant sow, the concentration of estrogen in urine and feces follows the same pattern as in blood (Choi *et al.*, 1987). Szenci *et al.* (1993) compared ultrasonography and the determination of unconjugated estrogen in feces, 25 to 30 days after insemination, for the diagnosis of pregnancy in pigs. Based on farrowing data the positive and negative predictive values for the ultrasound were 93% and 100%, respectively. For the determination of unconjugated estrogens, the corresponding predictive values were 94% and 55%, respectively.

D. Horse

1. *Equine Chorionic Gonadotropin*

Although pregnancy diagnosis has been done in mares through the measurement of equine chorionic gonadotropin (eCG) formerly named pregnant mare serum gonadotropin (PMSG), the main drawback to its use is that the presence of eCG does not guarantee the presence of a fetus but indicates that a viable fetus was present at the time of endometrial cups formation. This is because endometrial cups have autonomy of function and continue to secrete PMSG for a period of time in spite of loss of the fetus (Allen, 1969). This means that both mares with normal pregnancies and mares that experience embryonic mortality after day 40 of gestation will have elevated eCG concentrations in blood. The use of eCG determinations as a positive pregnancy diagnosis test will consequently yield some mares to have been diagnosed pregnant but not delivering a foal (Fig. 21-8; Jeffcott *et al.*, 1987; Mitchell, 1971). Complementation with estrone-sulfate measurements after 100 days of pregnancy can compensate for this shortcoming.

2. *Progesterone*

Progesterone analysis is useful for establishing the presence or absence of ovarian activity in animals with puzzling behavioral patterns. Agitated or aggressive behavior, often interpreted as sexual in orientation, occurs without regard to luteal status. Progesterone analysis can be helpful because elevated values directly indicate the presence of a CL and, additionally, are evidence that folliculogenesis and ovulation are normal. Relatively low luteal phase values for progesterone (1 to 3 ng/ml; 3 to 10 nmol/liter) versus normal luteal phase values ($>$3 ng/ml; $>$10 nmol/liter) are often associated with the presence of a persistent CL (Stabenfeldt *et al.*, 1974a). Progesterone values of mares with persistent luteal activity are low because some $PGF_{2\alpha}$ synthesis and release often occurs about 14 days postovulation, albeit insufficient to cause complete luteolysis (Neely *et al.*, 1979).

Progesterone analyses can also be useful in mares that fail to manifest sexual receptivity yet have cyclic ovarian activity. Progesterone analysis at 5-day intervals over 20 days (approximately one estrus cycle length) can verify the presence or absence of cyclic ovarian activity. The time of ovulation can also be predicted within a 2- to 3-day interval, a prediction that can be helpful to the veterinary practitioner anticipating the next time of ovulation. Breeding may have to occur by artificial means in these situations. Hinrichs *et al.* (1988) compared the accuracy of determining day of ovulation $\pm$1 day using three different methods: (1) an immediate, qualitative ELISA for progesterone in blood; (2) a quantitative ELISA for progesterone in blood; and (3) daily teasing to detect estrus. Ovulation was detected by ultrasound examination per rectum. The accuracy in determining day of ovulation $\pm$1 day using the three methods was 72% for the qualitative progesterone assay, 88% for the quantitative progesterone assay, and 86% for teasing.

3. *Conjugated Estrogens*

Estrone in its unconjugated form (free estrogen) reflects important physiological events in the mare beginning at about day 75 of gestation when the fetoplacental unit begins to produce estrone in rapidly increasing amounts (Nett *et al.*, 1975). More important, it has been shown that estrone is rapidly conjugated after secretion to water-soluble estrogen conjugates and the ratio between free and conjugated forms is 1:100 (Terqui and Palmer, 1979). Terqui and Palmer (1979) and Kindahl *et al.* (1982) have both shown that significant increases in estrone conjugate concentrations occur between days 35 and 40 of gestation (Fig. 21-8). Kindahl *et al.* showed the increase to be 10- to 20-fold between days 35 and 40. Concentrations then decline slightly with a further increase noted at the same time that free estrone concentrations begin to increase. The initial source of increased estrone production during gestation days 20 and 70 is the ovaries (Daels *et al.*, 1990); later on its occurrence is likely driven by the attachment of the embryo and the production of eCG (PMSG). A study in miniature mares showed that the determination of estrone sulfate concentrations in blood after day 100 of pregnancy is a reliable method for determining pregnancy status, as well as eliminating "false-positive" diagnosis by eCG measurements between day 40 to 100 (Henderson *et al.*, 1998).

Also estrone conjugate concentrations in urine can be used to document pregnancy in the mare and, in fact, may be more accurate than plasma analysis because of the concentrating aspects associated with urine formation (Daels *et al.*, 1991). Increased amounts of fecal estrogens and

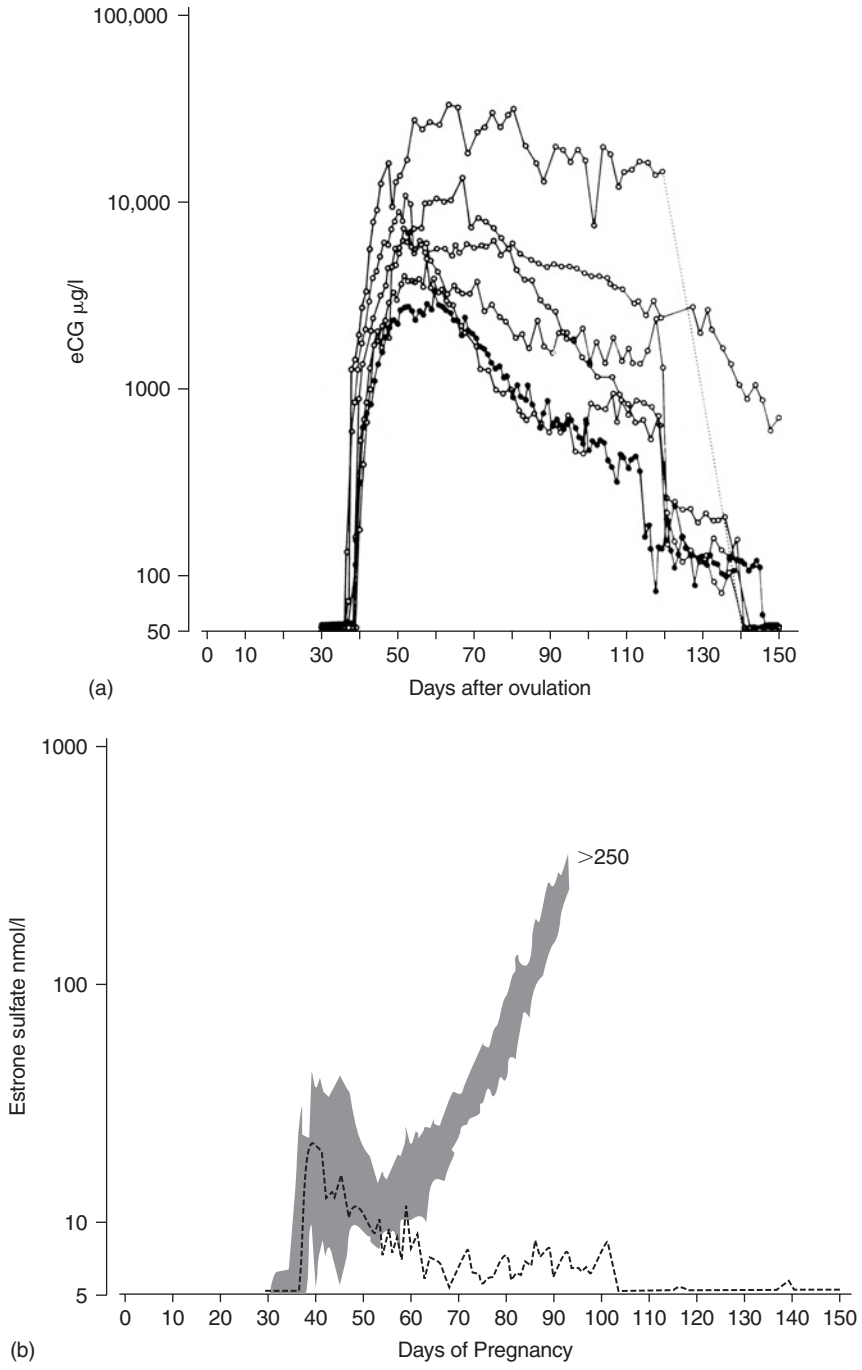

FIGURE 21-8 (a) Blood plasma concentrations of eCG in five normal pregnant mares (○) and in one mare in which the fetus died around day 50 of pregnancy (•). (b) Geometric means of blood plasma concentrations of estrone sulfate in the five normal mares (shaded area) and the estrone sulfate concentration in the mare in which the fetus died around day 50 and was aborted on day 113 of pregnancy (Darenius *et al.,* 1988).

gestagens have also been reported in the pregnant mare (Schwarzenberger *et al.*, 1991), and fecal estrone sulfate may be a noninvasive alternative from day 150 (Henderson *et al.*, 1998).

In addition to being a means of confirmation of pregnancy, estrone conjugate analysis also allows the soundness of the pregnancy to be assessed because estrogen concentrations reflect the dynamics of a growing fetus. Thus, it is possible not only to indicate that pregnancy is in progress by estrone conjugate analysis but also to indicate whether the pregnancy is proceeding well or that it is in some state of compromise. Analysis of estrone conjugates is an important aid for the verification of pregnancy in the mare and does not suffer the drawback with false-positive diagnosis as is the case for eCG (Fig. 21-8). Estrone conjugate analysis also has been used to assess follicle growth

patterns in nonpregnant mares, an approach that was difficult to do with the determination of free estradiol-17β (Daels *et al.*, 1991; Makawiti *et al.*, 1983).

4. Other Pregnancy-Associated Substances

A test (a lateral flow assay using antibodies with colloid gold as the indicator) for equine early conception factor (a pregnancy-associated immunosuppressive protein) is suggested to be a quick, easy, and noninvasive method for detecting nonpregnant mares. However, a controlled study shows that a large proportion (60%) of animals give a positive test result even before breeding (Horteloup *et al.*, 2005).

5. Testosterone

Testosterone values vary in the mare according to the reproductive state. Values, usually less than 15 pg/ml (>52 pmol/liter) during anestrus, range between 20 and 40 pg/ml (69 to 139 pmol/liter) during cyclic ovarian activity with the higher values being observed during the follicular phase of the cycle immediately before ovulation. Testosterone determinations have been used to aid the diagnosis of granulosa-theca cell tumors in the mare (Stabenfeldt *et al.*, 1979) and to differentiate granulosa-theca cell tumors from ovarian teratoma (Panciera *et al.*, 1991). Leydig-like cells in the theca appear to be the source of testosterone. In cases of granulosa-theca cell tumors, testosterone values vary with values ranging from 40 pg (139 pmol/liter). Values over 100 pg/ml (347 pmol/liter) are considered diagnostic of granulosa-theca cell tumors in mares. These tumors are generally slow in development, and it is not known whether this slow development also reflects a slowly developing capacity for testosterone production or whether there is variability as to the number of testosterone secreting cells among tumors. Aggressive stallion-like behavior is associated with high values of testosterone (Stabenfeldt *et al.*, 1979). Inhibin is usually elevated in granulosa-theca cell tumors in mares and thus suppresses pituitary FSH release (Bailey *et al.*, 2002).

Testosterone determinations in the male horse have been used as an aid in the diagnosis of cryptorchidism. Cox (1975) reported that horses with <40 pg/ml (<139 pmol/liter) plasma should be considered castrated, whereas animals with concentrations >100 pg/ml (>347 pmol/liter) should be considered as having testicular tissue present. Although some cryptorchid animals have testosterone concentrations <100 pg/ml (<347 pmol/liter), most have values ranging from 200 to 1000 pg/ml (693 to 3467 pmol/liter) (Cox, 1975). Testosterone concentrations in intact males usually range from 1000 to 2000 pg/ml (3467 to 6934 pmol/liter) (Berndtson *et al.*, 1974; Cox *et al.*, 1973). HCG administration for the purpose of stimulating testosterone production by the testes has been suggested as a means of resolving cases in which values are between 40 and 100 pg/ml (139 to 347 pmol/liter). Dosages of injected hCG have been 6000 to 12,000 IU. (Cox *et al.*, 1986; Silberzahn *et al.*, 1989) and the second sample for analysis of testosterone obtained after 30 to 120 min (Cox *et al.*, 1986) or after 3 days (Silberzahn *et al.*, 1989). The responses to hCG may be lower in horses less than 18 months of age and during the nonbreeding season (winter).

It has been suggested that the analysis for estrone sulfate conjugates for the diagnosis of cryptorchidism is preferred over testosterone on the basis that it requires only one analysis and that the accuracy is slightly improved (Cox *et al.*, 1986). It should be noted, however, that estrone sulfate analysis for cryptorchidism cannot be used in horses less than 3 years of age or in donkeys because little estrone sulfate is produced in either of these situations. Androstenedione is the precursor hormone of androgens and estrogens and can also be used for the diagnosis of cryptorchidism (Illera *et al.*, 2003).

Castration and thus withdrawal of androgens causes increased levels of gonadotropins, which thus can be measured as a complement to testosterone.

The presence of sexual behavior in suspected cases of cryptorchidism is not necessarily dependent on elevated testosterone concentrations in that many patients (about one-third) referred because of behavioral problems are, in fact, castrated. In essence, some animals can maintain normal libido with low circulating concentrations of testosterone. In this situation, testosterone analysis is helpful from the point of view of either eliminating unnecessary surgery or indicating to the surgeon that testicular tissue is present and should be found on surgical entry.

E. Dog

1. Progesterone

In the bitch, there is little difference between the progesterone pattern of the pregnant and nonpregnant luteal phase. Plasma concentrations of progesterone are elevated throughout the luteal phase. However, although mean concentrations of progesterone are higher during the latter part of the pregnant luteal phase compared with the nonpregnant luteal phase, these differences are not significant to allow progesterone determinations to be used as a pregnancy diagnosis test.

Bitches usually ovulate at the onset of sexual receptivity, remain sexually receptive for about the first week of luteal activity, and, in fact, are fertile during this period of time (Holst and Phemister, 1974). Progesterone analysis can be used to confirm the occurrence of ovulation with concentrations usually increasing slightly above baseline in the periovulatory period reaching about 15 nmol/liter at ovulation followed by a sustained increase beginning 24 h following ovulation (Fig. 21-9) (Concannon *et al.*, 1975). This approach may be used in a retrospective analysis of a breeding cycle in an attempt to correlate the time of ovulation with other criteria such as vaginal cytological changes. The determination of

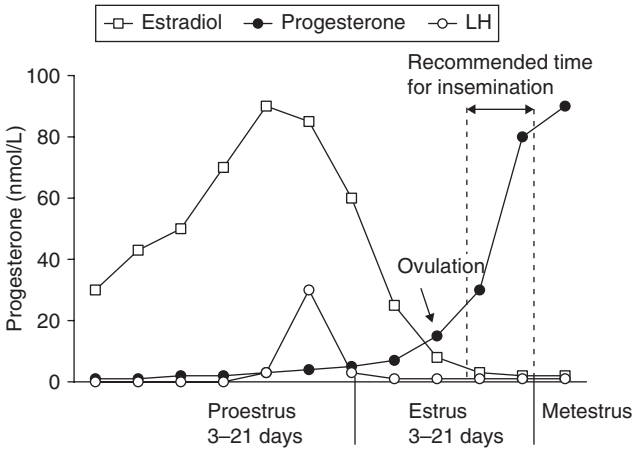

FIGURE 21-9 Schematic representation of the temporal relationship among estradiol, progesterone, peak of luteinizing hormone (LH), and ovulation in the bitch. The recommended time of mating or artificial insemination is based on the progesterone concentration.

progesterone in daily samples of blood obtained during the periovulatory period gives a more precise timing of ovulation than can be obtained by vaginal cytology.

In situations wherein a particular pairing of animals does not result in a mutual sexual attraction and where artificial insemination must be used, progesterone analysis is a useful tool to verify ovulation. Artificial insemination with frozen-thawed semen usually results in lower pregnancy rates than artificial inseminations using fresh semen. Using progesterone determinations to pinpoint ovulation it was found that the pregnancy rate following insemination with frozen-thawed semen could be improved when the insemination was performed at progesterone concentrations >30 nmol/liter (Fig. 21-9) (Linde-Forsberg and Forsberg, 1989, 1993).

Progesterone analysis can also be useful in cases of short estrus cycle intervals to determine if ovulatory failure has occurred, a situation in which progesterone concentrations are low following the termination of estrus.

Analysis of progesterone (alone or in combination with estrogen) is also useful in cases when there is some question as to the completeness of removal of ovarian tissue during an ovariohysterectomy (ovarian remnant syndrome). Stimulation by hCG/eCG or GnRH can improve the possibility of finding any remnant ovarian tissue. An important distinction as concerns the dog is that, unlike other domestic species, the bitch is keyed into sexual receptivity at the end of the follicular phase by progesterone. Dogs may be sexually attractive because of odors arising from the vagina because of factors such as infection, but bitches will only accept males in the presence of increased progesterone concentrations, a situation that is almost always associated with luteal tissue as part of a remaining ovarian remnant.

2. *Testosterone*

The most common endocrine test in male dogs is testosterone for the purpose of checking the secretory status of the Leydig cells. Testosterone values in normal dogs range from about 1 ng/ml (3.5 nmol/liter) to about 10 ng/ml (35 nmol/liter) because of the pulsatile release pattern of testosterone. Testosterone concentrations in castrated dogs are less than 0.5 nmol/liter.

Assays of basal testosterone concentration may allow the diagnosis of the absence of testicular tissue in the same manner as described previously for the male horse. Sometimes the positive confirmation of presence of testicular tissue may require the use of hCG or GnRH to stimulate testosterone production. In this situation, a resting blood plasma sample is collected immediately before the administration of the stimulating hormone, and a second blood sample is collected an hour later. A significant increase in plasma testosterone concentration is diagnostic of testicular tissue.

Testosterone analysis is done in conjunction with fertility examinations, often in stud animals that are presented as infertility cases following a prolonged show tour. Most of these animals have testosterone concentrations that are compatible with normal spermatogenesis, although sperm counts are often very low. The management of this syndrome is still uncertain.

Feminizing syndromes in intact male dogs have been observed, in which concentrations of testosterone are greatly decreased below normal (to 100 pg/ml or less; <350 pmol/liter) and estradiol values are two to three times normal (30 to 45 pg/ml versus the normal 15 pg/ml; 110 to 165 pmol/liter and 55 pmol/liter). It is thought that a majority of these cases involve Sertoli cell tumors. Dogs with confirmed Sertoli cell tumors have high peripheral blood plasma levels of inhibin and suppressed levels of LH and testosterone (Grootenhuis *et al.*, 1990). These authors were, however, unable to detect differences in blood concentrations of estradiol between dogs with Sertoli cell tumors and control dogs.

3. *Relaxin*

Relaxin is in the pregnant dog is first detected at day 18 to 25 of gestation but is undetectable during anestrus, throughout nonpregnant ovarian cycles, and in male dogs (Steinetz *et al.*, 1987, 1996). Maximal concentrations are attained by days 40 to 50 of pregnancy and are followed by slight declines before parturition. Relaxin is produced predominantly by syncytiotrophoblasts in the placenta (Klonisch *et al.*, 1999) but also by the ovary, and it is the closest thing to a pregnancy-specific canine hormone (Tsutsui and Stewart, 1991). Commercial available assays for canine relaxin can be used to diagnose pregnancy as early as 21 days after breeding, although negative results should be rechecked after a week. However, relaxin cannot be used to estimate litter size and remains elevated after pregnancy loss.

F. Cat

1. Progesterone

Progesterone analysis can be used to verify the occurrence of ovulation in the cat following coitus. Ovulation usually occurs 24 to 36 h after coital contact with a male at the appropriate time of the follicular phase of the estrus cycle (Shille *et al.*, 1983). If the breeding schedule is very limited in time, it is possible for a cat to be bred too early in the follicular phase with coitus failing to elicit LH release. Or more rarely, females may allow copulation at times other than the follicular phase. In both these situations, ovulatory failure would be documented by the finding of low progesterone values 10 days postbreeding. In one study, progesterone concentration >1.87 ng/ml; >6 nmol/liter was consistently associated with luteal-phase ovaries, and values <0.15 ng/ml; <0.5 nmol/liter were associated with follicular phase ovaries (Lawler *et al.*, 1991).

2. Estrogen

As the cat is an induced ovulator (requires coitus), estradiol analysis can be used to assess the presence of ovarian follicle activity with values ranging from 10 pg/ml (37 pmol/liter) in the interfollicular phase to 60 pg/ml (220 pmol/liter) during folliculogenesis. As indicated previously, queens have ovarian follicle growth patterns that last 5 to 7 days followed by a slightly longer interval before the next growth phase (Shille *et al.*, 1979b). Estrogen analysis could document the presence or absence of ovarian follicular activity in animals that fail to manifest sexual activity. It also could be used to assess the completeness of an ovariohysterectomy in cats that are spayed but who present signs suggestive of sexual receptivity. The usual finding is that of low estrogen concentrations, which indicates the behavior is not sexual in orientation.

In the domestic cat, estrogen metabolites are primarily excreted in the feces (Möstl *et al.*, 1993; Shille *et al.*, 1990). Analysis of fecal steroids is a useful noninvasive approach of monitoring ovarian function in exotic Felidae (Graham *et al.*, 1993).

3. Testosterone

Testosterone analyses can be used to evaluate Leydig cell function in the testis of the male cat. The range of values is usually between 1 and 10 ng/ml (3.5 to 35 nmol/liter).

4. Relaxin

Relaxin is produced by the fetoplacental unit beginning about day 20 of gestation; maximal concentrations are achieved by day 30 to 35 (Addiego *et al.*, 1987). Relaxin concentrations thus can be used to assess pregnancy status in the cat and even to assess its normalcy based on the fact that fetoplacental units in jeopardy produce less relaxin.

V. GENERAL COMMENTS

A. Hormone Concentrations

The foregoing presentation did not emphasize hormone concentrations. This is because there is still some variability as to the values reported by various laboratories. It is important that clinical endocrinology laboratories understand and have experience with their assay systems in relation to particular clinical syndromes. For example, the actual concentration of progesterone during the follicular phase of the estrus cycle of domestic animals is approximately 100 pg/ml (318 pmol/liter), certainly no greater than 200 pg/ml (636 pmol/liter) plasma. Some laboratories, however, report basal values of 1 to 2 ng/ml (3.2 to 6.4 nmol/liter) for progesterone. The reference values developed by laboratories depend on the type of assay used.

It is possible to have a wide range of values for a particular hormone and still have normal physiological conditions. Luteal phase progesterone concentrations in the cow, for example, range between 2 and 12ng/ml (6 to 38nmol/liter) because of pulsatile gonadotropin secretion (Walters *et al.*, 1984) with no adverse effect on the preparation of the animal for the nurture of a potential embryo. Hormone values can also depend on the type of material used in the assay. Luteal phase progesterone values are approximately 4ng/ml (13nmol/liter) in fat-free milk, between 5 and 35ng/ml (16 to 111nmol/liter) in whole milk, and approximately 250ng/ml (795nmol/liter) in milk fat.

B. Analysis and Storage Effects

1. Blood

The treatment and storage of samples before analysis can influence the hormone value obtained for a blood sample. It has been known that red blood cells from cow have the capacity to metabolize progesterone to other steroids (Short, 1958; Fig. 21-10). The rapid decrease, about 10% to 20% reduction/hour, in the progesterone content in heparinized bovine blood samples appears to be due to the conversion of progesterone to 20β-hydroxylated gestagens. Also other 20-keto-gestagens like pregnenolone and 17α-hydroxyprogesterone undergo a similar conversion to 20β-hydroxylated gestagens and reduce their blood concentration during storage (Choi *et al.*, 1989). The drop in progesterone concentration in heparinized whole blood follows glycolysis, and when glucose concentrations are low the enzymatic degradation of progesterone in heparinized cow blood is to some degree reversed (Oltner and Edqvist, 1982; Fig. 21-10). The use of anticoagulants blocking or preventing glucolysis like sodium fluoride much reduces the rate of decline in whole blood progesterone concentrations (Pulido *et al.*, 1991; Vahdat *et al.*, 1979). Temperature also plays a significant role in regulating the rate of decline

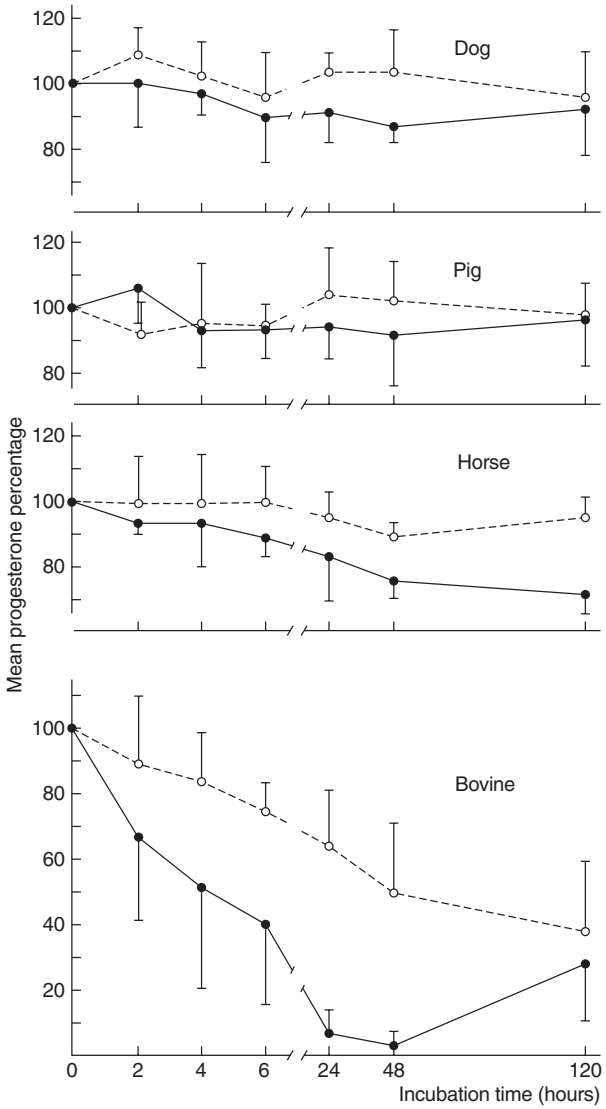

FIGURE 21-10 Mean (and SD) plasma progesterone percentage after storage of heparinized whole blood from four dogs, four pigs, four horses, and eight cows at 20°C (•) and at 4°C (◦). The initial progesterone value at time 0 has arbitrarily been set as 100% (Oltner and Edqvist, 1982).

in progesterone, the lower the temperature of storage, the slower is the rate of progesterone decline (Fig. 21-10).

The enzymes responsible for the progesterone conversion are present in the red blood cells; harvesting serum or plasma as soon as possible after the collection of the sample prevents the metabolism of progesterone (Vahdat *et al.*, 1979). If this cannot be done within half an hour, the sample should be put on ice to retard the enzymatic processes.

A decline in progesterone concentrations also occurs in stored whole blood from the ewe (Van der Molen and Groen, 1968; Wiseman *et al.*, 1983), although the decline is not as rapid and pronounced as in the cow. In the female goat, on the other hand, no significant decrease in whole blood progesterone was found during storage at room temperature for 24 h (Navarro *et al.*, 1990). Some decline in progesterone also seems to occur during storage of equine whole blood (Fig. 21-10). For other domestic animals dealt with here, no major effects of storage on progesterone concentrations have been reported.

Storage of bovine whole blood also results in significant decreases of 17-keto-androgens (e.g., androstenedione, dehydroepiandrosterone) and 17-keto-estrogens (e.g., estrone) because 17α-hydroxysteroid dehydrogenase present in red blood cells converts the steroids to epitestosterone and estradiol-17α, respectively (Choi *et al.*, 1989). Concentrations of testosterone and estradiol-17β are not influenced when storing whole bovine blood over 24 h at 20°C (Choi *et al.*, 1989).

Plasma or serum samples can be stored frozen for long periods of time without a significant loss in reproductive hormone concentration. Sample handling procedures from blood collection to the freezing of serum or plasma should be standardized for each species and hormone determined.

2. Milk

Milk samples for progesterone analysis can be preserved with sodium azide, potassium dichromate, or thimerosal

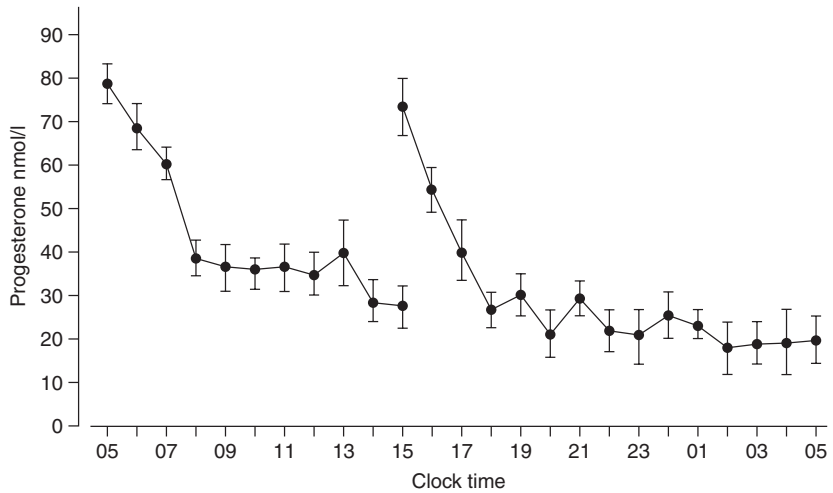

FIGURE 21-11 Hourly changes in whole-milk concentrations of progesterone due to the variation in fat content during 24 h, mean and SE of 12 cows (Garcia and Edqvist, 1990).

for storage at room temperature for about 3 weeks and for several months if the milk is stored at 4 to 5°C (Nachreiner *et al.*, 1992). There is a difference in progesterone content among fore milk, composite milk, and strippings because of the variation in milk fat content (Fig. 21-11) (Garcia and Edqvist, 1990). This difference is less obvious when using skim milk for the immunoassay of progesterone, but the temperature must be controlled at centrifugation because warm butterfat will absorb progesterone more readily than cold butterfat (Nachreiner *et al.*, 1992). A common recommendation for sampling of milk for analyses of progesterone is to obtain strippings after milking.

I. INTRODUCTION

Of the 103 elements in the periodic table, about 30 are presently considered essential or important for the normal health and growth of animals. Of these, 16 are often designated as essential trace elements, a classification initially based on the difficulty of measuring such elements with precision in biological tissues. Although the development of new instrumentation has greatly facilitated measurement, the term *trace elements* has been retained and is still commonly applied to those elements that occur in the body at concentrations in the submicromolar to micromolar range (Fraga, 2005; O'Dell and Sunde, 1997; Reilly, 2004; Ullrey, 2002).

This chapter focuses on six elements—cobalt (Co), copper (Cu), manganese (Mn), molybdenum (Mo), selenium (Se), and zinc (Zn)—to illustrate the concepts important to trace element metabolism and disease (Reilly, 2004). These elements have been chosen because there is evidence that perturbations in their metabolism are relatively common. Other biologically active trace elements, although potentially important, often require special conditions or long periods of deprivation before signs of deficiency are recognized, and exposures at 10 to 100 times normal intakes are required before toxic signs are observed (Subcommittee on Dairy Cattle, National Research Council [NRC], 2001; Subcommittee on Mineral Toxicity in Animals, NRC, 1980). In conventional settings, deficiencies of elements such as vanadium, chromium, silicon, nickel, and tin are rarely encountered. Further, arguments for their nutritional essentiality remain controversial. If there is a nutritional need, it is likely to be in the microgram per kilogram of diet range, whereas the relative need for Co, Cu, Zn, Mn, Mo, and Se approaches, or exceeds, amounts in the milligram per kilogram of diet range (Tables 22-1 and 22-2).

A. General Properties of Minerals

Most elements accumulate in tissues to some extent. The essential elements, however, are distinguished in that

they are intimately associated with the functions of specific organic molecules, mostly proteins with enzymatic properties. When metals function to facilitate enzymatic catalysis, they typically fall into two categories, metalloenzymes and metal-enzyme complexes. Stability constants that define metal binding dictate whether metalloenzyme or metal-enzyme complex is the best designation (Reedijk and Bouwman, 1999; Taylor, 2002). For metalloenzymes there is often good stoichiometry between the moles of metal bound per mole of protein or protein subunit following purification. Metalloenzymes have metal-binding constants of 10^8 to 10^9 or greater. Metal protein complexes have constants of 10^5 or less. Metals in such complexes are easily dissociated upon dialysis of the complex (Reedijk and Bouwman, 1999).

TABLE 22-1 Trace Elements Essential for the Development and Health of Mammals and Birds

Subject to Natural Deficiencies	Experimentally Produced[a]
Cobalt	Arsenic
Copper	Chromium
Iodine	Fluoride
Iron	Nickel
Manganese	Silicon
Molybdenum	Vanadium
Selenium	Lithium
Zinc	Boron

[a] *Deficiency induced experimentally using purified diets in a rigidly controlled environment; "deficiency" is often dependent on and a function of the controlled environment.*

Trace elements that are nutritionally essential are localized to the fourth and fifth rows of the periodic table. All have incompletely filled d orbitals, except for Cu and Zn. How a given metal facilitates catalytic functions is related in part to its ability to engage in redox (the loss or gain of an electron[s]) or modulate an energy excitable transition state during a catalytic event. Such modulations in protein transition states are sometimes referred as entasis. The entasis (structural dictating) domains of most proteins utilize O, S, or N as electron donors (Riordan and Valle, 1974). When associated with given complexes, if one or two outer shell valence electrons are involved, the result is one oxidation state (e.g., Na^{+1}, Ca^{+2}, or Mg^{+2}); two or more valence electrons can result in two oxidation states (Fe^{+2} or Fe^{+3}). The use of electrons in orbitals other than the outermost valence orbitals (e.g., transition metals), however, can have a variety of oxidation states. Some metals can also function as a Lewis acid (i.e., can accept electrons from a base). Enzymes that utilize this property act as acid catalysis (e.g., Zn and the hydrolysis of phosphate esters by alkaline phosphatase (Taylor, 2002).

B. Typical Configurations of Metal Complexes

In simple metal complexes, the basicity of the electron donating group and the ability to approach the metal ion (steric effects) are the primary factors that influence stability. However, when the electron donor groups are bound together into a single molecule capable of binding a given metal, the importance of steric effects is greatly increased and stability depends on a number of other factors including the size and number of rings formed. Five- or six-membered rings have more stability; usually five-membered rings are more stable than six-membered rings. Four-membered rings are rare. Rings larger than six members are less unstable.

TABLE 22-2 Cobalt, Copper, Manganese, Molybdenum, Selenium, and Zinc Requirements for Young and Adult Dogs, Swine, Sheep, and Beef and Dairy Cattle Expressed as Mg per Kg of Ration for Adequate Intakes[a]

	Dogs	Swine	Sheep	Beef Cattle	Dairy Cattle
Co	30–60mg as vitamin B_{12}	30–60mg as vitamin B_{12}	0.1–0.3mg as Co	0.1–0.3mg as Co	0.1–0.3mg as Co
Cu	5–10	5–10	5–10	5–10	5–10
Mn	3–20	3–20	20–40	20–40	20–40
Mo[b]	1–2	1–2	1–2	1–2	1–2
Se	0.25–0.3	0.25–0.3	0.15–0.40	0.15–0.4	0.15–0.4
Zn	80–100	80–100	30–60	30–60	30–60

[a] *Values were taken from several industrial and* NRC *sources (Committee on Animal Nutrition,* NRC, 1985; *Subcommittee on Dairy Cattle Nutrition,* NRC, 2001; *Subcommittee on Laboratory Animal Nutrition,* NRC, 1995; *Subcommittee on Mineral Toxicity in Animals,* NRC, 1980; *Subcommittee on Swine Nutrition,* NRC, 1998; *The Salt Institute, www.saltinstitute.org/index.html*).

[b] *For ruminant animals, the Cu:Mo ratio should exceed 5 or more given the interactions and negative effects Mo has on Cu availability (see text).*

The stability of calcium complexes of ethylenediamine tetraacetic acid (EDTA) and its homologues with increasing number of C atoms in the bridge between N atoms is as follows:

N	Atom in Bridge Carbon	Log K_a
2	5	10.5
3	6	7.1
4	7	5.2
5	8	4.6

Such complexes are called chelates. Note that the stability also increases as the number of rings increases:

Ligand	Number of Rings	Log K_a
H_2NCH_2COOH	1	5.2
CH_2COOH		
$NHCH_2COOH$	2	7.0
CH_2COOH		
NCH_2COOH		
CH_2COOH	3	10.6

Although a further discussion of ligand basicity and steric effects is beyond the scope of this chapter, knowledge of the following relationship can be useful where various coordinating groups are compared in order of decreasing affinity for given metal ions:

$$-C{=}C{-}O^- > NH_2 > N{=}N- >{=}N-$$
$$>COO^- >- O- >>-C{=}O$$

Enolates > Amino > Azo > Ring N > Carboxylate > Ether >> Carbonyl

These relationships are important to the types and shapes of complexes that metal ions form, their stabilities, and their redox potentials.

C. Biological Perspectives

1. *Trace Elements as Essential Components in Evolution and Animal Diversity*

A reasonable question to ask is why are certain elements more nutritionally important than others? From an evolutionary perspective, relative abundance and, in many cases, the ability to form complexes with catalytic (redox) potential are among the most important reasons. Figure 22-1 shows the distribution of elements in seawater, bacteria, fungi, plants, and animals (Banin and Navrot, 1975). That

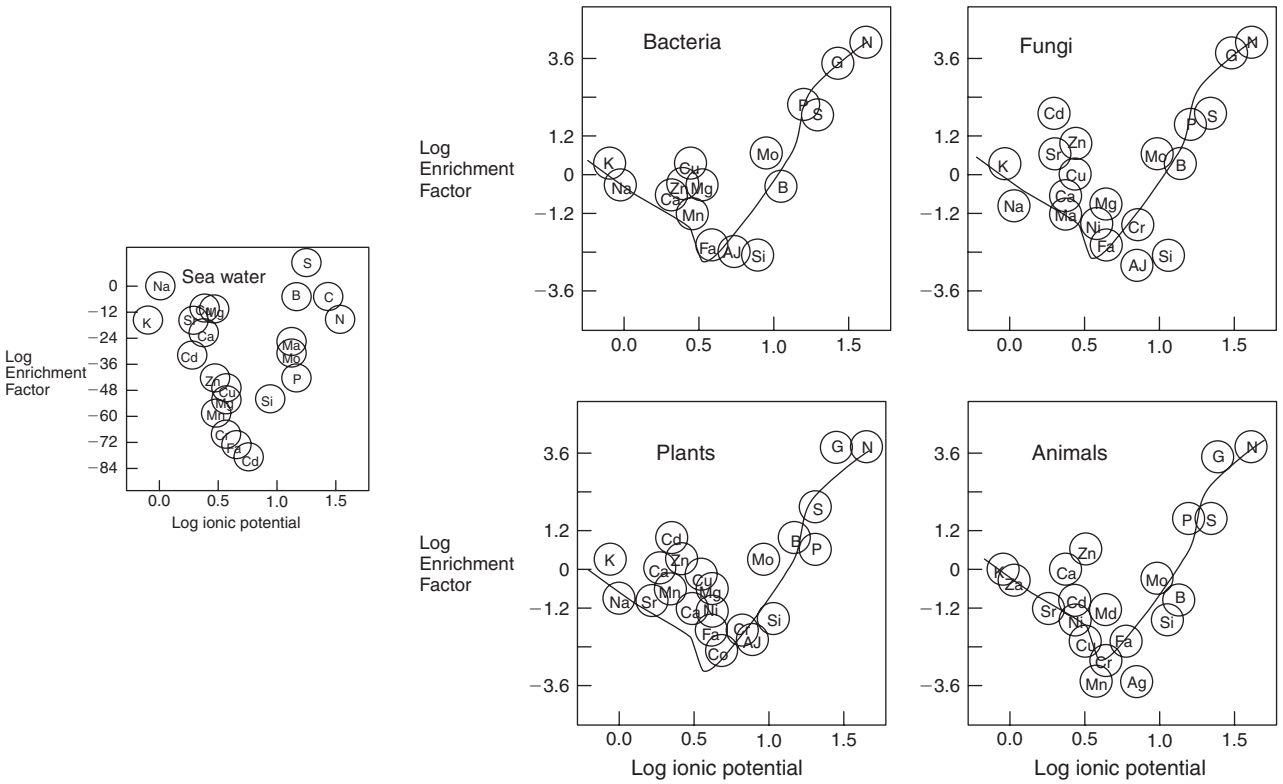

FIGURE 22-1 Distribution of elements in seawater, bacteria, fungi, plants, and animals relative to the earth's crust plotted as a function of the ionic potential (see text).

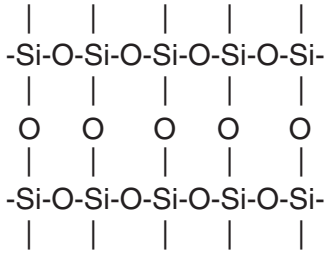
the patterns are similar suggests common chemical principles have persisted as a part of natural selection. To the extent that the ionic potential of an element is related to its relative abundance in seawater, one can argue that evolutionary choice as it relates to metal utilization is based in part on chemical properties that dictate its interaction with water. For example, when the ionic potential is high (>10), the positive ion appropriates one or more oxygen ions, freeing the hydrogen and forming an oxyanion. Oxyanions are generally soluble; thus, relative to the earth's crust, the log enrichment is high. This is a characteristic of the nonmetals in the upper right corner of the periodic table (e.g., C, N, O, S, P). Such elements are also the smallest in size to form stable multiple bonds. With time carbon can become a carbonate ion in water and eventually CO_2 (O=C=O, a gas) when oxidized further. Contrast that with silicon, carbon's tetravalent homologue in period 4 of the periodic table. Silicon in water forms silicates, which easily polymerize and are oxidized to the end product silicon dioxide or quartz, a solid, because of the inability to form stable multiple bonds:



For elements with low to intermediate ionic potential values, such as silicon (IP < log 0.5), the log of the enrichment factor is often in the range of −1 to +1, indicating small enrichment or even depletion relative to the crust. Metals with low, but positive, intermediate, or slightly negative ionic potentials tend to form hydroxides in water, most with low solubility. Many of the essential trace elements fall in this category. Finally, elements with negative ionic potentials tend to form hydrated shells and interact by organizing water structure, a role that is important to understanding the functions of Na, K, Mg, and Ca in cells.

2. *Utilization of Trace Elements and Metabolic Regulation and Metabolism*

As an additional perspective, it can be generalized that dietary requirements across species (Table 22-2 and Fig. 22-2) are more similar than dissimilar (Rucker, 2007). This is particularly the case when given requirements are expressed per unit of energy consumed or per unit weight of ration. Figure 22-2 shows the relationship for selected mineral requirements and metabolic body size. The requirements of trace elements scale allometrically in a manner that is similar in principle to scaling algorithms (e.g., $kWt^{3/4}$) for basal metabolism. If a set of common principles was involved in

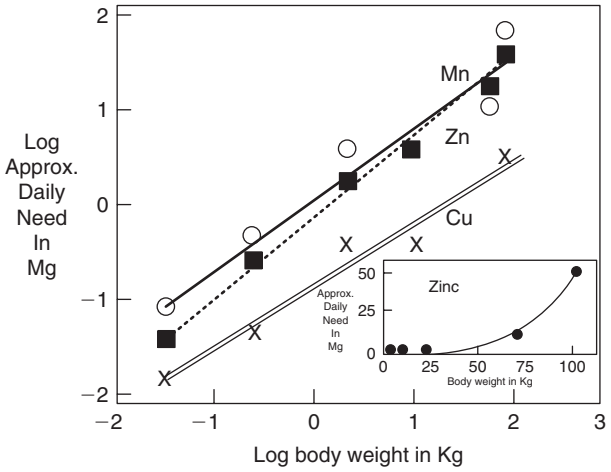


FIGURE 22-2 Relationship of mineral requirements and metabolic body size. Log plots of the daily intake of selected minerals for mice, rats, chickens, dogs, humans, and pigs versus their respective body weights in kilograms. The data for individual minerals plotted in this fashion result in reasonably linear plots with slopes that range from 0.6 to 0.8. For any given mineral, plots of daily intake versus units of body weight are not linear and require polynomial equations to describe the function (insert).

the selection of the elements important to life, it follows that nutrition requirements would be influenced by the same principles (e.g., all cells utilize in principle the same metabolic strategies). Indeed, a strong case can be made that when expressed per unit of food-derived energy or relative to metabolic body size, requirements for essential elements are similar for a diverse array of species. As substances important to catalyst and entasis, it follows consequently that their relative nutritional needs are also driven by factors and principles important to energy utilization.

Why do deficiencies or excess occur? Nutritional deficiencies obviously result when the intake of essential nutrients consistently falls below the minimal requirement (i.e., a primary deficiency). In animal nutrition this is regrettably common given the tendency to feed monotonous diets or foods common to a given region. Secondary mineral deficiencies can also arise through a variety of mechanisms that include poor bioavailability, interactions with other competing substances, and genetic influences (e.g., polymorphisms that dictate an increased need for given nutrients; Keen, 1996). Table 22-3 provides a list of several mechanisms underlying the development of deficiencies and common interactions that will be amplified in each of the sections that follow.

II. COBALT

A large animal (50 to 100 kg) can contain 1 to 2 mg of Co with liver containing about 0.1 mg (1.7 μmol), skeletal muscle 0.2 mg (3.4 μmol), bone and hair 0.3 mg (5.1 μmol) each, and adipose tissue 0.4 mg (6.8 μmol) (Smith *et al.*, 1987).

TABLE 22-3 Potential Causes of Trace Element Deficiencies

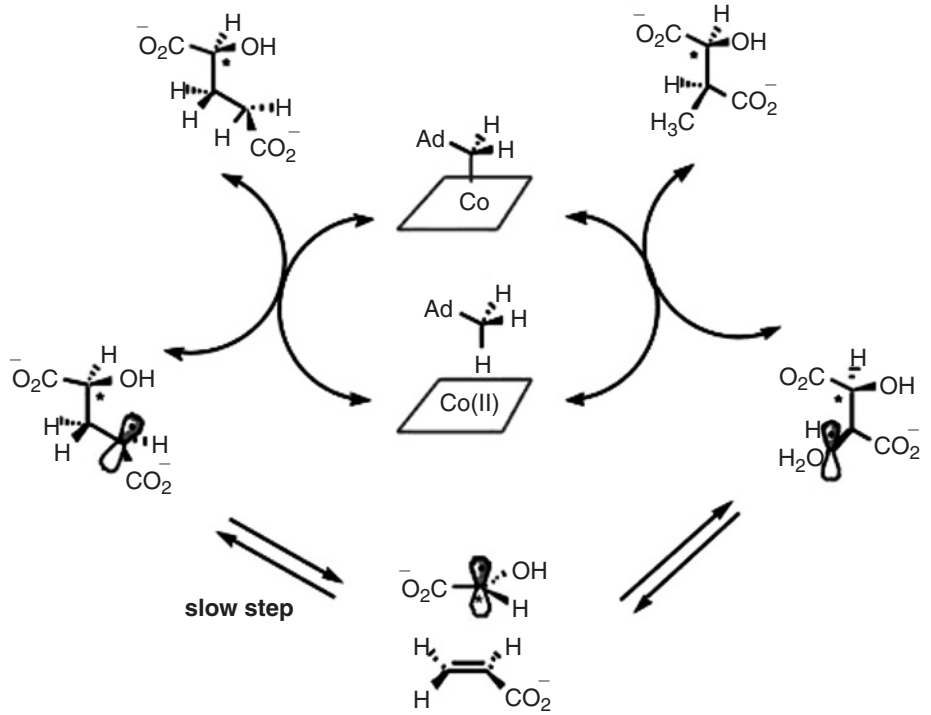
Cause	Mechanism
Food processing	Loss of elements because of refining
Dietary interactions	Competitive interactions between elements
Drug interactions	Impaired absorption or increased excretion; redistribution of elements among tissue pools; decreased absorption (chelators, laxatives); increased excretion (diuretics)
Disease or genetic	Increased requirement because of a block in the normal metabolism of the element (primary); increased requirement because of decreased absorption or increased excretion secondary to the disorder (secondary)

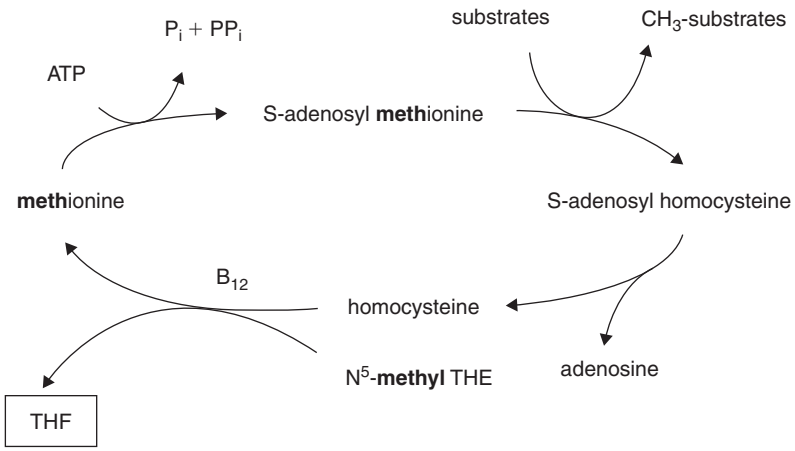
In tissues, Co is normally found associated with vitamin 12 or cobalamin in all animals that require preformed vitamin B_{12}. Cobalt in most tissues is low (picomolar concentrations), with liver, heart, and bone containing the highest tissue levels. Low normal serum cobalamin is approximately 2 to 3ng cobalamin/ml (1.5 to 2.3 nmol/liter). In contrast to Zn, Cu, and Fe, Co does not accumulate with fetal age and it is not stored to any appreciable degree in the adult animal (Ammerman and Goodrich, 1983; Keen, 1996). With toxicity, tissue Co can increase over 10-fold in cattle (Barceloux, 1999; Domingo, 1989; Lauwerys and Lison, 1994).

A. Cobalt Function

Cobalt is novel because there is no evidence that any organism needs the cobalt ion, either in the free form or as a simple protein complex. Cobalt in the form of a specific complex, vitamin B_{12} or one of the cobalamides, is essential for animals and many bacteria. Plants contain cobalt, but there is no evidence that it occurs as a cobalamide. Vitamin B_{12} is also unique among vitamins in that plants do not produce it.

The role of rumen microflora in the economy of ruminant animals makes ionic cobalt of particular significance to this group of animals. Although one cannot dismiss the possibility that some organisms require cobalt other than that in a corrinoid (B_{12}-related) complex, there is no such evidence at present and this discussion will hinge primarily around the metabolism and metabolic function of cobalt as it exists in the cobalamides. In aqueous solution, Co is generally in the +2 or +3 oxidation state. Cobaltous ion forms complexes with both octahedral and tetrahedral geometry (Burgess, 1999; Kerber and Goldberg, 2006). All Co complexes are octahedral and most involve nitrogen as the electron donor. The skeletal structure of the cobalamides can be visualized by representing the corrin ring of cobalamides with a planar ring and the ligands by X and Y (see Chapter 23). Both the cobalamides and cobaloximes (simpler cobalt corrin-like structures) act as the catalytic site for intramolecular mutations and single carbon transfer reactions (Frausto da Silva and Williams, 1991). Such reactions are important to tissue and cellular growth; as such, Co is primarily associated with erythropoiesis, granulopoiesis, and glucose homeostasis. Two important enzymes that require vitamin B_{12} as a cofactor are (1) methylmalonyl-CoA mutase, which catalyzes the molecular rearrangement of methylmalonyl-CoA to succinyl-CoA:





and (2) 5′-methyltetrahydrofolate-homocysteine methyltransferase, which demethylates 5′-methyltetrafolate and regenerates methionine and tetrahydrofolate.

The former reaction is critical for glucose homeostasis in ruminants because a primary gluconeogenic precursor for these animals is propionic acid. Because propionic acid has three carbons, propionyl-CoA cannot enter b-oxidation nor the citric acid cycle; thus, in most vertebrates it is carboxylated to D-methylmalonyl-CoA, isomerized to L-methylmalonyl-CoA, and rearranged to yield succinyl-CoA via the vitamin B_{12}-dependent step shown previously. Succinyl-CoA is an intermediate of the citric acid cycle and can be readily incorporated there.

Another aspect of Co in mammalian systems is the potential pharmacological effect of high doses of Co on erythropoietin production (Katsuoka *et al.*, 1983). Whether physiological concentrations of Co influence erythropoietin production is not known. Dietary requirements (as B_{12}) in most animals are usually met either by ingestion of animal tissues or products or by coprophagy. Because of the rumen microflora, ruminants can be fed ionic Co, and the microbes will synthesize cobalamin for absorption. Nevertheless, the relative inefficiency of vitamin B_{12} production in the rumen and poor absorption of B_{12} predispose ruminants to deficiency. Between 2 and 5 mg/day (1.5 to 3.9 μmol/day) of CoCl for sheep and 20 to 30 mg/day (15.4 to 23.1 μmol/day) for cattle are required for normal B_{12} production (Kennedy *et al.*, 1995; Kincaid *et al.*, 2003).

B. Absorption and Transport

In rats, 80% of orally administered Co appeared in the feces. High amounts of iron in the diet can depress Co absorption and vice versa. Co absorption is enhanced in iron deficiency (Domingo, 1989). Excretion of Co is primarily via the kidneys and is linearly related to the ingested dose. Additional sites of excretion have been reported to be the large intestine in chicks and the bile and small intestine in mammals.

Absorption of vitamin B_{12} depends on normal gastric parietal cell synthesis of intrinsic factor and a healthy ileal mucosa for the binding and transport of the vitamin B_{12}. Response to therapy and a ration containing less than 0.08 mg Co/g (1.4 μmol/g) of diet is diagnostic of Co deficiency in ruminants. In sheep, hepatic vitamin B_{12} levels of less than 0.1 μg/g (0.07 nmol/g), or serum levels of less than 0.3 ng/ml (0.2 nmol/liter), are associated with impending or frank deficiency. Thus, vitamin B_{12} status can be used to assess Co adequacy in sheep. Although measurement of plasma cobalamin levels has been considered sufficient for assessment of Co status in sheep, it has been suggested that liver cobalamin should also be included in assessment studies as plasma levels do not always reflect soft tissue levels (Mills, 1987). In this regard, it should be considered that the measurement of plasma cobalamin is complicated by the presence of cobalamin analogues that interfere with the assay (Halpin *et al.*, 1984). Therefore, the measurement of plasma methylmalonate levels is used as an indirect indicator of the functional cobalamin status of the animal. The increase in methylmalonate is due to a reduction in the activity of mehylmalonyl-CoA mutase, for which adnosylcobalamin is a cofactor (discussed earlier).

C. Disorders of Cobalt Metabolism

The signs and biochemical lesions that are manifested in Co deficiency are referable to a deficiency of vitamin B_{12}. The pathways that are most severely impaired are those of purine biosynthesis and glucogenesis. Deficiencies of Co have been correlated with a reduction in blood glucose and an increase in methylmalonic acid excretion. A primary defect in Co deficiency underlying the previous discussion has been attributed to a reduction in the activity of

methylmalonyl CoA mutase in ruminants. The hepatic lipidosis observed in Co-deficient animals has been attributed to a reduction in choline biosynthesis caused by a reduction in the activity of homocysteine methyltransferase. Vitamin B_{12} deficiency reduces the regeneration of methionine, which can impair choline biosynthesis. With a reduction in the activity of this enzyme, Co deficiency can result in a reduction in the regeneration of tetrahydrofolic acid, which can then result in the development of megaloblastic anemia and pancytopenia secondary to impaired purine biosynthesis. A reduction in tetrahydrofolate reduces the available methyl donors and therefore reduces purine biosynthesis (see Chapter 23). The primary signs of Co deficiency are referable to pernicious anemia, granulocytopenia, and chronic wasting, which is secondary to aberrations in amino acid, nucleic acid, carbohydrate, and potentially, lipid metabolism. Another disorder, white liver disease, is a Co-responsive disease of sheep that is characterized by unthriftiness, listlessness, weight loss, ocular discharge, anemia, pale liver, and occasionally, photosensitivity and neurological dysfunction (Kennedy *et al.*, 1997; Mitchell *et al.*, 2007; Smith *et al.*, 1987).

Toxicity in animals under natural conditions has not been reported. Toxic levels appear to be at least 300 to 1000 times the requirement in most species. Cases of toxicity are invariably the result of accidental oversupplementation to prevent deficiency or inhalation of Co sources. Doses in excess of 4-mg/kg body weight (68 μmol/kg) can be toxic for sheep and ingestion of greater than 1.1 mg/kg (18.7 μmol/kg) in cattle can be toxic. The major clinical signs include polycythemia, anorexia, fatty infiltration of the liver, pulmonary edema, and depressed grow. Noteworthy, cases of Co intoxication from ingestion of beer have been reported in humans (Barceloux, 1999; Lauwerys and Lison, 1994). In humans, signs of Co toxicity are hyperthyroidism, thyroid hyperplasia, cardiomegaly, and heart failure. Symptoms related to inhalation toxicosis are mostly referable to the lungs and skin with hypersensitivity, dermatitis, and pulmonary fibrosis being the major lesions (Mitchell *et al.*, 2007; Watson, 1998).

III. COPPER

A. Copper Distribution

A large animal can contain 50 to 120 mg (780 to 1889 μmol) of Cu. In the adult, about one-third of the total body Cu is found in the liver and brain. Most nonruminant species have liver Cu concentrations that are between 2 and 10 μg/g (0.032 to 0.16 μmol/g). Skeletal muscle, although considered low in Cu, represents about one-third of the total body Cu because of its mass. The remainder of the Cu is fairly evenly distributed throughout the body. The highest concentrations of Cu (>5 μg/g; >0.079 μmol/g) are normally present in liver, brain, heart, and hair. Tissues with intermediate levels or Cu (1.5 to 5 μg/g; 0.024 to 0.078 μmol/g) include kidney, pancreas, skin, muscle, and bone. Tissues with low concentrations of Cu (<1.5 μg/g; <0.024 mol/g) include pituitary, thyroid, thymus, ovary, and testis (Keen *et al.*, 2003; Mason, 1979; Smart *et al.*, 1981; Stern *et al.*, 2007). The normal range of Cu in the blood of most healthy animals is between 0.5 and 1.5 μg/ml (7.9 to 23.6 μmol/liter). In most species, plasma/serum and whole blood Cu concentration are similar. Birds, fish, and marsupials are characterized by blood Cu concentrations that are about half that of other species (Mason, 1979).

Ruminants have a high storage capacity for Cu in their livers, often exceeding two-thirds of the total body pool. Typical liver Cu concentrations in sheep and cattle range from 20 to 150 μg/g (0.315 to 2 to 36 μmol/g). Similarly high liver Cu levels have been reported for ducks and some fish. The high liver Cu in ruminants compared to nonruminants is thought to reflect a higher retention rather than a difference in dietary intake of Cu or absorption. Copper concentrations in other ruminant tissues are similar to those reported for nonruminants. For most species, the newborn is characterized by liver Cu concentrations that are markedly higher than those found in adults. However, the Cu in most other tissues tends to be higher in the adult than in the newborn (Stern *et al.*, 2007).

It has been suggested that the high liver Cu in the newborn can represent a reserve pool of Cu for the rapidly growing neonate. Several cases of Cu deficiency have been reported in premature infants. In sheep, liver Cu in the newborn is lower than in adults, and in cattle, newborn and adult liver Cu is similar (Keen, 1996).

For all species studied, the pigmented tissues of the eye are particularly high in Cu, with very high levels associated with the melanins. The function of this Cu in the eye is not known. Except in certain disease states and in deficiency, the body Cu content is homeostatically controlled, and there is little accumulation of Cu in the eye (Krajacic *et al.*, 2006).

B. Copper Functions

Copper has two major functions. It can be a structural component in macromolecules acting as a coordination center. It is also a common redox cofactor for a number of oxidases and monooxygenases that are essential for life, owing to its ability to cycle between reduced and oxidized states.

Perturbations in the activity of these enzymes because of poor Cu dietary status can be linked to specific biochemical steps and lesions. For example, poor growth, reproduction, skeletal, and vascular formation can result from a lack of lysyl oxidase and cytochrome C oxidase. Impaired immunity, neurological function, oxidant defense, and depigmentation resulting from Cu deprivation can also

be linked to specific enzymes such as Cu-Zn superoxide dismutase (CuZnSOD), which catalyzes the dismutation of the superoxide anion; dopamine β-hydroxylase, responsible for noradrenalin and adrenaline production; and melaninase, responsible for melanin production (Keen *et al.*, 2003; Rucker *et al.*, 1998; Stites *et al.*, 2000; Tinker and Rucker, 1985).

A diverse array of physiological symptoms, particularly during the perinatal period, can occur including hypotension, muscle hypotonia, hypothermia, and hypoglycemia. Moreover, elastin and collagen from Cu-deficient animals have an elevated content of lysine and a low content of various cross-linking amino acids. Loss of cross-linking results in defects in the elastic properties of arteries and decreases in bone strength and the tensile strength of various connective tissues. A reduction in CuZnSOD can increase hydrogen peroxide and superoxide radicals that can irreversibly oxidize proteins, nucleic acids, lipids, and carbohydrate components within cytoskeletal structures and the cell wall.

Changes in Cu status, particularly in the fetus and neonates, have been associated with perturbations in nitric oxide (NO) metabolism, a key signaling molecule to endothelial cell responsiveness (e.g., contraction and relaxation). Moreover, when an increase in hydroxyl radical occurs, because of a reduction in CuZnSOD activity, the reaction of peroxide radicals with NO can produce peroxynitrite. Peroxynitrite, another potent oxidant, can cause ATP depletion and peroxynitrite-induced nitration of tyrosine residues on proteins. Many of the neurological signs and endothelial changes associated with Cu deficiency are thought to be the result of altered NO metabolism (Schuscha, 1997; Yang *et al.*, 2007) and peroxynitrite-induced lesions (Fig. 22-3).

Other Cu-containing enzymes include tryptophan oxygenase, ascorbate oxidase, tyrosinase, amine oxidases, peptidyl-glycine-α-amidating monooxygenase, and possibly some fatty acid desaturase enzymes such as C18 Δ°-desaturase. It has been suggested that Cu can also be involved in a nonenzymatic manner in neuropeptide release from the brain.

C. Dietary Copper

Copper absorption from diets is relatively efficient, although some dietary constituents can affect bioavailability. Copper hydroxides, iodides, glutamates, and citrates are more easily absorbed than molybdates, sulfates, and phytates. High intakes (100 or more mg/kg of diet) of Ag and Zn can interfere with intestinal copper transport. Moreover, the extended use of supplements that contain iron can negatively affect copper status. Cu absorption is greater in neonates than in adults (Committee on Copper in Drinking Water, 2000; Stern *et al.*, 2007).

Another interaction that has attracted attention involves Cu, Mo, and sulfate. Particularly in ruminants, dietary sulfate intensifies the harmful effects of Mo on Cu absorption. $CuSO_4$ and Na_2MoO_4 react to form an insoluble complex referred to as a thiomolybdate, which renders Cu biologically less active and less bioavailable (see Section V).

Nutritional Cu deficiency occurring outside of the laboratory has been well documented in a variety of species including humans, cattle, sheep, pigs, and horses. The recommended minimal daily requirements for Cu for a number of species are presented in Table 22-2. Given that the uptake of Cu from a diet can be influenced by other dietary factors as well as the physiological state of the animal, under some conditions, a diet cannot contain sufficient Cu for the animal even though the level of Cu in the diet is at the level suggested in the NRC tables.

Food items that are high in Cu include nuts, dried legumes, dried vine, and dried stone foods (300 to 400 μg/g; 4.72 to 6.30 μmol/g). Food items considered low in Cu content ($<1\,\mu$g/g; 0.016 μmol/g) include dairy products and sugar, refined cereals, fresh fruits, and nonleafy vegetables contain about 7 μg Cu/g (0.11 μmol/g). Copper in typical animal feeds can range from 20 μg/g (0.315 μmol/g) (cottonseed meal) to 2 (0.032 μmol/g) (corn), with the concentration being highly dependent on soil conditions and fertilizer practices.

D. Copper Metabolism, Absorption, and Transport

1. *Cellular Transport and Regulation*

Copper is absorbed in all segments of the gastrointestinal tract. For most species, absorption occurs in the upper small intestine, but in sheep considerable absorption also occurs in the large intestine. Absorption of Cu is about 30% to 60% with a net absorption of about 5% to 10% owing to the rapid excretion of newly absorbed Cu into the bile. A delicate balance between Cu uptake and efflux maintains copper homeostasis (Cromwell *et al.*, 1989; Gooneratne *et al.*, 1989; O'Dell and Sunde, 1997; Reilly, 2004; Stern *et al.*, 2007; Theile, 2003).

Cu uptake occurs through both high- and low-affinity transport systems (Fig. 22-4). Environmental factors can influence the response to transporters. Most important are factors that influence solubility and redox state. Cu exists in two different valence states; the cupric ion (Cu^{+1}) is the primary substrate for the transport systems that take Cu across plasma membranes. Reduction ($Cu^{+2} \rightarrow Cu^{+1}$) is catalyzed by plasma membrane reductases (Theile, 2003). However, the cuprous ion (Cu^{+2}) in the intestinal lumen is more soluble than the cupric ion (Cu^{+1}). Chemical reduction of luminal contents (e.g., by reducing agents such as ascorbic acid) can decrease the amount of Cu that is bioavailable (i.e., affectively delivered to the surface of intestinal cells). It is important, however, to note several caveats. Observations in humans suggest that the effects of ascorbic

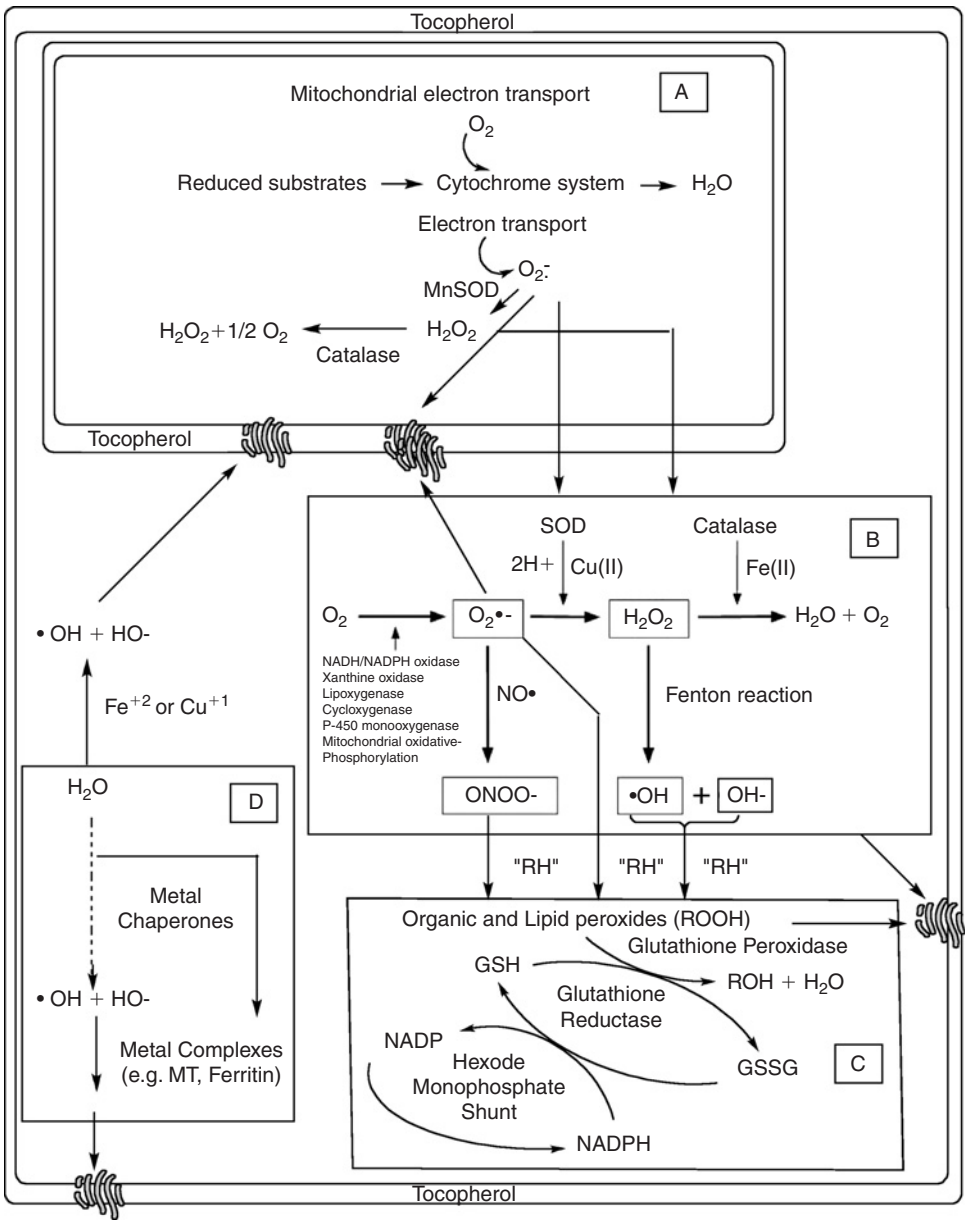


FIGURE 22-3 Major sources and regulation of reactive oxidant species (ROSs) in cells. Depending on the stage of development and condition, on a per mole basis ROSs are normally generated at rates of 1% to 4% of the oxygen consumed or greater when ROS regulation is disrupted. A major source of ROS is derived from superoxide anion (O_2^-) generated in the mitochondrion (A) because of uncoupling from the cytochrome oxidase system during mitochondrial electron transport. In addition to water and oxidized metabolites as products, superoxide anion and H_2O_2 are produced. Enzymes, such as catalase and MnSOD (localized in the mitochondria) control excess production of O_2^- and H_2O_2. When there is subsequent leakage from mitochondria, an increase in the cellular pool of ROS occurs owing both to ROSs from mitochondria and production from other organelles and cytosol (B). Sources of ROSs from other organelles and cytosol are the products from reactions catalyzed by NADH and NAPH oxidases, xanthine oxidase (activated during ischemic injury), lipoxygenase, and P450 monooxygenase enzymes (localized mainly in the smooth endoplasmic reticulum and responsible for the metabolism of xenobiotics, drugs, and secondary metabolites). In addition, excess ROS can potentially alter nitric oxide metabolism (e.g., formation of peroxynitrites) and cause the generation of organic and lipid peroxides and so-called Fenton products (C). For example, "RH," used to depict numerous aromatic and lipid-derived possibilities as potential reactants, can be converted to ROOH, potential organic peroxide-containing products. Excess superoxide anion, ROOH, OH-, OH·, and other ROSs can then damage proteins, nucleic acids, and lipids, particularly lipid structures in cell and organelle membranes. Important to this discussion, metals can act as both catalysts for ROS formation and cofactors for antioxidant enzymes that modulate influence ROS metabolism. For example, (1) MnSOD and CuZn SOD (superoxide dismutases) cause the dismutation of excess superoxide anion to peroxide, (2) catalase (contains Fe) and glutathione peroxidase (contains Se) can control excess of both hydrogen and organic peroxides. As an additional defense, metal chaperones (see text), metallothionein (MT), or ferritin control "free" metal ion concentrations in cells that are capable of redox (D). Redox metals (Fe or Cu) can act as Fenton catalysts and promote the homolytic cleavage of H_2O_2 to OH· and OH-, which are highly damaging oxidants. Reduction in the concentration or sequestration of metals (depicted by the dashed line) markedly reduces potential Fenton products. As a final line of defense, tocopherols and polyphenolic and related phytochemicals, which localize to lipid membranes, provide additional ROS defense.

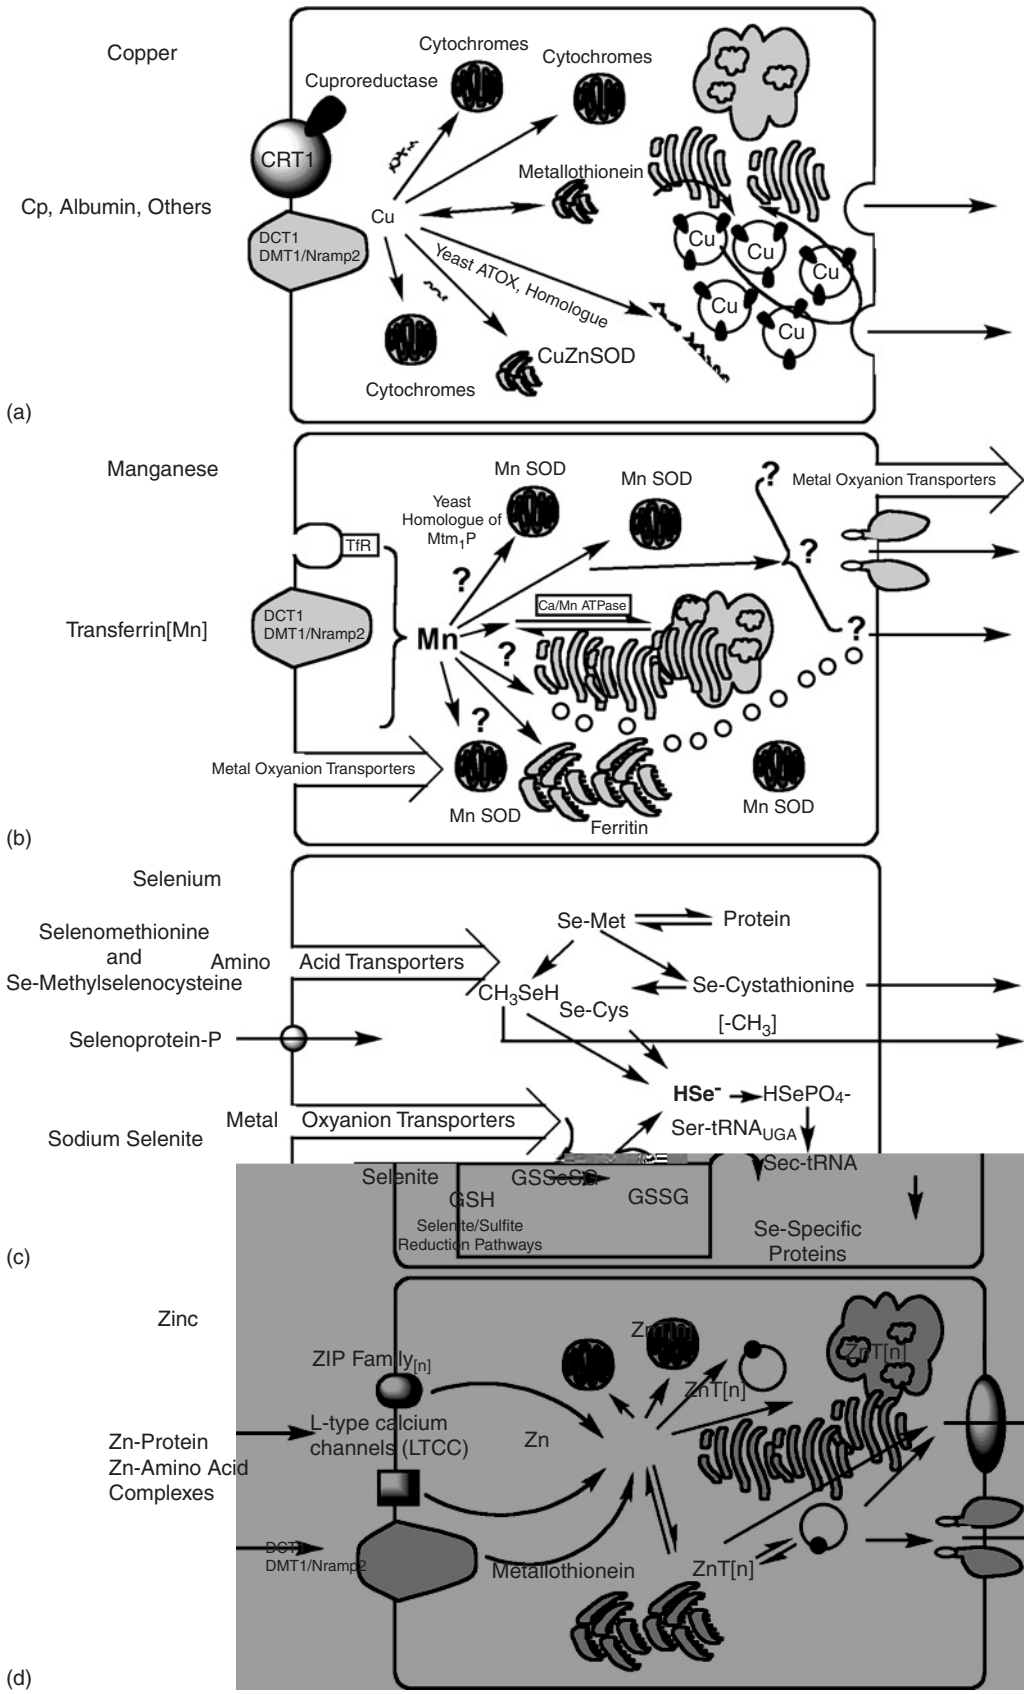

FIGURE 22-4 Cellular transport. Features important to the transport of copper, manganese, selenium, and zinc are summarized. For features related to cobalt (and vitamin B_{12}), refer to the vitamin chapter and for molybdate see Figure 22-5. (a) Dietary copper is presented to intestinal cells in the form of protein and amino acid complexes, and in plasma, Cu is bound to a number of proteins; however, it is most often associated with albumin and ceruloplasmin. The transport and cellular metabolism of Cu depend on a series of membrane proteins and smaller soluble peptides that constitute a functionally integrated system for maintaining cellular Cu homeostasis. The high-affinity copper transporter (CTR1) of the plasma membrane mediates

acid on Cu absorption are modest and probably occur only at the extremes of ascorbate intake (Jacob *et al.*, 1987; Lonnerdal, 1998; Stern *et al.*, 2007).

From a conceptual perspective, studies in yeast have shed light on proteins involved in the process of Cu transport. For example, in *S. cerevisiae*, high-affinity Cu ion uptake has been characterized as temperature and ATP dependent. Cu ion uptake appears to be coupled with K^+ efflux with a 1:2 stoichiometry, suggesting that the process takes place via a $Cu^+/2K^+$ antiport mechanism. In yeast, the gene for Cu reductase activity, designated *FRE1*, is regulated by activation of a transcription factor in response to cellular Cu levels (Pena *et al.*, 1999; Puig and Theile, 2002; Stern *et al.*, 2007; Theile, 2003). In mammalian cells, the entry of Cu into cells is first orchestrated by the action of a reductase and then contact with a high-affinity Cu transporter, currently designated as Ctr1 and Ctr3 (Ctr2 is a low-affinity transporter). High-affinity Cu uptake is saturable with a K_m of $1-4\,\mu$mol/l. Under Cu-limiting conditions, there is evidence that the transporters and proteins involved in Cu redox are up-regulated, whereas under Cu-replete conditions, they are down-regulated (Theile, 2003). Of some significance, Ag and Zn ions can compete for Cu by using the Crt transporters Zn and Ag ions have similar chemical characteristics as Cu^{+1}. Effective competition does not occur except at intakes 5 to 10 or more fold the Zn requirement and when Cu intake is marginal (Committee on Cu in Drinking Water, 2000; Stern *et al.*, 2007).

In addition to the transporters, cellular chaperones specific for Cu deliver Cu to specific cellular proteins (Fig. 22-4). Other important features of Cu regulation include the role of metallothionein, a divalent metal-binding protein for Cu, Zn, Hg, and Cd, which acts to buffer shifts in the cellular concentrations of Cu (and Zn). Cu egress or transport out of cells is controlled by P-ATPase Cu-transporters that are located on the surface of vesicles that arise from Golgi processing. Although a change in Cu status does not appear to alter Cu-transporting P-ATPase gene expression, it can affect the movement of copper-containing vesicles to and from that outer cell membrane. Cu homeostasis must be coordinated, as the release of free Cu ions can cause damage to cellular components by catalyzing the generation of reactive oxidant species (ROS).

Free cuprous ions (and ferric) react readily with hydrogen peroxide to yield deleterious hydroxyl radicals. Accordingly, Cu homeostasis is regulated tightly, and unbound Cu is extremely low in concentration (~one atom/cell). For example, Atox1, a chaperone that delivers Cu into egress or efflux pathways, docks with a Cu-transporting ATPase (ATP7B in the liver or ATP7A in other cells). ATP7B directs Cu to plasma ceruloplasmin or to biliary excretion in concert with another chaperone, Murr1, the protein missing in certain types of canine Cu toxicosis. ATP7A directs Cu within the trans Golgi network to the proteins dopamine β-monooxygenase, peptidylglycine α-amidating monooxygenase, lysyl oxidase, and tyrosinase, depending on the cell type (Stern *et al.*, 2007; Theile, 2003).

FIGURE 22-4 (*Continued*) nearly all Cu uptake under low copper conditions. It is one of a family of proteins involved in Cu transport that is transcriptionally induced at low copper levels and degraded at high copper levels. Associated with this transporter is a copper reductase that maintains Cu in the +1 state (its most soluble form) while in the vicinity of the transporter. Next, Cu is transferred to chaperones whose functions are to carry copper to specific proteins within the cell (e.g., COX-17 → cytochromes, ATOX → vesicular P-ATPases, CCS → SOD). Copper egress (efflux) is accomplished by a novel process, the transport of copper into secretory vesicles via post-Golgi processing. This occurs coincidently with efflux of specific apocuproproteins (see text) that are localized to the same vesicles. On the membrane of the vesicles, two membrane-bound Cu-transporting ATPase enzymes, ATP7A and ATP7B, catalyze an ATP-dependent transfer of Cu to intracellular compartments or expel Cu from the cell (from the Golgi to and from the cell membrane). In response to a high level of cellular Cu, there is recycling of the vesicles at higher rates to more effectively remove copper. Within the vesicles, apocuproproteins can also become activated. Consequently, secreted cuproproteins with enzyme activity, such as lysyl oxidase or ceruloplasmin, often reflect Cu status or dietary intake. Some evidence also suggests DMT or Nramp transporters important to iron transport can play a minor role in copper uptake. (b) Intestinal and systemic cellular manganese transport is mediated mostly by divalent metal transporter 1 (DMT1) and is up-regulated in iron deficiency. Within the body, Mn bound to transferrin is taken up by transferrin receptors. Unlike other transition metals, which are not found in "free" ion forms in cells, the behavior of Mn is analogous to Mg (i.e., dissociable ion exists). Less is know currently about specific chaperones than for copper or zinc. Excess Mn in cells is sequestered on ferritin. A Golgi-derived ATPase has been described to facilitate the movement of Mn from and to the nucleus and cis- and trans-Golgi compartments. Although the evidence is indirect that other types of ion channels and vesicular egress play a role in Mn cellular transport, given that MnO_4 anion can be transported in addition to Mn^{+2} and Mn^{+3}, a role for oxyanion transport is indicated. (c) Selenium is delivered to cells via amino acid and oxyanion transporters and when present in plasma via processes that recognize selenoprotein P. The selenite and selenate forms must first be reduced (via a glutathione reduction system) to HSe- before Se can be utilized as a cofactor. Selenomethionine, if not incorporated into protein, can also be eventually converted to HSe-. Next, for incorporation into specific Se-proteins (e.g., GPx, 5′-ID, or Se-protein P), HSe- is phosphorylated (requires ATP). Then following transfer to Ser-$tRNA_{UGA}$ to form Se-Cys-$tRNA_{UGA}$, the stage is set for translation of Se-containing proteins. Regarding cellular efflux, Se is lost from cells as secreted Se-proteins, such as selenoprotein P, Se-cystathionine, or as volatile forms of methylated Se (e.g., CH_3-Se-CH_3). (d) Zinc uptake and cellular translocation are controlled by two large families of metal transporters for which there more than two dozen variants. More specifically, the two solute-linked carrier (SLC) gene families encode the zinc transporters: ZnT (SLC30) and Zip (SLC39). The ZnT transporters reduce intracellular zinc availability by promoting zinc efflux from cells or into intracellular vesicles, whereas Zip transporters increase intracellular zinc and promote extracellular zinc uptake. The ZnT and Zip transporter families exhibit unique tissue-specific expression and differential responsiveness to dietary Zn intake and to physiological stimuli. Temporary influxes of Zn are buffered by the induction of metallothionein. DMT1 and over-ion channels can play minor roles in Zn transport.

2. Systemic Regulation of Cu

From the intestine, a case can be made for the transport of Cu on albumin and in the form of low-molecular-weight complexes (e.g., histidine) to target tissues, particularly the liver. From the liver, ceruloplasmin seems to aid in the transport of Cu to other tissues. Ceruloplasmin is the predominant Cu-containing protein in mammalian serum, a glycosylated multi-Cu ferroxidase that carries >95% of total serum Cu. Surprisingly, whereas ceruloplasmin can function in Cu transport, the absence of ceruloplasmin has not been shown to alter Cu levels in the peripheral tissues. Such observations come from what is known about individuals and animal models that have aceruloplasminemia, a genetic disorder of ceruloplasmin deficiency. Moreover, analbunemic rats do not have significantly impaired Cu metabolism. Apparently Cu movement from serum proteins to the cell surface reductase-Ctr transporters is not highly specific (Hellman and Gitlin, 2002).

3. Disorders of Cu Metabolism-Cu Deficiency

A number of pathologies are associated with Cu deficiency that represent perturbations in the functions of Cu outlined earlier. For example, anemia (microcytic hypochromic or normocytic hypochromic) is probably the most frequent sign associated with chronic Cu deficiency. Cu deficiency results in impaired normal iron absorption (O'Dell and Sunde, 1997), mobilization, and utilization, partly because of Cu's role as a redox cofactor in various membrane associated ferrioxidases that oxidize Fe^{+2} and Fe^{+3}, thereby promoting the transfer of iron to transferrin. Reduced aminolevulinic acid dehydrase, important to the first step in heme synthesis, is also decreased in Cu deficiency. Heinz body anemia caused by ROS can also develop with a significant depression of CuZnSOD activity (O'Dell and Sunde, 1997).

Cardiovascular defects have been associated with Cu deficiency since the 1950s. In cattle, Cu deficiency can result in severe degeneration of the myocardium with fibrosis ("falling disease"). Sudden death is a frequent observation and is thought to be due to acute heart failure. Cardiac failure associated with cardiac hypertrophy has also been reported in Cu-deficient rats. A number of biochemical lesions can underlie the changes in the heart observed with Cu deficiency (e.g., decreased cytochrome oxidase activity, abnormalities in cardiac and vessel wall elastin and collagen structure because of lysyl oxidase, and low cardiac norepinephrine levels, which can decrease coronary resistance and reduce systolic pressure) (Tinker and Rucker, 1985). In experimental Cu deficiency in young animals, such as turkey poults, aortic aneurysms can occur (Savage *et al.*, 1966). This is the result of poor biomechanical properties of elastic fibers (constitutes as much as 50% of the total protein in aorta) that are weakened as a result of defective and reduced cross-linking. Such elastin is also susceptible to degradation and lost. Contrast this condition with normal elastin that normally has a biological half-life best measured in months to years (Tinker and Rucker, 1985).

In addition, skeletal defects have been reported in Cu-deficient dogs, sheep, chicks, cattle, foals, and humans. The primary biochemical lesion underlying development of bony lesions in Cu-deficient animals is again a reduction in the activity of lysyl oxidase leading to a reduction in the cross-linking of bone collagen, thus reducing bone stability and strength analogous to the situation with elastin (Tinker and Rucker, 1985).

An increased rate of tissue lipid peroxidation is another mechanism by which Cu deficiency can contribute to a wide variety of lesions. In addition to the depression in CuZnSOD activity, Cu deficiency can reduce the activity of selenium(Se)-dependent glutathione peroxidase (GPx). Thus, two major components of the cells' antioxidant defense system can be affected by Cu deficiency. Another lipid alteration is hypercholesterolemia (Engel *et al.*, 2000; Gooneratne *et al.*, 1989; Keen *et al.*, 2003; Mills, 1987; Schuscha, 1997). In Cu-deficient animals, total cholesterol and free cholesterol levels are elevated and are associated with high concentrations of high- and low-density lipoproteins (HDL and LDL). The lipid composition of HDL isolated from Cu-deficient animals has been reported to be similar to that of Cu-supplemented animals, but the HDL has been shown to be enriched in apo F. A primary biochemical lesion underlying the hypercholesterolemia is a reduction in hepatic HDL binding that results in a slower turnover of HDL and leads to an accumulation of apo E-rich HDL. Both of these phenomena, lipid peroxidation and abnormal lipid transport, are important features that underlie abnormal membrane function.

Important to Cu's role in oxidative defense are observations that link Cu status to NO metabolism, an important mediator of cellular regulation. NO can be synthesized in both the cytosol and mitochondria (Wu and Meininger, 2002). Among its major functions as a signaling molecule, NO modulates oxidative phosphorylation and protects mitochondria from oxygen radicals. This process, however, depends on optimal cytochrome oxidase and CuZnSOD activities. Cu deficiency limits NO availability, because in the presence of ROS, NO is converted to products, such as peroxynitrite, thus altering NO-dependent signaling and contributing to processes that can range from abnormal development to aging to neurological and cardiovascular disorders. Indeed, many neurological signs can be associated with Cu deficiency, owing to Cu's role as a cofactor in dopamine β-monooxygenase and in influencing NO metabolism (Wu and Meininger, 2002). A classical example of a neurological disorder is neonatal ataxia.

Neonatal ataxia has been shown to be a consequence of perinatal Cu deficiency in lambs, goats, swine, guinea

pigs, deer, camels, and rats. Originally described in lambs, the disorder, which is often referred to as enzootic ataxia or swayback, is characterized by spastic paralysis, especially of the hind limbs, severe in coordination of movement, blindness in some cases, and anemia. The brains of affected animals are smaller than normal with collapsed cerebral hemispheres and shallow convolutions and are characterized by a paucity of myelin. It has been suggested that the neural lesions associated with enzootic ataxia are in part the result of a Cu deficiency-induced reduction in brain cytochrome oxidase activity and impairment in phospholipid synthesis with a subsequent block in myelin synthesis. Motor incoordination and tremors have been ascribed to the effects of perinatal Cu deficiency on brain catecholamine metabolism. Norepinephrine levels are decreased in the whole brain and brainstem. The reduction in norepinephrine levels is most likely due to a decreased activity of dopamine beta-hydroxylase (monooxygenase), which catalyzes the hydroxylation of dopamine to norepinephrine (Engel *et al.*, 2000; Gambling and McArdle, 2004; Gooneratne *et al.*, 1989; Keen *et al.*, 1998).

Additional consequences of Cu deficiency, particularly during early development, are alterations in the immune system and systemic metabolism. Regarding immune function, effects of Cu deficiency include impaired neutrophil function, increased susceptibility to bacterial infections, decreased resistance to tumor challenge, reduced cell-mediated and humoral immunity, and alterations in lymphocyte subpopulations. Arthur and Boyne (Arthur and Boyne 1985; Boyne and Arthur, 1986, 1990) reported that the loss of neutrophil microbicidal activity associated with Cu deficiency in cattle is secondary to a failure to produce superoxide within the neutrophil phagosome. A primary biochemical defect can also be a reduction in lymphopoiesis secondary to a decrease in erythropoiesis. Cu deficiency also reduces splenocyte production of interleukin-1 and T cell replacing factor. Thus, it is possible that some of the immune defects observed in Cu-deficient animals are the result of reductions in hormonal signals (Arthur and Boyne, 1985; Boyne and Arthur, 1986, 1998; Gooneratne *et al.*, 1989; Keen *et al.*, 1998; Milanino and Buchner, 2006).

Regarding metabolism, abnormal pancreatic function is associated with marginal Cu deficiency.

Histological lesions suggest that the basic biochemical defect is one of excessive membrane lipid peroxidation or serum protease infiltration (Tosh *et al.*, 2007). Altered insulin secretion and glucose regulation can also be disturbed.

4. Cu Excesses

Acute Cu toxicity is rarely a serious problem in domestic animals, probably because of the strong emetic effect of the element. In contrast, chronic Cu toxicosis is a frequent occurrence in some species, particularly sheep. In sheep, there are two phases associated with Cu toxicosis. In the first phase, there is a gradual accumulation of Cu in tissues and a rise in serum aspartate aminotransferase, lactate dehydrogenase, sorbitol dehydrogenase, arginase, and glutamic dehydrogenase. As liver Cu accumulates, there is swelling and necrosis of the hepatic parenchymal cells and Kupffer cells resulting in a focal necrosis of liver tissue. The primary biochemical lesion arising from Cu toxicosis is thought to be Cu-initiated free radical damage. The hemolysis can also occur with Cu toxicity and is thought to be a result of changes within the erythrocyte rather than a direct effect of Cu on the erythrocyte membrane. During the hemolytic crisis, sheep have swollen, partially cirrhotic livers and dark, hemoglobin stained kidneys. Renal and hepatic tissues from Cu intoxicated sheep with hemolytic crises have cytoplasmic lipofuscin granules in the renal tubular epithelium and hepatic parenchyma, suggesting lysosomal rupture. Additional pathology can occur in the white matter of the cerebrum, pons, and cerebellum.

Liver Cu has also been shown to be markedly elevated in animal models for diabetes, but it is not clear if similar increases occur in spontaneous diabetes or whether the increased liver Cu represents increased risk of liver disease. Kidney Cu concentrations can also be markedly increased with diabetes. However, similar to other metabolic and inflammatory-induced elevations in hepatic Cu levels, it is not known if the diabetes-associated changes in renal Cu represent a threat (Keen and Uriu-Adams, 2005).

5. Cu-Related Genetic Models and Other Conditions (*e.g.*, Prions)

Genetic defects mimicking Cu deficiency have been reported for humans (Menkes' disease) and mice (mottled mutants). Menkes' disease is X-linked and is characterized by progressive degeneration of the brain and spinal cord, hypothermia, connective tissue defects, and failure to thrive (Keen *et al.*, 1998; Pena *et al.*, 1999; Puig and Thiele, 2002; Stern *et al.*, 2007; Thiele, 2003). Death often occurs before 3 years of age. The mottled mutants have been developed as animal models for Menkes' disease. It is now appreciated that the major defect is gene deletions and transpositions associated with Cu-ATPase-7A. There is a lack of normal cupper egress from cells. Cu is not directed to lysyl oxidase and some cases other proteins (dopamine beta-monooxygenase, peptidylglycine a-amidating monooxygenase, or tyrosinase depending on the cell type). Thus, lesions arise associated with defects in collagen and elastin metabolism and Cu catalyzed oxidative damage.

Similarly, genetic defects mimicking Cu toxicity have been reported in humans (Wilson's disease) as well (Theile, 2003). Wilson's disease is an autosomal recessive inherited disorder of Cu metabolism in which there is a failure to excrete Cu through the biliary system because of a mutation in the gene coding for an ATPase Cu pump.

Corresponding defects in the Cu-transporting ATPase, P-ATPase-7B, in the liver also occur. Recall that this ATPase directs Cu to plasma ceruloplasmin or to biliary excretion. Patients with Wilson's disease frequently present with one of three major clinical problems, liver disease (liver failure, hepatitis, or chronic cirrhosis), neurological signs (slurred speech, difficulty controlling facial muscle, or dystonia), or psychiatric problems. Unlike Menkes' disease, Wilson's disease is treatable if diagnosed early with Zn, Cu chelators (e.g., penicillamine).

A proposed analogue of this disorder in animals is Cu toxicosis in Bedlington terriers, which affects up to 60% of the breed (Haywood, 2006). Dogs homozygous for the gene are characterized by extremely high liver Cu concentrations often exceeding 500 micrograms/g (7.87 micromol/g) compared to controls of less than 75 micrograms/g (1.180 micromol/g). The associated hepatic injury is thought to be due to a Cu-initiated, free radical damage and lysosomal rupture. Several other breeds, including West Highland white terriers, Skye terriers, Dobermans, Dalmatians, and Keeshounds, have been identified as having Cu-associated liver disease as well (Haywood, 2006).

The mechanism by which Cu toxicosis occurs in Bedlington terriers, however, adds another dimension to Cu regulation and the P-ATPase relationship. Although eleven polymorphisms, two in the coding region, have been identified in the Bedlington terrier ATP7B gene, another gene, COMMD1 (Cu metabolism gene MURR1), has been identified that seems to function as a Cu chaperone. COOMD1 belongs to a family of multifunctional proteins whose functions have been linked to inhibition of nuclear factor NF-κB to Cu transport (Forman *et al.*, 2005; Haywood, 2006; Spee *et al.*, 2006). COMMD1 was implicated as a regulator of Cu metabolism by its proposed role in Cu delivery to P-ATPase-7B (see Fig. 22-4). Without P-ATPase-7B or the chaperone, Cu is sequestered in liver and promotes ROS-related lesions (Haywood, 2006).

With regard to Cu toxicity, chelation therapy can be effective for the treatment. The chelating drugs with worldwide application are dimercaprol, succimer, unithiol, D-penicillamine, N-acetyl-D-penicillamine, calcium disodium ethylenediaminetetraacetate, calcium trisodium or zinc trisodium diethylenetriaminepentaacetate, deferiprone, triethylenetetraamine (trientine), N-acetylcysteine (NAC), and Prussian blue. Penicillamine and diethylenetriaminepentaacetate derivatives are often used first when there are clear indications that an excess of Cu is the problem. Monitoring Cu status, however, is important with the use of any chelating agent or dietary approach (increasing the Zn intake) to diminish the prospects of a secondary Cu deficiency (Seguin and Bundy, 2001; Willis *et al.*, 2005).

As a final comment, transmissible spongiform encephalopathies (TSEs) are a family of neurodegenerative diseases characterized by their long incubation periods, progressive neurological changes, and spongiform appearance in the brain. There is now evidence that TSEs are caused by an isoform of the normal cellular surface prion protein PrPC. The normal function of PrPC is still unknown, but it exhibits properties of a cuproprotein, capable of binding Cu ions.

There are two differing views on Cu's role in prion diseases. Whereas one view looks at the PrPC Cu binding as the trigger for conversion to PrPSc, the opposing viewpoint sees a lack of PrPC Cu binding resulting in the conformational change into the disease-causing isoform. Manganese and Zn have also been shown to interact with PrPC (Leach *et al.*, 2006).

E. Evaluation of Cu Status

Measurement of plasma/serum Cu concentrations can be useful in suspected cases of Cu deficiency as low levels are diagnostic. Similarly, measurement of plasma/serum ceruloplasmin levels in suspected cases of deficiency can be useful, as 90% of the Cu present in plasma/serum is associated with this protein. Another possibility is the analysis of diamine oxidase (Legleiter and Spears, 2007). However, it should be noted that because synthesis of ceruloplasmin (an acute phase protein) can increase in acute or chronic infections; thus, a normal or elevated plasma or serum ceruloplasmin level does not rule out a deficiency. Increased synthesis of ceruloplasmin is thought to be in part mediated by a leukocyte endogenous mediator, and excessive production of ceruloplasmin is a consequence of a number of diseases that can result in marked redistribution of hepatocyte Cu pools into plasma. Elevated plasma or serum Cu concentrations have been reported to occur as a result of excessive Cu feeding in rats, sheep, and pigs, however, given that high plasma/serum Cu levels can also reflect a number of stress syndromes, a finding of high whole blood or plasma Cu levels should not be the sole criterion for diagnosis of Cu toxicosis (Stern *et al.*, 2007).

In sheep and cattle, Cu concentrations below 0.5 μg/ml are considered diagnostic for Cu deficiency. Although measurement of whole blood Cu has been widely used in diagnosing Cu deficiency, it is currently thought that measurement of erythrocyte CuZnSOD is preferable as it better reflects the functional Cu status of the animal. Complementary measurements of Cu chaperones, such as CCS, may also be eventually used for assessment (Keen and Uriu-Adams, 2006).

Liver Cu concentrations have been used as an indicator of Cu status in animals. The effect of low Cu diets on liver Cu levels can be dramatic. Ataxic lambs suffering from Cu deficiency can have levels below 5 μg/g (0.079 μmol/g) compared to control levels of 25 to 75 μg/g (0.394 to 1.181 μmol/g). Similarly, high levels of dietary Cu elevate hepatic Cu content. Levels in excess of 500 μg/g (7.87 μmol/g) in adult sheep have been reported.

IV. MANGANESE

A. Manganese Distribution

A large animal can contain from 10 to 20 mg (182 to 364 micromole) of Mn, which is fairly uniformly distributed throughout the body. There is relatively little variation among species with regard to tissue Mn concentrations (O'Dell and Sunde, 1997). Bone, liver, and kidney tend to have higher concentrations (1 to 3 microgram/g; 18 to 2 to 54.6 micromole/g) than other tissues. Manganese in brain, heart, lung, and muscle is typically less than 1 microgram/g (18.2 micromole/g); blood and serum Mn levels are about 0.01 microgram/ml (0.182 micromol/l) and 0.001 microgram/ml (0.0182 micromol/l), respectively.

Expressed as a percentage of the total, skeletal Mn can account for up to 25% of the total body pool. Bone Mn can be raised or lowered by substantially varying dietary Mn, but skeletal pools of Mn exchange slowly; thus, they are not thought to constitute an important pool for rapid mobilization (Reilly, 2004). Regarding development features of Mn metabolism, the fetus does not normally accumulate liver Mn before birth, and the levels of Mn in fetal liver are lower than in adult liver. This appears to be due to the expression of Mn enzymes such as arginase, pyruvate carboxylase, and MnSOD that occurs predominantly after birth (Bourre, 2006; Keen *et al.*, 1999).

B. Manganese Function

Mn functions both as an enzyme activator and as a constituent of metalloenzymes. For Mn-activated reactions, it can act by binding either to a substrate (such as ATP) or to the protein directly, to facilitate subsequent conformational changes. Whereas there are relatively few Mn metalloenzymes, there are a large number of enzymes that can be activated upon Mn additions (e.g., various hydrolases, kinases, decarboxylases, and transferases). Although the extent to which such activation is specifically related to Mn can be questioned (e.g., Mg can replace Mn), some appear Mn specific (e.g., several glycosyltransferases). Other divalent cations do not readily activate glycosyltransferases, and some of the pathological defects associated with Mn deficiency can be ascribed to a low activity of enzymes in this classification (Bourre, 2006; Keen *et al.*, 1999). For example, it has been suggested that xylosyl transferase is specifically activated by Mn. Cartilage isolated from Mn-deficient chicks is xylose poor, and fetuses born of Mn-deficient rats have limb deformities that can be related to reduced glycosylation (Lui *et al.*, 1994). In addition, Mn can activate phosphoenolpyruvate carboxykinase *in vivo*; low activity of phosphoenolpyruvate carboxykinase has been reported in Mn-deficient rats. Other Mn-containing and sensitive enzymes include arginase, pyruvate carboxylase, MnSOD, and glutamine synthase. All except glutamine synthase have been reported to be low in Mn-deficient animals (Aschner and Aschner, 2005; Crossgrove and Zheng, 2004; Ensunsa *et al.*, 2004; Spears, 2003).

C. Dietary Manganese

Nutritional Mn deficiency occurring outside the laboratory has been documented in a number of species including cattle, chickens, and rats. In humans, abnormal Mn metabolism has been reported to be a potential problem in epilepsy, Down's syndrome, osteoporosis, and diabetes (Aschner and Aschner, 2005; Crossgrove and Zheng, 2004; Spears, 2003). The recommended daily requirements for Mn for a number of species are shown in Table 22-2. Diets containing less than 1 micrograms Mn/g (0.018micromol/g) are unable to support normal reproduction in several species (i.e., sheep, goats, cattle, pigs, mice, rats, and rabbits). For perspective, the maximum reproductive performance in cattle does not occur until diets contain more than 20 micrograms Mn (0.31 micromol) per gram diet on a dry weight basis. The minimum dietary Mn requirement for poultry for growth and normal egg production and hatchability is about 40 micrograms/g (0.73 micromol/g) under normal dietary conditions. Excess dietary fiber, calcium, and phosphorus can markedly increase Mn requirements by reducing Mn bioavailability. The higher Mn requirements of birds compared to mammals can be due to a lower efficiency of absorption (Hansen *et al.*, 2006; Miranda *et al.*, 2006; Nocek *et al.*, 2006; Subcommittee on Mineral Toxicity in Animals, 1980; Subcommittee on Poultry Nutrition, 1994; Weis and Socha, 2005). Food items considered high in Mn include nuts, whole cereals, dried fruits, and leafy vegetables. Meats, dairy products, poultry, and seafood are considered to be poor sources of Mn. Manganese in typical animal feeds can range from 10 microgram/g (0.18 micromol/g) in corn to 105 microgram/g (2.73 micromol/g) in ryegrass and red clover, with the concentration highly dependent on soil conditions and fertilizer practice.

D. Manganese Metabolism, Absorption, and Transport

Absorption of Mn is thought to occur throughout the small intestine. The efficiency of Mn absorption is relatively low and is not thought to be under homeostatic control (Keen *et al.*, 2000; Sandstrom, 2001). It has been reported that adult humans typically absorb approximately 3% to 4% of dietary Mn, although absorption is increased in those with iron deficiency. High dietary intakes of dietary calcium, phosphorus, and phytate can increase requirements for Mn. Mn absorption and retention are higher in neonates than in adults, and it has been suggested for this reason neonates can be particularly susceptible to Mn toxicosis (Keen *et al.*, 2000). The overall health status of the animal can also

influence absorption and its susceptibility to Mn toxicity. Studies in poultry have demonstrated that under conditions of duodenal coccidiosis Mn is utilized more efficiently. Coccidial infection exacerbated Mn toxicity as evidenced by depressed hematological parameters and increased bone and bile Mn concentrations (Southern and Baker, 1983).

In contrast to other essential trace elements, Mn absorption does not appear to be increased under conditions of Mn deficiency (Keen *et al.*, 2000). Mn absorption is increased under conditions of Fe deficiency. Because of the connection between the transport of iron and Mn, the transferrin receptor (TfR) and the divalent metal transporter-1 (DMT-1) seem to play a role in Mn transport, which could be the basis for the connection (Aschner and Aschner, 2005; Culotta *et al.*, 2005; Keen *et al.*, 2000). Mn from the gastrointestinal tract entering the portal blood can either remain free or rapidly becomes bound to alpha-2-macroglobulin and transferrin, particularly as Mn^{+3}. Mn uptake by cells is usually unidirectional and saturable.

The metabolic fate of newly absorbed Mn entering the hepatocyte has not been well defined, although several cellular pools of Mn can be identified. The first represents Mn taken up by the lysosomes. Lysosomal uptake of Mn is also considered to be an essential step to egress as it is thought that lysosomes concentrate Mn for delivery to the bile canaliculus (i.e., whole body homeostatic regulation of Mn is maintained through biliary excretion). In this regard, up to 50% of Mn injected intravenously can be recovered in the feces within 24 h. Another pool of Mn is associated with the mitochondria. Mitochondria have a large capacity for Mn^{+2} uptake, and it has been suggested that mitochondrial Mn^{+2} and Ca^{+2} uptake can be linked. Nuclear, cytoskeletal (microsomal), and cytosolic pools of Mn^{+2} also exist. In contrast to Zn, Cu, and Fe for which only a few atoms per cell exist in free form, a portion of Mn can be viewed as dissociable, somewhat analogous to Ca^{+2} and Mg^{+2} (Keen *et al.*, 2000).

E. Deficiency and Excesses

1. *Deficiency*

Manifestations of Mn deficiency in domestic animals include impaired growth, skeletal abnormalities, disturbed or depressed reproductive function, ataxia of the newborn, and defects in lipid and carbohydrate metabolism (Keen *et al.*, 2000). Biochemical lesions associated with these defects are discussed later.

The effects of Mn deficiency on skeletal development have been reported extensively. Mn deficiency results in limbs that are shortened and thickened and joints, which are swollen and enlarged (Lui *et al.*, 1994). Multiple reports of Mn deficiency in cattle are also present in the literature. One interesting case describes 47 Holstein calves with dwarfism, joint laxity, superior brachygnathism, and domed foreheads that were born to heifers grazing naturally on one farm in South Africa. Seepage from seawater evaporation pans on an adjacent farm was believed to cause Mn deficiency in the dams by leaching Mn from the soil. The seawater contained high levels of strontium, calcium, and iron, which likely further inhibited Mn absorption (Staley *et al.*, 1994). As noted earlier, a basic biochemical lesion underlying the development of bone defects with Mn deficiency is a reduction in proteoglycan biosynthesis, which is secondary to a reduction in the activities of glycosyltransferases. These enzymes are specifically activated by Mn and are needed for the synthesis of chondroitin sulfate side chains of proteoglycan molecules (Hansen *et al.*, 2006).

Ataxia in the offspring of Mn-deficient animals was first observed in the chick and in rats in the 1940s. Ataxia is the result of impaired vestibular function caused by impaired otolith development in utricular and secular maculae. The precise biochemical lesion underlying the block in otolith development has not been identified, although it is thought to involve a defect in proteoglycan biosynthesis. Further, defects in carbohydrate metabolism, in addition to those known to arise from impairment of the activities of glycosyltransferases, have been observed in Mn-deficient rats and guinea pigs. In the guinea pig, Mn deficiency results in severe pancreatic pathology with aplasia or marked hypoplasia of all cellular components including fewer and less intensely granulated islet cells than controls. When glucose is given either orally or intravenously to Mn-deficient guinea pigs, they display diabetic-like glucose tolerance curves. Mn supplementation completely reverses the abnormal glucose tolerance. Mn deficiency can also affect carbohydrate metabolism through an effect on insulin metabolism (Keen *et al.*, 2000; O'Dell and Sunde, 1997).

Mn associated with the islet cell exists in two pools: a readily exchangeable pool associated with the cell surface and an intracellular pool. Mn fluxes between these pools can affect insulin release. Accumulation of Mn associated with the islet cell membrane inhibits insulin release, whereas increases in the intracellular concentration of Mn are associated with a stimulation of insulin synthesis or release, consistent with the idea that Mn has a regulatory role in insulin synthesis/release. In rats, Mn deficiency depresses pancreatic insulin synthesis and secretion, and it enhances intracellular insulin degradation (Keen *et al.*, 2000).

Regarding lipid metabolism, Mn-deficient pigs, rats, and mice are characterized by deposition of excess fat in the liver. Abnormal lipid metabolism has been suggested as a cause of some of the ultrastructural abnormalities seen in tissues of Mn-deficient animals, which include alterations in the integrity of cell membranes, swollen and irregular endoplasmic reticulum, and elongated mitochondria with stacked cristae. The effect of Mn deficiency on cell membrane integrity could be due to changes in membrane

lipid composition or an increased rate of lipid peroxidation in cell membranes, as the activity of MnSOD is lower in Mn-deficient animals than in controls (Keen *et al.*, 2000).

Another step at which Mn can be critical for lipid metabolism is as a cofactor in steroid biosynthesis (O'Dell and Sunde, 1997). Enhancement by Mn of cholesterol synthesis from acetate in liver preparations has been demonstrated, and hypocholesterolemia has been reported in a human case of Mn deficiency. The metabolic site in cholesterol synthesis wherein Mn is thought to be required is farnesyl pyrophosphate synthase, which catalyzes geranyl and isopentyl pyrophosphate condensation to form farnesyl pyrophosphate. Defects in subsequent steroid synthesis can also underlie some of the observed reproductive dysfunctions in Mn-deficient animals. Mn deficient females have absent or irregular estrous cycles, whereas Mn-deficient males have sterility associated with degenerating cells in the epididymis (O'Dell and Sunde, 1997). In addition, lipoprotein metabolism is affected in Mn deficiency. Mn-deficient rats have low plasma cholesterol and low HDL. In addition, Mn-deficient rats have a shift to a smaller plasma HDL particle, lower HDL apo E levels, and higher apo C levels. High levels of dietary Mn have also been reported to affect lipid metabolism when animals are fed high-fat diets. Repletion with Mn increases the activity of several key glycolytic enzymes including hexokinase, glyceraldehydes-3-phosphate dehydrogenase, enolase, lactate dehydrogenase, and glycerol-3-phosphate dehydrogenase. Increases are also found for enzymes of the pentose phosphate pathway and of lipogenesis. Thus, the supplementation of Mn to the high-fat diet can increase the potential for glucose oxidation and for lipogenesis thereby enhancing carbohydrate conversion to fat. The mechanism(s) by which excess Mn induces the enzyme changes is not known, but it is suggested that an effect on insulin metabolism could be involved (Keen *et al.*, 2000). Mn can activate guanylate cyclase and phosphodiesterase, so another possibility is that Mn might change levels of cyclic nucleotides, which then act as second messengers.

2. *Manganese Toxicity*

Although Mn excess can produce toxic effects, it is often considered to be among the less toxic of the essential trace elements to birds and mammals (Subcommittee on Mineral Toxicity in Animals, 1980). For example, chicks, calves, pigs, and sheep have been reported to tolerate diets up to 3000, 1000, 500, and 200 micrograms Mn/g (54.6, 18.2, 9.1, and 3.6 micromol/g), respectively (Failla, 1999; Subcommittee on Mineral Toxicity in Animals, 1980).

In domestic animals, the major reported biochemical lesion associated with dietary Mn toxicosis is an induction of iron deficiency, which is thought to be the result of an inhibitory effect of Mn on iron absorption. In humans, incidents of Mn toxicity mainly occur as a result of chronic inhalation of massive amounts of airborne Mn (>5 mg/m; >91micromol) with particle sizes less than 5-micrometer diameter, a situation that can occur in Mn mining. In individuals working in environments contaminated with Mn, overt signs of toxicity normally occur after months or several years of chronic exposure. The initial expression of Mn toxicity is often characterized by severe psychiatric disorders that include signs of memory impairment, disorientation, hallucination, speech disturbances, and compulsive behavior. If the person is removed from the high Mn environment, some improvement of the psychiatric signs can occur. With progression of toxicity, there can be extrapyramidal signs that are remarkably similar to Parkinson's disease (Crossgrove and Zheng, 2004). Removal of a person or animal from the high Mn area at this time may not lead to an improvement in clinical condition, even though tissue Mn levels can return to normal. Secondary conditions that exacerbate Mn toxicity, such as liver failure, can be the underlying cause. The mechanisms underlying the cellular toxicity of Mn have not been clearly identified, although evidence has been provided that Mn-initiated tissue lipid peroxidation can be a primary biochemical lesion.

A second lesion that can underlie some of the pathologies is a disturbance in carbohydrate metabolism (Crossgrove and Zheng, 2004; Keen *et al.*, 2000). With acute Mn toxicity, there is a rapid uptake of Mn by the pancreas, a sharp reduction in circulating insulin, and an increase in plasma glucose. Thus, similar to Mn deficiency, Mn toxicity can affect insulin production or release from the pancreas (Aschner *et al.*, 2007; Keen *et al.*, 2000).

3. *Other Disorders*

Abnormal Mn metabolism occurs in experimental animal models for diabetes (Failla, 1999). It has been shown that the high Mn concentrations in the liver of diabetics are associated with arginase (Failla, 1999; Keen *et al.*, 2000). Although an increase in arginase activity seems reasonable in light of the increased gluconeogenic demands of the diabetic, the functional necessity of this increase has not been shown. It has been reported that Mn metabolism can also be abnormal in some forms of epilepsy. The significance of this observation is underscored by the observation that Mn-deficient animals have a reduced threshold to drug-induced and electroshock-induced seizures. Finally, whole blood Mn levels are often low in humans with osteoporosis and have been proposed to be important to the development of osteopenic bone disease in aging humans and animals (Gonzalez-Reyers *et al.*, 2007; Keen *et al.*, 2000).

F. Evaluation of Manganese Status

Measurement of whole blood Mn concentrations can be useful in suspected cases of Mn deficiency because low whole blood Mn levels have been found to reflect low soft

tissue Mn concentration. Caution must be exercised in interpreting serum Mn values, however, because they can reflect recent dietary history rather than the long-term Mn status of the animal (O'Dell and Sunde, 1997). Although measurement of hair Mn has been used as an indicator of Mn status, most investigators agree that the value of this analyte is limited owing to excessive environmental contamination with Mn (Bouchard *et al.*, 2007). Liver Mn concentrations have been used as an indicator of Mn status in animals, but their main value is in the identification of Mn deficiency conditions. Currently there are no satisfactory laboratory tests for the identification of Mn toxicity (Reilly, 2004), although high levels of tissue Mn can be assessed with imaging techniques, such as MRI (Jiang *et al.*, 2007).

V. MOLYBDENUM

A. Molybdenum Distribution

The highest concentrations of Mo are in the liver (0.5 to 0.7 μg/g) and kidney (0.3μg/g). In sheep, whole blood Mo is about 0.02μg/ml (0.21μmol/liter) but is sensitive to changes in dietary intake (Spears, 2003; Suttle, 1991). The most important function is as a cofactor for xanthine dehydrogenase/oxidase, aldehyde oxidase, and sulfite oxidase. Mo is present in these enzymes as molybdopterin or a molybdenum cofactor (Fig. 22-5). Xanthine oxidase was first characterized as a Mo enzyme in the early 1950s (Mendel and Bittner, 2006; Schwarz and Mendel, 2006).

B. Molybdenum Functions

In its usual form as xanthine dehydrogenase, the reaction, $XH + H_2O + NAD^+ \rightarrow X{=}O + NADH$, is catalyzed. The most common substrates are purines. Uric acid forms the metabolic endpoint of purine degradation. The last metabolic steps in the process (from hypoxanthine to xanthine and from xanthine to uric acid) are promoted by xanthine dehydrogenase (oxidoreductase, EC1.1.3.22). The overall mechanism is complex. Xanthine dehydrogenase is a flavoprotein that contains both iron and Mo and uses NAD+ as electron acceptor (Mendel and Bittner, 2006; Schwarz and Mendel, 2006).

Moreover, xanthine dehydrogenase exists in two interconvertible forms, xanthine dehydrogenase and xanthine oxidase. In its oxidase form, the enzyme transfers the reducing equivalent generated by oxidation of substrates to molecular oxygen with the resultant production of superoxide anion and hydrogen peroxide (Fig. 22-3). Hydrogen peroxide can be converted to free hydroxyl radicals. For example, during ischemia, reperfusion, or reoxygenation of an injured tissue can occur, and xanthine dehydrogenase can be converted to xanthine oxidase (Mendel and Bittner, 2006; Schartz, 2005). In this latter form, the reaction sequence is $XH + H_2O + O_2 \rightarrow X = O + H_2O_2$. Given that in such conditions ATP is depleted and there is an increase in the purine pool, such available substrate promotes production of large quantities of superoxide radicals are released, which can be a major source of tissue peroxidation. Aldehyde oxidase is a related Mo enzyme that catalyzes many of the same reactions as xanthine dehydrogenase. Both of these enzymes are needed in ruminants to catabolize exogenous pyrimidines. The third known Mo enzyme is sulfite oxidase, a mitochondrial enzyme that catalyzes the oxidation of sulfite to sulfate during the degradation of sulfur amino acid (Mendel and Bittner, 2006; Schwarz and Mendel, 2006).

C. Molybdenum Metabolism, Absorption, and Transport

Other than thiomolybdates, Mo is well absorbed by all species. It has been proposed that Mo is transported by a carrier-mediated process and that sulfate and Mo can compete for the same carrier or inhibit membrane transport in the intestine and renal tubules (Brondino *et al.*, 2006; Failla, 1999; Spears, 2003), hence impairing Mo absorption and retention. An alternate postulate is that formation of insoluble thiomolybdates precludes absorption. Cu and sulfur influence Mo absorption. High dietary levels of vitamins E and C, zinc, iron, tungsten, and dietary protein levels can also affect optimal status. Cu or sulfur reduces Mo availability via a mechanism whereby reactive sulfides or hydrogen sulfide ions displace oxygen in molybdate to form thio- and oxythiomolybdates (see Section III) (Spears, 2003; Suttle, 1991). This complex can in turn react with Cu to form an insoluble complex. This is primarily applicable to the strong reducing environment of the rumen. Because of this interaction, excess Mo will induce a secondary Cu deficiency (e.g., dietary Mo in excess of 10 μg/g; 0.104 μmol/g; Johnson *et al.*, 2007; Spears, 2003; Suttle, 1991).

Excretion in nonruminants appears to be mostly through the urine, but in ruminants fecal and milk losses can represent significant losses. Although Mo deficiency does occur, it is apparently relatively rare. In animals, growth and production have been reported to be impaired in poultry and sheep (Suttle, 1991). In the case of birds, the high flux of metabolites through purine-related pathways accounts in part for the need for Mo (e.g., as a cofactor for xanthine oxidase). For the ruminant, one postulate has been a depression in microbial Mo enzyme activities.

The clinical syndrome of Mo toxicity can be characterized by achromotrichia, anemia, cartilaginous dysplasia, abnormal endochondrial ossification, subperiosteal ossification, and abnormal fibrogenesis (Spears, 2003; Suttle, 1991). These lesions are characteristic signs of an induced Cu deficiency. Additionally, Mo has been suggested to specifically induce mandibular exostosis, aberrations in phosphorus metabolism that can contribute to bone and joint lesions, testicular degeneration, and central nervous system changes.

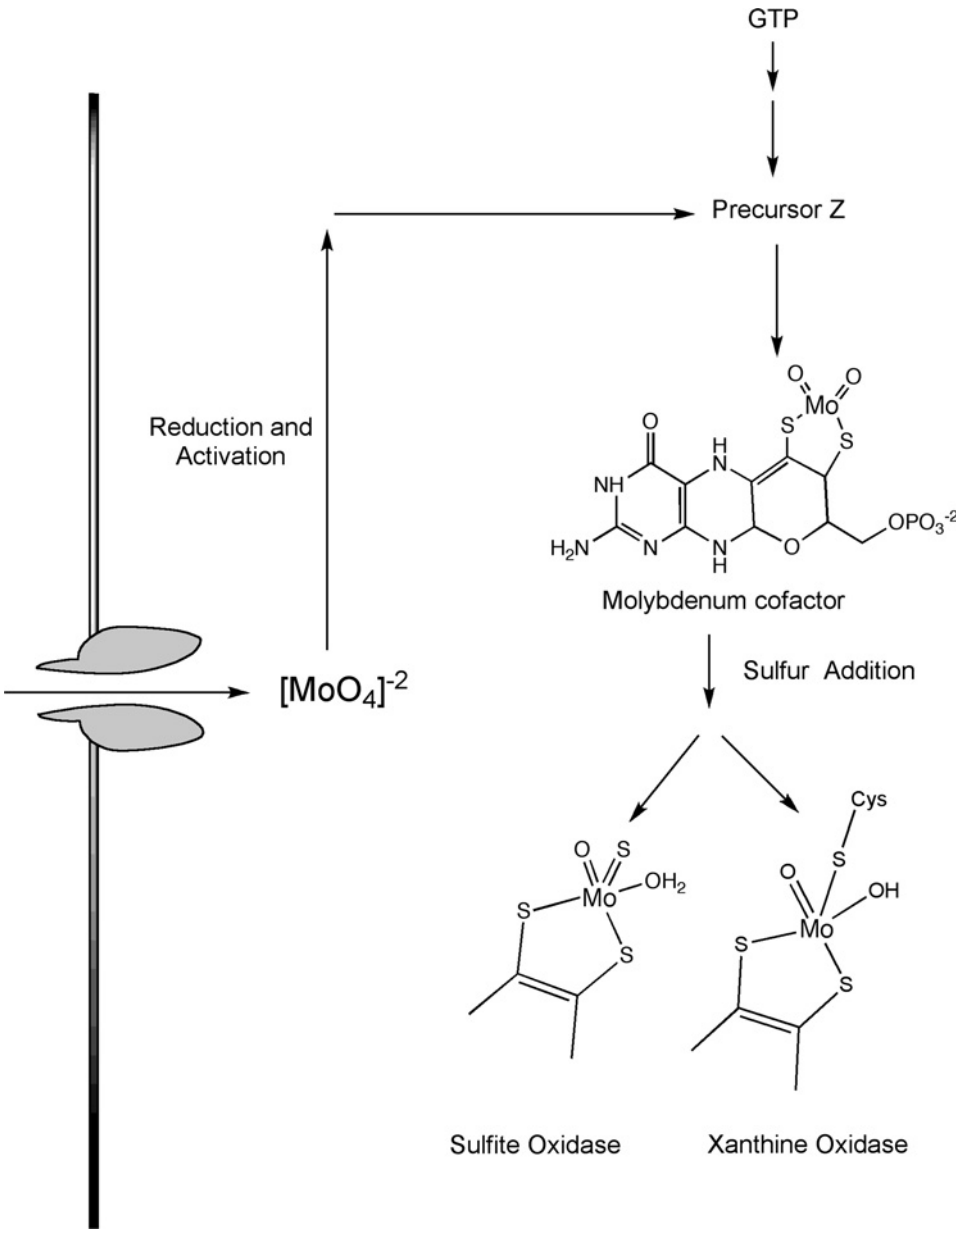

FIGURE 22-5 Molybdenum cofactor. Mo as molybdates enter cells by way of oxyanion transporters. A series of complex condensation and reductive steps (e.g., formation of the pterin precursor from guanidine triphosphate [GTP] and condensation with molybdenum) result in the formation of the molybdenum cofactor. The cofactor is essential for the activities of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase (see text).

The clinical signs of molybdenosis also include lameness; weight loss; anorexia; loss of color and quality of the wool or hair; and in cattle, diarrhea. Thiomolybdates are used to treat chronic Cu toxicosis, to help mobilize stored Cu and reduce the high oxidizing of free Cu (Brewer *et al.*, 2006; Spears, 2003; Suttle, 1991).

D. Other Disorders

In human animals, combined deficiencies of xanthine dehydrogenase/oxidase and sulfite oxidase have been reported in humans. The cause of the decreased enzyme activities is thought to be the loss of Mo cofactor that results in a functional Mo deficiency. Single enzyme deficiencies of xanthine dehydrogenase/oxidase and sulfite oxidase have also been described (Mendel and Bittner, 2006; Schartz, 2005). Xanthinuria and elevated serum uric acid have been reported in patients with xanthine dehydrogenase deficiency. A severely debilitating condition in children is sulfite oxidase deficiency that leads to severe aberrations in sulfur and sulfur amino acid metabolism (Mendel and Bittner, 2006; Schartz, 2005).

VI. SELENIUM

A. Dietary Selenium

A large animal (50 to 100kg) contains 10 to 20 mg (126 to 253 micromol) of Se. Se is found throughout the body with highest concentrations normally in the kidney and liver (0.5 to 1.5 and 0.2 to 0.8 micrograms/g [0.0063 to 0.019 and 0.0025 to 0.010 micromol/g], respectively). Skeletal muscle has a mean Se concentration of about 0.2 microgram/g (0.0025 micromol/g), and muscle contains about 50% of the total body pool. Blood Se concentrations are highly responsive to diet, with values in humans ranging from 0.02 to 7.0 microgram/ml (0.25 to 0.88 micromol/liter) in low Se and high Se areas, respectively (Ammerman *et al.*, 1995; Finley, 2006; Hostetler and Kincaid, 2004; O'Dell and Sunde, 1997; Spears, 2002).

Plant foods are the major dietary sources of Se in most countries throughout the world. The amount of Se in soil, which varies by region, can determine the amount of Se in the food chain, wherein Se is found as selenomethionine and selenocysteine. Se is one of the few mineral elements in which the soil concentration can influence the relative amounts found in food. Because Se bioavailability varies markedly with the form of Se ingested and other competing factors, it has been difficult to define what constitutes either deficient or toxic amounts. Various dietary forms of Se are given in Figure 22-6. Each can accumulate to some degree in tissue proteins. Accordingly, whole body and tissue concentrations of Se tend to correlate with environmental exposure (Ammerman *et al.*, 1995; Finley, 2006; Gunther *et al.*, 2002; Hostetler *et al.*, 2003; O'Dell and Sunde, 1997; Spears, 2002). Suggested Se intakes for a number of species are given in Table 22-2. Foods that contain Se include nuts (0.5 to 10.0μg/g), fish, poultry and beef (0.5 to 0.8μg/g), grains (0.2 to 0.4μg/g can vary with high Se soils), whole eggs (0.1 to 0.3μg/g), and cheese (0.1 to 0.2μg/g). Se-accumulating plants can have concentrations that exceed 5mg/g (63.3 micromol/g), whereas pastures and forages in areas without Se deficiency syndromes can be as low as 0.1μg/g (0.0013 micromol/g). In grazing animals, deficiency signs occur when feed concentrations are below 0.05μg/g (0.0063 micromol/g), and adverse effects can occur when dietary levels exceed 3μg/g (0.038 micromol/g) (Ammerman *et al.*, 1995; Finley, 2006; Gunther *et al.*, 2002; Hostetler and Kincaid, 2004; O'Dell and Sunde, 1997; Spears, 2002).

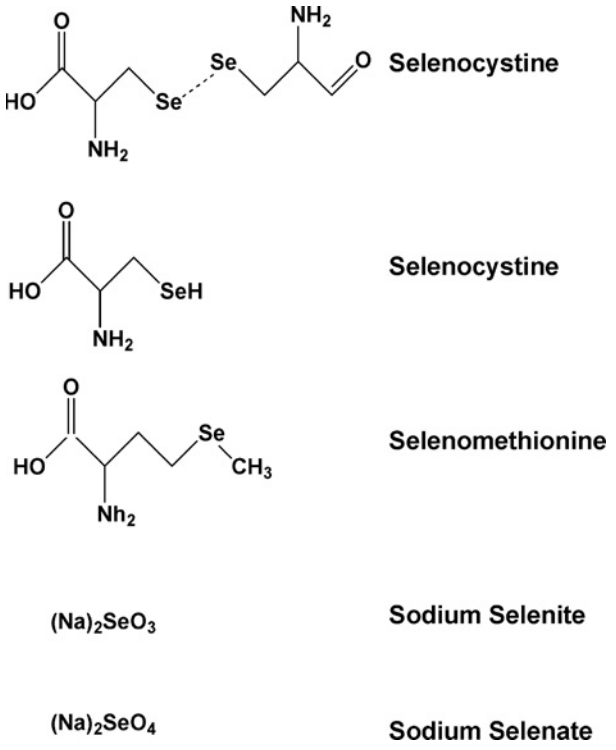

FIGURE 22-6 Common forms of dietary selenium.

B. Selenium Functions

Perspectives regarding the nutritional importance of Se have changed markedly. In the 1930s, Se was identified as the toxic agent causing so-called alkali disease in animals (O'Dell and Sunde, 1997). In the 1940s and early 1950s, research was conducted to identify the specific selenocompounds causing toxicity. Throughout the 1960s, concerns regarding Se focused on its putative procarcinogenic potential. However, following the demonstration that Se was an essential nutrient for laboratory animals, the scope of work quickly shifted to identifying deficiency syndromes and signs. Se deficiency was soon identified as a cause of white muscle disease. However, it was not until 1979 that the U.S. Food and Drug Administration published regulations that legalized Se supplementation of diets for dairy cattle and eventually humans and other animals (Subcommittee on Mineral Toxicity in Animals, 1980).

1. *Glutathione Peroxidase*

The best-defined function of Se is as a component of glutathione peroxidase (GPx). GPx catalyzes the reduction of hydrogen and organic peroxides (ROOH) to their respective alcohols and water (Herbette *et al.*, 2007). It is now recognized that there are two different GPx activities in tissues, one that is Se dependent and a second that is not. The non-Se-dependent GPx enzymes are referred to as GSH S-transferases, and their activities can increase under conditions of severe Se deficiency.

Regarding the Se-containing GPx, there are several isozymes encoded by different genes that vary in cellular location and substrate specificity. GPx1 is the most abundant and is found in the cytoplasm. Although H_2O_2 is the preferred substrate ($2GSH + H_2O_2 \rightarrow GS - SG + 2H_2O$, where GSH represents reduced monomeric glutathione, and GS – SG represents glutathione disulfide), fatty acid

and other lipid peroxides (ROOH) also function as substrates. The product is an acyl moiety wherein the [−OOH] group is converted to an [=OH] group. Mice genetically designed to lack GPx1 are in many respects phenotypically normal, indicating that the enzyme is not critical for life. However, other variants (e.g., GPx4) are lethal and die during early embryonic development (Burk and Hill, 2005; Stadtman, 2000).

2. *Iodothyronine Deiodinase*

In addition, another family of selenoproteins is the 1,5′-iodothyronine deiodinase (EC 3.8.1.4) (5′-ID). The enzyme, 5′-ID, catalyzes the 5′-monodeiodination of thyroxin, the major secretory product of the thyroid gland, to its active form 3,3′,5-triiodothyronine (Koenig, 2005). Deiodination by 5′-ID occurs in peripheral tissues (e.g., liver, kidney, and muscle). In Se deficiency, activity of type 1,5′-iodothyronine deiodinase is decreased along with the concentration of thyroxin.

3. *Other Proteins*

A number of proteins have been identified that are presumably important to Se transport and delivery to organelles and tissues (e.g., the plasma protein, selenoprotein P) (Burk and Hill, 2005). Selenocysteine is also found in thioredoxin reductases, formate dehydrogenases, and glycine reductases. In addition, Waschulewski and Sunde (1988) demonstrated that in dietary methionine deficiency, selenomethionine could be incorporated into proteins in place of methionine. This important observation indicates that several identified "selenoproteins" cannot be dependent on Se per se for their structure or function, but rather might arise from the incorporation of the methionine.

4. *Se and Viruses*

Recent work has also demonstrated that deficiencies in either Se or vitamin E can in certain cases increase viral pathogenicity by changing relatively benign viruses into virulent ones, an example wherein host nutritional status should be considered a driving force for the emergence of new viral strains or newly pathogenic strains of known viruses (Beck, 2007).

C. Selenium Metabolism, Absorption, and Transport

Absorption of Se occurs mainly in the duodenum with little evidence of uptake by the rumen, abomasums, stomach, jejunum, or ileum. In monogastric animals, absorption of soluble forms of Se (selenite, selenocysteine, selenomethionine) is very high (>80%) and does not appear to be homeostatically controlled (Finley, 2006). Absorption of Se in ruminants is lower than in nonruminants (about 40%), presumably because of the reduction of selenite to insoluble forms of Se in the rumen. Elemental Se and Se sulfide are not absorbed to any appreciable degree (Ammerman *et al.*, 1995; Spears, 2000, 2003). After absorption, there appears to be a rapid distribution of water-soluble Se compounds to most organs.

Transport in plasma to various organs seems to involve selenoprotein P (Burk and Hill, 2005). Selenoprotein P is an abundant extracellular glycoprotein that is rich in selenocysteine. Four isoforms of selenoprotein P have been identified. They share the same *N* terminus and amino acid sequence. One isoform is full length and the three others terminate at the positions of the second, third, and seventh selenocysteine residues normally present in the full-length protein. In rats, it has been estimated that 25% of whole-body Se passes through this protein each day. Selenoprotein P knockout mice have low Se concentrations in the brain, testis, and fetus. Measurement of selenoprotein P in human plasma has shown that it is depressed by Se deficiency and by cirrhosis. Of potential importance, Se supplementation optimizes glutathione peroxidase activity before Se in selenoprotein P is optimized, indicating that plasma selenoprotein P can be a better index for assessing Se nutritional status.

Although the intracellular processing of Se remains poorly understood, it is known that before the incorporation of inorganic Se (selenite or selenate) into amino acids, it must be reduced to selenide (-SeH), a process requiring glutathione. Se is excreted primarily through the urine and appears to be dependent on a renal threshold. Fecal and respiratory losses are important routes, depending on species. Ruminants have relatively higher fecal Se losses than nonruminants, because of reduction or the complexing of Se in the rumen making it unavailable for absorption.

Concentrations in the diet of sulfur (inorganic and as sulfur-containing amino acids), proteins containing high amounts of sulfur amino acids, and phosphates can affect Se absorption/excretion. The order of uptake in Cacao cells is SeO_3 < or = to selenocysteine < to selenomethionine < to SeO_4. Both amino acid-related and anion transporters are involved in Se transport. Many of the details, however, have yet to be resolved. For example, the transport of selenomethionine is inhibited by its sulfur analogue, methionine, whereas inhibition of the transport of selenocysteine by cysteine is not observed. The transport of SeO_4 is inhibited by thiosulfate, but not sulfate (Burk and Hill, 2005; Finley, 2006; Spears, 2003). A number of intestinal inflammatory diseases and short-bowel syndrome can lead to Se deficiency (Burk and Hill, 2005; Finley, 2006; Spears, 2003).

In other cells, common Se compounds (selenate, selenite, selenomethionine, and selenocysteine), are taken up rapidly through anion-exchange transporter systems. Uptake through anion-exchange carriers is followed by

reduction by glutathione-requiring steps. Important is that some oxyanions, such as chromate, can inhibit uptake, which GPx activity and activation and subsequently, glutathione depletion. As a final point, respiratory losses (as methyl selenides) increase as Se intake increases, although respiratory losses of Se are thought to be minimal under most circumstances (Burk and Hill, 2005; Finley, 2006; Spears, 2003).

1. Novel Aspects of Se Metabolism

Unlike other amino acids, selenocysteine, which is at the active site of selenoproteins, is not coded using a conventional codon. Selenocysteine is encoded in a special way by a UGA codon that normally acts as a stop codon in transcription (Stadman, 2002). The UGA codon is made to encode selenocysteine by the presence of a SECIS element (the selenocysteine insertion sequence) in selenoprotein mRNAs. SECIS elements are stem-loop structures located in the 3′ untranslated regions (UTRs) of eukaryotic selenoprotein mRNAs that are required for directing cotranslational selenocysteine incorporation at UGA codons. Previous characterization studies of the mammalian SECIS elements indicate these elements are highly conserved in type 1 deiodinase, GPx, and selenoprotein P (Burk and Hill, 2005).

When cells are grown in the absence of Se, translation of selenoproteins terminates at the UGA codon, resulting in a truncated, nonfunctional enzyme. The primary and secondary structures of selenocysteine tRNA also differ from those of standard tRNAs, most notably, a long variable region arm, and substitutions at several well-conserved base positions (Stadman, 2002).

The selenocysteine tRNAs are initially charged with serine by seryl-tRNA ligase, but the resulting Ser-tRNA is not used for translation because it is not recognized by other translation factors. Rather, the tRNA-bound seryl residue is converted to a selenocysteyl-residue by the pyridoxal phosphate-containing enzyme selenocysteine synthase. The resulting selenocysteyl-containing tRNA (Sec-tRNA) is recognized and is next specifically bound to a translational elongation factor that delivers Sec-tRNA in a targeted manner to the ribosomes translating mRNAs for selenoproteins. Other details regarding this process are beyond the scope of this chapter. Suffice to say that Se metabolism from translation to cellular delivery is novel in keeping with its sulfur-like electronegative chemical properties (Stadman, 2002).

D. Disorders of Selenium Metabolism

1. Se Deficiency

The major biochemical lesions that are associated with Se deficiency are low GPx and 5′-ID activities (Beck, 2007; Koenig, 2005). Excess cellular free-radical damage can be the initial lesion underlying the widespread pathologies. Consistent with this idea are the observations that simultaneous deficiencies of other antioxidants (i.e., hypovitaminosis E and A) amplify the signs of Se deficiency when they occur.

Signs of Se deficiency in humans and domestic animals have been well described and include degenerative changes of several tissues, reproductive and growth defects, immune defects, increased susceptibility to cardiovascular disease, and some cancers. The interplay of many nutrients will greatly influence expression of disease (Fig. 22-3).

Se status, either toxicity or deficiency, will directly affect the free-radical scavenging system, which can be expressed as clinical disease. For example, nutritional muscular dystrophy is a Se-responsive disorder that principally affects young farm animals (sheep, cattle, pigs, horses, poultry). This myopathy is typically associated with excessive peroxidation of lipids, particularly the mitochondrial lipids, resulting in degeneration, necrosis, and subsequent fibrosis of myofibers. Often this is associated with cardiac involvement and, depending on the species, hepatic necrosis (Arthur, 1998).

Poultry and swine can be affected by exudative diathesis and edematous conditions that respond to supplemental Se. In poultry, the condition typically affects the pectoral muscles but can also involve the gizzard and other skeletal muscles. In mammalian species, the muscles of locomotion are usually more severely affected (dorsal spinous and appendicular muscles). Nutritional pancreatic atrophy is a specific Se-responsive condition in chicks. Deficiency of Se alone will induce the condition, and it is apparently related to a severe alteration of the endoplasmic reticulum and not mitochondria as previously thought. This condition results in a loss of functional pancreatic acinar cells.

In swine and cattle, mastitis has been shown to be Se responsive (Arthur, 1998; Koenig *et al.*, 1997; Smith *et al.*, 1987; Spears, 2000). Testicular degeneration and impaired sperm production, infertility, abortion, weak and stillborn young and retained placentas have all been shown to be responsive to Se supplementation. A reduction in testicular selenoprotein can underlie the reduced spermatogenesis or maturation leading to the testicular atrophy associated with Se. The mechanisms involved in Se deficiency-induced infertility and retained placenta have not been defined (Arthur, 1998; Koenig *et al.*, 1997; Smith *et al.*, 1987; Spears, 2000).

As might be expected given the links to mitochondrial function and ROS defense, altered immunocompetence has been linked to Se deficiency. Mastitis, diarrhea, metritic, and "unthriftiness" can be envisioned as being precipitated by a reduced ability to respond to invading pathogens. Reduction in mitogen responsiveness, phagocytotic killing of pathogens, and antibody production have all been associated with Se deficiency. Although the negative effects

of Se deficiency on immunocompetence are recognized, the biochemical lesions underlying these effects have not been delineated. Anemia appears to involve a depression in GPx activity and subsequent Heinz body formation (Arthur, 1998; Koenig *et al.*, 1997; Smith *et al.*, 1987; Spears, 2000).

In humans, Keshan disease is an endemic congestive cardiomyopathy affecting primarily children and women of childbearing age with lesions that are very similar to the characteristic lesions of nutritional cardiomyopathy associated with white muscle disease (Burk and Hill, 2005). The disease derives its name from a serious outbreak of the disorder in the Keshan province of Northern China in 1935. That Se supplementation improves many of the clinical signs of Keshan's disease identifies it as a Se-responsive disorder. The soils of the Keshan area are low in Se as well as locally produced produce. Another human disorder is Keshan-Beck disease, an endemic osteoarthropathy that occurs in several regions of eastern Asia. The disease is characterized by chronic, disabling, degenerative osteoarthrosis and frequently occurs in young children. In the initial phase, the patient complains of general limb weakness and joint stiffness. With progression, the disease results in shortening of the fingers and long bones with severe enlargement and dysfunction of the joints. Although other aspects of the etiology of the disease have not been defined, it has been suggested that Se deficiency can be a principal underlying cause.

2. *Se and Viral Infections*

The study of Keshan disease also has led to an association between Se and increased susceptibility to infection with certain enteroviruses. The discovery that the cardiomyopathy of Keshan disease likely had a dual etiology (nutritional and infectious) provided impetus for additional studies of relationships between nutritional Se status and viral infection. Observed was that an amyocarditic strain of coxsackievirus B3, CVB3/0, was converted to a highly virulent strain when it was inoculated into Se-deficient mice. This conversion was accompanied by changes in the genetic structure of the virus so that its genome closely resembled that of other known virulent CVB3 strains. Similar alterations in virulence and genomic composition of CVB3/0 could be observed in mice fed normal diets but genetically deprived of GPx (e.g., the use of knockout mouse models; Beck, 2007). In addition, more recent observations have shown that two strains of influenzavirus exhibit increased virulence when given to Se-deficient mice. Again, this increased virulence is accompanied by multiple changes in the viral genome in a segment previously thought to be relatively stable. Ongoing research should resolve many of the mechanistic details. Important herein is the concept that there is a basis for linking the expression of viral diseases to nutrition (Beck, 2007).

3. *Se Toxicity*

Three types of Se toxicity have been identified in livestock: acute and chronic blind staggers and chronic alkali disease (Subcommittee on Mineral Toxicity in Animals, 1980). Abnormal movement and posture, breathing difficulties, diarrhea, and rapid death characterize acute Se toxicity. Chronic Se toxicity of the blind staggers type occurs when animals consume Se toxic accumulator plants (usually over a period of weeks or months). They develop blindness, severe abdominal pain, and paralysis. Death often results from respiratory failure.

Se toxicity of the alkali disease type occurs when animals consume high Se diets (5 to 50 microgram/m; 0.063 to 0.63 micromol/g) for prolonged periods of time. Alkali disease is characterized by emaciation, a lack of vitality, cardiac atrophy, erosions of the joints of the long bones, hepatic cirrhosis, and anemia (Subcommittee on Mineral Toxicity in Animals, 1980). Se has also been reported to affect normal development of the embryo and fetus in cattle, pigs, and sheep following consumption of seleniferous diets, and Se toxicity has been shown to induce malformations and reduce hatching success, growth, and survival of young in poultry, quail, and mallards (Hamilton, 2004).

In the high Se areas of Wyoming, South Dakota, and Nebraska in the United States, human Se toxicosis was suggested to be a problem, but this has not been substantiated and is less of concern now that foods are available from around the world rather than a local region. Endemic Se toxicity has also been reported in the Hubei province of China. The selenosis has been linked to high Se contamination of the soil. It has been estimated that affected individuals can have consumed 5mg Se/day (63.3 micromol/day) or more for several years. Signs of toxicity included hair loss in the early stages and, in the later stages, convulsions, paralysis, and motor disturbances. Human intakes throughout most of the world are between 20 and 300 microgram Se/day (0.25 to 3.80 micromol/day) and other large animals perhaps two to three times that amount (Burk and Hill, 2005).

E. Evaluation of Selenium Status

Because deficiency-related disorders are more common than selenosis (Se toxicity), most laboratories assess Se adequacy indirectly by measurement of erythrocyte GPx activity or selenoprotein P (Reilly, 2004). Plasma GPx measurements can also be used as an index of Se status. Plasma GPx levels, however, can be affected by erythrocyte GPx leakage. Erythrocyte GPx activity is 25 to 100 times higher than plasma GPx activity so that even minor hemolysis negates the value of plasma GPx.

Although most commonly used, the sole use of GPx is often questioned given the wide tissue variation in GPx activity that is storage dependent, reflecting the adequacy

of the animal at the time of incorporation of selenocysteine into GPx, and that at higher Se concentrations there is an increase in activity as compared to tissue Se levels, which can plateau (Reilly, 2004). Few of these criticisms apply to selenoprotein P, which reflects current history and directly responds to recent Se intake (Burk and Hill, 2005). Also, it is important when measuring GPx activity that hydrogen peroxide be used as the substrate and azide used to inhibit catalase activity if the purpose of the assay is to determine Se-dependent GPx activity. For diagnosis of Se toxicosis, whole blood, hepatic, or renal tissue Se concentrations can be of value. Urinary excretion of trimethyl Se can also be of value in severe Se toxicosis (Subcommittee on Mineral Toxicity in Animals, 1980).

VII. ZINC

A. Zinc Distribution

A large animal can contain as much as 1.4 to 2.3g (0.024 to 0.035mmol) of Zn. Next to calcium and magnesium, Zn, is the most abundant intracellular cation. A large amount of Zn is presented in bone and muscle (>70%), but Zn is not easily mobilizable in response to Zn deficiency (Keen *et al.*, 2003; Park *et al.*, 2004; Watson, 1998). Thus, a Zn-deficient diet can significantly reduce certain tissue pools, such as plasma. In the rat, for example, consumption of a Zn-deficient diet can result in a 50% reduction in plasma Zn within 24 h. Eventually, muscle catabolism can result in a significant release of Zn into the circulation. Moreover, very high Zn concentrations are found in integumental tissues (skin, hair, wool, and nails), retina, and male reproductive organs. Typical plasma or serum Zn concentrations for most species range between 0.5 and 1.5 microgram/ml (7.6 to 22.9 micromol/liter), with whole blood concentrations being about 10 times higher (Keen *et al.*, 2003; Park *et al.*, 2004; Watson, 1998).

B. Functions of Zinc

Zn is essential for the function of more than 200 enzymes. Zn-containing enzymes are found in all of the major metabolic pathways involved in carbohydrate, lipid, protein, and nucleic acid metabolism (Keen *et al.*, 2003; O'Dell and Sunde, 1997). Zn can function as a structural component of an enzyme (entasis), as a proton donor at the active site of an enzyme, and as a bridging atom between the substrate and the enzyme. Mammalian Zn enzymes include carboxypeptidases, alkaline phosphatase, alcohol dehydrogenase, carbonic anhydrase, and superoxide dismutase. Given the variety of enzymes that contain Zn, a cellular deficiency of Zn would be expected to have profound consequences.

In addition to its enzymatic roles, Zn is also thought to be involved in stabilizing the structures of RNA, DNA, and ribosomes (Keen *et al.*, 2003). Zn has been shown to promote conformational transformations of DNA from the beta to the Z form. A large family of nuclear binding proteins has Zn binding domains (Zn-binding fingers). The structure of each individual finger is highly conserved and consists of about 30 amino acid residues, constructed as a $\beta\beta\alpha$ fold and held together by the Zn ion. Many transcription factors, regulatory proteins, and other proteins that interact with DNA contain Zn fingers (e.g., at the major groove along the double helix of DNA in which case the Zn fingers are arranged around the DNA strand). In young developing animals, even a short-term Zn deficiency can have a profound effect on transcriptional regulation important to development.

In addition to its roles in enzymes and nucleic acids, Zn is also important to the stabilization of biomembranes. Membrane-bound Zn alters the fluidity and stabilization of membranes (O'Dell and Sunde, 1997). Zn deficiency contributes to oxidative stress to membranes, because of structural strains, altered activities of membrane-bound enzymes, and changes in membrane receptors. An example is the increase in the sensitivity of erythrocytes from Zn-deficient animals to osmotic shock that quickly reverses upon Zn repletion. Membrane lipid damage can also be an important component in the teratogenic pathology of Zn deficiency (Keen *et al.*, 2003). In addition to membrane proteins, Zn has also been shown to specifically bind to cytoskeletal proteins, such as tubulin, and cause polymerization. Such interactions have been linked to abnormal cell signaling (Mackenzie *et al.*, 2002).

C. Dietary Zinc

Nutritional Zn deficiency has been well documented in a number of species including humans, cattle, dogs, and sheep. Similar to Cu, the uptake of dietary Zn is influenced by a variety of dietary factors, and conditioned Zn deficiencies are common. Foods that are high in Zn include shellfish (>200 microgram/g; >3.0 micromol/g), other seafood and meat (20 to 50 microgram/g; 0.31 to 0.76 micromol/gram), and whole grains, legumes, and nuts (20 to 30 microgram/g; 0.31 to 0.46 micromol/g) (Ammerman *et al.*, 1995; Spears, 2003). Food items considered low in Zn (<1 microgram/g; 0.015 micromol/g) include dairy products, fruits, and vegetables. Typical Zn concentrations in pastures in nonindustrial areas range from 20 to 50 microgram/g (0.31 to 0.76 micromol/g). Cereal grains of pig and poultry rations typically contain 20 to 40 microgram/g (0.31 to 0.61 micromol/g). Soybean, peanut, and linseed meals contain 50 to 70 microgram/g (0.76 to 1.15 micromol/g), and fish and meal can contain up to 100 microgram/g (1.53 micromol/g) (Ammerman *et al.*, 1995; Spears, 2003).

D. Zinc Metabolism, Absorption, and Transport

1. Absorption

In monogastric animals, Zn is mainly absorbed from the duodenum, jejunum, and ileum, with little being absorbed from the stomach. In cattle, about one-third of the Zn is absorbed from the abomasums. In most species, the initial absorption of Zn is about 10% to 20% (Cousins, 1998; Liuzzi and Cousins, 2004; Cousins *et al.*, 2006; Sekler *et al.*, 2007). Phytate (myoinositol hexaphosphate), which is found in all plant seeds and most roots and tubers, can significantly inhibit Zn absorption in many species and in humans by forming insoluble complexes. The consumption of high phytate diets has been linked to the induction of Zn deficiency, but usually in situations wherein the diets are marginal in Zn content.

Similar to other trace elements, a number of dietary constituents can influence Zn availability. High dietary iron decreases Zn absorption, although its significance with regard to overall Zn balance can be questioned. Several amino acids form Zn complexes with high stability constants, and it has been suggested that such complex formation facilitates Zn uptake (Cousins *et al.*, 2006; Liuzzi and Cousins, 2004; Sekler *et al.*, 2007). Zn absorption is higher in neonates than in adults and is increased in Zn deficiency in rats and cattle.

2. Transport

Zn travels across the brush border via carrier-mediated processes (Fig. 22-4). Active transport dominates at low or normal intake, whereas passive diffusion contributes more significantly at high intake. The mechanisms underlying the regulation of Zn absorption have long remained elusive. Low-molecular-weight cellular proteins, such as metallothionein (MT), bind Zn, Cu, and cadmium. Zn induces MT, but only at very high intakes. The Zn transporter 1 (ZnT-1) appears to be involved in the export of Zn across the enterocyte basolateral membrane, whereas ZnT-2 and ZnT-4 are involved in the flux of Zn in the endosomes, possibly regulating intracellular trafficking of Zn. ZnT-1 is localized to the basolateral membrane, and ZnT-2 is found in acidic vesicles that accumulate Zn (Cousins, 1998; Liuzzi and Cousins, 2004; Cousins *et al.*, 2006; Sekler *et al.*, 2007). These transporters are found primarily in villus cells and much less frequently in crypt cells. The ileum is the major site for ZnT-1. ZnT-2 is found in the duodenum and jejunum, and ZnT-4 in all parts of the small intestine.

Regarding cellular uptake, in contrast to cellular egress and intracellular organelle transport, a superfamily of human Zn transport proteins has been identified (Zn importer proteins, ZIP1 and ZIP2, plus others that constitute a large family of proteins). These proteins are localized in the plasma membrane and have structural characteristics typical of other transport proteins (e.g., permeable membrane domains, a transport channel, high-affinity binding domains).

E. Zinc Deficiency

An early effect of severe Zn deficiency in many species is anorexia and cyclic feeding. Regardless of the direct biochemical explanation for the anorexia, the cyclical food intake patterns of Zn-deficient animals can represent an adaptation of the animal to the Zn-deficient diet, because during the periods of low food intake there will be substantial muscle catabolism and release of Zn into the plasma pool (Keen *et al.*, 2003; Park *et al.*, 2004; Watson, 1998). Hepatic and extrahepatic tissues for Zn-requiring processes can then use this released Zn.

If the period of Zn deficiency is prolonged, additional hallmarks of Zn deficiency are decreased efficiency of food utilization, impaired growth, and severe dermatitis. The dermatological lesions are frequently characterized histopathologically as parakeratosis. The biochemical lesions that underlie these pathologies have not been firmly identified, although it is recognized that a reduction in cell division is an early event with Zn deficiency. The reduction in cell replication in Zn deficiency has been related to the role of Zn in nucleic acid synthesis, protein synthesis, nucleotide transport, chromatin condensation, and assembly of mitotic spindle via condensation, and assembly, in addition to affecting cell cycle-related regulation and oxidative stress (Clegg *et al.*, 2006; Oteiza and Mackenzie, 2005).

Zn responsive dermatosis is a well-documented disease in dogs and can be manifested as two syndromes (White *et al.*, 2001). Syndrome I occurs primarily in northern-breed dogs (Alaskan malamute, Samoyed, and Siberian husky), but it has been documented in other breeds as well. Although these dogs are generally consuming Zn-adequate diets, they frequently require Zn supplementation, either orally or parenterally, in some cases, for life (White *et al.*, 2001). Syndrome II occurs in young dogs consuming diets that are not adequate in Zn or contain high concentrations of calcium or phytates. Changing the dog to a Zn-adequate diet is the only treatment necessary in most cases, along with transient Zn supplementation.

Because of the diverse roles of Zn in nucleic acid and protein synthesis and in gene expression, a Zn deficiency during early development is teratogenic in mammals. Typical malformations associated with Zn deficiency include cleft lip and palate, brain and eye malformations, and numerous abnormalities of the heart, lung, skeletal, and urogenital systems (Keen *et al.*, 2003).

In addition to a high incidence of early postnatal death, marginal Zn deficiency has been associated with altered skeletal development and behavioral abnormalities (Ganes and Jheon, 2004; Keen *et al.*, 2003).

Perhaps the most striking effect of a marginal prenatal Zn deficiency is on the ontogeny of the immune system. In both mice and rhesus monkeys, marginal prenatal Zn deficiency impairs immunoglobulin M production and decreases sensitivity to a number of mitogens. Of particular interest are the observations that these immune defects can persist well into adulthood despite the introduction of Zn-replete diets at birth. Immune defects associated with postnatal Zn deficiency include reduced thymic hormone production and activity, impaired lymphocyte, natural killer cell and neutrophil function, and impaired antibody-dependent cell mediated cytotoxicity. Postulated defects include impaired cell replication, gene expression, and cell motility and alterations in cell surface recognition sites (Cousins, 1998; Fraker and King, 2004).

There can also be a reduction in glucose utilization in Zn deficiency that has been linked to increased lipid metabolism. It is secondary to reduced insulin release, increased insulin degradation via glutathione insulin transhydrogenase, and an increase in peripheral insulin resistance. As with Cu and Mn, Zn deficiency can result in marked alterations in lipoprotein metabolism. A Zn deficiency-induced hypercholesterolemia has been demonstrated in rat models. This hypercholesterolemia is primarily due to a decrease in HDL cholesterol; the HDL isolated from Zn-deficient animals is enriched in apo E and low in apo C content (Fekete and Brown, 2007; Hughes and Samman, 2006).

In addition to lipoprotein metabolism, Zn deficiency has been shown to affect essential fatty acid metabolism, and many of the signs of Zn deficiency mimic essential fatty acid deficiency. For example, the delta-desaturation of linoleic acid is markedly elevated in Zn-deficient rats, and Zn deficiency has consistently been shown to increase tissue arachidonic acid levels (Fekete and Brown, 2007; Hughes and Samman, 2006). In addition, Zn deficiency is associated with a reduction in growth hormone production and output. This defect can be secondary to the Zn deficiency-induced reduction in food intake rather than resulting from a direct role in growth hormone synthesis and release. The growth retardation associated with Zn deficiency is refractory to growth hormone therapy, however, unless Zn therapy is also instituted, suggesting that Zn is required for growth hormone uptake, or that reduction is required for growth hormone uptake, or that reduction in cellular Zn is the rate-limiting step with regard to cell growth (O'Dell and Sunde, 1997). A classic sign of Zn deficiency in humans is hypogonadism. In Zn-deficient animals, the testes are significantly reduced in size with atrophy of the seminiferous epithelium. The resulting testicular hypofunction affects both spermatogenesis and output of testosterone by Leydig cells. Current evidence suggests a primary defect in Leydig cell function with a secondary effect of Zn deficiency per se. There are also specific effects of Zn deficiency on prostate, epididymal, and seminal vesicle size that are independent of the reduction in food intake, suggesting a defect in testosterone's target cell response. Tissue and circulating levels of hypothalamic pituitary hormones are consistent with a primary failure of Leydig cell function. Levels of LHRH, FSH, and LH have all been reported to be normal or elevated with Zn deficiency. Prolactin, thyroid hormone, and corticosterone metabolism have all been reported to be either unaffected or affected by Zn deficiency.

At least five genetic errors in Zn metabolism that mimic Zn deficiency have been identified in mammals. They are Adema disease (inherited parakeratosis) of cattle, chondrodysplasia, congenital Zn deficiency (lethal acrodermatitis) in bull terriers, acrodermatitis enteropathica (AE) in humans, and lethal milk syndrome in mice. Bovine hereditary Zn deficiency, Adema disease, is an autosomal recessive disorder that results in inadequate amounts of Zn being absorbed from the gastrointestinal tract and leads to a number of clinical abnormalities. The first clinical manifestation is diarrhea, followed by skin lesions, poliosis, and a decreased ability to sustain a suckle reflex (Watson, 1998). It is similar in many respects to acrodermatitis enteropathica in humans. The oral administration of Zn acetate caused a reversal of all clinical, biochemical, and histological abnormalities in affected calves. Adema disease occurs predominantly in black pied cattle of Frisian descent. Affected calves are born "normal," but the signs of the disease usually appear 30 to 60 days after birth; in addition to diarrhea, other signs include dry scaly coat, alopecia, hyperkeratotic conjunctivitis, diarrhea, poor weight gain, immunological dysfunction (in particular severe thymic atrophy), and death at 3 to 4 months of age. An additional sign of the disease is delayed sexual maturation. Mature dwarfs produce spermatozoa with 45% acrosomal defects compared to 5% in controls. Significantly, this defect in spermatozoa can be corrected by dietary Zn supplementation. Of interest, many of these same signs occur in humans with acrodermatitis enteropathica (O'Dell and Sunde, 1997). Lethal milk syndrome is an autosomal recessive disorder caused by a mutant gene in the C57BL/6J(B6) mouse strain. Phenotypic characteristics of this genotype are similar to some signs observed in AE and Adema diseases. Offspring, which suckle from affected dams, exhibit stunted growth, alopecia, dermatitis, immune incompetence, and rarely survive past weaning (Keen *et al.*, 2003).

Lethal acrodermatitis (congenital Zn deficiency) is an autosomal recessive disorder in bull terriers (Colombini, 1999; McEwan *et al.*, 2000). The syndrome is clinically characterized by growth retardation, progressive acrodermatitis, chronic pyoderma, diarrhea, pneumonia, and abnormal behavior. Laboratory findings include nonregenerative anemia, neutrophilia, low serum alkaline phosphatase, and hypercholesterolemia. Pathological findings include parakeratosis, hyperkeratosis, and a reduction in lymphocytes in the T-lymphocyte areas of lymphoid tissue.

Overall, the expression of lethal acrodermatitis in bull terriers is similar to experimental Zn deficiency in dogs.

Although the syndrome described for bull terriers is similar to cattle with Adema disease and humans with AE, two significant differences should be noted. Serum Zn is not consistently low in affected pups, and the syndrome is not responsive to Zn therapy. These observations suggest that the genetic lesion in Zn metabolism in bull terriers is quite different from that in previously described disorders.

Chondrodysplasia (short-limbed dwarfism) in Alaskan malamutes causes several deformities, but it is not life threatening. Malamutes have been reported to have a decreased ability to absorb Zn from the gastrointestinal tract (Brown *et al.*, 1978). Mutant dogs have severe bowing of the forelimbs with gross changes in size and shape of the humerus, radius, and ulna. There is no difference between dwarf and normal dogs in mineral content of the long bones and forelimbs, but in some regions calcium is more soluble than normal. In addition to the apparent abnormality of calcium binding, the dwarfs have high levels of urinary acid mucopolysaccharides, suggesting a disturbance in normal bone maturation. Dogs with this genetic lesion can also have hemolytic anemia. In anemic dwarfs, red cells are macrocytic, hypochromic, and without reticulocytosis. Erythrocytes are fragile and have higher than normal intracellular cadmium and potassium and lower than normal glutathione. The specific defect that predisposes the cells to premature destruction is not known.

F. Zinc Toxicity

The risk for Zn toxicity and the likelihood of achieving excessive dietary intakes of Zn are both low. Zn has been characterized as a relatively nontoxic element with a wide margin of safety. However, given the diversity of enzymes

In addition to plasma Zn analysis, whole blood or erythrocyte Zn has been used to assess Zn status; however, whereas low erythrocyte Zn indicates a Zn deficiency, it is often too insensitive for accurate diagnosis. Neutrophil Zn has been reported to be more sensitive to Zn status than erythrocyte Zn, but its usefulness is limited, as an assay requires about 10 to 20 ml of blood for conventional assays. In experimental settings, liver Zn has been useful in diagnosing Zn toxicity, but it is of little value in diagnosing Zn deficiency as values rarely decrease by more than 20% even in severe deficiencies. Liver metallothionein has been used to gauge Zn deficiency in nonhuman primates. The use of Zn transporter measurements to assess status has also been proposed (Keen and Uriu-Adams, 2006).

VIII. CONCLUDING COMMENTS

Metal ions in combination with numerous organic accessory and catalytic factors (e.g., various vitamins) play important roles in enhancing specificity and providing additional properties that allow complementary forces and arrangements to improve the orientation and efficiency of catalysis. In enzyme transition states, metals influence the entropic components of enzymatic reactions. Metals allow the formation of metastable bonds and play roles in entasis (enzyme shape and configuration). Some minerals are important to organizing water structure; others act as Lewis acids and bases.

Appropriate intake levels of certain chemical elements are required to maintain optimal health. On a per food energy basis (e.g., kcal or joules), the requirements of most animals are similar. Most commonly, a conventional diet will meet the requirements. However, most deficiency situations occur when the diet is simple and monotonous in terms of composition. The extensive range of supplements, such as for Se, Fe, and Zn, reflect the success of research in ways that were unimaginable even a decade ago.

I. INTRODUCTION AND BRIEF HISTORY

The concept that food components are linked to tissue growth and repair was evident in the writings of Greek philosophers as early as the fifth century B.C. In human medicine, nutrition is a topic found in the Hippocratic collection. The first disease to be recognized as nutrition related may have been night blindness. An ancient Egyptian medical text, the *Papyrusebers* (written about 1550–1570 B.C.), prescribed "beef liver, roasted, squeezed, placed against the eye" for various eye diseases, including night blindness. In China, liver applied topically to the eye was also used as a treatment for night blindness.

By the mid-1700s, the curative effects of certain foods had been linked to a number of diseases. James Lynn, a physician in England, assembled his classic treatise that fresh fruits and vegetables seemed effective in curing scurvy. By the 1800s, the association of corn to pellagra (niacin deficiency) was made; by the 1900s, Eijkman, a Dutch physician working in Java, reported that consumption of polished rice was related to polyneuritis, associated with the nutrition disease beriberi. These studies are also noteworthy because they are among the first to utilize experimental animals to produce a vitamin deficiency in a controlled setting. However, the concept that specific diseases could be caused by the lack of a dietary component did not evolve until the beginning of the 20th century. Because of the success of Pasteur and the "germ theory," many diseases now recognized as nutritional in origin were initially attributed to infectious agents. It was widely held that only the gross constituents of the diet (i.e., carbohydrates, protein, fat, and minerals) were needed for complete nourishment. As F. G. Hopkins, one of the founders of nutrition as a science, noted in his 1929 Nobel lecture, "the quantitative character of the data obtained and the attractive circumstance that such data appeared to supply . . . induced a feeling that knowledge concerning these needs had become highly adequate and was approximating even to finality . . . and a feeling that knowledge concerning nutrition was adequate and complete" (Hopkins, 1930). Nevertheless, the concept that a small amount of certain factors seemed necessary for optimal growth and development soon evolved (Goldblith and Joslyn, 1964).

The pursuit to define the nature of vitamins was first directed at lipid substances that were demonstrated to

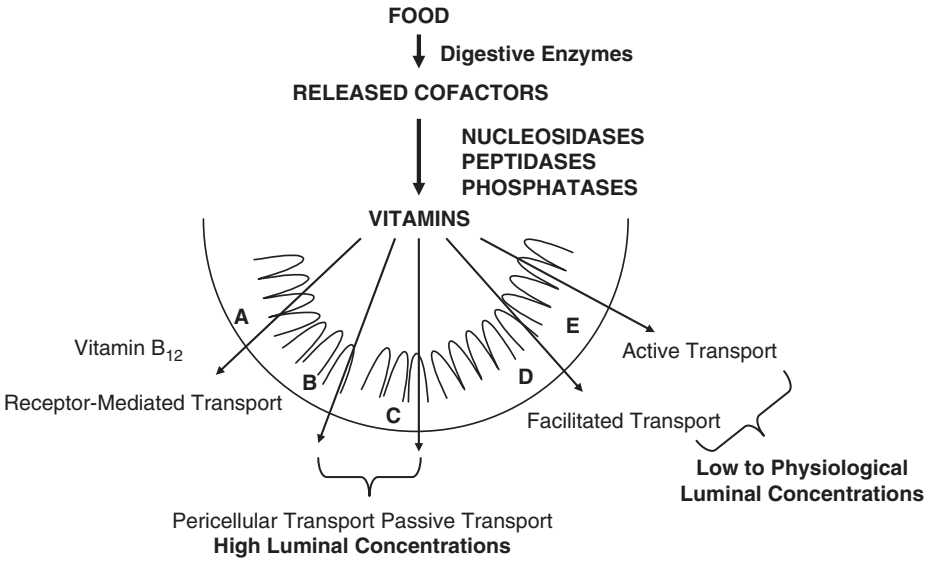

FIGURE 23-1 Vitamin absorption. Vitamins in foods are often present as cofactors or in highly modified forms. Pancreatic and intestinal cell-derived enzymes are required to initiate normal uptake in absorption. Nucleosidases, phosphatases, and peptidases are key factors in processing cofactors to vitamins. Transport of given vitamins can be receptor mediated and occur via pericellular-related processes, passive transport (usually at high luminal concentrations), active transport (requires energy), or facilitated processes (requiring a transporter or chaperone).

be essential in the diet of animals. McCollum and Davis at Wisconsin confirmed that butter or egg yolk, but not lard, supplied a lipid soluble factor that was necessary for growth in rats. As a consequence, the first fat-soluble substance with growth promoting properties (designated as vitamin A) was reported in the early 1900s, a time that most considered the beginning of the "age" of vitamin exploration (Goldblith and Joslyn, 1964).

Now there is constant awareness and sensitivity to the possibility of dietary vitamin deficiencies (and excesses). Nutritional deficiencies are not uncommon in animals, particularly animals fed diets of a limited (or restricted) number of dietary ingredients. A number of subsidiary and contributory factors may also lead to vitamin-related diseases. These factors include interference with normal food intake, loss of appetite (anorexia), impaired absorption or utilization, increased excretion, and the presence of antagonists. Stressful physiological states that increase nutrient demands (e.g., lactation) may also perturb the vitamin status of animals.

II. DEFINITION, GENERAL PROPERTIES, AND OVERVIEW OF FUNCTIONS

No definition for vitamins is totally satisfactory. Vitamins have been defined as organic substances present in minute amounts in natural foodstuffs that are essential to normal metabolism, the lack of which causes deficiency diseases. This definition, however, is not specific and can apply to a number of compounds derived from the secondary metabolism of amino acids, simple sugars, and fatty acids. Suffice to say that in most mammals they represent essential organic compounds, not easily classified with the macronutrients. Some may be synthesized, but in insufficient amounts to meet normal needs during critical developmental periods.

Vitamins can be further classified according to chemical and physical properties, such as whether they are soluble in aqueous solution or lipid solvents. Those vitamins that are soluble in lipid solvents (vitamins A, D, E, and K) are absorbed and transported by conventional lipid transport processes. For water-soluble vitamins, respective solubility coefficients are major factors that dictate the availability and ease of absorption. Within physiological ranges of intake, active processes are usually involved in the absorption of water-soluble vitamins. Although for some, at high concentrations (10 times or more the typical requirements), passive processes may also be involved. In this regard, the diversity and complexity of vitamin metabolism and processing should be appreciated at the onset. Vitamins in foods are often present as cofactors or in highly modified forms. Pancreatic and intestinal cell-derived enzymes are required to initiate normal uptake in absorption. Nucleosidases, phosphatases, and peptidases are key factors in processing cofactors to vitamins (Fig. 23-1).

Vitamins serve a broad range of functions. For example, some of the actions of vitamin A and vitamin D are consistent with the actions of steroid hormones; derivatives of vitamin A and also vitamin E can act as signal transduction mediators; vitamin K acts principally as an enzymatic

TABLE 23-1 Requirements for Selected Water Soluble Vitamins Expressed as mg/1000kcal or 4.2Mjoules[a]

Vitamin	Animal				
	Cat	Rat	Mouse	Chick	Human
Thiamin	2–3	2	2	1	1–2
Riboflavin	1–2	1	1	0.5	1
Niacin[b]	20–30	8	8	6–8	5
Pyridoxine[b]	2–4	2	2	1–2	1
Folate	3–4	0.5	0.5	0.5	0.3

[a] *Taken from the National Research Council publications dealing with requirements for animals or humans. Values were obtained by dividing the recommended safe and adequate intake by the recommended energy intake.*

[b] *Cats do not effectively convert tryptophan to niacin; thus, there is absolute need for niacin. In this regard, ~10 mg of niacin is produced per 4.2MJ of typical diets containing high-quality protein when utilized by the rat, mouse, chick, or human. The higher pyridoxine need in the cat is due to the higher protein requirements of carnivores and higher concentrations of enzymes dedicated to nitrogen metabolism. If expressed on a unit protein basis rather than energy basis, the pyridoxine requirements of most homeothermic animals are similar.*

cofactor; vitamin E can act as an agent that scavenges free-radical containing lipids and oxidants, independent of a direct association with an enzyme, although recent information indicates possible roles in cell signaling. Regarding the water-soluble vitamins, most serve as cofactors or co-substrates for enzymes or in cell signaling.

These varied functions of vitamins have also complicated the development of a simple system of classification or nomenclature. When the vitamins were originally discovered, they were isolated as fractions from selected foods, and as their exact chemical composition was seldom known, a system of letter designations was developed. However, this system became complicated when it was discovered that some functions originally ascribed to vitamins were due to other substances, such as one of the essential amino acids. Consequently, the designation of vitamins by letters was not systematically pursued. Similarly, the lack of chemical composition data resulted in a complex system of expressing dosages as arbitrarily defined units. Regarding requirements, when expressed on an energy basis, vitamin requirements are often of the same order from one species to the next. Some examples are given in Table 23-1. Differences in dietary requirements between species for given vitamins (in contrast to physiological or metabolic requirements) are usually due to presence of unique pathways for their production, degradation, or disposal. Good examples are ascorbic acid and niacin, which cannot be made in some animals and therefore are true vitamins for such animals. Taurine is another example of a nutrient (although not a true vitamin as classically defined) where continual disposal or loss from the body results in a nutritional need, even though taurine can be synthesized. Further, young and growing animals may have a relatively higher nutritional need for some nutrients. Many species during neonatal periods have requirements for certain compounds, which later in life may be sufficiently produced (e.g., choline, carnitine, or inositol). There are also numerous possibilities for deleterious interactions that can have physiological consequences and affect given requirements (Committee on Animal Nutrition, 2001a, 2001b; McDonell, 2001; Rucker and Steinberg, 2002; Subcommittee on Laboratory Animal Nutrition, Board on Agriculture, National Research Council, 1995).

III. FAT-SOLUBLE VITAMINS

A. Vitamin A

1. *Introduction*

Observations by Hopkins, Stepp, and others that a growth-stimulating factor could be extracted from milk by means of lipid solvents, concentrated, and tested in experimental animal models were seminal steps that eventually led to the identification of vitamin A (Goldblith and Joslyn, 1964). This growth-promoting factor was also described as being present in egg yolk, butter, and cod liver oil. In later studies, "Factor A" or vitamin A was shown to be present as lipid esters in animal tissues and in the form of a "pro-vitamin A" in plants (e.g., compounds in the carotenoid family). The structures and recommended names of naturally occurring and commercial forms of vitamin A and carotenoids are shown in Figure 23-2. Once chemical features for the carotenoids and retinoids were resolved in the 1940s and 1950s, studies of their biological function were undertaken and commercial synthesis of vitamin A and vitamin A-like molecules proceeded rapidly.

2. *Proforms of* Vitamin A: *The Carotenoids*

Carotenoids comprise a group of more than 700 compounds (most often red, yellow, and orange pigments in

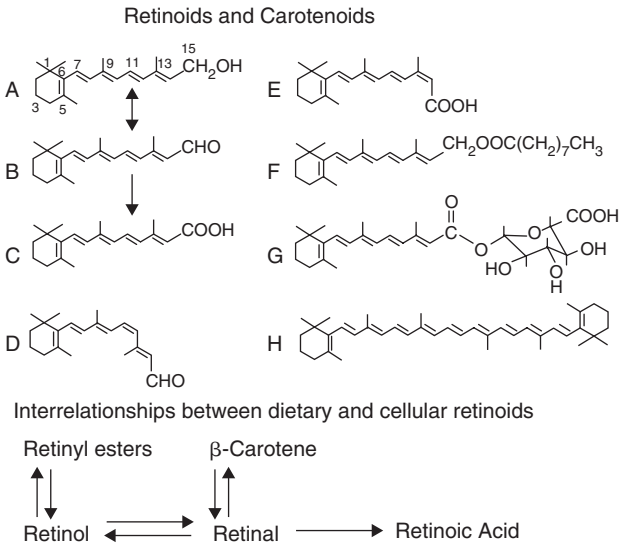

FIGURE 23-2 Structures of retinoids and carotenoids related to vitamin A. The structures are for (A) retinol, (B) retinal or retinaldehyde, (C) retinoic acid [all-trans], (D) retinoic acid [11-cis], (E) retinoic acid [13-cis], (F) retinyl ester [palmitate], (G) retinoyl β-glucuronide, and (H) β-carotene. β-Carotene is a precursor to retinal, which in turn may be reduced to retinol or irreversibly oxidized to retinoic acid. In animal cells, retinol is "stored" as retinyl ester.

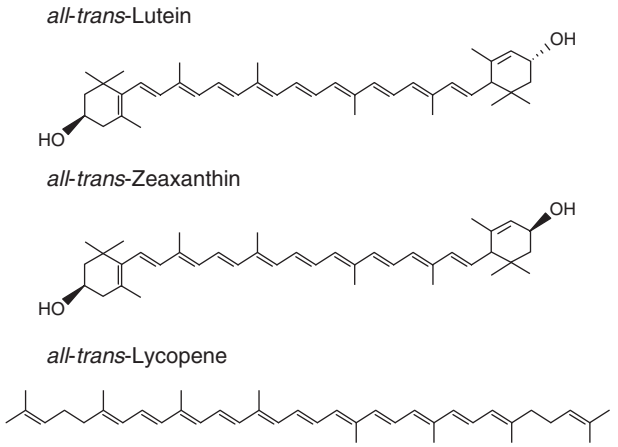

FIGURE 23-3 Structures of carotenoids without vitamin A activity. Lutein is found in green leafy vegetables and is employed as an antioxidant and for blue light absorption. Lutein covalently bound to one or more fatty acids is present in some fruits and flowers, notably marigolds. As a pigment, lutein and other xanthophylls (e.g., zeaxanthin) are used as natural colorants (e.g., in chicken feed to provide the yellow skin color). Lutein is also found to be present in a concentrated area of the macula, a small area of the retina responsible for central vision. As a consequence, there is interest in lutein and diseases of the eye, such as age-related macular degeneration. Lycopene is a bright red carotenoid pigment found in tomatoes and other red fruits.

their isolated states) found in many fruits and vegetables (Stahl and Sies, 2005). To act as a provitamin A, a carotenoid must contain a β-ionone structure (i.e., the ring structure shown in Figure 23-2 containing a single double bond and three methyl groups). The carotenoids represent an unusual class of biological pigments. Carotenoids are rich in conjugated double bonds and are designed to interact with light. Green plants are the main sources of carotenoids in the diet of most animals.

In plants and prokaryotes, carotenoids serve as mediators of photo-energy-related processes by capturing energy from light (Stahl and Sies, 2005). Carotenoids are also readily destroyed by intense light, particularly UV light. From a chemical perspective, this is important given the wide range of functions involving carotenoids and vitamin A. Carotenoids can also quench singlet oxygen and may act as both antioxidants and prooxidants. The resulting products of such reactions may also have unwanted side effects, a problem that is not often appreciated.

When hays are stored for long periods (e.g., a year or more), the carotenoid content may be markedly reduced or modified because of chemical or physical (UV light) oxidation. Moreover, in plants, carotenoids occur in association with chloroplasts complexed with protein and other lipids and provide the main source of provitamin A for animals. In nonruminant animals, poor digestion of complex organelle structures, such as chloroplasts, in turn may lead to poor digestibility of carotenoid components.

Grains, with some exceptions (e.g., corn) are minor sources of provitamin A. Among the legume grains, chickpeas, green and black grams are the best sources of provitamin A. The richest source of carotenoid is red palm oil, which contains 500 g of mixed α- and β-carotene per milliliter. Of the carotenoids, six are known to be biologically important: α-carotene, lycopene, lutein, zeaxanthin, cryptoxanthin, and β-carotene (e.g., because of its role as a precursor to vitamin A). The structures of lycopene, lutein, and zeaxanthin are shown in Figure 23-3. The following sections focus mostly on β-carotene and vitamin A followed by short descriptions for the other carotenoids, which serve as important biofactors, although with no specific or known vitamin functions.

3. *Metabolism*

Following ingestion, retinyl esters in animal products are hydrolyzed to retinol by pancreatic hydrolases (esterases) or lipid hydrolases localized on the surface of the brush border of intestinal cells (Harrison, 2005). Bile and dietary lipids facilitate the absorption process, as retinyl esters must be a part of a lipid micelle to be absorbed. The micellar structures enhance fusion into the microvillus of intestinal cells. Similarly, lipid micelles enhance the uptake of carotenoids into intestinal cells. The bioavailability and digestion of vitamin A and carotenoids are affected by the overall nutritional status and the integrity of the intestinal microvillus. Absorption of physiological doses of vitamin A in most animals is 70% to 90%, but the efficiency of absorption for carotenoids added to diets is 40% to 60%, depending on the type of carotenoid. Carotenoids contained in plant chloroplasts, however, are often poorly

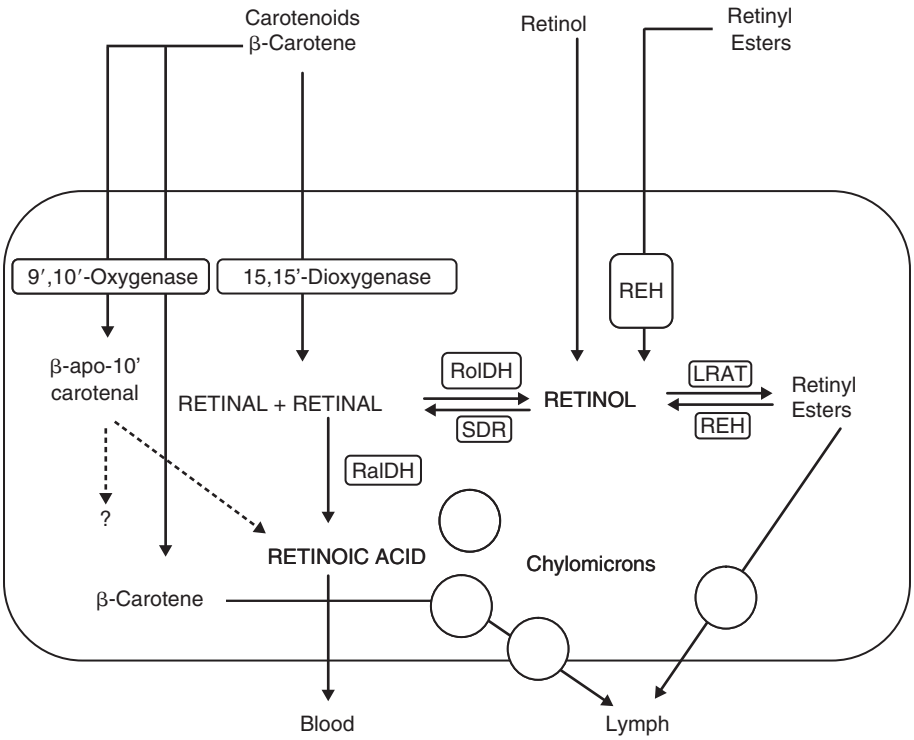

FIGURE 23-4 Absorption and cellular metabolism of carotenoids and retinoids. In the intestinal mucosal cell, some carotenoids are oxidized to both carotenals and retinals. Retinal can be reduced by alcohol dehydrogenases (RolDH) to retinol and re-esterified by lethichin retinol acyl transferase (LRAT). Retinol and associated esters are then incorporated into chylomicra, which are released into the lymph. Retinol can also be released from retinyl esters by action of retinyl ester hydrolase (REH). Moreover, retinol can be oxidized to retinal by short-chain dehydrogenases/reductases (SDR). Retinoic acid is formed from retinal by the action of retinal dehydrogenase (RalDH). Retinoic acid is sufficiently polar so that movement is directed to plasma. In contrast, owing to their nonpolar nature, given carotenoid pigments and retinyl esters are partitioned into chylomicrons for delivery into lymph. Retinol transport and carotenoid transport differ. ROL enters intestinal cells by diffusion and effluxes in part by a basolateral transporter in the ABCA1 transport family of protein transporters. Carotenoid uptake is mediated by the apical transporter SR-B1, and carotenoid efflux occurs exclusively via secretion in CM.

absorbed (less than 10%), because of the low digestibility of chloroplasts and release of carotenoids.

In the intestinal mucosal cell, some carotenoids are oxidized to both carotenals and retinals (Fig. 23-4). Most of the retinal is next reduced by alcohol dehydrogenases to retinol and re-esterified. Retinol and associated esters are then incorporated into chylomicra, which are released into the lymph.

Chylomicra particles in lymph are carried to the liver where about 75% of the retinol-derived products are cleared in most animals. In liver, there is active exchange of retinyl and other retinoids between stellate (also known as Ito cells) and parenchyma cells. To buffer such cells from an excess of vitamin A, it may be "stored" in lipid vacuoles. The storage form is as retinyl esters, where retinyl palmitate is usually the most predominant form.

As the body needs vitamin A, retinyl ester in the liver is hydrolyzed and released as retinol bound to retinol-binding protein (RBP), which binds one molecule of vitamin A as retinol per molecule of RBP (Fig. 23-5). When released into circulation, RBP exists as a complex not only with vitamin A, but also with another protein, transthyretin, which binds thyroxin. The RBP and the transthyretin complex transport not only vitamin A, but also thyroxin to targeted cells. The primary target cells for vitamin A are epithelial in nature (e.g., fetal epidermal cells, the cells of the gastrointestinal mucosa, the reproductive tract, pulmonary secretary cells, and the salivary gland) (Debier and Larondelle, 2005; Harrison, 2005).

In regard to uptake and entry into targeted cells, such as epithelial cells, the exact role of RBP at the cell surface is unclear. The association constant (K_a) between retinol and the transthyretin-RBP complex is relatively low, approximately 10^6 M/l. For example, this association constant is about the same as that for the binding of retinol to other proteins (e.g., albumin), which does not imply a high degree of specificity. In cell cultures, RBP is not essential for retinol uptake. However, the interaction of retinol within RBP's hydrophobic binding domain protects retinal from oxidation. The complex is also not cleared by the kidney, which helps to sustain retinol levels in circulation (Harrison, 2005).

Inside the targeted cells, vitamin A, as retinol, interacts with cellular-binding proteins that function to control its subsequent metabolism (e.g., oxidation to retinal and to retinoic acid). Retinal metabolites do not exist "free" in

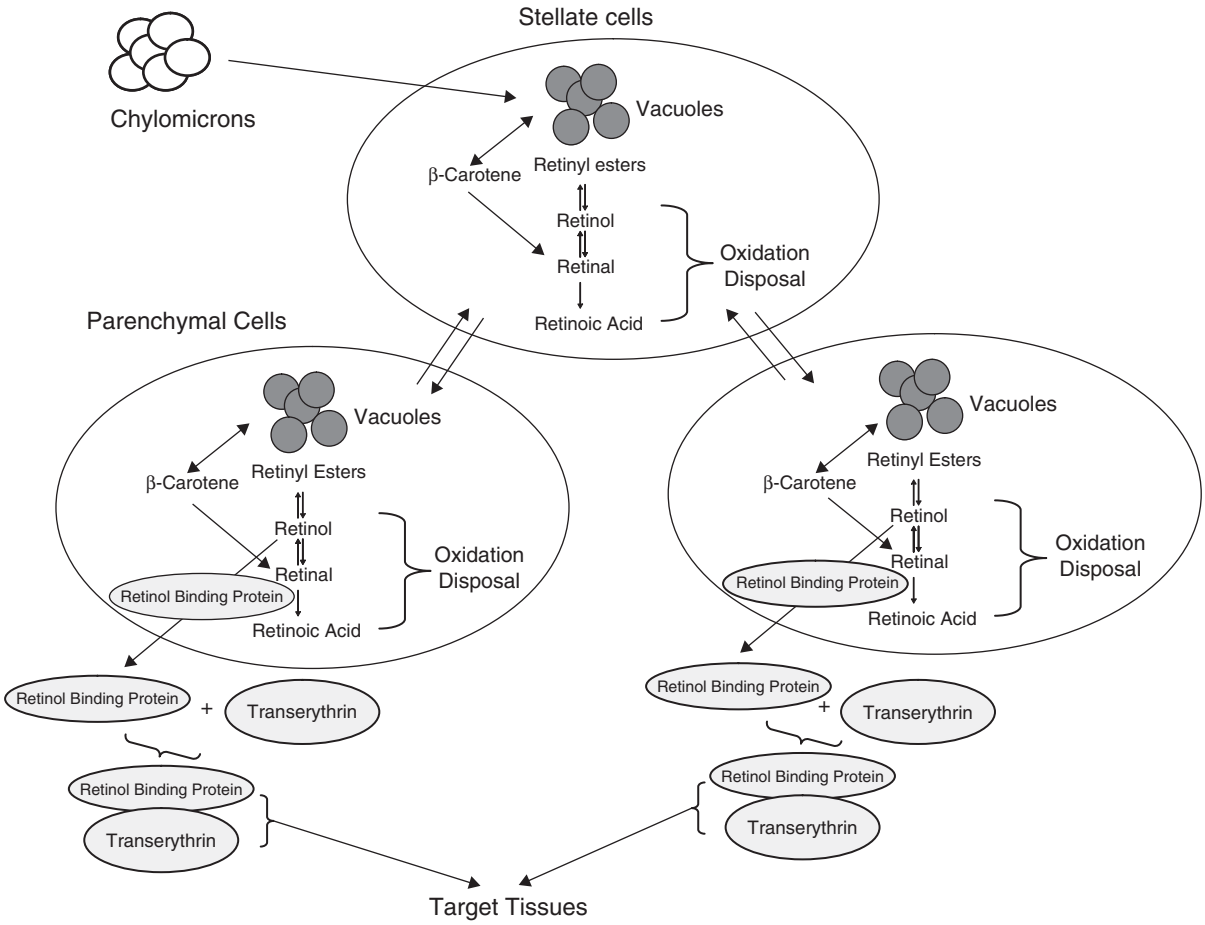

FIGURE 23-5 Steps in vitamin A processing in liver Stellate and parenchymal cells. Retinoids and carotenoids are transported from the intestine in chylomicron particles and are cleared primarily by the liver. The stellate cell is designed to sequester lipid-like compounds until needed. Fluids in the liver sinusoids derived from blood and lymph bathe stellate cells. The stellate cells are in communication with liver parenchymal cells. As the body needs vitamin A, retinyl esters and β-carotene sequestered in lipid vacuoles are released and eventually converted to retinol. The next steps involve the binding of vitamin A to retinol-binding protein (RBP). When released into circulation, RBP exists as a complex not only with vitamin A but also with another protein, transthyretin, which binds thyroxin. The RBP and the transthyretin complex transport not only vitamin A but also thyroxins to targeted cells. The primary target cells for vitamin A are epithelial in nature (e.g., fetal epidermal cells, the cells of the gastrointestinal mucosa, reproductive tract, pulmonary secretory cells, and salivary gland).

cells but are associated with specific binding proteins. The binding to and release from such proteins is rapid. Because the binding proteins are contiguously associated as a part of the cellular scaffolding, it is possible for given retinoid metabolites to move vectorially along given paths to specific locations in the cell.

Regarding the retinoid metabolites, retinoic acid is the most important, serving as a ligand for nuclear receptors (Velazquez and Fernendez-Mejia, 2004; Velazquez *et al.,* 2005). These receptors are a part of a family of transcription factors that include nuclear receptors that also interact with glucorticoids, thyroxin, and the so-called peroxisomal proliferation activator agonists or ligands. Retinoic acid influences the transcriptional regulation of at least 600 known genes. Both excesses and deficiencies of vitamin A can markedly influence the expression.

The catabolism of excess retinal may be initiated by one of several alcohol dehydrogenase isozymes with subsequent oxidation via peroxisomal enzymes. Microsomal enzymes (cytochrome P450 hydroxylases) are also involved. Examples of some of some of the events and products are given in Figure 23-6. Important interactions involve agents that can induce cytochrome P450 hydroxylases (or monooxygenases). For example, phenobarbital can cause depletion of liver retinol by induction of a microsomal oxidase system that promotes retinoid oxidation.

4. *Functions*

The major roles of vitamin A are in cellar differentiation, tissue growth, and vision. In vision, vitamin A, as a component of rhodopsin, facilitates the efficient transfer of energy

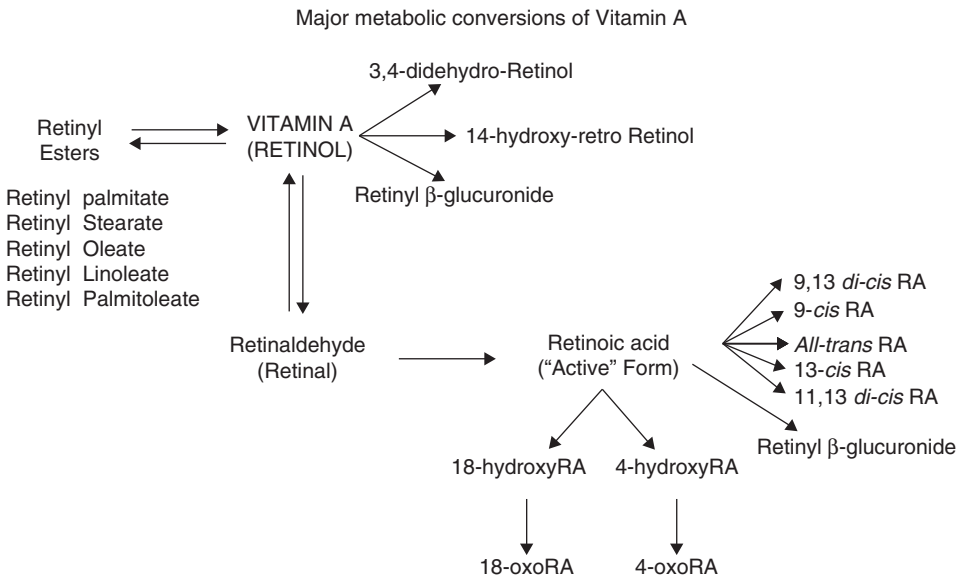

FIGURE 23-6 Steps in the metabolic conversion of vitamin A. The catabolism of excess retinol/retinal may be initiated by one of several alcohol dehydrogenase isozymes with subsequent oxidation via peroxisomal enzymes. Microsomal enzymes (cytochrome P450 hydroxylases) are also involved. Shown are some of some of the events and products. Some of these products may become sufficiently oxidized so that they are excreted by the kidney. Others, such as the glucuronide, are deposed by transport and eventual delivery into bile.

from photons of light to electrochemical signals. The series of events leading up the propagation of this signal are as follows: vitamin A as 11-*cis* retinal, forms a protonated Schiff base by binding to a lysine residue in the protein opsin to yield the visual pigment, rhodopsin (Lamb and Pugh, 2004). When a photon of light strikes rhodopsin, *cis-trans* isomerization occurs and the process results in a highly strained form of rhodopsin, bathorhodopsin, which is converted to metarhodopsin with subsequent deprotonation (Jang *et al.,* 2000). The deprotonated metarhodopsin interacts with transducin, one of the proteins in the transmembrane G-protein family. This interaction causes a subunit of transducin to bind GTP and stimulate cGMP phosphodiesterase activity. This results in a decrease in cGMP, which constitutes a significant amplification of the initiating event, the conversion of light-derived energy through 11-*cis* to transisomerization of retinal and specific changes in protein conformation (Fig. 23-7). Next, the local change in cGMP concentration results in changes in cation flux (Na and Ca ions) across rod cell membranes (Lamb and Pugh, 2004; McCabe *et al.,* 2004). This initiates an electrochemical event, the firing of cells of the optic nerve. Further, metarhodopsin is phosphorylated during these final steps and interacts with a protein designated as arrestin. The metarhodopsin-arrestin complex inhibits the transducin response and causes the release of all-*trans* retinal and the return to rhodopsin (opsin), thus completing the cycle.

In quantitative terms, only a small fraction of the total vitamin A requirement is involved in the visual process because of extensive recycling of retinal. With vitamin A deficiency, there is an inability to appropriately saturate opsin with 11-*cis* retinal to form rhodopsin and its subsequent complexes. This decreases the sensitivity of the visual apparatus, so that light of low intensity is not perceived leading to nyctalopia or night blindness. An important note, which underscores the importance of having some knowledge of vitamin A chemistry and physiology, is that night blindness is not uncommon in cattle or sheep that have been grazing on dry weathered pasture for long periods such as during prolonged drought (Barnett *et al.,* 1970; Booth *et al.,* 1987). Although most cattle in feedlots are supplemented with vitamin A, if vitamin A is accidentally left out of the ration and stored hay is fed that has lost its carotene content or grain (other than yellow corn), night blindness can occur.

5. *Growth and Cell Differentiation*

As work on vitamin A progressed, it became appreciated that although retinol and retinal were important to vision, the retinoic acid would not correct night blindness but was essential to growth and normal development (Debier and Larondelle, 2005). Within cells all-*trans* retinol associates with cytosolic retinol-specific binding proteins, and the resulting complex become vehicles for subsequent processing. For example, all-*trans* retinol may be oxidized and isomerized to all-*trans*, 9-*cis*, or 13-*cis* retinoic acid, which subsequently binds to retinoic acid-specific binding proteins that act as transcription factors in protein regulation and cellar differentiation (Fig. 23-8). The details of such interactions are beyond the scope of this chapter. However, it is important to appreciate that in response to very low

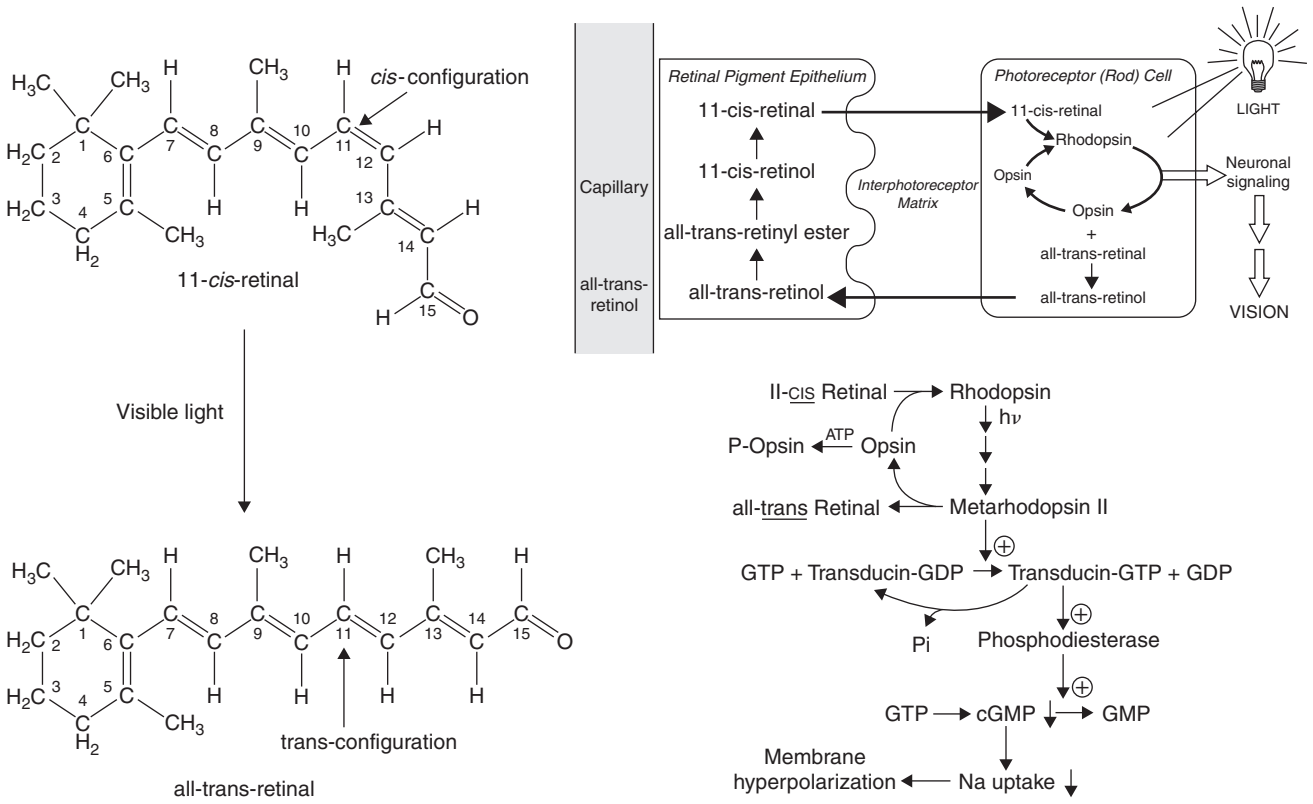

FIGURE 23-7 Vitamin A and vision. Retinal, as a component of rhodopsin, facilitates the transfer of energy from photons of light to electrochemical signals. The series of events includes the *cis-trans* isomerization, which results in a highly strained form of rhodopsin that is converted to metarhodopsin with subsequent deprotonation. The deprotonated metarhodopsin interacts with transducin, one of the proteins in the transmembrane G-protein family. This interaction stimulates cGMP phosphodiesterase activity, which results in a decrease in cGMP and signal amplification. The local changes in cGMP concentration result in turn in changes in cation flux (Na and Ca ions) across rod cell membranes to initiate firing of cells of the optic nerve.

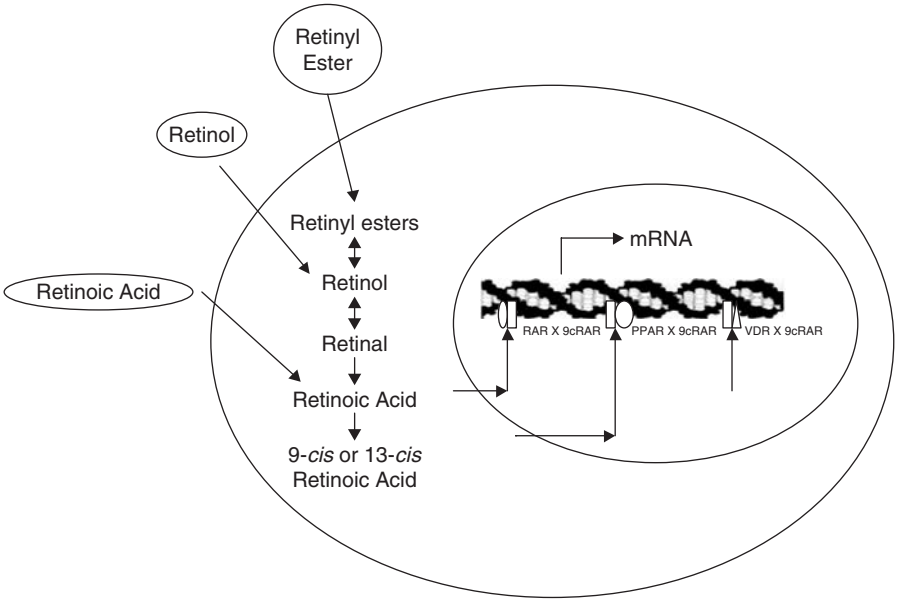

FIGURE 23-8 Vitamin A and cell regulation. Within cells all-*trans* retinol associates with cytosolic retinol-specific binding proteins, and the resulting complex become vehicles for subsequent processing. For example, all-*trans* retinol may be oxidized and isomerized to all-*trans,* 9-*cis,* or 13-*cis* retinoic acid, which subsequently binds to retinoic acid-specific binding proteins that act as transcription factors in protein regulation and cellular differentiation. The nature of the metabolic control has many facets including the regulation of specific receptor concentrations and their combination to form specific signaling complexes. The figure shows duplexes for the retinoic acid receptor (RAR) with (1) an isomeric form, (2) complexes with peroxisomal activation receptors, and (3) receptors under the control of vitamin D derivatives.

doses of retinoids, epithelial cells undergo a "terminal differentiation." Epithelial cells lose their normal columnar shape, become flattened or squamous, and increase their cytosolic content of keratin (stabilized by transglutaminase catalyzed cross-links).

In dermis, this process normally results in a protective outer layer, scales, and other specialized surfaces. With a deficiency, however, the skin can thicken and become hyperkeratinized. If the primary function of the epithelial cell is the provision of a moist surface or absorption (e.g., an enterocyte or lung secretory cell), squamous hyperkeratinization leads to loss of functional integrity. Lack of protective mucus secretions sets the stage for infections of the lungs and other tissues that depend on a mucus barrier. In the intestine, hyperkeratinization induces premature sloughing of enterocytes and malabsorption. The gradient delivery of retinoids to epithelial cells helps to explain why some epithelial cells undergo terminal differentiation, whereas others undergo cell cycling and periodic turnover, although important details need to be resolved. Other cells that are responsive to retinoids include phagocytic cells and cells associated with the immune response (e.g., the normal proliferation of the B cells and T cells requires vitamin A) (Ross *et al.,* 2000).

6. *Requirements*

For any given animal, the requirement for vitamin A depends on age, sex, rate of growth, and reproductive status. For optimal maintenance, the allowance for many animals ranges from 100 to 200 international units per kilogram of body weight per day (one international unit is equal to 0.3 g of retinol). In young growing animals, a more precise method of expressing the vitamin A requirement is on an energetic basis. In animal feeds, 4000 to 10,000 international units per kilogram of feed is considered adequate in the United States to provide vitamin A requirements for most animals.

Pathological conditions that influence vitamin A status include malabsorption, including pancreatic insufficiency and cholestatic disease, cystic fibrosis, liver disease, and kidney disease. Many forms of liver disease interfere with the production or release of RBP, which results in a lower plasma level of vitamin A. Renal failure can result in loss of RBP in urine. Factors that impair lipid absorption and transport might also be expected to influence vitamin A status.

7. *Evaluation of Vitamin A Status of Animals*

The vitamin A status of animals may be evaluated on the basis of physiological, clinical, and biochemical procedures. Clinical testing for night blindness and the elevation of CSF pressure has been used to indicate vitamin A status. The concentration of retinol and its esters is readily measured in biological samples by HPLC using various detectors and indicates the vitamin A status. As the concentration of retinol in plasma is well maintained until liver reserves are depleted, plasma retinol is not an index of vitamin A reserves. The latter is best provided by analysis of liver biopsy samples. In many carnivores, the plasma contains, in addition to retinol, equal or greater concentrations of retinyl palmitate and retinyl stearate bound to albumin, the immunoglobulin fraction, or to VLDL. Plasma retinol concentrations in excess of 30 g/dl generally indicate that vitamin A is not limiting. In most species, liver concentrations of 100 g of retinol/g liver are generally adequate.

8. *Pharmacology and Toxicity*

Vitamin A and various retinoids are used increasingly to treat skin disorders (acne and psoriasis) and certain forms of cancer. A vitamin A responsive dermatosis in cocker spaniels is well recognized and has been previously described (Scott, 1986). Retinyl-β-glucuronide and hydroxyethyl retinamide are commercial preparations of retinoids that have such activity but are less toxic than retinoic acid. The mechanisms by which these agents function most probably relate to the complex pathways involved in epithelial and epidermal cell differentiation.

Vitamin toxicities may be classified under three broad categories: acute, chronic, and teratogenic. When a single dose of vitamin A (greater than 100 mg) is injected into animals (20 to 50-kg weight range), symptoms such as nausea, vomiting, increased cerebral spinal fluid pressure, and impaired muscular coordination result. A lethal dose of vitamin A (100 mg) given to young monkeys has been reported to cause coma, convulsions, and eventual respiratory failure.

Chronic toxicity may be induced by intakes of vitamin A in amounts 10 times the normal requirements. Doses of vitamin A in this range can lead to alopecia, ataxia, bone and muscle pain, and purities. Although cats have a high tolerance to excessive intakes of vitamin A, hypervitaminosis A occurs in cats that are given a diet largely of liver. Affected cats exhibit skeletal deformations, particularly exostoses of the cervical vertebra, which precludes effective grooming. Vitamin A is also a powerful teratogen. A single large dose during pregnancy (in the 50- to 100-mg range) for an animal weighing 20 to 50 kg can result in fetal malformations. Chronic intakes (exceeding 10 times the requirements for given animals) can also be teratogenic. Carotenoids, unlike retinoids, are generally nontoxic, and many animals routinely ingest gram amounts of carotenoids on a daily basis with no deleterious effects (old world primates, herbivores, etc.).

9. *Other Carotenoids*

In addition to β-carotene, of the other carotenoids, the most information is available for α-carotene, lycopene, lutein, zeaxanthin, and cryptoxanthin. To reiterate, these carotenoids along with hundreds of others are the natural pigments in

plant tissues and give them color (Fig. 23-3). Carotenoid pigments attach themselves to proteins or fats and can produce blue, green, purple, or brown pigments in addition to yellow, orange, and red. If an animal's skin or feather color comes from carotenoids and it is not available in food, some or all of the color fades. For example, many birds develop bright red, orange, or yellow carotenoid pigmentation that they use presumably to attract mates. Because animals often obtain several different carotenoids from plant and animal food sources, it is possible that these pigments are accumulated at different levels, which results in the ultimate color expression of individual animals. As an example, when finches are fed a lutein-zeaxanthin mix, proportionally more zeaxanthin was found than lutein than occurred in the diet (i.e., there is preferential accumulation in the body). In fish, pigmentation is influenced by diet and sex. Presumably, males absorb/retain more pigments than females. Often consumers of various products (notably egg yolk, eggshell, broiler skin, and salmon flesh) prefer a specific type and degree of coloration. Although some birds can be sexed by visual inspection of their genitalia, mating resulting in sex-associated color phenotypes is becoming more in use. The genetic markers involved affect the color of the plumage and the cloning of genes involved in pigmentation offers the prospect of deciphering the genetic control of animal pigmentation and modifying it to meet specific pigmentation needs (Castaneda *et al.,* 2005; Johnson *et al.,* 2000).

Regarding specific carotenoids, α-carotene is one of the most abundant carotenoids in the diet and can be converted to vitamin A, but with only one-half the activity as β-carotene (contains only one β-ionone ring in contrast to two for β-carotene). Other differences in biological activity have also been reported. The α-carotene is a better inhibitor toward certain growth factors (e.g., N-myc activity) than β-carotene. N-myc is in the oncogene family of growth factors. Because of its abundance, α-carotene is also an excellent biomarker of intake of fruits and vegetables (Stahl and Sies, 2005). Another carotenoid, lycopene, is a red pigment found in fruits and vegetables. In human epidemiological studies, its consumption in modest amounts is weakly associated with a reduced risk of certain cancers. Lutein and zeaxanthin are carotenoids found in green, leafy vegetables and algae and have been considered recently for potential benefits to sight and vision, particularly a decrease in the risk of cataracts. Cryptoxanthin has even been reported to decrease bone loss in ovariectomized rodents. Thus, there are a wide range of health effects, which may have nutritionally and pharmacological potential (Stahl and Sies, 2005).

B. Vitamin D

1. *Introduction*

Sir Edward Mellanby in 1921 reported the induction of rickets in dogs through dietary manipulation. He discovered that the disease could be corrected with cod liver oil. McCollum in 1922 reported the curative factor in cod liver oil was not vitamin A and appeared to be another fat-soluble substance. This substance was later identified as vitamin D, based on the ability to inactivate the vitamin A factor in cod liver by mild oxidation with the retention of antirachitic activity (Goldblith and Joslyn, 1964).

2. *Sources, Functions, and Metabolism of Vitamin* D

The D vitamins are a family of 9,10-secosteroids that differ only in the structure of the side chain attached to carbon-17. The two forms of vitamin D significant in veterinary medicine are ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3). The differences in the side chain result in the vitamins having disparate potencies with some species of animal and differing in toxicity when consumed in large amounts. These two forms of vitamin D are produced in a two-step reaction when their respective sterols ergocalciferol and 7-dehydrocholesterol absorb ultraviolet radiation and undergo photolysis, which is then followed by thermal isomerization (Fig. 23-9). Excessive ultraviolet radiation of the sterols produces inactive compounds. Under most instances, animals can synthesize sufficient quantities of cholecalciferol if they receive adequate exposure to ultraviolet light of wavelength 280 to 320 nm (Hendy and Goltzman, 2005; Hendy *et al.,* 2006; Xue *et al.,* 2005). This is particularly true when the calcium and phosphorus requirements of the animal are met. As vitamin D is produced at one site and acts at other sites including bone and intestine, it fulfills the definition of a prohormone.

In most animals, 7-dehydrocholesterol is abundant in skin, being the ultimate precursor for cholesterol, which is synthesized from acetate. However, the skin of cats and dogs and possibly other carnivores contains only small quantities of 7-dehydrocholesterol, which does not permit adequate synthesis of vitamin D. These animals are solely dependent on the diet for this vitamin. With the exception of animal products, most natural foods contain low vitamin D activity. Fish, in particular saltwater fish, such as sardines, salmon and herring, and fish liver oils contain significant to large quantities of vitamin D. Many plants also contain hydroxylated ergosterol derivatives, some of which have potent vitamin D activities (Wasserman, 1975).

Initially, it was speculated that vitamin D might serve as an enzymatic cofactor for reactions that served to maintain calcium and phosphorus (as phosphate). When isotopes of calcium became available, it was soon appreciated that there was considerable lag between the administration of vitamin D and its effect on calcium-related metabolism. This lag was shown to be due to the conversion of vitamin D to an active form. Investigations throughout the 1960s and 1970s led to the sequence of events that is outlined in Figure 23-9. For example, the kidneys were identified

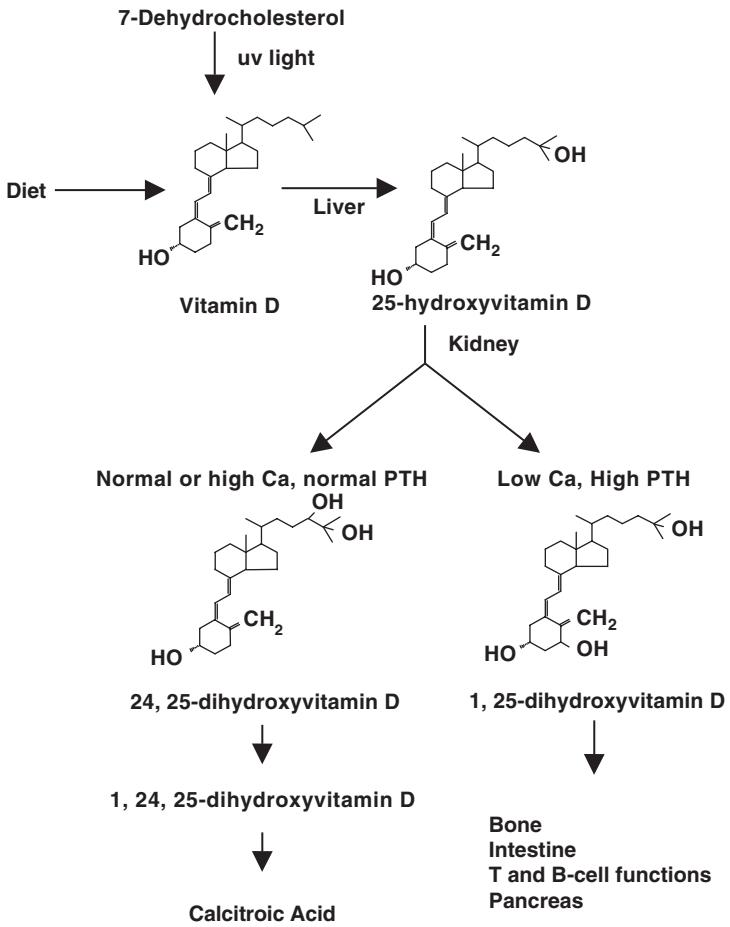

FIGURE 23-9 Vitamin D metabolism. Vitamin D is formed in the skin of most animals after exposure to ultraviolet radiation. Vitamin D can also come from the diet. It is hydroxylated in the liver to 25-hydroxyvitamin D, and in the kidney to 1,25-dihydroxyvitamin D, which is the active form. The production of 1,25-dihydroxyvitamin D is normally regulated through feedback control and the influence of parathyroid hormone (PTH) on the activities of the 1α-OH or 25-OH-vitamin D hydroxylase. A fall in plasma calcium triggers the release of PTH from the parathyroid gland, which stimulates 1α-hydroxylase production and leads to an increase in output. A separate hydroxylase, which catalyzes 24,25-$(OH)_2$-vitamin D_3 production, is activated under eucalcemic and hypercalcemic states. The major sites of action in relation to calcium homeostasis are bone and intestine. The immune system and the pancreas are also sensitive to changes in vitamin D status.

as the site of 1,25-dihydroxycholecalciferol (calcitriol or 1,25-$(OH)_2$-D_3) production. This discovery, together with the finding that 1,25-$(OH)_2$-D_3 was in the nuclei of intestinal cells, suggested that vitamin D was functioning in a manner analogous to that for steroid hormones. The production of calcitriol is normally closely regulated through feedback control and the influence of parathyroid hormone (PTH) on the activities of the 1α- and 24-OH-hydroxylases. A fall in plasma calcium triggers the release of PTH from the parathyroid gland, which stimulates 1α-hydroxylase production and leads to an increase output of calcitriol from the kidney. A separate hydroxylase, which catalyzes 24,25-$(OH)_2$-D_3 production, is activated under eucalcemic and hypercalcemic states. Whether 24,25-$(OH)_2$-D_3 serves an essential function is controversial. However, there is evidence that 24,25-$(OH)_2$-D_3 is required for some of the biological responses attributed to vitamin D (Dusso *et al.,* 2005; Norman *et al.*, 2002). Norman and coworkers (Norman *et al.*, 2002) have shown that hatchability in chickens markedly improves if both 1,25-$(OH)_2$-D_3 and 24,25-$(OH)_2$-D_3 are administered into eggs containing viable embryos from hens rendered rachitic (vitamin D deficient) before egg production. The two major sites of action of calcitriol in relation to calcium homeostasis are bone, where it acts rapidly in concert with PTH in response to hypocalcemia, and at the intestine, where the response time is longer. In addition to 1,25-$(OH)_2$-D_3 and 24,25-$(OH)_2$-D_3, more than 20 other hydroxylated intermediates and end products have been identified. Most of these are probably routed into elimination pathways, although some may be potentially functional (e.g., 1,24,25-trihydroxycholecalciferol, which has some vitamin D activity).

Calbindin, a calcium binding protein, is a major product synthesized in intestinal cells in response to calcitriol. Calbindin influences the movement of calcium across the intestinal cell. Binding of calcium to this protein allows the intracellular concentration of calcium to be elevated. The hormone forms of cholecalciferol also stimulate the production of the calcium, sodium-dependent ATPases, which reside on the luminal surface of the intestinal cell. This facilitates the vectorial movement of calcium out of the cell into circulation. In addition, evidence also indicates that 1,25-$(OH)_2$-D_3 can stimulate secondary messenger systems (e.g., protein kinase and adenyl cyclase-controlled dependent messenger systems) (Dusso *et al.,* 2005).

In addition to intestinal cells, the osteoblasts of bone are another target of vitamin D metabolites and play a major role in short-term calcium homeostasis. In addition,

1,25-$(OH)_2$-D_3 is required for normal bone mineralization during skeletal growth and remodeling of bone. Vitamin D receptors (VDR) in bone are located in osteoblasts and progenitor cells of bone and control the synthesis and secretion of a number of bone-specific proteins in osteoblasts such as osteocalcin, osteopontin, collagen, and alkaline phosphatase. The actions of vitamin D metabolites are both direct (e.g., transcriptional regulation via VDR interactions) and indirect (modulation of secondary signaling pathways, e.g., protein kinase C regulated pathways). Although osteocalcin and osteopontin synthesis have been shown to be regulated at the transcriptional level of their respective genes, for the most part vitamin D metabolites attenuate the action of polypeptide hormones, such as PTH or calcitonin, which stimulates bone resorption and accretion, respectively. Of these two processes, maintaining bone resorption is the most important, because under normal conditions, the serum calcium and phosphate ion concentrations are at levels that favor bone apposition or accretion (Dusso *et al.,* 2005).

Naturally occurring deficiencies of vitamin D occur in lambs born to ewes not supplemented prepartum with D_3 in northern latitudes during the winter months. Vitamin D deficiency also occurs in lambs reared indoors on grain diets (often barley), which do not supply an adequate amount of vitamin D_2. Deficiency is frequently manifested as skeletal limb abnormalities. As an unusual and specific example, there are also published reports of vitamin D deficiency in llama offspring (crias) in Oregon during the winter months (Judson and Feakes, 1999; Murray *et al.,* 2001; Van Saun *et al.,* 1996).

3. Other Functions of Vitamin D

Vitamin D receptors (VDR) have been found in a large number of cell types, ranging from skeletal muscle to cells important to immune and phagocytic functions (e.g., macrophages). In pancreatic β-cells, 1,25-$(OH)_2$-D_3 has also been observed to be important to normal insulin secretion. Vitamin D increases insulin release from isolated perfused pancreatic cells. Moreover, vitamin D metabolites can suppress immunoglobulin production by activated B-lymphocytes. T cells are also affected by vitamin D metabolites; 1,25-$(OH)_2$-D_3 exhibits permissive or enhancing effects on T cell suppressor activity.

A specific transport protein delivers 1,25-$(OH)_2$-D_3 and other active forms of vitamin D to targeted cells. The active form of vitamin D then interacts with receptor proteins, which in turn signals enhanced expression of selected proteins. The vitamin D-binding protein (DBP), also known as group-specific component or Gc-globulin, is a multifunctional plasma protein. DBP is expressed as a single polypeptide chain with a molecular mass of ~56 kDa and circulates in plasma at 6 to 7 M. Because of its extensive polymorphism, DBP initially was named the group-specific component of serum, later shortened to Gc-globulin. DBP is a member of the albumin, α-fetoprotein, and α-albumin/afamin gene family. In addition to functioning as a circulating vitamin D transport protein, it has been demonstrated to scavenge G-actin released at sites of necrotic cell death and prevents polymerization of actin in the circulation (Dusso *et al.,* 2005).

4. Requirements and Toxicity

Most animals require about five micrograms cholecalciferol per 1000 kcal of diet. When intake exceeds five to ten times this amount, there is a risk of toxicity, characterized by hypercalcemia and soft tissue calcification, in particularly the blood vessels of the lung, kidney, and heart. Acute doses of vitamin D (>100 times the requirement) can eventually result in a negative calcium balance, because bone resorption is accelerated. As noted, some plants (e.g., Solanum malacoxylon, Cestrum diurnun, and Trisetum flavescens) contain compounds with vitamin D activity (mostly glycosylated forms of ergocalciferols) and vitamin D intoxication can follow their ingestion. Rodenticides containing cholecalciferol as the active ingredient have resulted in toxicity in companion animals that ingest the bait directly, or carcasses of rodents that have ingested the bait. Naturally occurring toxicity has occurred in cats in Japan given a commercial diet containing large amounts of tuna viscera. Tuna viscera contains extremely high amounts of vitamin D, most of it in the liver.

5. Assessment of Vitamin D Status

Reliable assays for the measurement of vitamin D, calcidiol, and calcitriol in plasma are available. Calcitriol occurs in picomolar concentrations (normal values 40 to 150 pmol/l or 16 to 60 pg/ml) and has a half-life of about 4 to 6 h in a large (50 to 100 kg) animal. Concentrations of vitamin D in plasma after oral administration are in the nanomolar range ("normal" values range from 0 to 310 nmol/l or 0 to 120 ng/ml). Vitamin D has a half-life of 24h, so the plasma concentration reflects immediate intake, rather than overall status. In contrast, 25-OH vitamin D has a half-life of about 3 weeks, provides the useful index of vitamin D status, and is the measurement of choice. Plasma concentrations of 25-OH vitamin D of 20 to 150 nmol/l or 8 to 60 ng/ml cover the normal range for most animals. Much higher levels than these have been observed in cats given diets containing high levels of cholecalciferol without apparent deleterious effects (Committee on Animal Nutrition, 2001a, 2001b; Subcommittee on Laboratory Animal Nutrition, Board on Agriculture, National Research Council, 1995).

C. Vitamin E

1. Introduction

In the early 1920s, Herbert Evans and Kathryn Bishop observed that rats failed to reproduce when fed diets

containing rancid lard, unless they were supplemented with lettuce or whole wheat. Later it was found that germ oils, particularly wheat germ oil, contained an active principle that seemed responsible for improving reproductive performance. These early studies provided yet another function for a fat-soluble substance. By the early 1930s, it was recognized that this substance was a factor that differed from vitamin A or vitamin D. The compound was designated as vitamin E by Barnett Sure and later as α-tocopherol from the Greek word "tokos" meaning childbirth or reproduction. By 1940, a number of compounds in the tocopherol family were identified and purified. With elucidation of tocopherol structures and eventual chemical synthesis (Fig. 23-10), studies quickly followed that demonstrated embryonic failure resulted from vitamin E deficiency. Pappenheimer, Olcott, Martill, and others observed that muscle degeneration was also a common deficiency symptom and that vitamin E seemed to function as an antioxidant. Next, other signs and symptoms were identified, including oxidative diathesis and encephalomalacia in chickens. In addition to these signs, liver necrosis and hemolytic anemias were observed in vitamin E-deficient animals (Traber, 2007).

2. *Chemistry, Metabolism, and Sources*

The principal sources of tocopherols are plant oils. Tocopherols are unique because they act primarily at a chemical level as antioxidants, although other possible roles in cell signaling have been described. Primarily, vitamin E protects unsaturated fatty acids found in the phospholipids of cell membranes. The quinone moiety of tocopherols is capable of quenching free radicals, such as the free radical of hydrogen ($H^{\bullet}$), superoxide radicals ($O_2^{\bullet -}$), hydroxyl radicals ($OH^{\bullet}$), and other lipid-derived radical species ($LOO^{\bullet}$). Vitamin E in the course of its action is sacrificed in acting as a free-radical scavenger. Vitamin E is very reactive and is in effect sacrificed thus inhibiting the formation of lipid-derived oxidation products (Traber, 2007).

Cell membranes contain vitamin E at a concentration of approximately 1mg per 5 to 10g of lipid membrane; a concentration sufficient to retard membrane lipid oxidation. Membrane lipids are constantly engaged in the process of turnover and repair. By prolonging the initiation time before a free-radical chain reactions occurs, vitamin E gives cells time to replace damaged membrane lipids through the process of normal cell turnover.

With regard to absorption and transport, tocopherols first must partition into the intestinal micelles and are absorbed with other dietary lipids. Following absorption, vitamin E is transferred into the lymph associated with chylomicrons and intestinally derived VLDL particles, similar to other fat-soluble vitamins. Vitamin E is cleared from chylomicrons and VLDL by the lung and the liver. From the liver, most of the vitamin E is found in association with VLDL and LDL particles. For example, there is preference for the α-tocopherol form of vitamin E. More specifically, tocopherol-binding proteins favor the retention of the most potent vitamin E homologue, RRR-α-tocopherol. The LDL particles contain the highest concentration of vitamin E. This is important in that high concentrations of vitamin E protect the LDL particle from oxidation. It is currently proposed that oxidized LDL particles are important mediators of vascular disease.

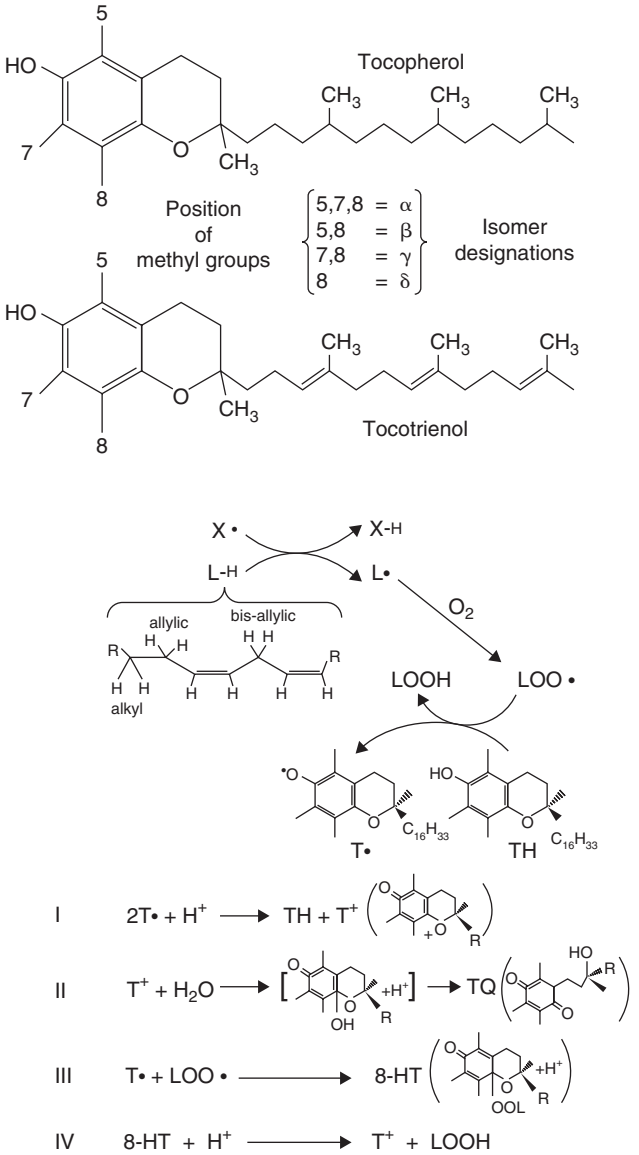

FIGURE 23-10 Vitamin E metabolism. The two principal forms of vitamin E are shown, tocopherol and tocotrienol. Methyl groups are found at the 5, 6, and/or 8 position, which may modulate antioxidant potency. Tocopherol is the most potent of the various forms of vitamin E in biological systems. Some of the mechanisms involving free-radical quenching are also shown. Vitamin E is particularly important in quenching free radicals that are generated from allelic and bis allelic nonconjugated bonds found in membrane polyunsaturated lipids. Resolutions of the vitamin radical and other intermediates are shown in steps I and IV,

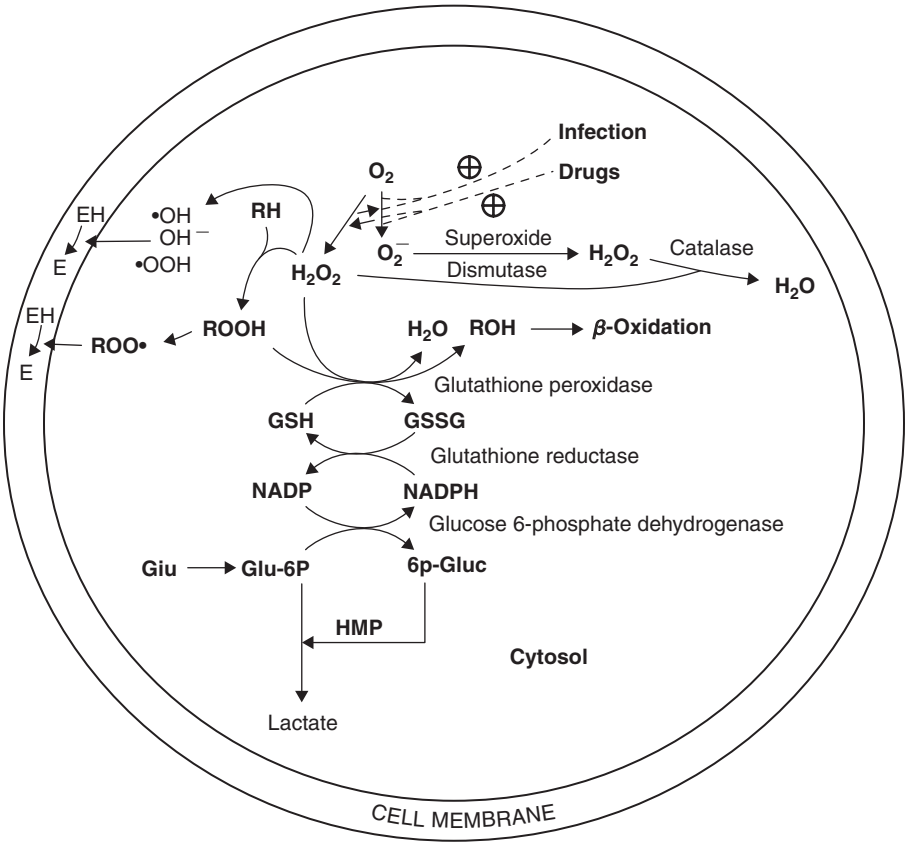

FIGURE 23-11 Vitamin E and antioxidant defense. A number of factors can influence the need for tocopherols in cells and subsequently their utilization at a cellular level. Vitamin E acts as the last line of defense for lipid oxidation, primarily residing in lipid membranes. Enzymes such as superoxide dismutases (catalyzes superoxide radicals to hydrogen peroxide), catalase (catalyzes hydrogen peroxide to water and oxygen), glutathione peroxidase (catalyzes lipid and hydrogen peroxides to water or hydroxy-fatty acids), and related systems for oxidant defense (generation of reductants, such as NADPH and reduced glutathione) also aid in providing additional oxidant defense. Without intracellular control of reactive oxygen species, such as hydrogen peroxide or hydroxide radicals, polyunsaturated lipids are targets for oxidation.

Vitamin E enters cells by processes similar to those for LDL uptake (Aguie, 1995; Traber *et al.,* 1993, 1994a, 1994b, 1994c). LDL membrane receptors, through receptor-mediated endocytosis, appear responsible for vitamin E uptake by scavenger receptor B type I and LDL receptors. Efflux from cells is less well understood but appears to be dependent on transporters in the ABCA1 transporter family (ATP-requiring transporters associated with cholesterol transport). Once in cells, vitamin E is incorporated into liquid membranes. About 40% of vitamin E is found in nuclear membranes; the remaining 60% is divided between lysosomal, mitochondrial and the outer cell wall membranes (Traber, 2007).

3. *Requirements and Functions*

The nutritional status of vitamin E is often difficult to assess. A number of factors can influence the concentration of tocopherols in cells. As noted, vitamin E acts as the last line of defense for lipid oxidation, primarily residing in lipid membranes. Consequently, enzymes such as superoxide dismutases, catalase, glutathione peroxidase, and related systems for oxidant defense can moderate the absolute need for vitamin E (Fig. 23-11). Further high dietary intakes of polyunsaturated dietary fats may increase the vitamin E requirement, because of their eventual deposition in cell membranes. Naturally occurring deficiencies of vitamin E occur in cats given human-grade canned tuna (which is not fortified with vitamin E). Deficiencies can also occur in cats given fish-based diets unless they are highly fortified with vitamin E. Proper handling of fish is essential to prevent the PUFAs in fish oil from readily oxidizing following their harvesting and processing. The requirement of most animals is on the order of 25 to 50 mg per kilogram dry diet or 4 to 8 mg per 1000 kcal or 4.2 MJ.

At the cellular level, vitamin E deficiency promotes increased lipid peroxidation, making cells more vulnerable to oxidative injury. Fortunately clinical manifestations of chronic vitamin E deficiency are rare and are usually seen only when fat malabsorption is present. In these cases, the neuromuscular, vascular, and reproductive systems may be affected. Vitamin E deficiency signs include

immunodeficiency, dermatosis, anorexia, myopathy, steatitis, focal interstitial, focal myositis of skeletal muscle, and periportal mononuclear infiltration in the liver. Signs of vitamin E deficiency are mostly attributed to membrane dysfunction as a result of the oxidative degradation of polyunsaturated membrane phospholipids and disruption of other critical cellular processes.

Vitamin E can also influence two major signal transduction pathways centered on protein kinase C and phosphatidylinositol 3-kinase (Singh and Jialal, 2005). Changes in the activity of these key kinases are associated with changes in cell proliferation, platelet aggregation, and NADPH-oxidase activation. Vitamin E status also influences genes that are involved in the uptake and degradation of tocopherols and antioxidant defense (e.g., α-tocopherol transfer protein, cytochrome P450-3A, γ-glutamyl-cysteine synthetase heavy subunit, and glutathione-S-transferase), genes that are involved in the modulation of extracellular matrix proteins (e.g., collagen-α-1 chains and connective tissue growth factor), genes that are connected to cell adhesion and inflammation (ICAM-1 integrins and TGF-β), and genes in the steroid superfamily (e.g., PPAR-γ) (Azzi *et al.,* 2004).

4. Evaluation of Vitamin E Status

Tocopherols in biological tissues can be measured by HPLC. Although the α-tocopherol can readily be separated from other tocopherols, the separation of the β- and γ-isomers is difficult. For nutritional assessment of vitamin E, the current indices are based on changes in total tocopherol concentrations in plasma and serum. Measurement of tocopherol concentration in erythrocytes may be an even better indicator for tissue vitamin E than plasma or serum levels. The platelet concentration of vitamin E is also a sensitive measure of vitamin E intake. Moreover, in the experimental setting the measurement of adipose levels of tocopherols seems to be a reliable index for assessing long-term vitamin E status. As in other cells, vitamin E partitions primarily into the membrane lipid compartments. Thus, the concentration of vitamin E per adipose tissue mass may even increase when there is loss of nonmembrane stored triglycerides. As plasma tocopherol concentration is affected by lipid concentration, an α-tocopherol/total lipid ratio of 0.6 to 0.8 mg/g of total lipids has been suggested as indicating adequate nutritional status. Functional tests such as the erythrocyte hemolysis in the presence of 2% peroxide have also been used to indicate status (Traber, 2007).

D. Vitamin K

1. Introduction

In 1929, Henrik Dam reported what was thought first to be an essential role for cholesterol in the diet of chickens. He noted that chicks fed diets that had been extracted with nonpolar solvents to remove sterols developed subdural and muscular hemorrhages and that blood seemed to clot at a slower rate. Edward Doisy in the United States did much of the work that led to the discovery of the structure and chemical nature of vitamin K. Dam and Doisy shared the 1943 Nobel Prize for medicine for this work. For several decades, the vitamin K-deficient chick model was the only method of quantitation of vitamin K in various foods: the chicks were made vitamin K deficient and subsequently fed diets with known amounts of vitamin K-containing food. The extent to which blood coagulation was restored by the diet was taken as a measure for its vitamin K content. As this work progressed, it was soon demonstrated that hemorrhagic disease in chicks could be reversed by extracts of alfalfa. In the 1940s, it became clear that substances synthesized by bacteria also could reverse hemorrhagic symptoms. In addition, it was discovered that compounds in spoiled clover and grasses seemed to cause hemorrhagic disorders in animals and serve as antagonist to vitamin K (Fig. 23-12).

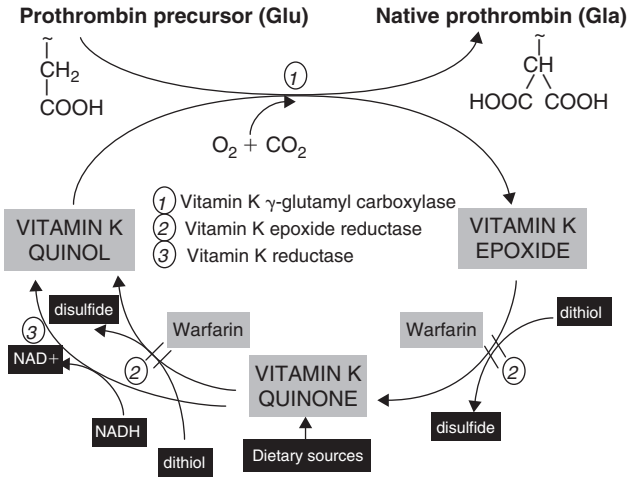

FIGURE 23-12 Major components in vitamins K's role in γ-carboxyglutamyl residue formation.

2. Function and Metabolism

With the isolation and identification of vitamin K, work toward an understanding of mechanisms proceeded, although not without controversy. At first there was the problem of reconciling how compounds present in the sweet clover acted as vitamin K antagonists. A number of questions were also raised regarding the structural requirements for vitamin K activity (Stafford, 2005; Suttie, 2007).

Now it is appreciated that a number of compounds in the 1,4-naphaquinone series possess vitamin K activity. For example, even relatively simple compounds, such as menadione, possess vitamin K activity. An active phylloquinone can be synthesized from menadione when combined with isoprenoids from the cholesterol synthesis pathway. Dietary

phylloquinones are transported to the liver by chylomicrons and intestinal VLDL particles and from liver by VLDL and LDL. From studies of vitamin K clearance, it was appreciated that the total pool of vitamin K in the body is replaced rapidly, within hours to days in contrast to the slower turnover of the other fat-soluble vitamins (weeks to months).

The mechanism of action for vitamin K became much clearer after it was demonstrated that the formation of -carboxyglutamic acid residues (GLA) in thrombin and other proteinases associated with the blood-clotting cascade was vitamin K dependent. The formation of GLA residues is a key in that they serve as calcium-binding sites in the proforms of proteinases associated with blood coagulation. Calcium binding is a requisite for their eventual activation. In this regard, vitamin K serves as cofactor for microsomal carboxylases, which are responsible for GLA formation. The vitamin K-dependent carboxylase utilizes oxygen and bicarbonate as substrates. The reaction only occurs if glutamic acid is a part of a polypeptide with the correct sequence for specificity. Only the reduced form of vitamin K serves as a cofactor, which led to an appreciation that a reductase system was necessary for vitamin K regeneration and that one of the intermediate forms was a vitamin K epoxide. As this pathway was resolved, it next was apparent that many of the vitamin K antagonists functioned as inhibitors of reductases important for vitamin K generation (Suttie, 2007). The rate of carboxylation is mainly controlled by the level of reduced vitamin K available for the reactions, whereas the dissociation rate constant depends on both the propeptide and the Gla domain of the substrate. In addition, there are allosteric effects that increase the rate of dissociation of the fully carboxylated substrates. Carboxylation requires the abstraction of a proton from the 4-carbon of glutamate by reduced vitamin K and results in the conversion of vitamin K to vitamin K epoxide. The vitamin K epoxide must be recycled to vitamin K before it can be reused, a reaction catalyzed by the enzyme vitamin K epoxide reductase.

Specifically, vitamin K provides important control of blood coagulation by regulating the activities of factor VIIIa (FVIIIa) and factor Va (FVa), cofactors in the activation of factor X and prothrombin, respectively. The system comprises membrane-bound and circulating proteins that assemble into multimolecular complexes on cell surfaces. Vitamin K-dependent protein C, the key component of the system, circulates in blood as zymogen to an anticoagulant serine protease. It is activated on the surface of endothelial cells by thrombin bound to the membrane protein thrombomodulin. An endothelial protein C receptor further stimulates the protein C activation. Moreover, activated protein C together with another protein, cofactor protein S, can also slow coagulation by degrading FVIIIa and FVa on the surface of negatively charged phospholipid membranes providing a level of reversible control (Suttie, 2007).

GLA residues are also found in bone proteins. The GLA-containing proteins in bone (osteocalcins) appear to be involved in the regulation of new bone growth and formation. The presence of GLA protein in bone helps to explain why administration of the vitamin K antagonist at levels that cause hemorrhagic diseases also may result in bone defects, particularly in neonates. The mineralization disorders are characterized by complete fusion of the proximal tibia growth plate and cessation of longitudinal bone growth (Suttie, 2007).

3. *Nutritional Requirements*

The establishment of the dietary requirement for many animals has been difficult, in part because of (1) the short half-life of vitamin K, (2) the fact that large amounts of vitamin K may be synthesized by intestinal bacteria, and (3) the extent to which different animal species practice coprophagy. Birds tend to have relatively high requirements for vitamin K; thus, chickens are often used as experimental animals in vitamin K studies (Stafford, 2005; Suttie, 2007). Recent work suggests that the vitamin K requirement depends on the relative content of vitamin K epoxide reductase activity. A low level of epoxide reductase activity can increase the requirement for vitamin K. Ruminal microorganisms synthesize large amounts of vitamin K; thus, ruminants do not need an external source for this reason.

Assessments of nutritional requirements suggest that small animals should obtain approximately 500 to 1000 g of phylloquinone per kilogram diet. Oxidized squalene and high intakes of vitamin E may act as vitamin K antagonists. Insufficient vitamin K can also occur with antibiotic treatment, treatment with coccidiostatic drugs, or long-term parenteral hyperalimentation without vitamin K supplements. Poultry and swine diets are regularly supplemented with menadione, but the need to supplement the diet of other species is questionable. Few hazards have been attributed to long-term ingestion of vitamin K in amounts of 1 to 10mg per kilogram diet of phylloquinone. However, menadione in amounts corresponding to 10 to 100mg per kilogram of diet may act as a prooxidant, and high dietary concentrations produce hemolysis. Phylloquinone (vitamin K_1) rather than menadione should be used parenterally to treat animals that have ingested warfarin or other anticoagulants. Menadione being water soluble, at high concentrations it can promote hemolysis. Like many quinones it may act as a prooxidant and initiate free-radical formation.

IV. WATER-SOLUBLE VITAMINS

We have chosen to organize the discussion of water-soluble vitamins based on physiological function. Most vitamins serve eventually as enzymatic cofactors. For example, niacin, riboflavin, and ascorbic acid serve primarily as redox cofactors. The roles of thiamin, pyridoxine (vitamin B_6), and pantothenic acid (as a component of coenzyme A)

are distinguished because of their importance to carbohydrate, amino acid, and acyl and acetyl transport, respectively. Biotin, folic acid, and vitamin B_{12} (cobalamin) will be discussed in relationship to their roles in single carbon metabolism. Several vitamin-like compounds will also be described. These compounds are products derived from carbohydrate, amino acid, or fatty acid metabolic pathways and primarily perform specialized transport functions or are associated with signal transduction mediators in cells. A nutritional case can be made that in some animal species, these compounds have important "conditional" requirements, and developmental periods may be identified in which a dietary source is required to maintain balance.

A. Vitamins Important to Redox: Ascorbic Acid, Niacin, and Riboflavin

1. *Ascorbic Acid*

a. Introduction

Ascorbic acid functions primarily as a cofactor for microsomal monooxygenases (hydroxylases) and oxidases. In most animals, ascorbic acid is synthesized from glucose in the liver or kidney (Fig. 23-13). In some animals, however, a deficiency of gulonolactone oxidase, a last step in ascorbic acid synthesis, results in the need for a dietary source. The enzymes for ascorbic acid production in the cold-blooded vertebrates (fishes, amphibians, and reptiles) are located in the kidneys. Present-day birds, whose ancestors appeared about the same time as the mammals, have a kidney-liver transition. The older order of present-day birds, such as the ducks, pigeons, and hawks, synthesize ascorbic acid in their kidneys, whereas in the more recent order they produce ascorbic acid both in their kidneys and livers (e.g., of the perching and song birds). Mammals produce ascorbic acid in the liver. Of the mammals that do not produce ascorbic acid (e.g., primates and guinea pigs), so-called pseudogenes for L-gulonolactone oxidase exist. The 164-nucleotide sequence of exon X of this gene contains nucleotide substitutions throughout its sequence with a single nucleotide deletion, a typical example of a pseudogene.

b. Chemistry

Ascorbic acid is of general importance as an antioxidant, because of its high reducing potential. However, under some conditions ascorbic acid can also act as a prooxidant. Ascorbic acid is a 2,3-enediol-L-gulonic acid. Both of the hydrogens of the enediol group can dissociate, which

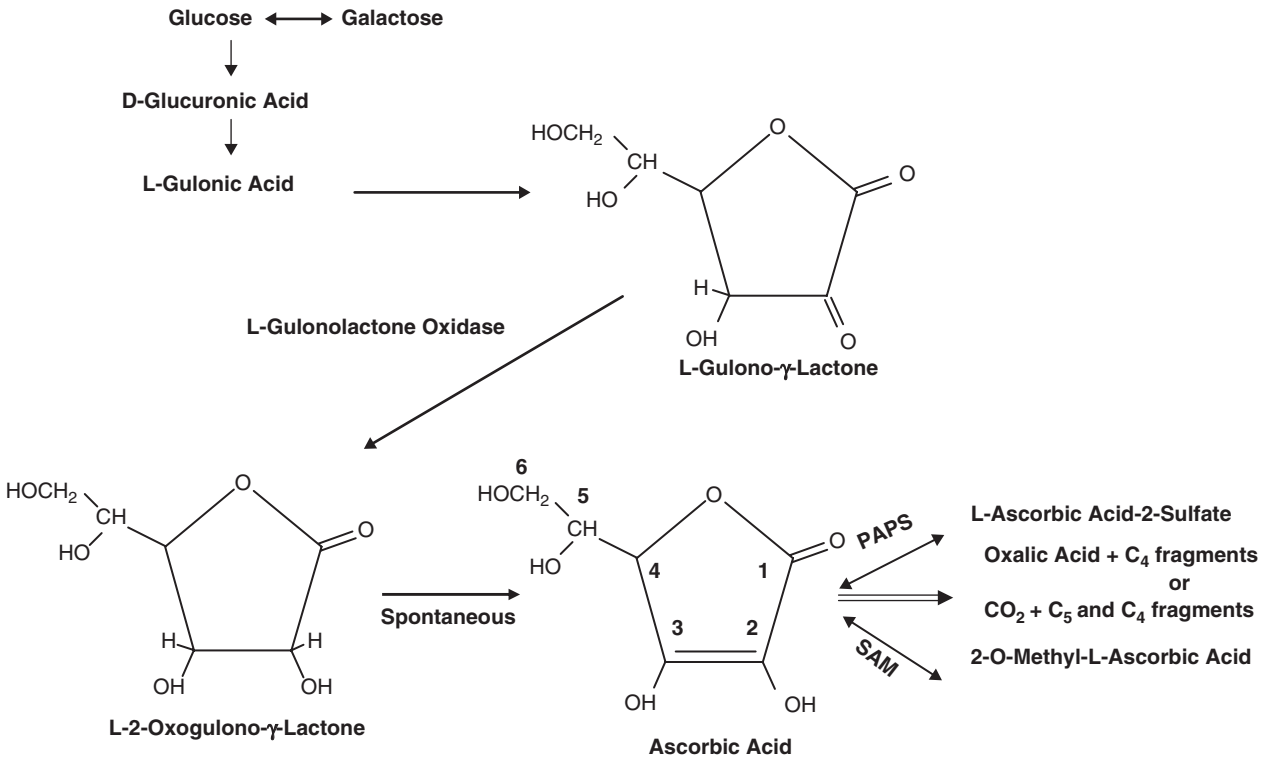

FIGURE 23-13 Ascorbic acid synthesis. The direct oxidative pathway for glucose is utilized in those animals that make ascorbic acid. Major metabolites are the 2-sulfate and 2-methyl derivatives of ascorbic acid, which require phosphoadenosyl phosphosulfate (PAPS) and S-adenosyl methionine (SAM) as sulfate and methyl donors, respectively. When ascorbate is in excess, catabolic enzymes can effectively decarboxylase or cleave ascorbic acid (between C-2 and C-3).

results in the strong acidity of ascorbic acid. Enediols are excellent reducing agents; the reaction usually occurs in a stepwise fashion with a semiquinone intermediate (Johnston *et al.,* 2007).

For ascorbic acid, this intermediate with monodehydroascorbic acid disproportionates to ascorbic acid, and dehydroascorbic acid. Dehydroascorbic acid is not as hydrophilic as ascorbic acid, because it exists in a deprotonated form. As such, dehydro of ascorbic acid can move easily across cell membranes. The dehydro form, however, is easily cleaved by alkali (e.g., to oxalic acid and threonic acid).

c. Absorption, Tissue Distribution, and Metabolic Functions

Dietary ascorbic acid is absorbed from the duodenum and proximal jejunum. Measurable amounts can also cross the membranes of the mouth and gastric mucosa. Although some controversy exists regarding the relationship between ascorbic acid intake and the intestinal absorption of ascorbic acid, most careful studies indicate that within the physiological ranges of intake (20 to 400 mg per kilogram of dry food), 80% to 90% of the vitamin may be absorbed.

With respect to tissue distribution, the highest concentration of ascorbic acid is found in the adrenal and pituitary glands followed by the liver, thymus, brain, and pancreas. In diabetic animals, the ascorbic acid content of tissue is often depressed, which suggests that factors responding to hyperglycemic states can compromise ascorbic acid status. This may be because dehydroascorbic acid uptake is facilitated by hexose transporters (Johnston *et al.,* 2007; Said, 2004). Uptake of reduced ascorbic acid involves a specialized Na+-dependent, carrier-mediated system; egress of ascorbic acid from enterocytes also utilizes a Na+-dependent carrier system. Regarding cellular retention, ascorbic acid is maintained in cells by several mechanisms. Ascorbate reductases maintain L-ascorbic acid in the reduced form, which prevents passive leakage from the cell as dehydroascorbic acid. Significant amounts of ascorbic acid, particularly in fish, may also exist as the 2-sulfate derivative. In rats, about 5% of a labeled dose of ascorbic acid is recovered in urine as 2-O-methyl ascorbic acid. Cellular modification of ascorbic acid is important for compartmentalization or modulation of functional ascorbic acid levels (Johnston *et al.,* 2007; Wilson 2005).

In the neonate, glutathione is important to ascorbate recycling and regeneration (Fig. 23-14). An argument can be made for a dietary need for ascorbic acid in some neonates of species not normally showing a requirement for ascorbate. For example, the levels of glutathione are relatively low in neonate rat and mouse tissue. Ascorbate is oxidized to dehydroascorbic acid, which is easily catabolized, thus the need for continual replacement.

As a cellular reducing agent, ascorbic acid plays a number of important roles. It serves as a cofactor for mixed-function oxidations that result in the incorporation

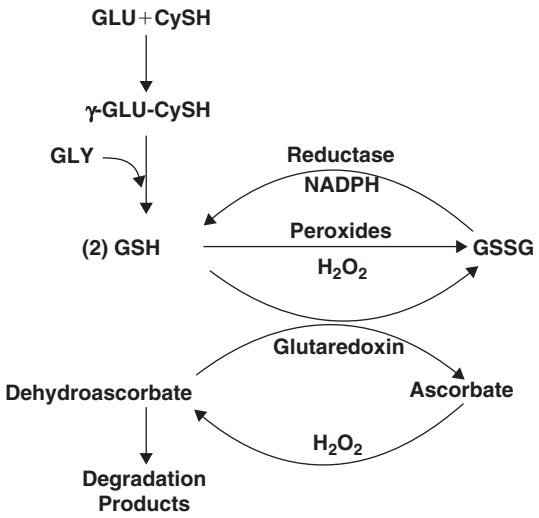

FIGURE 23-14 Interaction between ascorbic acid and glutathione. The most important reductant in the cell is glutathione L-(-glutamyl-L-cysteine-glycine, GSH), which is synthesized by a two-step reaction involving L-glutamyl cysteine synthetase and GSH synthetase. In addition to reducing equivalents derived from the pentose shunt or hexose monophosphate shunt pathway via NADPH, reduced ascorbic acid can transfer reducing equivalents to oxidized glutathione (GSSG) catalyzed by glutaredoxin.

of molecular oxygen into various substrates. Examples include the hydroxylation of proline in collagen, elastin, C1q complement, and acetylcholine esterase. Hydroxylases (monooxygenases) and some P450-dependent hydroxylases that carry out the hydroxylation of steroids, drugs, and other xenobiotics utilize ascorbic acid as a reductant. Moreover, the hydroxylation steps in the biosynthesis of carnitine, hydroxylation of tyrosine in the formation of catecholamines, and hydroxylation of proline in collagen represent other important and essential catalytic functions of ascorbic acid. Most of the enzymes involved in these processes are metal-requiring enzymes in which ascorbic acid's role is to maintain the metal (usually Cu or Fe) in its reduced state (Johnston *et al.,* 2007).

d. Requirements and Toxicity

Ascorbate is synthesized by most animals with the exception of primates, guinea pigs, some snakes, fruit-eating bats, birds (passerines), and salmonid fish. For these animals, impaired collagen synthesis is a principal feature of ascorbate deficiency. Scurvy is characterized by poor wound healing, impaired bone formation in higher animals, and kyphosis and scoliosis in fish (Committee on Animal Nutrition, 2001a, 2001b; Subcommittee on Laboratory Animal Nutrition, Board on Agriculture, National Research Council, 1995). Connective tissue lesions are primarily a result of underhydroxylated collagen (at specific prolyl and lysyl residues) being abnormally susceptible to degradation. In addition, the inability to deal with metabolic stress requiring normal adrenal gland function and the reduced

ability to metabolize fatty acids (carnitine synthesis) contribute signs of scurvy.

To maintain these functions, most animals generate 10 to 60 mg of ascorbic acid per 1000 kcal utilized in the course of normal metabolism. Similarly, requirements for ascorbic acid, when required in the diet, range from 50 to 250 mg per kilogram of diet (i.e., about 50 mgs per 1000 kcal), which correspond to the amount in mammalian milk (Rucker and Steinberg, 2002). It is noteworthy that when fed in excess of metabolic need, tissue levels of ascorbic acid are homeostatically maintained. Homeostasis occurs by the induction of ascorbic acid decarboxylases and cleavage enzymatic activity, which results in CO_2 plus ribulose or oxalic acid plus threonic acid. These conversions are probably to protect cells against nonspecific and oxidative reactions resulting from excesses of reduced metals, such as iron and copper (Johnston *et al.,* 2007).

2. N*iacin*

a. Introduction

Through the elegant work of Goldberger and others, pellagra was identified as a nutritional deficiency in the 1900s. Commonly known as the "disease of the four D's—dermatitis, diarrhea, dementia, and death"—it was first recognized in Spain and Italy as a specific disease in the late 1700s, as *mal de la* Rosa and pellagra, respectively, from *pelle* (skin) and *agra* (rough). In 1810, another Italian, Giovanni Battista Marzari, proposed that the disease was caused by overreliance on corn as the main dietary staple. Indeed, there were two schools of thought: the *Zeists*, who supported the corn theory, and the *anti-Zeists*, who discredited it (Goldblith and Joslyn, 1964). Niacin deficiency comes about when foodstuffs (e.g., corn) are consumed that are low in bioavailable niacin and the amino acid tryptophan. Tryptophan is important to niacin status (Bender, 1996), because niacin can be generated upon tryptophan degradation (Fig. 23-15). Although niacin deficiency is observed infrequently in free-ranging animals, it nevertheless is a good example of a vitamin-related disease that occurs from consuming a monotonous diet. In this regard, dogs played an important role as models for pellagra, as they exhibited a condition called "black tongue," when given a diet similar to that which produces pellagra in humans. Black tongue is characterized by initial reddening of the mucosa of the lips and mouth that progresses to necrosis of the mucosa accompanied by ropy saliva, a fetid odor, and diarrhea. In 1937, Elvehjem discovered that dogs with "black tongue" responded dramatically both to nicotinic acid and to nicotinamide, which was isolated from liver extracts that had previously been found to have relatively high antipellagra activity. The acid and the amide were tested with human pellagrins and gave relief of the irritation of the mucous membrane of the mouth and digestive tract and the disappearance of acute mental symptoms within a few days (Bender, 1996; Kirkland, 2007).

With regard to pellagra and corn, niacin is not highly bioavailable unless the corn is finely ground or processed under alkaline conditions (e.g., ground in the presence of limestone). In human populations, this was not the practice in Western Europe and the southern United States, although it was the practice in Central and South America. Normally, niacin is derived from food by hydrolysis of nicotinamide adenosyl dinucleotide (NAD) and nicotinamide adenosyl phosphodinucleotide (NADP) to niacin by the action of pancreatic or intestinal nucleosides and phosphatases. Facilitating NAD and NADP hydrolysis by alkali treatment of corn or increasing surface area is important to increasing the bioavailability of niacin. Given that most animals consume diets that contain adequate tryptophan, and available NAD and NADP, niacin deficiency is usually not a problem. An exception to this generalization is cats. In this species, the degradation of tryptophan does not proceed along a pathway that leads to nicotinic acid, even though all the enzymes for the pathway are present. High activity of the enzyme picolinic carboxylase, at a branch point in the pathway, results in diversion from eventual NAD production. For cats and probably all other felids, available niacin is an obligatory dietary factor.

b. Functions

NAD and its phosphorylated form, NADP, are two coenzymes derived from niacin (Fig. 23-15). Both contain an unsubstituted pyridine 3-carboxamide that is essential to function in redox reactions with a chemical potential near -0.32 V. Virtually all cells are capable of converting niacin to NAD (Kirkland, 2007). Most enzymes requiring NAD are oxidoreductases (dehydrogenases) that aid the catalysis of a diverse array of reactions, such as the conversion of alcohols and polyols to aldehydes or ketones. The most common mechanisms involve the stereospecific abstraction of a hydride ion (H:) from the substrate with subsequent transfer. Further, cells utilize NAD in catabolic pathways, whereas NADP is utilized in synthetic pathways. An additional and equally important function of NAD is its role as a substrate in poly- and monoribosylation reactions. Mono- and polyribosylations are important to many cellular regulatory functions. Enzymes that undergo monoribosylation can become activated or deactivated upon addition of ADP-ribose. Somewhat analogous to phosphorylation, ribosylation represents another example of covalent modification as a regulatory control.

In the nuclei of cells, polyribosylation of histone precedes the normal process of DNA repair (Hageman and Stierum, 2001). This later phenomenon is important in that pellagra-related lesions often involve the skin, following exposure to UV light. UV damage of epidermal cell DNA is an underlying mechanism for the dark pigmented lesions associated with pellagra. Lack of niacin and therefore NAD is thought to be a contributing factor to the skin lesions because of the inability of cells to carry out polyribosylation reactions. It is this nonredox function of NAD

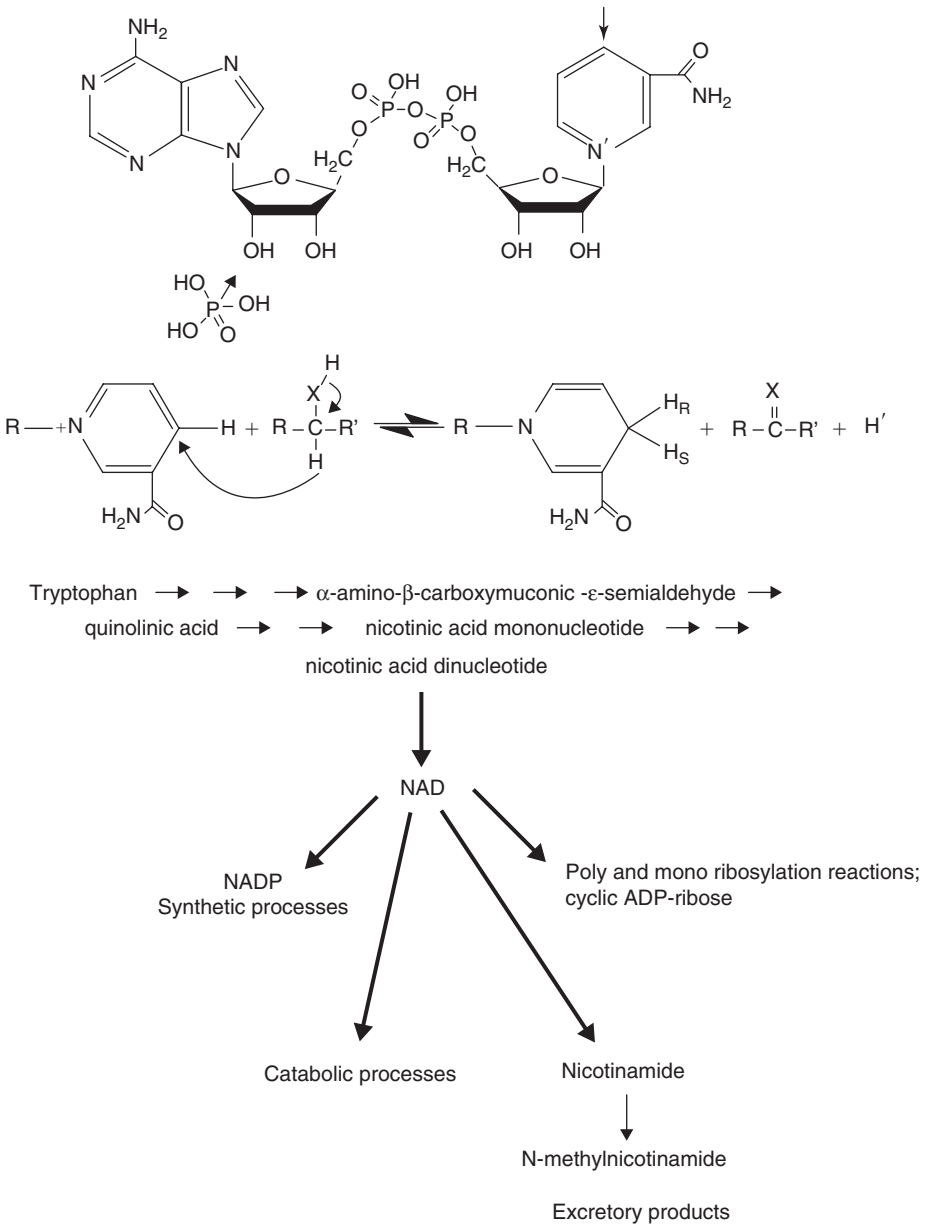

FIGURE 23-15 Niacin and NAD(P). Niacin can be derived from tryptophan degradation or the diet. In cells, niacin is eventually converted to NAD(P). Most enzymes requiring NAD are oxidoreductases (dehydrogenases). The most common mechanisms involve the stereospecific abstraction of a hydride ion (H:) from the substrate with subsequent transfer. NAD is usually associated with catabolic pathways, whereas NADP is utilized in synthetic pathways. An additional and equally important function of NAD is its role as a substrate in poly- and monoribosylation reactions. Mono- and polyribosylations are important to many cellular regulatory functions (e.g., DNA repair); cyclic-ADP ribose is important in calcium-related cell signaling pathways.

that accounts for the rapid turnover of NAD in cells. Some estimates suggest that as much as 40% to 60% of the NAD in cells is involved in mono- or polyribosylation reactions.

NAD is also the substrate for cyclic ADP-ribose (cADPR), which is a Ca2+ mobilizing second messenger found in various cell types, tissues, and organisms. Receptor-mediated formation of cADPR involves ADP-ribosyl cyclases located within the cytosol or in internal membranes of cells. cADPR activates intracellular Ca2+ release (Jacobson *et al.,* 1995).

c. Requirements and Pharmacology

Niacin is needed in amounts corresponding to 10 to 25mg/kg of diet. Depending on species, the conversion of tryptophan to niacin produces about 1mg of niacin for every 60mg of tryptophan degraded. Niacin (nicotinamide) is relatively nontoxic, although nicotinic acid can cause vasodilatation when consumed in excess of 100mg per kilogram of diet. Consequently, there are a number of therapeutic uses for pharmacological doses of niacin-derived compounds, when increased blood flow is desirable.

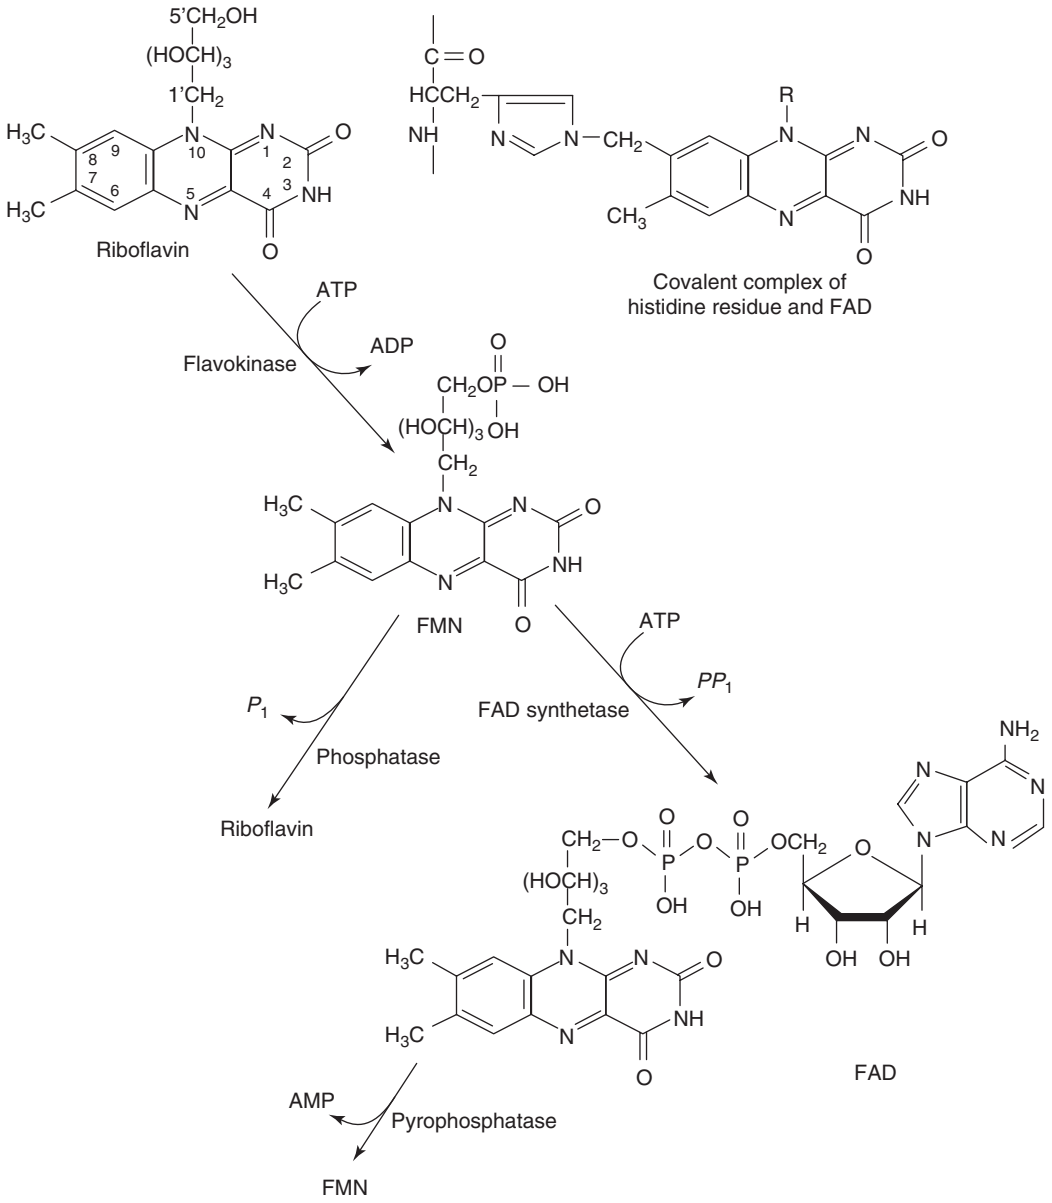

FIGURE 23-16 Riboflavin. The major forms of riboflavin found in cells are flavin adenine mononucleotide (FMN) and flavin dinucleotide (FAD). In some enzymes, riboflavin may also be covalently bound to the enzymes that it serves, for example, succinic dehydrogenase.

d. Determination of Niacin Status

A nicotinamide loading test has been used to determine niacin status of patients. The patient is given an oral dose of nicotinamide, and the urinary excretion products, which are species dependent, are measured. For humans, monkeys, dogs, rats, and swine largely methylated products are produced. Analytical approaches in measuring nicotinic acid and niacin now involve hydrophilic interaction chromatography or capillary electrophoresis using UV, florescence, or mass spectrophotometry for detection (Kirkland, 2007).

3. *Riboflavin*

a. Introduction

Riboflavin was one of the first of the B vitamins identified. Riboflavin is present in tissue and cells as flavin adenine dinucleotide (FAD) and flavin adenine mononucleotide (FMN). FAD and FMN are cofactors in aerobic processes, usually as cofactors for oxidases, although FAD also can function in an anaerobic environment as a dehydrogenase cofactor. Many flavin-containing proteins are also found in the smooth endoplasmic reticulum of cells associated with microsomal enzymes (Fig. 23-16).

b. Functions

Enzymes containing flavins are distinguished, because they are capable of transferring hydrogen directly to molecular oxygen with the formation of hydrogen peroxide as a product (Powers, 2003; Rivlin, 2007). Oxygen prefers to participate in reactions involving one electron, one hydrogen transfers proceeding in a stepwise manner. The chemical characteristics of riboflavin are ideally suited for such reactions. Thus, with the addition of riboflavin containing cofactors to biological systems, it is possible for the system to carry out a range of redox reactions utilizing mechanisms that involve ion hydride transfers (via NAD or NADP), radical hydrogen ion transfers (via FMN, FAD) or ascorbic acid, and one electron plus one proton transfer (via FMN or FAD).

c. Metabolism and Requirements

FMN and FAD in foods are hydrolyzed in the upper gut to free riboflavin. Riboflavin is absorbed by active processes and is transported in blood to target tissues in association with albumin (Said, 2004). Once in cells, riboflavin is phosphorylated to FMN. FMN is also released from cells and may bind to albumin for reutilization by other cells. Active transfer mechanisms are responsible for the uptake of FMN. In this regard certain drugs (e.g., penicillin and theophylline) can displace riboflavin from binding proteins that are important to its transport. Urine is the major route of excretion for riboflavin, although some FAD is excreted in bile (Rivlin, 2007).

Requirements for riboflavin are lower than those for niacin or ascorbic acid. This is primarily because riboflavin is tightly associated with the oxidases and dehydrogenases it serves as cofactor; thus, riboflavin turnover is dependent on the turnover of the proteins to which it is associated. In some cases, FMN is even covalently bound (e.g., as in succinic dehydrogenase). Because of the high affinity with the enzymes that it serves as a cofactor, in most animals the half-life of riboflavin is several weeks. Two to six milligrams of riboflavin per kilogram of diet is required (Committee on Animal Nutrition, 2001a, 2001b; Rivlin, 2007; Subcommittee on Laboratory Animal Nutrition, Board on Agriculture, National Research Council, 1995).

When signs of riboflavin deficiency are observed they usually include lesions of the oral cavity, around the periphery of the lips, and particularly the angle of the mouth (cheilosis). There can also be inflammation of the tongue (glossitis) and accompanying seborrheic dermatitis. In severe cases of riboflavin deficiency, the filiform papillae of the tongue are lost and the tongue changes color from its usual pink to magenta. Anemia and increased vascularization of the eye are other common signs of riboflavin deficiency in some animals. Ariboflavinosis is the clinical name for riboflavin deficiency. Riboflavin deficiency is rarely found in isolation; it occurs frequently in combination with deficiencies of other water-soluble vitamins. In addition to anemia, severe riboflavin deficiency may result in decreased conversion of vitamin B_6 to its coenzyme form and decreased conversion of tryptophan to niacin.

Lean meats, eggs, legumes, nuts, green leafy vegetables, dairy products, and milk provide riboflavin in the diet. Because riboflavin is destroyed by exposure to light, foods with riboflavin should not be stored in glass containers that are exposed to light. Moreover, as grains are a poor source of riboflavin, deficiencies frequently occur in animals given diets based on cereal grains. One of the more striking and specific signs of riboflavin deficiency in birds is "curled toe syndrome." Curled toe paralysis has been of economic significance to the broiler industry. In young animals, growth failure, lost of feathers, or alopecia may be observed (Rivlin, 2007).

d. Determination of Riboflavin Status

The erythrocyte glutathione reductase activity coefficient (EGRAC) is the preferred clinical test of riboflavin adequacy. This enzyme stimulation test measures the reduction of oxidized glutathione by the enzyme glutathione reductase with and without the addition of exogenous FAD. In dogs, a ratio of greater than 1.3 has been taken as deficient. Similar to the other B-vitamins, analytical approaches involve hydrophilic interaction chromatography or capillary electrophoresis using UV, florescence, or mass spectrophotometry for detection (Rivlin, 2007).

B. Vitamins Directed at Specific Features of Carbohydrate, Protein, or Lipid Metabolism: Thiamin, Pyridoxine, and Pantothenic Acid

1. T*hiamin*

a. Introduction

Studies related to thiamin were important to the development of early concepts associated with the role and importance of vitamins. Another aspect of this work, particularly efforts by the Dutch medical officer Christian Eijkman, was that the polyneuritis associated with human beriberi could also be produced in an experiment animal model by dietary manipulation. Eijkman and his colleagues fed a diet of polished rice, presumably low in thiamin, to chickens and observed a characteristic feature—head retraction. The focus on rice and the observation that there appeared to be a curative principle in rice bran led to the eventual isolation of thiamin. This sequence of discovery provided the underpinnings that led to the discovery of vitamins as precursors to cofactors and their roles as regulators (Goldblith and Joslyn, 1964).

b. General Functions

Thiamin is found in cells either as the pyrophosphate (TPP) or the triphosphate (TPPP) (Fig. 23-17). TPPP predominates in neural tissue and in the brain (Davis, 1983). There

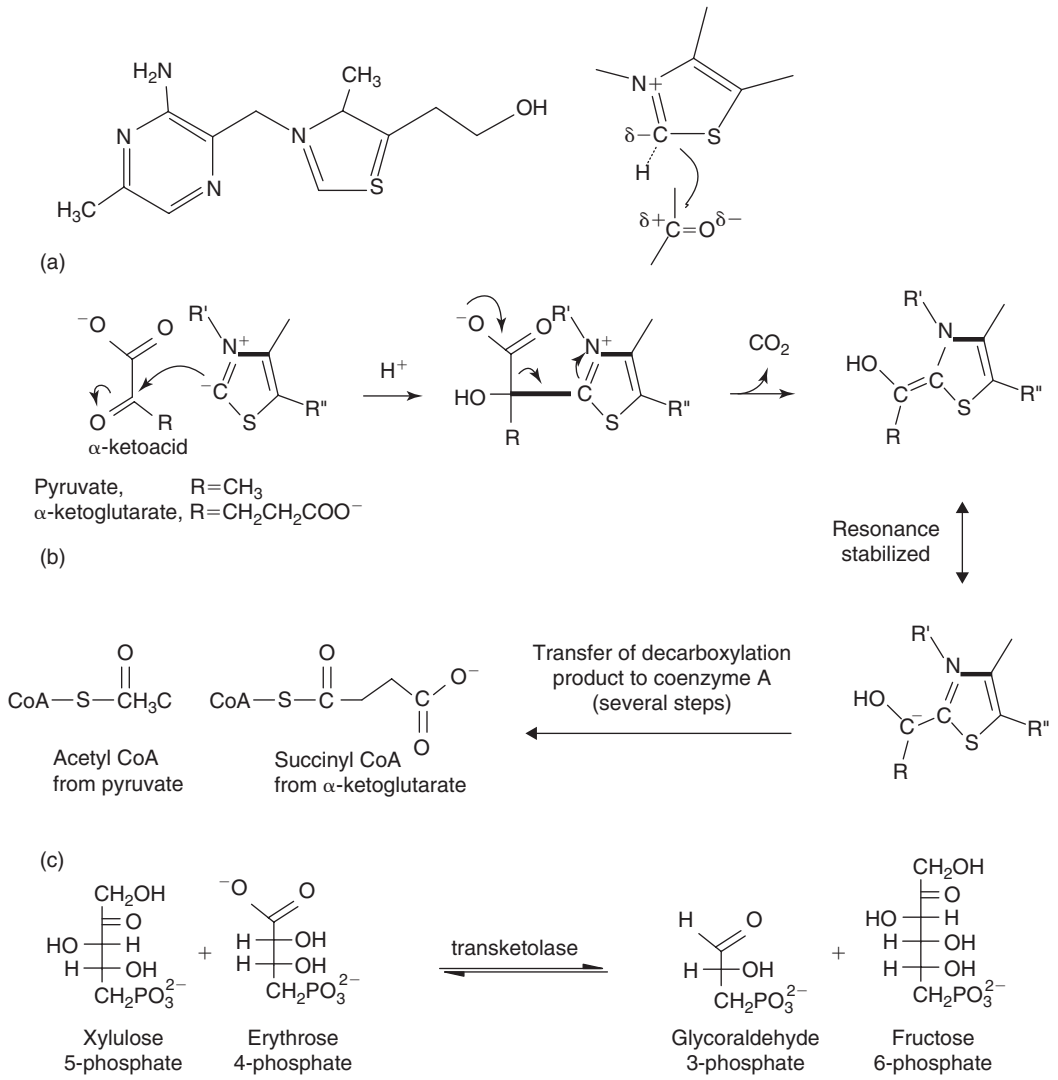

FIGURE 23-17 Thiamin. The structure of thiamine (a) is shown in its vitamin form. Along with magnesium, thiamin as thiamin pyrophosphate is designed to interact with C=O moieties to initiate active aldehyde transfer reactions. One example is the decarboxylation of α-keto acids or transketolase reactions (b). Thiamin also facilitates the transformation of "ketols" (ketose phosphates) in the pentose phosphate pathway (c).

are two general types of reactions wherein TPP functions. TPP is a coenzyme for active aldehyde transfer reactions, most often coordinated with magnesium. One example is the decarboxylation of α-keto acids. This type of reaction is called the transketolase reaction. TPP also facilitates the transformation of "ketols" (ketose phosphates) in the pentose phosphate pathway. The importance of these reactions cannot be overstated. The first type of reaction, decarboxylation of "keto acids, is essential to the flux of substrates through the TCA cycle (i.e., the conversion of pyruvic acid to acetyl CoA and the conversion of α-ketoglutarate to succinyl CoA). In the pentose phosphate pathway, NADP is also reduced to NADPH, an essential reducing agent for synthetic reactions (see niacin). Consequently, with a deficiency of thiamin there is impaired metabolism of carbohydrates, because of defective TCA cycle regulation. Further, if there are perturbations in the pentose phosphate-related carbohydrates pathway, there can be decreased production of NADPH, which may impact other synthetic processes, such as fatty acid biosynthesis.

Another function that may be ascribed to thiamin occurs in brain and neural tissue. In the brain, TPPP is proposed to be involved in sodium-gating processes (i.e., the flux of sodium ions, across neuronal cell membranes) (Bettendorff, 1996). This aspect of thiamin metabolism may be related to the psychosis and impairment of neuromuscular control that is observed in thiamin deficiency.

c. Requirements

Thiamin status should be routinely considered in disease assessment, because a number of factors influence thiamin availability and may induce deficiency. Thiamin is heat and alkali unstable, so extensive destruction of thiamin can

occur in the various steps of food processing and preservation. Canning, with its elevated temperatures and often alkaline conditions, can result in very low recoveries of thiamin. Thiamin can also be destroyed enzymatically by thiaminases, which are abundant in the flesh of some fish, particularly spoiled fish, and bacteria associated with fermentation processes. Thiamin deficiency has been observed in fish-eating birds, seals, dolphins, even other fish (Ceh *et al.,* 1964; Cowey *et al.*, 1975; Evans, 1975; Geraci, 1972, 1974; Murai and Andrews, 1978; Rigdon and Drager, 1955; Vimokesant *et al.*, 1982; White, 1970), when spoiled or uncooked fish has been routinely fed. Thiaminase activity is strikingly high, particularly in tuna and sardines (i.e., the destruction of mg quantities of thiamin per hour per gram of fish muscle). Thiamin deficiency has also been reported in foxes fed uncooked fish products and in cats given both fresh fish and canned cat food that has suffered excessive processing losses. Naturally occurring thiamin deficiency has also been reported in cats given diets that have been preserved by sodium metabisulfite that degrades the thiamin in the diet (Donoghue and Langenberg, 1994). A novel case of thiamin deficiency in fish has reported for which consumption of shad was proposed as the mechanism. Shad contain high concentrations of thiaminase, which was inferred to be the mechanism. So-called early mortality syndrome is a noninfectious disease affecting lake trout and other salmonids associated with thiamin deficiency. It is characterized by loss of equilibrium, hyperexcitability, anorexia, and eventually death.

In herbivores, thiamin deficiency can occur from the ingestion of bracken fern (*Pteridium aquillnimum*) or nardoo (*Marsilea drumen*). In both herbivores and monogastric animals, the most predominant characteristic of thiamin deficiency is polioencephalomalacia, primarily of the deep cordial gray matter, periventricular gray matter, and alteration in the vestibular and lateral geniculate nuclei (Frye *et al.,* 1991). A relationship between excessive production of hydrogen sulfide in the rumen of cattle and sheep and polioencephalomalacia has recently been demonstrated. The availability of thiamin in foodstuffs is comprised of high levels of tannins. As a general requirement, animals should receive from 4 to 10 mg of thiamin per kilogram of dry food (Committee on Animal Nutrition, 2001a; Donoghue and Langenberg, 1994).

d. Determination of Thiamin Status

Traditionally the erythrocyte transketolase saturation test, which is a measure of the stimulation of the transketolase reaction, has been used to assess thiamin status. A stimulation of greater than 16% has been taken as a thiamin deficiency. A more sensitive test, however, is the measurement of thiamin-phosphorylated esters in plasma; the level of phosphate esters declines in plasma before any change occurs in erythrocyte transketolase values. A thiamin loading test, which measures the urinary excretion of thiamin following an oral dose of thiamin, has also been used. However, this test lacks sensitivity compared to measuring metabolites in plasma.

2. P*yridoxine*

a. Introduction

Vitamin B_6 is a collective term for pyridoxine, pyridoxal, and pyridoxamine (Fig. 23-18). Pyridoxine is most abundant in plants, and pyridoxal and pyridoxamine are most abundant in animal tissues (Coburn, 1996). Each can be converted to the other. The active form pyridoxal (B_6 cofactor form) is phosphorylated. When pyridoxal-5-phosphate is in excess, it is converted to pyridoxic acid (-CHO→-COOH), which is then excreted.

Vitamin B_6 is essential in reactions important to amino acid metabolism and glycogen hydrolysis. The major types of reactions involving amino acids fall into three general categories. The most common of these is the transaminase reaction. Transaminations are essential to the interconversion of amino acids to corresponding WA α-keto acids. The transamination mechanism also applies for reactions important to producing racemic amino acid mixtures, for example, the conversion of L-alanine to D-alanine, and α,β-additions or elimination reactions. Examples of α,β-elimination reactions are the conversion of serine to pyruvic acid and the conversion of homocysteine plus serine to cystathionine. The basic feature of a transamination-type mechanism involves electron withdrawal from the α-carbon resulting in a proton liberation that sets the stage for substitution and additions reactions (Fig. 23-18).

The second most common reaction involves electron withdrawal from the α-carbon and carboxylic acid group carbon. This facilitates decarboxylation. Examples of decarboxylation reactions include the conversion of tyrosine to tyramine, 5-hydroxytryptophan to serotonin, histidine to histamine, and glutamate to gamma-aminobutyric acid (GABA). The convulsions associated with vitamin B_6 deficiency are attributed to insufficient activity of PLP-dependent L-glutamate decarboxylase leading to a deficit of the inhibitory neurotransmitter GABA.

A third type of reaction involves electron withdrawal from the α,β-carbons of amino acids. This sets the stage for hydride condensations or aldol reactions. A good example of an aldol reaction is the conversion of serine to glycine with the transfer of the β-carbon (as formaldehyde) to another vitamin cofactor, tetrahydrofolic acid. An excellent example of a hydride condensation is the formation of α-aminolevulinic acid, the first step in heme biosynthesis (Bender, 1994; Coburn, 1996).

Regarding glycogen, vitamin B_6 (as pyridoxal 5′-phosphate) is a cofactor for glycogen phosphorylase (Helmreich, 1992). Glycogen phosphorylase catalyzes the hydrolysis of ether bonds in glycogen to form 6-phosphoglucose. Ether bonds are best catalyzed through acid-mediated mechanisms.

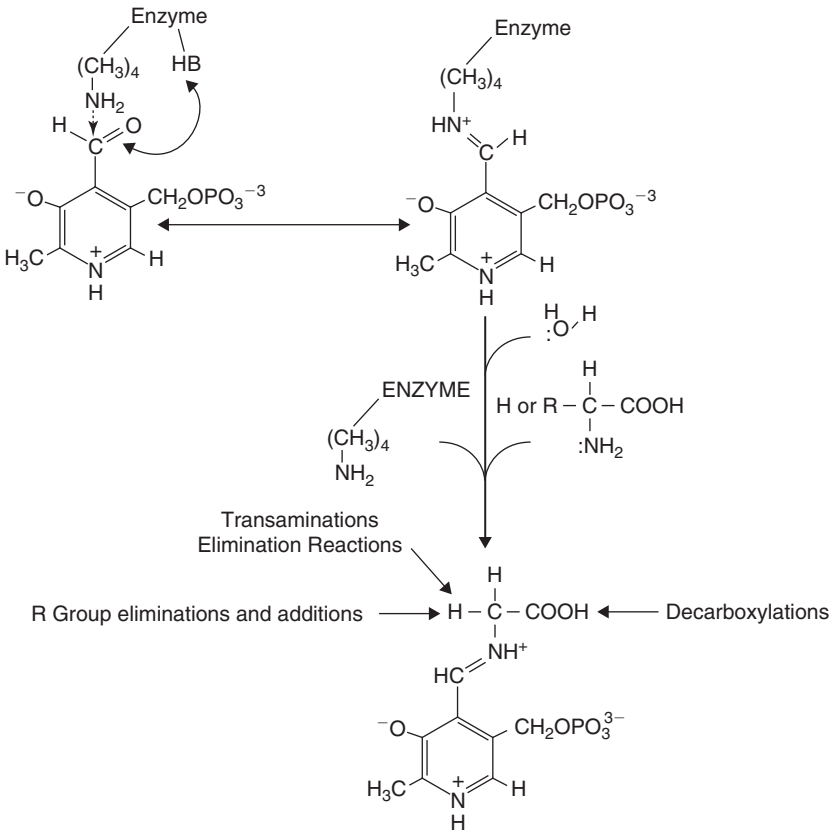

FIGURE 23-18 Pyridoxine. Vitamin B_6 is a collective term for pyridoxine ($-CH_2OH$), pyridoxal (-CHO), and pyridoxamine ($-CH_2-NH_2$). The active form pyridoxal (B_6 cofactor form) is phosphorylated. The type of reactions carried out by vitamin B_6 fall into three general categories. These are mainly reactions that apply to the metabolism and interconversion of amino acids. The most common of these is the transaminase reaction. Transaminations are essential to the interconversion of amino acids to corresponding α-keto acids. The transamination mechanism also applies for reactions important to producing racemic amino acid mixtures. Examples of α,β-elimination reactions are the conversion of serine to pyruvate or the conversion of homocysteine plus serine to cystathionine. The second most common reaction involves electron withdrawal from the α-carbon and carboxylic acid group carbon. This facilitates decarboxylation reactions. A third type of reaction involves electron withdrawal from the α,β-carbons of amino acids. This sets the stage for hydride condensations or aldol reactions (e.g., the formation of α-aminolevulinic acid), the first step in heme biosynthesis.

The acid proton in this instance is derived from the phosphate group of pyridoxal 5′-phosphate. Before the elucidation of this important function, it was speculated that the association of vitamin B_6 with glycogen phosphorylase was primarily some type of storage mechanism. Indeed, muscle is a good source of vitamin B_6, but its presence in muscle relates mostly to its role as a catalyst in glycogen hydrolysis.

b. Metabolism and Requirements

The requirement of vitamin B_6 by animals is positively related to their intake of protein and amino acids; however, vitamin B_6 deficiency is rarely seen in animals as most diets provide adequate amounts. Normally, B_6 is needed in amounts that range from 2 to 6 mg/kg diet. Ruminants and many herbivores meet a substantial part of their vitamin B_6 requirement from intestinal microbes. Administration of the tuberculostatic drug isoniazid induces a metabolic deficiency of vitamin B_6.

As might be expected, the most important signs of B_6 deficiency relate to the inability to carry out normal amino acid metabolism. Neurological signs occur as a result of the inability to synthesize important biogenic amines from amino acid precursors and anemia results from decreased heme synthesis. Under experimental conditions, some animals may show signs of oxaluria with long-term deficiencies in vitamin B_6 (Committee on Animal Nutrition, 2001b).

c. Determination of Vitamin B_6 Status

A number of tests have been used as an index of vitamin B_6 status. These include measurement of the activities of enzymes that require pyridoxal phosphate such as kynureninase and aminotransferases. However, the most sensitive methods involve the measurement of pyridoxal and pyridoxal phosphate in blood plasma. The relative ratio of these two forms and their response to dietary intake of pyridoxine depends on the species of animal.

3. *Pantothenic Acid*

a. Introduction

Pantothenic acid was first recognized as a growth factor for yeast and lactic acid bacteria in the 1930s. Later,

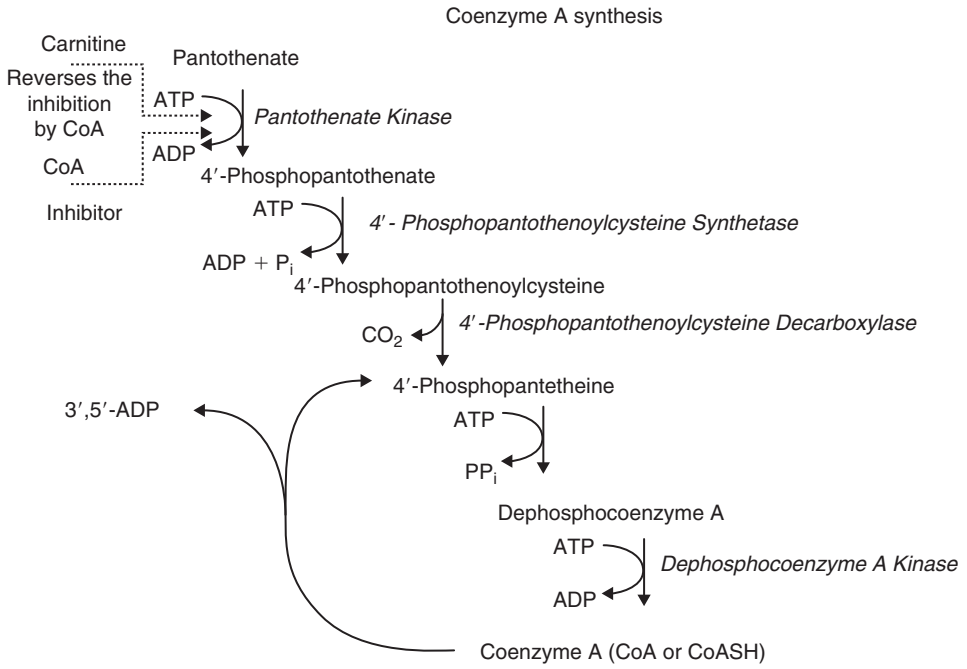

FIGURE 23-19 Pantothenic acid and coenzyme A. The most important control step in CoA synthesis is the phosphorylation of pantothenic acid to 4′-phosphopantothenic acid by pantothenic acid kinase. There is feedback regulation from CoA and carnitine reverses that inhibition. Most cells are able to conserve pantothenic acid by reutilizing 4′-phosphopantothenic acid.

Elvehjem, Jukes, and others demonstrated pantothenic acid to be essential for animals. Pantothenic acid is a component of coenzyme A (Fig. 23-19). Pantothenic acid (as a part of phosphopantetheine) is also present at the active site of acyl carrier protein (ACP), a component of the fatty acid synthesis complex. Both forms are present in foods. Consequently, absorbed pantothenic acid must first be released from coenzyme A and ACP, steps that involve the actions of peptidases and nucleosidases.

b. Absorption and Regulation

Intestinal phosphatases and nucleosidases are capable of very efficient hydrolysis of coenzyme A so that near quantitative release of pantothenic acid occurs as a normal part of digestion. In rats, pantothenic acid was initially found to be absorbed in all sections of the small intestine by simple diffusion (Rucker and Bauerly, 2007). However, subsequent work in rats and chicks indicated that at low concentrations, the vitamin is absorbed by a saturable, sodium-dependent transport mechanism (Rucker and Bauerly, 2007; Said, 2004). Further, the overall km for pantothenic acid intestinal uptake is 10 to 20 m. At an intake of ~20/30mg/kg diet as coenzyme A or pantetheine, a concentration typical of many foodstuffs, the pantothenic acid concentration in luminal fluid would be ~1 to 2 m. At this concentration, pantothenic acid does not saturate the transport system, and should be efficiently and actively absorbed. Pantothenic acid shares a common membrane transport system in the small intestine with another vitamin, biotin (Said, 2004). Following uptake, the maintenance of pantothenic acid cellular concentration depends on its incorporation into cellular CoASH and pantetheine. The most important control step in this process is the phosphorylation of pantothenic acid to 4′-phosphopantothenic acid by pantothenic acid kinase. At least four known enzyme isoforms serve as pantothenic acid kinases. They possess a broad pH optimum (between pH 6 and 9). The K_m for pantothenic acid in the liver enzyme of most animals is ~20 m. Mg-ATP is the nucleotide substrate for the phosphorylation reaction.

c. Metabolism Functions and Requirements

CoA is the principal moiety for the vectorial transport of acyl and acetyl groups in synthetic and catabolic reactions, and a deficiency is characterized by impaired acetyl and acyl metabolism. The ability to utilize fatty acids as fuels is compromised. There is also an increased production of short chain fatty acids and ketone bodies, which can lead to severe metabolic acidosis.

CoA is involved in a broad array of acetyl and acyl transfer reactions, which also includes carbohydrates and amino acids as cosubstrates, as well as processes related primarily to lipid oxidative metabolism and catabolism, whereas ACP is involved in mostly synthetic reactions involving primarily lipids and possibly amino acids. Protein acetylations and acylations are also key functions catalyzed with CoA as a cosubstrate in reactions. Aminoterminal acetylations occur cotranslationally and posttranslationally

on processed eukaryotic regulatory peptides. Proteins with serine and alanine termini are the most frequently acetylated, although methionine, glycine, and threonine may also be targets. This type of acetylation is usually irreversible and occurs shortly after the initiation of translation. The biological significance of aminoterminal modification varies in that some proteins require acetylation for function, whereas others do not have an absolute requirement. Lysine residues are also targets for acetylations. The acetylation of histones, transcription factors, co-transcriptional activators, nuclear receptors, and α-tubulin is proteins in which acetylation modulates or alters function (Rucker and Bauerly, 2007). The acylation of proteins with fatty acids (e.g., palmitic acid) or isoprene moieties in the cholesterol synthesis pathway imparts lipid character to proteins, which is often essential to lipid transport and docking at specific locations in cells.

For most animals the need for pantothenic acid is 10 to 20 mg per kilogram of diet, which is easily met, because of the ubiquitous presence of pantothenic acid. In animals, the classical signs of deficiency include growth retardation and dermatitis as a secondary consequence of altered lipid metabolism. Neurological, immunological, hematological, reproductive, and gastrointestinal pathologies have also been reported.

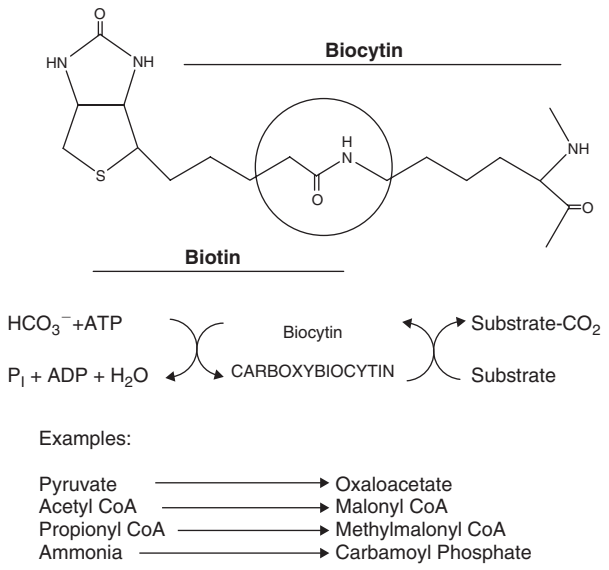

FIGURE 23-20 Biotin. Biotin is covalently bound in carboxylases and transcarboxylases by peptidyl linkage between the carboxylic acid moiety of biotin and the -amino group of peptide bound lysine. The biotin-lysine adduct is called biocytin and can be released from carboxylases after proteolysis and cleavage of peptides containing biocytin by biocytinase. Three major carboxylation reactions that use biotin as a cofactor are shown. All involve the transfer of CO_2 to the respective substrate. Not shown is 3-methylcrotonyl-CoA conversion to 3 methyl glutaconyl-CoA, a reaction important to leucine degradation. Carbamyl phosphate also requires biotin. Carbamyl phosphate is a substrate for urea synthesis and purine synthesis.

C. Vitamins Involved in Single-Carbon Metabolism: Biotin, Folic Acid, and B_{12}

1. *Biotin*

a. Introduction

Biotin functions in enzymatic carboxylations as a cofactor for three CO_2-fixing enzymes: acetyl CoA carboxylase, which is essential for fatty acid synthesis; propionyl CoA carboxylase, which participates in odd chain fatty acid metabolism; and pyruvate carboxylase, which is involved in the formation of oxaloacetate, an important obligatory step in reverse glycolysis and gluconeogenesis (Fig. 23-20).

b. Metabolism and Requirements

Biotin is found in highest concentrations in the liver. In food, biotin is present in relatively high concentrations in cereals including soybeans, rice, barley, oats, corn, and wheat. However, the bioavailability of biotin from cereals varies widely. Biotin is covalently bound to the enzymes that it serves as cofactor; the chemical linkage is to a peptide bond between the carboxylic acid moiety on biotin and the -amino function of peptidyl lysine in the enzyme. The biotin-enzyme peptide bond requires an ATP-dependent step (Zempleni, 2005).

Biotin is the coenzyme for four carboxylases: (1) acetyl coenzyme A carboxylase, found in both the mitochondria and cytosol, catalyzes the carboxylation of acetyl-CoA to malonyl-CoA. Malonyl-CoA is the immediate precursor for fatty acid synthesis. (2) Pyruvate carboxylase, which is located in the mitochondria, catalyzes the carboxylation of pyruvate to form oxaloacetate. Oxaloacetate can be metabolized in the tricarboxylic acid cycle or it can be converted to glucose in the liver and kidney and other tissues that are involved in gluconeogenesis. Pyruvate carboxylate is the principal enzyme that replenishes tricarboxylic acid cycle intermediates. (3) Methylcrotonyl-CoA carboxylase, also located in the mitochondria, is involved in the metabolism of L-leucine. (4) Propionyl-CoA carboxylase, also found in mitochondria, is involved in the metabolism of L-isoleucine and L-valine, and L-threonine and L-methionine. All four of the carboxylase enzymes using bicarbonate as their one-carbon substrate share a common biochemical mechanism.

Evidence is also emerging that biotin participates in processes other than classical carboxylation reactions. Specifically, novel roles for biotin in cell signaling, gene expression, and chromatin structure have been identified in recent years. Biotinylation of histones appears to play a role in cell proliferation, gene silencing, and the cellular response to DNA repair. Roles for biotin in cell signaling and chromatin structure are consistent with the notion that biotin has a unique significance in cell biology (Gravel and Narang, 2005; Zempleni, 2005).

When biotin-containing carboxylases are degraded, biotin is released as biocytin (Fig. 23-20). Biocytinase is an important liver enzyme that catalyzes the cleavage of the peptide linkage between biotin and lysine to release free biotin for reutilization. The biotin requirement in animals is relatively low (i.e., in the microgram per kilogram of diet range). Furthermore, biotin can also be produced by gut microflora and the biotin that is covalently attached to enzymes is reutilized.

Nevertheless, there can be nutritional problems associated with biotin status. Biotin and biocytin have affinity for certain proteins, particularly avidin in egg white. The use of raw eggs can cause biotin deficiency because of the association of biotin with avidin in uncooked eggs. The response in fur-bearing animals to ingestion of significant quantities of raw egg white has been described as "egg white injury." Native (nondenatured) avidin in eggs causes egg white injury because it binds tightly to biotin, preventing its absorption.

The relationship of biotin to avidin is important, particularly to industries that utilize fur-bearing animals for profit. It was subsequently found that egg white injury could be cured by a liver factor that was first called protective factor X and later determined to be biotin. Because biotin cured the skin disorder of egg white injury, it was called vitamin H (for *haut*, the German word for skin). Conditions that may increase biotin requirements in pregnancy, lactation, and therapies are the use of anticonvulsants or exposure to high concentrations of lipoic acid. Spontaneous biotin deficiency occurs rarely in animals because biotin is well distributed among foodstuffs, and a good part, if not all, of the requirement for the vitamin is met by microbial synthesis in the gut. As noted, the deficiency can, however, be induced by the inclusion of unheated (raw) egg white in the diet (Zempleni, 2005). For most monogastric animals, 50 to 100 g of biotin per 1000 kcal or ~0.2 to 0.4 mg per kilogram of diet is probably sufficient.

Biotin deficiency leads to impaired gluconeogenesis and impaired fat metabolism. Alopecia and dermatitis are characteristics of biotin deficiency in most animals and birds. Biotin deficiencies can also cause severe metabolic acidosis. The inability to carry out fat metabolism markedly affects the dermis in biotin-deficient animals. Unless there is an inborn error or genetic polymorphism involving one of the carboxylase enzymes, the likelihood of a biotin-related metabolic compromise or deficiency is low, except when uncooked egg white is the major protein source.

Biotin turnover and requirements can be estimated on the basis of (1) concentrations of biotin and metabolites in body fluids, (2) activities of biotin-dependent carboxylases, and (3) the urinary excretion of organic acids that are formed at increased rates if carboxylase activities are reduced. Urinary excretion of biotin and its metabolite, bisnorbiotin, activities of propionyl-CoA carboxylase and beta-methylcrotonyl-CoA carboxylase in lymphocytes, and urinary excretion of 3-hydroxyisovaleric acid are good indicators of marginal biotin deficiency.

2. Folic Acid and Vitamin B_{12}

a. Introduction

Knowledge regarding folic acid and B_{12} evolved from efforts to better understand macrocytic anemias and certain degenerative neurological disorders (Scott, 1994). Combe, the Scottish physician, recognized in the early 1800s that a certain form of macrocytic anemia appears related to a disorder of the digestive organs. In classic studies by Minot and Murphy, Castle, and others, it became clearer that the disorder was associated with gastric secretions and in some cases could be reversed by consuming raw or lightly cooked liver. Through careful clinical investigations and inferences, Castle postulated the existence of an intrinsic factor in gastric juice, which appeared to combine with a dietary extrinsic factor to modulate the severity of the anemia (Goldblith and Joslyn, 1964).

In parallel studies, folic acid was also associated with macrocytic anemia. Large-scale efforts by a number of pharmaceutical companies throughout the 1940s and 1950s and careful clinical and basic studies at academic institutions eventually led to the isolation of folic acid and vitamin B_{12}.

b. Chemistry and Functions

The structures for folic acid and vitamin B_{12} are given in Figures 23-21 and 23-22. Folic acid is part of a family of compounds with a pteridine moiety. In the case of folic acid, the pteridine moiety is associated with aminobenzoic acid and glutamyl residues conjugated by a methylene bridge to para-aminobenzoic acid, which in turn is joined to glutamyl residues by a peptide linkage. Figure 23-21 presents an overview of one-carbon transfers involving tetrahydrofolate (THF) coenzymes and their metabolic origins. The reactions include the generation and utilization of formaldehyde and formimino groups in the synthesis of pyridine nucleotides, interconversion of some amino acids, and eventual reduction of the methylene form of THF to methyl THF to facilitate the conversion of homocysteine to methionine (Goldblith and Joslyn, 1964; Scott, 1994).

To set the stage for these conversions, folic acid must be in its completely reduced state. The reductions occur at positions 5, 6, 7, and 8 to form a tetrahydrofolic acid (THFA) (Fig. 23-21). The reduction brings the nitrogen at positions 5 and 10 closer together and changes electrochemical properties of both nitrogens, which facilitates the formation of the various THFA single carbon derivatives that are involved in the metabolic conversions shown in Figure 23-21. The formyl, methanyl, and methylene forms are utilized for purine synthesis and important steps in thymidylate (i.e., DNA-related) synthesis. These reactions are therefore of obvious importance and are essential to cell

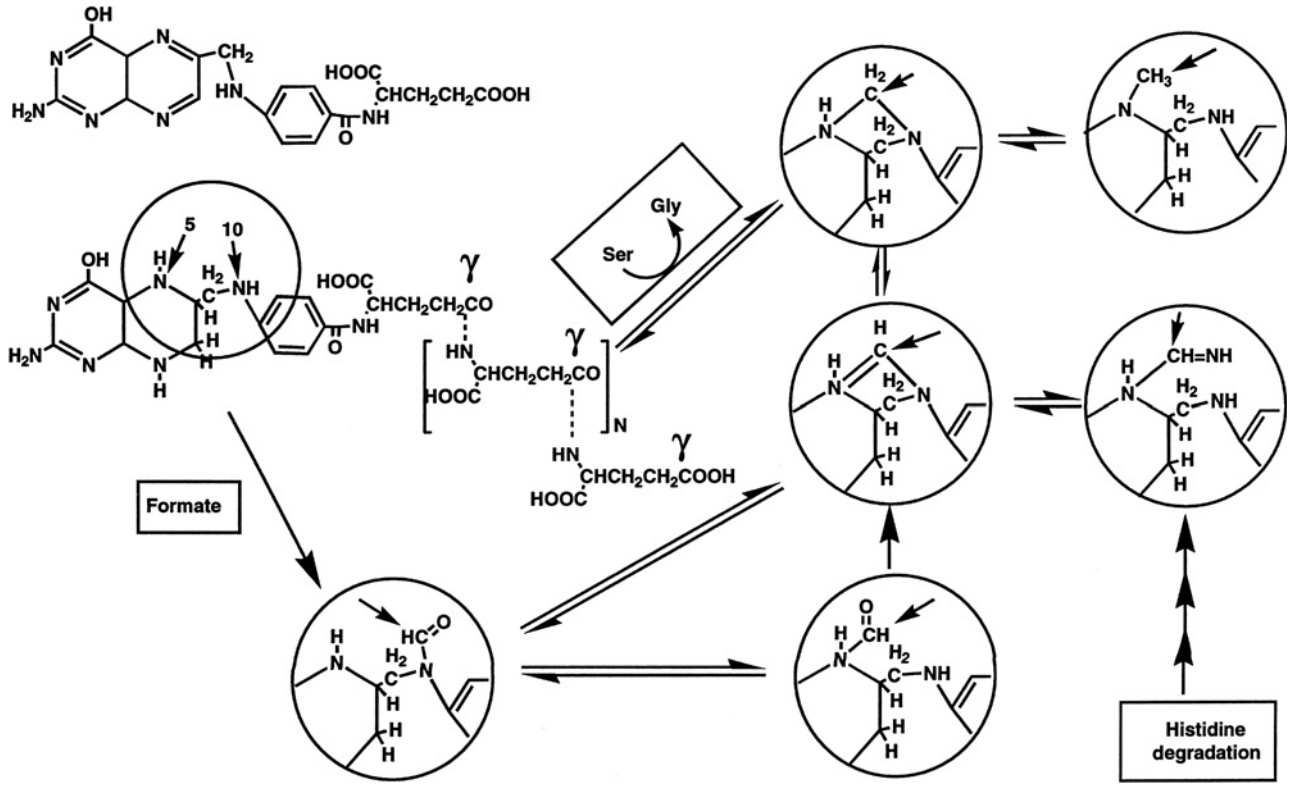

FIGURE 23-21 Folic acid. Structures of oxidized and reduced tetrahydrofolic acid (THFA) are shown. The 5 and 10 positions of the molecule are highlighted because these sites are important to single-carbon transfer. Folic acid is found in foods as γ-linked polyglutamyl folic acid (*n* ranges from 3 to 5 units). In the intestine, γ-peptidases (also referred to as conjugases) cleave the polyglutamyl residues to the single glutamate (as shown for the oxidized structure of folic acid). Single carbon units can enter into THFA by a number of routes. Formimino groups can arise from glycine and histidine degradation. Cylization results in N^5,N^{10}-methenyl THFA. Reduction of this product results in N^5,N^{10}-methylene THFA. This product can also be derived directly from an aldol-type condensation reaction arising from the conversion of serine to glycine (see Fig. 24-17). This step represents a major source of single carbon units. Subsequently, all of the forms of methylated THFA may be ultimately reduced to N^3-methyl THFA.

division and proliferation. As a final step, when 5-methyl THFA transfers its methyl moiety to vitamin B_{12}, one of the resulting products is the oxidized form of folic acid, which must be reduced to THFA to reinitiate the cycle.

With regard to vitamin B_{12}, the methylated form is also shown in Figure 23-22 and is the B_{12} cofactor utilized in the THFA-homocysteine transmethylase system. The other reactions involving vitamin B_{12} utilize B_{12} as deoxyadenosylcobalamin (Fig. 23-22). An example is methylmalonyl-CoA mutase. Without B_{12}, methylmalonic acid accumulates. Otherwise, methylmalonic acid is converted to succinyl-CoA for ultimate use as a metabolic fuel, a reaction that is essential for the eventual delivery of carbon from odd-chained fatty acids into the TCA cycle. This is an important process for animals, such as some herbivores and ruminants, which depend in part on odd-chain fatty acids as a source of gluconeogenic precursors.

c. Metabolism

The steps in absorption, transport, and the utilization of folic acid and vitamin B_{12} are more complex than for other water-soluble vitamins (Said, 2004). In the case of the folic acid, the conjugated glutamyl residues must be removed for effective absorption (e.g., to monoglutamyl tetrahydrofolate) in the jejunum where it is absorbed. Next, folates enter plasma and are rapidly cleared by the liver and other organs. Biliary drainage results in a large enterohepatic circulation of folate (Scott, 1994).

Folic acid is found in circulation primarily as methyltetrahydrofolate. Thus, it may be assumed that reduction and methylation are essential steps in the eventual transfer of folic acid across cellular barriers and membranes. The enzymes found in the intestinal cells that carry out the hydrolysis of conjugated glutamyl residues are commonly referred to as conjugases. Specific serum transport proteins exist for folic acid and cellular uptake is by active processes (Said, 2004).

For B_{12}, the steps important to processing (Fig. 23-22) involve first the release of B_{12} from foods under acidic conditions; vitamin B_{12} then binds to proteins produced by cells of the gastric fundus (and also the pancreas and salivary gland in some species). Two proteins have been identified, which have been designated as R protein

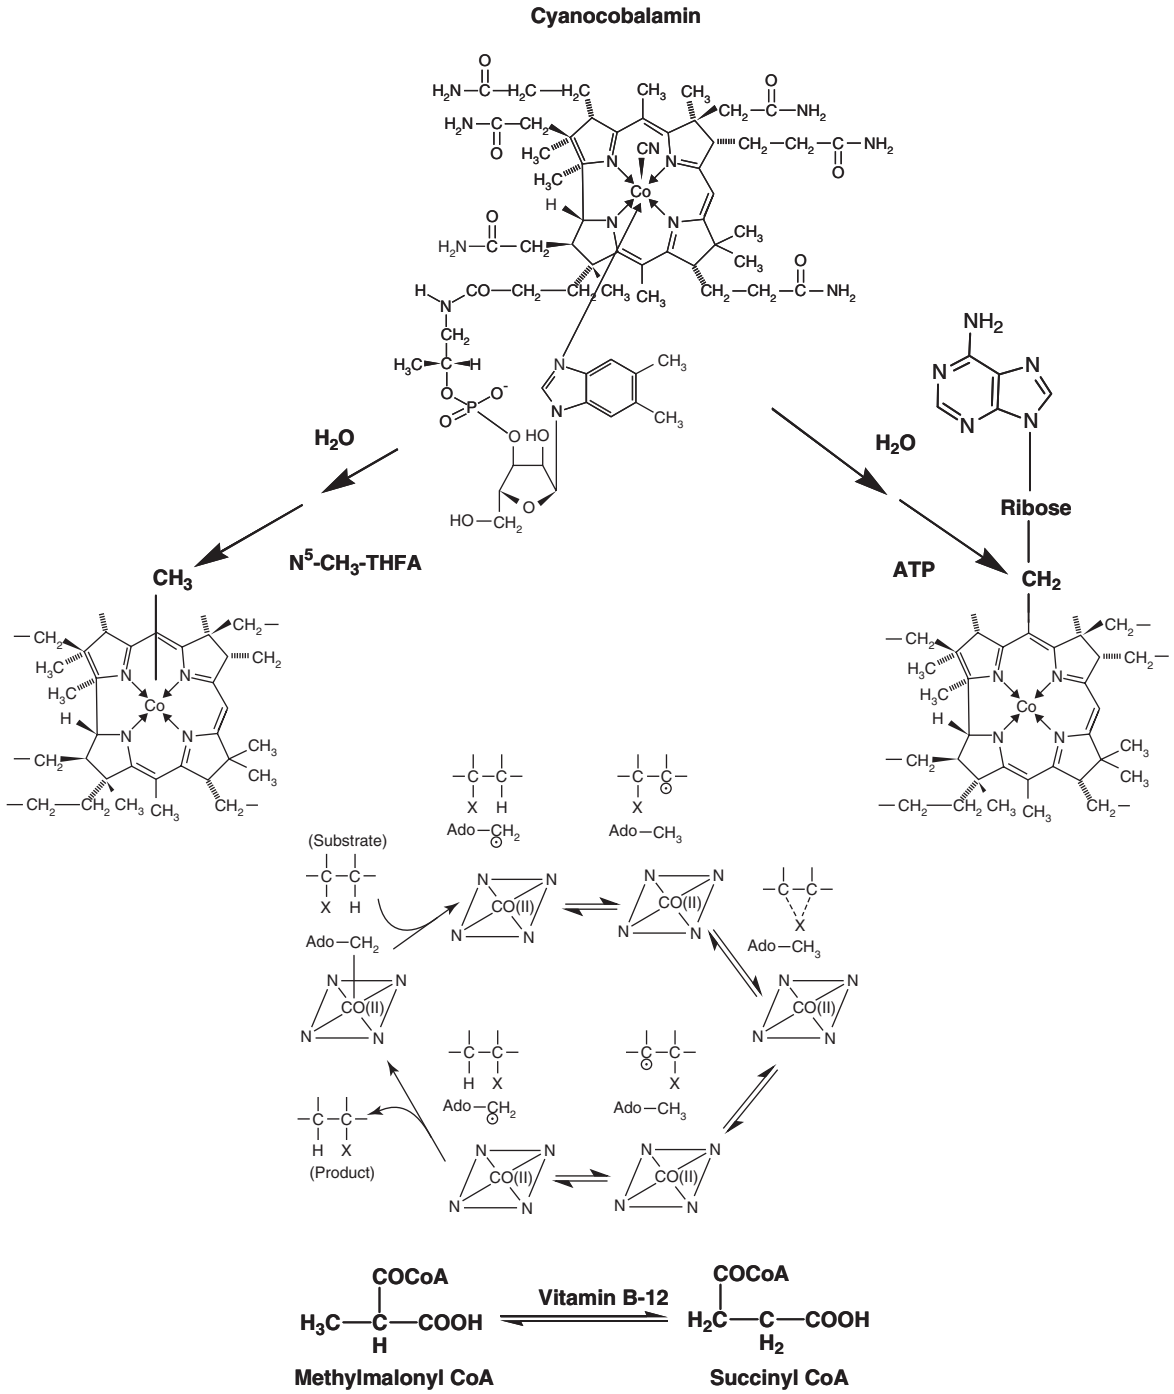

FIGURE 23-22 Cyanocobalamin. Commercial preparations of vitamin B_{12} usually have a cyano group coordinated with the cobalt (associated with the corrin ring of vitamin B_{12}). In an aqueous environment, the cyano group can be displaced by water for the eventual transfer of a methyl group (donated by N^5-methyl-THFA) or an adenosyl moiety (from ATP). Methylated vitamin B_{12} serves as a cofactor for methionine synthetase (see Fig. 23-7). Adenosylated vitamin B_{12} serves as a cofactor for unusual isomerase reactions, such as the conversion of methylmalonyl CoA to succinyl CoA. A mechanism for this process is shown, which involves the redox of cobalt in the corrin ring of cobalamin ($Co^{+3} \leftrightarrow Co^{+2}$).

(and more recently as small-molecular-weight haptocorrin) and intrinsic factor (IF). Vitamin B_{12} first binds to R proteins and is apparently released in the intestinal lumen by the action of pancreatic and intestinal proteinases and peptidases. Next, vitamin B_{12} associates with an intrinsic factor, a binding protein made in the stomach. The vitamin B_{12}-intrinsic factor complex then interacts with receptors on the intestinal brush border localized in the midgut

(i.e., ileum). In the small intestine, following uptake via the IF receptor, there is subsequent proteolytic release of B_{12} and binding to intracellular transcobalamin II (TcII). The TcII receptor then transports the TcII-VB_{12} complex across the cell, whence it is released into the circulation. Vitamin B_{12} is transported in plasma by one of at least three known transport proteins: transcobalamin I, II, or III. The transcobalamins transport vitamin B_{12} to cells, where it is again transferred into targeted cells by endocytotic mechanisms (Selhub, 2002).

Interference with R protein or intrinsic factor production (e.g., as caused by inflammatory diseases affecting the ileum, or overproduction of intestinal microflora) can influence availability of vitamin B_{12}. With bacterial overproduction, there is competition between the host and bacteria for vitamin B_{12} and production of bacterial proteins that bind B_{12} and interact with its uptake. Gut bacteria can also be a source of B_{12}. Many animals obtain vitamin B_{12} through coprophagy. In ruminants, vitamin B_{12} is synthesized in ample quantities by ruminal bacteria.

d. Requirements and Deficiency

The requirements for folic acid range from 1 to 10mg per kilogram of diet for most animals. There are some conditions in which the folic acid requirements are conditionally high (e.g., when either natural or pharmacological folic acid agonists are present in the diet). With the discovery that THFA is required for DNA synthesis, a number of antimetabolites were developed starting in the 1950s and 1960s that function as inhibitors of folic acid reductase. The best example is methotrexate, which ultimately inhibits the proliferation and regeneration of rapidly replicating cells. Cell division is blocked in the S phase, because of impaired DNA synthesis. As a consequence, drugs such as methotrexate are widely used in cancer chemotherapy particularly for tumors of the lymphoreticular system (Baily, 2007; Scott, 1994; Selhub, 2002).

The requirement for vitamin B_{12} for most animals is in the 2 to 15 g per kilogram of diet range. Although deficiencies of folic acid and vitamin B_{12} are uncommon in free-ranging animals, diseases of the proximal duodenum or stomach and ileum and pancreatic insufficiency can affect folic acid and vitamin B_{12} absorption, respectively. Moreover, cobalt deficiency can result in vitamin B_{12} deficiency in ruminants because of the need for cobalt to vitamin B_{12} synthesis by rumen microorganisms.

Deficiencies of both vitamin B_{12} and folic acid include macrocytic anemia and dyssynchronies in growth and development owing to the importance of folic acid to purine and DNA synthesis (Bohnsack, 2004). Chronic deficiencies of either folic acid or B_{12} can also promote fatty liver disease and indirectly influence extracellular matrix maturation stability by causing abnormal elevations in homocysteine. Such signs and symptoms are attributable to both THFA and B_{12} deficiencies, because of the integral relationship of vitamin B_{12} to THFA regeneration. Dietary intakes of folic acid, sufficient to maintain functional THFA levels, can mask the initial signs of vitamin B_{12} deficiency (e.g., macrocytic and megaloblastic anemia). Prolonged vitamin B_{12} deficiency can result in serious neurological disorders (e.g., degeneration of the myelin sheath). A number of environmental conditions can alter folate concentrations in foodstuffs (excessive heat, UV light). Storage of eggs for more than several weeks may depress hatchability and increase hematological abnormalities characteristic of mild macrocytic anemia. Such changes can result from deficiencies of folic acid. Regarding aging animals, malabsorption of B_{12} can be a problem. Analogous to pernicious anemia in humans, an autoimmune disease that affects the gastric parietal cells, destruction of these cells also can occur in old animals. This curtails the production of intrinsic factor and subsequently limits vitamin B_{12} absorption. This should be explored in aging animals with signs of macrocytic or megaloblastic anemia (Baily, 2007; Scott, 1994; Selhub, 2002).

In humans, it is also becoming clear that periconceptional folic acid at the suggested optimal levels of intake reduce the risk of neural tube and related developmental defects (NTDs). This has led to fortification of foods in many countries and policies for supplementation in others. However, some potential adverse effects, such as masking vitamin B_{12} deficiency, increasing twinning rates, or accelerating preexisting malignant neoplasms, have also been reported (Scott, 1994; Selhub, 2002).

e. Assessment of Vitamin B_{12} and Folate Status of Animals

An independent role of vitamin B_{12} involvement in propionate metabolism and folate in histidine metabolism provides the basis for classical methods of assessment of clinical adequacy, independent of their mutual roles in methyl transfer. Vitamin B_{12} is a component of the coenzyme for methylmalonyl-CoA mutase, which catalyses the conversion of L-methylmalonyl-CoA to succinyl-CoA. Although assays based on B_{12} absorption (e.g., the Schilling's test) are utilized to assess the potential for B_{12} deficiency in humans, B_{12} assessments in animals most often involve administration of a loading dose of valine (1g/kg body weight). L-valine is a precursor of methylmalonyl-CoA, which is excreted in excess the urine of a vitamin B_{12}–eficient animal in that it is not converted to succinyl-CoA. Similarly in histidine metabolism THF is required for the removal of the formimino group from formimino glutamic acid. In the folate-deficient animal given a loading dose of histidine (0.2 g/kg body weight), there is enhanced urinary excretion of unchanged formiminoglutamic acid.

Serum folate and cobalamin concentrations are also commonly used to access status in clinical practice.

V. VITAMIN-LIKE COMPOUNDS

A. Lipotropic Factors

Nutritional requirements exist for a number of compounds at specific periods in development, particularly neonatal development, and periods of rapid growth. These compounds typically perform specialized transport functions particularly in relation to fatty acids. Apart from specific amino acids such as methionine and glycine in feathered animals, examples include choline, inositol, and carnitine.

1. *Choline*

Choline is particularly noteworthy because it plays a key role in methyl group metabolism, carcinogenesis, and lipid transport as a component of lecithin (Garrow, 2007). Choline is normally produced in sufficient amounts; however, in young growing animals, a positive growth response can occur upon addition of choline, commercially available as trimethyl hydroxyethyl ammonium chloride or as the bitartrate. Choline is generally added to diets to reduce the need for activated methyl groups supplied by methionine. It is more economical to add choline for these methyl groups than to add methionine.

Choline is one of the precursors of acetylcholine. Choline is also a component of sphingomyelin and lecithin. Formation of betaine from choline provides important sources of labile methyl groups for transmethylation reactions. Choline can also be synthesized *de novo* from ethanolamine, when methionine or dimethylcysteine, or betaine is in adequate supply. The most abundant source of choline in the diet is lecithin. The primary sign of choline deficiency is fatty liver. In monkeys, dogs, cats, and rats, it has also been shown that prolonged choline deficiency results in cirrhosis. In mice and rats, prolonged deficiency ultimately results in hepatocellular cancer, a unique example of nutrition deficiency resulting in neoplasm. Five hundred to 1000 mg of choline are often added per kilogram of diet (Garrow, 2007).

2. *Inositol*

Inositol is also a component of phospholipids and, similar to choline, results in a fatty liver, if insufficient in supply (Holub, 1986, 1992). Inositol is synthesized from glucose-6-phosphate after cyclization. In some animals, particularly gerbils and hamsters, there is a nutritional need for inositol when they are given diets containing coconut oil. Myoinositol is plentiful in foodstuffs. The estimated daily intake for large animals can be as high as 1 or 2g per day. Inositol is particularly important in cellular signal transduction and phospholipid assembly. Plasma levels of inositol are increased during renal disease and nephrectomy. The presence of myoinositol hexabisphosphate (InsP6) in biological fluids (blood, urine, saliva, interstitial fluid) of animals has been clearly demonstrated. The existence of intracellular InsP6 in mammalian cells has also been established. A relationship between InsP6 ingestion and the InsP6 distribution in various tissues exists. Whereas intracellular inositol depends on endogenous synthesis, depletion of extracellular InsP6 occurs at high rates when InsP6-poor diets are consumed. Consequently, there are probably health benefits that are linked to dietary inositol and InsP6 intake. The suggestion that inositol is important in young animals came from studies carried out throughout the 1970s and 1980s. In particular, it was noted that female gerbils fed a diet containing high coconut oil (relatively saturated) develop an intestinal lipodystrophy that is not seen in animals fed a diet containing 20% safflower oil (relatively unsaturated) or a diet of 20% coconut oil supplemented with 0.1% inositol. The level of inositol in the intestinal tissue of animals fed the coconut oil diet not supplemented with inositol has been shown to decrease. Clearance of lipid (i.e., resolution of the lipodystrophy) was dependent on inositol (Holub, 1986, 1992).

3. *Carnitine*

Oxidation of fatty acids requires their transportation from the cytosol into the mitochondrial matrix where they undergo β-oxidation. Carnitine plays a major role in this transport process by accepting activated fatty acids at the outer mitochondrial membrane. Carnitine comes both from the diet and synthesis from lysine by a process that is ascorbic acid dependent. These steps are not carried out efficiently in some newborns. Given the importance of carnitine to β-oxidation of long-chain fatty acids, carnitine deficiency can have profound effects on lipid utilization. An inherited carnitine deficiency has been recognized in some dogs such as the boxer (Keene, 1991; Keene *et al.,* 1991; Kittleson *et al.,* 1997; Mc Entee *et al.,* 2001). Moreover, American cocker spaniels that are taurine deficient have been shown to be responsive to a combination of taurine and carnitine supplementation (Kittleson *et al.,* 1997).

Meats and dairy products in contrast to plant foods are good sources of carnitine. Cereal grains besides being low in carnitine are also generally low in the precursors of carnitine: lysine and methionine. Drugs, such as mildronate (3-(2,2,2,-trimethylhydrazinium) propionate) can also lower carnitine levels and inhibit synthesis. Mildronate is a butyrobetaine analogue that is known to inhibit gamma-butyrobetaine hydroxylase, the enzyme catalyzing the last step of carnitine biosynthesis. In humans, mildronate is used to ameliorate cardiac function during ischemia by modulating myocardial fatty acid oxidation to the more favorable glucose oxidation. When given to pregnant animals, carnitine levels increase in the milk. Correspondingly, an increase in triglyceride levels is observed in liver, heart, and muscle of mildronate pups (i.e., biochemical modifications compatible with a carnitine deficiency status).

4. *Taurine*

Although taurine is not generally considered a vitamin, the requirement for taurine by some animals is of the similar order as choline. Taurine, 2-aminoethanesulfonic acid, is present in all animal tissues and is one of the principal free amino acids. Some tissues such as the retina, olfactory bulb, and granulocytes have particularly high concentrations of taurine. Many animals use taurine or glycine as a conjugate for the bile acids. Some of the taurine excreted in the bile is returned to the liver in the enterohepatic circulation (MacDonald *et al.,* 1984). Most animals can synthesize adequate amounts of taurine from the oxidation of cysteine; however, some animals, particularly domesticated and wild felids, and human infants do not synthesize adequate amounts of taurine. Dogs normally synthesize adequate amounts of taurine; however, when they are given low-sulfur amino acid diets, taurine may become limiting. Taurine deficiency occurs in cats when the diet does not contain adequate amounts of the amino acid. Defective synthesis in cats is a result of low activity of two enzymes in the synthetic pathway: cysteine dioxygenase and cysteine sulfinic acid decarboxylase and an obligatory requirement for taurine to conjugate bile acids. A wide array of clinical signs has been described in taurine-deficient cats including central retinal degeneration, reversible dilated cardiomyopathy, reproductive failure in queens, teratogenic defects, and abnormal brain development in kittens (MacDonald *et al.,* 1984).

Dietary concentrations of taurine required to maintain adequate levels in plasma and whole blood of cats are a function of type of diet, which affects the degree of microbial degradation that occurs in the enterohepatic circulation. For most expanded diets 1g taurine/kg is adequate, but canned diets may require concentrations up to 2.5 g taurine/kg dry matter.

Plasma and whole blood concentrations of 40 and 300 M of taurine appear to be adequate in cats for reproduction, which is the most demanding physiological state for taurine (MacDonald *et al.,* 1984).

B. Other Vitamin-Like Compounds

The following compounds are highlighted because of their known role as coenzymes in prokaryotes and potential role as probiotics (growth- promoting substances) in higher animals. These compounds include queuosine coenzyme Q, pteridines (other than folic acid), such as biopterin and the pteridine cofactor for the Mo-Fe flavoproteins, lipoic acid, and pyrroloquinoline quinone (PQQ).

1. *Queuosine*

Queuosine is included because it represents a known and novel product arising from a microbe-host interaction. Queuine is the nucleoside base, which is modified to queuosine. Queuosine resembles guanidine and is preferably utilized in some t-RNAs. The importance of this interaction has yet to be fully understood. Germ-free animals survive without a source of queuine or queuosine (Farkas, 1980).

2. *Coenzyme* Q

Although claims have been made for a nutrition requirement for coenzyme Q, more work is needed to fully clarify a true nutritional role for this compound. Ubiquinone or coenzyme Q is found in mitochondria. Coenzyme Q is structurally similar to vitamins E and K. As a quinone, coenzyme Q is ideally suited to interact with cytochromes to affect the flow of electrons in the mitochondrial respiratory chain. Coenzyme Q can be synthesized and is easily absorbed from the intestine by the same route as other fat-soluble vitamins. However, there is no known requirement for coenzyme Q in higher animals.

Of the lipophilic substances with redox cycling capacity, the ubiquinones (coenzyme Q) are a group of ubiquitous 2,3-dimethoxy-5-methyl benzoquinones substituted at the position 6 with terpenoid chains of varying lengths. In mitochondria, coenzyme Q causes two electron processes and helps initiate two single electron transfers through semiquinone intermediates. Coenzyme Q is found mainly in the mitochondrial intermembrane. Although there is no apparent dietary requirement, coenzyme Q is present in food and promoted for various putative health benefits. Coenzyme Q that is absorbed from the intestine is transported by the same transport system as vitamin E and vitamin K.

3. *Pteridines*

In animals, tetrahydrobiopterin (commonly abbreviated BH_4) is an important redox cofactor, best known for its role at the catalytic site for phenylalanine and tyrosine hydroxylases. Tetrahydrobiopterin is made in sufficient quantities from pathways related to guanine synthesis. A related cofactor is the molybdenum cofactor, also in the pterin family, a cofactor for xanthine oxidase and aldehyde oxidase (important to purine metabolism) and sulfite oxidase (important in sulfur amino acid metabolism; see the Molybdenum section in Chapter 22).

4. *Lipoic Acid*

Lipoic acid (LA) is made in the liver of most animals. This coenzyme is linked by amide linkage to lysyl residues within transacetylases (Fuchs and Zimmer, 1997). Lipoyl moieties functions in the transfer of electrons and activated acyl groups from the thiazole-moiety of thiamin pyrophosphate to CoASH. In this process, the disulfide bond is broken and dihydrolipoyl transiently generated. Reoxidation is required to reinitiate this cycle. Although most reactions in biological systems may be described as nucleophilic in

nature, reactions involving oxidized lipoic acid involve electrophilic mechanisms owing to the oxidized state of the two sulfurs in lipoic acids.

Reduction of oxidative stress by LA supplementation has been demonstrated in animal models (Fuchs and Zimmer, 1997). To determine how normal development or pathological conditions are affected by genetic alterations in the ability of mammalian cells to synthesize LA and whether dietary LA can circumvent its endogenous absence, mice deficient in lipoic acid synthase (Lias) have been generated. Mice heterozygous for disruption of the Lias gene develop normally, and their plasma levels of thiobarbituric acid-reactive substances do not differ from those of wild-type mice. However, the heterozygotes have significantly reduced erythrocyte glutathione levels, indicating that their endogenous antioxidant capacity is lower than those of wild-type mice. Homozygous embryos die by day 8 to 12 of gestation. Of nutritional interest, supplementing the diet of heterozygous mothers with LA (1.65 g/kg of body weight) during pregnancy fails to prevent the prenatal deaths of homozygous embryos. Apparently, an endogenous LA synthesis is essential for developmental survival and cannot be replaced by LA in maternal tissues and blood via the diet (Fuchs and Zimmer, 1997).

5. *Pyrroloquinoline Quinone*

Pyrroloquinoline quinone (PQQ) is a cofactor that was originally isolated from methylotrophic bacteria. PQQ is utilized in bacteria as a redox cycling cofactor. It has been shown to be present in mammalian tissue; however, its primary function is still not clear, although recent evidence suggests that gestational deficiency affects mitochondriogenesis (Steinberg *et al.,* 1994, 2003; Stites *et al.,* 2000a, 2000b, 2006). PQQ is a growth stimulant in mammals fed chemically defined diets, particularly in mice. If there is a requirement for PQQ, however, it is yet to be established. The growth response in neonates is most obvious in offspring from dams that have been nutritionally deprived of PQQ throughout their adult lives.

VI. CONCLUDING REMARKS

Vitamins evolved to serve unique and complex roles: as cofactors, as signaling agents in cells, as regulators of gene expression, and as redox and free-radical quenching agents. All natural vitamins are organic food substances found only in living things. With few exceptions, the body cannot manufacture or synthesize vitamins. They must be supplied in the diet. As is the case for any substance that is essential to a given function, all vitamins at some point in development can be viewed as limiting nutrients, the absence of which results in specific deficiency signs and symptoms.

Chapter 24

Lysosomal Storage Diseases

I. LYSOSOMAL BIOLOGY

In 1955, de Duve *et al.* named the cytoplasmic particles that contain a series of hydrolytic enzymes lytic bodies, or "lysosomes." These organelles have a single lipoprotein membrane and contain several dozen different acid hydrolase enzymes (Holtzman, 1989), which typically catalyze catabolic reactions $A\text{-}B + H_2O \rightarrow A\text{-}H + B\text{-}OH$, optimally at acid pH. Lysosomes and their "housekeeping" enzymes degrade many substrates that are found in all nucleated mammalian cells. Deficiencies of these enzymes lead to lysosomal accumulation of their substrates, thereby causing lysosomal storage disease (LSDs), many of which have been discovered and characterized in domestic animals.

In normal cells, most lysosomal hydrolases are synthesized as preproenzymes on rough endoplasmic reticulum (ER) ribosomes. Through a signal-recognition particle complex, the enzymes are translocated into the lumen of the ER where high mannose oligosaccharides are added (Fig. 24-1; reviewed in Kornfeld and Sly [2001]). These oligosaccharides are trimmed, and the glycoprotein moves to the Golgi apparatus where further shortening occurs. Further posttranslational modification results from the action of two enzymes that add a mannose 6-phosphate (M6P) marker. Deficiency in activity of these transferases can result in unique forms of LSD (e.g., mucolipidosis II in domestic shorthair cats). The M6P moiety can be recognized by two similar integral membrane glycoprotein receptors, which transfer the enzyme to the lysosome. These two receptors are (1) small and cation dependent for binding and (2) large and cation independent, which in some species also bind insulin-like growth factor II. Both receptors appear responsible for the transport of the enzymes from the Golgi apparatus via clathrin-coated vesicles to the prelysosomal/endosomal compartment. Once the lysosomal enzymes dissociate, the receptors recycle to the Golgi apparatus.

A proportion of the M6P modified enzyme in the Golgi may also leave the cell via secretory granules (Fig. 24-1). The secreted enzymes can then move from the extracellular space into the circulation. Different enzymes appear to be secreted from cells in varied amounts (Dobrenis *et al.*, 1994). Thus, the level of activity in serum of any particular enzyme is related to how much is secreted and its stability at plasma pH. Secreted enzymes can ultimately reach the lysosome of other cells because the cation-independent receptor is present in the plasma membrane on many cells (Distler *et al.*, 1979; Kaplan *et al.*, 1977; Natowicz *et al.*, 1979). Thus, enzymes that connect with this receptor can be internalized and transferred to lysosomes. This pathway provides the mechanism for therapy for lysosomal storage diseases discussed later.

Although posttranslational glycosylation is common to most lysosomal enzymes, other modifications or activator proteins are necessary for the function of a subset of the hydrolases. For example, the lysosomal sulfatases (17 in humans; 14 in rodents) undergo an additional posttranslational modification by sulfatase modifying factor 1 (SUMF-1), which converts a cysteine residue into C (alpha)-formylglycine (FGly) at the active site (Dierks *et al.*, 2005; Preusser-Kunze *et al.*, 2005). The absence

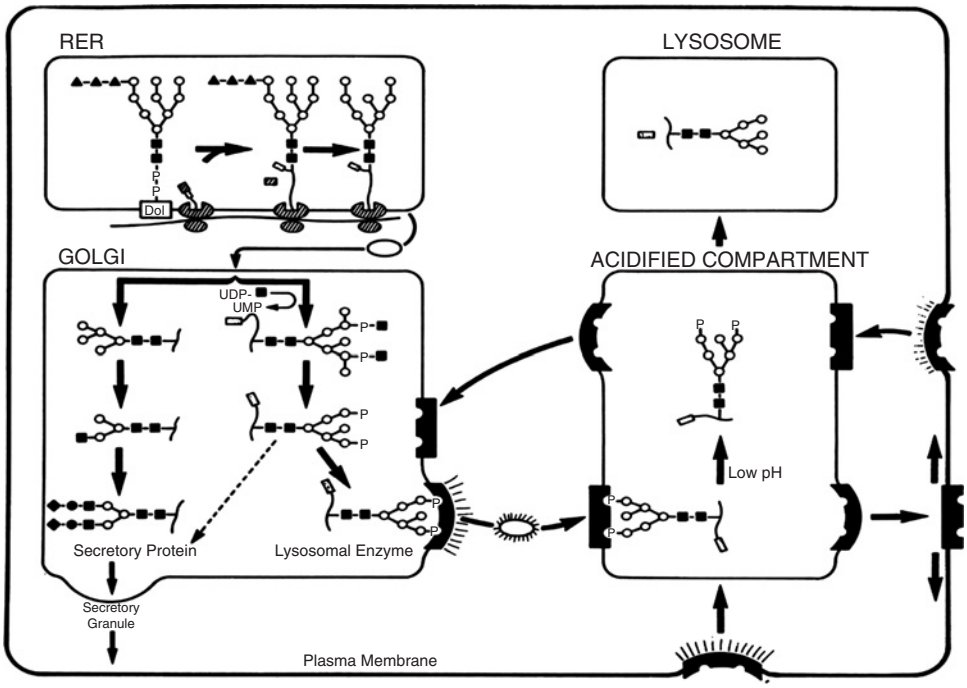

FIGURE 24-1 Schematic diagram of how lysosomal enzymes are processed and delivered to the lysosome. From Kornfeld, 1987, with permission.

of this conversion results in multiple sulfatase deficiency. A second factor, SUMF-2, which is also part of this system, apparently down-regulates SUMF-1 activity (Zito *et al.*, 2005). The degradation of sphingolipids with short hydrophilic head groups requires sphingolipid activator proteins (SAPs), which are small, nonenzymatic glycoproteins (reviewed in Sandhoff *et al.*, 2001). Deficiency in activity of SAPs is also known to cause lysosomal storage diseases.

Lysosomes degrade large complex substrates that have been taken into a cell by endocytosis or autophagy (the degradation/turnover of a cell's own molecules). The endosome containing the substrates fuses with a primary lysosome, producing a secondary lysosome, which contains the mixture of hydrolases and substrates. Degradation of most substrates occurs by the activity of a cascade of hydrolases, each step requiring the action of the previous hydrolase to modify the substrate, thereby permitting catabolism to proceed to the next enzyme step in the pathway. If one step in the process fails, further degradation ceases. For example, the glycosaminoglycans (GAGs), formerly known as mucopolysaccharides, are long molecules of repeating subunits and are, as part of proteoglycans, a component of the ground substance of the extracellular matrix. Figure 24-2 illustrates the series of hydrolases that are responsible for the sequential stepwise degradation of one of the glycosaminoglycans, dermatan sulfate. Each of the enzymes in this pathway has been described as deficient in a domestic animal causing different mucopolysaccharidosis.

II. LYSOSOMAL STORAGE DISEASES (LSDs)

The LSDs are defined as a group of individually rare genetic disorders of cellular catabolism involving the lysosome. The earliest detailed clinical reports of an LSD were in humans by Tay (1881) and Sachs (1887). Eight decades later, the stored material in "Tay-Sachs disease" was defined as GM2 ganglioside (Svennerholm, 1962); 7 years later, the enzyme that is deficient in activity (beta-hexosaminidase A) was identified (Okada and O'Brien, 1969; Sandhoff, 1969). Isolation and sequencing of the cDNA coding for the alpha subunit of beta-hexosaminidase A was reported 15 years later (Korneluk *et al.*, 1986; Myerowitz and Proia, 1984) and was quickly followed by the identification of the first of more than 50 mutations responsible for Tay-Sachs disease (Myerowitz and Hogikyan, 1986, 1987) and sequencing of the entire gene (Proia and Soravia, 1987). Similar rapid progress has been made in identifying and characterizing the molecular bases of all lysosomal diseases since the 1980s.

LSDs are inherited as autosomal recessive traits (except MPS II, which is X-linked) and result from mutations in the coding sequence of one of the acid hydrolases located in the lysosome. Point mutations, deletions, insertions, and other alterations in sequence may occur anywhere along the length of DNA coding the enzyme protein. Each individual alteration will produce a unique change in the protein affecting structure, stability, and function. Thus, these

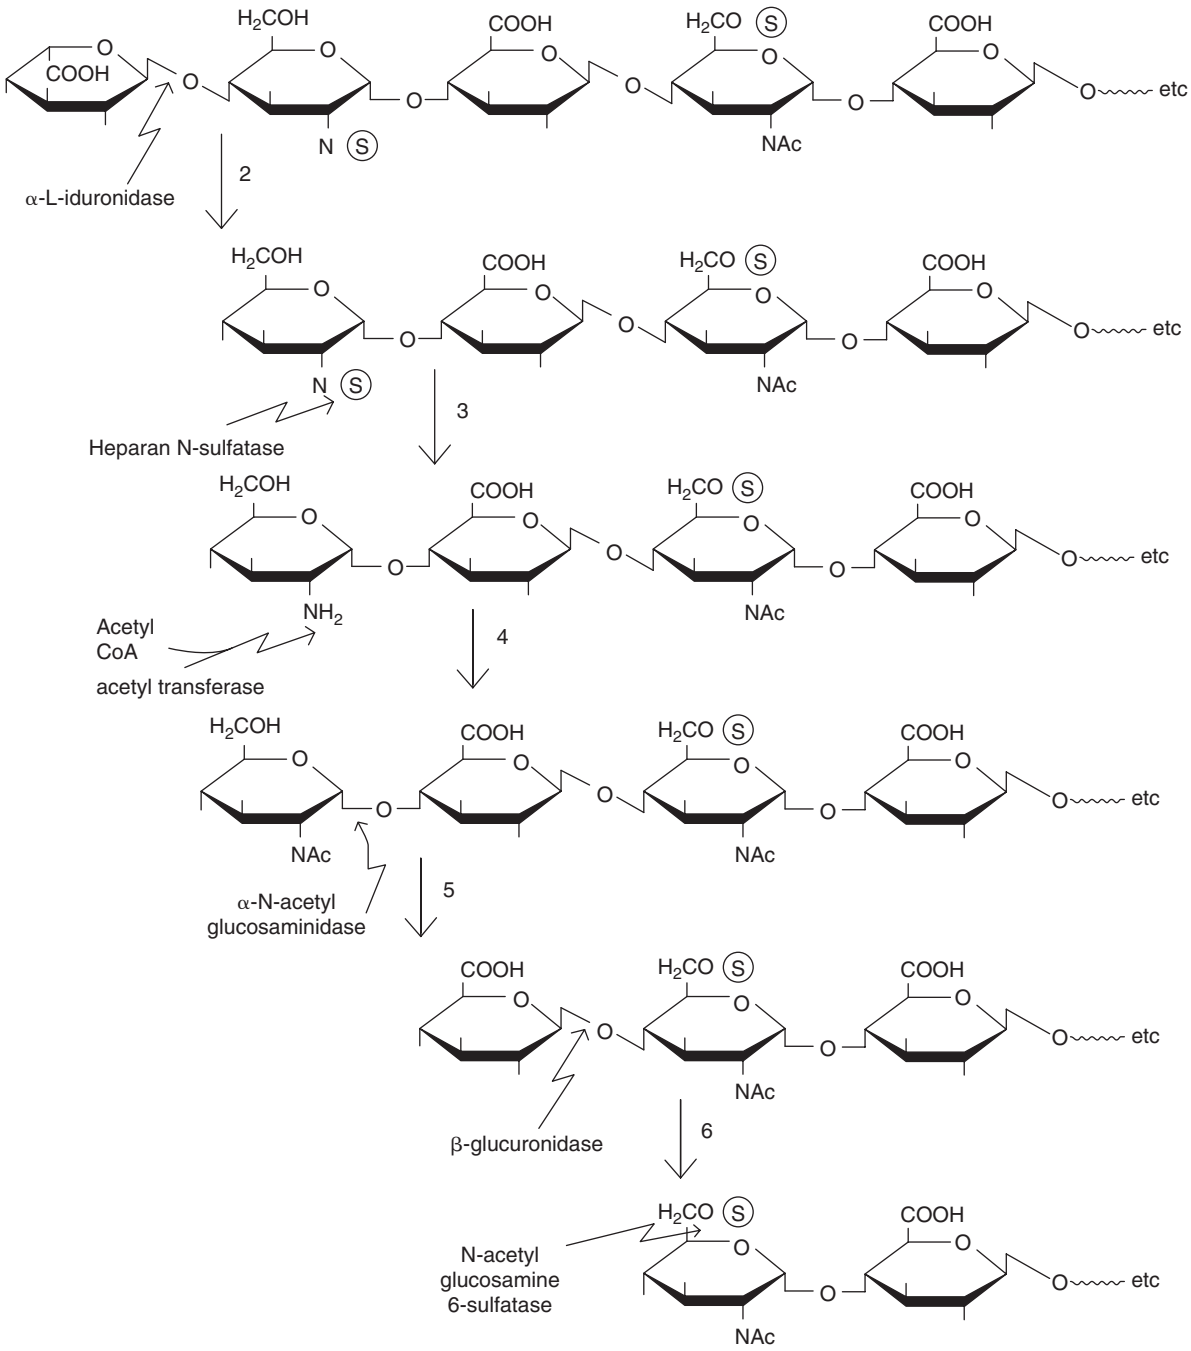

FIGURE 24-2 The stepwise degradation of the glycosaminoglycan dermatan sulfate by a series of lysosomal enzymes, all of which have been determined to be deficient in activity in domestic animals. From Neufeld and Muenzer (1995), with permission.

genetic abnormalities result in the reduction or elimination of the catalytic activity of the particular enzyme. This, in turn, results in the accumulation within the lysosome of the substrate of that enzyme (Fig. 24-3), hence the name LSD. In many LSDs, the reduction in the amount of product of the metabolic pathway does not appear to produce disease. However, the storage of cholesterol in Niemann-Pick type C disease may result in a downstream deficiency

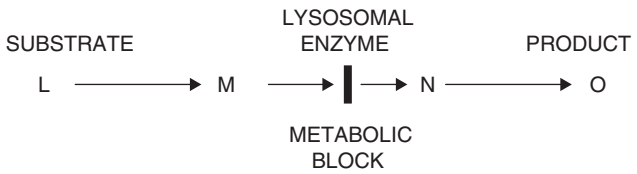

FIGURE 24-3 The reduction in catalytic activity of the enzyme, which converts M to N, results in the accumulation of M within the lysosome.

TABLE 24-1 Naturally Occurring Lysosomal Storage Diseases in Animals

Disease	Deficient enzyme	Species & selected References
Ceroid lipofuscinosis	Cathepsin D CLN2 (TTP1) CLN5 CLN6 CLN8 Undefined	American bulldogs (Awano *et al.*, 2006b), sheep (Tyynela *et al.*, 2000) Dachshund (Awano *et al.*, 2006a) Border collie (Melville *et al.*, 2005) Mice (Wheeler *et al.*, 2002), Merino and Hampshire sheep (Broom *et al.*, 1998; Cook *et al.*, 2002) English setter dog (Katz *et al.*, 2005) 18 breeds of dog including Labrador retriever (Rossmeisl *et al.*, 2003), cocker spaniel (Minatel *et al.*, 2000), miniature schnauzer (Jolly *et al.*, 1997). Polish Owczareed Nizinny (Narfstrom and Wrigstad, 1995), Tibetan terrier (Riis *et al.*, 1992), Australian cattle (Sisk *et al.*, 1990), dalmatian (Goebel *et al.*, 1988), blue heeler (Cho *et al.*, 1986), Saluki (Appleby *et al.*, 1982); Holstein cattle (Hafner *et al.*, 2005); domestic cat (Weissenbock and Rossel, 1997)
Fucosidosis	Alpha-fucosidase	English springer spaniel dog (Friend *et al.*, 1985; Healy *et al.*, 1984; Kelly *et al.*, 1983; Skelly *et al.*, 1996, 1999; Smith *et al.*, 1996)
Galactosylceramide lipidosis (globoid cell leukodystrophy; Krabbe disease)	Galactosylceramidase (galactocerebroside beta-galactosidase)	Cairn terrier dog (Austin *et al.*, 1968; Fankhauser *et al.*, 1963; Fletcher and Kurtz, 1972; Fletcher *et al.*, 1966, 1971; Hirth and Nielsen, 1967; Howell and Palmer, 1971; McGrath *et al.*, 1968; Suzuki *et al.*, 1970, 1974) West Highland white terrier dog (Fankhauser *et al.*, 1963; Fletcher and Kurtz, 1972; Fletcher *et al.*, 1971; Jortner and Jonas, 1968) Dorset sheep (Pritchard *et al.*, 1980) Twitcher mouse (Duchen *et al.*, 1980; Kobayashi *et al.*, 1980) Domestic shorthair cat (Johnson, 1970) Miniature poodle dog (Suzuki *et al.*, 1974) Beagle dog (Johnson *et al.*, 1975) Blue tick hound dog (Boysen *et al.*, 1974) Irish setter dog (Wenger *et al.*, 2001) Rhesus monkey (Luzi *et al.*, 1997)
Glucocerebrosidosis (Gaucher disease)	Acid beta-glucosidase (Glucocerebrosidase)	Sydney silky terrier dog (Farrow *et al.*, 1982; Hartley and Blakemore, 1973; Van De Water *et al.*, 1979) Sheep (Laws and Saal, 1968) Pig (Sandison and Anderson, 1970)
Glycogen storage disease II (Pompe disease)	Acid alpha-glucosidase	Lapland dog (Mostafa, 1970; Walvoort *et al.*, 1982, 1984, 1985) Domestic shorthair cat (Sandstrom *et al.*, 1969) Corriedale sheep (Manktelow and Hartley, 1975) Shorthorn cattle (Howell *et al.*, 1981; Jolly *et al.*, 1977) Brahman cattle (O'Sullivan *et al.*, 1981; Wisselaar *et al.*, 1993) Japanese quail (Fujita *et al.*, 1991; Higuchi *et al.*, 1987; Nunoya *et al.*, 1983; Suhara *et al.*, 1989)
G_{M1} Gangliosidosis	Beta-galactosidase	Siamese cat (Baker *et al.*, 1971; Farrell *et al.*, 1973; Handa and Yamakawa, 1971; Holmes and O'Brien, 1978a, 1978b) Domestic shorthair cat (Blakemore, 1972; Purpura and Baker, 1976, 1978; Purpura *et al.*, 1978) Korat cat (Baker *et al.*, 1976; Martin *et al.*, 2004) Beagle mix dog (Alroy *et al.*, 1985; Read *et al.*, 1976; Rittmann *et al.*, 1980; Rodriguez *et al.*, 1982) Springer spaniel dog (Alroy *et al.*, 1985, 1992; Kaye *et al.*, 1992) Portuguese water dog (Alroy *et al.*, 1992; Saunders *et al.*, 1988; Shell *et al.*, 1989) Frisian cattle (Donnelly *et al.*, 1973a, 1973b) Suffolk sheep (Murnane *et al.*, 1991a, 1991b, 1994) Sheep (Ahern-Rindell *et al.*, 1988a, 1988b, 1989)

of neurosteroids (Griffin *et al.*, 2004; Mellon *et al.*, 2004). LSDs are classified by the primary substrates that accumulate and are defined by the individual enzyme that is deficient in activity. For example, the mucopolysaccharidoses (MPSs) are a group of diseases resulting from defective catabolism of GAGs (previously mucopolysaccharides). Each of the MPSs is caused by impaired function of one of 12 enzymes required for normal GAG degradation. In humans, these disorders were initially defined by clinical phenotype then by the particular GAGs (heparan, dermatan, chondroitin, keratan sulfates) present in the patient's urine. Now, in addition to defining the diseases by the specific enzyme deficiency, many are subdivided by the particular mutation in the coding sequence of the gene responsible for the defect.

Different mutations of the same gene may produce similar diseases or somewhat varied degrees of disease as is seen in humans with MPS IH (Hurler) and MPS IS (Scheie), with and without CNS disease, respectively (Neufeld and Meunzer, 2001), and in cats with MPS VI

(Crawley *et al.*, 1998). Affected individuals can be either homozygous for the same mutation in both alleles (typical of most LSDs in animals) or heteroallelic (having one mutation in the allele on one chromosome and a different mutation in the allele on the other chromosome [Crawley *et al.*, 1998], common in humans with LSDs). In addition, if the substrates being stored in different diseases have similar pathological effects, defects in different lysosomal enzymes may produce similar diseases, as has been described in humans and animals with MPS III A-D (Aronovich *et al.*, 2001; Bhaumik *et al.*, 1999; Ellinwood *et al.*, 2003; Fischer *et al.*, 1998; Jones *et al.*, 1998; Neufeld and Meunzer, 2001; Yogalingam *et al.*, 2002). Furthermore, it is now recognized that the expression of lysosomal genes, similar to other inborn errors of metabolism, is also influenced by other (modifying) genes and the environment, which explains the phenotypic variation in animals homozygous for the same mutation. Finally, the clinical features and disease course of animals with all types of LSDs closely resemble their human counterparts.

Animals of several species were diagnosed clinically and pathologically as having an LSD before recognizing that the group of diseases were caused by deficiencies in hydrolase activity. Because of the distinctive central and peripheral nervous system lesions, the first of these diseases to be described was globoid cell leukodystrophy in Cairn and West highland white terriers (Fankhauser *et al.*, 1963). These two related dog breeds (primarily a color variation) are now known to have the same mutation in the gene coding for galactosylceramidase (Victoria *et al.*, 1996), which apparently originated in the 19th century from an ancestor common to these two breeds that diverged around the beginning of the 20th century. The first definitive discovery of an enzyme deficiency in a nonhuman mammal was GM1 gangliosidosis in a Siamese cat by Baker and colleagues in 1971 (Baker *et al.*, 1971). Since then, naturally occurring LSDs defined by a deficiency in lysosomal enzyme activity have been recognized in cats, cattle, dogs, goats, mice, pigs, rats, horses, sheep, and two avian species, emus and flamingos (Table 24-1).

Additional storage diseases do not involve lysosomal enzymes and, thus, are not strictly LSDs, but some have been included in Table 24-1. These include glycogen storage disease IV Niemann-Pick disease C, and ceroid lipofuscinoses. Many mouse models of LSDs have been created by gene knockout technology, but have not been included in Table 24-1. In creating murine knockouts, the phenotype has ranged from essentially the same as in humans, to no disease, to being fatal soon after birth. New knockout models of LSDs will continue to be created in mice to learn more about the pathogenesis of these debilitating disorders and to evaluate therapy. However, companion animals appear often to be better disease homologues and are important to translating novel therapies to humans.

III. PATHOGENESIS

In LSDs, the continued presentation of substrates to the cell and their lack of degradation result in their storage and swelling of the lysosomes. By electron microscopy, lysosomes within the cytoplasm can be seen as membrane-bound inclusions containing the stored substrate (Fig. 24-4). As the lysosomes become larger, they can be seen with light microscopy (Fig. 24-5). However, in some LSDs, the accumulated substrate may be lost during tissue processing, leaving empty vacuolar artifacts. The accumulation of the primary substrate for a particular enzyme pathway may also interfere with other lysosomal hydrolases necessary for different catabolic pathways (Kint *et al.*, 1973), thereby leading to the secondary accumulation of additional substrates. As more substrates accumulate, the lysosomes occupy more of the cytoplasm (Fig. 24-6). This increase in the number and size of lysosomes may obscure the other

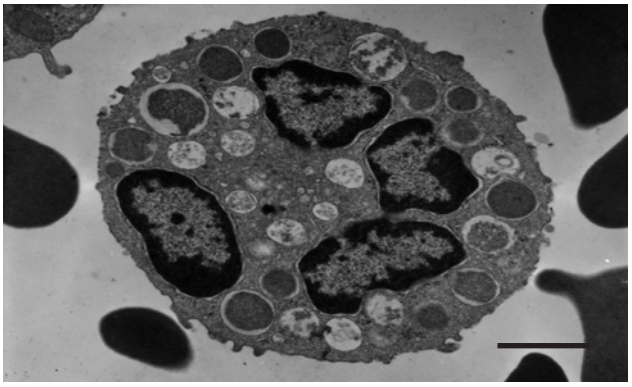

FIGURE 24-4 An electron micrograph of a polymorphonuclear leukocyte from a cat with MPS VI showing the enlarged lysosomes containing granular material (dermatan sulfate). Bar = 1u.

cellular organelles and may deform the nuclear outline. As the process continues, the affected cells enlarge, which is one cause of organomegaly. Just as with the CNS, cartilage, and bone, pathophysiology is probably not solely related to the increase in the cell, tissue, or organ size. The storage of GAGs within the mitral heart valve causes the normally fusiform cells to become rounded (Fig. 24-6). This, in turn, causes the valve leaflet and cordae tendinea to become thick (Fig. 24-7), interfering with normal valve function and producing mitral regurgitation. Similarly, storage within the cells of the cornea (Fig. 24-8) results in reflection and refraction of light, producing the cloudiness observed grossly and by ophthalmoscopy (Fig. 24-9). However, in the cornea there is also an abnormality in collagen biosynthesis resulting in larger fibrils that are more widely spaced than normal (Alroy *et al.*, 1999), and the cornea of the MPS VI cat, rather than being thicker because of increased cell size, is thinner than normal (Aguirre *et al.*, 1992).

In many LSDs, the CNS contains swollen neurons (Fig. 24-10) with lysosomes that contain lamellar substrate

(Fig. 24-11). The pathogenesis of the CNS lesions includes the development of meganeurites and neurite sprouting, which appear correlated to alterations in ganglioside metabolism (Purpura and Baker, 1977, 1978; Purpura *et al.*, 1978; Siegel and Walkley, 1994; Walkley, 1988; Walkley *et al.*, 1988, 1990, 1991). Gangliosides, whether stored as a primary substrate (in G_{M1} and G_{M2} gangliosidosis) or secondarily (in MPS I and III), appear to stimulate the development of neurite sprouts with synapses. The presence of new neurites and their synapses apparently plays a role in the CNS dysfunction of these diseases (Walkley, 2003).

Mucolipidosis II, also known as I-cell disease (named for the inclusions seen in cultured fibroblasts (Tondeur *et al.*, 1971), is an exception to the usual pathogenesis of LSDs (reviewed in Kornfeld and Sly [2001]). Studies of fibroblasts from patients with this disease were seminal in providing insight into the M6P transport system (Hickman and Neufeld, 1972). This disorder results from a failure in the first enzyme in the pathway responsible for the post-translational phosphorylation of the mannose moiety of most lysosomal hydrolases (Hasilik *et al.*, 1981; Reitman *et al.*, 1981). The consequence of a defect in this phosphotransferase enzyme is to produce lysosomal enzymes that lack the signal responsible for efficiently directing the enzymes to the lysosome by the M6P receptor-mediated pathway. Thus, little amounts of the enzymes reach the lysosomes, whereas large amounts are secreted extracellularly into the plasma. Because the phosphotransferase activity has been difficult to measure, the diagnosis of I-cell disease has usually been reached by demonstrating the low intracellular activity of most lysosomal enzymes and consequent high enzyme activity in serum. The gene for this phosphotransferase has been cloned for both humans and cats, and mutations have been identified (Giger *et al.*, 2006; Kudo *et al.*, 2006). Although a clinical and pathological phenotype that combines all of the lysosomal storage diseases would be expected in I-cell disease, this does not occur. Although I-cell is a severe disease in children and cats, most of the pathology is found in mesenchymally derived cells; Kupffer cells and hepatocytes are essentially normal (Martin *et al.*, 1975, 1984; Mazrier *et al.*, 2003). Although mental retardation is present in children, and death occurs before adulthood, there is relatively little CNS pathology (Martin *et al.*, 1984; Nagashima *et al.*, 1977). All cell types examined to date have been deficient in phosphotransferase activity, yet many organs (including liver, spleen, kidney, and brain) still have near normal intracellular lysosomal enzyme activities. This observation indicates that there is either an intracellular M6P-independent pathway to lysosomes, or that secreted enzymes are internalized by cell surface receptors that recognize other carbohydrates on enzymes, such as nonphosphorylated mannose (Waheed *et al.*, 1982). An M6P-independent pathway to the lysosome has been demonstrated for beta-glucocerebrosidase and acid phosphatase (Peters *et al.*, 1990; Williams and Fukuda, 1990).

IV. CLINICAL SIGNS

As a group, LSDs are chronic, progressive disorders generally with an early age of onset and characteristic clinical signs. The predominant clinical signs are related to the CNS, skeleton, joints, eye, cardiovascular system, and organomegaly. Most LSDs can be divided clinically into those with or without CNS involvement. Head and limb tremors that progress to gait abnormalities, spastic quadriplegia, seizures, and death are commonly observed. The disorders in animals with marked CNS signs include fucosidosis, galactosylceramide lipidosis, gangliosidosis, mannosidosis, MPS III, and sphingomyelinosis.

Non-CNS clinical signs associated with lysosomal storage disorders include failure to thrive, growth retardation (Fig. 24-12), umbilical hernia, corneal clouding, hepatosplenomegaly, cardiac murmurs, renal dysfunction, and skeletal abnormalities including facial dysmorphia and vertebral, rib, and long bone deformities (Fig. 24-13). The MPS disorders, in general, have more organ systems affected than the other diseases. The age of onset and severity of clinical signs are usually relatively consistent for a particular disease in animals; however, some variability can exist even in a family having the same disease-causing mutation. In research colonies of dogs and cats with LSDs kept in a relatively consistent environment, the explanation for variation in clinical signs rests with the variable genetic background (modifying genes) on which the mutation is expressed.

Most LSDs are manifest within a few months after birth, with some evident at birth or before weaning and fewer with adult onset (canine MPS IIIA and B). In severely

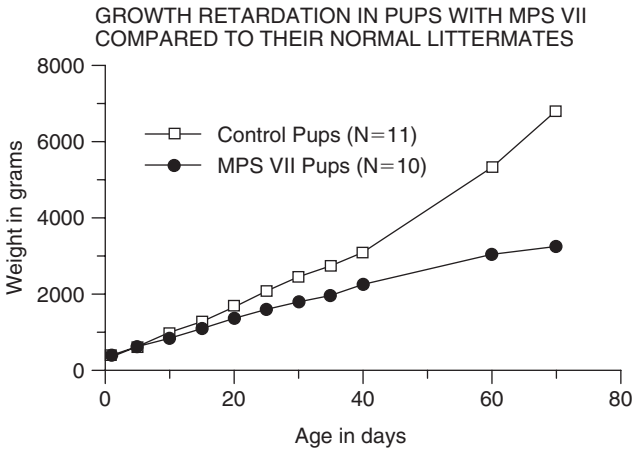

FIGURE 24-12 This graph illustrates the growth retardation often seen in animals with lysosomal storage disorders.

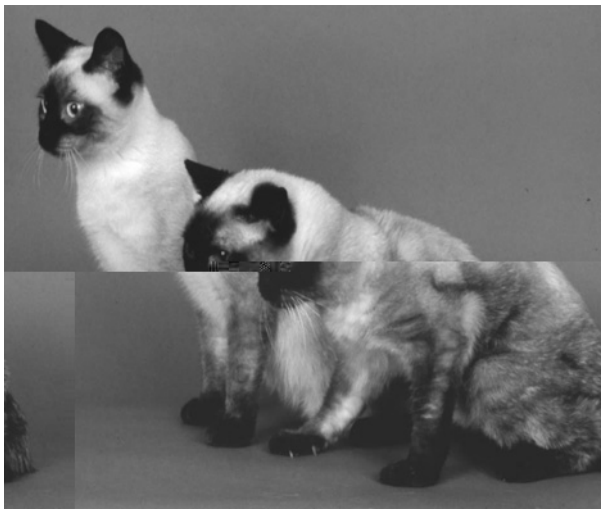

FIGURE 24-13 A normal Siamese cat next to a littermate with MPS VI. Note the outward manifestations of the skeletal abnormalities: flattened facies, small size, low posture associated with fusion of the cervical and lumbar spine.

affected animals, death often occurs at birth or before weaning.

In humans with LSDs, although frequently no consistent, specific mutations in some diseases have been associated with a particular pattern of clinical severity and progression (genotype-phenotype correlations). Null mutations that produce little RNA or unstable RNA resulting in no enzyme protein synthesis (cross-reacting material [CRM] negative) usually have a severe phenotype. Although specific mutations have been identified for several LSDs in animals, there is still not enough information to be useful in prognosis.

V. DIAGNOSIS

The approach to a diagnosis of an LSD includes a complete history and physical examination with evaluation of the chest, abdomen, CNS, skeleton, and eyes. Laboratory tests should include a complete blood count with evaluation of granulocyte and lymphocyte morphology (cytoplasmic inclusions), skeletal radiographs, and urine screening for abnormal metabolites, particularly GAGs and oligosaccharides. Fresh EDTA blood or fresh-frozen serum can be used to assess lysosomal enzyme activities. Establishing a fibroblast culture from a skin biopsy and a fresh-frozen liver biopsy may be helpful for further biochemical analyses. The disease may progress quickly, and the diagnosis may only follow a complete postmortem examination.

A pedigree analysis should be performed as part of the history to determine information about the inbreeding of the parents and the presence of other family members with similar clinical signs or that died early. As most LSDs are inherited as autosomal recessive traits, parents are often related and are carriers (heterozygotes) but are clinically (phenotypically) normal. On average, one-fourth of the offspring of heterozygous parents are affected, two-thirds of unaffected offspring are carriers, and other relatives may also be affected (Fig. 24-14).

Abnormal metabolites may be found in urine and their presence points toward specific metabolic pathways that warrant further evaluation. A metabolic screen of urine (Fig. 24-15) (Giger and Jezyk, 1992; Jezyk *et al.*, 1982) for GAGs is a relatively simple and inexpensive approach to identify the mucopolysaccharidoses and some cases of gangliosidosis (toluidine blue or MPS spot test; Fig. 24-16). Thin layer chromatography of urinary oligosaccharides is helpful to identify mannosidosis. Urine samples to be evaluated should be kept refrigerated or frozen and sent to an appropriate laboratory.[1]

A final diagnosis for LSDs requires the demonstration of a particular enzyme deficiency by either determining the lack of enzyme activity or a disease-causing mutation in an enzyme gene; these tests do not only identify affected animals but are also helpful in identifying carriers. Enzyme assays using artificial substrates can usually be performed on serum, white blood cells, cultured fibroblasts, or liver. Generally, there is a profound deficiency in activity of the enzyme, making the diagnosis straightforward. In addition, the activities of other lysosomal enzymes in the cells or tissues are frequently higher than normal. The biochemical status of the clinically normal parents should be evaluated when possible. In an autosomal recessive disease, heterozygous parents are expected to have half-normal activity of the enzyme in question because each parent carries one normal and one mutant allele. Although in a population, heterozygotes (carriers) have on average half-normal

[1]One such laboratory is the Metabolic Screening Laboratory, Section of Medical Genetics, Veterinary Hospital of the University of Pennsylvania, 3900 Delancey Street, Philadelphia, PA 19104-6010. A complete history including signalment of the animal should be included with the samples (http://www.upenn.edu/research/penngen).

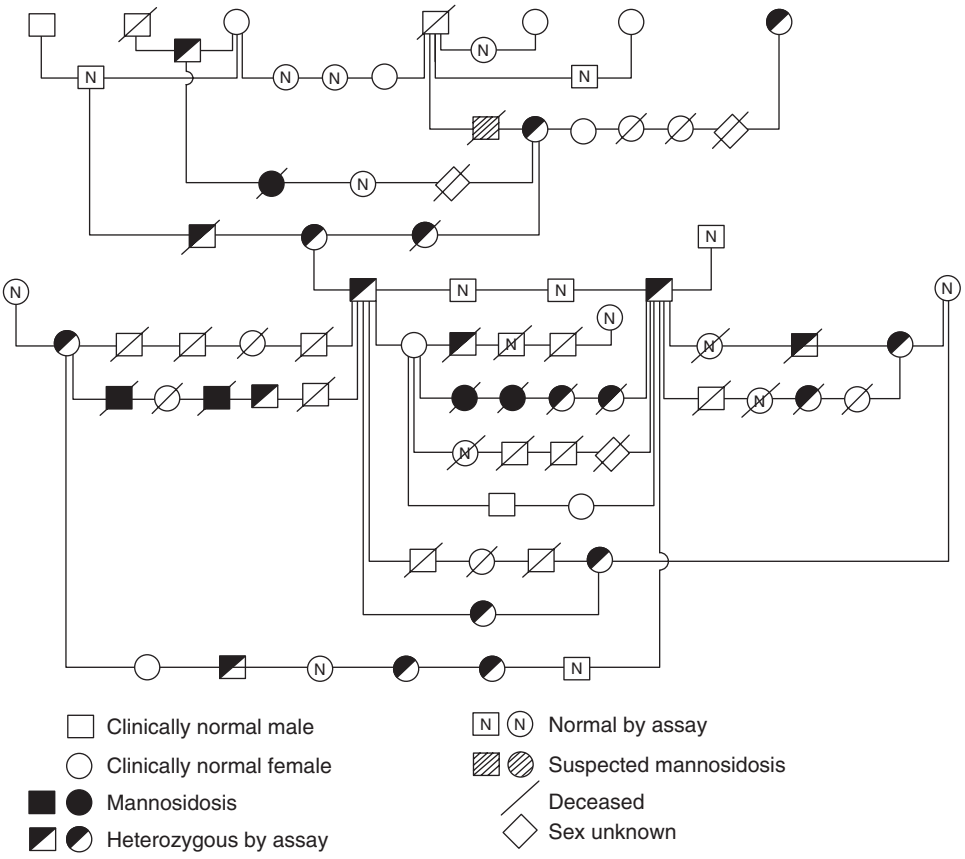

FIGURE 24-14 The pedigree of a family of cats with alpha-mannosidosis.

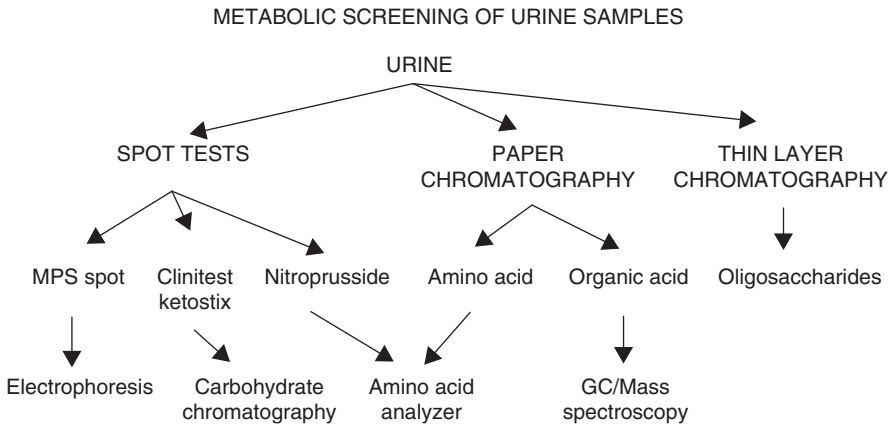

FIGURE 24-15 The scheme used to detect metabolic diseases, including some lysosomal storage disorders, by examining compounds present in urine.

activity, there is overlap between the ranges for enzyme activity values from normal and obligate heterozygous animals (Fig. 24-17). Thus, accurate determination of an asymptomatic individual as normal or a carrier may be difficult with an enzyme assay alone but can best be achieved by molecular DNA tests for the specific mutation in those diseases and families where the mutation has been identified.[2]

An animal with clinical signs suspected of having an LSD that dies or requires euthanasia should have a complete postmortem examination, including the CNS, skeletal, and ocular

[2] One such laboratory is the Josephine Deubler Genetic Disease Testing Laboratory, Section of Medical Genetics, Veterinary Hospital of the University of Pennsylvania, 3900 Delancy Street, Philadelphia, PA 19104-6010 (http://w3.vet.upenn.edu/research/centers/penngen/services).

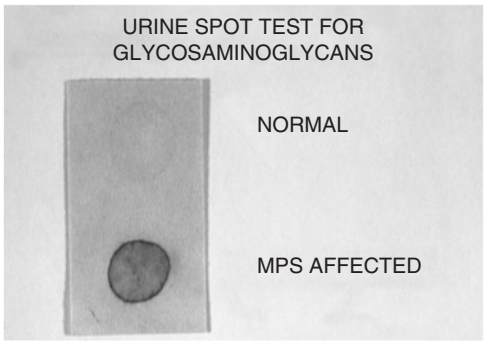

FIGURE 24-16 The results of a urine spot test detecting abnormal amounts of glycosaminoglycans in the urine of animals with MPS.

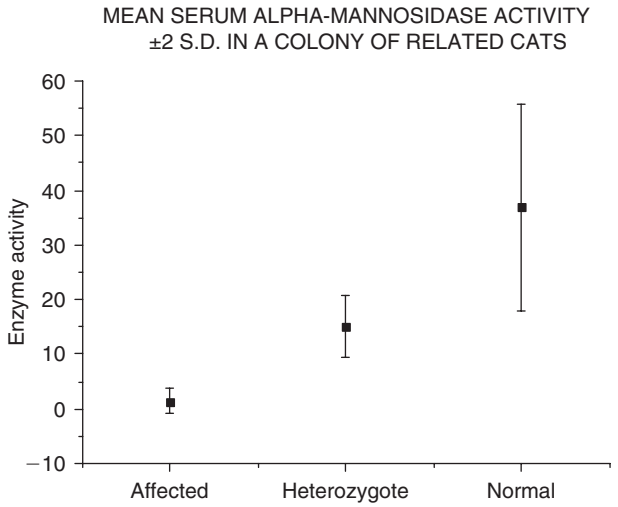

FIGURE 24-17 Serum alpha-mannosidase activity of a colony of cats illustrating the overlap that exists between normal and heterozygous animals. Although heterozygote detection is possible in a population, detection is difficult for an individual. Molecular techniques overcome these difficulties in carrier detection when the mutation is known.

systems. Liver should be frozen as quickly as possible for subsequent determination of accumulated substrate, enzyme activities, and RNA and DNA analyses. Fibroblast cultures can be established from skin, linea alba, or pericardium (using sterile technique) for future studies that may require living cells. Liver, brain, and other tissues should be preserved in formalin, and samples should be taken for thin section and electron microscopy (in glutaraldehyde-paraformaldehyde), particularly from the liver and CNS.

VI. THERAPY

The combination of secretion of lysosomal enzymes by cells and uptake of enzymes by diseased cells via the M6P receptor system forms the basis for the present approaches to therapy for the LSDs. Providing a source of normal enzyme to abnormal cells will permit that enzyme to be taken up by the plasma membrane receptor, resulting in delivery of the normal enzyme to the lysosome where it can catabolize stored substrate (except for mucolipidoses). Fortunately, the amount of enzyme needed in the lysosome for sufficient function and, thus, phenotypic correction of an individual cell is only a small proportion of normal. The three approaches to providing normal enzyme to a patient's cells are (1) enzyme replacement therapy (ERT), (2) bone marrow transplantation (BMT), and (3) gene therapy. In general, the most difficult target tissue in the LSDs is correction of the CNS lesions. Approximately 60% of LSDs have a CNS component, for which systemic therapy is limited by the blood-brain barrier. Successful treatment of the neuropathic LSDs will require direct therapy to the CNS or systemic therapy that crosses the blood-brain barrier. Animal models have been used extensively to evaluate these approaches to therapy for LSDs in humans. Although these novel therapies could be adapted for domestic animals, supportive care is generally used in clinical practice and emphasis is placed on prevention of the production of affected animals in future generations.

A. Enzyme Replacement Therapy (ERT)

The efficacy of the parenteral injection of purified recombinant enzyme has been tested in various animal models of LSDs, including MPS VII mice, MPS I dogs and cats, MPS VI cats, and glycogen storage disease in Japanese quail (Ellinwood *et al.*, 2004; Haskins *et al.*, 2002). In knockout mice, enzyme derived from rabbit milk or from Chinese hamster ovary cells has been shown to be useful (Ioannou, 2000; Kakkis *et al.*, 1996, 2001; Wraith, 2001). Today, ERT by intravenous infusion is the standard therapy for non-neuronopathic Gaucher disease in human patients and is available or under evaluation for the treatment of Fabry disease, Pompe disease, MPS I, MPS II, and MPS VI.

B. Bone Marrow Transplant (BMT)

Heterologous BMT as therapy for LSDs has been performed for decades (reviewed in Brochstein [1992], Haskins *et al.* [1991], Hoogerbrugge and Valerio [1998], Krivit *et al.* [1999], and O'Marcaigh and Cowan [1997]). This approach provides both normal bone marrow and bone marrow-derived cells, which are available to release enzyme continuously for uptake by other deficient cells. In addition, some monocyte-derived cells can cross the blood-brain barrier, becoming microglia and secreting an enzyme that can be available to neurons. BMT in animal models of LSDs has been carried out in MPS VII mice, mannosidosis, and mucolipidoses II cats, GM2 gangliosidosis mice, MPS VI cats, and the MPS VII dog, among others (Haskins, 1996; Haskins *et al.*, 1991). A combination of neonatal ERT followed by BMT at 5 weeks of age in MPS VII mice had positive long-term effects (Sands *et al.*, 1997).

C. Gene Therapy

The most striking clinical results of gene therapy involving an LSD have been those seen in a series of neonatal gene transfer studies conducted using viral vectors in the murine and canine models of MPS VII documenting significant improvement of cornea, joint, and cardiac disease (Daly *et al.*, 1999, 2001; Ponder *et al.*, 2002; Xu *et al.*, 2002a, 2002b). In spite of the rarity of MPS VII (1/250,000 live births in humans), these disease models have become a paradigm for LSDs in general because of the ability to detect the normal enzyme (β-glucuronidase) activity directly using a histochemical technique. Intracranial injection of vector carrying the feline alpha mannosidase gene has produced remarkable clinical improvement in affected cats (Vite *et al.*, 2005).

ACKNOWLEDGMENTS

The authors wish to thank Dr. Donald F. Patterson for his vision and for establishing the first Section of Medical Genetics in a veterinary school; Dr. Peter Jezyk for developing a metabolic screening laboratory for animals; Mr. James Hayden for the illustrations; Ms. Ping Wang, Ms. Marisa Van Hoeven, and Ms. Angie Huff for metabolic and enzyme analyses; Drs. Cathy Just and Meg Weil; Ms. Patricia O'Donnell; many Medical Genetics residents; and a cadre of veterinary students for animal care. Supported by NIH grants RR02512, DK25795, and DK54481.

Chapter 25

Tumor Markers

Michael D. Lucroy
VCA Veterinary Specialty Center
Indianapolis, Indiana

I. INTRODUCTION

Biomarkers, particularly tumor markers, represent an exciting tool for the clinical discipline of oncology. However, as various markers of disease, including physiological, biochemical, and genetic changes, are identified, they may become more than useful diagnostic tests. These biomarkers may also play a role in drug discovery and development and become useful tools for predicting the response to therapy and prognosis.

To help address the issues surrounding biomarkers and their application to various disciplines of clinical medicine and biomedical research, the National Institutes of Health (NIH) formed a working group on definitions to develop a set of preferred terms and descriptions, along with a conceptual model, that could be broadly applied to the increasing use of biomarkers. The working group defined a biomarker as an objectively measured and evaluated characteristic that is an indicator of a normal biological processes, a pathogenic process, or a response to a therapeutic intervention (Downing, 2000). The NIH Working Group on Definitions also characterized several important applications for biomarkers including their use for diagnosis, for staging disease, as indicators of disease risk, and as tools to predict and monitor clinical responses to therapy (Downing, 2000).

This chapter focuses on how various biomarkers have an application to cancer management in veterinary medicine. Ideally, in addition to the attributes listed in the introduction, tumor markers should be both sensitive and specific for the detection of cancer, to minimize both false-positive and false-negative test findings, and they should use methodology that is minimally invasive to increase acceptance and compliance by animal owners. Tumor markers should also reflect the total tumor burden, identify tumor recurrence after treatment, and be unaffected by cancer treatment or adverse events associated with cancer treatment. Tumor markers should be reproducible among laboratories and have a well-defined reference range to distinguish between health and disease. In human medicine, testing for tumor markers is recommended only in situations where it is demonstrated to result in a better patient outcome, increased quality of life, or reduced overall cost of care (Duffy, 2004).

The rapid technological advances in immunology, biochemistry, and cell and molecular biology will continue to offer new opportunities to evaluate candidate tumor markers. However, few tumor markers, including those that are

commonly used in veterinary medicine, have been rigorously tested. To determine whether a candidate tumor marker has clinical utility, it is vital that it undergo critical evaluation. In evidence-based medicine, there are several criteria for interpreting the usefulness of a diagnostic test (Jaeschke *et al.*, 2002). First, it should be useful for situations or cases where clinicians routinely face diagnostic uncertainty. For example, the diagnostic evaluation of hematuria in an older dog is one situation in which an effective tumor marker would be highly useful. Second, candidate tumor markers should be blindly evaluated against an independent "gold standard" diagnostic test in cancer patients, sick noncancer patients, and healthy patients. Only after the usefulness of a tumor marker has been established can clinicians begin to determine how effectively the test result and its interpretation will improve patient management. The likelihood ratio (Letelier *et al.*, 2002) is one tool that can help clinicians interpret and apply test results, and it may be useful to apply to veterinary tumor markers. Briefly, the clinician must have an idea about the patient's probability for having cancer based on signalment, history, physical findings, and other factors before tumor marker testing. Given knowledge of the likelihood of a high test value occurring in a patient with cancer compared to the likelihood of a high test value occurring in a patient suspected of cancer that was later ruled out, it is possible to calculate the posttest probability for the patient having cancer given a high, low, or intermediate test result. For the interested reader, the Evidence-Based Medicine Working Group has detailed the critical evaluation of diagnostic tests, results interpretation, and application to clinical patients (*Users' Guide to the Medical Literature: A Manual for Evidence-Based Clinical Practice*, 2002).

Historically, using a broad definition, veterinary tumor markers have included various molecules found in serum, flow cytometry, proliferation and apoptosis markers, immunohistochemistry, cytochemistry, and cytogeneticis. With the advent of new technologies, molecular markers of cancer will become more important in human and veterinary oncology. Likewise, the explosion of the "-omics," including genomics, proteomics, and metabolomics, may also be important to the diagnosis and management of cancer in the future. Each of these issues will be considered in turn.

II. SERUM TUMOR MARKERS

A. Oncofetal Proteins

Oncofetal proteins originate within tumor cells and enter the bloodstream either by secretion from the tumor or as a breakdown product of tumor cells. Normally oncofetal proteins are present during embryogenesis and may increase with certain cancers, making them potentially useful tumor markers. *Carcinoembryonic antigen* (*CEA*) and *alpha-fetoprotein* (*AFP*) are the most widely used oncofetal protein tumor markers (Garrett and Kurtz, 1986). CEA has been well studied in human medicine, and since the 1970s it has been recognized as a useful marker for cancers of the lung, colonrectum, breast, ovary, and prostate gland (Go, 1976). CEA is the most useful tumor marker to distinguish benign from malignant pleural effusions (Shirit *et al.*, 2005). Preoperative serum CEA levels may also predict survival in human colorectal cancer patients (Park *et al.*, 2005). In veterinary medicine, CEA has received little attention, and its role as a tumor marker in domestic animal species remains undefined.

In humans, AFP is commonly used to diagnose hepatocellular carcinoma and predict its prognosis (Zhou *et al.*, 2006). AFP has been measured in the serum of cancer-bearing dogs (Hahn and Richardson, 1995). However, in this report, the mean serum concentration of AFP in dogs with various malignancies was not significantly different from the mean serum AFP concentration of the 16 dogs without cancer. A single dog with hepatic involvement with lymphoma had a serum AFP concentration >225 ng/ml, suggesting AFP may have a role for diagnosing primary or secondary hepatic cancer in the absence of other serum biochemical abnormalities. Indeed high serum concentrations (>250 ng/ml) of AFP have been detected in a small number of dogs with primary liver tumors (Lowseth *et al.*, 1991). Because serum AFP concentration is higher in canine hepatocellular carcinoma compared to other hepatic diseases, it may be a useful tool for diagnosing hepatocellular carcinoma in dogs (Yamada *et al.*, 1999).

In a study of serum AFP concentrations in healthy dogs and dogs with multicentric lymphoma (Lechowski *et al.*, 2002), the mean serum AFP concentration was higher in dogs with lymphoma compared to the healthy dogs. Serum AFP concentration was also found to increase with advancing clinical stage of lymphoma, and decrease to levels similar to normal dogs as the lymphoma went into remission with chemotherapy. These observations suggest serum AFP may be a useful biomarker for determining lymphoma remission in the dog and potentially an early indicator of relapse. Serum AFP has not been carefully evaluated as a tumor marker in other domestic species.

B. Hormones and Ectopic Hormones

1. *Inhibin*

Inhibin is a nonsteroidal hormone that is involved in the follicular phase of the human menstrual cycle (Groome *et al.*, 1996). Inhibin has also been identified as a regulatory hormone in the follicular phase of the equine estrous cycle (Medan *et al.*, 2004). Serum inhibin concentrations have been shown to be elevated in mares with granulosa theca cell tumors (GTCT) (Christman *et al.*, 1999). Measuring inhibin concentrations can be helpful in diagnosing equine GTCT, especially if serum testosterone concentrations are not elevated, and distinguishing GTCT from other diseases of the ovary. Increased serum inhibin concentrations have

also been identified in dogs with Sertoli cell tumors, making it a potentially useful marker for identifying testicular tumors (Grootenhuis *et al.*, 1990).

2. *Serum Parathyroid Hormone*

Increased serum parathyroid hormone (PTH) in the presence of hypercalcemia has been considered sufficient for the diagnosis of primary hyperparathyroidism. However, a retrospective case-control study suggests that normal PTH concentrations in the presence of hypercalcemia are an inappropriate physiological response by the parathyroid gland and are also consistent with primary hyperparathyroidism (Feldman *et al.*, 2005). Although primary hyperparathyroidism is an uncommon disease of dogs and cats, both adenomas and carcinomas of the parathyroid glands are reported in the literature and should be considered among the differential diagnoses.

3. *Parathyroid Hormone-Related Protein*

Hypercalcemia of malignancy is a well-recognized paraneoplastic syndrome in animals. Hypercalcemia of malignancy may arise from local bone resorption stimulated by metastatic bone lesions or through endocrine factors that disrupt normal calcium homeostasis (Clines and Guise, 2005). Ectopic production of PTH by tumors is a rare phenomenon, and most humoral hypercalcemia of malignancy may be explained by the inappropriate production of parathyroid hormone-related protein (PTHrP) by a variety of tumors. Canine PTHrP is similar in structure and function to PTH (Rosol *et al.*, 1995). In dogs, PTHrP has been implicated in hypercalcemia associated with apocrine gland adenocarcinoma of the anal sac and lymphoma (Rosol *et al.*, 1992), melanoma (Pressler *et al.*, 2002), thymoma (Foley *et al.*, 2000), and poorly differentiated carcinoma. Increased serum PTHrP concentration has been identified in a small number of cats with humoral hypercalcemia of malignancy associated with a variety of carcinomas and lymphoma (Bolliger *et al.*, 2002). Increased serum PTHrP has also been described in a horse with hypercalcemia and multiple myeloma (Barton *et al.*, 2004).

4. *Thyroxine/Thyroglobulin*

Estimates of the proportion of dogs with thyroid masses that are revealed to be carcinoma range from 51% to 100% (Scarlett, 1994). It is reported that 70% of dogs with thyroid carcinomas have increased concentrations of serum thyroglobulin, although these findings were not strongly correlated with serum thyroxine (T_4) concentrations (Verschueren *et al.*, 1991). It is generally accepted that most dogs with thyroid carcinomas are euthyroid, but the contemporary peer-reviewed literature is sparse with respect to the prevalence of functional thyroid tumors in dogs.

In cats elevated serum total or free T_4 is generally diagnostic for hyperthyroidism, although some cats with nonthyroidal disease may have elevated free T_4 (Peterson *et al.*, 2001). Cats with equivocal results may require additional evaluation with the triiodothyronine (T_3) suppression test to confirm the diagnosis of hyperthyroidism (Graves and Peterson, 1994). Unlike dogs, most cats with hyperthyroidism have a functional adenoma or adenomatous hyperplasia rather than an underlying thyroid carcinoma. Serial T_4 determinations are useful to monitor response to therapy and detect a relapse following radioiodine treatment (Peterson and Becker, 1995).

5. *Adrenocorticotropin Hormone/Cortisol*

Hyperfunctioning adrenocortical tumors can be diagnosed by measuring basal plasma cortisol concentration or changes in plasma cortisol concentration from a variety of provocative tests using natural or synthetic adrenocorticotropin hormone (ACTH) stimulation or dexamethasone suppression. The measurement of endogenous ACTH may help distinguish primary adrenal disorders from those secondary to pituitary gland dysfunction. The ratio of the precursor hormones pro-opiomelanocortin and proadrenocorticotropin has been recently correlated to the size of pituitary tumors in dogs with hyperadrenocorticism (Granger *et al.*, 2005). Measurement of basal ACTH and the use of provocative testing with ACTH have been reported for the diagnosis of equine pituitary pars intermedia adenomas (van der Kolk *et al.*, 1995).

6. *Sex Steroid Hormones*

Measurement of plasma sex steroid hormones is useful for characterization of equine GTCT in mares with clinical signs attributable to high plasma concentrations of testosterone or estrogen (Meinecke and Gips, 1987; Stabenfeldt *et al.*, 1979). Occasionally plasma progestins are elevated. Considerable variation in sex steroid hormone profiles exists among affected horses and may be due to the presence of abnormal ovarian follicles, defects in aromatase activity, or possible feedback inhibition affecting gonadotropin secretion (Hoque *et al.*, 2003).

Determination of plasma concentrations of androstenedione, 17-hydroxyprogesterone, and estradiol may be useful in diagnosing adrenocortical neoplasia in ferrets (Rosenthal and Peterson, 1996). Likewise, increased plasma concentrations of these adrenal sex hormones have been observed in dogs with adrenal gland adenocarcinoma with provocative testing using ACTH (Hill *et al.*, 2005). Elevated plasma progesterone has been described in a cat with a well-differentiated adrenocortical adenocarcinoma (Boord and Griffin, 1999).

Much literature exists surrounding the presence of estrogen and progesterone receptors in mammary gland tumors of the dog. Recent findings reveal that dogs with biologically aggressive inflammatory mammary carcinomas had increased serum and tissue concentrations of androgens

when compared to dogs with noninflammatory malignant mammary tumors (Illera *et al.*, 2006).

The presence of progesterone receptors has been described in lymphomas of the horse (Henson *et al.*, 2000). A case report describing the regression of a cutaneous lymphoma in a mare after removal of GTCT hints at the biological significance of progesterone receptors in equine lymphomas (Henson *et al.*, 1998).

7. *Insulin*

Increased secretion of insulin from the beta cells of the pancreas is the hallmark of insulinoma (beta cell tumor, pancreatic islet cell tumor). Although several variations on the insulin-glucose ratio appear in the literature, documentation of the abnormal physiological condition of fasting hypoglycemia and measurable serum insulin is sufficient for the diagnosis of insulinoma. Measuring serum fructosamine and glycated hemoglobin may also be helpful in the diagnosis of insulinoma. In a few small series of dogs with insulinoma, decreased serum fructosamine concentrations (Loste *et al.*, 2001; Mellanby and Herrtage, 2002) and decreased serum glycated hemoglobin concentrations (Elliott *et al.*, 1997; Marca *et al.*, 2000) have been observed. Low serum fructosamine may indicate the presence of insulinoma despite normoglycemia (Mellanby and Herrtage, 2002).

C. Enzymes

1. *Lactate Dehydrogenase, Serum Alkaline Phosphatase, Prostatic Acid Phosphatase, Thymidine Kinase*

Lactate dehydrogenase (LDH), an enzyme that catalyzes the interconversion of pyruvate and lactate, has been studied in humans with a variety of malignancies, but it is best validated as a marker for evaluating prognosis in patients with nonseminomatous germ cell tumors (Duffy, 2004). LDH activity, along with activity of several of its isoenzymes, is increased in dogs with lymphoma; dogs with lower serum LDH activity had overall longer survival times compared to dogs with increased LDH activity, suggesting this may be a useful marker for canine lymphoma (Zanatta *et al.*, 2003). Increased plasma and urine LDH activity have been observed in cows with urinary bladder cancer (Dawra *et al.*, 1991).

Elevated serum alkaline phosphatase (ALP) activity is a prognostic factor in humans with a variety of advanced cancers (Hauser *et al.*, 2006) and may predict outcome in a variety of cancers including prostate cancer (Cho *et al.*, 2003) and advanced uveal melanoma (Eskelin *et al.*, 2003). Serum ALP activity has apparently no value as a tumor marker for canine lymphoma or canine mammary tumors (Karayannopoulou *et al.*, 2003; Wiedemann *et al.*, 2005). Pretreatment elevated serum ALP activity and failure to return to normal ALP activity after treatment correlate with poor survival of dogs with appendicular osteosarcoma (Ehrhart *et al.*, 1998; Garzotto *et al.*, 2000).

Prostatic acid phosphatase (PAP), a neutral protein tyrosine phosphatase, was widely used as a tumor marker before the discovery of prostate-specific antigen. Serum PAP activity is increased in men with prostate cancer and has important cellular functions in carcinogenesis of the prostate (Veeramani *et al.*, 2005). However, this increase does not appear to occur in dogs with prostate cancer (Bell *et al.*, 1995).

Thymidine kinase (TK), a phosphotransferase enzyme found in most living cells, has been evaluated as a tumor marker in women with breast cancer, showing a decrease in serum activity after surgical treatment of the primary tumor (He *et al.*, 2000). It may also provide prognostic information in humans with non-Hodgkin's lymphoma and multiple myeloma (Diem *et al.*, 1993; Hallek *et al.*, 1992). In dogs with lymphoma, serum TK activity appears to be a predictor of survival (von Euler *et al.*, 2004). TK can now be measured with nonradiometric methods, making it more appealing for routine laboratory use (von Euler *et al.*, 2006).

D. Immunoglobulins

A long-standing use of a serum tumor marker in veterinary medicine is the measurement of serum immunoglobulins. In diseases of B cells, including multiple myeloma and Waldenström's macroglobulinemia, hyperglobulinemia is often present. Electrophoresis of the serum proteins reveals a typical monoclonal gammopathy, and immunoelectrophoresis is used to further characterize the antibody class of the immunoglobulins. The hyperglobulinemia resolves with successful treatment and therefore makes a convenient measure to assess response and recurrence. IgM, IgG, and IgA gammopathies have been described in the dog (Giraudel *et al.*, 2002; Lautzenhiser *et al.*, 2003; Ramaiah *et al.*, 2002). It should be noted that hypergammaglobulinemia does not occur with all cases of myeloma, and there may be hypogammaglobulinemia with a normal electrophoretic pattern. Canine ehrlichiosis infection can also cause a monoclonal gammopathy and should be considered among the differential diagnoses for increased serum immunoglobulins (Breitschwerdt *et al.*, 1987).

E. Tumor-Associated Antigens

1. CA-125

Cancer antigen 125 (CA-125) is a product of the MUC16 gene and has found use in human medicine as a tumor marker for epithelial ovarian cancers, although the sensitivity and specificity are poor (Moss *et al.*, 2005). Serum CA-125 may be elevated in other cancers, such as endometrial cancer, cancer of the fallopian tubes, lung cancer, breast cancer, and

cancer of the gastrointestinal tract and nonneoplastic diseases such as endometriosis. CA-125 has not found application in veterinary medicine.

2. Prostate-Specific Antigen

Prostate-specific antigen (PSA) is a tumor-associated antigen identifiable in the serum of men with prostate cancer, and it has become a widely used tumor marker for prostate cancer screening programs. Evidence suggests it may not adequately discriminate between cancer and benign enlargement of the prostate gland (Constantinou and Feneley, 2006). One study failed to identify PSA in canine serum, although weak immunoreactivity was noted on immunohistochemistry of canine prostatic adenocarcinoma specimens (Bell *et al.*, 1995).

3. Other Tumor-Associated Antigens

Tumor-associated antigens, 1A10 and SB2, have been identified in the serum of dogs with a variety of cancers with the use of murine monoclonal antibodies developed against a canine mammary carcinoma cell line (Wang *et al.*, 1995). However, the clinical importance of these antibodies has not been defined.

F. Miscellaneous Serum Tumor Markers

1. Fibronectin

Fibronectin (FN) is a large glycoprotein that is a component of the extracellular matrix and occurs in its soluble form in plasma. A study of plasma FN concentrations in dogs with malignancies documented both increased and decreased plasma FN (Feldman *et al.*, 1988). A study of canine and feline pleural and abdominal effusions revealed no useful distinction in FN concentrations between malignant and nonmalignant effusions, although the FN/albumin ratio was higher in dogs with malignant effusions compared to those with congestive heart failure (Hirschberger and Pusch, 1996).

2. Sialic Acid

Sialic acid describes derivatives of neuraminic acid, which are potentially useful tumor markers because of the aberrant glycosylation in cancer cell membranes. Although the cancer specificity of sialic acid is reported to be high, its sensitivity is low because sialic acid-rich glycoproteins are present in inflammatory diseases (Narayanan, 1994). Increased serum sialic acid concentration has been observed in cancer-bearing dogs (Poli *et al.*, 1986); however, further studies suggest the increase is not specific for cancer (Thougaard *et al.*, 1998).

3. Acute-Phase Proteins

The acute-phase proteins (APP) are those plasma proteins, made primarily by hepatocytes, whose concentrations change after tissue injury or infection. Their relationship with cancer has long been recognized in human medicine (Cooper and Stone, 1979). An increase in APP at the time of diagnosis is a negative prognostic indicator in human cancer patients, and increases may also occur with advancing disease (Cooper, 1988). APP that may have use as tumor markers include ceruloplasmin (Cp), complement components C3 and C4, α1-acid glycoprotein (AGP), α1-proteinase inhibitor (α1-antitrypsin), α1-antichymotrypsin, haptoglobin (Hp), fibrinogen (Fbn), C-reactive protein (CRP), and serum amyloid A (SAA). As an example, increased serum CRP has been shown to be a poor prognostic indicator in people with multiple myeloma, melanoma, lymphoma, and ovarian, renal, pancreatic, and gastrointestinal tumors (Mahmoud and Rivera, 2002). Because interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF-α) induce synthesis of CRP and potentially other APP, they are also receiving attention as potential biomarkers and therapeutic targets.

APP have been studied in veterinary medicine. In a recent study of APP in diseased dogs, significant increases in Cp, Hp, and CRP were observed in dogs with cancer and other inflammatory diseases, and decreases with treatment were associated with more favorable outcomes (Tecles *et al.*, 2005). Increased serum concentrations of AGP at diagnosis have been observed to decrease with cancer treatment and onset of clinical remission in dogs with lymphoma, suggesting its potential as a biomarker (Hahn *et al.*, 1999).

III. FLOW CYTOMETRY

A. DNA Ploidy

The flow cytometer is frequently employed to determine the DNA content of cancer cells in various veterinary tumors (Culmsee and Nolte, 2002). Most normal tissues, reactive tissues, and benign tumors have diploid (2N) DNA values. The different DNA content of tumor cells compared to normal tissues may be the result of abnormal DNA (aneuploidy) or due to increased DNA content with cell division. Although aneuploidy has been identified in a wide variety of veterinary tumors, it has not been studied carefully as a prognostic indicator. Aneuploidy may predict aggressive tumor behavior in canine hemangiopericytoma (Kang *et al.*, 2006), canine mammary tumors (Hellmen *et al.*, 1993), canine melanoma (Bolon *et al.*, 1990), and possibly canine mast cell tumors (Ayl *et al.*, 1992). However, aneuploidy does not seem to predict biological behavior or prognosis in equine melanomas (Roels *et al.*, 2000a) or canine lymphomas (Teske *et al.*, 1993).

B. Cell Surface Determinants

With the use of specific monoclonal antibodies, the flow cytometer can be used to characterize cell populations based on their cell surface determinants. Although particularly well suited for the study of leukemias, this technique may also be adapted to the study of solid tumors. Aberrant expression of cluster differentiation (CD) molecules has been identified as a common, and distinguishing, feature of canine lymphomas (Wilkerson *et al.*, 2005). The flow cytometer also allows rapid immunophenotyping of lymphomas using an aspirate specimen (Culmsee *et al.*, 2001). Further work is needed to determine how these findings may correlate with prognosis.

IV. PROLIFERATION MARKERS/ APOPTOSIS

A. Mitotic Counts

Determining the frequency of mitotic figures visible in histological sections of biopsy specimens is a long-standing method for assessing cell proliferation. Cells in the mitotic phase are easily recognizable on routinely prepared specimens. There are various methods for reporting the mitotic activity, including number of mitoses visible per certain number of high, dry microscopic fields or the number of mitoses present in a certain number of cells (mitotic index). It has been shown that the mitotic index correlates better to other indices of proliferation and tumor grade compared to mitoses per area (Sarli *et al.*, 1999). Although determining mitotic counts is technically simple, it is limited in its usefulness because of lack of reproducibility, and errors in interpretation may be introduced by delays in tissue fixation, variation in section thickness or size of microscopic field of view, and in difficulty recognizing mitoses.

High mitotic index has been reported as a negative prognostic indicator of various tumors, including canine ocular melanoma (Wilcock and Peiffer, 1986), feline fibrosarcoma (Bostock and Dye, 1979), and canine soft tissue sarcomas (Kuntz *et al.*, 1997). However, the mitotic index may have limited value for predicting the behavior of canine melanoma (Spangler and Kass, 2006), canine skin cancers (Martin De Las Mulas *et al.*, 1999), or canine lymphoma (Kiupel *et al.*, 1999).

B. Thymidine-Labeling Index and BrdU Incorporation

The synthesis of DNA occurring in the S phase of the cell cycle can be measured by labeled DNA precursor incorporation. Although there are radiometric methods using tritiated thymidine, bromodeoxyuridine (BrdU), a halogenated thymidine analogue, is more commonly used for direct estimation of DNA synthesis. The use of specific monoclonal antibodies to BrdU allows immunohistochemical detection in paraffin-embedded sections with simultaneous morphological examination of the tissues. The thymidine labeling index is defined as the ratio of the number of positively stained cells to the total number of cells. The S-phase fraction of the cell cycle can be determined by counting nuclei labeled with BrdU providing an accurate assessment of the proliferative capacity of the tumor. One drawback to this technique is that it requires infusing patients with BrdU before surgery to permit its incorporation into tumor DNA.

BrdU incorporation and calculation of tumor potential doubling time has been associated with biological behavior and prognosis in canine chondrosarcoma, osteosarcoma, epulides, and lymphoma (Ohta *et al.*, 2004; Schwyn *et al.*, 1998; Vail *et al.*, 1996; Yoshida *et al.*, 1999).

C. Nucleolar Organizing Regions

Quantifying the proteins associated with nucleolar organizing regions (NORs) of interphase chromosomes is another method to assess the proliferation rates of tumors. The NORs are visualized microscopically with a simple silver-staining method that is effective because of the argyrophilia of their nonhistone acidic proteins. The staining procedure can be done on both histological and cytological specimens. These argyrophilic nucleolar organizing regions (AgNORs) are representative of actual or potential transcriptional activity of ribosomal DNA and may be used as a marker for cell proliferation. AgNOR counts may be expressed as the mean number of AgNORs per nuclei or as the percentage of tumor cells with >5 AgNORs per nucleus. It is believed that the mean AgNOR count reflects DNA ploidy, whereas the percentage of tumor cells with >5 AgNORs per nucleus represents the proliferative activity.

Increasing AgNOR scores have been shown to be predictive of poor outcome in canine soft tissue sarcoma (Ettinger *et al.*, 2006), canine mast cell tumors (Bostock *et al.*, 1989; Scase *et al.*, 2006; Simoes *et al.*, 1994), canine mammary gland tumors (Sarli *et al.*, 2002), canine lymphoma (Kiupel *et al.*, 1998, 1999; Vail *et al.*, 1996), transmissible venereal tumors (Harmelin *et al.*, 1995), and feline mammary carcinoma (Preziosi *et al.*, 2002). However, AgNOR scores do not seem to be predictive of outcome in feline lymphoma (Rassnick *et al.*, 1999; Vail *et al.*, 1998), and other studies suggest that AgNOR scores do not predict outcome in canine mammary gland tumors (Lohr *et al.*, 1997).

D. Proliferation Markers

Methods for detection of cell cycle-related antigens are described in Section V.D.

E. Image Analysis

Obtaining morphometric and densitometric measurements from individual nuclei and providing information about ploidy, S-phase fraction, and nuclear area, are possible with image analysis of cytocentrifuge preparations of Feulgen-stained nuclei extracted from formalin-fixed, paraffin-embedded tissues. Morphometric measurements can also be obtained from hematoxylin and eosin (H&E) and panoptic-stained cytology specimens. Nuclear morphometry and ploidy may aid in the classification of canine mast cell tumors (Strefezzi Rde *et al.*, 2003), distinguish benign from malignant melanocytic tumors in dogs and cats (Roels *et al.*, 2000b), and predict the outcome of feline mammary carcinomas (De Vico and Maiolino, 1997).

F. Apoptosis

Apoptosis is an energy-dependent process that may be considered a "programmed" form of cell death, distinct from the "accidental" cell death of necrosis. During apoptosis, there is activation of endogenous nucleases, which create oligonucleosomal fragments that have a characteristic orderly ladder appearance when separated by electrophoresis, compared with the smeared appearance of DNA degraded during necrosis. Cells undergoing apoptosis have characteristic morphological features including condensation of nuclear heterochromatin and resultant crescent apposed to the nuclear membrane, cell shrinkage, cytoplasmic condensation, and bud formation at the cell membrane, which may condense into "apoptotic bodies." Another characteristic of apoptosis is the absence of inflammation, which is typically present with necrosis.

Although features of apoptosis may be identified with light microscopy of H&E-stained cells, electron microscopy or fluorescence microscopy with dyes such as propidium iodine or acridine orange may also be useful.

The apoptotic index predicts the initial relapse-free survival in dogs with lymphoma, but not its overall survival (Phillips *et al.*, 2000). However, the apoptotic index does not appear to correlate with survival in feline mammary tumors (Sarli *et al.*, 2003).

V. IMMUNOHISTOCHEMISTRY/ IMMUNOCYTOCHEMISTRY

Immunohistochemistry is now a well-accepted and routinely applied method in most every veterinary diagnostic laboratory. Similar techniques have been applied to cytology specimens with good result. These methods involve the use of antibodies, which bind specific cellular components representing specific markers of the cell type of origin. By linking the antibodies to a dye, the immunoreactivity between the tissue specimens and antibodies can be visualized with the light microscope.

The use of immunohistochemistry and immunocytochemistry has advanced the understanding of tumor differentiation and allowed for improved tumor typing. Immunohistochemistry facilitates the determination of histogenesis of many tumors that might otherwise be classified as undifferentiated on the basis of light microscopy of routine H&E stained tissues. Although the antibodies used for immunohistochemical staining do not recognize unique attributes of the tumor nor do they differentiate benign from malignant cells per se, the accurate determination of histogenesis may allow the clinician to choose appropriate treatment and formulate an accurate estimate of the prognosis. It is beyond the scope of this chapter to exhaustively review all immunohistochemical and immunocytochemical markers useful for veterinary cancer diagnosis. What follows are examples of those markers that well illustrate the use of these techniques as tumor markers.

A. Epithelium

It is often difficult to distinguish carcinoma for other poorly differentiated or undifferentiated neoplasms. The immunohistochemistry (IHC) markers that are commonly used to characterize tumors of epithelial origin are antibodies directed against the cytokeratin intermediate filaments. The cytokeratin proteins are unique among the intermediate filaments of the cytoskeleton because of their high degree of diversity in polypeptide units and the fact that cytokeratin intermediate filaments are highly correlated with the degree of tissue differentiation. Therefore, identification of specific cytokeratins can be useful for confirming epithelial histogenesis and distinguishing glandular from squamous differentiation independent of other morphological features. As epithelial tumors progress from dysplastic epithelium to carcinoma *in situ* to invasive squamous cell carcinoma, there is a concurrent decrease in expression of both high- and low-molecular-weight cytokeratins. Although a majority of canine and feline carcinomas will have immunoreactivity of at least some neoplastic cells for cytokeratins, the use of a panel of anticytokeratin antibodies, to include both high- and low-molecular-weight keratins, may improve the sensitivity of the immunohistochemistry. It is noteworthy that many studies of cytokeratin intermediate filaments in domestic animal tumors have used antibodies directed against human cytokeratins, and there are clear differences in the observed immunoreactivity among species for many of these antibodies.

Specific cytokeratins have been proposed as diagnostic markers for some tumors owing to a change in cytokeratin expression as a consequence of tumorigenesis. For example, poorly differentiated prostatic carcinoma in dogs has positive immunoreactivity for cytokeratin AE1/AE3 (Grieco *et al.*, 2003), yet cytokeratin 7 is not sufficient to distinguish prostatic from transition cell carcinomas in dogs (LeRoy *et al.*, 2004). Various canine skin tumors may

be distinguished based on the observed immunoreactivity to a cytokeratin panel (Walter, 2000). Cytokeratin 6 is present in all epithelial skin tumors with the exception of pilomatrixoma. Cytokeratin 14 reactivity occurs in basal cell-derived neoplasms and in sebaceous and perianal gland tumors, whereas reactivity to cytokeratin 10/11 is limited to spinous cell-derived tumors and cytokeratin 8/18 immunoreactivity occurs only in tumors of sweat gland origin. Cytokeratin immunostaining has also been used to detect micrometastases in lymph nodes of dogs with mammary gland carcinoma that were considered negative on routine evaluation of H&E stained specimens (Matos *et al.*, 2006).

B. Mesenchyme

1. Vimentin

Vimentin intermediate filaments are used to mark nonmuscle sarcomas (Fox *et al.*, 2002; Mazzei *et al.*, 2002). Vimentin expression is lost during the process of differentiation of skeletal muscle and is absent in normal mature myofibrils. Vimentin intermediate filaments have been reported, however, in poorly differentiated rhabdomyosarcomas (Brockus and Myers, 2004).

2. Desmin

Desmin is the cytoskeletal component that holds myofibrils in place, and it has found use as a marker for canine leiomyomas and leiomyosarcomas (Sato *et al.*, 2003). Canine skeletal muscle tumors are also reactive to desmin antibodies (Illanes, 2002). Canine hemangiopericytoma may also express desmin (Mazzei *et al.*, 2002).

3. Fibrillary Acid Protein

Glial fibrillary acid protein (GFAP) is found in glial cells in the central nervous system, in Schwann cells and schwannomas, and other tissues. In dogs, GFAP reactivity occurs in glial cells, including fibrous astrocytes, Schwann cells, axons, and cell bodies of peripheral ganglia. It has also been identified in glioblastoma multiforme of dogs (Lipsitz *et al.*, 2003).

C. Drug Resistance

An important mechanism for cellular resistance to anticancer drugs involves the overexpression of the product of the MDR-1 gene, P-glycoprotein (Pgp). Pgp is an ATP-dependent transmembrane efflux pump that reduces the intracellular concentration of a variety of chemotherapy drugs. The presence of Pgp can be detected with immunohistochemistry, and Pgp expression is associated with a poor clinical outcome in dogs with lymphoma (Lee *et al.*, 1996).

D. Proliferation

1. Ki-67

The monoclonal antibody (MIB-1) directed against Ki-67 recognizes a nonhistone nuclear protein expressed in proliferating cells during G1-, S-, G2-, and M-phases of the cell cycle, but it is not present in quiescent (G0) cells. Immunostaining for the Ki-67 antigen offers an efficient method for estimating the proliferative fraction of a tumor and correlates well with other measures of proliferation. Ki-67 labeling index may have prognostic significance in canine mammary gland tumors (De Matos *et al.*, 2006; Zuccari *et al.*, 2004), soft tissue sarcomas (Ettinger *et al.*, 2006), and melanoma (Laprie *et al.*, 2001; Millanta *et al.*, 2002). The Ki-67 labeling index is of limited value in predicting outcome in canine lymphoma (Phillips *et al.*, 2000). Low Ki-67 labeling of feline squamous cell carcinoma was predictive of a poor response to radiation therapy (Melzer *et al.*, 2006).

2. Proliferating Cell Nuclear Antigen

Cyclin, also known as proliferating cell nuclear antigen (PCNA), is a nonhistone nuclear protein that is present throughout the cell cycle in proliferating cells, reaching its maximum during S phase. Use of PCNA to estimate tumor proliferation rate has value in predicting response to treatment in dogs undergoing radiation therapy for meningioma (Theon *et al.*, 2000). PCNA immunoreactivity does not correlate with survival canine mast cell tumors (Scase *et al.*, 2006), canine or feline lymphoma (Kiupel *et al.*, 1998; Phillips *et al.*, 2000; Vail *et al.*, 1998), canine or feline melanoma (Roels *et al.*, 1999), or canine soft tissue sarcomas (Ettinger *et al.*, 2006).

E. Leukocyte Markers

The study of immune system malignancies has been advanced by the development of monoclonal antibodies with specific reactivity to canine and feline leukocyte antigens. At present, leukocyte antigens are defined by cluster-differentiation (CD) numbers assigned by international workshops. Panels of antibodies against leukocyte antigens are useful for classifying round cell malignancies and may provide prognostic information (Fernandez *et al.*, 2005). Commonly used antibodies to identify various cell types of origin include CD3 (T cells), CD79a (B cells), CD18 (leukocytes), canine CD11d (macrophages and T cells), factor VIII-related antigen (megakaryocytes), and CD45RA (leukocytes). T cells can be further characterized as T cell helpers (CD4 reactive) or cytotoxic T cells (CD8 reactive). Peripheral T cells (thymocytes) can be identified by their reactivity to Thy-1. B cells can also be identified with CD20 (Jubala *et al.*, 2005). MCH-II may also be used to identify antigen-presenting cells. Plasma cells may be identified by their immunoreactivity to canine immunoglobulin antibodies (Day, 1995).

The immunophenotyping of canine lymphoma has received considerable attention as a potential prognostic indicator. Several studies suggest that dogs with B cell lymphoma may have longer survival than those with T cell lymphoma (Dobson *et al.*, 2001; Kiupel *et al.*, 1999; Ponce *et al.*, 2004; Teske *et al.*, 1994). It is unclear if immunophenotype is an important prognostic factor in feline lymphoma (Patterson-Kane *et al.*, 2004).

Different anatomic forms of lymphoma have also been associated with specific cell types of origin. For example, in the dog, cutaneous lymphoma is primarily of T cell origin, and epitheliotrophic lymphoma is exclusively of T cell origin (Day, 1995). There also appears to be breed differences in lymphoma. In one study, 82% of boxer dogs had T cell lymphoma, whereas other only 50% of the golden retrievers and rottweilers studied had T cell lymphoma (Lurie *et al.*, 2004). In cats, mediastinal and intestinal lymphoma appear to be predominantly T cell in origin (Gabor *et al.*, 1999; Zwahlen *et al.*, 1998); however, there may be some worldwide geographic differences in the distribution of B cell lymphomas among cats.

Similar immunophenotyping techniques have been successfully applied to fine needle aspirate samples of lymph nodes using flow cytometry (Gibson *et al.*, 2004) and cytospin cytology preparations (Caniatti *et al.*, 1996). Immunophenotyping of leukocyte tumors has also been applied in other species including the horse (Kelley and Mahaffey, 1998), cow (Vernau *et al.*, 1997), and ferret (Coleman *et al.*, 1998).

F. Other Markers

1. *Von Willebrand's Factor* (*Factor* VIII-*Related Antigen*)

Von Willebrand's factor, part of the factor VIII complex, is restricted to endothelial cells, megakaryocytes, and platelets. Positive immunoreactivity to factor VIII-related antigen is useful in diagnosing vascular neoplasia in a variety of species. Factor VIII-related antigen has also been used to identify tumor microvessels, and various determinations of microvessel density may carry prognostic significance. In one study of malignant canine mammary tumors, a high tumor vascular density was associated with an increased likelihood of local tumor recurrence (Griffey *et al.*, 1998). Intratumoral vascular density has also been shown to predict survival in dogs with mast cell tumors (Preziosi *et al.*, 2004).

2. *Actin Microfilaments*

Vertebrates have at least six tissue-specific forms of actin. There are actins specific for skeletal muscle, cardiac muscle, vascular smooth muscle, and enteric smooth muscle. Alpha-smooth muscle actin may be a useful marker to distinguish canine hemangiopericytomas from other peripheral nerve sheath tumors (Chijiwa *et al.*, 2004).

3. *Skeletal Myosin*

Antibodies that distinguish between smooth muscle and sarcomeric myosin found in skeletal and cardiac muscle may be helpful in determining the cell of origin for muscle tumors.

4. S-100 *Proteins*

S-100 was originally isolated from brain and thought to be specific for glial cells; however, S-100 proteins have subsequently been identified in a variety of non-neuroectodermal tissues. In dogs, S-100 immunoreactivity has been identified in melanoma and amelanotic melanoma, gastrointestinal stromal tumors, and schwannomas, making it nonspecific for melanoma (Choi and Kusewitt, 2003). Because the diagnosis of canine melanoma is often challenging, having positive immunoreactivity for S-100, vimentin, and neuron-specific enolase and negative immunoreactivity for cytokeratins supports a tentative diagnosis of melanoma. However, other immunohistochemical markers, such as tyrosinase-related protein-2 (TRP-2), have apparently greater specificity for melanocytic tumors and may be more useful than S-100 (Choi and Kusewitt, 2003).

5. *Neuron-Specific Enolase*

Neuron-specific enolase (NSE) is the γ-subunit of the enolase enzyme involved in the glycolytic pathway and is characteristic of neural cells. Several tumors have been shown to be immunoreactive with NSE including medullary thyroid (C-cell) tumors, chordomas, and ganglioneuroblastomas. Meningiomas and melanomas may also have positive immunoreactivity with NSE (Barnhart *et al.*, 2002; Koenig *et al.*, 2001).

6. *Chromogranin* A

The diagnosis of cancers arising from neuroendocrine cells, those with neurotransmitter, neuromodulator, or neuropeptide hormone production; dense-core secretory granules; and the absence of axons and synapses, is aided by the use of neuroendocrine markers, particularly chromogranin A (Barakat *et al.*, 2004). Chromogranin A is present in the secretory granules of endocrine cells and has been a useful immunohistochemical marker for diagnosing a variety of neuroendocrine tumors of animals, including carcinoid, pheochromocytoma, insulinoma, and neuroendocrine carcinoma (Barthez *et al.*, 1997; Doss *et al.*, 1998; Morrell *et al.*, 2002; Myers *et al.*, 1997; Sako *et al.*, 2003, 2005).

7. *Type* IV *Collagen and Laminin*

Type IV collagen and laminin make up basement membranes and can be visualized with light microscopy through

the periodic acid Schiff reaction. However, immunohistochemical staining allows specific and sensitive evaluation of the integrity of the basement membrane, facilitating the distinction between benign tumors with intact basement membranes and invasive cancers with degraded basement membranes (Peña *et al.*, 1995). Fragmentation, loss, or absence of the basement membrane is associated with tumor invasion and metastasis in human colorectal cancer (Ogawa *et al.*, 2005). Immunostaining with antibodies directed against matrix metalloproteinase enzymes (e.g., MMP-9), which degrade basement membrane proteins, may also be important for understanding the relationship between the extracellular matrix and cancer progression (Yokota *et al.*, 2001).

8. *Integrins*

The integrins mediate cell-to-cell adhesions and play a role in interactions between cells and the extracellular matrix proteins including fibronectin, collagens, and laminin. Decreased expression of integrins correlates with the metastatic potential of the tumor (Kawaguchi, 2005). Expression of other integrins, such as alpha(v)beta3, may reflect the angiogenic activity of the tumor, as has been observed in canine melanoma (Rawlings *et al.*, 2003).

9. *Amyloid*

Antibodies, directed against amyloid of immunoglobulin lambda light-chain origin and amyloid-A, have been used to confirm that the amyloid associated with plasma cell tumors is of immunoglobulin origin (Cangul *et al.*, 2002). These immunoreactivity patterns have also been useful to show plasmacytoid differentiation in some tumors.

10. *Oncoproteins*

Antibodies directed against proteins of oncogenes or tumor suppressor genes may serve as biomarkers for cancer. Antibodies have been developed against human p53, Rb, PTEN, Bcl-2, BCRA1, c-*myc*, c-*ras*, and c-*erbB*-2, among others; reports in the veterinary literature suggest cross-reactivity with some of them to domestic animal tissues. In canine lymphoma, expression of the p53 protein is associated with high-grade histology and the T cell immunophenotype (Sueiro *et al.*, 2004), both of which suggest a poor prognosis. Likewise, overexpression of the p53 protein was associated with a poor prognosis for dogs with mammary gland tumors (Lee *et al.*, 2004). Changes in expression of PTEN and p53 proteins have been associated with canine melanoma (Koenig *et al.*, 2002). The expression Bcl-2, a regulator of apoptosis, did not predict survival in a study of feline lymphoma (Dank *et al.*, 2002). Overexpression of c-*ras* has been associated with the development of feline hyperthyroidism (Merryman *et al.*, 1999).

VI. CYTOCHEMISTRY

Light microscopy of blood films and bone marrow aspirate specimens has been aided by cytochemistry to distinguish various hematological disorders, most notably the acute leukemias. Although various new techniques, including immunophenotyping, various molecular methods (Grindem, 1996), and flow cytometry (Fernandes *et al.*, 2002), are improving the classification of these diseases, cytological evaluation remains an integral part of diagnosis. The myeloperoxidase reaction and Sudan black C stain are useful for identifying neutrophilic differentiation, along with chloroacetate esterase. In the dog and cat, acute myeloid leukemia can be diagnosed on the basis of alkaline phosphatase reactivity because their normal neutrophils lack alkaline phosphatase reactivity. The "nonspecific" esterase reactions, including α-naphthyl acetate esterase, are useful for identifying monocytic differentiation. The lipase stain can also be a marker for monocytic differentiation. Acute monoblastic leukemia has been diagnosed in the dog based on reactivity with N-butyrate esterase and the lack of chloroacetate esterase or leukocyte peroxidase reactivity (Modiano *et al.*, 1998). Myelomonocytic leukemias can be recognized by simultaneous cytochemical reactivity, often alkaline phosphatase and nonspecific esterase (Jain *et al.*, 1981). Basophilic leukemia has been reported to be negative for peroxidase and naphthol AS-D chloroacetate esterase reactivity (Mahaffey *et al.*, 1987). Cytochemical evaluation of acute megakaryoblastic leukemia may be of limited diagnostic value (Colbatzky and Hermanns, 1993). Similar cytochemical techniques have also been applied to lymph node samples, both imprint and aspirate, to distinguish B and T cell regions and cell types (Raskin and Nipper, 1992).

VII. CYTOGENETICS

Cytogenetics refers to both the study of the structure of chromosome material and the study of diseases caused by structural and numerical abnormalities of chromosomes. It includes the routine analysis of G-banded chromosomes, other cytogenetic banding techniques, and molecular cytogenetics such as fluorescent *in situ* hybridization (FISH) and comparative genomic hybridization (CGH). In human medicine, cytogenetics has played an important role in the diagnosis and clinical management of lymphomas, leukemias, and various solid tumors (Campbell, 2005; Gebhart, 2004; Mundle and Sokolova, 2004). Breakthroughs in karyotype analysis have overcome the impediments presented by the complexity of the canine karyotype ($2N = 78$) in identifying rearranged chromosomes (Milne *et al.*, 2004). Both numerical and structural chromosome abnormalities have been identified in canine soft tissue sarcomas (Milne *et al.*, 2004). Although many of the cytogenetic studies of animal tumors have been small case series, the advent and development of microarrays for canine CGH

analysis will facilitate future studies (Thomas *et al.*, 2003, 2005).

In a small study of canine leukemia, cytogenetic abnormalities did not correlate with survival (Grindem and Buoen, 1986). Similarly, a small study of feline leukemia found no relationship between cytogenetic abnormalities and prognosis (Grindem and Buoen, 1989). In a study of the cytogenetics of canine lymphoma, dogs with tumors having trisomy 13 had a significantly longer median survival time compared to dogs with tumors having other chromosomal aberrations (Hahn *et al.*, 1994). Further studies are needed to determine the prognostic importance of chromosomal aberrations in veterinary oncology.

VIII. MOLECULAR ONCOLOGY

The literature detailing the application of molecular biology techniques in human clinical oncology is vast. Not only have methods studying alterations in gene expression and DNA mutations contributed greatly to the understanding of cancer biology, they also are useful for defining subgroups of patients with similar histology yet different prognoses, identifying patients that will benefit from targeted therapy, and predicting the risk for toxicity from treatment (Khanna and Helman, 2006). A complete review of molecular biology applications in oncology is beyond the scope of this chapter, and they are reviewed elsewhere (Costa and Lizardi, 2005). Canine mast cell tumors illustrate the potential of molecular techniques to advance veterinary oncology. Mutations, notably tandem duplications in exons 11 and 12, have been discovered in the protooncogene c-*kit* of malignant canine mast cells (London *et al.*, 1999). These changes can lead to the constitutive activation of Kit, a type 3 receptor tyrosine kinase, in the absence of its ligand, stem cell factor. Dysregulation of Kit may play a role in the uncontrolled growth or inappropriate survival of canine mast cells, potentially leading to mast cell tumor formation. These observations led to *in vitro* studies of tyrosine kinase inhibitors in canine mast cell tumors, which showed promise as targeted therapeutic agents for tumors with Kit dysregulation (Liao *et al.*, 2002). These targeted inhibitors then entered clinical trials in veterinary medicine (London *et al.*, 2003; Pryer *et al.*, 2003). Although the presence of c-*kit* mutations does not predict biological behavior of canine mast cell tumors (Downing *et al.*, 2002), cytoplasmic immunoreactivity with anti-Kit (CD 117) antibodies does appear to predict local recurrence and survival time (Preziosi *et al.*, 2004; Webster *et al.*, 2004).

IX. PROTEOMICS, GENOMICS, METABOLOMICS

The advent of sophisticated methods for protein separation and rapid identification has provided the ability for researchers to study global patterns of protein and gene expression or activity in metabolic pathways, in emerging disciplines known as proteomics, genomics, and metabolomics. The applications of proteomics to veterinary medicine have revealed a series of fucosylated proteins, including CD44 and E-selectin, that are elevated in dogs with lymphoma and decrease during the course of chemotherapy treatment (Xiong *et al.*, 2003). With the completion of the sequencing of the canine genome, a microarray is being developed to study the changes in tumor gene expression in canine tumors (Thomas *et al.*, 2003), which may lead to improved early diagnosis methods and targeted therapeutic strategies. These technologies are not yet ready for widespread clinical use, in part because of the challenges of analyzing the massive amounts of data generated and the persistent concerns about reproducibility of results. Despite these challenges, the "-omics" have tremendous potential to become rapid, high-throughput systems for identifying candidate tumor markers for more careful study. See Chapter 5 for more detailed information about proteomics.

I. INTRODUCTION

The analysis of cerebrospinal fluid (CSF) has been described as the central nervous system (CNS) equivalent of the complete blood count (Jamison and Lumsden, 1988), and the analogy is appropriate. CSF analysis is a general index of neurological health and often provides evidence of the presence of disease. Similar to a complete blood count, CSF analysis has reasonable sensitivity but low specificity. The possible alterations of CSF are relatively limited compared to the varieties of neurological diseases that exist (particularly if the analysis is restricted to total cell counts and total protein determination). Additionally, the type and degree of CSF abnormality seem to be related as much to the location of disease as to the cause or the severity of lesion; meningeal and paraventricular diseases generally produce greater abnormalities than deep parenchymal diseases. Previous therapy may affect the type, degree, and duration of CSF (Jamison and Lumsden, 1988) abnormalities as well. The CSF abnormalities identified are also dependent on the CSF collection site with respect to lesion location

(Thomson *et al*., 1989, 1990). Lastly, the CSF of animals with neurological disease is not always abnormal (Tipold *et al*., 1995). Only occasionally does CSF analysis provide a specific diagnosis (Kjeldsberg and Knight, 1993)—for example, if infectious agents (bacteria or fungi) or neoplastic cells are observed. In most situations, the chief utility of CSF analysis is to assist in the diagnostic process by excluding the likelihood of certain disease processes being present. As is the case with all tests of relatively low specificity, examination of CSF is most useful when the results are correlated with the history, clinical findings, imaging studies, and ancillary laboratory studies. As stated by Fankhauser (1962), "It is futile to make a diagnosis based solely on the CSF findings and particularly on single alterations of it. Only the entire picture of all findings linked with the other clinical symptoms is of value in reaching a diagnosis."

TABLE 26-1 Composition of the Brain–Fluid Interfaces

Interface	Cell Type	Junction Type
Blood-brain	Brain capillary endothelium	Tight junction
Blood-CSF		
Blood-CSF	Choroid plexus epithelium	Apical tight junction
CSF-blood	Arachnoid cells	Tight junction
	Arachnoid villi	Valve
CSF-brain	Ependyma	Gap junction
	Pia mater	Gap junction

Modified from Rosenberg (1990).

II. FUNCTIONS OF CEREBROSPINAL FLUID

Cerebrospinal fluid has four major functions: (1) physical support of neural structures, (2) excretion and "sink" action, (3) intracerebral transport, and (4) control of the chemical environment of the central nervous system. Cerebrospinal fluid provides a "water jacket" of physical support and buoyancy. When suspended in CSF, a 1500-gm brain weighs only about 50 gm. The CSF is also protective because its volume changes reciprocally with changes in the volume of intracranial contents, particularly blood. Thus, the CSF protects the brain from changes in arterial and central venous pressure associated with posture, respiration, and exertion. Acute or chronic pathological changes in intracranial contents can also be accommodated, to a point, by changes in the CSF volume (Fishman, 1992; Milhorat, 1987; Rosenberg, 1990).

The direct transfer of brain metabolites into the CSF provides excretory function. This capacity is particularly important because the brain lacks a lymphatic system. The lymphatic function of the CSF is also manifested in the removal of large proteins and cells, such as bacteria or blood cells, by bulk CSF absorption (see Section II.D). The "sink" action of the CSF arises from the restricted access of water-soluble substances to the CSF and the low concentration of these solutes in the CSF. Therefore, solutes entering the brain, as well as those synthesized by the brain, diffuse freely from the brain interstitial fluid into the CSF. Removal may then occur by bulk CSF absorption or, in some cases, by transport across the choroid plexus into the capillaries (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990).

Because CSF bathes and irrigates the brain, including those regions known to participate in endocrine functions, the suggestion has been made that CSF may serve as a vehicle for intracerebral transport of biologically active substances. For example, hormone releasing factors, formed in the hypothalamus and discharged into the CSF of the third ventricle, may be carried in the CSF to their effective sites in the median eminence. The CSF may also be the vehicle for intracerebral transport of opiates and other neuroactive substances (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990).

An essential function of CSF is the provision and maintenance of an appropriate chemical environment for neural tissue. Anatomically, the interstitial fluid of the central nervous system and the CSF are in continuity (see Section II.A); therefore, the chemical composition of the CSF reflects and affects the cellular environment. The composition of the CSF (and the interstitial fluid) is controlled by cells forming the interfaces, or barriers, between the "body" and the neural tissue. These semipermeable interfaces, the blood-brain barrier, the blood-CSF barrier, and the CSF-brain barrier, control the production and absorption of CSF and provide a fluid environment that is relatively stable despite changes in the composition of blood (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990).

III. CSF FORMATION, CIRCULATION, AND ABSORPTION

The brain (and the spinal cord) as an organ is isolated in many ways from the body and the systemic circulation. This isolation is accomplished anatomically by several interfaces between brain tissue and systemic fluids (Table 26-1). At these interfaces, selective carriers and ion pumps transport electrolytes and essential nutrients and thereby control the brain's microenvironment. A substantial portion of this control is achieved through the formation, circulation, and absorption of CSF at these brain-fluid interfaces (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990).

A. Anatomy of Brain-Fluid Interfaces

1. *Blood-Brain Barrier*

The important blood-brain (and blood-spinal cord) interface is formed by the endothelial cells of the intraparenchymal capillaries. In most areas of the brain and spinal cord,

the capillary endothelium differs from that of other body tissues in the following ways: (1) the absence of fenestrae, (2) the presence of tight junctions between adjacent cells, (3) a lower number of pinocytotic pits and vesicles, (4) a higher number of mitochondria, and (5) closely applied, perivascular, astrocytic foot processes. These features result in the capillary endothelium being a selective barrier—the blood-brain barrier—that regulates the entry, and probably the exit, of biologically important substances and aids in the maintenance of a precise, stable environment for the neural tissues (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990).

2. Blood-CSF Barrier

The epithelial cells of the circumventricular organs form one part of the blood-CSF interface. The circumventricular organs, which include the four choroid plexuses, the median eminence, the neural lobe of the hypophysis, and other specialized areas, border the brain ventricles and are involved with specific secretory activities that appear to require a direct contact with plasma. The capillaries within these organs are fenestrated, similar to capillaries in other organs of the body. Overlying each of the organs are specialized epithelial cells joined by intercellular tight junctions at their apical (ventricular) borders. These epithelial cells also are characterized by an abundance of intracellular organelles and lysosomes. These organelles are probably an important aspect of the barrier and secretory functions of these cells (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990). The choroid plexuses are the major source of CSF. They are formed by evaginations of the ependyma and the pial blood vessels into the ventricles, and they consist of a single row of cuboidal, specialized epithelial cells thrown into villi around a core of blood vessels and connective tissue. The apical (ventricular) surface of the epithelial cells has a brush border of microvilli with occasional cilia. The basal and lateral cell surfaces have numerous infoldings. Overall, the structure of these cells resembles other epithelia specialized for fluid transport, such as proximal renal tubular epithelium (Davson and Segal, 1996; Fishman, 1992; Milhorat, 1987; Rosenberg, 1990). Autonomic nerve terminals have also been identified in the choroid plexus, but their function is unclear (Fishman, 1992; Nilsson *et al*., 1992).

The second part of the blood-CSF interface is formed by the arachnoid membrane at the arachnoid villi. These villi are microscopic evaginations of the arachnoid membrane into the lumen of the dural sinuses. The barrier function of these arachnoid cells is demonstrated by their tight junctions. Their transport function is indicated by giant intracellular vacuoles, some of which have both basal and apical openings, and pinocytotic vesicles. The sinus surface of a villus is covered by sinus endothelium (Milhorat, 1987; Rosenberg, 1990). Endothelium-lined channels may link directly with the subarachnoid space (Bell, 1995; Davson and Segal, 1996). Arachnoid villi are not limited to intracranial venous sinuses but also are present at the spinal nerve roots penetrating into the spinal veins (Bell, 1995; Milhorat, 1987).

3. CSF-Brain Interface

The extensive CSF-brain (and spinal cord) interface consists of the ependyma within the cavities of the central nervous system and the pia mater covering the central nervous system. These two layers are each composed of a single layer of cells joined by gap junctions. The ependyma and the pia mater are not important permeability barriers; the CSF (ventricular and subarachnoid) and the brain interstitial fluid are directly continuous (Davson and Segal, 1996; Milhorat, 1987).

B. CSF Formation

1. Choroidal and Extrachoroidal Formation

Cerebrospinal fluid is formed principally by the choroid plexuses, with a smaller amount formed extrachoroidally (Davson and Segal, 1996; Milhorat, 1987). Choroidal formation involves two processes that occur in series; first is filtration across the choroidal capillary wall, and second is secretion by the choroidal epithelium. Within the choroid plexus, hydrostatic pressure of the choroidal capillaries initiates the transfer of water and ions to the interstitial fluid and then to the choroidal epithelium. Water and ions are then transferred into the ventricles either by (1) intracellular movement across the epithelial membranes, or (2) intercellular movement across the apical tight junctions between epithelial cells. Both of these processes probably depend on ion pumps. Secretion of CSF results from the active transport of sodium, which is dependent on the membrane-bound, sodium-potassium activated ATPase present at the apical (ventricular) surface of the choroidal epithelium (Davson and Segal, 1996; Rosenberg, 1990). The presence of autonomic nerve terminals in the choroid plexus suggests a neural control of CSF secretion. However, the functional role of this innervation in normal and pathological conditions is unknown (Fishman, 1992; Nilsson *et al.*, 1992).

Spurred primarily by clinical evidence that excision of the choroid plexus did not benefit human patients with hydrocephalus, experimental evidence now supports the existence of an extrachoroidal source of CSF. The diffusion of brain interstitial fluid across the ependyma or pia mater is the apparent source of this extrachoroidal CSF component. Formation of the interstitial fluid is thought to occur by active transport processes (secretion) at the cerebral capillaries, but an alternative theory proposes passive permeability of the capillary endothelium and active transport by the surrounding astrocytes (Milhorat, 1987; Rosenberg, 1990). The relative contributions of choroidal and extrachoroidal sources to CSF in normal and pathological conditions are not certain. Some investigators report the choroid plexus to be the major if not the sole source of CSF; whereas others conclude

TABLE 26-2 Rate of CSF Formation in Various Species[a]

Species	Rate (μl/min)
Mouse	0.325
Rat	2.1–5.4
Guinea pig	3.5
Rabbit	10
Cat	20–22
Dog	47–66
Sheep	118
Goat	164
Calf[b]	290
Monkey	28.6–41
Human being	350–370

that at least one-third of newly formed CSF is extrachoroidal (Davson and Segal, 1996; Milhorat, 1987).

2. *Rate of* CSF F*ormation*

Regardless of the amount of extrachoroidal formation, the rate of CSF formation is closely correlated to the weight of the choroid plexus and varies among species (Table 26-2) (Cserr, 1971; Welch, 1975). Increases and decreases in formation rate have been achieved experimentally, but the general tendency is for the formation rate to remain relatively constant. The formation rate directly parallels the rate of sodium exchange, which is linked to the bicarbonate ion. The enzyme carbonic anhydrase plays an important role because it provides the bicarbonate. Inhibition of carbonic anhydrase slows (but does not abolish) sodium, bicarbonate, and chloride flow, resulting in a reduction of CSF secretion (Maren, 1992). Several drugs and conditions inhibit CSF production (Table 26-3), but their clinical utility is limited either by their time frame of action or toxicity (Davson and Segal, 1996; Pollay, 1992; Rosenberg, 1990).

Moderate variations in intracranial pressure probably do not affect CSF formation. However, studies of chronically hydrocephalic animals have shown a reduction of CSF formation with increasing intraventricular pressure. The secretion process may also be affected by chronically increased intracranial pressure (Fishman, 1992).

C. CSF Circulation

Cerebrospinal fluid flows in bulk from sites of production to sites of absorption. Fluid formed in the lateral ventricles flows through the paired interventricular foramina (foramen of Monro) into the third ventricle, then through the mesencephalic aqueduct (aqueduct of Sylvius) into the fourth ventricle. The majority of CSF exits from the fourth ventricle into the subarachnoid space; a small amount may enter the central canal of the spinal cord. In people, CSF enters the subarachnoid space through the lateral apertures (foramina of Luschka) and the median aperture (foramen of Magendie) of the fourth ventricle. Animals below the anthropoid apes do not have a median aperture (Fankhauser, 1962; Fletcher, 1993). Cerebrospinal fluid has also been shown to flow from the spinal subarachnoid space into the spinal perivascular spaces, across the interstitial space, then into the central canal (Stoodley *et al*., 1996). Mechanisms for propelling the CSF along its route probably include (1) the continuous outpouring of newly formed ventricular fluid, (2) the ciliary action of the ventricular ependyma, (3) respiratory and vascular pulsations, and (4) the pressure gradient across the arachnoid villi (Milhorat, 1987).

TABLE 26-3 Factors Influencing CSF Formation

Effect	Substance or Condition	Site of Action
Increase	Cholera toxin	cAMP
	Phenylephrine[b]	Cholinergic pathways
Decrease	Acetazolamide, furosemide	Carbonic anhydrase
	Atrial natriuretic hormone	cGMP
	Diazepam analogue[c]	Choroidal benzodiazepine receptor
	Dopamine D_1 receptor agonist	Choroidal dopamine receptor
	Hyperosmolarity	Choroidal capillaries
	Hypothermia	Metabolism (decreased)
	Noradrenaline[a]	cAMP/choroidal Na^+-K^+ ATPase
	Omeprazole[b]	H^+-K^+ ATPase?
	Ouabain	Na^+-K^+ ATPase
	Serotonin receptor agonist	Choroidal serotonin receptor
	Steroids[b]	Choroidal Na^+-K^+ ATPase
	Vasopressin	Choroidal vasopressin (V_1) receptor

D. CSF Absorption

Absorption of CSF occurs by bulk absorption of the fluid and by absorption or exchange of individual constituents of the fluid (i.e., ions, proteins, and drugs). Bulk absorption occurs directly into the venous system and depends primarily

on the CSF hydrostatic pressure; as the pressure rises, the absorption rate increases (Davson and Segal, 1996). If intracranial pressure falls below a critical point, bulk absorption decreases, a homeostatic response to stabilize the intracranial pressure and the CSF volume. The primary site of bulk absorption, at least in people, is the arachnoid villi that project into the dural sinuses. Two other routes are through lymphatic channels in the dura and through the perineural sheaths of cranial nerves (particularly the olfactory nerves) and spinal nerves. Perineural absorption may be through arachnoid villi projecting into perineural veins, lymphatics, or connective tissue (Davson and Segal, 1996; Milhorat, 1987). The importance of these various absorption routes varies with the species (Bell, 1995).

Absorption through the arachnoid villi occurs transcellularly through micropinocytotic vesicles and giant intracellular vesicles, but it may also occur through endothelium-lined, intercellular clefts. The mechanisms appear to vary among species (Bell, 1995). Absorption is unidirectional from the CSF into the venous blood—the villi act like one-way valves. The basis for the valve-like mechanism appears to be transport by the giant vesicles (see Section II.A.2). Particles ranging in size from colloidal gold (0.2 μm) to erythrocytes (7.5 μm) can be transported across the villi. In disease conditions, accumulations of larger size particles (e.g., protein molecules, erythrocytes, leukocytes) within the villi may impair absorption leading to hydrocephalus (Fishman, 1992; Milhorat, 1987). The choroid plexus also has an absorptive function, acting on specific substances in the CSF rather than by bulk fluid absorption. A variety of compounds are actively transported from the CSF, in a fashion reminiscent of the proximal renal tubule. Solutes may also be cleared from the CSF by diffusion into adjacent brain cells or capillaries (Fishman, 1992; Milhorat, 1987).

IV. CELLULAR COMPOSITION OF NORMAL CSF

A. Total Erythrocyte and Nucleated Cell Count

Cerebrospinal fluid normally does not contain erythrocytes (Chrisman, 1992; Cook and DeNicola, 1988; Rand *et al.*, 1990b; Wilson and Stevens, 1977). Erythrocytes in a CSF sample are most commonly iatrogenic, because of trauma associated with the needle placement. However, CSF erythrocytes may also originate from pathological hemorrhage. The normal nucleated cell count of CSF in domestic animals is in Table 26-4. The most widely accepted reference ranges for the numbers of leukocytes in the CSF of dogs and cats is 0 to 5 cells/μL (de Lahunta, 1983; Oliver and Lorenz, 1993) to 0 to 8 cells/μL (Duncan, 1994). However, these ranges are too broad in our experience and other studies confirm this (Jamison and Lumsden, 1988). Jamison examined 50 clinically and histopathologically normal dogs and derived cerebellomedullary CSF reference limits of 0 to 2 cells/μL (Jamison and Lumsden, 1988). In fact,

all except one of these dogs had counts of 0 to 1 cells/μL (personal communication). Bailey and Higgins examined 31 dogs that were clinically and histopathologically normal. For cerebellomedullary CSF, the mean nucleated cell count was 1.45 cells/μL with the 95% confidence intervals 1.04 to 1.86, and the observed range 0 to 4 cells/μL. Twenty-six of 31 dogs had counts between 0 to 2 cells/μL. They also found that lumbar CSF had a significantly lower nucleated cell count, with a mean of 0.55 cells/μL, a 95% confidence interval of 0.22 to 0.88 and an observed range of 0 to 4 cells/μL, although 30/31 dogs had counts of 0 to 2 cells/μL (Bailey and Higgins, 1985). In our opinion, a normal nucleated count for cerebellomedullary CSF in dogs is 0 to 2 cells/μL, with 3 cells/μL being questionably abnormal and 4 cells/μL definitely abnormal.

Rand and colleagues (1990b) derived reference limits for cerebellomedullary CSF from 33 cats that were clinically and histopathologically normal. The samples did not have blood contamination. The mean ± 1 SD for the white blood cell count was 0.1 ± 0.4 with an observed range of 0 to 2 cells/μL. Thirty of 33 cats had counts of 0 cells/μL. Three cells or more per microliter is therefore abnormal in feline cerebellomedullary CSF.

B. Differential Cell Count

1. *Leukocytes*

Excellent morphological descriptions of the cell types normally found in the CSF of domestic animals can be found elsewhere (Cook and DeNicola, 1988; Jamison and Lumsden, 1988; Rand *et al.*, 1990b). Normal CSF consists of varying proportions of small lymphocytes and monocytes. The proportions are species and age dependent (Kjeldsberg and Knight, 1993). In dogs, monocytic type cells predominate (Jamison and Lumsden, 1988), although there is individual variation. In cats (Jamison and Lumsden, 1988; Rand *et al.,* 1990b), (unreactive) macrophages also predominate, with a mean of 87%, whereas small lymphocytes have a mean of 9%. This same trend is observed in horses, with 73.6% monocytes (macrophages) and 26.2% lymphocytes (Furr and Bender, 1994). However, small lymphocytes predominate in cattle (Welles *et al.*, 1992) and llamas (Welles *et al.*, 1994). In the literature published before 1975 that focused on humans, any neutrophils present in the CSF were thought to be indicative of disease (Kjeldsberg and Knight, 1993). However, with the advent of techniques for concentrating CSF specimens, such as cytocentrifugation, it became clear that a very small number of neutrophils may be found in normal human CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). Similar observations have been made in many veterinary species, and rare neutrophils may be a normal finding in the CSF of all domestic species. Eosinophils are not present in normal CSF, although a single cell is occasionally seen on cytocentrifuge slides in animals with normal total nucleated cell counts. Large foamy activated macrophages or phagocytes are not seen in normal CSF (Christopher *et al.*, 1988; Fishman, 1992), and their presence is nonspecific evidence of an inflammatory disorder. Plasma cells are not seen in normal CSF (Fishman, 1992; Kjeldsberg and Knight, 1993; Pelc *et al.*, 1981). Their presence indicates underlying inflammatory disease. In people, plasma cells are seen particularly in acute viral disease and various chronic inflammatory conditions including tuberculous meningitis, syphilis, multiple sclerosis, and the Guillain-Barré syndrome (Kjeldsberg and Knight, 1993; Pelc *et al.*, 1981). In animals, plasma cells have been observed in various conditions including distemper (Vandevelde and Spano, 1977), other viral meningitis (Bichsel *et al.*, 1984a; Vandevelde and Spano, 1977), rabies (Green *et al.*, 1992), granulomatous meningoencephalomyelitis (Bailey and Higgins, 1986a; Vandevelde and Spano, 1977), neoplasia, and abscesses (W. Vernau, personal observations). Therefore, although they are abnormal, no specificity is associated with their presence in CSF. Similarly, reactive lymphocytes are not found in normal CSF, but their presence has no specificity. They can be seen in active or resolving infectious disease, immune mediated diseases, and neoplasia (Cook and DeNicola, 1988).

2. *Other Cells*

Cells other than leukocytes can be seen in both normal and abnormal CSF. Cells lining the leptomeninges, choroid plexus cells, and ependymal cells can be seen as single cells or, more often, as small papillary clusters or sheets. Cytologically, choroid plexus cells and ependymal cells are indistinguishable (Cook and DeNicola, 1988; Garma-Avina, 2004; Kjeldsberg and Knight, 1993). The majority of lining cells seen in normal CSF is choroid plexus cells (Kjeldsberg and Knight, 1993). Excellent descriptions and illustrations of these cell types can be found elsewhere (Cook and DeNicola, 1988; Garma-Avina, 2004; Kjeldsberg and Knight, 1993; Rand *et al.*, 1990b). Chondrocytes are occasionally observed in CSF sampled by lumbar puncture, likely resulting from the spinal needle puncturing the intervertebral disk (Bigner and Jonston, 1981). Squamous cells can be observed in CSF and may be due to skin contamination or an underlying pathological process such as epidermoid cysts (Kornegay and Gorgacz, 1982) or metastatic carcinomas. Bone marrow cells (immature hematopoietic precursors) have been described in the CSF of people (Kjeldsberg and Knight, 1993) and dogs (Christopher, 1992). In people, bone marrow cells in the CSF are usually associated with lumbar puncture, usually in infants or in patients with vertebral bone abnormalities that create difficulties during the sampling process. The cells are present because of sampling from the vertebral body or articular process bone marrow. Christopher (1992) observed hematopoietic cells in the lumbar CSF of two dogs and speculated that it was due either to marrow penetration or to dural extramedullary hematopoiesis (Christopher, 1992).

Extramedullary hematopoiesis was observed in the choroid plexus of five dogs that did not have underlying hematological abnormalities or the presence of extramedullary hematopoiesis elsewhere (Bienzle *et al.*, 1995). Although the CSF was normal in these dogs and hematopoietic cells were not observed, this site could provide another potential source for the presence of these cells in CSF. Metastatic myeloid leukemia could conceivably produce similar findings, but peripheral blood and marrow examination would clarify the origin of the cells in question. Neurons, astrocytes, glial cells, and neural tissue may be observed in the CSF of people (Bigner and Jonston, 1981) and also in cerebellomedullary cisternal samples associated with traumatic CSF taps in animals (Fallin *et al.*, 1996). White matter in CSF is more common in lumbar versus cisternal CSF samples in dogs, most likely because of the sampling method,[1] although the presence of underlying malacia is another potential cause (Mesher *et al.*, 1996). White matter in the CSF is not correlated with a negative prognosis when compared to dogs without white matter in the CSF.[1]

V. BIOCHEMICAL CONSTITUENTS OF NORMAL CSF

Because CSF is a product of plasma filtration and membrane secretion, its composition is different from plasma. In general, CSF is a clear, colorless, nearly acellular, low protein fluid. Various ions, enzymes, and other substances are also found in normal CSF. In health, the CSF composition is maintained relatively constant by the various membrane interfaces, although some fluctuations occur with fluctuations in plasma composition. The chemical composition of the CSF of various animal species is summarized in Tables 26-5 through 26-8. These values should serve only as a guide; normal values must be established for individual laboratories.

A. Ontogeny of CSF

In people and animals, differences in CSF appearance and composition exist between neonates and adults. Human neonatal CSF is usually xanthochromic, probably because of a greater protein and bilirubin content than adult CSF. Glucose content is also increased, more closely approximating the blood glucose level. Many of these differences (e.g., protein content) are attributed to immaturity of the blood-brain barrier. Immaturity of the blood-brain barrier may be due to an increased number of fenestrae in the brain capillaries or inadequate closure of their endothelial tight junctions. Other factors that may contribute to age differences in CSF composition are the integrity of the blood-CSF barrier, the rate of CSF secretion and efficiency of absorption, the volume of the extracellular space of the brain, and the lipid-solubility of the substances (Davson and Segal, 1996; Fishman, 1992). Protein also decreases with age in foals and puppies (Furr and Bender, 1994; Meeks *et al.*, 1994; Rossdale *et al.*, 1982). In contrast, two studies of calves found that CSF protein increased with age (Binkhorst, 1982; St. Jean *et al.*, 1995). Foals also had xanthochromia and a higher CSF glucose and creatine kinase level than adults (Furr and Bender, 1994; Rossdale *et al.*, 1982). The white blood count (WBC) decreased with age in puppies and calves (Binkhorst, 1982; Meeks *et al.*, 1994).

Studies done in prenatal, neonatal, and adult laboratory animals (including rats, rabbits, pigs, sheep, cats, dogs, and monkeys) and people have shown that, in general, the CSF/plasma concentration ratios (R_{CSF}) of Na^+, Mg^{2+}, and Cl^- increase with age. The R_{CSF} of K^+, HCO_3^-, and urea decrease. In some instances, however (e.g., Cl^- and K^+), changing plasma levels of these substances contribute to the change in the R_{CSF}. The R_{CSF} of total protein, as well as the individual proteins, decreases with age. The decreasing concentration of proteins in the CSF compared to plasma protein is an indication of the maturation of the blood-brain and blood-CSF barriers. In rats, the R_{CSF} of amino acids also falls quickly with age, although large individual variations exist. Taurine, for example, has a higher level in the adult than the newborn. This fact, as well as the species-specific transport of some proteins (e.g., albumin) into the CSF, indicates a special mechanism of transport based on factors other than molecular weight (Davson and Segal, 1996).

B. Proteins in the Cerebrospinal Fluid

Proteins identified in the CSF are given in Tables 26-9 and 26-10. In general, the concentration of a CSF protein is inversely related to its molecular weight. If the blood-brain barrier is normal, serum proteins with a molecular weight greater than 160,000 daltons are largely excluded. However, Felgenhaur (1974) reported CSF:serum protein distribution ratios to be better correlated with the hydrodynamic radii than with the molecular weight of the proteins. Almost all the proteins normally present in CSF are derived from the serum. The exceptions are transthyretin (prealbumin) and transferrin, which are also synthesized by the choroid plexus, and beta and gamma trace proteins, tau protein (tau fraction, modified transferrin), glial fibrillary acidic protein, and myelin basic protein, which appear to be synthesized intrathecally (Thompson, 1988).

1. *Albumin*

With electrophoretic techniques, protein in the CSF can be separated into prealbumin, albumin, and alpha, beta, and gamma globulins. The major protein in CSF is albumin, which is synthesized only in the liver. The limited entry of albumin into the CSF is dependent on the blood-brain/CSF

barrier to macromolecules. When total CSF protein increases, the albumin concentration increases disproportionately. This phenomenon illustrates the role of molecular size in determining the distribution of serum proteins into the CSF (Felgenhauer, 1974).

2. *Alpha and Beta Globulins*

Immunoelectrophoresis can separate the alpha and beta globulins into several proteins (Table 26.9). The origin of tau protein (beta$_2$ transferrin) is uncertain. This protein may be modified serum transferrin (beta$_1$ transferrin) or it may be a unique protein, "tau protein," in the CSF (Fishman, 1992). In veterinary and human medicine, no correlation has been made between changes in the concentrations of these globulins and specific neurological disease (Fishman, 1992; Sorjonen *et al.,* 1991). Thus, their measurement has limited clinical use at this time.

3. *Gamma Globulins*

Because of the changes found in association with multiple sclerosis and other inflammatory diseases, the gamma globulins have received a great deal of attention. Electrophoretic techniques define the gamma globulins as a heterogeneous group of proteins with migrations at similar rates (see Table 26.9). The gamma globulin fraction contains immunoglobulins. Immunological assays identify three major immunoglobulins

in normal CSF: IgG, IgM, and IgA. Minute amounts of other immunoglobulins have also been detected in normal CSF (Fishman, 1992; Kjeldsberg and Knight, 1993).

a. IgG

The major immunoglobulin in normal CSF is IgG, which normally originates from the serum. An increased level of CSF gamma globulin is reported in a number of inflammatory central nervous system disorders. In disease conditions, gamma globulin may enter the CSF through dysfunctional blood-brain/CSF barriers, or it may be synthesized intrathecally by cells that have migrated into the brain or CSF and are participating in the disease process (Fishman, 1992; Kjeldsberg and Knight, 1993).

b. IgM and IgA

Cerebrospinal fluid IgM and IgA also originate normally from the serum. However, in certain diseases, particularly

inflammatory diseases, these immunoglobulins are produced within the central nervous system as well (Fishman, 1992; Kjeldsberg and Knight, 1993). IgM is ontogenetically and phylogenetically the most primitive immunoglobulin and is therefore detected at an earlier stage of the general immune response of the body. IgM is also the first immunoglobulin to return to normal when the offending antigen disappears. The characteristics of IgM and IgA participation in the intrathecal immune response still need to be resolved, however (Felgenhauer, 1982; Tipold and Jaggy, 1994).

4. *Other Proteins*

Many other proteins have been identified in CSF including myelin basic protein, S-100 protein, C-reactive protein, interferon, embryonic proteins, fibronectin, and glial fibrillary acidic protein. In general, the CSF concentrations of these proteins may be altered by a number of neurological disease processes. The utility of assaying these proteins in clinical veterinary or human medicine has yet to be established (Fishman, 1992; Kjeldsberg and Knight, 1993).

C. Glucose

CSF glucose is derived solely from the plasma by facilitated diffusion. The concentration of CSF glucose depends on the blood glucose concentration, the rate of glucose transport into the CSF, and the metabolic rate of the central nervous system. The normal CSF glucose level is about 60% to 80% of the blood glucose concentration, reflecting at least in part the high metabolic rate of the central nervous system. Equilibration with plasma glucose requires about 1 to 2h; thus, ideally, plasma glucose should be determined about 1 h before CSF aspiration and analysis. In people, a glucose gradient exists along the neuraxis; the concentration decreases from ventricular to lumbar fluid (Fishman, 1992; Kjeldsberg and Knight, 1993). In people, a CSF:serum glucose ratio less than 0.4 to 0.5 is abnormal and associated with bacterial and fungal infections, as well as metastasis to the leptomeninges (Deisenhammer *et al*., 2006). CSF glucose and serum CSF: glucose ratio is not routinely used in veterinary medicine, possibly because of the lack of specificity and availability of more specific tests in most instances.

D. Enzymes

Numerous enzymes have been assayed in the CSF of animals (see Tables 26.5 to 26.8) (Jackson *et al.*, 1996; Lobert *et al*., 2003; Rand *et al*., 1990a; Wilson, 1977) and people (Banik, 1983). These enzymes have three possible sources: (1) blood, (2) neural tissue or neural tumors, and (3) cells within the CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). The blood enzyme levels are usually higher than the CSF levels. Unfortunately, many studies of CSF levels in disease fail to report the concurrent blood level and a measure of blood-brain/CSF barrier integrity. However, studies of CSF creatine kinase (CK) in dogs and horses did not find a relationship between WBC counts, serum CK, or CSF total protein and CSF CK (Furr and Tyler, 1990; Jackson *et al.*, 1996). Regarding correlation of CSF red blood count (RBC) with CSF CK, one study reported a significant correlation (Indrieri *et al.*, 1980), whereas another study did not find a statistical association between the two parameters (Jackson *et al.*, 1996). CSF lactate is independent of blood glucose, and it may be measured in people and animals (Deisenhammer *et al.*, 2006; Lobert *et al.*, 2003). In people, blood:CSF lactate ratio may be elevated with mitochondrial disease and correlates inversely with the blood:CSF glucose ratio. To date, none of the enzyme assays is sufficiently sensitive or specific to warrant routine use in clinical practice (Fishman, 1992; Indrieri *et al.*, 1980; Jackson *et al.*, 1996; Kjeldsberg and Knight, 1993; Rand *et al.*, 1994a).

E. Neurotransmitters

Because they are produced by neurons, neurotransmitters and their metabolites have been extensively studied in people for their potential use as markers of neuronal activity and neurological and psychiatric disease (Davis, 1990). The concentrations of several neurotransmitters (e.g., γ-aminobutyric acid [GABA], glutamate, aspartate and dopamine) and their metabolites (e.g., 5-hydroxyindolacetic acid, homovanillic acid, and dihydroxyphenylacetic acid) have been measured in the CSF from various sites in dogs, sheep, goats, cattle, and horses (Bardon and Ruckebusch, 1984; Ellenberger *et al.*, 2004; Faull *et al.*, 1982; Holt *et al.*, 2002; Loscher and Schwartz-Porsche, 1986; Podell and Hadjiconstantinou, 1997; Ruckebusch and Costes, 1988; Ruckebusch and Sutra, 1984; Sisk *et al.*, 1990; Vaughn *et al.*, 1988a, 1989). Some metabolite concentrations have a gradient along the neuraxis (Ruckebusch and Costes, 1988; Ruckebusch and Sutra, 1984; Vaughn *et al.*, 1988b; Vaughn and Smyth, 1989), and some are age-related (Ruckebusch and Costes, 1988; Smyth *et al.*, 1994; Vaughn and Smyth, 1989).

Despite intense interest, more research is needed to verify the clinical utility of assay of these substances in the CSF (Fishman, 1992; Kjeldsberg and Knight, 1993).

F. Other CSF Constituents

Many other substances have been measured in CSF in experimental and clinical situations. These include electrolytes, gases, organic and amino acids, ammonia, urea, creatinine, prostaglandins, cytokines, and hormones. Assay of these substances is not particularly helpful in the diagnosis of neurological disease in people because the substances are not generally associated with specific disease (Fishman, 1992; Kjeldsberg and Knight, 1993). Some substances, such as S-100B, a calcium-binding protein, have been used as a marker protein in

people with brain injury, but its utility in veterinary medicine is unproven (Shimada *et al.*, 2005). The usefulness of these substances in veterinary medicine has yet to be established.

G. Concentration Gradient along the Neuraxis

In cats (Hochwald *et al.*, 1969), dogs (Bailey and Higgins, 1985; Vaughn *et al.*, 1988b), horses (Andrews *et al.*, 1990a; Vaughn and Smyth, 1989), rhesus macaques (Smith and Lackner, 1993), and people (Davson and Segal, 1996; Fishman, 1992), the total protein concentration increases along the neuraxis from rostral to caudal. For example, in people the total protein concentration of ventricular, cerebellomedullary cistern, and lumbar subarachnoid fluid is about 26, 32, and 42 mg/dl, respectively (Weisner and Bernhardt, 1978). Total protein, albumin, and globulin content of cerebellomedullary cistern and lumbar subarachnoid CSF for dogs, cats, and horses is given in Tables 26.5, 26.6, and 26.7, respectively. The concentration of the albumin and globulin fractions also increases from ventricular to lumbar fluid. The increased protein content may be the result of a greater permeability of the spinal blood-CSF barrier than of the ventricular barrier to albumin (Fishman, 1992), additions of protein from adjacent nervous tissue (e.g., IgG from lymphocytes located in or near the CSF pathway (Weisner and Bernhardt, 1978), progressive equilibration of CSF with plasma through the capillary walls (Weisner and Bernhardt, 1978), and low flow rates of lumbar CSF (Davson and Segal, 1996).

A study of healthy dogs also identified a small but significant gradient for the CSF WBCs; lumbar fluid contained significantly fewer cells than cerebellomedullary fluid (Bailey and Higgins, 1985). Another study did not find a difference in WBC counts between fluids from the two sites (Vaughn *et al.*, 1988b). However, 4 of the 10 dogs in this study had CSF total WBC counts $>3/\mu$l, and none of the dogs was necropsied to verify its health. Therefore, some of these dogs may have had subclinical neurological disease, disguising a small cellular gradient. The small number of WBCs in normal fluid may make a cellular gradient more of a theoretical issue than a practical issue, however. If a cellular gradient exists, it may be due to fewer cells entering the lumbar CSF than the cerebellomedullary CSF, a greater rate of cell lysis in the lumbar CSF, a greater migration rate of WBCs from lumbar CSF back into the blood, or loss of WBCs that entered the CSF rostrally and lysed as CSF circulated to the caudal subarachnoid space.

A gradient has also been reported for CSF neurotransmitter metabolites in the dog (Vaughn *et al.*, 1988b) and the horse (Vaughn and Smyth, 1989). In each species, the neurotransmitter metabolite content of cerebellomedullary CSF was greater than that of lumbar subarachnoid CSF. This gradient probably reflects the major source of the neurotransmitter (brain) and transport of the metabolite from the CSF into the blood along the spinal axis (Vaughn *et al.*, 1988a).

VI. CSF COLLECTION AND ANALYTICAL TECHNIQUES

A. Collection

1. *General Techniques*

Specific details about the collection of CSF from the various species are covered in many excellent articles and textbooks (Boogerd and Peters, 1986; Brewer, 1983, 1987, de Lahunta, 1983; Fowler, 1989; Holbrook and White, 1992; Kornegay, 1981; Mayhew, 1989) and will not be covered here except for the authors' preferred technique for collection from the cerebellomedullary cistern of dogs and cats (discussed later). Considerations that apply regardless of species are sterility, use of a specialized spinal needle, and collection from animals with increased intracranial pressure. To prevent iatrogenic central nervous system infection, sterility during the collection procedure is essential. A generous area around the puncture site should be clipped and surgically prepared. Preparation of too small an area can lead to contamination if any difficulty in palpating landmarks or entering the subarachnoid site is encountered. Additionally, the use of a fenestrated drape is highly recommended. Spinal puncture is contraindicated in an area of severe pyoderma/furunculosis or cellulitis. A needle with a stylet (spinal needle) should be used to prevent implantation of a plug of epidermis in the subarachnoid space that not only could lead to infection but also could seed an epidermoid tumor. Replacement of the stylet upon withdrawal is controversial, either preventing or causing entrapment and severance or dislocation of nerve root filaments (Fishman, 1992). Collection of CSF from animals with increased intracranial pressure may result in brain herniation. Appropriate anesthetic agents, hyperventilation, and mannitol (to treat intracranial hypertension) may decrease the probability of herniation. Use of the smallest gauge needle possible may also help prevent herniation by decreasing CSF leakage through the puncture hole in the meninges. Only the minimal amount of CSF necessary to perform the desired tests should be withdrawn. Brain herniation can occur following lumbar taps as well as cerebellomedullary cistern taps.

2. *Collection Site*

Cerebellomedullary puncture should be done under general anesthesia. In most instances, lumbar puncture can be done with sedation and local anesthesia. Therefore, if general anesthesia is contraindicated, a lumbar puncture should be done.

The choice of collection site is influenced by the species and breed of animal, the location of the neurological lesion, and anesthetic considerations. The size of some animals may make lumbar subarachnoid puncture difficult, if not impossible. However, cerebellomedullary puncture usually can be accomplished even in large or obese animals. Because of differences in anatomy, the type or breed influences the exact site for lumbar puncture in the dog; L4-5 is

recommended for large breed, nonchondrodystrophic dogs (e.g., German shepherd dogs), whereas L5 to 6 is recommended for small, chondrodystrophic dogs (e.g., dachshunds) (Morgan *et al.*, 1987). The puncture site chosen should be as close to the lesion as possible without penetrating the lesion, or the site should be caudal to the lesion. In animals with spinal disease, cerebellomedullary fluid is abnormal more frequently with cervical disease than it is with thoracolumbar disease, but overall lumbar fluid is abnormal more often than cerebellomedullary fluid. With intracranial disease, CSF from both sites is usually abnormal, perhaps because both sites are caudal to the lesion (Scott, 1992; Thomson *et al.*, 1989, 1990). Occasionally, CSF is collected from both sites. Although the order of collection (cerebellomedullary or lumbar CSF collected first) appears not to influence significantly the analytical results (Bailey and Higgins, 1985), aspiration from the relatively small lumbar subarachnoid space is easier if the CSF pressure has not just been lowered by cerebellomedullary CSF collection.

3. CSF Collection from the Cerebellomedullary Cistern

The authors' preferred technique for CSF collection from the cerebellomedullary cistern is to utilize the palpable bony landmarks that are the closest to the puncture site. These structures are the vertebral arch of C1 and the external occipital protuberance. After anesthetic induction and intubation, the animal is placed in right lateral recumbency, and padding is placed under the neck to align the dorsal cervical and cranial midline parallel to the tabletop. The assistant is instructed to tuck in the animal's chin (flex the neck) and push the external occipital protuberance toward the operator. This procedure flexes the atlantooccipital joint and maximizes the space between the occipital bone and C1. Asking the assistant to simply flex the neck seems to produce flexion of the midcervical area more than the atlantooccipital area.

The clinician faces the dorsal aspect of the patient's neck, kneeling on a pad. The external occipital protuberance, the C2 spinous process, and the C1 vertebral arch are palpated. The latter structure is located by rolling a fingertip off the cranial edge of the C2 spinous process and palpating firmly, feeling for a transverse bony ridge (the C1 vertebral arch). The C1 vertebral arch can usually be palpated, and if so, the puncture is made on the midline just in front of the fingertip palpating the vertebral arch. If C1 is not palpable, the distance between the cranial edge of the C2 spinous process and the occipital protuberance is noted, and the puncture is made on the midline about one-third of that distance cranial to the cranial edge of the C2 spinous process. In rare cases, neither C1 nor C2 can be palpated. In this situation, the lateral edge of each C1 transverse process is palpated and a triangle from each edge to the occipital protuberance is constructed visually. The puncture is made on the midline in the center of that triangle. The needle should be advanced slowly and the stylet removed regularly. A "pop" may be palpated when the dura mater is punctured with the needle. The clinician should hold the spinal needle with one hand (to hold it steady) and remove the stylet with the other hand. The CSF should be allowed to drip out of the spinal needle into a tube. A volume of at least 0.5 mLs should be collected for a full CSF analysis (partial analysis may be done with smaller volumes). Larger volumes may be collected for other tests such as culture and sensitivity, polymerase chain reaction for infectious agents, antigen/antibody testing, immunophenotyping, and clonality assessment. To collect CSF for culture and sensitivity testing, aspirate CSF directly from the spinal needle hub using a needle and syringe.

B. Physical Examination: Clarity, Color, and Viscosity

After collection, the CSF is examined visually and the color, clarity, and viscosity are recorded. Normal CSF is clear and colorless and has essentially the same viscosity as water. For accurate assessment, the CSF can be compared to the same amount of distilled water in the same type of container. The containers can be held against a white, typewritten page to judge color and clarity, and gently shaken to assess viscosity. If the CSF appears abnormal, the color and clarity of the supernatant after centrifugation should be noted.

C. Cytological Analysis

1. General Techniques

Collection of CSF in a plastic or silicon coated glass tube is preferred because monocytes will adhere to glass and can activate in the process (Fishman, 1992). This can result in erroneous cell counts and also alter morphology. In practical terms, this is of little consequence in those specimens that are rapidly processed, but it becomes important as the delay between collection and processing increases. A complete cytological examination includes both a total and differential cell count, as well as thorough morphological assessment. A differential and thorough morphological assessment should be done routinely, even on those samples that have cell counts within normal limits. In our experience, very low cell counts alone cannot be used as an indicator of normality. In one study utilizing cytocentrifugation, about 25% of canine CSF samples with cell counts in the normal range had abnormalities in cell type or morphology (Christopher *et al.*, 1988). Abnormalities included the presence of phagocytic macrophages, increased percentage of neutrophils in the differential, and the presence of reactive lymphocytes and plasma cells. Malignant cells have been observed in samples with normal nucleated cell counts (Bichsel *et al.*, 1984b; Grevel and Machus, 1990). CSF samples should be processed as soon as possible after collection. Cells degenerate quickly in CSF (Chrisman, 1992; Fishman, 1992; Fry

et al., 2006; Kjeldsberg and Knight, 1993; Steele *et al.*, 1986), likely secondary to the CSF hypotonicity and very low protein content (in nonpathological specimens). Proteins and lipids tend to have a membrane stabilizing effect (Fry *et al.*, 2006; Steele *et al.*, 1986). A multitude of veterinary references state that CSF must be processed within 30 min of collection (Chrisman, 1983; Cook and DeNicola, 1988; Oliver and Lorenz, 1993; Thomson *et al.*, 1990). However, these references do not cite scientific data to support this statement. One study systematically evaluated the effects of time, initial composition and stabilizing agents on the results of abnormal (TNCC $\geq$ 5 cells/ul) canine CSF evaluation (Fry *et al.*, 2006). Statistically significant changes ($p = <0.05$) in the total nucleated cell count were not noted at any time point (0, 2 h, 4 h, 8 h, 12h, 24h, and 48h) in unaltered (refrigerated) CSF, CSF with added fetal calf serum, or CSF with added hetastarch. However, differential cell percentages deteriorated in a time dependent fashion and macrophages were the most labile cell type in this study with their differential percentage being significantly decreased by 2 h. Concurrently, the percentage of unrecognizable cells was significantly increased at 2 h. At 12 and 24 h, the percentages of lymphocytes and neutrophils, respectively, were significantly decreased. Samples with a higher protein concentration ($\geq$50 mg/dl) were less susceptible to deterioration than those with a lower protein concentration ($<$50 mg,dl). The addition of fetal calf serum or hetastarch improved the stability of the CSF. Ultimately, the authors supported the contention that CSF should be analyzed as soon as possible post collection but that delays of 4 to 8 h were unlikely to alter the overall clinical interpretation (Fry *et al.*, 2006). If the protein concentration is $>$50 mg/dL, the analysis may be delayed up to 12 h without altering the overall clinical interpretation as the mean percentage of unrecognizable cells was only 6% at this time point (versus 33% in samples with protein concentration $<$50 mg/dl) (Fry *et al.*, 2006). Several reports recommend altering CSF processing when it is not analyzed within 1 h of collection (Bienzle *et al.*, 2000; Fry *et al.*, 2006). If there is a delay in processing, CSF samples should be divided into two aliquots. The unaltered aliquot should be submitted for TNCC and protein concentration. The second aliquot should be treated by the addition of either 20% fetal calf serum or 10% autologous serum, and the differential cell counts and morphology should be assessed on the second altered aliquot.

In a study of feline CSF, there was excellent correlation between the total numbers of cells on the slides and the differential cell count between sediment slides processed immediately and those preserved with fetal bovine serum (200 μl of CSF and 200 μl of fetal bovine serum) and cytocentrifuged 2 to 4 h later (Rand *et al.*, 1990b).

There have also been several human studies performed on the effects of time and temperature on CSF (Kjeldsberg and Knight, 1993; Steele *et al.*, 1986; Stokes *et al.*, 1975). Interestingly, in these studies, and in contrast to the above study assessing canine CSF, neutrophils and not large mononuclear cells were the most labile cell type. Refrigeration at 4°C markedly reduced the rate of lysis of all cell types in the human CSF studies. Therefore, the recommendation that analysis be performed within 30 min is reasonable, but it is predicated by the conditions that the sample is exposed to. Refrigeration obviously slows lysis, likely long enough for transport to reference laboratories in some instances. Addition of protein to the sample helps preserve cells and therefore attenuates the temporal effects involved in transport of samples to more remote facilities.

2. *Total Leukocyte and Erythrocyte Counts*

Electronic cell or particle counters are typically not sensitive enough to be used for enumeration of cells in CSF. The level of background counts with these counters is frequently in excess of the counts present in the majority of CSF samples that are analyzed. Therefore, cells are usually counted with a standard hemacytometer chamber with Neubauer ruling (Brobst, 1989; Cook and DeNicola, 1988; Jamison and Lumsden, 1988). The chamber is charged with undiluted fluid. Ideally, the cells are allowed to settle for 10 min in a humidified environment. This allows all the cells to be visible in the same plane of focus. The cells in the nine largest squares on both sides of the chamber are counted (18 squares in total) and the result multiplied by 0.55 to obtain the number of cells per microliter. Alternatively, the cells in nine large squares are counted and the number multiplied by 1.1 to determine the count per microliter. To the untrained observer, unstained leukocytes and erythrocytes may be difficult to differentiate. Leukocytes are larger, and the presence of nuclei gives them a more granular appearance than erythrocytes. With experience, nuclear morphology can often be appreciated (Cook and DeNicola, 1988). The cytoplasmic border is usually slightly irregular. In contrast, erythrocytes are usually smaller, smooth, and refractile, although they may become crenated upon standing (Jamison and Lumsden, 1988). Differentiating nucleated cells and erythrocytes in a hemacytometer chamber can be expedited by staining with New Methylene Blue before counting (Fry *et al.*, 2006). This latter technique can be used without significant dilutional effects.

A laser based cell counter and dedicated software are used to count and differentiate cells in human CSF (Aune *et al.*, 2004; Mahieu *et al.*, 2004). This technique has the advantage of markedly superior precision and accuracy. The same methodology has been used to assess canine CSF (Ruotsalo *et al.*, 2005). Although there was good correlation between the leukocyte and erythrocyte concentrations when compared with standard hemacytometer methods, the current software algorithms were not suitable for determining an accurate differential count in canine CSF. Additionally, it is likely that the cost and logistics of this methodology will preclude routine use in veterinary medicine.

3. *Cytological Examination*

There are a variety of methods to facilitate cytological examination of CSF (Barrett and King, 1976; Ducos *et al.*, 1979; Grevel, 1991; Hansen *et al.*, 1974; Jamison and Lumsden, 1988; Kolmel, 1977; Roszel, 1972; Sornas, 1967; Steinberg and Vandevelde, 1974; Woodruff, 1973). There is controversy as to which method is optimal, and all have their strengths and weaknesses. Methods include simple centrifugation, sedimentation, and variations thereof; membrane filtration; and cytocentrifugation (Jamison and Lumsden, 1988). Consult these references for specific methodological details. Simple centrifugation usually produces slides that are unsatisfactory for cytological examination. The chief advantage of membrane filtration techniques is excellent cellular recovery with yields approaching 90% to 100% (Barrett and King, 1976). However, the methodology is laborious and time consuming, the cellular morphology relatively poor, many cells are partly hidden in the filter substance, which itself stains variably, and the technique requires specialized, nonroutine staining techniques that most veterinary clinical pathologists do not have experience or expertise in interpreting. For these reasons, they are not recommended. Cytocentrifugation (Hansen *et al.*, 1974; Woodruff, 1973) is the method of choice in both human (Fishman, 1992; Kjeldsberg and Knight, 1993) and veterinary medicine (Christopher *et al.*, 1988; Jamison and Lumsden, 1988). It is rapid, simple, and produces slides with good cytological detail. The technique is enhanced by the addition of protein to the CSF sample before centrifugation, which helps to preserve cell morphology. Conditions of cytocentrifugation vary from laboratory to laboratory. We prefer the method described by Rand and colleagues (Rand *et al.*, 1990b). The disadvantages of cytocentrifugation are the expense of the instrument and the relatively low cell yield. In one comparative study (Barrett and King, 1976), the following cell yields were determined: millipore filtration 81 $\pm$ 3% (SEM), nucleopore filtration 69 $\pm$ 3%, and cytocentrifugation 11 $\pm$ 1%. The Sornas method of centrifugation results in a cell yield, after staining, of approximately 20% (Sornas, 1967). The sedimentation technique of Sayk, modified by Kölmel (Grevel, 1991; Grevel and Machus, 1990; Kolmel, 1977), results in a yield of approximately 30% (Kolmel, 1977), although this can be increased to almost 90% if a membrane filter is substituted for direct sedimentation onto a slide. We have some experience with the Kölmel apparatus and technique and have found the cell morphology to be at least as good as cytocentrifugation with an apparently superior cell yield, although this needs to be confirmed with controlled comparative studies. Therefore, most studies suggest that sedimentation techniques result in greater cell yields than does cytocentrifugation. However, there is at least one study that found the yield of cytocentrifugation to be marginally higher than sedimentation (Ducos *et al.*, 1979). Standard Romanowsky stains are recommended for staining of slides. They provide good cellular detail on air-dried CSF preparations and are familiar to most observers. These stains include the Wright's and Wright–Giemsa staining methods as well as a variety of rapid staining methods including Diff-quik and Camco-quik (Jamison and Lumsden, 1988).

4. *Immunocytochemistry*

In people, the value of cytological diagnosis of CSF can be improved if morphological studies are appropriately supplemented by immunocytochemistry (Kjeldsberg and Knight, 1993). Immunophenotypic studies of cytocentrifuge slides are useful in the differential diagnosis of leukemia, lymphosarcoma, primary brain tumors, and metastatic tumors (Bigner, 1992; Bigner and Jonston, 1981; Jorda *et al.*, 1998; Kjeldsberg and Knight, 1993; Tosaka *et al.*, 2001). Few veterinary studies document CSF immunocytochemistry. In dogs, immunophenotyping is useful in the diagnosis of lymphoma and infiltrative leukemia[2] and histiocytic sarcoma, both postmortem (Zimmerman *et al.*, 2006) and antemortem.[3]

Panels of monoclonal antibodies are typically used for the immunocytochemical assessment of CSF. The greatest limitation is therefore the volume and cellularity of the specimen available for the marker studies. Undifferentiated tumor panels frequently include leukocyte common antigen and cytokeratin antibodies. These can be helpful in distinguishing single carcinoma cells from lymphocytes or monocytes (Bigner, 1992; Bigner and Jonston, 1981; Kjeldsberg and Knight, 1993). Glial fibrillary acidic protein has proven to be helpful in distinguishing a glial origin, but there are currently no specific markers to distinguish primary brain tumors. Immunocytochemistry can be used also to characterize the lymphocyte subpopulations present in CSF. Seventy-five to 95% of the lymphocytes found in normal human CSF are T cells, with a mean of approximately 85% (Kjeldsberg and Knight, 1993). Within the population of T cells, T-helper cells predominate and account for up to 88% of T cells. Alterations of these percentages have been shown to have significant associations with disease in people (Kjeldsberg and Knight, 1993). Similar studies assessing CSF lymphocyte subset alterations in disease are lacking in domestic animals but may be useful. Lymphocyte subset distribution has been assessed in the brains of dogs with different types of diseases (Tipold *et al.*, 1999). T cells predominated in viral encephalitides, whereas B cells predominated in bacterial and protozoal diseases and in steroid responsive meningitis-arteritis (Tipold *et al.*, 1999). However, it has not been determined if similar changes are reflected in the CSF. Lymphocyte subset distribution has been assessed in normal dogs and horses (Duque *et al.*, 2002; Furr *et al.*, 2001; Tipold *et al.*, 1998) Similar to people, T lymphocytes predominate in canine CSF but are present as a lower percentage than in people, accounting for approximately 50% to 60% of lymphocytes (Duque *et al.*, 2002; Tipold *et al.*, 1998). However, there appears to be

[2]Vernau, W., unpublished observations.
[3]Tzipory, Vernau, Moore, in preparation.

much individual variation that may complicate use of this type of assessment clinically (Tipold *et al.*, 1998). Horses appear to be more similar to people, with T cells accounting for approximately 80% of lymphocytes in the CSF (Furr *et al.*, 2001). However, in contrast to people, CD8+ T cells in normal equine CSF may constitute a greater subset of T cells, accounting for approximately 30% of CSF T cells in one study (Furr *et al.*, 2001). In people, most central nervous system lymphomas are B cell in origin; immunocytochemistry assessing immunoglobulin light chain expression can be used to document monoclonality (Bigner, 1992; Bigner and Jonston, 1981). This is strong evidence (but not definitive proof) of malignancy. This assessment cannot be made in most domestic animals because of the marked light chain skewing that exists normally in these species (Arun *et al.*, 1996: Butler, 1998, #387). The B cell origin of the lymphocytes can also be confirmed with demonstration of immunoglobulin light chain expression. For patients with T cell lymphomas, marker studies can be more difficult to interpret as T cells predominate in normal and inflammatory CSF (Kjeldsberg and Knight, 1993). If there is systemic involvement, then comparison with the peripheral phenotype is useful to confirm presence in the CSF. Immunocytochemistry has also been utilized to detect infectious agents such as cytomegalovirus and mycobacterium tuberculosis in human patients (Stark *et al.*, 1993; Sumi *et al.*, 2002) and distemper virus in dogs (Abate *et al.*, 1998).

5. *Polymerase Chain Reaction*

Polymerase chain reaction (PCR) technology is a powerful adjunct to routine cytological assessment of CSF that may increase both the sensitivity and specificity of diagnosis. Because PCR exponentially increases *in vitro* the number of original DNA copies to a final number dependent on the number of cycles programmed, it is uniquely suited to the low volumes and small cell numbers frequently found in CSF samples. In people, one of the most useful applications of PCR methodology is the confirmation of malignancy and detection of minimal residual disease in lymphomatous meningitis (Rhodes *et al.*, 1996). This is accomplished via detection of clonal immunoglobulin or T cell receptor gene rearrangements and the detection of clone specific rearrangements, respectively. However, the exquisite sensitivity may result in false positive results because of either contamination or very low initial numbers of cells producing an artifactual clonal band. Tumor specific quantitative reverse transcriptase PCR (qRT-PCR) has been used for the sensitive detection of (neoplastic) neuroblastoma cells in the CSF of a human patient (Rosanda *et al.*, 2006). Other applications in people include detection of a wide variety of infectious agents, such as toxoplasma, borrelia, tuberculosis, human immunodeficiency virus, rabies virus, herpes simplex virus, and various amebas (Christen *et al.*, 1995; Guffond *et al.*, 1994; Lin *et al.*, 1995; Novati *et al.*, 1994; Qvarnstrom *et al.*, 2006). In the majority of these studies, PCR results in a more rapid diagnosis with superior sensitivity and specificity when compared to standard culture and serological diagnostic techniques (Deisenhammer *et al.*, 2006).

In veterinary medicine, PCR is used to detect several infectious agents in CSF samples, such as bacteria (*listeria monocytogenes* and *Streptococcus equi*), protozoa (*sarcocystis neurona*, *toxoplasma gondii*, *neospora caninum*), and viruses (canine distemper virus, West Nile virus, and equine herpesvirus-1) (Amude *et al.*, 2006a, 2006b; Cannon *et al.*, 2006; Fenger, 1994; Finno *et al.*, 2006; Frisk *et al.*, 1999; Goehring *et al.*, 2006; Kim *et al.*, 2006; Peters *et al.*, 1995; Schatzberg *et al.*, 2003; Stiles *et al.*, 1996). Some agents such as listeria, encysted neospora or toxoplasma bradyzoites in the CNS parenchyma may not gain access to the meningoventricular system. This may result in negative CSF PCR results in confirmed positive cases (Peters *et al.*, 1995). A combination of diagnostic information (clinical information, CSF assessment, serology, PCR, biopsy, and immunohistochemistry) is the most practical way to make a clinical diagnosis, rather than the use of a single test result, such as PCR (Schatzberg *et al.*, 2003). PCR assays for the detection of clonal immunoglobulin or T-cell receptor gene rearrangements in dogs and cats have now been developed (Burnett *et al.*, 2003; Moore *et al.*, 2005; Vernau and Moore, 1999; Werner *et al.*, 2005). These assays have been used for the confirmation of malignancy in the CSF of dogs with suspected CNS lymphoma (W. Vernau, unpublished data). Recently, qRT-PCR was used to assess the cytokine profiles present in the CSF of horses with different neurological disorders (Pusterla *et al.*, 2006b). Some differences were noted between the different types of diseases but significant overlap of values also occurred. Further developmental work in conjunction with additional prospective studies will be required before the true utility of PCR based CSF diagnostics can be accurately assessed in domestic animals.

D. Protein Analysis

1. *Measurement of* CSF *Total Protein*

An increase in the concentration of CSF total protein was recognized as an indicator of neurological disease soon after the introduction of lumbar puncture in human medicine. A number of tests were developed to assess qualitative changes in CSF protein, such as Lange's colloidal gold test, the Nonne-Appelt test, the Pandy test, and others. These qualitative tests have largely been replaced by quantitative methods. Urinary dipsticks have been used to determine CSF protein concentration, but false negative and false positive test results occur using this methodology, which preclude recommendation for routine use (Behr *et al.*, 2003; Jacobs *et al.*, 1990). Techniques for quantitative measurement of CSF total protein include turbidimetric methods, biuret procedures, and Lowry's method. The accuracy of these methods in many clinical laboratories is no better than ±5% (Fishman, 1992). Dye binding microprotein assays such as Coomassie Brilliant Blue, Ponceau

S red, and Pyrogallol red (Marshall and Williams, 2000; Pesce and Strande, 1973) are more accurate and are now the methods of choice for measurement of CSF protein concentration. Total CSF protein values are reported in numerous articles and vary noticeably with the methodology and the laboratory performing the assay. Therefore, clinicians must use laboratory-specific normal values when assessing CSF protein concentration.

2. CSF Protein Fractionation

A number of techniques for fractionation of CSF proteins have been developed. These include electrophoresis using paper or cellulose acetate, agar, agarose, polyacrylamide, and starch gels. Immunoelectrophoresis, electroimmunodiffusion, radioimmunoassay, isoelectric focusing, and high-resolution protein electrophoresis are more recent techniques (Behr *et al.*, 2006; Fishman, 1992; Kjeldsberg and Knight, 1993). Because of the normally low protein content, most of these methods require concentration of the CSF, which can create technical artifacts in the measured protein content. Techniques that do not require CSF concentration, such as electroimmunodiffusion, are therefore advantageous (Fishman, 1992).

3. Albumin and the CSF/Serum Albumin Index

Because albumin is synthesized only extrathecally, increased CSF albumin indicates damage to the blood-brain/CSF barriers, intrathecal hemorrhage, or a traumatic CSF tap. In these conditions, albumin will leak into the CSF in general proportion to its serum concentration. Therefore, in the absence of intrathecal hemorrhage (pathological or iatrogenic), the ratio of CSF albumin to serum albumin can be used as an indicator of barrier dysfunction (Link and Tibbling, 1977; Tibbling *et al.*, 1977). This ratio is also called the albumin index (a.k.a. albumin quota, albumin quotient) and is calculated as follows (Kjeldsberg and Knight, 1993):

$$\text{Albumin Index} = \frac{\text{CSF albumin (mg/dl)}}{\text{serum albumin (g/dl)}}$$

Values above the normal range indicate increased barrier permeability. The use of this index is potentially limited, however, because the large variability of CSF albumin in normal animals (at least in dogs and horses) (Andrews *et al.*, 1990a, 1994; Bichsel *et al.*, 1984b; Krakowka *et al.*, 1981) results in a large variability in the values for this index (Davson and Segal, 1996). In people, the albumin index is age dependent, being highest in newborns, and lowest in childhood. The albumin index increases with age (Deisenhammer *et al.*, 2006).

4. Quantitative Measurement of Immunoglobulins

a. IgG and the IgG/Albumin Index

The identification of intrathecal production of immunoglobulin is helpful in the diagnosis of neurological disease. Immunoglobulin G is the dominant CSF immunoglobulin. However, the IgG content of CSF is not a particularly useful measurement by itself because the IgG present in CSF may be of serum-origin (via a dysfunctional blood-brain/CSF barrier, intrathecal hemorrhage, or traumatic puncture) or intrathecally produced (as in various neural diseases). Varied opinions exist regarding the best way to calculate the contribution of IgG from each source (Thompson, 1988; Trotter, 1989). To determine the probable origin of CSF IgG, it can be related mathematically to a protein of purely extrathecal origin. Because albumin is synthesized entirely extrathecally, it is the preferred comparison protein and is the most widely used (Fishman, 1992). Transferrin and alpha$_2$ macroglobulin have also been recommended because of their extrathecal origin (Schliep and Felgenhauer, 1974).

The simplest formula for correction of the CSF IgG level for extrathecal "contamination" (Zimmerman *et al.*, 2006), and thereby demonstration of intrathecal IgG synthesis, is the IgG/albumin index (Link and Tibbling, 1977; Tibbling *et al.*, 1977). This index is calculated using the CSF and serum concentrations of albumin and IgG as follows (Kjeldsberg and Knight, 1993):

$$\text{IgG Index} = \frac{\dfrac{\text{CSF IgG (mg/dl)}}{\text{serum IgG (g/dl)}}}{\dfrac{\text{CSF albumin (mg/dl)}}{\text{serum albumin (g/dl)}}}$$

The denominator of this index (CSF albumin/serum albumin) is the albumin index. Because albumin is synthesized only extrathecally, the albumin index assesses the amount of albumin crossing the blood-brain/CSF barriers and therefore is a measure of barrier integrity. Blood contamination of the CSF with as little as 0.2% serum (equivalent to about 5000 to 10,000 RBC/μl) by a traumatic puncture falsely elevates the IgG index in people (Peter and Tourtellotte, 1986). Also, the IgG index loses reliability when CSF protein levels are less than 25 mg/dl or greater than 150 mg/dl (Boerman *et al.*, 1991).

An additional problem with the IgG index is its basic premise that the selectivity of the protein transfer at the blood-CSF barrier is independent of the actual permeability condition. This concept has been shown to be incorrect and the IgG index, as well as the IgA and IgM indices, vary in a nonlinear fashion with progressive impairment of the barrier (Reiber and Felgenhauer, 1987). Therefore, Reiber and Felgenhauer (1987) developed a formula to calculate the intrathecally synthesized fractions of IgG, IgM, and IgA in the CSF.

b. IgM and IgA Indices

As with IgG, CSF IgM and IgA may be of serum origin or intrathecally produced. Indices for IgM and IgA can be calculated in the same fashion as for IgG (Fryden *et al.*, 1978). However, because of high variability in normal IgM and IgA levels and the biological variation of these large molecules, the application of the same formula for IgM and IgA indices as used for the IgG index may only

provide rough estimates (Reiber and Felgenhauer, 1987; Tipold *et al.*, 1994).

5. Qualitative Immunoglobulin Assays

Qualitative assays of CSF immunoglobulins include agarose-gel electrophoresis, acrylamide immunoelectrophoresis, isoelectric focusing, and immunofixation. These tests separate the proteins into "bands" and provide information regarding the CSF protein composition. Although abnormal band patterns are not specific for a particular disease, they do indicate pathology and may indicate a type of disease. Abnormal band patterns may be detected even in patients with a normal IgG index. Thus, both quantitative and qualitative immunoglobulin assays are useful in the assessment of central nervous system disorders in both people and animals, particularly immunological or inflammatory diseases (Bichsel *et al.*, 1984b; Deisenhammer *et al.*, 2006; Fishman, 1992; Kjeldsberg and Knight, 1993).

E. Antibody/Antigen Tests

A variety of CSF antibody and antigen tests are available for viruses, fungi, rickettsia, protozoa, parasites, and other organisms (Berthelin *et al.*, 1994a; Duarte *et al.*, 2006; Dubey, 1990b; Jacobs and Medleau, 1998; Lunn *et al.*, 2003; Madhusudana *et al.*, 2004; Porter *et al.*, 2004; Rossano *et al.*, 2003). For antibody titers, two samples taken 2 weeks apart should be assayed. Because of interrun variability, the samples should be assayed at the same time in the same analytical run. Interpretation of CSF antibody titers must take into account the possibility of passage of serum antibodies through a defective blood-brain/CSF barrier. Serum antibodies could be present because of disease, previous exposure to antigen, or vaccination. Ideally, the CSF/serum albumin index and IgG index are also determined (see Sections V.D.3 and V.D.4) to identify blood-CSF barrier dysfunction and intrathecal production of immunoglobulin. Intrathecal production of antigen-specific antibody (specific Ig) can be determined with an antibody index in the same fashion as intrathecal IgG production is detected with the IgG index. The formula is (Reiber and Lange, 1991):

$$\text{Antibody Index} = \frac{\dfrac{\text{CSF specific Ig}}{\text{serum specific Ig}}}{\dfrac{\text{CSF total Ig}}{\text{serum total Ig}}}$$

A modification of this formula accounting for large local synthesis of polyclonal IgG in the central nervous system may be necessary (Reiber and Lange, 1991). An antibody index >1 suggests intrathecal production of the specific antibody (Munana *et al.*, 1995; Reiber and Lange, 1991). Antibody indices have been calculated in human patients with a variety of diseases (Reiber and Lange, 1991). The diagnostic reliability of these indices and application to clinical veterinary medicine need further study.

Antigen detection tests include immunoelectrophoretic techniques, agglutination tests, and enzyme-linked immunosorbent assay (ELISA) for bacterial antigens and latex agglutination for cryptococcal antigens. The polymerase chain reaction (PCR) procedures detect the presence of specific antigen DNA (or RNA) in CSF and can be highly sensitive, specific, and rapid (see Section V.C.5).

F. Microbial Tests

The Gram stain, the Ziehl-Neelson acid-fast stain, and both aerobic and anaerobic cultures of CSF are time-honored methods for diagnosis of bacterial central nervous system infections. Bacteriological tests must be performed as soon as possible after CSF acquisition because some bacteria undergo rapid autolysis in the test tube. Additional tests such as the acridine orange stain for bacteria, tests for microbial antigens by counterimmunoelectrophoresis or agglutination techniques, and the G test for the broad spectrum detection of fungi (tests for (1,3)-β-D-glucan in most fungal cell walls) (Stevens, 2002) may also be useful (Fishman, 1992). PCR may be used to detect microbes in CSF (Finno *et al.*, 2006; Peters *et al.*, 1995; Stevens, 2002).

G. Blood Contamination

Erythrocytes may be present in CSF samples because of subarachnoid hemorrhage or, more commonly, because of traumatic puncture. Blood contamination resulting from traumatic puncture is a common problem during CSF collection and, depending on its degree, can interfere with cytological interpretation. Blood contamination is more likely to occur with lumbar puncture as opposed to cerebellomedullary cisternal puncture (Bailey and Higgins, 1985; Oliver and Lorenz, 1993; Thomson *et al.*, 1990). Blood contamination is a source of leukocytes and hence can affect both the leukocyte count and the differential. In one study of CSF analysis in cats (Rand *et al.*, 1990b), the total leukocyte count, the neutrophil percentage and the eosinophil percentage were positively correlated with the CSF erythrocyte count once this count exceeded 500 erythrocytes per microliter. However, there was no significant increase in total white blood cell count or alteration in the differential percentages with up to 500 RBC/μl of CSF. Numerous correction factors have been used to correct leukocyte counts for the effect of blood contamination and include the following: in people, 1 white blood cell per 700 red blood cells is subtracted from the total white blood cell count (Fishman, 1992); in dogs, 1 white blood cell per 500 red blood cells is subtracted from the total count (Bailey and Higgins, 1985); in cats, a maximum of

one white blood cell per 100 red blood cells is subtracted (Rand *et al.*, 1990b). A more accurate formula takes into account the actual white blood cell and red blood cells counts of the patient and hence compensates for any significant alterations in these counts (Fishman, 1992):

$$W = WBC_F - \frac{WBC_B \times RBC_F}{RBC_B}$$

where W is the white blood cell count of the fluid before blood was added (i.e., the corrected count), WBC_F is the total white blood cell count in the bloody fluid, WBC_B is the white blood cell count in the peripheral blood per microliter, and RBC_F and RBC_B are the numbers of red blood cells per microliter in the CSF and blood, respectively. Despite all of these elaborate corrections, our own experience is that many thousands of red blood cells in contaminated samples of CSF will frequently be observed without any accompanying white blood cells, suggesting that these correction factors may not be valid. This empirical observation has been made by others (de Lahunta, 1983). This lack of validity has been proven by several studies (Novak, 1984; Wilson and Stevens, 1977). In one article, blood contamination appeared to have little effect on white blood cell numbers, and the above correction formula was considered unreliable. The authors evaluated 91 samples from both normal and diseased animals where there were numerous red blood cells but no white blood cells. Some of the red blood cell counts exceeded 15,000 RBC/μL, but white blood cells were still absent (Wilson and Stevens, 1977). In another article, the authors concluded that the standard computations frequently overcorrect white blood cell counts in blood contaminated CSF, and the magnitude of the overcorrection may obscure disease in some instances—in eight infants with marked blood contamination but proven bacterial meningitis, correction computations normalized or overcorrected the white blood cell counts (Novak, 1984). The mechanism of this overcorrection was not defined, but it is clear that the presence of low numbers of neutrophils should not be immediately discounted when red cells are concurrently found (Christopher *et al.*, 1988).

A study of feline CSF (Rand *et al.*, 1990a) also found that values for CSF total protein, lactate dehydrogenase, creatine kinase, IgG ratio, and γ-globulin percentage were affected by blood contamination. The CSF total protein value of blood-contaminated CSF may be corrected using the formula for white blood cell correction given previously but substituting the total protein levels of the bloody CSF and the serum for the corresponding white blood cell counts (Kjeldsberg and Knight, 1993). In people, bloody contamination of CSF with as little as 0.2% serum (equivalent to about 5000 to 10,000 RBC/ml) elevates the IgG index (Fishman, 1992).

VII. GENERAL CHARACTERISTICS OF CSF IN DISEASE

A. Physical Characteristics: Clarity, Color, and Viscosity

Normal CSF is clear and colorless, and has the consistency of water. In pathological conditions the clarity, color, or consistency may change.

1. *Clarity*

Cloudy or turbid CSF is usually due to pleocytosis; about 200 WBC/μl or 400 RBC/μl will produce a visible change. With these low levels of cellularity, the CSF may appear opalescent or slightly hazy. Microorganisms, epidural fat, or myelographic contrast agent may also produce hazy or turbid CSF.

2. *Color*

Although the term xanthochromia means yellow color, it has often been used to describe pink CSF as well. The color of CSF is most usefully described as (1) pink or orange, (2) yellow, or (3) brown. These colors correspond to the major pigments derived from red cells: oxyhemoglobin, bilirubin, and methemoglobin. Oxyhemoglobin is red in color, but after dilution in the CSF it appears pink or orange. Oxyhemoglobin is released from lysed red cells and may be detected in the CSF supernatant about 2 h after red cells enter the CSF. The level of oxyhemoglobin reaches its peak about 36 h later and disappears over the next 4 to 10 days. Bilirubin is yellow in color. Bilirubin is derived from hemoglobin and is formed by macrophages and other leptomeningeal cells that degrade the hemoglobin from lysed red blood cells. Bilirubin is detected about 10 h after red cells enter the CSF, reaches a maximum at about 48 h, and may persist for 2 to 4 weeks. Bilirubin is also the major pigment responsible for the abnormal color of CSF with a high protein content. Methemoglobin in CSF is dark yellow-brown. Methemoglobin is a reduction product of hemoglobin characteristically found in encapsulated subdural hematomas and in old, loculated intracerebral hemorrhages (Fishman, 1992; Kjeldsberg and Knight, 1993). Occasionally the CSF may be black tinged CSF in animals with melanin-producing tumors in the nervous system.

Causes of a CSF color change other than red cell contamination include icterus resulting from liver disease or hemolytic disease, markedly increased CSF total protein level, and drug effects. Both free and conjugated bilirubin may be present in the CSF, although the amount of bilirubin in the CSF does not correlate well with the degree of hyperbilirubinemia. If the CSF protein level is increased, the color change will be greater because of increased amounts of the albumin-bound bilirubin. High CSF protein content alone can impart a yellow color to the CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). The drug rifampin imparts an

orange-red color to body fluids. Rifampin is 90% bound to protein; hypoproteinemia may result in rifampin staining of CSF in patients receiving this drug (Fishman, 1992).

3. *Viscosity*

Increased viscosity is usually due to a very high CSF protein content, particularly fibrinogen. If pleocytosis is present, a surface pellicle or a clot may form. In this situation, collection of the CSF in a heparinized or EDTA tube may be necessary to obtain an accurate cell count. Cryptococcosis may increase CSF viscosity because of the polysaccharide capsule of the yeast. Epidural fat or nucleus pulposus in the CSF may also increase viscosity or result in globules within the fluid (Fishman, 1992; Kjeldsberg and Knight, 1993).

B. Cytology

An increase in the cellularity of CSF is termed pleocytosis. In general terms, the degree of pleocytosis depends on several factors, including the nature of the inciting cause and the severity and location of the lesion with respect to the subarachnoid space or ventricular system (Cook and DeNicola, 1988). A normal CSF analysis does not exclude the presence of disease (Fishman, 1992; Kjeldsberg and Knight, 1993). This is especially true with deep parenchymal lesions that do not communicate with the leptomeninges, and hence the subarachnoid space, or the ependymal surfaces. In these cases, despite the presence of neurological disease that is often severe, the lesion may not affect the CSF cellularity (Cook and DeNicola, 1988). Abnormal CSF findings always indicate the presence of pathology.

1. N*eutrophilia*

A marked pleocytosis with neutrophil predominance suggests either bacterial meningitis (Kjeldsberg and Knight, 1993; Kornegay *et al.*, 1978) or suppurative, nonseptic (corticosteroid responsive) meningitis (Meric, 1988, 1992a; Tipold and Jaggy, 1994). Total leukocyte counts in excess of 2000 cells per microliter are frequently encountered in these diseases and may even exceed 10,000 cells per microliter (Meric, 1992a). Observation of bacteria or a positive culture confirms septic meningitis. In our experience, bacteria are more commonly observed in the CSF of large animals afflicted with septic meningitis than in dogs or cats with septic meningitis. Neutrophil nuclear morphology is often used as criteria for determining the likelihood of sepsis with nuclear degenerative changes or karyolysis interpreted as evidence of bacterial disease. However, the neutrophils in confirmed cases of septic meningitis in dogs and cats are frequently well preserved, especially if there has been prior therapy. Therefore, absence of bacteria or degenerative nuclear changes in neutrophils cannot be used to unequivocally exclude a diagnosis of septic meningitis, although it does make it less likely. In people, acute viral meningoencephalitis initially causes a neutrophilic pleocytosis (Converse *et al.*, 1973; Fishman, 1992; Kjeldsberg and Knight, 1993) that may persist from a few hours to several days before the development of the more typical mononuclear reaction. A similar phenomenon is documented in animals (Green *et al.,* 1993). Occasionally, distemper virus infection causes massive encephalomalacia (Vandevelde and Spano, 1977) resulting in a neutrophilic pleocytosis, in contrast to the more typical moderate mononuclear pleocytosis. Central nervous system neoplasia may result in a neutrophil predominance in the CSF, especially if there is significant necrosis and inflammation associated with the tumor. Moderate to marked pleocytosis with neutrophil predominance may be noted in dogs with meningioma (Bailey and Higgins, 1986b). However, in another study of dogs with meningioma, about 30% of dogs had a normal CSF analysis (Dickinson *et al.*, 2006). In this study, a significant association between meningiomas in the caudal portion of the cranial fossa and an elevated CSF nucleated cell count was found; but only 19% of the dogs had an elevated total nucleated white cell count with a predominance of neutrophils (Dickinson *et al.*, 2006).

Canine intervertebral disk disease is associated with variable alterations in CSF that depend on factors such as disease severity and chronicity (Thomson *et al.*, 1989). Acute severe disease may result in counts greater than 50 cells per microliter with more than 50% neutrophils (Thomson *et al.*, 1989). This finding may be a reflection of acute inflammation secondary to trauma that may be exacerbated by myelomalacia in some instances. The authors have seen a similar phenomenon associated with fibrocartilaginous embolic myelopathy in dogs. A neutrophilic pleocytosis of varying severity often occurs following myelography with iodinated contrast agents (Carakostas *et al.*, 1983; Johnson *et al.*, 1985; Widmer *et al.*, 1992). These changes usually peak at 24 h postmyelogram (see Section VII for further details). Similarly, a neutrophilic pleocytosis has been observed postictally in people. We have occasionally observed similar findings in dogs (see Section VII).

2. L*ymphocytosis*

Alterations in both numbers and morphology of lymphocytes (see Section III.B) in the CSF occur in a variety of diseases. Central nervous system viral infections often result in a predominantly lymphocytic pleocytosis, documented in dogs (Vandevelde and Spano, 1977), cats (Dow *et al.*, 1990; Rand *et al.*, 1994b), horses (Green *et al.*, 1992; Hamir *et al.*, 1992; Wamsley *et al.*, 2002), sheep, goats (Brewer, 1983), and numerous other species. In people, CSF lymphocytosis has been observed in bacterial meningitis following antibiotic therapy (Cargill, 1975; Converse *et al.*, 1973; Fishman, 1992; Kjeldsberg and Knight, 1993), indicating that therapy and chronicity can alter the CSF findings. A similar finding has been reported in dogs (Sarfaty *et al.*, 1986; Tipold and Jaggy, 1994) and calves (Green and Smith, 1992). We have noted that dogs with chronic or acute on chronic type I intervertebral disk disease have a pleocytosis that is more commonly lymphocytic than neutrophilic (Windsor *et al.*, 2007). The CSF

findings with granulomatous meningoencephalitis (GME) are somewhat variable, but a marked lymphocytic pleocytosis is common (Bailey and Higgins, 1986a; Thomas and Eger, 1989). Similarly, dogs with necrotizing meningoencephalitis (small breed dogs including pug dogs, Yorkshire terriers, and Maltese terriers) frequently have a marked lymphocytic pleocytosis (Cordy and Holliday, 1989; Stalis *et al.*, 1995; Tipold *et al.*, 1993a).

3. Eosinophilia

Eosinophils are not present in normal, uncontaminated (by blood) CSF. Single eosinophils are occasionally noted on cytocentrifuge slides from animals with normal CSF (normal nucleated counts and protein concentration). Although the presence of eosinophils in CSF is abnormal and evidence of underlying disease, no diagnostic specificity is associated with their presence in human CSF, as they can be found in a variety of diseases (Bosch and Oehmichen, 1978). Additionally, CSF eosinophilia and peripheral blood eosinophilia do not necessarily occur together and if they do, no positive correlation exists between the magnitude of peripheral blood eosinophilia and the severity of the CSF eosinophilia (Bosch and Oehmichen, 1978; Smith-Maxie *et al.*, 1989). In one case series of eight dogs with eosinophilic meningoencephalitis, five of eight had concurrent peripheral eosinophilia, but no correlation was present between the peripheral and CSF eosinophil counts. The two dogs with the highest CSF eosinophil counts had peripheral eosinophil counts within normal reference limits. In people, central nervous system invasion by parasites, especially *Angiostrongylus cantonensis*, is the most frequent cause of eosinophilic pleocytosis; in many of these cases eosinophils predominate in the CSF differential cell count (Bosch and Oehmichen, 1978; Kuberski, 1979). A marked eosinophilic pleocytosis is also reported in dogs with neural angiostrongylosis (Lunn *et al.*, 2003; Mason, 1989). CSF eosinophilia can also occur in association with bacterial, fungal, and viral infections and hence can be seen concurrently with suppurative, granulomatous, and lymphocytic inflammatory processes of the central nervous system (Jamison and Lumsden, 1988; Smith-Maxie *et al.*, 1989). However, in many of these cases, eosinophils represent less than 5% of the total cell count in CSF (Bosch and Oehmichen, 1978; Smith-Maxie *et al.*, 1989). Other documented causes in people include neurosyphilis, tuberculosis, rickettsial disease, foreign body reactions to shunt tubes, intrathecal penicillin or contrast agents, hypereosinophilic syndrome, multiple sclerosis, lymphoma, Hodgkin's disease, leukemia, melanoma, disseminated glioblastoma, idiopathic, and systemic allergic reactions (Bell *et al.*, 2006; Fishman, 1992; Kjeldsberg and Knight, 1993; Kuberski, 1979; Smith-Maxie *et al.*, 1989). In animals, CSF pleocytosis that consists predominantly, or almost exclusively, of eosinophils is rare. We have personally seen CSF eosinophilia with marked eosinophil predominance in association with idiopathic or steroid responsive eosinophilic meningoencephalitis (Smith-Maxie *et al.*, 1989), canine neural angiostrongylosis (Mason, 1989), and histopathologically confirmed canine CNS neosporosis.[4] Golden retriever dogs and rottweilers may be predisposed to idiopathic or steroid responsive eosinophilic meningoencephalitis (Bennett *et al.*, 1997; Smith-Maxie *et al.*, 1989). Pleocytosis with eosinophil predominance has also been described in central nervous system cryptococcosis (Vandevelde and Spano, 1977), although this finding is not common in our experience. Other documented causes of CSF eosinophilia (though not necessarily predominance) in animals include bacterial encephalitis, distemper, rabies, toxoplasmosis, neosporosis, cuterebral encephalitis, central nervous system nematodiasis and cestodiasis, protothecosis, granulomatous meningoencephalomyelitis, lymphoma, astrocytoma, cerebral infarction, canine neural angiostrongylosis, and salt poisoning (Chrisman, 1992; Darien *et al.*, 1988; Jamison and Lumsden, 1988; Lester, 1992; Mac Donald *et al.*, 1976; Mason, 1989; Oruc and Uslu, 2006; Smith, 1957; Tyler *et al.*, 1980; Vandevelde and Spano, 1977).

4. Neoplastic Cells

Lymphoma has been diagnosed on the basis of CSF assessment in both small and large animals (Lane *et al.*, 1994; Pusterla *et al.*, 2006a; Vandevelde and Spano, 1977). However, the observation of neoplastic cells in CSF samples from animals with central nervous system neoplasia other than lymphoma is uncommon in our experience. Few veterinary studies have investigated the prevalence of positive CSF cytology in animals with confirmed central nervous system neoplasia. In one study involving 77 histopathologically confirmed cases of primary central nervous system neoplasia in dogs, neoplastic cells were not observed in any sample (Bailey and Higgins, 1986b). However, in this study, cytological assessment was done only on those samples with an elevated cell count and these only accounted for 41.3% of cases. Tumor cells have been observed in the CSF when the CSF cell counts were within normal limits (Grevel and Machus, 1990; Grevel *et al.*, 1992). Additionally, in the study assessing primary brain tumors in 77 dogs (Bailey and Higgins, 1986b), CSF differential and cytology were done on cytospin samples. The cell yield with cytospin slide preparation is low, approximating 10% (Barrett and King, 1976) in some studies, and this may partly explain the failure to observe neoplastic cells in the above study. Other veterinary studies utilizing different techniques report a higher prevalence of neoplastic cells in the CSF from confirmed cases of central nervous system neoplasia. In two studies utilizing a Kölmel sedimentation apparatus, tumor cells were seen in the CSF in five of eight dogs (Grevel and Machus, 1990) and four of nine dogs (Grevel *et al.*, 1992). In the former study, two of the five cytologically

[4] W. Vernau, unpublished data.

positive cases had normal cell counts. The Kölmel technique results in a higher cell yield than cytocentrifugation, which may be partly responsible for the increased incidence of neoplastic cell observation in the CSF. Despite the low yield of cytospin slides, the presence of neoplastic cells in cytospin CSF slides from animals with CNS tumors other than lymphoma has been reported in cats with intracranial oligodendroglioma, dogs with CNS histiocytic sarcoma, and dogs with choroid plexus carcinoma (Dickinson *et al.*, 2000; Zimmerman *et al.*, 2006).[3,5]

A large number of studies assess the prevalence of neoplastic cells in the CSF of people with central nervous system neoplasia. Overall sensitivities that are frequently quoted are 70% for CNS leukemia, 20% to 60% for metastatic meningeal carcinoma, and approximately 30% for primary CNS tumors (Kjeldsberg and Knight, 1993), regardless of the technique utilized. The detection rate of malignant cells in the CSF is improved by the collection of multiple samples (Olson *et al.*, 1974). These figures are supported by one study utilizing cytocentrifugation in 117 cases of histopathologically confirmed central nervous system neoplasia (Glass *et al.*, 1979). Overall, 26% (31/117) were positive. However, if only those people with leptomeningeal involvement were considered, the prevalence increased to 59%. Conversely, of 66 cases in which the tumor did not reach the leptomeninges, only a single sample was positive. In another study, only 13.9% of all gliomas had a positive CSF cytology (Balhuizen *et al.*, 1978). This low prevalence is likely because the majority of gliomas does not extend into the subarachnoid space (Balhuizen *et al.*, 1978). As a result of these studies, the following generalizations are frequently made in human medicine: (1) a positive CSF cytology is a reliable indicator of central nervous system malignancy and almost always reflects a leptomeningeal tumor (or one involving the ventricular system), and (2) a negative cytology does not exclude the presence of an intracerebral tumor, particularly a deep parenchymal mass that does not breach the pia or the ventricular system. Controlled studies are required in veterinary medicine to determine the prevalence of positive CSF cytology in confirmed cases of different types of central nervous system neoplasias, and also to compare the sensitivities of different preparative methods. These studies may be hampered by the general lack of experience at identifying cells derived from central nervous system neoplasms. Tumor cells can be erroneously identified as normal ependymal or choroid plexus cells. Solitary tumor cells from metastatic carcinomas can be mistaken for lymphocytes or monocytes (Kjeldsberg and Knight, 1993). The need for the above type of study has been somewhat decreased by the advent of more routine access to advanced imaging and biopsy techniques (Koblik *et al.*, 1999; Vernau *et al.*, 2001).

C. Protein

1. *Changes in* CSF *Total Protein Content*

An increase in the total protein content of CSF is the single most useful alteration in the chemical composition of the fluid (Fishman, 1992). However, this alteration accompanies many diseases and is therefore nonspecific. Increased total protein may be caused by (1) increased permeability of the blood-brain/spinal cord/CSF barriers allowing passage of serum proteins into the CSF, (2) intrathecal globulin production, and (3) interruption of CSF flow or absorption. Particular emphasis has been put on CSF flow rate as a major factor in CSF protein content (Reiber, 1994). In many diseases, two or all three of these mechanisms are at work. In complete spinal subarachnoid space blockage (e.g., by a compressive lesion or arachnoiditis), CSF withdrawn caudal to the block may clot when aspirated. In people, this phenomenon is called Froin's syndrome and results from very high CSF protein levels caused by the defective flow and absorption and blood-spinal cord barrier breakdown (Fishman, 1992; Kjeldsberg and Knight, 1993).

Decreased total protein is much less common. Theoretically, low levels of CSF protein could result from decreased entry of protein into the CSF or increased removal. No evidence exists to support the first mechanism. Increased removal can occur, however, if intracranial pressure is increased while the barriers to serum protein remain normal. In this situation, bulk flow absorption of CSF is increased, whereas entrance of protein into the CSF remains normal. Protein content of fluid collected from the lumbar site could be decreased if large volumes are removed or if ongoing leakage of CSF from the lumbar area is occurring. In these situations, lumbar CSF is replaced more quickly than normal by ventricular CSF, which has a lower protein content than lumbar CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). Low CSF protein has also occurred in people with hyperthyroidism, leukemia, or water intoxication (Fishman, 1992; Kjeldsberg and Knight, 1993).

2. *Albuminocytological* Dissociation

In many disease processes, the CSF cell count and CSF total protein increase in rough parallel. In some disorders, the cell count remains normal, whereas the total protein is notably increased, a phenomenon termed albuminocytological dissociation. Some degenerative disorders, ischemia/infarction, immune-mediated diseases (e.g., polyradiculoneuritis), tumors, and neural compression produce albuminocytological dissociation (Laterre, 1996).

3. *Increased* CSF *Albumin and Albumin Index*

Elevation of CSF albumin (which originates in the serum), and consequently an increased albumin index, indicates dysfunction of the blood-brain/spinal cord/CSF barriers or

contamination of the CSF by blood (from intrathecal hemorrhage or traumatic spinal tap). Barrier damage occurs in most types of neurological disorders, including inflammatory diseases, neoplasia, trauma, compression, and occasionally metabolic diseases (Bichsel *et al.,* 1984b; Krakowka *et al.*, 1981; Sorjonen, 1987; Sorjonen *et al.*, 1991).

4. *Increased* CSF *IgG and IgG Index*

The CSF IgG can be increased by movement of protein across damaged blood-brain/CSF barriers, intrathecal hemorrhage (pathological or iatrogenic), or intrathecal IgG synthesis. An elevated CSF IgG content and increased IgG index, indicating intrathecal IgG synthesis, are typical for infectious inflammatory diseases (Tipold *et al.*, 1993b, 1994). In contrast, animals with noninflammatory diseases usually have normal IgG indices (Tipold *et al.*, 1993b). In a few animals with noninfectious disorders mild intrathecal IgG synthesis occurs, reflecting the presence of inflammatory infiltrates around the lesion (Tipold *et al.*, 1993b). Therefore, the IgG index is often useful for distinguishing between inflammatory and noninflammatory lesions, which is not always possible on the basis of CSF cell counts alone (Bichsel *et al.*, 1984b). In one study (Tipold *et al.*, 1993b), 7 of 66 dogs with inflammatory lesions had no pleocytosis but had an elevated IgG index; in contrast, 17 of 32 dogs with noninflammatory disease had pleocytotic CSF and a normal IgG index. The authors of this study consider an IgG index ≥ 2.8 as proof of intrathecal synthesis allowing a diagnosis of meningoencephalomyelitis, and an IgG index between 1.3 and 2.8 as suggestive of inflammatory disease. In a few dogs with marked inflammatory lesions and intrathecal IgG production, the IgG index may not be elevated because of marked IgG exudation against which the local IgG synthesis is undetectable (Bichsel *et al.*, 1984b). Traumatic puncture and red blood cell contamination of the CSF can artifactually increase the IgG index. Additionally, the normal IgG index of cerebellomedullary fluid and lumbar fluid are likely to be different because of the different protein concentrations of these fluids.

5. *Classification of Disease Based on Albumin Index and IgG Index*

Alterations of the albumin index and the IgG index can be grouped into three pathogenetical categories: (1) blood-brain/CSF barrier disturbance (increased albumin index), (2) intrathecal IgG synthesis (increased IgG index), and (3) barrier disturbance combined with intrathecal IgG production (both indices increased). These categories correlate somewhat with certain types of diseases. Barrier disturbance may be seen in degenerative, inflammatory, metabolic, space-occupying, vascular, and traumatic conditions (Bichsel *et al.*, 1984b; Sorjonen, 1987; Sorjonen *et al.*, 1991). Intrathecal IgG synthesis is typical of inflammatory conditions (Tipold *et al.*, 1994) but also occurs in noninfectious disorders that have secondary inflammation such as some tumors (Tipold *et al.*, 1993b). Barrier disturbance coupled with intrathecal IgG production is typical of infectious-inflammatory diseases (Bichsel *et al.*, 1984b).

6. *Increased* CSF *IgM, IgA, and IgM and IgA Indices*

The immunoglobulins IgM and IgA may be increased in the CSF of animals with inflammatory neurological disease. A study of 69 dogs with inflammatory disease detected IgM elevations in 16 dogs and IgA elevations in 40 (Tipold *et al.*, 1994). An increased CSF IgM index is considered by some investigators to be a good indication of recent or persistent immunological stimulation in people (Sharief and Thompson, 1989). In contrast, one study reported that IgM was present through all stages of human herpes and bacterial meningitis, and increased and decreased with IgG (Felgenhauer, 1982). Perhaps a transition from IgM to IgG production does not occur in the central nervous system (Tipold *et al.*, 1994), or perhaps, in the presence of a normal or near-normal blood-CSF barrier, IgM accumulates in the CSF (Felgenhauer, 1982). In people with *Borrelia* infection, CSF IgM is persistently produced and the IgM index is a better indicator of this disease than is the IgG index (Fishman, 1992). Anti-West Nile Virus (WNV) IgM antibody production appears to occur intrathecally in horses and detection of CSF anti-WNV IgM may be used to differentiate previously vaccinated horses versus infected horses (Porter *et al.*, 2004) Further studies need to be done in animals to determine the sensitivity and specificity of the various immunoglobulin alterations occurring in disease.

7. *Electrophoretic Patterns of CSF Protein in Disease*

Abnormalities in the CSF electrophoretic pattern can suggest categories of diseases (Sorjonen, 1987; Sorjonen *et al.*, 1991). In one study, dogs with inflammatory diseases had one of three patterns: (1) little or no blood-brain barrier disturbance (as determined by CSF albumin concentration and the albumin quota) with decreased gamma globulin, (2) mild blood-brain barrier disturbance with markedly increased gamma globulin, and (3) moderate or marked blood-brain barrier disturbance with increased gamma globulin. Dogs with intervertebral disk protrusion or cervical spondylomyelopathy had a pattern of normal barrier function or severe barrier disturbance with decreased alpha globulin. Dogs with brain neoplasia had marked barrier disturbance and normal or mildly increased alpha and beta globulins (Sorjonen *et al.*, 1991). However, a more recent study using high-resolution agarose electrophoresis was unable to differentiate various categories of neurological disease in dogs using this technique (Behr *et al.*, 2006).

In the gamma globulin region, three patterns of protein bands can occur: monoclonal, oligoclonal, and polyclonal.

Oligoclonal bands are associated with disease and are seen in a high percentage of people with multiple sclerosis or encephalitis. These bands, readily identifiable against the low background of normal polyclonal IgG in the CSF, are thought to represent the products of a limited number of plasma cell clones. Oligoclonal bands unique to CSF (i.e., not present in serum) indicate intrathecal synthesis of immunoglobulin and may be more sensitive than the IgG index in detecting this synthesis. People with multiple sclerosis may have a normal IgG index yet have CSF oligoclonal banding; thus, the demonstration of these bands is considered by some to be the single most useful test in the diagnosis of multiple sclerosis (Kjeldsberg and Knight, 1993). Oligoclonal bands are also seen in patients with inflammatory diseases and in some patients with neoplasia (Fishman, 1992). Occasionally, a single (monoclonal) band is identified in the CSF electrophoretic pattern of people. Monoclonal bands have been seen in neurologically normal people as well as in patients with neurological disease (Kjeldsberg and Knight, 1993).

8. *Other* CSF *Proteins*

Numerous attempts have been made to correlate specific CSF proteins, particularly "brain-specific" proteins, with specific diseases. Proteins such as C-reactive protein, interferon, myelin basic protein, and S-100 are increased in the CSF associated with neurological disease, but these increases are found in many heterogeneous conditions. This nonspecificity limits the clinical utility of many of these specific protein assays. However, the measurement of some of these proteins is thought to be useful as a screening procedure for neurological disease or as an indication of prognosis (Fishman, 1992; Kjeldsberg and Knight, 1993; Lowenthal *et al.*, 1984). Immunoassay detection in the CSF of the brain-derived protein 14-3-3 appears to be helpful for the diagnosis of transmissible spongiform encephalopathies in both animals and people (Hsich *et al.*, 1996; Sanchez-Juan *et al.*, 2006). An autoantibody against canine glial fibrillary acidic protein present in astrocytes has been detected in the CSF of two pug dogs affected with necrotizing encephalitis (Uchida *et al.*, 1999). However, it is unknown if the presence of this antibody is a primary or secondary phenomenon.

9. *Plasma Proteins in the* CSF

Alterations in plasma proteins may be reflected in the CSF. For example, in people, the serum protein monoclonal gammopathy of multiple myeloma may be evident in the CSF. Bence Jones proteins are also readily seen in the CSF. The high molecular weight paraproteins do not cross the normal blood-brain barrier, however. Serum protein electrophoresis is indicated in patients with elevated CSF globulins to clarify the source of the globulins (Fishman, 1992).

D. Antibody Titers

The CSF antibody titer can be measured for a number of diseases (Dubey, 1990b; Greene, 1990). Interpretation of the results is confounded by the need to differentiate among titers caused by vaccination, exposure to the antigen without development of the disease, and actual disease. Interpretation of CSF antibody titers could be aided by an accurate vaccination history, comparison of CSF and serum titers, assessment of blood-brain/CSF barrier function, and intrathecal immunoglobulin production by determination of albumin and immunoglobulin indices, determination of CSF IgM levels, and analysis of acute and convalescent samples (Chrisman, 1992; Green *et al.*, 1993; Porter *et al.*, 2004).

E. Glucose

Increased CSF glucose usually reflects hyperglycemia. Decreased CSF glucose occurs with several disorders of the nervous system, particularly acute, bacterial, fungal, amebic, or tuberculous meningitis. In people, low CSF glucose is also characteristic of diffuse carcinomatous meningitis, meningeal cysticercosis or trichinosis, and syphilitic meningitis. The major factors responsible for low CSF glucose levels are inhibition of the entry of glucose because of the alteration of membrane glucose transport and increased anaerobic glycolysis by neural tissue. As noted previously, hyperglycemia elevates the CSF glucose, which may mask a decreased CSF level. Therefore, calculation of a CSF/serum glucose ratio has been recommended to identify pathologically low CSF glucose levels (Deisenhammer *et al.*, 2006; Kjeldsberg and Knight, 1993). A CSF/serum glucose ratio less than 0.4 to 0.5 is considered to be pathological in people (Deisenhammer *et al.*, 2006). A low CSF glucose level in the absence of hypoglycemia indicates a diffuse, meningeal disorder, rather than focal disease (Fishman, 1992; Kjeldsberg and Knight, 1993). Decreased CSF glucose classically has been associated with bacterial meningitis, but many human patients with bacterial meningitis have normal CSF glucose levels. Therefore, the recommendation has been made that CSF glucose need be measured only if the opening CSF pressure, cell count, cytospin differential, and protein are inconclusive (Hayward *et al.*, 1987). CSF glucose concentration and CSF/serum glucose ratio are not routinely measured in veterinary medicine, possibly because of the lack of specificity and availability of more specific tests in most instances.

F. Enzymes

Numerous enzymes have been assayed in the CSF of animals (Furr and Tyler, 1990; Jackson *et al.*, 1996; Rand *et al.*, 1994b; Wilson, 1977). Of these, creatine kinase has received the most attention, and opinions of its usefulness are conflicting. Although Furr and Tyler confirmed previous observations that CSF creatine kinase activity was elevated in

several neurological diseases, they concluded that the greater frequency of elevation in the CSF of horses with protozoal myelitis versus horses with cervical compressive myelopathy indicated this enzyme assay was useful in differentiating these two diseases (Furr and Tyler, 1990). This conclusion was disputed by Jackson *et al.* (1996), who did not find the sensitivity or specificity of creatine kinase measurement sufficient for diagnosis of a specific disease. Jackson *et al.* (1996) also concluded that contamination of the CSF sample with epidural fat or dura mater may contribute to previously unexplained elevations in CSF creatine kinase activity. Their conclusion regarding this enzyme's lack of sensitivity and specificity reflects the current situation with all of the enzymes in CSF studied to date—none has sufficient specificity to warrant its routine use as diagnostic test (Fishman, 1992; Indrieri *et al.,* 1980; Jackson *et al.*, 1996; Kjeldsberg and Knight, 1993; Rand *et al.*, 1994b). The site of CSF collection with respect to the location of the lesion may be responsible for some of the lack of diagnostic significance in CSF enzyme analysis. Cerebellomedullary fluid may be less affected than lumbar fluid in animals with spinal disease (Indrieri *et al.*, 1980). Measurement of enzyme isomers may increase the specificity (Kjeldsberg and Knight, 1993).

To date, none of the enzyme assays are sufficiently sensitive or specific to warrant routine use in clinical practice (Fishman, 1992; Indrieri *et al.*, 1980; Jackson *et al.*, 1996; Kjeldsberg and Knight, 1993; Rand *et al.*, 1994a).

G. Other Constituents

1. *Interferon*

Interferon is increased in the CSF in a large percentage of people with viral encephalitis-meningitis. This finding is not specific, however, as increases are also found in patients with bacterial meningitis (Glimaker *et al.*, 1994) or multiple sclerosis and occasionally in patients with noninflammatory neurological disease (Brooks *et al.,* 1983). In an experimental study of canine distemper, interferon appeared to be a valid marker for persistence of the virus in the central nervous system (Tsai *et al.*, 1982).

2. *Neurotransmitters*

Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter, whose dysfunction has been suggested to play a role in experimental (Griffith *et al.*, 1991) and clinical seizure disorders. Conversely, glutamate (GLU) is a major excitatory neurotransmitter in the CNS that plays an important role in the initiation, spread, and maintenance of epileptic activity in people (Meldrum, 1994). Increased extracellular concentrations of glutamate in the CNS may also mediate secondary tissue damage and cell death (Meldrum, 2000). A study of epileptic dogs found the average CSF concentration of GABA to be significantly reduced, a situation similar to that in people (Loscher and Schwartz-Porsche, 1986). Inhibitory and excitatory neurotransmitters have been assayed in the CSF of epileptic dogs (Ellenberger *et al.*, 2004; Podell and Hadjiconstantinou, 1997). In one study, epileptic dogs were found to have lower levels of CSF GABA and higher levels of CSF glutamate than normal dogs (Podell and Hadjiconstantinou, 1997). In another study, CSF GABA was also found to be decreased in epileptic Labradors, but in contrast to the former report, these dogs had lower levels of CSF glutamate than normal dogs or epileptic non-Labradors (Ellenberger *et al.*, 2004). CSF neurotransmitters have also been assayed in dogs with portosystemic shunts (PSS) and clinical signs of hepatic encephalopathy (Holt *et al.*, 2002). Dogs with PSS had significantly higher levels of glutamine, tryptophan, and 5-hydroxyindoleacetic acid. These alterations may play a role in the neurological abnormalities associated with hepatic encephalopathy (Holt *et al.*, 2002). Because of its potential role in secondary tissue damage, glutamate concentrations in lumbar CSF have been measured in dogs with intervertebral disk herniation and acute and chronic compressive spinal cord lesions (Olby *et al.*, 1999). Dogs with severe, acute thoracolumbar disk herniations have two- to ten-fold increases in their lumbar CSF 12 h or more after injury. The severity of the clinical signs appeared to be related to the lumbar CSF glutamate concentration (Olby *et al.*, 1999). Dogs with chronic compressive thoracolumbar lesions have a two-fold elevation of lumbar CSF glutamate concentration. However, focal spinal cord injuries did not alter glutamate concentrations in cisternal CSF (Olby *et al.*, 1999).

Increased CSF levels of the biogenic amine neurotransmitter metabolites homovanillic acid and 5-hydroxyindoleacetic acid were found in 2 of 10 collies experimentally given ivermectin (Vaughn *et al.*, 1989). Both of these collies had severe neurological deficits. Neurotransmitter metabolite concentrations were also elevated in the CSF of goats demonstrating neurological abnormalities after experimental boron toxicosis (Sisk *et al.*, 1990). Significant differences in neurotransmitter concentrations were found between the CSF of normal dogs and narcoleptic dogs (Faull *et al.*, 1982). Hyopocretins are neuropeptides that bind to the G-protein coupled hypocretin receptors Hcrtr 1 and Hcrtr 2. Hypocretins are undetectable in the CSF of sporadic narcoleptic dogs but are normal in familial narcoleptic dogs that have mutations in the hypocretin receptor 2 gene (Ripley *et al.*, 2001).

3. *Quinolinic Acid*

Quinolinic acid is a neuroexcitotoxic metabolite of L-tryptophan and an agonist of N-methyl-d-aspartate receptors. Increased levels have been found in people with a variety of neurological diseases including AIDS (Heyes *et al.*, 1992) and macaques infected with simian immunodeficiency virus (Smith, 1995). Quinolinic acid levels

may be elevated in the CSF of animals with inflammatory nervous system disease. Therefore, they may be useful as a marker of inflammation and perhaps also as an indicator of prognosis (Smith, 1995). Increased CSF quinolinic acid concentrations were also found in dogs with portosystemic shunts (PSS) and signs of hepatic encephalopathy (HE) (Holt *et al.*, 2002); it was speculated in this study that quinolinic acid and other tryptophan metabolites may contribute to the neurological abnormalities present in dogs with PSS and HE.

4. *Lactic Acid*

In people, the measurement of CSF lactic acid has been advocated in differentiating bacterial from viral meningitis. CSF lactate concentration is also increased in CNS fungal infections and leptomeningeal metastatic disease (Deisenhammer *et al.*, 2006). CSF lactate concentration is independent of blood lactate concentration (Deisenhammer *et al.*, 2006). In people, CSF lactate concentration may be elevated in diseases resulting in severe or global brain ischemia and anaerobic glycolysis or mitochondrial disease. It correlates inversely with the CSF: blood glucose ratio. However, because many diseases may elevate CSF lactic acid, the overlapping CSF lactate levels limit the value of CSF lactate assay (Fishman, 1992; Kjeldsberg and Knight, 1993). In a study of dogs with a variety of CNS diseases, blood and CSF pyruvate and lactate levels were measured. Levels of pyruvate were variable. Lactate levels were significantly elevated only in dogs with disk disease over CSF lactate levels in normal dogs (Lobert *et al.*, 2003). A study of CSF lactate levels in horses with neurological disease found elevated lactate levels in several types of central nervous system diseases (Green and Green, 1990). Therefore, as with people, increased CSF lactic acid in the horse appears to be a nonspecific indicator of central nervous system disease. Interestingly, in the horses studied, elevated lactic acid was the only CSF abnormality associated with brain abscess (Green and Green, 1990).

5. *3-OH Butyrate*

The measurement of serum 3-OH butyrate concentration is useful in the feeding management of pregnant ewes and in the diagnosis of pregnancy toxemia. Following death, however, rapid autolytic change renders serum biochemical analysis useless. Scott *et al.* (1995) compared the 3-OH butyrate concentrations of serum collected antemortem and aqueous humor and CSF collected within 6 h of death. Their results indicated either fluid was suitable for postmortem determination of 3-OH butyrate levels and that such data could be extrapolated to indicate antemortem serum 3-OH butyrate concentration and the possibility that pregnancy toxemia contributed to the death of the animal.

VIII. CHARACTERISTICS OF CSF ASSOCIATED WITH SPECIFIC DISEASES

A. Degenerative Disorders

This group of disorders includes a variety of diseases such as the inherited, breed-specific polyradiculoneuropathies, myelopathies, and encephalopathies; motor neuron diseases; and cerebellar abiatrophies. The storage diseases can also be included in this group. The inclusion of canine degenerative myelopathy is arguable, awaiting further clarification of its pathogenesis. The CSF in animals with degenerative disorders is characteristically normal, reflecting the lack of inflammation in the disease process (Braund, 1994; Oliver and Lorenz, 1993). A mild to moderate increase of CSF total protein may occur in several of these disorders, however. Increased total protein is also found in people with motor neuron disease, Parkinson's disease, and with various hereditary neuropathies and myelopathies. The mechanism of the protein increase is unknown. Electrophoretic studies of CSF associated with some human neurodegenerative disorders have shown a transudative pattern. Intrathecal immunoglobulin production has also been found in people with motor neuron disease (Fishman, 1992). In storage diseases such as globoid cell leukodystrophy, mucopolysaccharidosis, and fucosidosis, accumulated metabolic material may be seen in the white blood cells in the CSF (Keller and Lamarre, 1992; Roszel, 1972; Silverstein Dombrowski *et al.*, 2004).

1. *Canine Degenerative Myelopathy*

Although the CSF of dogs with degenerative myelopathy may be normal, a mild elevation of the white blood cell count is present occasionally (Bichsel *et al.*, 1984b). More common is a normal cell count coupled with a mild to moderate elevation of total protein (approximately 40 to 70 mg/dl). This albuminocytological dissociation may support the theory that this disorder is an immune-mediated disease (Waxman *et al.*, 1980). However, concurrent, chronic, spinal cord compression by type II disk protrusion in many of these dogs complicates the situation, because chronic cord compression may also produce an increase in total protein. The elevated total protein concentration in canine degenerative myelopathy is probably the result of increased CSF albumin (Bichsel *et al.*, 1984b). The CSF IgG index is usually normal (Bichsel *et al.*, 1984b; Tipold *et al.*, 1993b), indicating a lack of intrathecal IgG production.

2. *Degenerative Myeloencephalopathy of Llamas*

A degenerative myeloencephalopathy has been identified in two adult llamas. Lesions consist of bilateral white matter degeneration in all spinal cord segments and degenerate

neurons in the brain stem nuclei or degeneration of brain stem white matter tracts. Inflammation is not evident. Lumbosacral CSF from both animals was normal (Morin *et al.*, 1994).

3. *Equine Motor Neuron Disease*

The CSF of horses with this (Loscher and Schwartz-Porsche, 1986) disorder is either normal or has albuminocytological dissociation (Cummings *et al.*, 1990; Divers *et al.*, 1994; Morin *et al.*, 1994). In a study of 28 cases (Divers *et al.*, 1994), 9 of 26 horses had elevated CSF protein. The albumin quotient was abnormal in only 2 of 19 horses. The IgG index was increased in 8 of 16 horses. The abnormalities in total protein and IgG index did not appear to be associated with the duration or severity of clinical signs. The increased protein and IgG index in these horses suggest that intrathecal immunoglobulin production occurs. Blood-brain barrier damage and intrathecal IgG production also occur in people with motor neuron disease (Apostolski *et al.*, 1991).

B. Idiopathic Diseases

1. *Granulomatous Meningoencephalomyelitis*

The CSF associated with granulomatous meningoencephalomyelitis (GME) is usually abnormal. The fluid may be clear or hazy and is generally colorless. The total white blood cell count is moderately to markedly elevated, as is the total protein. The white blood cell differential is variable, but typically lymphocytes predominate, with monocytes/macrophages and neutrophils comprising the remainder in about equal percentages (Bailey and Higgins, 1986a; Braund, 1994; Sarfaty *et al.*, 1986; Thomas and Eger, 1989; Tipold, 1995). A 15% to 30% neutrophilic component suggests GME, but the white blood cell differential can range from 95% neutrophils (Sorjonen, 1990) to 100% mononuclear cells. Plasma cells, cells undergoing mitosis, and large, mononuclear cells with abundant foamy cytoplasm are occasionally present (Bailey and Higgins, 1986a; Braund, 1994). Lumbar fluid is also abnormal, although it generally has fewer cells and less protein than cerebellomedullary fluid (Bailey and Higgins, 1986a). Electrophoresis of CSF suggests blood-brain barrier dysfunction is present in the acute stage of disease; intrathecal IgG production with resolution of the barrier dysfunction occurs in chronic disease (Sorjonen, 1990). The albumin quota is elevated (Sorjonen, 1987), and the IgG index is usually elevated (Bichsel *et al.*, 1984b; Tipold *et al.*, 1993b, 1994). If barrier dysfunction is severe, with marked transudation of protein, the IgG index may be normal because the amount of intrathecally produced IgG is small in comparison to the amount of transudated serum IgG (Bichsel *et al.*, 1984b; Fishman, 1992).

2. *Necrotizing Encephalitis of Pug Dogs, Maltese Dogs, and Yorkshire Terriers*

A necrotizing encephalitis (NE) of unknown cause is recognized in pug dogs (Cordy and Holliday, 1989; de Lahunta, 1983), Maltese dogs (Stalis *et al.*, 1995), and Yorkshire terriers (Ducote *et al.*, 1999; Jull *et al.*, 1997; Kuwamura *et al.*, 2002; Tipold *et al.*, 1993a). The lesions are similar in each breed, although the distribution of lesions in the pug and Maltese dogs (large, diffuse, cerebral) is different from that in the Yorkshire terriers (well-defined multifocal brain stem). The CSF associated with the pug and Maltese dog diseases has a moderate to marked, predominantly lymphocytic, increased white blood cell count (although one Maltese had 62% neutrophils) and moderate to marked elevation in total protein (Bradley, 1991; Cordy and Holliday, 1989; Stalis *et al.*, 1995). The CSF of the Yorkshire terriers has mild to moderate increases in white blood cells and protein, with a predominantly mononuclear differential count (Ducote *et al.*, 1999; Tipold, 1995; Tipold *et al.*, 1993a). Seizures are a consistent clinical sign for the pugs and the Maltese dogs but not the Yorkshire terriers.

An autoantibody against canine astrocytes has been detected in the CSF of dogs with NE (Matsuki *et al.*, 2004; Uchida *et al.*, 1999). This autoantibody, which recognizes glial fibrillary acidic protein, has also been detected in the CSF of dogs with GME and with intracranial tumors (Matsuki *et al.*, 2004); therefore, it is not a specific finding in dogs with NE. It is unknown if the presence of this antibody is a primary or secondary phenomenon. Further research is necessary to determine the clinical utility of the presence of this autoantibody in CSF.

C. Immune-Mediated Diseases

1. *Acute Idiopathic Polyradiculoneuritis/Coonhound Paralysis*

Acute idiopathic polyradiculoneuritis is one of the most common canine polyneuropathies, and coonhound paralysis is the most common form. The disorder resembles Guillain-Barre syndrome of people. In affected dogs, the classical CSF abnormality is albuminocytological dissociation. The abnormality is more obvious in lumbar CSF than in cerebellomedullary CSF (Cuddon, 1990; Cummings *et al.*, 1982). The CSF IgG level and IgG index may also be increased, indicating intrathecal immunoglobulin production (Cuddon, 1990; Tipold *et al.*, 1993b).

2. *Equine Cauda Equina Neuritis*

This disease is thought to be an autoimmune polyneuritis. The CSF of affected horses may be xanthochromic and typically has a prominent, usually lymphocytic pleocytosis (at least in the chronic stage) and moderately elevated

protein. The CSF can also be normal (Mayhew, 1989; Yvorchuk, 1992).

3. *Steroid-Responsive Meningitis/Arteritis*

Steroid-responsive meningitis/arteritis is a common, suppurative meningitis of dogs. The CSF has a marked, often extreme, neutrophilic pleocytosis, and moderately to markedly increased protein. Occasionally a single sample collected early in the disease is normal (de Lahunta, 1983; Meric, 1988; Tipold *et al.*, 1995). The IgG index is typically elevated (Tipold and Jaggy, 1994; Tipold *et al.*, 1993b), and IgM and IgA levels are often elevated as well (Tipold and Jaggy, 1994; Tipold *et al.*, 1995). Microbial cultures are negative. In protracted or inadequately treated cases, the pleocytosis is mild to moderate with a mixed population or even a mononuclear cell predominance; the protein level may be normal or slightly elevated. The CSF may even be normal (Tipold and Jaggy, 1994). A polyarteritis/vasculitis reported in beagles, Bernese mountain dogs, German short-haired pointers, and sporadically in other breeds (Meric, 1988) has similar CSF abnormalities and pathological changes and may be the same disease as steroid-responsive meningitis/arteritis (Tipold and Jaggy, 1994). Boxer dogs may also be predisposed to this disease (Behr and Cauzinille, 2006).

D. Infectious Diseases

The variety of CSF abnormalities associated with infectious disease reflects the variety of infectious diseases affecting the central nervous system. If the infection causes inflammation, the total white blood cell count and protein usually will be elevated, but the degree and type of abnormality depend on the infectious agent, the immune status of the animal, the location of the infectious process (e.g., surface-related versus parenchymal), the duration of the infection, and previous treatment. The general rules of inflammation resulting from infection apply (i.e., bacterial infections result in suppurative inflammation whereas viral infections result in nonsuppurative inflammation). Several important exceptions exist, however.

1. *Bacterial Diseases*

In central nervous system aerobic or anaerobic bacterial infections, the CSF may be clear, hazy, or turbid (depending on the cell count), and colorless or amber with moderate to marked elevations of total white blood cell count and total protein concentration. Because of the elevated protein concentration, the CSF may clot or foam when shaken. The white blood cell differential count characteristically has a high percentage of neutrophils (>75%), which may be degenerate (Baum, 1994; Dow *et al.*, 1988; Foreman and Santschi, 1989; Green and Smith, 1992; Kornegay, 1981; Meric, 1988; Rand *et al.*, 1994b; Santschi and Foreman, 1989; Scott, 1995; Sturges *et al.*, 2006; Tipold, 1995). The protein is composed of albumin that has crossed the diseased blood-brain/CSF barrier and immunoglobulin produced intrathecally; therefore, the IgG index is usually elevated (Tipold *et al.*, 1993b, 1994). The IgM and IgA levels may be normal or increased (Tipold *et al.*, 1994). The CSF of animals with chronic or treated bacterial infections may be nonsuppurative with mild to moderate elevations of total white blood cell count and total protein concentration (Green and Smith, 1992; Sturges *et al.*, 2006). Occasionally extracellular or intracellular bacteria may be seen, either on a routine Wright's stain or a Gram stain (Foreman and Santschi, 1989; Green and Smith, 1992; Kornegay, 1981). Because prior antibiotic therapy is common, and some bacteria undergo rapid autolysis in the test tube, bacterial culture of these infections is often unrewarding. Nonetheless, culture should be attempted. Polymerase chain reaction techniques may be used to detect the presence of bacterial DNA (Finno *et al.*, 2006; Peters *et al.*, 1995).

a. Listeriosis

Despite being a bacterial infection, the CSF of cattle with meningoencephalitis caused by *Listeria monocytogenes* typically has mild to moderate elevations in total white blood cell count and total protein, with the white cells mostly mononuclear cells (Rebhun and deLahunta, 1982). These mild (to moderate) changes probably reflect the characteristic lesions of this disease, which are mononuclear vascular cuffing and parenchymal microabscesses. The disease in sheep may produce a CSF similar to that of infected cattle (Scarratt, 1987). However, two studies reported ovine CSF with moderate to marked elevations in white blood cell count and protein, with a neutrophilic pleocytosis (53% to 100% neutrophils) (Scott, 1992, 1993). The mononuclear CSF reported in cattle likely reflects a more chronic stage or resolution of the disease (Green and Smith, 1992; Kjeldsberg and Knight, 1993). A study of bacterial culture and polymerase chain reaction (PCR) for the detection of *L. monocytogenes* in the CSF of 14 infected ruminants yielded no positive cultures and only one positive PCR. Direct culture of brain tissue was more frequently positive. The authors concluded that *L. monocytogenes* only occasionally gains access to the meningoventricular system in the course of the disease, and that reliable, *in vivo* diagnosis of listeric encephalitis generally cannot be based on the detection of the organism in the CSF (Peters *et al.*, 1995).

b. Neuroborreliosis (Lyme Disease)

Although neuroborreliosis caused by the Lyme disease spirochete, *Borrelia burgdorferi,* has been suspected in dogs (Feder *et al.*, 1991; Mandel *et al.*, 1993) and horses (Burgess and Mattison, 1987; Hahn *et al.*, 1996), the actual incidence in animals is unknown. The diagnostic difficulties arise from a delay or repression of seroconversion

after infection; the high number of seropositive, clinically normal animals; the persistence of infection and seropositivity despite resolution of clinical disease; antibody cross-reactivity; and difficulty in culturing the organism from tissue or fluid samples (Appel *et al.*, 1993; Levy *et al.*, 1993; Madigan, 1993; Parker and White, 1992). The CSF associated with neuroborreliosis in animals has not been characterized. In people, CSF abnormalities are related to the stage of the disease. When present, typical abnormalities are a mononuclear pleocytosis (T lymphocytes, plasma cells, and IgM-positive B cells (Sindern and Malin, 1995) with a moderately elevated total protein and normal or decreased CSF glucose (Fishman, 1992). Persistent CSF oligoclonal bands and intrathecal synthesis of IgG, IgM, and IgA occur (Henriksson *et al.*, 1986). Diagnosis is enhanced by the determination of intrathecal synthesis of specific *B. burgdorferi* antibodies (Kaiser and Lucking, 1993), but cross-reactivity is a problem (Fishman, 1992). *Borrelia burgdorferi* antibodies have also been detected in the CSF of dogs (Feder *et al.*, 1991; Mandel *et al.*, 1993). Polymerase chain reaction (PCR) techniques for CSF have been developed, but the diagnostic success rate is variable (Lebech, 1994). The CSF of a horse was reported PCR positive for *B. burgdorferi* (Hahn *et al.*, 1996).

c. Ehrlichial and Rickettsial Diseases

Ehrlichiosis, usually caused by *Ehrlichia canis,* and Rocky Mountain spotted fever, caused by *Rickettsia rickettsii,* sporadically involve the central nervous system of animals. In dogs with neural ehrlichiosis, the CSF resembles that of viral diseases (i.e., the white blood cell count and protein may be normal or slightly to moderately elevated with a predominantly mononuclear pleocytosis) (Buoro *et al.*, 1990; Firneisz *et al.*, 1990; Greene *et al.*, 1985; Maretzki *et al.*, 1994; Meinkoth *et al.*, 1989). The albumin quotient is reported to be elevated (Sorjonen *et al.*, 1991). Occasionally, *Ehrlichia* morulae may be observed in CSF mononuclear cells or neutrophils (Maretzki *et al.*, 1994; Meinkoth *et al.*, 1989). The few reports of CSF associated with Rocky Mountain spotted fever suggest a difference from ehrlichiosis in that the CSF pleocytosis of Rocky Mountain spotted fever may be predominantly neutrophilic, particularly early in the disease (Breitschwerdt, 1995, Breitschwerdt *et al.*, 1985; Greene *et al.*, 1985; Rutgers *et al.*, 1985). A predominantly neutrophilic pleocytosis has also been reported in dogs experimentally infected with *R. rickettsii* (Breitschwerdt *et al.*, 1990). In this same study, IgG or IgM antibodies were not detected in the CSF of experimentally infected dogs, but they were detected in the CSF of one naturally infected dog that also had a high serum titer (Breitschwerdt *et al.*, 1990).

d. Thromboembolic Meningoencephalitis

In cattle, *Hemophilus somnus* causes bacteremia and thromboembolism, with some preference for neural tissue. The vascular lesion results in multifocal hemorrhages. Consequently, the CSF is characteristically yellow with a high red blood cell count (not iatrogenic in origin), and moderately to markedly increased white blood cell count (predominantly neutrophils) and protein (Ames, 1987; George, 1996; Little and Sorensen, 1969; Mayhew, 1989). The bacterium can be cultured only occasionally from CSF and more easily from septicemic animals (Little, 1984; Nayar *et al.*, 1977)

2. *Viral Diseases*

The CSF associated with viral diseases is characterized by nonsuppurative inflammatory changes. The total white blood cell count and total protein are generally mildly to moderately elevated. The white cell population may be mixed with a majority of mononuclear cells or may be entirely mononuclear cells. Occasionally, neutrophils predominate, particularly in the early stages of disease or in certain diseases (discussed later). The IgG index is commonly elevated (Bichsel *et al.*, 1984b; Tipold *et al.*, 1994). The IgA and IgM levels may also be elevated. The CSF of viral infections may also be normal, particularly if the meninges or ependyma is not involved (Fankhauser, 1962; Fishman, 1992; Rand *et al.*, 1994b; Tipold, 1995; Tipold *et al.*, 1994).

a. Canine Distemper

The CSF abnormalities associated with canine distemper (CDV) vary strikingly with the stage of the disease. Dogs with acute, demyelinating, noninflammatory distemper encephalitis may have normal or near normal CSF (mild elevations of total cell count and total protein) (Johnson *et al.*, 1988; Tipold, 1995). Protein elevation is most likely the result of blood-brain barrier dysfunction (Bichsel *et al.*, 1984b). The IgG index may also be normal or occasionally mildly elevated, which correlates with the histological findings of multifocal demyelination with few or no infiltration of inflammatory cells (Bichsel *et al.*, 1984b; Johnson *et al.*, 1988; Tipold *et al.*, 1993b, Vandevelde *et al.*, 1986). The acute form of nervous canine distemper is an exception to the usual association of an elevated IgG index with infectious neurological diseases because infiltration with inflammatory cells occurs only in the chronic stage of distemper encephalitis (Vandevelde *et al.*, 1986). The CSF IgM and IgA content is also usually normal (Johnson *et al.*, 1988; Tipold *et al.*, 1994). The CSF of subacute/chronic, inflammatory distemper usually has a moderately elevated total white blood cell count, primarily mononuclear, and moderately elevated protein (Bichsel *et al.*, 1984b; Tipold, 1995). The IgG index is typically elevated (Bichsel *et al.*, 1984b; Vandevelde *et al.*, 1986), and IgA levels are commonly increased. Interestingly, IgM levels are increased more often in the dogs in the chronic stage than in the dogs with acute, noninflammatory distemper (Tipold *et al.*, 1993b, 1994). The IgM and IgA are presumably of intrathecal origin (Tipold *et al.*, 1994), although blood-brain barrier dysfunction is also present in some dogs and

therefore protein could be of serum origin (Bichsel *et al.*, 1984b; Sorjonen, 1987; Sorjonen *et al.*, 1991). Occasionally the CSF is normal or has only mild changes in cell count or total protein content (Bichsel *et al.*, 1984b; Sorjonen *et al.*, 1991; Tipold, 1995; Tipold *et al.*, 1993b, 1994; Vandevelde *et al.*, 1986). Antimyelin antibody and antiviral antibody have also been identified in the CSF of inflammatory distemper (Vandevelde *et al.*, 1986). Canine distemper virus antibody is normally absent from CSF; when present it is diagnostic of infection. False-positive results can occur, however, if the CSF is contaminated by serum distemper virus antibody by either iatrogenic or pathological blood-brain barrier disturbance. The CSF of delayed-onset canine distemper (a.k.a. old dog encephalitis) has an elevated protein and nonsuppurative, inflammatory cytology. The IgG index is elevated, and much of the CSF IgG is virus-specific, suggesting an intrathecal antiviral immune response. The IgM and IgA concentrations are normal (Johnson *et al.*, 1988). Occasionally, distemper virus infection causes massive encephalomalacia (Vandevelde and Spano, 1977), resulting in a neutrophilic pleocytosis. Because of the variable presentations and CSF findings associated with CDV infection, definitive antemortem diagnosis can be difficult. Fluorescent antibody testing (IFA) for the detection of viral antigen in conjunctival, tonsillar, and respiratory epithelium has proven useful but only in the acute phases of illness (Greene and Appel, 2006). In subacute and chronic disease, antibody coating of viral antigen may interfere with diagnostic immunofluorescence (Amude *et al.*, 2006a; Andrews *et al.*, 1994; Greene and Appel, 2006). RT-PCR for the detection of viral RNA is likely the most sensitive method for detecting CDV infection; however, sensitivity may be higher in urine than in CSF (Amude *et al.*, 2006a; Frisk *et al.*, 1999; Kim *et al.*, 2006).

b. Equine Herpesvirus Myeloencephalitis

With its predilection for endothelial cells, the equine herpes virus 1 (EHV-1) may cause vasculitis and perivascular hemorrhage in the brain and spinal cord. As a result, the CSF is often xanthochromic. The total white blood cell count may be normal, whereas the total protein level is moderately to markedly elevated (albuminocytological dissociation). The CSF/serum albumin ratio is increased (Klingeborn *et al.*, 1983). In some cases, the total protein is normal, perhaps because the CSF is analyzed early in the course of the disease before the protein level has risen or late in the disease after the level has subsided (Kohn and Fenner, 1987). Antibodies to the virus may be identified in the CSF (Blythe *et al.*, 1985; Jackson *et al.*, 1977; Klingeborn *et al.*, 1983). Antiviral CSF antibodies are not present routinely in neurologically normal horses, horses vaccinated with modified live EHV-1, or horses with other neurological diseases (Blythe *et al.*, 1985). However, because of destruction of the blood-brain barrier, serum antiviral antibodies may pass into the CSF and confound the interpretation of the CSF titers (Blythe *et al.*, 1985; Jackson *et al.*, 1977; Klingeborn *et al.*, 1983; Kohn and Fenner, 1987). Determining the CSF IgG index may help to assess the relevance of a positive CSF EHV-1 titer.

c. Feline Infectious Peritonitis

The feline infectious peritonitis (FIP) coronavirus may cause a multifocal, pyogranulomatous meningitis, choroid plexitis, and ependymitis characterized by perivascular granulomas around small blood vessels. The CSF associated with these lesions consistently has a moderate to marked elevation of white blood cell count and protein concentration. In one study, the CSF of cats with FIP was distinctive compared to that of cats with other inflammatory central nervous system diseases in having greater than 200 mg/dl total protein (Rand *et al.*, 1994b). Despite being a viral disease, the white cell population is dominated by neutrophils, commonly greater than 70% (Baroni and Heinold, 1995; Kline *et al.*, 1994; Rand *et al.*, 1994b). Prolonged glucocorticosteroid therapy may result in a normal CSF in rare instances; the authors have observed this on at least one occasion.

d. Feline Immunodeficiency Virus

The CSF associated with feline immunodeficiency virus (FIV) neurological disease typically has a mild, primarily lymphocytic, pleocytosis (Dow *et al.*, 1990; Phillips *et al.*, 1994). In experimentally infected cats, the pleocytosis appears related to the duration, and perhaps route, of infection, as well as the age of the cat. In one study, pleocytosis appeared within 2 to 8 weeks of inoculation of adult cats, then disappeared by 20 weeks (Dow *et al.*, 1990). In a study of kittens, the total and differential cell counts were normal at 3 and 12 to 16 months postinoculation (Podell *et al.*, 1993). The total protein content is typically normal, although the albumin quotient and IgG index may be elevated (Dow *et al.*, 1990; Podell *et al.*, 1993). Antibodies to the virus may be detected in the CSF, and their presence in CSF that has not been contaminated by peripheral blood is presumptive evidence of FIV neural infection (Dow *et al.*, 1990; Phillips *et al.*, 1994). In experimentally inoculated cats, FIV antibodies developed in the CSF 4 to 8 weeks after the appearance of CSF pleocytosis (Dow *et al.*, 1990). The virus can be recovered from the CSF of most cats that have intrathecal antibodies (Dow *et al.*, 1990; Phillips *et al.*, 1994). In the immunodeficient, chronic stage of FIV infection, the effect of possible opportunistic neural infections on CSF must be considered.

e. Rabies

Because rabies is an overwhelmingly fatal, zoonotic disease, there is a paucity of information regarding its CSF abnormalities. In people, the total white blood cell count is normal or has a mild, lymphocytic pleocytosis, and total protein is mildly increased. Occasionally, the pleocytosis is marked

(Fishman, 1992). The CSF of animals with rabies may be normal or abnormal. Typical abnormalities include a mild to moderate mononuclear pleocytosis and mild to moderate elevations in total protein. The white cells may be predominantly lymphocytes, with macrophages, neutrophils, and occasionally plasma cells and eosinophils (Braund, 1994; Coles, 1980; Green *et al.*, 1992; Hamir *et al.*, 1992; Hanlon *et al.*, 1989). A neutrophilic pleocytosis reported for one horse was thought to reflect an early stage of the disease (Green, 1993). Xanthochromia was detected in the CSF of three of five horses in one study (Green *et al.*, 1992), perhaps because of antemortem head trauma. The CSF IgM titer increases in 2 to 3 weeks or more after the onset of clinical rabies (Murphy *et al.*, 1980). Because of this delay, a negative titer result does not eliminate rabies infection as a possibility (Greene, 1998). Infective virus may be isolated from the CSF before clinical signs of the disease appear, and neutralizing antibodies in the CSF may not be identified until after clinical signs develop (Fekadu and Shaddock, 1984). Because of the human health hazard, CSF collection should be avoided if rabies is suspected.

f. West Nile Virus

West Nile virus (WNV) is a mosquito-borne flavivirus that is endemic in Africa, Europe, and Asia and emerged as a pathogen in the United States in 1999 (Cannon *et al.*, 2006; Davis *et al.*, 2006; Long *et al.*, 2006; Porter *et al.*, 2004). Disease occurs most commonly in birds, horses, and humans and in several other animal species, and rarely in dogs. Clinical signs frequently include fever and neurological disease most often manifest by ataxia, weakness, and muscle tremors (Cannon *et al.*, 2006). Nonsuppurative (lymphoplasmacytic and histiocytic) polioencephalomyelitis is seen histopathologically in the CNS of animals (Cannon *et al.*, 2006; Cantile *et al.*, 2000, 2001; Kiupel *et al.*, 2003; Wunschmann *et al.*, 2005). CSF is usually abnormal in horses (Wamsley *et al.*, 2002). A mild to moderate mononuclear pleocytosis with lymphocyte predominance and mildly increased protein concentration are the most common CSF findings (Wamsley *et al.*, 2002). However, macrophages may predominate, and occasionally only elevated protein concentration is present (albuminocytological dissociation). The albumin quotient is usually normal and the IgG index is elevated in lumbar (but not in cisternal) samples, perhaps reflecting spinal cord involvement, intrathecal IgG production in this location, and the tendency for pelvic limb weakness in many horses with clinical WNV disease (Porter *et al.*, 2004). In one study of horses with neurological disease attributable to WNV infection, all measured CSF parameters were within reference limits in 27% (8/30) of horses (Wamsley *et al.*, 2002). The current gold standard for diagnosis of active WNV infection in horses is the IgM capture ELISA (MAC-ELISA) for the detection of WNV-specific IgM antibodies. This test appears capable of distinguishing infected horses from vaccinated horses (Porter *et al.*, 2004). Additionally, use of the MAC-ELISA in CSF may be slightly more sensitive than application of the same test in serum for horses with WNV infection (Porter *et al.*, 2004).

3. *Fungal Diseases*

Fungal infection of nervous tissue is relatively uncommon, although *Cryptococcus neoformans* has a predilection for the central nervous system. The CSF associated with neural cryptococcosis is quite variable. The total white blood cell count can be near normal or markedly increased. The white blood cell differential count is typically mixed with a majority of neutrophils (Berthelin *et al.*, 1994b; Steckel *et al.*, 1982). However, mononuclear CSF has been reported (Berthelin *et al.*, 1994b; de Lahunta, 1983), as has eosinophilic fluid (de Lahunta, 1983; Vandevelde and Spano, 1977). The total protein is typically elevated, although sometimes only marginally so. The albumin quotient and IgG index are mildly to markedly elevated (Sorjonen *et al.*, 1991). Cryptococcal organisms are commonly seen in the CSF (93% in one report/review) (Berthelin *et al.*, 1994b), and cultures are often, but not invariably, positive. Latex agglutination for cryptococcal antigen in the CSF may also be positive (Berthelin *et al.*, 1994b; Jacobs and Medleau, 1998).

There are only a few reports of the CSF abnormalities associated with CNS aspergillosis, blastomycosis, coccidioidomycosis, or histoplasmosis. The CSF abnormalities are variable; but a mixed pleocytosis and elevated protein are typical (Coates, 1995; Gelatt *et al.*, 1991; Kornegay, 1981; Mullaney *et al.*, 1983; Nafe *et al.*, 1983; Schaer *et al.*, 1983; Vandevelde and Spano, 1977). In a case of aspergillosis of the brain of a dog, the CSF had a normal total nucleated cell count (differential count was not done) and a normal protein (Parker and Cunningham, 1971). The tropism of some fungi for CNS white matter might result in failure to access the meninges or ventricular system and hence result in normal CSF.

4. *Prion Disorders*

The transmissible spongiform encephalopathies (TSEs) are a group of neurodegenerative diseases of people and animals caused by prions (proteinaceous infectious particles). The diseases in this group include Kuru and Creutzfeldt-Jakob disease of people, bovine spongiform encephalopathy, scrapie of sheep and goats, transmissible mink encephalopathy, and spongiform encephalopathies in deer, captive ungulates, and domestic cats (Schreuder, 1994a, 1994b). The CSF associated with the spongiform encephalopathies in animals has normal cytology, protein content, and electrophoretic pattern. Thus, these diseases, although apparently infectious, do not appear to damage the blood-brain barrier or elicit an immune response in the central nervous system (Green *et al.*, 2007; Lowenthal and Karcher, 1994;

Millson *et al.*, 1960; Scott *et al.*, 1990; Strain *et al.*, 1984). However, immunoassay detection in the CSF of the brain derived protein 14-3-3 appears to be useful for the diagnosis of TSE in both animals and people (Hsich *et al.*, 1996; Sanchez-Juan *et al.*, 2006).

E. Ischemic Disorders

In general, neural ischemia causes blood-brain/CSF barrier dysfunction resulting in increased CSF protein. If infarction occurs, the tissue destruction and cellular response may result in CSF pleocytosis. With extensive, particularly acute, infarction the pleocytosis may be substantially neutrophilic (Fishman, 1992). In animals, CSF abnormalities are reported for fibrocartilaginous embolism and cerebral ischemia/infarction.

1. *Fibrocartilaginous Embolism*

The CSF characteristics associated with fibrocartilaginous embolism (FCE) are reported for dogs and horses. About one-third of the reported canine cases have normal CSF, about one-third have a mononuclear pleocytosis and increased protein, and about one-third have albuminocytological dissociation (Bichsel *et al.*, 1984a, 1984b; Cauzinille and Kornegay, 1996; Gandini *et al.*, 2003; Grunenfelder *et al.*, 2005). Similar findings are reported for two horses (Jackson *et al.*, 1995; Taylor *et al.*, 1977). However, we have seen marked neutrophilic pleocytoses associated with (histopathologically confirmed) severe, acute FCE in dogs (unpublished observation). The type of pleocytosis, neutrophilic or mononuclear, probably depends on the size, location, and age of the infarct. The CSF albumin is reported to be normal, and the IgG index either normal or slightly elevated, the latter possibly reflecting the subsequent inflammation around the lesion (Bichsel *et al.*, 1984b; Tipold *et al.*, 1993b). Dogs with normal CSF may have a better prognosis for recovery (Cauzinille and Kornegay, 1996; Gandini *et al.*, 2003).

2. *Cerebral Ischemia/Infarction*

Cerebral infarction (ischemic encephalopathy) is reported primarily in cats, but also in a few dogs. In cats within the first week of onset, the CSF white blood cell count is normal or mildly elevated with a mixed, predominantly mononuclear, pleocytosis, and protein is mildly to markedly elevated (de Lahunta, 1983; Rand *et al.*, 1994a). Dogs with cerebral infarction have similar CSF characteristics (Bichsel *et al.*, 1984b; de Lahunta, 1983; Joseph *et al.*, 1988; Vandevelde and Spano, 1977), although two dogs in one report had a mixed, but predominantly neutrophilic, pleocytosis and normal protein (Vandevelde and Spano, 1977). The neutrophilic pleocytosis reflected the acute encephalomalacia noted on histopathological examination (Vandevelde and Spano, 1977). In one dog of another report, the CSF albumin and IgG index were normal (Bichsel *et al.*, 1984b). Another dog with a deep, parenchymal, hemorrhagic infarct in the basal nuclear region had normal CSF (Norton, 1992).

F. Malformations of Neural Structures

Although reports with CSF analysis are relatively few, the CSF of animals with neural malformations is generally normal (Greene *et al.*, 1976; Meric, 1992b; Milner *et al.*, 1996; Rand *et al.*, 1994a; Shell *et al.*, 1988; Vandevelde and Spano, 1977; Wilson *et al.*, 1979). However, if the malformation interferes with CSF circulation or absorption, abnormalities in protein and even cell count may be present. The CSF may also be altered by secondary or additional unrelated processes (Rishniw *et al.*, 1994). For example, intraventricular hemorrhage can occur in hydrocephalic animals, producing xanthochromic CSF with an increased white blood cell count and protein content.

1. *Intracranial Intra-Arachnoid Cysts*

Although several reports describe intracranial intra-arachnoid cysts (ICIACs) in dogs (Duque *et al.*, 2005; Kitagawa *et al.*, 2003; Saito *et al.*, 2001; Vernau *et al.*, 1997, 2002; Von Kurnatowski *et al.*, 2006), most do not report the CSF findings present with this condition. Several dogs with ICIACs are diagnosed with concurrent inflammatory brain disease (Duque *et al.*, 2005; Kitagawa *et al.*, 2003; Vernau *et al.*, 1997; Von Kurnatowski *et al.*, 2006), and some authors believe that ICIACs may therefore be incidental in some animals. One report describes two dogs with ICIACs with intracystic hemorrhage. One of these dogs had a normal CSF nucleated cell count but had some degenerate red blood cells and a moderate elevation of protein. The other dog had a mild mononuclear pleocytosis, a mild elevation of protein, and there was evidence of erythrocytophagia (Vernau *et al.*, 2002).

2. *Spinal Arachnoid Cysts*

Most dogs with spinal arachnoid cysts have normal CSF analysis (Gnirs *et al.*, 2003; Hashizume, 2000; Jurina and Grevel, 2004; Rylander *et al.*, 2002; Sessums and Ducote, 2006; Skeen *et al.*, 2003). In dogs with a spinal arachnoid cyst that have abnormal CSF, the most common abnormality is an albuminocytological dissociation (Gnirs *et al.*, 2003; Rylander *et al.*, 2002) with protein concentrations that may exceed 100 mg/dl. Less commonly, dogs may have a mild mononuclear pleocytosis and increased protein concentration as high as 216 mg/dl (Rylander *et al.*, 2002).

G. Metabolic/Nutritional Disorders

Cerebrospinal fluid analysis is not done commonly in animals with metabolic or nutritional neurological disorders

because most of these disorders are diagnosed from historical and physical findings and laboratory tests of blood and urine. When other procedures are nondiagnostic, or when therapy does not eliminate or perhaps worsens the neurological dysfunction, CSF analysis is indicated to investigate other causes of the neurological signs. In most cases, routine analysis of CSF associated with metabolic or nutritional disorders does not detect abnormalities (Bichsel *et al.*, 1984b; Fishman, 1992; Scott, 1995; Vandevelde and Spano, 1977). Although brain edema is relatively common with some of these disorders (e.g., hypoxia, hyponatremia, or the osmotic dysequilibrium syndromes of hemodialysis or diabetic ketoacidosis), the edema is usually cytotoxic rather than vasogenic. Therefore, the blood-brain/CSF barrier is usually intact and CSF protein is normal. If edema is severe enough to result in brain ischemia, infarction, or herniation, the blood-brain/CSF barrier becomes dysfunctional, vasogenic edema occurs, and CSF protein rises. If neural necrosis ensues, the white blood cell count may also increase. Even in the (apparent) absence of vasogenic edema, blood-brain barrier leakage may occur, perhaps because of the biochemical effects of the disorder on the barrier cells. Animals and people with uremic or hepatic encephalopathies or hypothyroidism may have increased total protein with a normal IgG index (Bichsel *et al.*, 1984b, 1988; Fishman, 1992). People with diabetic neuropathy may also have increased CSF protein (Fishman, 1992). Animals with severe metabolic encephalopathies often suffer seizures and the effect of seizures on the CSF must also be considered (see Section VII.H). Disorders in which neural necrosis is a primary feature, such as the polioencephalomalacia of thiamine deficiency, typically have a pleocytosis and increased total protein (Bichsel *et al.*, 1984b; de Lahunta, 1983; George, 1996). Specific biochemical analysis of CSF may show abnormalities, such as abnormalities in osmolality or electrolyte content with salt or water intoxication (Kopcha, 1987; Mayhew, 1989), abnormalities in amino acid levels (such as glutamine) with hepatic encephalopathy (Grabner and Goldberg, 1991; Schaeffer *et al.*, 1991), and elevated citrulline in bovine citrullinemia (Healy *et al.*, 1990).

H. Miscellaneous Conditions

1. Alterations in CSF Following Myelography

Changes in the composition of CSF following myelography have been reported in people (Fishman, 1992) and animals (Burbidge *et al.*, 1989; Widmer and Blevins, 1991). Many contrast agents are low-grade leptomeningeal irritants, resulting in leptomeningeal inflammation that is reflected in the CSF. By 90 min after myelography, the total white blood cell count and total protein can be elevated and the white blood cell differential count altered. The pleocytosis is typically a mixed mononuclear/neutrophilic response, with the proportion of mononuclear cells to neutrophils varying with the contrast agent used and the time interval after myelography. The pleocytosis may resolve within 10 days (Johnson *et al.*, 1985), although individual animals may have a slightly increased total white blood cell count up to 14 days following contrast injection (Spencer *et al.*, 1982; Wood *et al.*, 1985). In contrast, one study of the contrast agents iohexol and iotrolan did not detect any alteration of total white blood cell count in CSF taken between 1 and 14 days following myelography (van Bree *et al.*, 1991). The CSF specific gravity and Pandy test score can also be elevated, presumably partly because of the presence of the contrast media (Widmer *et al.*, 1992). Increased CSF albumin and immunoglobulin levels may be due predominantly to blood-brain/CSF barrier leakage, and may return to normal levels within 5 days (Johnson *et al.*, 1985). In summary, any alteration of CSF within the first week or two following myelography must be assessed cautiously.

2. Seizures: Interictal and Postictal CSF Characteristics

Patients with seizures resulting from progressive intracranial or some extracranial disorders typically have CSF changes reflecting the disorder. In contrast, the interictal CSF of patients with nonprogressive, intracranial disease should be normal. Postictal CSF is often abnormal, however. Pleocytosis of postictal CSF has been well documented in people (Barry and Hauser, 1994; Fishman, 1992; Rider *et al.*, 1995). The white blood cell counts may be up to 80/μl with a neutrophilic component from 5% to 92%. The cell counts are highest at about 24 h after the seizure. The mechanism of the pleocytosis is obscure (Fishman, 1992). Convulsive seizures, regardless of cause, may also induce a reversible increase in blood-brain/CSF barrier permeability, resulting in a transient elevation of CSF protein. Brain metabolism is also stimulated during the seizure, resulting in an increase in brain lactate production and a decrease in brain pH (Fishman, 1992). However, differentiating the effects of the local (brain) phenomena from the effects of systemic phenomena that occur during seizures (hypertension, acidosis, hypoxia, etc.) is difficult. For example, severe, experimental hyperthermia in dogs (core body temperature > 41.2°C) results in increased CSF enzymes, calcium, and chloride, probably because of increased blood-brain/CSF barrier permeability (Deswal and Chohan, 1981). Interpretation of postictal CSF must be done cautiously because of the potential confusion of a postictal, "idiopathic epileptic" condition with a progressive disease that alters the CSF primarily. For children with seizures, the recommendation has been made that CSF with >20 white blood cell/μl or >10 polymorphonuclear cells/μl not be attributed to the seizures (Rider *et al.*, 1995).

I. Neoplasia

The CSF associated with neoplastic conditions affecting the central nervous is variable, reflecting the variety of tumors,

locations, and tissue reactions to the disease. The CSF is usually clear and colorless, although xanthochromia may be present if hemorrhage has occurred. The total white blood cell count is often normal, but pleocytosis may occur, particularly with meningiomas and choroid plexus tumors (and occasionally other tumors) (Bailey and Higgins, 1986b; Carrillo *et al.*, 1986). Pleocytosis is usually mononuclear, although meningiomas may have > 50% neutrophils (Bailey and Higgins, 1986b). However, in another study of dogs with meningioma, about 30% of dogs had a normal CSF analysis (Dickinson *et al.*, 2006). In this study, a significant association between meningiomas in the caudal portion of the cranial fossa and an elevated CSF nucleated cell count was found; but only 19% of the dogs had an elevated total nucleated white cell count with a predominance of neutrophils (Dickinson *et al.*, 2006). Neural lymphosarcoma often has a lymphocytic/lymphoblastic pleocytosis (Couto and Kallet, 1984; Lane *et al.*, 1994; Williams *et al.*, 1992), except in cattle in which the tumor is usually extradural (Sherman, 1987). One study of brain tumors in dogs found that pleocytotic CSF is associated with a significantly shorter survival time than is normal or albuminocytological CSF (Heidner *et al.*, 1991). The most common CSF abnormality present with CNS neoplasia is increased total protein, with choroid plexus tumors producing the most marked elevations (Bailey and Higgins, 1986b; Brehm *et al.*, 1995; Heidner *et al.*, 1991; Mayhew, 1989; Moore *et al.*, 1994; Rand *et al.*, 1994a; Roeder *et al.*, 1990; Sarfaty *et al.*, 1988; Waters and Hayden, 1990). Dogs with neural neoplasia, particularly of the meninges or choroid plexus, commonly have blood-brain/spinal cord barrier disturbance and subsequently an increased albumin quotient (Bichsel *et al.*, 1984b; Moore *et al.*, 1994; Sorjonen, 1987; Sorjonen *et al.*, 1991). In one study, this abnormality was most common with choroid plexus tumors and least common with astrocytomas (Moore *et al.*, 1994). Alpha and beta globulin levels are usually normal; gamma globulins are normal or mildly increased (Moore *et al.*, 1994; Sorjonen, 1987; Sorjonen *et al.*, 1991). The IgG index may be elevated, reflecting the presence of inflammatory infiltrates around the lesion (Bichsel *et al.*, 1984b; Tipold *et al.*, 1993b).

The CSF associated with spinal neoplasia is reported to be normal more often than is the CSF of brain tumors (Fingeroth *et al.*, 1987; Luttgen *et al.*, 1980; Schott *et al.*, 1990). This finding may reflect the fact that most spinal neoplasia is extradural or that most spinal tumors are relatively small at the time of diagnosis. It may also reflect the site of CSF collection—that most of the samples are cerebellomedullary rather than lumbar, although many reports do not state the puncture site. Cerebrospinal fluid collected caudal to the lesion is abnormal more often than is CSF collected cranial to the lesion (Thomson *et al.*, 1990). Neoplastic cells can also be observed in CSF, facilitating a definitive diagnosis. Lymphoma has been diagnosed on the basis of CSF assessment in both small and large animals (Lane *et al.*, 1994; Pusterla *et al.*, 2006a; Vandevelde and Spano, 1977). However, the observation of neoplastic cells in CSF samples from animals with central nervous system neoplasia other than lymphoma is more uncommon in our experience. This may be partly because cytocentrifugation has been the most common technique employed for the cytological assessment of CSF. Although cytospin slides produce excellent morphology, the cell yield is low (Barrett and King, 1976), which may increase the incidence of false negative results in confirmed cases of CNS neoplasia. Additionally, the general lack of experience of veterinary clinical pathologists at identifying cells derived from central nervous system neoplasms may also result in false negative results. Despite these limitations, the presence of neoplastic cells in cytospin CSF slides from animals with CNS tumors other than lymphoma has been reported in cats with intracranial oligodendroglioma, dogs with CNS histiocytic sarcoma, and dogs with choroid plexus carcinoma (Dickinson *et al.*, 2000; Zimmerman *et al.*, 2006)[3,5]

J. Parasitic Diseases

1. *Equine Protozoal Encephalomyelitis*

Equine protozoal encephalomyelitis (EPM), caused by *Sarcocystis neurona (S. falcatula)* (Dame *et al.,* 1995), is characterized by multifocal areas of mononuclear, perivascular inflammation and necrosis; severe lesions may be hemorrhagic and have neutrophilic infiltration (Madigan and Higgins, 1987; Mayhew *et al.,* 1978). The CSF may be normal or have mild to moderate mononuclear pleocytosis and increase in total protein (Mayhew, 1989). Xanthochromia is occasionally present, as well as neutrophils and eosinophils (Mayhew, 1989). The CSF albumin concentration and albumin quotient are reported to be normal and the IgG index elevated, indicating intrathecal IgG production (Andrews and Provenza, 1995). IgG antibodies to *S. neurona* can be identified in the CSF by immunoblot analysis (Granstrom, 1993). The test is very sensitive and specific for the diagnosis of EPM; however, its accuracy depends on an intact blood-brain/CSF barrier because many infected and previously infected horses have serum antibodies to *S. neurona* but do not have clinical disease (Andrews and Provenza, 1995; Fenger, 1995). Therefore, it may be useful to also measure the albumin quotient and IgG index in CSF that is submitted for *S. neurona* immunoblotting. However, some have questioned the utility of doing this and recommend a CSF RBC count instead, with RBC counts >50 RBCs/μL invalidating interpretation of a positive CSF immunoblot result (Furr *et al.,* 2002). Conversely, a negative CSF result, even when concurrent with RBC counts >50 RBCs/μL, would indicate that EPM is highly unlikely. The development of a Sarcocystis neurona specific IgM capture ELISA, similar to that developed for WNV infection, may further improve EPM clinical diagnostics (Murphy *et al.,* 2006). Detection of *S. neurona* in the CSF

by polymerase chain reaction provides definitive evidence of the presence of the parasite in the central nervous system. The results of polymerase chain reaction assay are independent of serum leakage across the blood-brain/CSF barrier (Fenger, 1994). However, although a powerful and highly specific test, the PCR test for detection of parasite antigen has not been found to be clinically useful because of the high incidence of false negative results (Furr *et al.*, 2002). The reasons for this are unclear but may be due to rarity of the parasite in CSF or rapid destruction of parasite DNA in the CSF environment or both (Furr *et al.*, 2002).

2. *Neosporosis, Toxoplasmosis*

Both *Neospora* and *Toxoplasma* can invade the central nervous system causing necrosis, vasculitis and a multifocal, granulomatous meningoencephalomyelitis. *Neospora* seems to have more of a predilection for the central nervous system than *Toxoplasma*, particularly in young dogs (Dubey *et al.*, 1988, 1989). The CSF associated with neural protozoal infections generally has a mild to moderate increase in white blood cell count and total protein. Typically, the white blood cell differential count shows a mixed pleocytosis with monocytes, lymphocytes, neutrophils, and eosinophils in order of decreasing percentage (Averill and DeLahunta, 1971; Cuddon *et al.*, 1992; Dubey, 1990a; Hass *et al.*, 1989; Kornegay, 1981; Rand *et al.*, 1994b; Tipold, 1995; Vandevelde and Spano, 1977). However, we have also seen marked pleocytosis with marked eosinophil predominance in histopathologically confirmed canine CNS neosporosis (W. Vernau, unpublished observation). Occasionally the white blood cell count and protein are normal (Parish *et al.*, 1987; Tipold, 1995). The CSF IgG index was elevated in three of three dogs studied; in two of two dogs, the IgM was normal and the IgA was elevated (Tipold *et al.*, 1993b, 1994). In a study of experimentally infected cats, *T. gondii*-specific IgG was intrathecally produced, but *T. gondii*-specific IgM was not detected (Munana *et al.*, 1995). Antiprotozoal antibodies in the CSF may be detected by a variety of methods (Cole *et al.*, 1993; Patton *et al.*, 1991; Ruehlmann *et al.*, 1995). However, the presence of antibodies does not necessarily indicate clinical disease (Dubey and Lindsay, 1993; Munana *et al.*, 1995). Polymerase chain reaction techniques have been developed to identify the protozoa in tissue and fluids, including CSF (Novati *et al.*, 1994; Parmley *et al.*, 1992; Schatzberg *et al.*, 2003; Stiles *et al.*, 1996). Occasionally the organisms themselves may be seen in CSF cells (Dubey, 1990a; Gaitero *et al.*, 2006; McGlennon *et al.*, 1990).

In considering the CSF abnormalities of toxoplasmosis and neosporosis, two issues must be kept in mind. First, reports of toxoplasmosis before 1988 (when *Neospora* was identified) must be carefully scrutinized because many of these cases were actually neosporosis. Second, because *T. gondii* is not a primary pathogen, clinical toxoplasmosis is relatively rare and is seen mostly in conjunction with a second disease, particularly canine distemper, which may itself alter the CSF (Dubey *et al.*, 1989).

3. *Migratory Parasites*

Neural invasion by migratory parasites is relatively common in large and exotic animals, yet rare in dogs and cats. The CSF may reflect the physical trauma and consequent inflammatory response, and in some cases an immune reaction, to the parasite tissue. The CSF abnormalities are variable and probably depend to some degree on the specific parasite as well as its location and the type of incited response. For example, *H. bovis* larvae in the cow normally lodge in the lumbar epidural space and their effect on the spinal cord may be primarily compression. The CSF in such a case could be normal or have only mildly to moderately elevated protein. Parasites that actually invade neural tissue may leave the CSF unchanged or produce CSF with mild to marked pleocytosis and protein elevation, as well as xanthochromia. An eosinophilic pleocytosis suggests parasitism and is typical of some parasites such *Parelaphostrongylus* (Baum, 1994; George, 1996; Mason, 1989; Pugh *et al.*, 1995) and *Angiostrongylus cantonensis* (Lunn *et al.*, 2003; Mason, 1989). However, eosinophilic pleocytosis is not pathognomonic for parasitism, nor does a lack of eosinophils in the CSF rule out neural parasitism (Braund, 1994; de Lahunta, 1983; Lester, 1992). The *Parelaphostrongylus*-specific ELISA may be useful to detect parasite antigen in the CSF (Dew *et al.*, 1992). *Angiostrongylus cantonensis*-specific antibodies can be detected in the CSF via ELISA (Lunn *et al.*, 2003).

K. Toxicity

Even though neurological signs may occur, the CSF associated with toxicity is usually normal (e.g., cows with lead poisoning, tetanus or botulism) (Fankhauser, 1962; Feldman, 1989). Mild elevations of the white blood cell count and protein may occur if the toxin causes breakdown of blood-brain/CSF barrier or neural degeneration or necrosis, such as in some cases of lead poisoning (Dorman *et al.*, 1990; Dow *et al.*, 1989; Fankhauser, 1962; George, 1996; Little and Sorensen, 1969; Mayhew, 1989; Swarup and Maiti, 1991). Lead has been shown to selectively poison capillary endothelial cells (Goldstein *et al.*, 1977), as well as cause cerebral cortical necrosis (Christian and Tryphonas, 1970). If necrosis is severe, the white blood cell count and the total protein can be markedly increased with a predominance of neutrophils, as with leukoencephalomalacia caused by moldy corn poisoning in horses. Xanthochromia is also a characteristic of moldy corn poisoning, reflecting the perivascular hemorrhages in the central nervous system (Masri *et al.*, 1987; McCue, 1989). With toxicities, biochemical alterations of the CSF may occur more commonly than alterations of CSF cell counts or protein. At the onset of fatal signs of lead poisoning, CSF glucose, urea, creatinine, and creatine

kinase levels are increased (Swarup and Maiti, 1991). Neurostimulatory toxins may result in elevated monoamine metabolites in the CSF (Sisk *et al.*, 1990). Ivermectin toxicity producing recumbency in dogs elevates the CSF concentrations of homovanillic acid and 5-hydroxyindoleacetic acid (Vaughn *et al.*, 1989). Interestingly, copper poisoning in sheep does not produce significant increases in CSF copper, zinc, or iron levels (Gooneratne and Howell, 1979).

L. Trauma/Compression of Neural Tissue

The CSF abnormalities associated with trauma or compression are variable depending on the rate at which the neural insult developed, the degree of neural damage, the location of the lesion (particularly with respect to the CSF collection site), the elapsed time since the onset of the neural insult, and the maintenance or progression of the insult. With acute trauma, the CSF may be pink and hazy or turbid, or actually bloody. After centrifugation, the supernatant can be clear. If hemorrhage occurred more than 48 h before CSF collection, the supernatant may be yellow because of bilirubin. The total red blood cell count may be markedly elevated. The white blood cell count may be mildly to moderately elevated, reflecting either hemorrhage into the subarachnoid space or inflammation instigated by the trauma. Erythrophagocytosis may be present. The pleocytosis is usually a mixed cell population, and a substantial proportion of neutrophils (40% to 50%) is possible; acute severe disease may result in counts greater than 50 cells per microliter with more than 50% neutrophils (Thomson *et al.*, 1989). In another larger study of canine intervertebral disk disease, mixed pleocytoses as high as 428 cells/μL were noted (Windsor *et al.*, 2007). Total protein may be moderately to markedly elevated because of the disruption of blood vessels, interruption of CSF flow and absorption, and necrosis (Green *et al.*, 1993; Thomson *et al.*, 1989). Thus, the CSF of acute trauma may have a distinct, inflammatory character. With spinal cord trauma/compression, lumbar CSF is more consistently abnormal than cerebellomedullary CSF (Thomson *et al.*, 1990). The CSF abnormalities of chronic trauma or sustained compression tend to be milder than the abnormalities of acute damage. The white blood cell count may be normal or mildly elevated with generally a mixed or mononuclear pleocytosis. We have noted that dogs with chronic or acute on chronic type I intervertebral disk disease have a pleocytosis that is more commonly lymphocytic than neutrophilic (Windsor *et al.*, 2007); white blood cell counts in these instances may be as high as 180 cells/μL. The cerebellomedullary CSF of horses with cervical stenotic myelopathy is reported to be hypocellular with a reduced number of lymphocytes (Grant *et al.*, 1993). The CSF protein associated with chronic trauma or sustained neural compression may be normal to moderately elevated (Mayhew, 1989; Thomson *et al.*, 1989). The albumin content and the albumin quotient of CSF associated with trauma/compression may be normal or increased, the latter reflecting the vascular damage and edema (Andrews and Provenza, 1995; Bichsel *et al.*, 1984b; Sorjonen, 1987; Sorjonen *et al.*, 1991). The gamma globulin percentage and the IgG index are usually normal. Occasional elevations probably reflect the presence of inflammatory cells in the lesion (Andrews and Provenza, 1995; Bichsel *et al.*, 1984b; Tipold *et al.*, 1993b).

I. INTRODUCTION

The availability of accurate historical information including a list of the animal species affected, clinical signs, toxins suspected, potential route of exposure, vehicle, relative amount, and timing of exposure is often a limiting factor in the diagnosis of toxic disease. This information permits the diagnostician to make a rational selection of samples and tests to be performed by considering the known target organs of the toxins suspected. Unfortunately, this information is often unavailable during the initial stages of an intoxication. In the absence of such detailed history, the identification of target organs using clinical biochemistry may help clinicians to create a list of potential toxins retrospectively.

There are species differences in the most useful biochemical markers of organ-specific cellular injury and in the susceptibility to various toxins (Kramer and Hoffmann, 1997). For this reason, the following discussion is organized on an organ system and species basis. Neither bacterial toxins nor hereditary disease predisposing to intoxication will be discussed.

II. HEPATOTOXICITY

Many toxins induce hepatic injury (Table 27-1). The susceptibility of the liver to toxic insult is in part a consequence of its location between the digestive tract and the rest of the body and the central role it plays in biotransformation and disposition of xenobiotics (Miyai, 1991; Snyder, 1979). Extrahepatic metabolism of toxins by mixed function oxidases may affect the target organ and potential hepatotoxicity of a given xenobiotic (Gram *et al.*, 1986). A variety of factors including the induction of these enzyme systems by drugs (Snyder, 1979) and suppression of enzyme activity by infectious agents and cytokines (Monshouwer *et al.*, 1995) may modify the response to a given toxin. Lipophilic compounds tend to be more hepatotoxic than hydrophilic ones because the latter are eliminated by the kidney (Kelly, 1993). Many toxins are hepatotoxic and nephrotoxic, however, and most toxins have multiple target organs.

The cytosolic enzyme alanine aminotransferase (ALT) is found in both hepatocytes and skeletal muscle of animals. The dog and cat have high levels of ALT in hepatocytes, making it a useful marker for hepatocellular injury in these species (Stockham and Scott, 2002). The plasma half-life of this enzyme in the dog is estimated to be approximately 60h. Increased serum levels parallel the magnitude of hepatocellular injury in acute disease. Several days following injury, ALT levels may be spuriously low.

TABLE 27.1 Hepatotoxins

Hepatotoxin	Disease Onset	Geography	Species Affected
Aflatoxin B_1 (*Aspergillus flavus*)	Acute to chronic	Worldwide	All
Agave lecheguilla	Acute	US, MEX	Cp, O
Blue-green algae (Cyanobacteria)	Acute	Worldwide	All
Chlorinated hydrocarbons	Acute to chronic	Worldwide	All
Copper	Acute to chronic	Worldwide	O, all
Compositae	Acute	AFR, AUS	B, O, P
Corticosteroids	Chronic	Worldwide	Cn
Cresols (pitch)	Acute	Worldwide	P
Cycadales	Acute to chronic	AUS, FL, PRDOM REP	B, O
Cylcopiazonic acid (*Penicillium cyclopium*)	Acute to chronic	UK	B, E, O
Dimethylnitrosamine	Acute to chronic	Worldwide	B, Cn, F, O
Ethanol	Acute to chronic	Worldwide	All
Fumonisin (*Fusarium moniliforme*)	Chronic	Worldwide	B, E, O, P
Gossypol (cottonseed)	Acute to chronic	Worldwide	B, Cp, E, O, P
Hymenoxys odorata (bitterweed)	Acute to chronic	US	O
Indospicine (*Indigofera* spp.)	Acute to chronic	AUS	B, Cn, E
Iron	Acute	Worldwide	P, E
Karwinskia humboldtiana (coyotillo)	Acute to chronic	MEX, TX	B, Cp, O
Kochia scoparia (fireweed)	Chronic	US	B
Lantana camara	Chronic	AUS, AFR, MEX, US	B, O, E
Mebendazole	Acute	Worldwide	Cn
Moldy hay	Chronic	US	B
Myoporaceae	Acute to chronic	AUS, NZ	B, O
Nolina texana (sacahuiste)	Chronic	US	B, Cp, O
Petroleum	Acute	Worldwide	All
Phalloidin (*Amanita*)	Acute	Worldwide	All
Phomopsin (mycotoxin on lupines)	Acute to chronic	AUS, US	B, O
Phenytoin/primidone	Chronic	Worldwide	Cn
Phosphorus	Acute	Worldwide	All
Pyrrolizidine alkaloids	Chronic	Worldwide	B, Cp, E, O, P
Ricinus communis (castor bean)	Acute	Worldwide	All
Rubratoxins (*Penicillium rubrum*)	Acute to chronic	Worldwide	B, CN, E, F
Sawfly larvae	Acute	AUS, DENMARK	B, Cp, O
Solanaceae	Acute	AFR, AUS S AM, US	B, Cp, O
Sporidesmin (*Pithomyces chartarum*)	Chronic	AUS, AFR, NZ	B, O
Tannic acid (*Quercus* spp., oaks)	Acute	Worldwide	B, Cp, E, O
Terminalia oblongata (yellowwood)	Acute to chronic	AUS	B, O
Tetradymia spp. (rabbit/horsebrush)	Chronic	US	B, Cp, O
Trema aspera (poison peach)	Acute	AUS	B
Trifolium hybridum (Alsike clover)	Chronic	Worldwide	B, E, O
Xanthium strumarium (Cocklebur)	Acute	US	B, P

Abbreviations: B, *bovine*; Cn, *canine*; Cp, *caprine*; E, *equine*; F, *feline*; O, *ovine*; P, *porcine*.

Therefore, ALT is not helpful in evaluating chronic liver disease. ALT levels also may be elevated by corticosteroid treatment and some anticonvulsant medications. ALT is not useful in evaluating hepatic disease in the horse and cow because of relatively low levels of ALT in hepatocytes relative to muscle (Lassen, 2004).

Aspartate aminotransferase (AST) is found in several different cell types including hepatocytes, erythrocytes, and cardiac and skeletal myocytes. However, it is most useful in evaluating hepatocellular and muscular injury because of its high activity in the cells of these tissues. AST is commonly used as a marker of hepatocyte damage in the equine and bovine, though muscle damage and hemolysis can also increase serum activity. AST is less specific for hepatocyte damage in the dog as compared to ALT (Stockham and Scott, 2002). As with ALT, AST may not be useful in detecting chronic liver disease (Lassen, 2004).

Alkaline phosphatase (ALP) activity is found in the cell membranes of many tissues including liver, bone, intestine, kidney, and placenta. Serum ALP is primarily of hepatic origin in the dog, cat, and horse, though bone isoenzyme can also be detected. Also dogs can have measurable levels of corticosteroid induced ALP in serum when the animal is subjected to increased levels of endogenous corticosteroids or with administration of glucocorticoids (Stockham and Scott, 2002). Hepatic isoenzymes have a longer half-life (days) than intestinal, renal, or placental (minutes) isoenzymes. Cholestasis induces hepatic ALP. An increase in serum ALP can precede hyperbilirubinemia. Corticosteroids, phenobarbital, dieldrin, and other compounds may induce hepatic ALP. Increased osteoblastic activity in hyperparathyroidism, bone healing, or osteosarcoma may elevate ALP. Horses and ruminants have wide reference intervals for ALP; therefore, this enzyme has decreased sensitivity for the detection of cholestatic disease in these animals (Lassen, 2004; Stockham and Scott, 2002).

Gamma glutamyltransferase (GGT) is found in many cells, but specifically the renal tubular epithelium, canalicular surfaces of hepatocytes, pancreas, and bile duct epithelium. The mammary gland is another source of GGT in cattle, sheep, and dogs, which can result in high serum levels in neonates of these species after nursing (Lassen, 2004). In renal disease, GGT is excreted in the urine (see nephrotoxicity). Serum GGT is generally of hepatic origin and is elevated by cholestasis. GGT has narrower reference intervals than ALP in horses and ruminants, which makes it more useful for detecting cholestatic disease in these species (Lassen, 2004; Stockham and Scott, 2002). Increased serum GGT activity proved to be a sensitive and long-lived indicator of liver insult in cattle exposed to moldy hay (Casteel *et al.*, 1995). Like alkaline phosphatase, GGT appears in serum as a result of increased synthesis, rather than as a result of leakage from cells (Pearson, 1990). In dogs, the increase of GGT tends to parallel that of ALP.

A high activity of sorbitol dehydrogenase (SDH) is found in hepatocellular cytoplasm of dogs, cats, horses, and ruminants (Lassen, 2004). The plasma half-life of this enzyme is very short, and serum activities may return to normal within 5 days of hepatocellular insult. Though this enzyme is more specific for hepatocellular damage than other enzymes in the horse and ruminant, the relatively low *in vitro* stability makes it less commonly used in the dog and cat compared to ALT.

Lactate dehydrogenase (LDH) is a tetrameric enzyme with five isoenzymes that catalyze the reversible conversion of L-lactate to pyruvate in all tissues. All LDH isoenzymes are found in varying concentrations in all tissues. LDH_1 is the principal isoenzyme in cardiac muscle and kidney of most species. It is also found in the liver of cattle and sheep. Unlike the other isoenzymes, it is heat stable at 65°C for 30 min. LDH_5 is the principal isoenzyme in skeletal muscle and erythrocytes. Serum LDH activity is tissue nonspecific; however, necroses of muscle, liver, and hemolysis are the major causes sources of elevations. Isoenzyme analysis would improve the specificity of LDH analysis for hepatocellular damage, but this is not commonly performed in most veterinary laboratories (Lassen, 2004; Stockham and Scott, 2002).

Bilirubin is derived from destruction of damaged or senescent erythrocytes by macrophages of the spleen, liver, and bone marrow. It is noteworthy that bilirubin at physiological levels is an antioxidant (Stocker *et al.*, 1987). Bilirubin is transported in plasma bound to proteins (albumin, globulin). Hepatic uptake and glucuronide conjugation render it water soluble. Conjugated bilirubin is secreted into bile canaliculi and transported to the intestine where the majority is transformed into urobilinogen by intestinal flora and excreted. Direct diazo assay for bilirubin detects conjugated bilirubin. Total bilirubin is measured after addition of alcohol, which allows additional color development. Unconjugated bilirubin is determined by the difference in direct and total bilirubin. Cholestasis results in conjugated hyperbilirubinemia. Bilirubinuria may occur as a result of "regurgitation" of conjugated bilirubin. Increased ALP or GGT can precede hyperbilirubinemia in most species. Hemolysis may result in unconjugated hyperbilirubinemia and elevations of LDH_5.

Sulfobromophthalein (BSP) injected intravenously is removed rapidly from the blood, conjugated by hepatocytes, and excreted in bile. The rate of hepatic blood flow, functional hepatic mass, and patency of the biliary system affect the hepatic clearance of this compound. Altered blood flow secondary to cardiotoxicity discussed later may increase BSP retention. The use of this test is limited as BSP is no longer commercially available, and similar information can be obtained by assessment of bile acids and total bilirubin (Stockham and Scott, 2002).

Bile acids are secreted from the liver into the bile and are subsequently reabsorbed in the intestine. The portal

blood flow delivers the bile acids to the liver where, in healthy animals, they are efficiently cleared by the hepatocytes. Increased serum bile acids in fasting animals are a result of decreased biliary excretion or decreased clearance by hepatocytes. Increased serum bile acids are highly sensitive for hepatobiliary dysfunction; however, there are many diseases that may cause hepatobiliary dysfunction (Stockham and Scott, 2002). Bile acids may be useful for detecting hepatic dysfunction in instances where enzyme levels or clinical signs are equivocal (Lassen, 2004). Acute toxic hepatic necrosis increases serum bile acids (cholic and chenodeoxycholic) in the dog, horse, sheep, and cow (Bain, 2003). Some studies have recommended tests for urine bile acids as a possible alternative to serum bile acids to detect hepatic dysfunction in the dog and cat (Balkman *et al.*, 2003; Trainor *et al.*, 2003).

Ammonia is generated by microbial activity and digestion of protein within the intestinal tract. It is absorbed from the intestine and transported to the liver by the portal venous system where it is converted to urea by the healthy liver. Elevations of plasma ammonia during fasting or following ammonia challenge suggest reduction in clearance from the blood, frequently resulting from a decrease in functional hepatic mass. Urea toxicosis in cattle and consumption of ammoniated forages by cattle can result in high plasma ammonia levels because of increased production and consumption of ammonia, respectively (Stockham and Scott, 2002).

Severe hepatic insufficiency may result in hypoproteinemia (Kaneko, 1997a) with reduction of plasma oncotic pressure that promotes tissue edema and effusions that mimic the effects of cardiotoxins (Table 27-3).

The clinical signs of acute submassive or massive hepatic necrosis may include anorexia, vomiting, icterus, hepatic encephalopathy, disseminated intravascular coagulopathy, edema, and effusions. Surprisingly, there may be few or no clinical signs in some cases. The activity of ALT and SDH with short half-lives may be elevated but often fall rapidly. Inducible enzymes such as ALP and GGT may increase gradually. All enzymes may return to normal in the presence of chronic severe liver disease. Hyperbilirubinemia may follow if lesions progress to chronicity and fibrosis.

Chronic hepatotoxicity has sequelae for most organ systems, but especially the nervous (hepatic encephalopathy), integumentary (secondary photosensitization in herbivores), and cardiovascular systems. Cardiotoxins and pneumotoxins may produce enzyme elevations suggestive of hepatic or renal disease as a result of ischemia/hypoxia.

Ingestion of toxic plants (Table 27-1) tends to be more common in herbivores than carnivores; however, nonherbivorous species are often susceptible if they are willing to ingest them. In addition to hepatotoxins, the blue-green algae (actually classified as cyanobacteria), which contaminate water (Carmichael, 1994), possess neurotoxins that may induce sudden death that precedes alterations of clinical biochemistry and morphological changes. However, one report documents marked elevations of ALT and AST in a dog 12 h post ingestion of a blue-green algae (DeVries *et al.*, 1993).

Therapeutic drugs can also occasionally have hepatotoxic effects in animals. Nonsteroidal anti-inflammatory drugs, barbiturates, antineoplastic agents, and antiparasitic compounds have all been found to have hepatotoxic effects (Kristal *et al.*, 2004; Macphail *et al.*, 1998; Roder, 2003). Carprofen, a nonsteroidal anti-inflammatory drug, has been reported to cause acute hepatocellular necrosis and cholestasis in some dogs. This adverse reaction is associated with marked increases in serum ALT, AST, ALP, and total bilirubin (Macphail *et al.*, 1998). The antineoplastic drug 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) is reported to occasionally cause hepatotoxicity in dogs with increases in ALT, AST, ALP, GGT, and bilirubin noted in the affected dogs (Kristal *et al.*, 2004).

Hepatotoxic plants of the order Compositae include *Asaemia axillaris, Athanasia trifurcata, Helichrysum blandowskianum, Lasiospermum bipinatum,* and *Xanthium* spp. The toxin in these plants has been identified as carboxyatractyloside. Profound hypoglycemia is reported as a finding in carboxyatractyloside poisoned animals (Barr and Reagor, 2001).

Cycadales contain methylazoxymethanol, which is converted by hepatic microsomal activity to potent alkylating agents. A report of dogs ingesting cycads indicates bilirubin, ALT, and ALP are most commonly elevated values on the chemistry panel (Albretsen *et al.*, 1998).

Hepatotoxic plants of the order Myoporaceae include *Myosporum deserti, M. acuminatum, M. insulare, M. tetramdum,* and *M. laetum*. These plants contain furanosesquiterpenoid oils, the best characterized of which is ngaione.

Chronic intoxication of swine with fumonisins, mycotoxins produced by *Fusarium moniliforme*, is associated with elevations of serum total bilirubin, ALP, AST, GGT, and cholesterol (Casteel *et al.*, 1994). In addition, fumonisins inhibit N-acetyl transferase resulting in loss of complex sphingolipids and accumulation of sphinganine and sphingosine in tissues and serum (Riley *et al.*, 1993).

Iron toxicity from nutritional supplements may produce hepatic necrosis in foals (Acland *et al.*, 1984) and pigs (Kelly, 1993). Excessive dietary copper may be associated with elevation of GGT in goats (Solaimen *et al.*, 2001) and llamas (Weaver *et al.*, 1999).

Hepatotoxic pyrrolizidine alkaloids are found in the plant species *Amsinckia intermedia*, *Crotolaria* spp., *Cynoglossum officinale*, *Echium plantagineum*, *Heliotropium europeaum*, *Senecio jacobea*, *S. vulgaris*, and *S. longilobus*. Acute intoxications with these plants result in large increases in AST, ALP, GGT, and SDH (Stegelmeier, 2003). Chronic exposure to small amounts of the plant is more difficult to detect, though serum GGT levels have been

suggested as a screening test for subclinical hepatic damage in horses exposed to *Crotolaria* spp. (Curran et al., 1996).

Hepatotoxic solanaceae include *Cestrum parqui, C. laevigatum,* and *C. aurantiacum*. The toxin in these plants has been identified as atractyloside.

Sawfly larvae (*Lophyrotoma interruptus* and *Arge pullata*) infesting eucalyptus and birch trees in Australia and Denmark, respectively, have been reported to induce hepatic necrosis in cattle, sheep, and goats browsing foliage.

Terminalia oblongata, the yellowwood tree of Australia, contains hepatotoxic tannins and pucicalagin, which induces acute hepatic necrosis (Kelly, 1993).

III. NEPHROTOXICITY

Acute nephrotoxicity (Table 27-2) may initially induce polyuria that is followed by oliguria or anuria. Nephrotoxins affecting approximately 66% of the nephrons will result in inability to concentrate urine to a specific gravity greater than 1.030 in the dog, 1.035 in the cat, and 1.025 in the horse and cow. Chronic toxicity may result in isosthenuria (constant urine osmolality in the range of glomerular filtrate, 1.008 to 1.012).

The majority of urea is synthesized in the liver from ammonia formed by protein catabolism or intestinal absorption. Urea enters the vascular system and is distributed throughout the total body water compartment by passive diffusion. The urea concentration of blood and glomerular filtrate is approximately equal. Urea passively diffuses from the tubular lumen back to the blood. Urine flow rate is inversely related to urea reabsorption. Gastrointestinal secretion is inconsequential in monogastrics; however, in ruminants up to 90% of urea in glomerular filtrate may be reabsorbed and enter the rumen via saliva for utilization in amino acid synthesis.

TABLE 27-2 Nephrotoxins

Nephrotoxin	Disease Onset	Geography	Species Affected
Amaranthus retroflexus (pigweed)	Subacute	US	B, P
Antibiotics	Acute to chronic	Worldwide	All
Cantharidin (blister beetle)	Acute	US	B, Cp, E, O
Chlorinated hydrocarbons	Acute	Worldwide	All
Ethylene glycol	Acute	Worldwide	B, Cn, F, P
Fumonisin (*Fusarium moniliforme*)	Acute to chronic	Worldwide	E, O, P
Gossypol (cottonseed)	Chronic	Worldwide	B
Hemoglobin	Acute		All
Hypercalcemia	Chronic	Worldwide	All
Isotropis spp.	Acute	AUS	B, O
Lantana camara	Chronic	US, MEX, AUS, AFR	B, E, O
Menadione	Acute	Worldwide	E
Metals (Cd, Hg, Pb, Tl)	Acute to chronic	Worldwide	All
Myoglobin	Acute		All
Ochratoxin (*Penicillium ochraceus*)	Chronic	Worldwide	P
Oxalates	Acute to chronic	Worldwide	B, Cp, O, P
Paraquat/diquat	Acute	Worldwide	All
Petroleum	Acute	Worldwide	All
Phenothiazine	Acute	Worldwide	E
Phenylbutazone	Acute	Worldwide	E
Phosphorus	Acute	Worldwide	All
Pyrrolizidine alkaloids	Chronic	Worldwide	B, Cp, E, O, P
Tannins (*Quercus* spp., oaks)	Acute	Worldwide	B, Cp, E, O
Terminalia oblongata (yellowwood)	Acute to chronic	AUS	B, O

Abbreviations: B, *bovine*; C*n*, *canine*; C*p*, *caprine*; E, *equine*; F, *feline*; O, *ovine*; P, *porcine*.

Azotemia, elevation in blood urea nitrogen (BUN) or creatinine, may occur as prerenal, renal, or postrenal. Prerenal azotemia may result from dehydration or decreased renal perfusion (e.g., cardiotoxins). Renal azotemia occurs only after approximately 75% of the nephrons have lost function.

Renal disease also results in elevation of serum creatinine. The majority of serum creatinine originates from the endogenous conversion of phosphocreatine in muscle, which occurs at a relatively constant rate. Creatinine is not reutilized. The creatine pool is modified by conditioning and muscle disease. Creatinine also is distributed throughout the compartment of total body water. It diffuses more slowly than urea, however, and is not reabsorbed within the tubules after leaving as glomerular filtrate. Creatinine concentration is not affected significantly by diet, protein catabolism, or urinary flow. Reduced renal perfusion affects BUN and creatinine similarly (Finco, 1997). Elevations of BUN and creatinine are not proportional in renal disease of ruminants because of reutilization of urea by the rumen. Ingestion of the plant *Nolletia gariepina* has been reported to cause renal failure in ruminants with a measurable increase in urinary GGT along with azotemia (Meintjes *et al.*, 2005).

Hyperkalemia may occur in renal failure with oliguria or anuria and acidosis. Hypercalcemia is common in equines as a result of decreased renal clearance of calcium. Hypocalcemia is more common in dogs, cats, and cattle with chronic renal disease. Cattle also tend to have hypokalemia, hyponatremia, and hypochloridemia with renal disease. Mild to moderate increases of amylase and lipase may also be seen in dogs with renal disease as these enzymes are inactivated in the kidney (Stockham and Scott, 2002).

Proteinuria in the absence of occult blood and cellular sediment suggests renal disease. Glomerular lesions typically result in high protein levels in which albumin is the major constituent. Acute tubular damage observed with many nephrotoxins generally results in lower protein levels containing higher levels of smaller globulins and some albumin (Stockham and Scott, 2002). Analysis of enzymes in the urine can potentially determine the primary site of renal damage because of the characteristic localization of enzymes within the nephron. Increases in the brush border enzymes, GGT and ALP, in the urine have been associated with renal proximal tubular damage in dogs, whereas increases in N-acetyl-beta-D-glucosaminidase have been observed in the early stage of renal papillary necrosis. However, evaluation of several enzymes at multiple time points is needed to compensate for normal enzyme variation and to identify potential anatomic site selectivity of the toxin (Clemo, 1998).

Hypoproteinemia secondary to chronic urinary loss (Kaneko, 1997a) promotes tissue edema and effusions that may mimic cardiotoxicity and hepatotoxicity, as discussed previously.

Bilirubin is considered to be mildly nephrotoxic. Bilirubinuria may occur because of "regurgitation" of conjugated bilirubin resulting from cholestatic hepatotoxins. Myoglobin is also nephrotoxic. Myoglobinuria may occur with toxic necrosis of skeletal and cardiac muscle. Hemoglobin appears to be nephrotoxic in the presence of concurrent dehydration or hypovolemia. Hemoglobinuria may occur with hemolytic toxins.

Dehydration exacerbates the nephrotoxicity of many agents, especially antibiotics in all species and nonsteroidal anti-inflammatory drugs (phenylbutazone) in the horse. Nephrotoxic antibiotics include the aminoglycosides (amikacin, gentamicin, kanamycin, neomycin, streptomycin, and tobramycin), amphotericin B, cephalosporins, polymixins, sulfonamides, and tetracyclines (Maxie, 1993). Elevation of GGT in urine is a sensitive indicator of aminoglycoside toxicity (Gossett *et al.*, 1987).

Hypercalcemia and hyperphosphatemia may result in nephrocalcinosis following iatrogenic hypervitaminosis D or ingestion of cholecalciferol rodenticide (Fooshee and Forrester, 1990) by any species. Ingestion of the toxic plants containing vitamin D-like analogues including *Cestrum diurnum, Dactylis glomerata*, some *Solanum* spp., and *Trisetum flavescens* by herbivores also may produce hypercalcemia with calcification of soft tissues including the kidney.

Nephrotoxic metals include arsenic, bismuth, cadmium, lead, mercury, and thallium (Maxie, 1993).

Plants containing toxic concentrations of soluble oxalates include the species *Amaranthus retroflexus* (pigweed), *Halogeton glomeratus, Oxalis* spp., *Rheum rhaponticum* (rhubarb), and *Sarcobatus vermiculatus* (greasewood). Intoxication with ethylene glycol from antifreeze is one of the more common accidental or malicious poisonings encountered in dogs and cats. Birefringent hippurate and oxalate crystals may be observed in urine sediments (Kramer *et al.*, 1984). An increased anion gap and decreased blood bicarbonate can be observed in animals with ethylene glycol intoxication (Dalefield, 2003). Blood calcium is lowered in animals intoxicated with oxalate containing plants that also have low calcium content. Blood calcium is also decreased in animals with ethylene glycol toxicosis (Stockham and Scott, 2002).

Nephrotoxic pyrrolizidine alkaloids include the plant species listed under hepatotoxicity.

Trees of the genus *Quercus* (oaks) and *Terminalia oblongata* (yellow-wood tree) contain tannins that induce acute tubular necrosis when leaves, buds, or acorns are ingested. *Amaranthus retroflexus* (pigweed), via an unidentified toxic principle, also induces similar renal disease in cattle (Casteel *et al.*, 1994) and pigs (Osweiler *et al.*, 1969) in the absence of oxalate nephrosis. At postmortem examination, there were consistent elevations of urea and creatinine concentrations in ocular fluid and serum.

IV. TOXINS AFFECTING SKELETAL AND CARDIAC MUSCLE

The clinical signs of weakness, dysmetria, and incoordination suggest not only the possibility of neurological disease but also skeletal muscular or cardiovascular disease. Acute toxicity of skeletal or cardiac muscle (Table 27-3) can be detected by elevations in serum creatine kinase (CK) (Cardinet, 1997). This dimeric enzyme catalyzes the reversible reaction, phosphocreatine + ADP <=> creatine + ATP, and has three isoenzyme types: CK_1, CK_2, and CK_3. CK_1 is found in brain, peripheral nerves, cerebrospinal fluid, and viscera, but it is not found in serum during neurological disease. CK_2 is found in cardiac muscle and minute amounts in skeletal muscle. CK_3 is found in cardiac and skeletal muscle. CK plasma half-life is short and is considered to be specific for muscle when hemolysis, elevated bilirubin, muscle fluid contamination during venipuncture, and dilution of CK inhibitors during sample processing can be excluded. When injury is not progressive, CK elevations maximize within 6 to 12 h and return to normal within 24 to 48 h. Continuing necrosis can result in persistent elevation.

Cardiac troponin T and I have been demonstrated to be sensitive and specific biomarkers of cardiac injury in dogs and laboratory animals (O'Brien, 2006; O'Brien *et al.*, 2006). Cardiac troponins have been demonstrated to correlated with myocardial injury in the dog, cat, and horse and may provide a more specific antemortem method of detecting myocardial compromise secondary to toxicosis in these species (Herndon, 2002; Oyama and Sisson, 2004; Schwarzald *et al.*, 2003).

As discussed previously, LDH_5 is the principal isoenzyme in skeletal muscle and erythrocytes. LDH activity is tissue nonspecific, but necroses of muscle, liver, and hemolysis are the major sources for elevations of serum activity. Necrosis of skeletal muscle may result in release of myoglobin and potassium resulting in myoglobinemia and hyperkalemia. Myoglobinuria, detectable by urinalysis, may induce secondary nephrotoxicity.

TABLE 27-3 Toxins Affecting Cardiac and Skeletal Muscle

Toxins	Disease Onset	Geography	Species Affected
Cardiac glycosides	Acute	Worldwide	All
Cassia occidentalis (Coffee senna)	Acute	Worldwide	B, Cp, O, P
Cantharidin (blister beetle)	Acute	US	E
Catecholamines	Acute		All
Eupatorium rugosum (white snakeroot)	Chronic	US	B, E
Fluoroacetate	Acute	AUS, S AFR	All
Gossypol (cottonseed)	Chronic	Worldwide	P, B, Cn
Hypercalcemia	Chronic	Worldwide	All
Iron	Acute	Worldwide	P
Karwinskia humboldtiana (coyotillo)	Acute to chronic	MEX, TX	Cp, O
Lantana camara	Chronic	AFR, AUS, MEX, US	B, E, O
Metals (As, Bi, Cd, Hg, Pb, Tl)	Acute to chronic	Worldwide	All
Methylxanthines (caffeine, theophyl-line, theobromine)	Acute	Worldwide	Cn
Monensin	Acute to chronic	Worldwide	B, E, Cp, O, P
Nephrotoxins (uremia, see text)	Chronic		All
Persea americana (avocado)	Acute	Worldwide	B, Cp, E, O
Phalaris	Acute	Worldwide	B, E, O
Phosphorus	Acute	Worldwide	All
Potassium	Acute to chronic	Worldwide	All
Pteridium aquilinum (Bracken fern)	Acute to chronic	Worldwide	B, Cp, E, O, P
Quinolizidine alkaloids (*Lupinus* spp.)	Chronic	Worldwide	B, O
Vicia villosa (hairy vetch)	Chronic	Worldwide	B, E

Abbreviations: B, *bovine*; Cn; *canine*; Cp, *caprine*; E, *equine*; F, *feline*; O, *ovine*; P, *porcine*.

Cardiac glycosides disrupt cardiac ion channels producing sudden dysrhythmias and often death (Cheville, 1988). Plants containing cardiac glycosides include *Bryophyllum tubiflorum, Digitalis* spp. (foxglove), *Homeria* spp. (cape tulip), *Nerium oleander* (oleander), *Thevetia peruviana* (yellow oleander), and *Tylecodon* spp. (Robinson and Maxie, 1993). Most intoxications occur in herbivores, although the cat is reported to have increased CK levels after ingestion of Easter lily plant. (Rumbeiha *et al.*, 2005). Amphibians producing cardiac glycosides include *Bufo alvarius, B. marinus,* and *Dendrobates* spp. (poison dart frog). Most intoxications occur in cats and dogs that become curious about these animals. Neurological signs may be the presenting complaint in intoxication from *B. marinus* (Roberts *et al.*, 2000).

Fluoroacetate containing plants include *Acacia georginae, Dichapetalum cymosum, Gastrolobium* spp., and *Oxylobium* spp. Fluoroacetate (compound 1080) also has been utilized as a rodenticide. It is not directly toxic, but combines with oxaloacetic acid to form fluorocitrate that inhibits *cis*-aconitase and succinic dehydrogenase of the citric acid cycle thus reducing ATP generation. Animals intoxicated with fluoracetate are reported to have hyperglycemia and hypocalcemia, along with increased serum citrate levels (Parton, 2003).

Glycosides and fluoroacetate may produce sudden death that precedes alterations of clinical chemistry or morphological changes. Hypercalcemia may induce cardiac calcinosis and nephrotoxicity as discussed earlier.

Hyperkalemia from myotoxicity (especially gossypol) (Albrecht *et al.*, 1969), nephrotoxicity, or adrenal necrosis (hypoaldosteronism) may exert a dysrhythmogenic (Q-T prolongation and high amplitude T waves) effect on the heart. Potassium chloride injection also has been used for lethal poisoning by individuals attempting to circumvent detection by insurance adjusters (Casteel *et al.*, 1989).

Cardiotoxic metals include lithium, cadmium, nickel, barium, lanthanum, manganese, vanadium, lead, and cobalt (Van Vleet and Ferrans, 1986). Iron-dextran toxicity in pigs may produce necrosis of skeletal muscle and hyperkalemia, sparing the myocardium (Kelly, 1993).

Quinolizidine alkaloids in *Lupinus* spp., *Laburnum anagyroides,* and *Thermopsis montana* have been shown to produce skeletal muscle necrosis in cattle with elevations of serum CK and AST in the absence of myoglobinuria (Keeler and Baker, 1990). Quinolizidine alkaloids are also teratogenic.

Elevations in serum creatine kinase have been reported in association with viper envenomation in dogs (Aroch *et al.*, 2004).

The numerous chemotherapeutic agents that have been associated with cardiotoxicity have been reviewed elsewhere (Van Vleet and Ferrans, 1986).

Cardiotoxins may produce serum enzyme elevations suggestive of hepatic or renal disease secondary to ischemia/hypoxia.

V. TOXINS AFFECTING THE LUNG AND RESPIRATORY TRACT

Disease affecting the respiratory tract is often clinically apparent on the basis of dyspnea. Dyspnea in veterinary medicine is more often the result of pneumonia rather than intoxication. However, when body temperature is normal, the possibility of pulmonary edema induced by toxins affecting the lung and respiratory tract (Table 27-4) or cardiovascular system should be considered. Because, with the exception of the horse, domestic mammals remove excess heat by panting, reduced respiratory capacity secondary to intoxication also may result in elevated body temperature.

TABLE 27-4 Toxins Affecting the Lung and Respiratory Tract

Toxins	Disease Onset	Geography	Species Affected
Eupatorium adenophorum	Chronic	AUS	E
Fumonisin (*Fusarium moniliforme*)	Acute to chronic	Worldwide	P
4-ipomeanol (*Fusarium solanii*)	Acute	Worldwide	B
Kerosene/Petroleum	Acute	Worldwide	All
3-methylindole	Acute	Worldwide	B
Myoporaceae	Acute	AUS, NZ	B, O
Organobromines/organochlorines	Chronic	Worldwide	All
O_2	Acute to chronic	Worldwide	All
Paraquat	Acute to chronic	Worldwide	All
Perilla frutescens	Acute	US	B, E, O
Pyrrolizidine alkaloids	Chronic	Worldwide	B, Cp, E, O, P

Abbreviations: B, *bovine*; Cn, *canine*; Cp, *caprine*; E, *equine*; F, *feline*; O, *ovine*; P, *porcine*.

Angiotensin converting enzyme (ACE) is concentrated on the luminal surface of pulmonary endothelial cells. Most circulating ACE originates from the lung; however, many tissues including tubular epithelial and endocrine cells contain this enzyme (Erdos, 1987). Serum ACE activity is altered in chronic and acute pulmonary disease (Hollinger, 1983). Unfortunately, assay for this enzyme is not readily available in most veterinary clinical biochemistry laboratories, and ACE remains primarily a research tool.

Acute pulmonary edema is the typical lesion resulting from toxins affecting the epithelial-endothelial interface of the alveolus. Because CO_2 is approximately 20 times more diffusible than O_2, early pulmonary edema typically results in decreased P_aO_2, whereas P_aCO_2 remains normal or may decrease with hyperventilation producing respiratory alkalosis. Severe pulmonary edema may result in elevated P_aCO_2 (hypercapnia and respiratory acidosis) (Carlson, 1997).

Chronic insult to the alveolar epithelial-endothelial interface may progress to pulmonary fibrosis (e.g., paraquat intoxication) and be associated with low PaO_2 and elevated $PaCO_2$. Pulmonary fibrosis impinging on the pulmonary vasculature may induce pulmonary hypertension and *cor pulmonale* associated with enzymological alterations suggestive of hepatoxicity resulting from passive hepatic congestion.

Cattle are susceptible to several toxins that induce acute pulmonary edema including ingestion of perilla ketone in *Perilla frutescens*, 4-ipomeanol in sweet potatoes (*Ipomoea batatas*) infected with *Fusarium solani* (Doster *et al.*, 1978), and the generation of 3-methyindole by ruminal *Lactobacillus skatoli* from tryptophan in lush pasture grasses (Breeze and Carlson, 1982).

Some of the pyrrolizidine alkaloids, notably monocrotaline from *Crotolaria spectabilis*, may induce chronic pulmonary arteriopathy resulting in pulmonary hypertension that progresses to right heart failure and elevation of enzymes suggestive of cardiotoxicity or hepatotoxicity. Similar pulmonary arteriopathy occurs in pigs with chronic fumonisin intoxication (Casteel *et al.*, 1994).

Organochlorines and organobromines include chlorinated naphthalenes, polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and dibenzofurans. These industrial toxins are cumulative and result in hypovitaminosis A that is associated with squamous metaplasia of columnar epithelium of the respiratory tract and hyperkeratosis as discussed under integumentary toxins.

The numerous chemotherapeutic agents that have been associated with pulmonary toxicity or hypersensitivity have been reviewed elsewhere (Myers, 1993).

VI. TOXINS AFFECTING THE GASTROINTESTINAL TRACT

Disease affecting the gastrointestinal tract is often clinically apparent on the basis of vomiting or diarrhea. In veterinary medicine, these are more often the result of infectious disease rather than intoxication. However, the possibility of gastrointestinal toxins (Table 27-5) should be considered, especially in acute outbreaks affecting several animals sharing the same environment.

Vomiting and diarrhea may produce dehydration that results in mild to moderate elevations of BUN, plasma protein, packed cell volume (PCV), and urine specific gravity.

Metabolic alkalosis (increased pH, normal or increased PCO_2, increased HCO_3^- and HCO_3^-/H_2CO_3) and hypochloridemia may result from chloride loss associated with vomiting (Tennant and Hornbuckle, 1997).

Metabolic acidosis (decreased pH, normal or decreased PCO_2, decreased HCO_3^- and HCO_3^-/H_2CO_3) may result from secretory loss of bicarbonate in diarrhea.

In the absence of evidence of malnutrition or hepatic or renal disease, chronic gastrointestinal malabsorption or protein loss should be considered as a potential cause of hypoproteinemia (Kaneko, 1997a).

Ingestion of strong acids or alkalis may induce immediate and severe damage to the gastrointestinal mucosa.

The seleniferous plants, which may be associated with acute gastroenteritis in herbivores, are discussed under the integumentary system.

Trichothecenes, especially T-2, produced by *Fusarium* spp. and the macrocyclic trichothecene produced by *Stachybotrys alternans* are highly irritant and produce acute ulceration and hemorrhage of the gastrointestinal tract. These mycotoxins also produce acute ulcerative and necrotizing lesions of the skin and chronic pancytopenia with hemorrhage.

The estrogenic mycotoxin, zearalenone, may induce rectal prolapse in pigs in addition to affecting reproductive performance.

VII. TOXINS AFFECTING ERYTHROCYTES AND THE HEMATOPOIETIC SYSTEM

Toxins inducing hemolysis (Table 27-6) may produce elevations of serum LDH, anemia, icterus, hemoglobinemia, hemoglobinuria with secondary nephrotoxicity, and unconjugated bilirubinemia.

Chronic, drug-induced, immune-mediated hemolysis has been associated with para-aminosalicylic acid, chlorpromazine, dipyrine, insecticides, penicillin, phenacetin, quinine, quinidine, and sulfonamides (Valli, 1993).

Mellitin is a hemolyzing component of Hymenopterous toxins and comprises approximately 50% of bee venom (Cheville, 1988). One report also attributes a case of immune-mediated hemolytic anemia in a young dog to exposure to bee venom (Noble and Armstrong, 1999).

Chronic nephrotoxicosis leading to uremia may decrease erythrocyte life span because products normally eliminated by the kidney are retained. This mechanism

TABLE 27-5 Toxins Affecting the Gastrointestinal Tract

is usually insufficient to produce acute hemolytic crises, and other factors, including decreased erythropoietin production, likely play a larger role in the anemia seen with chronic renal disease (Stockham and Scott, 2002). The anthelmintic, phenothiazine, may be acutely hemolytic in sheep and horses. It also may induce primary photosensitization as discussed under integumentary toxins. Zinc intoxication in dogs can produce a severe intravascular hemolysis (Dziwenka and Coppock, 2003).

The venom of various, snakes including Crotalidae, Elapidae, Hydrophidae, and Viperidae, contains a mixture of toxins of which phospholipase A_2 (PLA_2) is an important component. PLA_2 is directly lytic for erythrocytes and may induce hemolysis, and for platelets and it may induce hemorrhage and coagulopathy (Cheville, 1988).

Basophilic stippling and inappropriate rubricytosis have been associated with lead intoxication in dogs (Stockham and Scott, 2002).

Additional toxins inducing hemorrhage (Table 27-7) include dicumarol derived from moldy sweet clover (*Melilotus* spp.) and the synthetic derivatives used as anticoagulant rodenticides such as brodifacoum, bromadiolone, diphacinone, fumarin, pindone, and warfarin. These agents are vitamin K antagonists. Prothrombin (factor II), and factors VII, IX, and X require vitamin K for their production. The half-life of factor VII is approximately 4 to 6 h, whereas, half-lives of factors IX and X are approximately 14 to 18 h, and for prothrombin the half-life is 40 h. Therefore, prolongation of the one-stage prothrombin time (PT) is thought to occur earliest, followed by prolongation of the activated partial thromboplastin test (PTT). Vitamin K antagonists do not affect fibrinogen or platelet numbers initially but may eventually exhaust their supplies. Excessive hemorrhage following slight trauma, epistaxis, melena, and hematuria may occur with these intoxications (Dodds, 1997). Testing for products of vitamin K antagonism or absence (PIVKAs) may help to detect this intoxication. This test is a modified PT assay, which detects decreased activity of factors II, VII, and X. Though anticoagulant rodenticide intoxication decreases the activity of these factors, other diseases may also prolong this test; thus this test is not specific for rodenticide intoxication (Stockham and Scott, 2002).

Chronic hepatotoxicity in which hepatic mass is reduced by 70% or more may result in sufficiently inadequate synthesis of both clotting factors and their inhibitors to prolong PT and PTT. Chronic cholestasis with interruption of the enterohepatic circulation of bile salts also may result in malabsorption of fat-soluble vitamin K producing a syndrome similar to anticoagulant intoxication.

Toxins inducing pancytopenia include estrogen, *Pteridium aquilinum* (bracken fern), and the trichothecene mycotoxins. Insufficient numbers of platelets promote hemorrhage and consumption coagulopathy (Valli, 1993).

VIII. TOXINS AFFECTING HEMOGLOBIN AND OXIDATIVE METABOLISM

Lead poisoning interrupts heme synthesis at the level of formation of protoporphyrin and causes accumulation of delta-aminolevulinic acid. Increased urinary excretion of this metabolite indicates lead intoxication.

Toxins inducing oxidation of ferrous iron in hemoglobin to ferric iron in methemoglobin (Harvey, 1989) include the herbicide sodium chlorate, the stalk parts of nitrate-accumulating plants such as corn and wheat, hay grown on heavily fertilized soils under drought conditions, fertilizer, or water contaminated by fertilizers or organic material. Wilted red maple leaves have also been reported to cause methemoglobinemia, in addition to hemolysis, in horses (Barr and Reagor, 2001). Ruminants are most susceptible to the nitrate-accumulating plants *Amaranthus* spp. (pigweed), *Avena sativa* (oats), *Chenopodium* spp. (lambsquarter), *Sorghum* spp., and *Triticum aestivum* (wheat) because of the ability of rumen microbes to reduce nitrate to the proximate

toxicant, nitrite. Monogastrics and ruminants are equally susceptible to nitrite-based fertilizers (Osweiler *et al.*, 1985). Nitrate/nitrite intoxication produces a brown discoloration of the blood caused by methemoglobinemia.

Carbon monoxide (CO) competes with oxygen binding to the heme moiety in hemoglobin and myoglobin. CO affinity for the hemoglobin binding site is approximately 200 times that of O_2, resulting in tightly bound carboxyhemoglobin and decreased blood oxygen transport. Because continuous delivery of O_2 is critical to the heart and brain, carbon monoxide may induce signs of cardiotoxicity or neurotoxicity. Anoxia of the liver, kidney, and muscle may elevate serum enzymes referable to these systems.

Acetaminophen, propylene glycol, and zinc intoxication in small animals and copper intoxication in ruminants have been associated with Heinz body anemia (Thrall, 2004).

CO, cyanide, and H_2S are potent inhibitors of cytochrome oxidase and may produce sudden death because of a failure of oxidative metabolism, which precedes alterations in clinical biochemistry or morphology.

Numerous plants contain cyanogenic glycosides that may affect herbivores, especially ruminants. The most common cultivated species include *Cynodon* spp., *Sorghum* spp., and *Prunus* spp. (Jubb and Huxtable, 1993).

IX. TOXINS AFFECTING THE ENDOCRINE SYSTEM

Carbadox/Mecadox is an antibacterial agent that, with prolonged exposure at levels greater than 25 ppm, induces degeneration of the zona glomerulosa of the adrenal gland associated with reduced plasma aldosterone, hyperkalemia, and hyponatremia (Capen, 1993).

The drug ortho,-para′2,2-bis(2-chlorophenyl-4-chlorophenyl)- 1,1-dichloroethane (o,p'DDD) is toxic to the zonae fasciculata and reticularis of the adrenal gland and is used as therapy for canine hyperadrenocorticism. This toxin reduces circulating cortisol levels.

Goitrogenic substances induce iodine deficiency or inhibit organification of iodine (Kaneko, 1997b). Thiocyanates, produced by ruminal digestion of cyanogenic glycosides from the toxic plants *Cynodon* spp. and *Trifolium repens*, and goitrin, derived from *Brassica* spp., are goitrogenic. Mimosine (discussed later under integumentary toxins) is metabolized in the rumen to a compound that inhibits organic binding of iodine by the thyroid gland. Thioamides (sulfonamides) inhibit thyroperoxidase. All of these substances may reduce serum T_4 and T_3. Iodine toxicity producing hyperplastic goiter in horses has been associated with feeding kelp.

Hepatic glucuronidation is the rate-limiting step for biliary excretion of T_4. Sulfation by phenol sulfotransferase is the rate-limiting step for excretion of T_3. Induction of hepatic microsomal enzymes may increase T_4/T_3 elimination and disrupt the hypothalamic-pituitary-thyroid axis resulting in excessive thyroid stimulating hormone (TSH). Xenobiotics that induce hepatic microsomal enzymes include benzodiazepines, calcium channel blockers, chlorinated hydrocarbons, phenobarbital, PCBs, PBBs, retinoids, and steroids (Capen, 1993).

Toxins inducing hypercalcemia are discussed in Section II. Certain species of the Solanaceous produce toxins that may induce chronic atrophy of parathyroid chief cells. Chronic nephrotoxicity, especially in the dog, may result in hypocalcemia and hyperphosphatemia, which stimulates excessive production of parathyroid hormone. Impaired intestinal absorption of calcium and increased mobilization from the skeleton also may occur secondary to insufficient renal production of 1,25-dihydroxycholecalciferol by the kidney (Capen, 1993).

Vicia villosa (hairy vetch) produces angiocentric eosinophilic granulomatous inflammation of the skin, myocardium, kidney, lymph nodes, thyroid, and adrenal glands. The mechanism is unknown. Biochemical alterations suggest cardiotoxicity, nephrotoxicity, and depression of serum thyroxine and cortisol levels may occur.

Ingestion of Xylitol, a sugar substitute used in cooking and in sugar-free chewing gum, can cause a severe hypoglycemia in dogs by inducing an exaggerated elevation of plasma insulin levels (Dunayer, 2004).

X. TOXINS AFFECTING THE NERVOUS SYSTEM

Many acute and chronic neurotoxins (Table 27-8) produce illness or death without alterations detectable by routine clinical biochemistry performed on blood or serum. The cerebrospinal fluid (CSF) is usually normal in neurotoxicity; however, mild elevations in protein and leukocyte count may occur with lead poisoning (Bailey and Vernau, 1997). Also, CSF sodium levels may be compared to serum sodium levels to assist in the diagnosis of sodium toxicosis. Sodium levels in serum may decline if the animal acquires access to water or is administered IV fluids, but the CSF sodium levels may remain elevated (Niles, 2003). Elevation of myelin basic protein has been reported in CSF in experimental fumonisin-induced leukoencephalomalacia in ponies (Brownie and Cullen, 1987).

Accumulations of endogenous toxins secondary to hepatotoxicity and nephrotoxicity may produce neurological dysfunction. Conversely, alterations that mimic hepatotoxicity, nephrotoxicity, muscle toxicity, respiratory, and gastrointestinal toxicity may occur secondary to ischemia/anoxia from depression of cardiopulmonary centers or by affecting sympathetic/parasympathetic balance.

Increased urinary excretion of delta-aminolevulinic acid is a potential indicator of lead intoxication. Organophosphates induce cholinesterase inhibition, which can be

TABLE 27-8 Toxins Affecting the Nervous System

Toxins	Disease Onset	Geography	Species Affected

detected as reduction of plasma or whole blood cholinesterase activity.

Subacute selenium intoxication in pigs exposed to complete rations containing 9.7 to 27 ppm selenium for 45 days is manifested as a central nervous system disorder characterized initially by hind limb ataxia progressing to posterior paralysis. The clinical syndrome is associated with focal symmetrical poliomyelomalacia of the ventral horns of the cervical and lumbosacral intumescences (Casteel *et al.*, 1985). Hoof separation at the coronary band also occurs. The clinical pathological alterations were consistent with dehydration from inability to reach water sources. Iatrogenic disease in the dog may result from parenteral administration of selenium preparations (Turk, 1980).

Solanum kwebense, *S. dimidiatum*, and *S. fastigiatum* produce neuronal vacuolation resembling a lysosomal storage disease. The biochemical basis of this lesion is unknown.

Swainsonine is an indolizidine alkaloid produced by certain species of the plants genera *Astragalus, Oxytropis,* and *Swainsona*. This toxin inhibits lysosomal alpha-mannosidase resulting in a lysosomal storage alteration that affects cells in many organs but is often lethal because of its neurological effect.

Thiaminases that may induce polioencephalomalacia in herbivores are present in *Equisetum arvense* and *Pteridium aquilinum*. Many uncooked fish species also contain thiaminase, which may produce encephalopathy affecting

primarily carnivores. The coccidiostat, amprolium, is a thiamine antagonist that produces polioencephalomalacia in ruminants. Calves early in the course of polioencephalomalacia may have reduced blood transketolase (which requires thiamine pyrophosphate as a cofactor) and increased pyruvate (Jubb and Huxtable, 1993).

XI. TOXINS AFFECTING THE INTEGUMENT

Most toxins affecting the skin (Table 27-9) will induce no or nonspecific alterations in clinical biochemistry. Fortunately lesions are usually readily visible by physical examination. Topical exposure to strong acids or alkalis may induce immediate and severe damage of the stratum corneum and epidermis.

Ergot and ergot-like syndromes are produced by the fungi *Claviceps purpurea* in infected rye and other cereal grains, and *Acremonium coenophilaum* in fescue and other pasture grasses. These fungi produce vasoconstrictive alkaloids, which are derivatives of lysergic acid including ergotamine, ergometrine, ergotoxine (*C. purpurea*), and ergovaline (*A. coenophilaum*). Skin lesions are the result of ischemic necrosis that is usually most impressive in the distal extremities.

Dermatotoxic heavy metals include thallium and arsenic (Yager and Scott, 1993). Thallium is still used as a rodenticide in some countries, but it is mainly of historical interest in many developed countries in which it has been banned. Thallium induces parakeratosis and alopecia. The mechanism is unknown, but it is speculated to center around alteration of sulfhydryl groups in keratin resulting in parakeratosis and alopecia. Arsenic toxicity exerts similar influences.

Mimosine is a toxic amino acid occurring in *Mimosa pudica* and *Leucaena leucocephala*. This toxin produces alopecia by mechanisms that are incompletely understood but may involve metal chelation that inhibits metalloenzymes.

Organochlorines and organobromines include chlorinated naphthalenes, polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and dibenzofurans. These industrial toxins are cumulative and result in alopecia, hyperkeratosis, and squamous metaplasia of columnar epithelium of the respiratory tract. Molybdenum toxicosis results in a relative copper deficiency in cattle and sheep that produces depigmentation as a consequence of the decreased activity of tyrosinase.

Toxic photosensitization, enhanced susceptibility of the skin to actinic radiation, occurs primarily in lightly pigmented skin of herbivores and may be primary or secondary to chronic hepatotoxicity (Yager and Scott, 1993). Primary disease is due to exogenous photodynamic agents that include treatment with the anthelmintic phenothiazine and grazing of toxic plants such as *Ammi majus* (Bishop's weed, furocoumarin), *Cymopterus watsoni* (spring parsley, furocoumarin) *Fagopyrum* spp. (buckwheat, fagopyrin), *Hypericum perforatum* (St. John's wort, hypericin), and *Thamnosma texana* (Dutchmen's britches, furocoumarin).

Secondary, or hepatogenous, photosensitization occurs in herbivores with diffuse liver damage that reduces the ability to excrete phylloerythrin. This photodynamic agent is formed from chlorophyll by gastrointestinal flora and is transported by the portal system to the liver where it is normally conjugated and excreted in the bile. When phylloerythrin escapes into the systemic circulation, it is poorly excreted by the kidneys and accumulates in tissues including the skin.

TABLE 27-9 Toxins Affecting the Integumentary System

Toxins	Disease Onset	Geography	Species Affected
Acids/alkalis	Acute	Worldwide	All
Ergotism	Acute to Chronic	Worldwide	All

Abbreviations: B, *bovine*; Cn, *canine*; Cp, *caprine*; E, *equine*; F, *feline*; O, *ovine*; P, *porcine*.

Plants classified as seleniferous actively concentrate Se. Seleniferous plants can be subclassified as obligate (requiring Se) and facultative (Se not required). *Astragalus* spp. (locoweed), *Machaeranthera* spp., *Oonopsis* spp. (goldenweed), *Stanleya* spp., and *Xylorrhiza* spp. (wood aster) are obligate accumulators of selenium. These species are generally nonpalatable and are consumed only by herbivores with little other available forage. Several plants are facultative accumulators of selenium including the genera *Asters, Atriplex, Catilleja, Gutierrezia,* and *Sideranthus,* which are more often associated with forage-associated selenium intoxication. In addition, various grasses and crops may accumulate from 1 to 25 ppm selenium when grown on seleniferous soils. The differences in selenium accumulation by these three groups are rather indistinct. Grasses are by far the most important group from the standpoint of sheer numbers of livestock affected.

Grazing of seleniferous plants may result in acute gastroenteritis, but it also induces what has historically been called "alkali disease" that manifests as alopecia and dystrophic growth of the hooves primarily in horses, cattle, and goats. There are conflicting reports regarding the hepatotoxicity, nephrotoxicity, and cardiotoxicity of selenium.

Vicia villosa (hairy vetch) produces angiocentric eosinophilic granulomatous inflammation of the skin, myocardium, kidney, lymph nodes, thyroid, and adrenal glands. The mechanism is unknown. The skin lesions are pruritic.

Chapter 28

Avian Clinical Biochemistry

J. T. Lumeij
Department of Clinical Sciences of Companion Animals
Faculty of Veterinary Medicine
Utrecht, University
Utrecht, The Netherlands

I. INTRODUCTION

Avian medicine and surgery have been recognized as an official specialty in veterinary medicine on three continents (Europe, Australia, and North America). The increasing demand for veterinary care for individual birds with a high sentimental or economical value and efforts to conserve endangered species facilitated this awareness. The commercial poultry flock approach to diagnosis, utilizing necropsy as

a primary diagnostic tool combined with comparatively fewer testing procedures on living birds, which had been practiced for decades, had only limited applicability for individual pet birds. As a result, alternative diagnostic and therapeutic techniques were developed. Clinical signs in birds are often nonspecific, and the information gained by physical examination is limited in regard to specific and detailed diagnosis. Earlier demands for large blood sample volumes and limited veterinary involvement in the diagnosis and management of individual and pet bird disease were major obstacles to the development of clinical biochemistry in avian medicine. The introduction of micromethods in clinical laboratories and the public demand for veterinary care for individual birds have removed these obstacles. The scientific and clinical work in avian clinical biochemistry since the 1980s has led to its widespread application in avian medicine.

Reference values are dependent on the methodology used. Factors such as type of coagulant, amount of blood, and analytical method may all influence the results. Therefore, values from clinical cases should be compared with reference values from the same species established with the same method in the same laboratory. Published reference values for many blood chemical variables can only be used as a rough guideline.

All efforts should be made to obtain a blood sample before any treatment is given. Treatments that have been administered before samples have been collected may severely affect plasma chemical values (see Fig. 28-16), which will jeopardize a correct diagnosis at a later stage. The time interval between restraint and blood sampling should be kept to a minimum to prevent stress-associated changes in clinical chemistry parameters (see Section VII). Paradoxically, blood samples should be obtained before an extensive clinical examination has been performed to avoid iatrogenic changes in the samples. In one study with pigeons, the percentage of heterophils more than doubled whereas the percentage of lymphocytes decreased after extensive handling for 3h. Creatine kinase and glucose both increased, whereas uric acid decreased (Scope *et al.*, 2002b). Although the changes associated with a short clinical examination might be negligible, the clinician should keep these iatrogenic effects in mind when performing more extensive procedures.

II. COLLECTION OF BLOOD SAMPLES

A. Size of Blood Samples

An important consideration when taking blood samples from small birds is response to blood loss. Kovách *et al.* (1969) studied the mortality of various avian and mammalian species following blood loss and showed that birds can better tolerate severe blood loss than mammals (Fig. 28-1). This is because of their greater capacity for extravascular fluid mobilization (Djojosugito *et al.*, 1968; Wyse and Nickerson, 1971). Kovách *et al.* (1969) found that in healthy individuals, the amount of blood that can be removed without deleterious effects is 3% of body weight in ducks and pigeons, 2% in chickens, and 1% in crows and pheasants (Fig. 28-1). Unless birds are severely debilitated, a maximum of 1% seems a safe limit for the amount of blood that can be collected for diagnostic purposes.

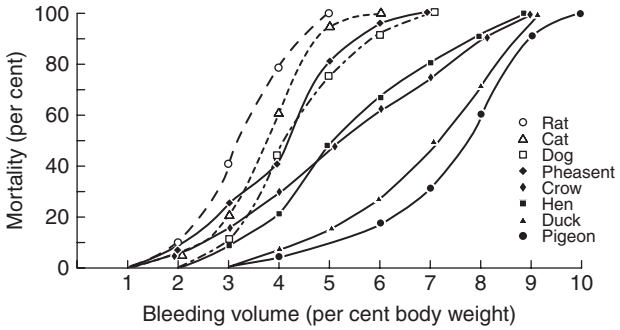

FIGURE 28-1 Mortality after identical blood losses in various avian and mammalian species (abscissa). Every hour, 1% of body weight blood was withdrawn from every animal (ordinate). The percentage of animals lost during the hour following bleeding has been recorded and plotted (see Kovách *et al.*, 1969). Reprinted with permission from Lumeij (1987a).

B. Handling of Blood Samples

Nearly all routine hematological and biochemical investigations can be performed when lithium heparin is used. The use of one single sample limits unnecessary blood spillage, which is an important consideration when dealing with small birds. When plasma is used instead of serum, more plasma can be harvested than serum from the collecting tube. Another reason for not using serum in avian samples is the risk of clotting of the supernatant when serum and cells are separated within a couple of hours after collection.

In mammals, EDTA is regarded as the best anticoagulant for preservation of cellular morphology and good staining characteristics (Schmidt *et al.*, 1963), but this is not necessarily true in hematology of all avian species. There are various avian species where EDTA causes disruption of the red blood cells. Hawkey *et al.* (1983) found that EDTA produced progressive hemolysis in blood samples from crowned cranes. Dein (1986a, 1986b) reported a similar reaction in crows, jays, brush turkey, and hornbills. Similar reactions to EDTA are observed in blood from crows and magpies (Lumeij, unpublished). Fourie (1977) found heparin to be the most suitable anticoagulant for hematology in pigeons. Good quality smears can also be obtained from whole blood without anticoagulants. Whatever method is used, blood smears should be made immediately after collection of the sample to prevent changes in blood cell morphology.

The normal time lag of up to 60min between collection of a blood sample and separation of plasma from cells, which is common in human medicine (Laessig *et al.*, 1976), is not acceptable in avian clinical biochemistry. Immediately after collection, plasma and cells should be separated by centrifuging. In pigeon blood at room temperature, a rapid

decline (10% in 10 min, 30% in 30 min, up to 65% in 2 h) of plasma potassium concentrations occurs, because of a shift of potassium ions from the plasma into the red blood cells. In chickens, decreases were smaller overall with a 29% decrease being noted after 2 h (Lumeij, 1985a). In ostriches, significant increases in plasma potassium concentrations were observed when blood was stored at 20°C (up to 20% in 2 h), whereas at 0°C significant decreases were observed (Verstappen *et al.*, 2002). Many reports on blood chemistry in birds are based on determinations in serum instead of plasma or plasma from blood samples that were not centrifuged immediately. Plasma potassium concentrations reported herein are often too low.

In suspected lead poisoning, heparinized whole blood samples should be sent to the laboratory, because the majority of lead is associated with the red blood cells (see Section XI.A).

C. Sampling Procedure

In most species, the right jugular vein is the preferred site for blood sampling. This thick walled vein is less prone to hematoma formation (Law, 1960; McClure and Cedeno, 1955; Stevens and Ridgeway 1966). The medial metatarsal vein is especially useful for multiple sampling of small blood volumes in larger birds such as pigeons. Blood can be collected using a needle and syringe or a blood lancet. In the pigeon, the jugular vein is not readily visible.

The basilic vein, which is readily visible as it crosses the ventral aspect of the elbow of all avian species, is the vein that is traditionally used in poultry. The vein is punctured with a blood lancet after being swabbed with alcohol (Gratzl und Koehler 1968). These authors warn against the use of the comb for blood collection in poultry because the high risk of exsanguination, especially during cold weather. In pet birds, the use of a blood lancet for blood collection from the basilic vein cannot be recommended because this site is prone to hematoma formation, often even when a needle is used. The advantage of the basilic vein, on the other hand, is that it can be located in all avian species.

In ostriches the operator should be aware of the risk of being kicked. Blood can be collected from the basilic vein using a sideway approach to the standing animal after it has been hooded and the wing has been lifted upward by two assistants (Fowler, 1978c). The jugular vein can also be approached in the same manner.

In ducks and geese, the venous occipital sinus is a good site for blood sampling (Vuillaume, 1983). It is located at the junction of the base of the skull and the first cervical vertebra. Although this site is especially useful for obtaining large samples, many clinicians will feel more comfortable using the easily accessible basilic and metatarsal veins in these species.

Cardiac puncture carries the risk of cardiac tamponade, and therefore this technique is not recommended for use in avian clinical practice.

Some individuals choose to clip a toenail to obtain a blood sample. Disadvantages of this method are that it is painful to the bird, the sample may become contaminated with tissue fluids, it may cause damage to the nail bed, and the amount of blood that can be obtained is limited. Furthermore, contamination of the sample with urates from the droppings may give false high readings (Ekstrom and Degernes, 1989; Rosskopf *et al.*, 1982). For the aforementioned reasons, this method should only be regarded as a last resort, and the nail should be thoroughly cleaned before obtaining a sample.

Different bleeding sites (e.g., venous blood versus blood collected by cardiac puncture) may cause variation in hematological or biochemical values (Kern and De Graw, 1978).

A vacuum system greatly facilitates blood sampling from the jugular and basilic veins and from the venous occipital sinus in Anseriformes. A 3-ml vacuum tube is sufficient for most cases (Venoject, Omnilabo, Breda, The Netherlands). For smaller birds, and thus smaller sample sizes, it is best to use small volume (e.g., 0.5 ml) Vacutainers (Veterinary Lab Supply, 315 E. Madison, Winterset, Iowa 50273, United States).

III. STARVATION, FLIGHT, AND POSTPRANDIAL EFFECTS: CIRCADIAN AND CIRCANNUAL RHYTHMS

A. Introduction

Some plasma chemical variables are influenced by starvation or food consumption. Up to 4 days of starvation in pigeons did not result in hypoglycemia, but rather a starvation hyperglycemia occurred after 3 days (Lumeij, 1987b). Variables that may have markedly increased values postprandially are uric acid and total bile acid concentrations. See Sections V.F. and VI.G (Lumeij, 1991; Lumeij and Remple, 1991, 1992). Furthermore, daily or yearly fluctuations have also been reported for some chemical variables. In fasted pigeons maintained on a natural daily 17-h photoperiod a circadian rhythm was found in plasma glucose concentrations (Lumeij *et al.*, 1987b) with high values early during the photophase (Fig. 28-2). Basal plasma thyroxine concentrations in racing pigeons were significantly higher in July than in September and December (Lumeij and Westerhof, 1988a). Age, sex, altitude, nutritional status, and egg laying may also cause variation (Driver, 1981; Kocan, 1972; Kocan and Pits, 1976; McGrath, 1971; Mori and George, 1978; Simkiss, 1967). Effects of long-term starvation and endurance flight are discussed in Sections III.B. and III.C, respectively.

B. Biochemistry of Long-Term Starvation

Many avian species depend on catabolism of lipid depots for survival through the night or winter to enable migratory

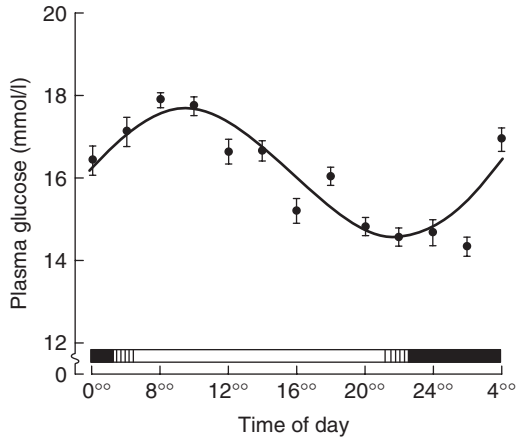

FIGURE 28-2 Mean (±SEM) plasma glucose concentration as a function of time in fasted racing pigeons. A cosine function y(t) is fitted to the data: $y(t) = 16.26 + 1.55 \cdot \cos(0.2618t \text{ to } 2.4646)$. The relevance of the fit as judged by means of the multiple correlation coefficient was significant ($R = 0.892$, $p < 0.01$). Reprinted with permission from Lumeij *et al.* (1987b).

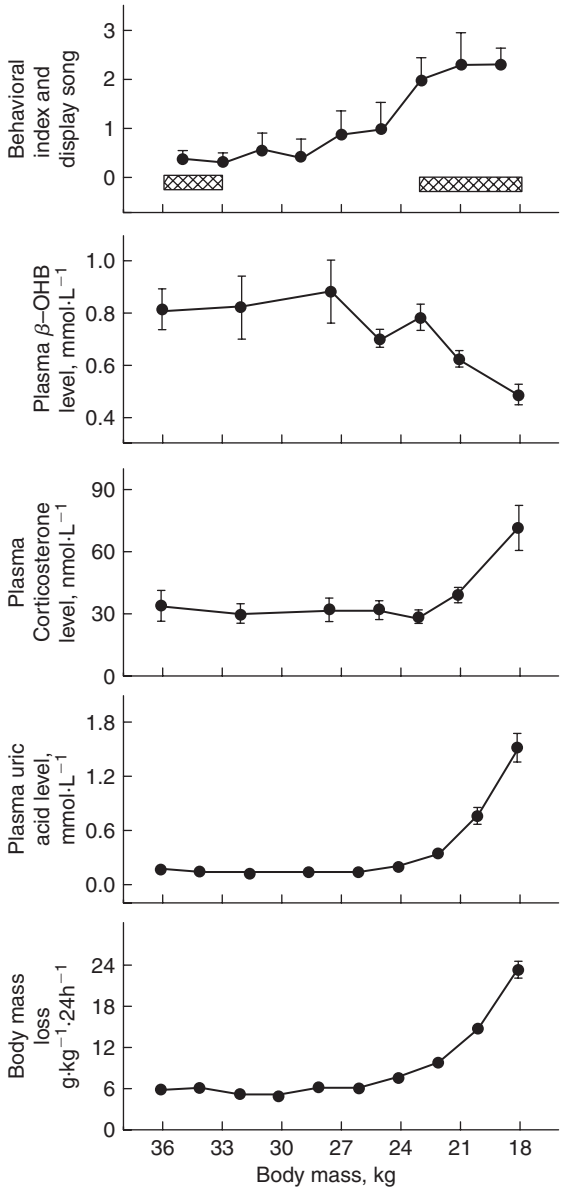

FIGURE 28-3 Changes in specific daily body mass, plasma uric acid, corticosterone, and β-hydroxybutyrate (β-OHB), and behavior versus body mass in spontaneously fasted emperor penguins (X ± SE; n = 6). Crosshatched bars represent periods of display songs. The behavioral index was calculated as number of days an animal was active during successive periods of fasting corresponding to a 2-kg loss in body mass. Reprinted with permission from Robin *et al.* (1998).

flights or to incubate eggs (Blem, 2000). During migratory flights, energy expenditure may be more than seven times the basic metabolic rate for 3 to 5 days (Battley, 2003). Lipid reserves in birds are stored as triglycerides, which have a high caloric density and do not require water. Storage of fat reserves may double the body mass in some cases.

Starved birds go through three phases. The total duration of the various phases depends on the size of the bird and the amount of lipid reserves and may vary from a few hours in hummingbirds to 5 months in emperor penguins (Robin *et al*., 1998).

In phase 1, food in the digestive tract and glycogen reserves are used; in phase 2, lipids are metabolized; and in phase 3, protein is used as a substrate for glucose synthesis. Phase 2 of starvation is characterized by an almost constant rate of body mass loss, a low respiratory quotient, and steady plasma concentrations of uric acid and β hydroxybutyrate. Although fatty acids provide the main energy source, about 5% of the energy is provided by protein breakdown, to generate citric acid intermediates, to act as substrate for gluconeogenesis, and for production of antioxidants (Battley, 2003). When critical depletion of fat stores is imminent, phase 3 of starvation is heralded by lowering of plasma concentrations of β-hydroxybutyrate and increased uric acid concentrations, reflecting a decreased contribution of lipids to energy metabolism and increased protein catabolism, respectively (Fig. 28-3). The refeeding drive is related to the attainment to a given energy status rather than to a given duration of fasting or body mass loss (Robin *et al*., 1998). The metabolic shift to an increased protein breakdown is regulated by an endocrine shift (elevated corticosterone concentration), after which a further adrenocortical response to an acute stressor is inhibited. The adrenocortical response typical for an emergency situation is only reached when muscle protein is dangerously low (Jenni *et al.*, 2000).

Mortality resulting from hepatic lipidosis has been described in a wide variety of avian species (James *et al*., 2000; Wadsworth *et al.*, 1984) including, among others, chickens (Butler, 1976), turkeys (Gazdinski *et al.*, 1994),

parrots (Baker, 1980; Murphey, 1992a), raptors (Cooper and Forbes, 1983; Forbes and Cooper, 1993), and bustards (Nichols *et al.*, 1997) and is known as fatty liver syndrome. Although the exact mechanism has not been elucidated, it seems that deficiencies of other nutrients, which are essential in lipid metabolism, like the amino acids methionine and cysteine and the vitamin biotin, may play a crucial role in the pathophysiology of this syndrome (Butler, 1976). Because of the lack of these essential components for lipid metabolism, a buildup of lipids occurs in the liver, which eventually leads to liver failure. The need to conserve body protein during starvation has been stressed in extremely obese persons who were treated by starvation, because slow loss of protein during complete starvation may lead to sudden death because of a cumulative protein loss (Le Maho *et al.*, 1988).

From a physiological point of view, birds thus seem to be well equipped to deal with prolonged periods of starvation through prolonged metabolism of fat as the major energy source, provided they have sufficient fat stores and sufficient essential amino acid and vitamin stores to facilitate lipid catabolism. When clinically monitoring obese birds during a forced starvation period, plasma concentrations of corticosterone, β-hydroxybutyrate and uric acid can be used to pinpoint the critical transition from phase 2 to phase 3 of starvation.

When starving obese birds, which have a history of malnutrition, to force them to change over to a balanced diet, it seems prudent to give a multivitamin injection and small amounts of a mixture of essential amino acids to avoid a deficiency of lipotrophic factors and starvation-related hepatic lipidosis.

C. Biochemistry of Endurance Flight

After a 90- to 160-min flight of 48 km, homing pigeons show marked changes in plasma chemistry, which include increased glucagon like immunoreactivity (GLI), increased concentrations of free fatty acids (FFA) and triglyceride (TG), decreased thyroxine (T4), triiodothyronine (T3), and T3/T4 ratio (George *et al.*, 1989). Viswanathan *et al.* (1987, 1988) observed significant increases in plasma glucose and lactate, FFA, and growth hormone (GH), but not corticosterone after a 80- to 90-min flight of 48 km. In contrast to George *et al.* (1989), they did not see changes in T4 and T3. George *et al. (*1992) documented under similar conditions a significant increase of plasma arginine vasotocine (AVT) without change in plasma osmolality. However, in free-flying tippler pigeons trained to fly continuously for up to 5 h, Giladi *et al.* (1997) found three- to eightfold increased plasma AVT (up to 100 pg/ml), *increased* plasma osmolality and *decreased* hematocrit values.

Bordel and Haase (1993, 2000) studied the influence of flight duration on blood parameters in homing pigeons that returned after 2 to 22 h from release sites 113 to 620 km away. Hematocrit values decreased from 54% in controls to 51% in flown birds. Plasma FFA levels increased significantly during flight, and TG concentrations gradually decreased with progressive flight duration. Plasma concentrations of glucose and lactate did not differ between experimental and control birds. Immediately after takeoff and up to $\approx$ 5 h of flight, plasma uric acid (UA) increased in a linear manner and reached values of 1500 μmol/after flight duration $>$5 h to 22h (two to fourfold increase of control values), whereas urea (UR) levels gradually rose with flight duration to 400% of control values. Plasma protein decreased in flown pigeons. The excretion of UR, uric acid and N^{τ}-methylhistidine was significantly higher in flown birds compared to controls during 1 to 3 days immediately following return, but immediately after flight N^{τ}-methylhistidine did not elevate.

These findings support the view that lipids are the main energy source during flight. The increase in lactate during short flights is compatible with the idea that carbohydrates are utilized as fuel mainly in the initial phase of flight and are used for the activity of the white glycolytic fibers in the flight muscles. Furthermore, protein catabolism increases during endurance flights. Because UR formation in pigeons occurs mainly through arginolysis (Bordel and Haase, 1998) and increased protein breakdown raises the availability of arginine (Robin *et al.*, 1987), the elevated plasma concentrations of UR and UA can be attributed to an accelerated protein breakdown during flight. The increased availability of free amino acids and their conversion into metabolites of the citric acid cycle could enhance the capacity of the tricarboxylic acid cycle and thereupon the oxidation of acetyl-CoA derived from lipolysis (Dohm *et al.*, 1985). In addition, protein degradation contributes to the prevention of dehydration during flight because the catabolism of a mixture of 70% lipids and 30% protein yields $\approx$20% more water than the catabolism of pure fat (Klaasen, 1996). Because the methylated amino acid N^{τ}-methylhistidine occurs almost exclusive in actin and myosin filaments and is excreted after myofilament breakdown, the findings suggest an increased breakdown of myofibrillar proteins in the immediate period *after* the flight, probably as a result of repair processes of contractile elements in the muscles as a reaction to protein breakdown during flight (Bordel and Haase, 2000).

The AVT increase can be regarded as an overall homeostatic mechanism during homing flights, whereby (1) lipid is mobilized, (2) water is conserved, and (3) temperature is regulated. There is a significant correlation between postflight AVT and body mass loss (which in flying birds represents mainly water loss). Water loss is related to the duration of flight and the environmental temperature.

Despite substantial water loss, the hematocrit of flying pigeons significantly decreases. This probably results from expansion of plasma volume through a shift of water from the interstitial fluid. The expanded plasma volume

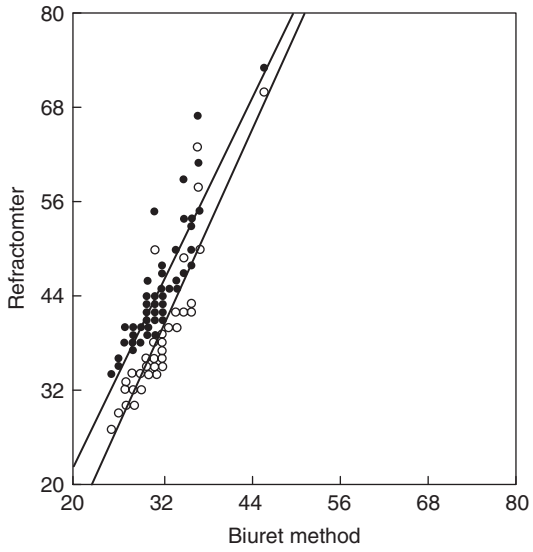

FIGURE 28-5 Relation between plasma total protein concentration by biuret method and two types of refractometers in pigeons (g/L; n = 58). Symbols: ●, temperature compensated refractometer (y = −16.38 + 1.93 X; r = 0.89); ❍, nontemperature compensated refractometer (y = −25.88 + 2.06 X; r = 0.89). From Lumeij and McLean (1996).

and reduced hematocrit may contribute to the maintenance of blood pressure, whereas the decreased hematocrit may enhance blood flow to metabolically active tissues.

The absence of changes in plasma corticosterone concentrations during the shorter flights can be considered as an absence of stress under the circumstances studied.

IV. PLASMA PROTEINS

A. Introduction

Plasma proteins are important complementary constituents in the diagnosis of gastrointestinal, hepatic, renal, or infectious diseases. Determination of plasma proteins seldom leads to a specific diagnosis (e.g., monoclonal gammopathies) but will help the clinician to evaluate the nature, severity, and progress of a disease.

B. Plasma versus Serum

In pigeons, the concentration of total protein (TP) in plasma is about 1.5 g/L higher than in serum, because the former also contains fibrinogen: $TP_{serum} = -1.7 + 1.01\ TP_{plasma}$ (Fig. 28-4). According to Lumeij and McLean (1996), the correlation is highly significant ($p < 0.000001$; R = 0.99; n = 50). Differences between plasma and serum were discussed in Section II.B. When plasma rather than serum is used, recognition of elevated fibrinogen concentration can be seen in the protein electrophoresis and is reflected by elevation of the acute phase (α or β) proteins (Roman *et al.*, 2005). See also Section XII.C.6.

C. Physiological Variation in Female Birds

In female birds, a considerable increase in plasma total protein concentration occurs just before egg laying because of an estrogen-induced increase in the globulin fractions (Griminger, 1976). The proteins are the yolk precursors (e.g., vitellogenin and lipoproteins), which are synthesized in the liver and transported to the ovary, where they are incorporated in the oocyte (Griffin *et al.*, 1984).

D. Refractometry versus the Biuret Method

Lumeij and De Bruijne (1985b) demonstrated that the refractometric method is unreliable for use in avian blood and therefore this method should not be used in avian practice. The refractometric method consistently yields higher values when compared to total protein concentrations determined with the biuret method, and the correlation coefficient between these two methods is low. One study suggested that only temperature compensated refractometers are reliable (Andreasen *et al.*, 1989). In another study in our laboratory (Lumeij and McLean, 1996), using plasma and serum of 58 pigeons, two types of refractometers were compared with the biuret method. Neither instrument proved to give an accurate measurement of plasma total protein. Both refractometers gave considerably higher values than the biuret method, with the temperature compensated instrument being consistently higher in readings than the nontemperature compensated one (Fig. 28-5). It was concluded that a species- and refractometer-specific conversion factor must be applied before refractometric

values can be used, and then only as a rough estimate of the TP. Another important consideration is that TP determinations (refractometric or by biuret method) without information on plasma protein electrophoresis have limited value (see later discussion). For avian clinical practice, it is advised that the clinician establish TP values using the biuret method.

E. Effect of Protein Standards

Most commercial laboratories use a human standard for TP and albumin (Alb) determinations, without validating the method for the species of which the blood sample is submitted. There are significant differences between TP concentrations when different standards are used (e.g., human, bovine, pigeon, and chicken standards), although there is a high correlation between the results obtained with the various standards (Lumeij *et al*., 1990; Spano *et al*., 1987,1988). When a pigeon standard was used to determine serum TP concentration (TP_p) with the biuret method, values found were significantly higher compared to values found determined with the biuret method using the human standard (TP_h), but there was a high correlation (Lumeij *et al*., 1990):

$$TP_h = 2.94 + 0.83\ TP_p\ (P < 0.0001;\ r = 0.93)$$

Spano *et al*. (1987, 1988) found consistently lower TP values in chicken serum using a chicken standard compared with a bovine standard. Because the use of a species-specific standard for all species presented to the avian practitioner is unrealistic and because a high correlation exists between the results obtained with the various standards, it is recommended that clinicians establish reference values for the various species using the standard that is most commonly used in commercial laboratories (i.e., the human standard).

F. Plasma Protein Electrophoresis: Albumin/Globulin Ratio

Plasma protein electrophoresis (PPE) on cellulose acetate membranes has been widely used in avian patients (Lumeij, 1987e; Lumeij and De Bruijne, 1985a). In many laboratories, agarose gel films are replacing cellulose acetate membranes. A good correlation (r = 0.998) exists between these methods in human serum (Archer and Battison, 1997). Protein fractions that can be observed include Alb, α, β, and γ globulin. The α and β globulins (including fibrinogen) are considered acute phase proteins, whereas the γ fraction is elevated in chronic conditions and includes the immunoglobulins. Often a prealbumin fraction can also be observed (Fig. 28-6). In healthy birds, the Alb fraction is the largest protein fraction. In acute or chronic inflammatory conditions, a rise in total protein caused by elevated globulin fractions may occur. Often Alb concentrations are decreased in these situations. The combined effect of these changes is a decrease in the Alb/Globulin (A/G) ratio. Often the total protein concentration is within the reference range, whereas the A/G ratio is decreased, therefore the A/G ratio is of greater clinical significance than the total protein concentration. Examples of diseases with a decrease in the A/G ratio are egg related peritonitis and chronic infectious diseases such as aspergillosis, psittacosis, and tuberculosis. In ducks, Liu *et al.* (1984) found that serum globulin increased with the severity of pathological changes of amyloidosis and that the globulin was also found in the amyloidotic tissue. Protein electrophoresis can also be used to monitor response to treatment. In liver failure, extremely low plasma protein concentrations can occur in combination with a decreased A/G ratio. Gastrointestinal and renal diseases can also lead to severe hypoproteinemia. In birds, protein malnutrition may lead to hypoproteinemia (Leveille and Sauberlich, 1961). Increased TP concentrations with a normal A/G ratio can be expected in dehydrated birds if the primary disease did not cause hypoproteinemia. To calculate the A/G ratio, prealbumin and Alb as determined by plasma protein electrophoresis are combined as "A" and all globulin fractions as "G" (Figs 28-8 through 28-11; Lumeij, 1987e).

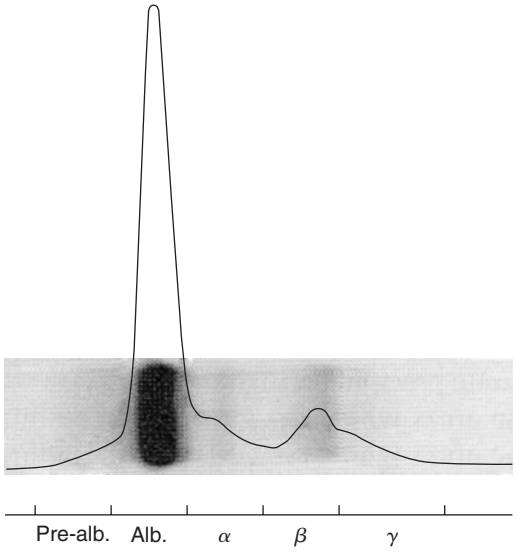

FIGURE 28-6 Densitometer scan and electrophoretic pattern on a cellulose acetate membrane from a representative pigeon serum. Prealbumin, albumin, α, β, and γ globulin. Reprinted with permission from Lumeij and De Bruijne (1985a).

In plasma of some species, the mobility of Alb in cellulose acetate and agarose gels is less compared to the usual patterns, as seen, for example, in chickens and pigeons. In the cockatiel, for example, prealbumin migrates to a position equivalent to chicken albumin, and albumin to a position equivalent to chicken α globulins (Fig. 28-7). Tatum *et al*. (2000) has confirmed the diagnostic value of PPE for a wide variety of raptor species.

Rosenthal *et al.* (2005a) questioned the reliability of PPE in birds. However, they limited their study to healthy

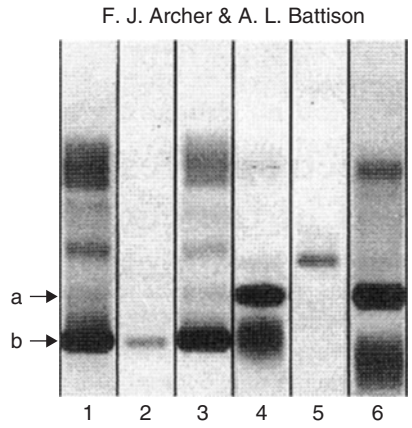

FIGURE 28-7 Agarose gel electrophoresis. From left to right, chicken (*Gallus gallus domesticus*) serum (lane 1), purified chicken albumin (lane 2), chicken plasma (lane 3), cockatiel (*Nymphicus hollandicus*) plasma (lane 4), purified cockatiel albumin (lane 5), and cockatiel serum (lane 6). Chicken albumin (lanes 1, 2, and 3, band b) migrated further than cockatiel albumin (lanes 4 and 6, band a). Cockatiel albumin migration was similar to that of chicken α globulins (lanes 1 and 3, band a), whereas cockatiel prealbumin migration (lanes 4 and 6, broad bands b) was similar to that of chicken albumin. Purification of cockatiel albumin (lane 5, single band) altered its migration pattern, whereas purification of chicken albumin (lane 2, single band b) did not have this effect. Reprinted with permission from Archer and Battison (1997).

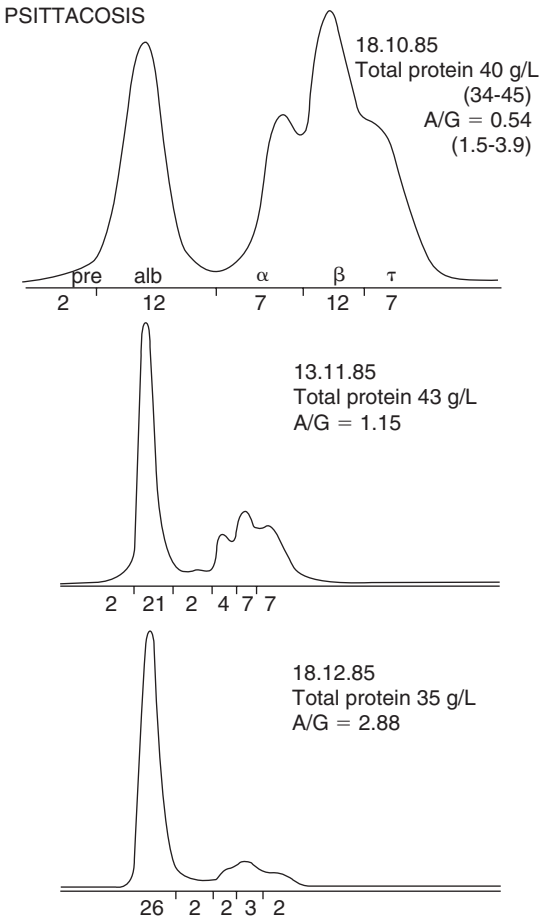

FIGURE 28-8 Plasma protein electrophoresis and the albumin:globulin ratio (A/G) in an African grey parrot (*Psittacus erithacus erithacus*) with psittacosis, before, during, and after treatment with doxycycline. Symbols: Pre, prealbumin; alb, albumin; α, β, γ, globulin fractions (reference values in parentheses). Reprinted with permission from Lumeij (1987e).

birds, and their data did not span the full range of clinical values. Because values of individual globulin fractions in healthy birds are low and boundaries between the various globulin fractions are not clear, it is to be expected that large bias is introduced when an arbitrary (manual) distinction between the various globulin fractions has to be made (Cray, 2005; Rosenthal *et al.*, 2005b). Their study did, however, confirm the high reliability of determinations of TP and Alb, whereas measurement of γ-globulins had fair to good agreement. Determination of the A/G ratio as described earlier and visual inspection of the globulin fractions in case of abnormal values will leave no doubt on the fractions responsible for the abnormalities, as, for example, in the hyperglobulinemia reported by De Wit *et al*. (2003).

G. Albumin Methodology

The labor-intensive PPE is not available in every laboratory, and Alb is commonly determined chemically by the bromcresol green (BCG) dye-binding method. The BCG method is unreliable in avian blood. Discrepancies between values obtained by dye-binding techniques and those obtained by electrophoresis have been demonstrated for chicken, duck, turkey, and pigeon (Lumeij *et al*., 1990; Spano *et al*., 1987, 1988). In general, Alb determinations performed with dry methods have not been validated for use in birds.

Furthermore, various Alb standards can be used in different laboratories, although most commercial laboratories will use a human standard for TP and Alb determinations. The method used should have been validated for the species in question and compared with reference values established in the same laboratory.

H. Prealbumin

Prealbumin is the most rapidly migrating fraction in avian plasma and has been associated with binding thyroxine and retinol (thyroxine binding prealbumin-TBPA; transthyretin). Although the protein travels anodal to albumin in birds, primates, and the horse, it is usually not visualized in the last. In other species transthyretin travels cathodal to albumin or has the same motility to albumin, which explains the absence of a "prealbumin" fraction in these species using routine electrophoresis techniques (Chang *et al.*, 1999; Larsson *et al.*, 1985). Seasonally high concentrations of plasma transthyretin concentrations (150 to 200 mg/L in May through July versus 80 to 100mg/L in September through January) have been associated with molting in storks (Cookson *et al.*, 1988).

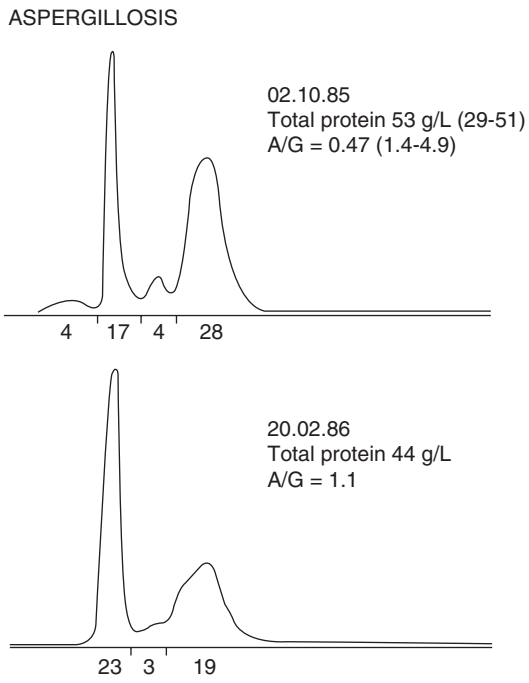

FIGURE 28-9 Plasma protein electrophoresis in an Amazon parrot (*Amazona* sp.) with aspergillosis. At 4½ months after a diagnosis was made and despite treatment with ketoconazole and 5-fluorocytosine, the globulin fraction was still elevated, causing the A/G ratio to decrease (reference values in parentheses). Reprinted with permission from Lumeij (1987e).

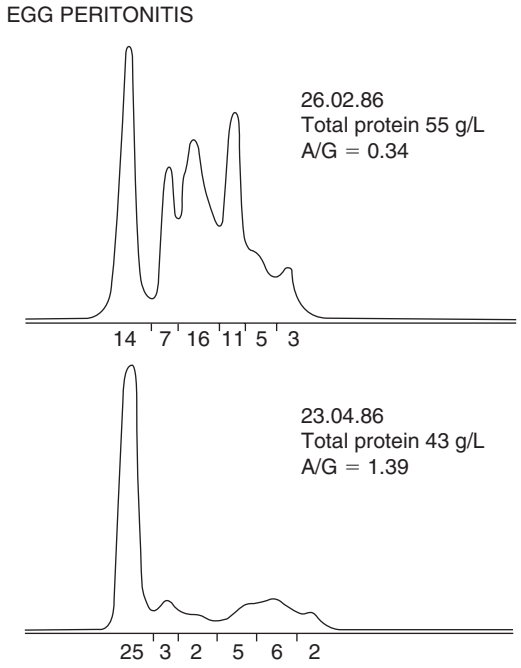

FIGURE 28-10 Serum protein electrophoresis and albumin:globulin (A/G) ratio in an Emu (*Dromiceius novaehollandiae*) with an egg-related peritonitis. Two months after surgical treatment and remission of clinical signs, a marked increase in the albumin fraction and decrease of the globulin fraction was observed. Reprinted with permission from Lumeij (1987e).

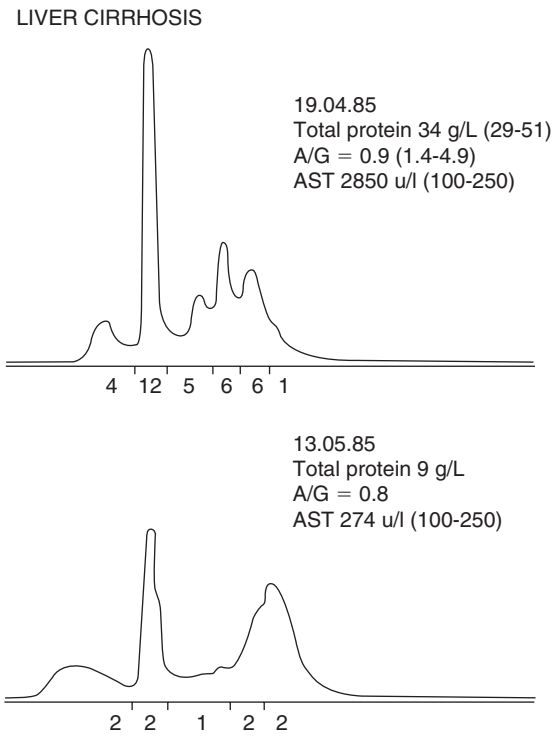

FIGURE 28-11 Total protein concentration, plasma protein electrophoresis, albumin:globulin ratio (A/G), and plasma aspartate aminotransferase (AST) activity in an Amazon parrot (*Amazona* sp.). At the first examination there was a marked elevation of AST and decreased A/G. Liver cirrhosis was diagnosed by means of histological examination of a liver biopsy. The second protein electrophoresis was made from a plasma sample collected just before the bird was euthanized 1 month later. Reference values in parentheses. Reprinted with permission from Lumeij (1987e).

V. RENAL FUNCTION

A. End Products of Protein Metabolism: Hyperuricemia and Gout

Uric acid (UA) is the major end product of nitrogen (N) metabolism in birds. It constitutes approximately 60% to 80% of the total excreted N in avian urine (Skadhauge, 1981). The formation of urea (UR) in pigeons occurs mainly through arginolysis (Bordel and Haase, 1998). Uricotelism permits excretion or storage of N waste in a small volume of water. UA is relatively nontoxic when compared to UR or ammonia (NH_3), which is essential for the development of the embryo in the egg of reptiles and birds. UA is synthesized in the liver, and 90% is excreted via tubular secretion, largely independent of urine flow rate (Skadhauge, 1981). The clearance of UA exceeds the glomerular filtration rate by a factor 8 to 16. The rate of secretion is largely independent of the state of hydration. Very high concentrations of UA can be found in ureteral urine in dehydrated birds. Renal function disorders can eventually lead to elevated plasma UA concentrations. Nonprotein nitrogen (NPN) substances in plasma such as UA, creatinine (Cr), and UR will only

be elevated when renal function is below 30% of its original capacity. For elevated UA and UR during starvation and endurance flight see Sections III.B and III.C.

B. Articular and Visceral Gout

Hyperuricemia can result in precipitation of monosodium urate monohydrate (MSUM) crystals in joints (articular gout) and on visceral surfaces (visceral gout). The exact mechanism of deposition or the predilection for certain sites is unknown, although lower temperatures at predilection sites have been suggested. Gout should not be regarded as a disease but as a clinical sign of any severe renal function disorder.

When birds are provided with dietary protein in excess of their requirements, the surplus protein is catabolized and the N released converted to UA. The total amount of UA formed may surpass the clearing capacity of this substance from the body and hyperuricemia, and articular gout may result. The use of high-protein poultry pellets as the bulk food in psittacines may result in an increased incidence of gout.

There is no consensus on the different etiologies of articular and visceral gout in birds. The following hypothesis, however, seems to explain all known facts about avian gout. A plasma UA concentration that is slightly above the solubility of MSUM will lead to UA precipitates in the body. Predilection sites are those areas where the solubility of MSUM is lower than in other areas. The joints and synovial sheaths may be predilection sites because of a comparatively low temperature. Articular gout is a sign of chronic moderate hyperuricemia. MSUM deposits grow with time with chronic hyperuricemia and form the typical tophi of articular gout.

If urates precipitate in the tubules or collecting ducts of the kidney or the ureters (e.g., severe dehydration of long duration, vitamin A deficiency), this will lead to an acute obstructive uropathy (postrenal obstruction). Anuria or gross oliguria and tubular secretion of UA are severely compromised. This leads to a rapid and severe increase in plasma UA with precipitation of urate crystals on many visceral surfaces and those predilection sites for articular gout. This condition of visceral gout will rapidly lead to death of the affected animal. This hypothesis is based on the fact that no inflammation or tophi are seen in typical predilection sites for articular gout, because the condition has a rapidly fatal course. There is no time for an inflammatory reaction or tophi to develop. In this situation, the kidney tubules, collecting ducts, and ureters may contain UA deposits. An alternative situation could occur in acute tubular failure. In this condition, visceral gout could develop without UA deposits in the tubules, collecting ducts, and ureters.

C. Acute versus Chronic Renal Failure

Renal function disorders may result from any progressive destructive condition affecting both kidneys (chronic renal failure), or from conditions wherein the function of the kidneys is rapidly and severely, but often reversibly, compromised (acute renal failure). In the latter condition, oliguria is usual, whereas in the former situation, polyuria is normally observed. It is important to differentiate between reversible conditions (e.g., prerenal renal failure caused by dehydration or shock of any cause, urolithiasis [postrenal renal failure] and acute nephritis) and chronic irreversible renal failure. Appropriate and timely treatment of acute renal failure can often prevent further damage and in some cases result in improved function. Extrarenal factors such as infection, gastrointestinal hemorrhage, and hypovolemia can disturb an otherwise stable, well-compensated asymptomatic chronic renal patient and precipitate a desperately dangerous condition.

D. Prerenal Azotemia

Prerenal azotemia can be defined as the clinical condition associated with reduced renal arterial tension leading to oliguria and retention of nitrogenous waste products in the blood. It is often seen during shock or severe dehydration. No increased plasma UA concentrations were observed in 4-day dehydrated racing pigeons, whereas plasma UR concentration had a significant 6.5- to 15.3-fold increase. Plasma UR appeared to be the single most useful variable for early detection of prerenal causes of renal failure (Lumeij, 1987c). This is because UR is excreted by glomerular filtration, whereas tubular reabsorption is dependent on urine flow, which in turn depends on the state of hydration. During hydration, almost all of the filtered UR is excreted and during dehydration nearly all of the filtered UR is reabsorbed. The active tubular secretion of UA, on the other hand, is not dependent on arterial pressure, because the tubules of the reptilian type nephrons are supplied by venous blood through the renal portal system. The tubular reabsorption of UR in conditions of renal failure accompanied by a low urine flow (e.g., dehydration) in combination with a nearly unchanged tubular secretion of UA causes a disproportionate increase in plasma UR concentration, resulting in an elevated UR/uric acid ratio. Although potentially useful for judging the hydration status of a bird, UR is normally present in low concentration in avian plasma and has traditionally been considered an inappropriate variable to evaluate renal function in birds.

When the dehydration becomes more severe, this may eventually lead to hyperuricemia. This might be caused by reduced tubular blood supply which leads to reduced uric acid secretion. Urates may also precipitate in the tubules when there is active tubular secretion of UA in the absence of urine flow. The latter condition looks much like acute uric acid nephropathy in humans (Watts, 1978).

E. Urea versus BUN

There is a great deal of confusion with respect to the conversion of urea (CH_4N_2O) to blood UR nitrogen or "BUN." Apart

from the fact that BUN only refers to the nitrogen part of the UR molecule, in the United States it is often expressed in mg/dl, whereas in Europe UR is usually expressed in SI units (mmol/L). It is sad to see how reference values that were presented in the previous edition of this book were erroneously converted to American units in the *Journal of Veterinary Clinical Pathology* (Harr, 2002).

To convert BUN in mg/dl to urea in mmol/L, the following steps must be performed:

1. Convert BUN (mg/dl) to urea (mg/dl) by multiplying BUN with the quotient of the molecular mass of urea and the molecular mass of nitrogen in the urea molecule $(12 + 4 \times 1 + 2 \times 14 + 16)/(2 \times 14)$.
2. Convert urea (mg/dl) to urea (mmol/L) by dividing urea (mg/dl) by the molecular mass of urea (60).
3. Convert mg/dl to mg/L by multiplying the result by 10.

Or more simply: to convert BUN (mg/dl) to urea (mmol/L), divide BUN with total mass of nitrogen in urea molecule and multiply by 10 (10/28) = 0.357). The conversion from UR (mmol/L) to BUN (mg/dl) is 1/0.357 = 2.8.

F. Postprandial Effects

In raptors, a significant postprandial increase in plasma UA and UR concentrations occurs (Lumeij and Remple, 1991, 1992). Postprandial UA was similar to that in birds with hyperuricemia and gout and was well above the theoretical limit of solubility of urate in plasma. It is not clear why under physiological conditions, no urate deposits occur in raptors, which have hyperuricemia for at least 12 h after ingesting a natural meal (Fig. 28-12). A similar effect was noted in the piscivorous blackfooted penguin (*Spenicus demersus*) (Kolmstetter and Ramsay, 2000). To avoid physiological food-induced elevations in UA and UR that can complicate interpretation of plasma chemistry results in raptorial or piscivorous birds, blood samples should ideally be collected after a 24-h fasting period. In small passerines, this is obviously not an option!

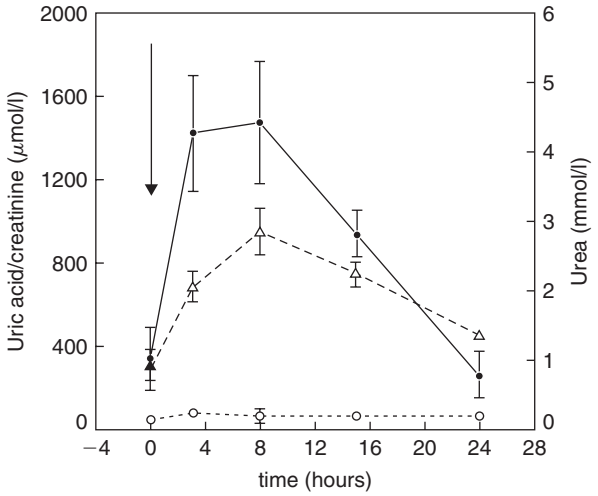

FIGURE 28-12 Fasting and postprandial nonprotein nitrogen substances in plasma of peregrine falcons, *Falco peregrinus* (mean ± SD). Symbols: ●, [uric acid] (μmol/L); △, [urea] (mmol/L); O, [creatinine] (μmol/L); ↓, feeding quail. Reprinted with permission from Lumeij and Remple (1991).

G. Other Changes Associated with Renal Failure

Hyperkalemia is a particular problem in acute renal failure that may lead to severe electrocardiographic changes and eventually to cardiac arrest. Hypocalcemia and hyperphosphatemia are usual in humans with renal failure. The former may lead to hypocalcemic tetany, especially with rapid correction of acidosis. In birds, special attention should be paid to these variables for further documentation of changes in renal disease because these changes may have therapeutic implications. Anemia has been documented in birds with chronic renal failure.

H. Murexide Test

Macroscopically, the aspirated urates from articular gout look like toothpaste. The presence of urate can be confirmed by performing the murexide test or by microscopic examination of aspirates of tophi or joint accumulations. The murexide test is performed by mixing a drop of nitric acid with a small amount of the suspected material on a slide. The material is evaporated to dryness in a Bunsen flame and allowed to cool. Then one drop of concentrated ammonia is added. If urates are present, a mauve color will develop.

I. Birefringent Crystals

Microscopically sharp needle-shaped crystals about the size of a leukocyte can be seen in smears of joint fluid from patients with articular gout. A polarizing microscope is helpful in identifying the typical birefringent crystals. Birefringent literally means splitting a ray of light in two. Crystals bend light and become visible in joint fluid when viewed through a microscope with crossed polarizing filters. When a compensator plate is used on the microscope, monosodium urate crystals parallel to the axis of the compensator appear yellow (negatively birefringent). In humans, pseudo-gout is diagnosed by finding positively birefringent calcium pyrophosphate dihydrate crystals that appear blue when parallel to the axis of the compensator. Calcium pyrophosphate dihydrate crystals are smaller and are rhomboid shaped.

VI. HEPATOBILIARY DISEASE

A. Clinical Enzymology

Clinical enzymology is described more fully in a separate chapter in this book, so only a brief synopsis is given here. Enzymes occur normally in the cytoplasm (e.g., aspartate aminotransferase [AST], alanine aminotransferase [ALT], lactic dehydrogenase [LDH]), mitochondria (glutamate dehydrogenase [GLDH] and AST), nucleus, or membranes (alkaline phosphatase [AP], gamma glutamyl transferase [GGT, γGT]) of body cells, where they catalyze specific reactions. The distribution of various enzymes is markedly different among organs and animal species, which explains the variation in organ and tissue specificities among animal species. Generally, increased plasma enzyme concentrations indicate recent organ damage rather then decreased organ function. Increased enzyme production has been reported in cholestatic liver disease in mammals (AP and GGT). Sometimes a decreased activity is of diagnostic value (e.g., decreased cholinesterase activity in organophosphate toxicity). Baseline activity of an enzyme in plasma is generally a reflection of the amount and turnover of the tissue that contains this enzyme. For example, the creatine kinase (CK) activity in plasma increases in direct proportion to the increase of skeletal muscle mass as a result of training. Increases in CK may also be observed simply as a result of the muscle cellular damage associated with capture and restraint. Conversely, in chronic liver diseases with severe fibrosis and a reduction in the number of functional hepatocytes, plasma activities of liver enzymes may be within normal limits. The increase of a particular enzyme also depends on factors such as its rate of release, rate of production, and rate of clearance from plasma. Cytoplasmatic enzymes will be released early in cell degeneration, whereas mitochondrial enzymes will be released after advanced cell damage (necrosis). Enzymes with high tissue concentrations but with short elimination half-lives are of limited value in clinical enzymology because of their rapid disappearance from plasma.

Generally, EDTA samples are not appropriate for enzyme assays, because this anticoagulant may chelate metal ions, which are required for maximal enzyme activity. Plasma and cells should be separated immediately after sampling to prevent leakage of intracellular enzymes into the plasma. Even if the cellular elements are separated from the plasma, freezing/thawing and refrigeration of plasma samples for several days may severely decrease enzyme activity and therefore should be avoided unless the effects of the storage procedure used is known.

B. Enzyme Activities in Avian Tissues

Enzyme profiles of the various organs have been studied in chickens, mallards, turkeys, racing pigeons, budgerigars and African grey parrots (Lumeij 1994d; Figs. 28-13 through 28-15).

C. Clearance of Enzymes from Plasma

The half-life of an enzyme is defined as the time required for its concentration to be reduced by half. When an enzyme is injected into plasma, its clearance from the plasma generally follows a biphasic exponential decline. Initially, there is a rapid decline, which is the primary mixing or distribution phase, followed by a slower secondary decline phase, which is the actual clearance of the enzyme from the plasma. During this secondary phase, a constant fraction of enzyme present is cleared per unit of time; hence, the decline is linear on a semilogarithmic scale. The ($t½\beta$)half-life of the enzyme can be calculated from the regression function of the secondary linear phase of the semilogarithmic concentration-time curve and is independent of plasma enzyme activity.

Clearance half-lives of various enzymes considered to be of use for the differential diagnosis of liver and muscle disease in pigeons have been established by studying the disappearance rates of enzymes from plasma after IV injections of supernatants of homologous liver and muscle homogenates (Lumeij *et al*., 1988a). For AST, ALT, and LD, the half-lives of the respective enzymes from liver and muscle were compared, whereas for GLDH and CK, only liver and muscle were used, respectively (Table 28-1).

D. Experimentally Induced Liver and Muscle Disease

Plasma enzyme profiles after experimentally or spontaneously occurring liver disease have been studied in a number of avian species. The results of studies in racing pigeons (Lumeij *et al*., 1988a, 1988b) with two different types of liver disease were compared to plasma chemistry changes after muscle injury. Liver disease was induced by ethylene glycol or D-galactosamine, and muscle injury was induced by an intramuscular injection of doxycycline in three groups of six pigeons each. Plasma chemical changes were correlated with histological findings from organ samples taken just after the last blood collection (Fig. 28-16, Table 28-2).

Plasma AST activity and bile acid (BA) concentration were the most sensitive indicators of liver disease in the racing pigeon, followed by ALT, GGT, and LD. Although all pigeons with histological proven ethylene glycol- or galactosamine-induced liver damage had increased AST activity and BA concentrations in their plasmas, these constituents were not raised at every sampling time. Increased plasma GLDH activities were associated with large necrotic areas in the liver. Moderate necrosis of liver cells resulted in slightly elevated GLDH activities. Degeneration

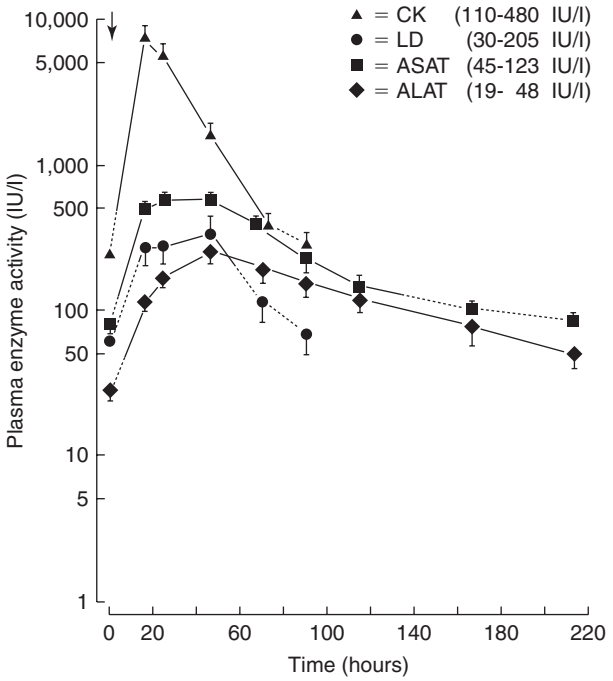

FIGURE 28-16 Mean (±SEM) plasma enzyme activities after intramuscular injection of 75 mg/kg doxycycline (Vibramycin^{R}-Pfizer, New York) in six racing pigeons. The parts of the curves that are above the reference range are indicated with continuous lines. Variables that did not show elevations above the reference range during the entire experiment (GLDH, AP, and bile acids) are not indicated. On histological examination at t = 215 h, degeneration and necrosis of muscle cells was observed. Reprinted with permission from Lumeij *et al*. (1988b).

of liver cells and hepatitis with single-cell necrosis did not give rise to elevated plasma GLDH activities. Plasma CK activity was never increased because of liver damage, whereas GLDH, GGT, and BA were never elevated during muscle damage. Thus, these four constituents are useful for differentiating between liver and muscle disease. GLDH is the most liver-specific enzyme in the racing pigeon. Because GLDH is localized within the mitochondria of the liver cells, increased plasma GLDH activities, however, are only observed after liver cell necrosis.

The enzymes that are the most specific indicators of muscle and liver cell damage (CK and GLDH, respectively) have shorter half-lives than AST and ALT, which are not specific indicators of damage to either organ. Thus, after muscle or liver cell damage, AST and ALT activities in plasma can be increased, even though CK or GLDH activities have returned to baseline values. The fact that LDH has a shorter half-life than CK makes this enzyme valuable for differentiating between muscle and liver disease in the pigeon. When plasma LDH activity is increased in the absence of elevated CK activity, muscle damage is unlikely. Enzyme profiles can only serve as rough guides to interpretation of elevated plasma enzyme activity and are not characteristic for a particular organ. The most important reason is that the enzyme profile alters after enzymes have entered the circulation resulting from different removal rates for the various components.

Based on the tissue enzyme studies, it seemed that LD was the most sensitive indicator of liver cell damage, whereas ALT, because of its low activity in liver, would be of limited value. It also seemed that LDH would be a more sensitive indicator of muscle cell damage than ALT. Experimentally induced liver and muscle damage, however, demonstrated that ALT activity in plasma is increased sooner than LDH activity. The relative increase of ALT was also larger than that of LDH, except in severe liver cell damage accompanied by large areas of necrosis. Plasma ALT activities were increased for a longer period after organ damage compared to LDH. These findings can be explained by differences between their clearance half-lives. The clearance half-life of LDH is 15 to 30 times less than that of ALT.

Campbell (1986) reported increased AST and ALT activities in 75% of pigeons with aflatoxin B1-induced liver damage and increased LDH activities in 33%. In addition, AP and GGT were not sensitive indicators of liver disease in pigeons, cockatiels, red-tailed hawks, and great horned owls. With the exception of GGT, these findings were confirmed by Lumeij *et al.* (1988a, 1988b). The discrepancy might reflect the difference in the hepatotoxic agents used. In the study of Lumeij *et al.* (1988a, 1988b), GGT activities were increased in the majority of pigeons with experimentally induced liver disease, though

TABLE 28-2 Summary of Specificity and Sensitivity of Plasma Chemical Variables in Liver and Muscle Disease Based on Experimental Studies in Pigeons by Lumeij *et al.* (1988a, 1988b)

Variable	Liver disease		Muscle disease	
	Specificity	Sensitivity	Specificity	Sensitivity
Bile acids	+++	+++	—	—
GGT	+++	+	—	—
AST	—	+++	—	+++
ALT	—	++	—	+++
AP	—	—	—	—
CK	—	—	+++	+++
LD	—	+	—	+
GLDH	+++	(+)[a]	—	—

[a] *Elevated* GLDH *activity is a sign of extensive liver cell necrosis, as* GLDH *is a mitochondrial and not a cytoplasmatic enzyme. Liver cell degeneration will not cause elevated* GLDH *activities. In the budgerigar* (Melopsittacus undulatus), GLDH *activity in liver tissue is relatively low when compared to humans and most of the domestic animals including cockerel, duck, turkey, and pigeon* (Lumeij and Wolfswinkel, 1987). *However, in Amazon parrots with extensive liver necrosis as a result of Pacheco's disease, elevated* GLDH *activities were observed in plasma, which indicates that this variable is also useful in at least some of the psittacine species* (Lumeij, *unpublished observations*).

no GGT activity could be detected in supernatants of liver tissue homogenates. This might be explained by synthesis of GGT during (cholestatic) liver diseases, as has been reported in mammalian species (Kaplan and Righetti, 1969; Kryszewski *et al*., 1973). Phalen *et al*. (1997) found that 5/5 Amazon parrots with bile duct carcinoma showed increased GGT activities and suggested that GGT may prove a valuable tool for early detection and staging of bile duct carcinomas.

In birds, increased AP activities are predominantly associated with increased osteoblastic activity, such as skeletal growth, nutritional secondary hyperparathyroidism, rickets, fracture repair osteomyelitis, as well as impending ovulation (Lumeij and Westerhof, 1987) (see Section VIII.E). Increased plasma AP associated with liver disease in birds is rare (Ahmed *et al*., 1974). In the experimental studies from Lumeij *et al.* (1988a, 1988b), AP and CK were never elevated after liver cell damage, whereas activities of these enzymes in liver tissue were negligible. Increased activities of liver enzymes in plasma may indicate recent damage to liver cells but do not give information on liver function. In end-stage liver disease (cirrhosis), it is possible to have normal activities of liver enzymes in the plasma, because active damage to liver cells has ceased (e.g., Fig. 28-11).

In psittacine birds, the use of a good anamnesis and plasma AST is sufficient to make a tentative diagnosis of liver disease. When birds are known to have been recently injected intramuscularly, elevated AST (and ALT) activity should be interpreted with caution. Including a plasma constituent that specifically gives information on liver function, for example, total bile acids, has proven to be of great value. When liver disease is suspected, a biopsy of this organ is essential to establish a definite diagnosis.

E. Bile Pigments

The excretion of green urates suggests liver disease in birds (Galvin, 1980; Lothrop *et al*., 1986; Steiner and Davis, 1981). This discoloration is caused by biliverdin, which is the most important bile pigment in birds (biliverdinuria). Icterus or jaundice, which is caused by a hyperbilirubinemia, is seen infrequently in birds. When in chickens both bile ducts are ligated the concentration of plasma bile pigments rises immediately but stabilizes after 2 weeks at about 85 μmol/L, which is a much lower concentration than in mammals with total biliary obstruction. In sera of healthy ducks, low levels of bilirubin may be detected and significantly elevated levels have been reported after experimental duck virus hepatitis infection. However, the observed levels of about 17 μmol/L were well below the serum concentration of 34 to 51 μmol/L, which has been mentioned as the level above which jaundice becomes apparent in humans. The infrequent occurrence of icterus in birds is explained by the absence of biliverdin reductase, which converts biliverdin to bilirubin (Lin *et al*., 1974; Lind *et al*., 1967; Tenhunen, 1971). It has been suggested that in birds biliverdin may be converted to bilirubin by bacteria or nonspecific reducing enzymes (Lewandowski *et al*., 1986). A yellow discoloration of avian plasma is often caused by the presence of carotenoids, which is often misinterpreted as being icteric.

F. Bile Acids

Plasma bile acids (BA) and their salts are formed in the liver from cholesterol and are excreted in the intestine, where they assist in digestion of lipids. There is a continuous secretion of bile in both birds with and without a gallbladder.

This is slightly increased postprandially because of the intrahepatic effects of intestinal hormones like secretin, avian vasoactive intestinal peptide (VIP), or cholecystokinin (CCK). The sites of the increased bile secretion and the regulatory mechanism are unknown (Lumeij, 1991). Via the enterohepatic recirculation, over 90% is reabsorbed in the jejunum and ileum (Hill, 1983). Plasma BA concentrations including their salts and corresponding glycine and taurine conjugates are a reflection of the clearing capacity for BA of the liver. All liver functions such as extraction, conjugation, and excretion are involved in this process, and the BA provides information on the combined effects of these functions. The plasma concentration of BA is a sensitive and a specific indicator of liver function, and it is widely used in humans and domestic animals, including birds (De Bruijne and Rothuizen, 1988; Hoffmann *et al*., 1987; Lumeij, 1988; Rutgers *et al*., 1988). Reference values for BA have been established for the racing pigeon, the most commonly kept psittacine species (Lumeij and Overduin, 1990; Lumeij and Wolfswinkel, 1988), ostriches, and peregrine falcons (Table 28-3). Lumeij (1987f) found that BA was the single most useful plasma constituent for detecting liver function disorders in the racing pigeon, where it is both specific and sensitive, the main advantage over AST being that the latter is not liver specific. In experimental liver disease, a 5- to 10-fold increase of BA over the upper limit of the reference range is common.

G. Postprandial Effects

There is a significant postprandial increase in BA in granivorous birds, with and without a gallbladder (Lumeij, 1991), as well as in carnivorous birds (Fig. 28-17; Lumeij and Remple, 1992). Although up to a 4.5-fold postprandial increase of BA was observed in individual birds, the concentrations were never increased more than 1.65 fold over the upper limit of the reference range, whereas in hepatobiliary disease 5- to 10-fold increases are common (Lumeij *et al*., 1988a). Even though postprandial increases might complicate interpretation of BA, differentiation between postprandial increases and increases that result from hepatobiliary disease is possible. Experimental findings suggest that values $>70\,\mu$mol/L in fasted racing pigeons and values $>100\,\mu$mol/L postprandially should be considered increased and suggestive for hepatobiliary disease.

H. Plasma Ammonia: Hepatoencephalopathy

A tentative diagnosis of hepatoencephalopathy is often made when neurological signs are observed in birds with liver disease. The syndrome, however, has not been well documented in birds. In mammals, hepatoencephalopathy and hepatic coma are most often observed in portosystemic shunting in which portal blood and its ammonia are shunted away from the liver. Hepatoencephalopathy is not a disease in itself, except for the anatomical anomaly, but a medical condition characterized by neurological symptoms caused by intoxication of the brain by products of protein digestion, namely ammonia (NH_3). Most likely, degradement products from protein act as false neurotransmitters. Protein-rich foods often trigger neurological symptoms in these patients. Fasting plasma NH_3 levels and plasma NH_3 levels 30min after oral loading with NH_4Cl in the form of the NH_3 tolerance test (ATT) can be used to establish the ability of the liver to convert NH_3 into UR. Fasting plasma NH_3 in healthy psittacines ranged from 36 to $274\,\mu$mol/L, which is well above the fasting concentrations reported in dogs (Lumeij and Peccati, 1993). Furthermore, some avian species will normally have up to an 8-fold increase of plasma NH_3 concentration on the ATT using the canine protocol. Therefore, an abnormal ATT is not diagnostic for portosystemic shunting in birds (Lumeij and Peccati, 1993).

I. Exogenous Markers

The hepatic clearance of exogenous drugs or compounds plays a central role in the diagnosis and monitoring of hepatic disease in humans, but so far it has received little attention in avian diagnostics. Jaensch *et al.* (2000a) performed galactose and indocyanine green clearance assays in normal chickens and following celiotomy and compared values with those after 13% hepatectomy. Partial hepatectomy resulted in elevation of galactose single point concentrations, but, paradoxically, galactose clearance values did not alter significantly. Partial hepatectomy did not alter clearance values of indocyanine green.

In galahs (*Eolopus roseicapillus*) a significant reduction in galactose clearance and galactose clearance as a function of body surface area (GEC-SA) was observed after 18% hepatectomy, compared to no reduction after celiotomy alone or 6% hepatectomy. Although galactose single-point concentrations did not elevate significantly, they were strongly correlated with galactose clearance and GEC-SA values (Jaensch *et al*., 2000b).

Further work is needed in birds to explore the potential of galactose clearance for use as a noninvasive method to monitor hepatic function.

J. Iron Storage Disease

A distinction should be made between hemosiderosis, which includes a range of disorders that lead to a buildup of iron pigment in hepatic tissue, and hemochromatosis, which is a genetic disorder in humans and possibly other species. There is no conclusive evidence that hemosiderosis has any clinical significance in birds, with the possible exception of the hemochromatosis syndrome in the Indian hill mynah

TABLE 28-3 Plasma Chemistry Reference Values (Inner Limits of $P_{2.5}$ to $P_{97.5}$ with a Probability of 90%, Unless Specified Otherwise in Footnotes) for Pigeons, Some Psittacine Species, Peregrine Falcon, and Ostrich as Established by the Division of Avian and Exotic Animal Medicine, Utrecht University Department of Clinical Sciences of Companion Animals[a,g]

[f] *Amann* et al. (2006).

[g] *It is recommended that clinicians use reference values established in the same laboratory and with the same methods as used for the patient under investigation. Furthermore, reference values based on the individual patient may help to improve diagnostic interpretation of clinical chemistry values because clinical chemistry values in birds have a high degree of individuality, measured by the index of individuality* (*Scope* et al. 2002*a*).

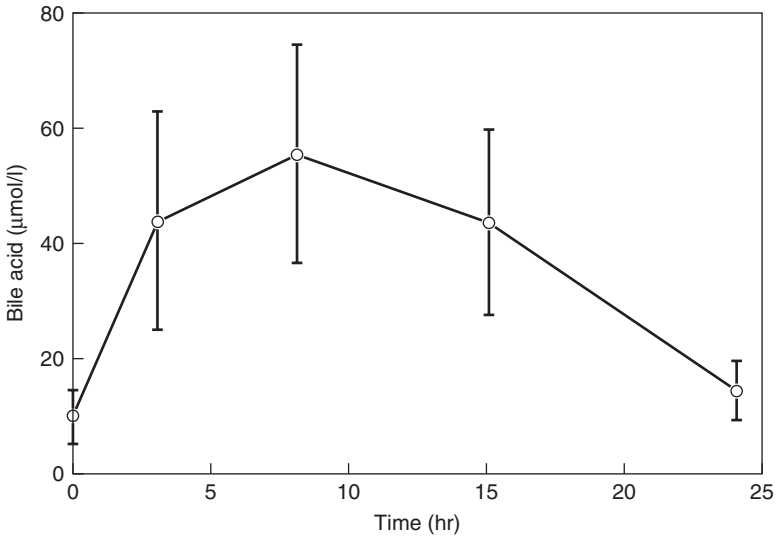

FIGURE 28-17 Plasma bile acid concentrations (mean ± SD) in peregrine falcons, *Falco peregrinus* (n = 6) after a 42-h fasting period and 3, 8, 15, and 24 h after birds were fed a complete skinned quail, *Coturnix coturnix*, at 0 h. Values at 3, 8, and 15 h are significantly different from values at 0 and 24 h ($p < 0.05$). Reprinted with permission from Lumeij and Remple (1992).

(*Gracula religiosa*) and toucans (*Rhamphastos* spp.). In these species, hemochromatosis is often associated with hepatic fibrosis, but the causal relation has not been confirmed.

Hemosiderosis should be considered in the differential diagnosis of avian hepatopathy. Diagnostically, determination of blood iron concentrations is not reliable. There is, however, a positive correlation between the concentration of stainable iron determined by image analysis of histological sections and biochemically determined liver iron concentration. For a review, see Cork (2000).

K. Clinical Diagnosis of Liver Disease

The index of suspicion of liver disease can be raised by the use of physical examination, plasma chemistry (enzymes, BA, TP, and PPE, galactose clearance test, and ultrasonography). However, to make a specific diagnosis, liver biopsy is the only method currently available (Lumeij, 1994a).

VII. MUSCLE DISEASE

Muscle enzyme profiles, half-lives of these enzymes in plasma, and plasma chemistry changes after experimentally induced muscle damage have been reported for racing pigeons (see Section VI.B). Enzyme profiles were studied for pectoral muscle, quadriceps muscle, and heart in pigeons and parrots (Fig. 28-13). Creatine kinase (CK) was the most important enzyme in these three muscles, followed by LDH, AST, and ALT. Muscle damage was induced by injection of doxycycline in the pectoral muscle in pigeons (Fig. 28-16). Creatine kinase activity in plasma was markedly elevated (about 20-fold) 16 h after injection. However, within 66 h plasma activities of CK had returned to the maximum value of the reference range. LD activities were only slightly elevated (about twofold) and only for about 40 h. AST activities showed a marked increase (about fourfold) for about 140 h, whereas ALT showed a marked increase (about fivefold) for about 214 h. Despite the fact that ALT activities in individual muscles are low, elevated plasma activities of this enzyme can be seen until 9 days after muscle damage. Plasma CK activities, on the other hand, return to within the reference range within 3 days after muscle damage, despite high tissue activities. LDH appeared to be a relatively poor indicator of muscle cell damage, despite relatively high activity of this enzyme in muscle (Fig. 28-16). These findings can be explained by the differences in elimination half-lives of the respective enzymes (LDH 50 min, CK 3h, AST 7h, ALT 12 h; Tables 28-1 and 28-2).

Not all elevated concentrations of muscle enzymes in plasma are an indication for muscle disease. Extreme muscular activity in the period preceding blood sampling is an important cause of elevated enzyme activities in plasma. In dogs, plasma CK activities increase approximately twofold with exercise (Heffron *et al*., 1976). Trained persons have plasma CK activities that are twice those of more sedentary people (Okinaka *et al*., 1964). In humans, elevated activities of plasma CK can persist for about 1 week after exercise (Newham *et al*., 1983). Chronic elevated plasma CK activities have been reported in certain occupational workers as a result of local muscular strain (Brewster and De Visser, 1988; Hagberg *et al*., 1982). In healthy turkeys, plasma CK activity is extremely sensitive to physical exercise and stress. With controlled conditions of minimal exercise, stress, and time of handling, however, iatrogenic elevations of plasma CK activities can be prevented (Tripp and Schmitz, 1982). Limited handling of penned mallards resulted in mean ± SD serum CK activities of 1325±1212 IU/L, whereas capture of wild mallards in entanglement nets resulted in serum CK activities of 12035±8125 IU/L, compared to 225±52 IU/L in control animals with minimal handling (Dabbert and Powll, 1993). Elevated plasma CK activities can be expected in birds with large muscle mass after capture stress (e.g., ostrich). Intramuscular injections in birds are a well-known

cause of elevated activities of plasma enzymes from muscle origin (Fig. 28-16). When physiological or iatrogenic causes of hyperCKemia can be ruled out, primary neuromuscular disease should be considered.

In birds, several causes of degenerative myopathy have been reported. In poultry, furazolidone and ionophore coccidiostats are well-known causes of myocyte degeneration (Julian, 1991). Ingestion of the beans of coffee senna (*Cassia* spp.) has been suggested as a possible cause of acute myocyte degeneration in birds (Rae, 1992). Two important causes of degenerative myopathy in birds are exertional rhabdomyolysis (capture myopathy) and nutritional myopathy.

One of the signs of a deficiency of selenium or vitamin E in birds is muscular degeneration. Some authors believe that exertional rhabdomyolysis is an acute manifestation of nutritional myopathy although it has been recorded in species with apparently normal vitamin E levels (Spraker, 1980).

Capture myopathy has been reported in flamingos (Fowler, 1978a, 1978b; Young, 1967), cranes (Brannian *et al*., 1987; Carpenter *et al*., 1991; Windingstad, 1983), Canada geese (Chalmers and Barrett, 1982), turkeys (Spraker *et al*., 1987), and ratites (Dolensek and Bruning, 1978; Phalen *et al*., 1990; Rae, 1992).

Nutritional related myopathies have been reported in piscivorous birds after feeding an unsupplemented diet of previously frozen fish, primarily smelt (Campbell and Montali, 1980; Carpenter *et al*., 1979; Nichols and Montali, 1987; Nichols *et al*., 1986). Vitamin E deficiency has also been associated with muscle lesions in raptors (Calle *et al*., 1989; Dierenfeld *et al*., 1989). Rae (1992) reported that a large percentage of young ratites submitted for necropsy exhibited evidence of degenerative myopathy and considered nutritional deficiency of vitamin E and possibly selenium as the most probable cause.

The muscle lesions produced by the various causes cannot be distinguished from each other and the clinical history is important to establish a diagnosis (Rae, 1992). The use of serum or plasma vitamin E concentrations has been advocated to enable a clinical diagnosis of nutritional myopathy in birds (Rae, 1992). Mean (±SE) plasma concentrations of vitamin E (quantified as α-tocopherol) established in 274 captive cranes were $6.57 \pm 0.82\,\mu$g/ml. Cranes species that evolved in temperate habitats had higher circulating levels of α-tocopherol than tropical or subtropical species: for example, Black crowned crane (*Balearica pavonina*) (n = 10) $2.77 \pm 0.23\,\mu$g/ml and Siberian crane (*Grus leucogeranus*) (n = 51) $9.41 \pm 0.64\,\mu$g/ml (Dierenfeld *et al*., 1993). In peregrine falcons (*Falco peregrinus*), circulating α-tocopherol concentrations $<10\,\mu$g/ml were considered a reflection of a marginal vitamin E status, whereas plasma concentrations $<5\,\mu$g/ml were considered deficient (Dierenfeld *et al*., 1989). Only limited data are available on normal plasma concentrations of α-tocopherol in ratites. In apparently healthy rheas, circulating α-tocopherol concentrations ranged between 9.0 and $14.5\,\mu$g/ml, whereas two rheas with muscular problems exhibited mean plasma concentrations of $1.34\,\mu$g/ml (Dierenfeld, 1989).

For the diagnosis of cardiac diseases in birds plasma chemistry has also been used. Enzymes that have been used include AST, LDH, and CPK. CPK activity in plasma from cardiac muscle origin (CPK-MB isoenzyme) was significantly higher in ducklings with furazolidone-induced cardiotoxicosis when compared to controls (Webb *et al*., 1991).

Cardiac troponin T (c TnT), a cardiac specific protein that forms part of the contractile apparatus of striated muscle, is a specific and sensitive serological indicator of acute myocardial infarction in human patients. Elevated serum c TnT concentrations have also been used as a marker for early myocardial damage in broiler chicks (Maxwell *et al*., 1995). Whether plasma or serum is used seems not to be critical, according to Dominici *et al*. (2004). In Siamese fighting fowl, sex-specific differences have been demonstrated in plasma c TnT concentrations (Sribhen *et al*., 2006).

VIII. CALCIUM AND PHOSPHORUS: METABOLIC BONE DISEASE

A. Relation between Calcium and Protein in Avian Plasma

Between 50% and 80% of plasma calcium is biologically inactive and consists of protein-bound calcium and complexed calcium. Total calcium (tCa) concentration is influenced by plasma protein concentrations. Ionized calcium (iCa) is important with regard to deposition of calcium salts and excitability of nervous tissues. In most laboratories, for technical reasons, only tCa is measured. Hence, when tCa is measured it is also important to measure plasma protein concentrations and to make allowances for any deviations from the normal in the latter. A significant linear correlation was found between tCa and Alb in the plasma of 70 healthy African grey parrots ($r = 0.37$; $p < 0.05$), and a correction formula was derived on the basis of the concentration of Alb: Adjusted tCa (mmol/L) = measured tCa (mmol/L) -0.015 Alb (g/L) + 0.4. Approximately 14% of the variability of tCa was attributable to the change in the concentration of plasma Alb ($R^2 = 0.137$) (Lumeij, 1990).

A significant correlation was also found between tCa and TP in 124 plasma samples of peregrine falcons ($r = 0.65$; $p < 0.01$). About 42% of the variability in tCa was attributable to the change in the plasma TP ($R^2 = 0.417$). The correlation between tCa and Alb was significant ($r = 0.33$; $p < 0.01$), but it was significantly smaller than the correlation between tCa and TP ($p < 0.01$). Only 11% of the tCa was attributable to difference in concentration of Alb ($R^2 = 0.108$). An adjustment formula for tCa concentration in the peregrine falcon was derived on the basis of TP: Adj.tCa (mmol/L) = measured tCa (mmol/L) − 0.02 TP (g/L) + 0.67 (Fig. 28-18; Lumeij *et al*., 1993a).

In ostriches a significant correlation was found between tCa and TP ($R^2 = 0.55$; $p < 0.001$). The adjustment

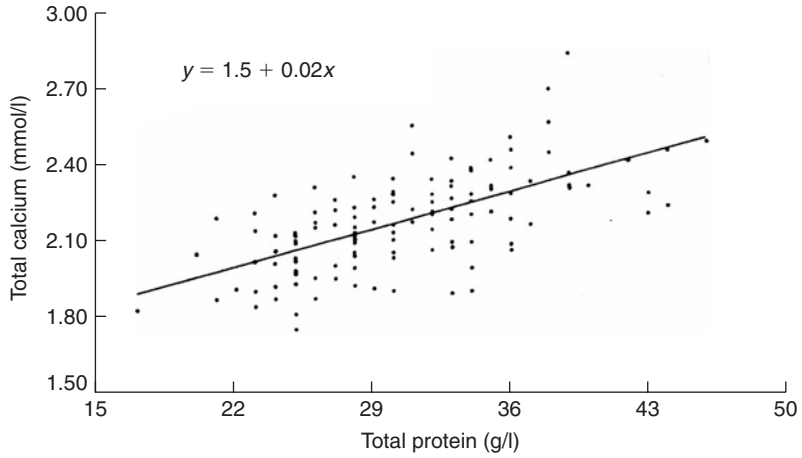

FIGURE 28-18 Significant relationship (r = 0.65; $p < 0.01$) between total protein and calcium in plasma of 124 peregrine falcons (*Falco peregrinus*). The least square regression line is indicated. As the concentration of total protein decreases, there is a concurrent decrease in plasma total calcium. About 42% of the variability in calcium was attributable to the changes in the plasma total protein concentration ($R^2 = 0.417$). Reprinted with permission from Lumeij *et al*. (1993a).

formula for tCa was: adjusted tCa (mmol/L) = measured tCa (mmol/L) − 0.09 TP (g/L) + 4.4.

Application of a correction formula in African grey parrots, peregrine falcons, ostriches, and most likely other species is indicated when extremely low or extremely high plasma protein concentrations are found. The aforementioned correction formulas are based on TP and Alb determinations with the methods as outlined before (Section IV).

Application of a correction formula based on TP or Alb, however, does not take into account the fraction of complexed calcium, which can vary in different conditions. With the development of ion selective electrodes, it is now possible to measure iCa. It is to be expected that direct measurement of iCa in avian blood will provide a more accurate assessment of Ca status, compared to adjusted tCa, as was the case in a canine study (Schenk and Chew, 2005). One study (Stanford, 2003a, 2003b) yielded reference values for serum [sic] iCa based on heparinized plasma samples from 80 "healthy" seed-fed African grey parrots of 0.96 to 1.22 mmol/L (3.84 to .88 mg/dl). Preliminary reference values for iCa in blood of racing pigeons as established in our clinic (n = 20; inner limits of percentiles $P_{2.5}$ and $P_{97.5}$ with 90% certainty) were 1.32 to 1.39 mmol/L when blood was sampled in electrolyte-balanced, 80 IU heparin, 2 ml syringes (Pico 50 Arterial Blood Sampler; Radiometer Medical A/S Denmark-2700 Brønshøj – Ref 956–552) and 1.21 to 1.38 mmol/L when sampled in 3 ml heparinized vacuum tubes (Venoject, Terumo Europe N.V., 3001 Leuven, Belgium). Preliminary data from our clinic from pellet-fed African grey parrots established in blood samples collected with balanced Pico syringes (Radiometer, Copenhagen) suggest that the reference values for tCa values in this species are 2.6 to 3.4 mmol/L and those for iCa are 1.35 to 1.68 mmol/L. Histological changes in the parathyroid gland consistent with nutritional secondary hyperparathyroidism were observed in individuals with tCa values between 2.1 and 2.6 mmol/L (n = 20; inner limits of percentiles $P_{2.5}$ and $P_{97.5}$ with 90% certainty). These reference values for iCa were significantly higher when compared to values established by Stanford (2003a, 2003b). It is most likely that the seed-fed parrots from Stanford (2003a, 2003b) were Ca-deficient, because Stanford (2003b) himself showed that after 1 year of pelleted diet, iCa values increased significantly in his experimental group of 20 parrots. Furthermore, our findings in pigeon blood have shown that the containers in which the blood is collected may affect iCa values. The guidelines of the International Federation of Clinical Chemistry specify that Ca can be bound by heparine and that plasma binding sites in the anticoagulant should be titrated in such a way that a maximum concentration of 15 IU/ml of heparine remains in the collecting tubes. In unbalanced heparine tubes about 0.1 mmol/L of Ca will be bound by 80 IU of heparine (Boink *et al*., 1991). For this reason, tCa values as reported in Table 28.3 of this chapter, which were determined in nonbalanced heparine tubes are likely too low. Howard *et al.* (2004) established reference values ("95% frequency intervals") for iCa in thick-billed parrots (*Rhynchopsitta pachyrhyncha*) from 0.82 to 1.3 mmol/L and for tCa from 1.37 to 2.06 mmol/L. These values were lower than those reported for other psittacine species.

B. Hypercalcemia

1. Introduction

Based on pathophysiological principles, the differential diagnosis for hypercalcemia in birds includes hyperproteinemia, estrogen-induced hypercalcemia, primary hyperparathyroidism, pseudo-hyperparathyroidism, tertiary hyperparathyroidism, metastatic, osteolytic skeletal tumors, and excess of dietary calcium or vitamin D_3 (Lumeij, 1994c), but actual clinical cases, apart from protein-induced (pseudo)hypercalcemia and vitamin D_3 toxicity, are poorly documented.

Clinical signs in true hypercalcemic states may include hypercalcemia, anorexia, polyuria, and polydipsia (PU/PD), delayed crop emptying, regurgitation, weight loss, depression, and renomegaly (Machlin, 1984). Gout has been associated with hypervitaminosis D-induced hypercalcemia (Brue, 1994; Ekstrom and Degernes, 1989; Flammer and Clubb,

1994; Phalen *et al.*, 1990; Takeshita *et al.*, 1986). PU/PD can be explained by the fact that in a hypercalcemic state, the ability of the renal tubules to respond to antidiuretic hormone decreases, thus inhibiting the reabsorption of water (Meric, 1995). The calcifications found in the kidneys may also contribute to the polyuria. Other clinical signs include muscle weakness, painful joints, demineralization of the bone and disorientation, the abnormalities eventually leading to death. Calcium is regulated within narrow limits and slight elevations above the reference range should be taken seriously.

At *postmortem* examination, metastatic calcifications in the liver, kidney, gastrointestinal tract, heart, and blood vessels can be found (Dumonceaux and Harrison, 1994; Lumeij, 1994b; Macwhirter, 1994; Phalen *et al.*, 1990; Takeshita *et al.*, 1986).

2. *Estrogen-Induced Hypercalcemia*

Estrogen-induced (pseudo)hypercalcemia may be seen in various avian species related to egg laying. About 4 days before female pigeons are due to ovulate, tCa rises from a normal value of about 2.2 mmol/L to a value of over 5.0 mmol/L at the time of ovulation. This rise in Ca is caused by an increase in the protein-bound Ca resulting from the estrogen-induced transport of yolk proteins to the ovary as Ca complexes, whereby the concentration of iCa remains constant (Simkiss, 1967). Because tCa is the sum of biologically active iCa, protein-bound Ca, and Ca chelated to anions, tCa should always be interpreted in conjunction with plasma proteins. When reference values for iCa are available for the species under consideration, determination of iCa is the method of choice (see Section VIII.A).

3. *Primary Hyperparathyroidism*

Primary hyperparathyroidism may result from hyperplasia, adenoma, or carcinoma of the parathyroid gland (Lumeij, 1994c). Although tumors of the parathyroid gland do occur in avian species, primary hyperparathyroidism has not been documented.

4. *Pseudohyperparathyroidism*

Pseudohyperparathyroidism occurs when nonendocrine tumors secrete hormone-like substances that cause hypercalcemia. This phenomenon may be seen, for instance, in malignant lymphoma. Hypercalcemia was reported in two Amazon parrots (*Amazona* spp.) associated with lymphocytic leucosis (de Wit *et al.*, 2003). Although a paraneoplastic syndrome was suggested, this was not convincingly demonstrated, and hyperproteinemia may have been the reason for elevated tCa in these cases.

5. *Tertiary Hyperparathyroidism*

Tertiary hyperparathyroidism might develop after prolonged nutritionally secondary hyperparathyroidism, where the chronically stimulated hyperplastic gland may develop an adenoma (Lumeij, 1994c). In contrast to secondary hyperparathyroidism, where the increased activity of the parathyroid is a consequence of hypocalcemia, tertiary hyperparathyroidism is associated with hypercalcemia.

6. *Calcium and Vitamin D_3 Toxicity*

Oversupplementation of the diet with calcium and vitamin D_3 is the most common cause of true hypercalcemia in birds.

Vitamin D_3 (1,25-dihydroxycholecalciferol) regulates the absorption of calcium by the gut (Lumeij, 1994c). Birds can synthesize vitamin D in their skin from 7-dehydrocholesterol and therefore only need dietary vitamin D_3 when they lack ultraviolet light (Lumeij, 1994c; Nott and Taylor, 1993). One can easily oversupplement a bird's diet because most commercial diets contain abundant vitamin D_3 (Dumonceaux and Harrison, 1994; Macwhirter, 1994). Vitamin D3 is considered to be in the toxic range at 4 to 10 times the recommended dose (Brue, 1994). Avian species that have been reported to be susceptible to hypervitaminosis D_3 are the macaw, cockatoo, African grey parrot, toucan, dove, and cardinal (Phalen *et al.*, 1990; Takeshita *et al.*, 1986; Dumonceaux and Harrison, 1994; Lumeij, 1994b). In literature on hypervitaminosis D in birds, there seldom is discrimination between vitamin D_3 and D_2. Because vitamin D_2 (ergocalciferol) is 30 times less active than vitamin D_3 (Nott and Taylor, 1993), an excess of vitamin D_3 occurs most easily. When amounts of vitamin D are expressed in international chicken units (ICU), they refer to vitamin D_3. The baby macaws described by Takeshita *et al.* (1986) showed symptoms when fed a diet containing 1000 to 4000 ICU vitamin D_3/kg. Other workers reported that toxic effects will appear when the birds are fed a diet containing more than 2500 ICU vitamin D_3/kg diet (Brue, 1994; Harrison, 1991). The diet of the two birds reported by De Wit *et al.* (2003) contained more than 25,000 ICU vitamin D_3/kg.

Recommended calcium concentrations for maintenance in avian diets are 5 to 10 g/kg. A level of 30 g calcium/kg diet will result in toxicity (Shane *et al.*, 1969). A high calcium intake alone can cause calcifications in the kidneys (Macwhirter, 1994). Nutritional errors can be prevented by the use of balanced commercial diets.

C. Physiological Marrow Ossification

Physiological marrow ossification is induced by the combined effects of estrogens and androgens and can be observed at about the same time as the estrogen-induced hypercalcemia in female birds (Simkiss, 1967). There is a large increase in the quantities of Ca and P, which are retained from the diet and laid down as medullary bone. This medullary bone may completely fill the marrow spaces of the long bones. It is most clearly seen in the limb bones but occurs in most parts of the skeleton. This period of bone

deposition coincides with increased osteoblastic activity. When the bird starts to secrete the eggshell the medullary bone is resorbed by osteoclastic activity. Ca is deposited in the eggshell as Ca-carbonate and the P is excreted from the body. Medullary bone might be mistaken for a pathological condition when radiographs are being evaluated.

D. Hypocalcemia Syndrome in African Grey Parrots

In birds of prey and African grey parrots a hypocalcemia syndrome is known, characterized by hypocalcemic seizures. A striking feature of this syndrome in African grey parrots, which is not known in other birds, is that demineralization of the skeleton is not obvious at the moment the seizures occur. The hypocalcemia syndrome is an important differential diagnosis in an African grey parrot that repeatedly falls of its perch. Reference values for tCa concentrations in African grey parrots range from 2.0 to 3.25 mmol/L (Rosskopf *et al*., 1982). Lumeij (1990), studying a population of 72 African grey parrots found reference values of 2.1 to 2.6 mmol/L (inner limits of the percentiles $P_{2.5}$ to $P_{97.5}$, with a probability of 90%) and a range from 2.0 to 3.4 mmol/L. Hochleithner (1989b), studying 68 African grey parrots and using a dry chemistry system (Kodak Ektachem), reported reference values for Ca of 1.75 to 2.38 mmol/L (inner limits of the percentiles $P_{2.5}$ to $P_{97.5}$). Hochleithner (1989a) reported five cases of hypocalcemia in African grey parrots with plasma calcium concentrations ranging from 0.75 to 1.5 mmol/L. Rosskopf *et al*. (1985) stated that the one consistent finding of the hypocalcemia syndrome is a "blood calcium level" below 1.5 mmol/L. Values as low as 0.6 mmol/L have been reported (Rosskopf *et al*., 1985). When borderline calcium concentrations are found, the correction formula reported in Section VIII.A should be used. Stanford (2005) reported that 5/19 cases of hypocalcaemia in African grey parrots as diagnosed by low iCa concentrations had normal tCa concentrations and therefore concluded that measurement of iCa concentration is vital to diagnose hypocalcaemia. This conclusion, however, was not supported by data on corrected tCa. With the current availability of ion selective electrodes, however, measurement of iCa seems to be the practical way of evaluating Ca status in birds. When timely treatment with parenteral Ca and vitamin D_3 preparations starts and sufficient dietary uptake of Ca is taken care of, clinical signs will regress in a short time. It is therefore likely that the disease is caused by Ca and vitamin D_3 deficiency. The higher incidence of the hypocalcaemia syndrome in African grey parrots might be related to the relatively higher dependence on ultraviolet light in this species (Stanford, 2005, p. 136).

E. Alkaline Phosphatase in Bone Disease

Alkaline phosphatases (APs) form a group of membrane-bound glycoproteins that hydrolyze monophosphate esters at alkaline pH. Three different isoenzymes have been identified. Although there is a significant activity of AP in various tissues, the physiological role is unclear, except for AP in bone tissue. AP activity in bone reflects the activity of osteoblasts, and this enzyme is involved in the formation and mineralization of the bone matrix. In humans, increased AP activity is observed during growth and in osteoproliferative disorders (Savova and Kirev, 1992).

Different techniques have been used to identify fractions responsible for increased plasma activities. The heat inactivation test has been developed to distinguish AP activity of bone origin from that of liver origin (Johnson *et al*., 1972; Posen *et al*., 1965). In humans, residual activities after heat inactivation at 56°C higher than 35% indicate hepatic disease, whereas residual values lower than 25% indicate bone disease with increased osteoblastic activity (Fennely *et al*., 1969; Fitzgerald *et al*., 1969; Stolbach, 1969). Using a guinea fowl model with bone tumors induced by osteopetrosis virus, Savova and Kirev (1992) were able to confirm these findings also for an avian species. They showed, by comparing the findings with the more sensitive wheat germ lectin method (Brixen *et al*., 1989; Rosalki and Foo, 1984), that for guinea fowl the AP activity of bone origin can be inactivated at 58°C rather than 56°C. Savova and Kirev (1992) found that AP activity of bone origin in 15-week-old guinea fowl was twice as high as that of 1-year-old birds. They also confirmed the positive correlation between the intensity of virus-induced excessive bone growth and serum AP activity reported previously by Sanger *et al*. (1986) and Barnes and Smith (1977). The presumed high proportion of AP of bone origin was supported by the low values of residual activity after heat inactivation at 58°C (14.7±3.7%) and after precipitation with wheat germ lectin (13±1.2%) during the period of active bone tumor formation (Savova and Kirev, 1992).

IX. DIABETES MELLITUS AND PLASMA GLUCOSE

The basic metabolic regulation of glucose metabolism in birds is identical to that in mammals, but there is a quantitative difference. Reference values for plasma glucose in birds range somewhere between 11 and 25 mmol/L (Lumeij and Overduin, 1990; Rosskopf *et al*., 1982). Physiological values up to 33 mmol/L have been observed postprandially in pigeons (Lumeij, 1987b). As a result of stress, plasma glucose concentrations up to 33 mmol/L may also be observed (Jenkins, 1994). The insulin content of the pancreas of granivorous birds is about one-sixth that of mammalian pancreata, whereas the glucagon content is about two to five times greater. Circulating plasma concentrations of glucagon (1 to 4 ng/ml) are 10 to 50 times higher in birds than in mammals. Insulin is synthesized in the B cells of the pancreas, whereas glucagon is synthesized in the A cells.

Spontaneous diabetes mellitus, as characterized by polyuria/polydipsia (PU/PD), glucosuria, persistent hyperglycemia, and loss of weight despite good appetite, has been reported in a number of avian species, including budgerigars, cockatiels, an Amazon parrot, an African grey parrot, toco toucans, a red-tailed hawk, and the pigeon (Altman and Kirmayer 1976; Candeletta *et al*., 1993; Lothrop *et al*., 1986; Lumeij 1994c; Murphey, 1992b; Schlumberger 1956; Spira, 1981; Wallner-Pendleton *et al*., 1993; Wiesner, 1971; Woerpel *et al*., 1987).

The species that will be most commonly encountered in clinical avian practice are budgerigars, cockatiels, and toco toucans. A tentative diagnosis can be made by finding glucose in the urine using a test strip (Testape, Eli-Lilly Benelux NV, Amsterdam), whereas a definitive diagnosis can be made by finding an elevated plasma glucose concentration. PU/PD accompanied by glucosuria does not always indicate diabetes mellitus. Diabetes mellitus can only be diagnosed if elevated plasma glucose concentrations have been demonstrated.

In mammals, Fanconi's syndrome is known, characterized by renal glucosuria, hyperaminoaciduria, and hyperphosphaturia, as well as renal loss of potassium, bicarbonate and water, and other substances conserved by the proximal tubule. Fanconi's syndrome should be considered as the final result of any one of many possible primary insults to proximal tubular function. The patient's symptoms reflect the disturbance of tubular function, in addition to the primary cause of the syndrome. The syndrome may be inherited or acquired.

There are some striking differences between birds and mammals with regard to pancreatic control of carbohydrate metabolism. In mammals, pancreatectomy results in diabetes mellitus. Reported effects of pancreatectomy in birds are controversial. However, the more recent experiments performed on granivorous birds indicate that surgical extirpation or destruction of the pancreas with cytotoxic agents leads to hypoglycemic crisis and death. The few reported pancreatectomies performed on carnivorous birds have always led to diabetes mellitus. It is generally accepted that glucagon is more effective in granivorous birds, which exhibit a marked insulin insensitivity. The limited data available on spontaneous diabetes mellitus in granivorous birds suggest that in these species diabetes mellitus is not caused by an insulin deficiency. Birds of prey may be much more insulin dependent.

Spontaneous diabetes mellitus in birds has been reported to be successfully treated with daily injections of insulin in dosages comparable to doses used in dogs. These successful treatments of diabetic birds (disappearance of clinical signs) are surprising, considering the relative insulin insensitivity that has been reported to occur in a variety of avian species.

Plasma insulin and glucagon concentrations have been established in three birds with hyperglycemia (Lothrop *et al*., 1986). In all cases, insulin concentrations were similar to those of controls, whereas glucagon concentrations, on the other hand, were extremely high or extremely low. In another case of diabetes mellitus (DM) in an African grey parrot, Candeletta *et al.* (1993) reported extremely low insulin concentrations. It is not clear whether these determinations were accurate. The findings, however, suggest that different etiologies were likely to be involved.

Speculations on possible etiologies of diabetes mellitus in birds have been discussed (Lumeij, 1994c).

X. EXOCRINE PANCREATIC DISEASE

Exocrine pancreatic hormones that are present in the duodenum of birds include amylase, lipase, trypsin, and chymotrypsin. They facilitate degradation of carbohydrates, fats, and proteins, respectively. The inactive precursors of trypsin and chymotrypsin, trypsinogen, and chymotrypsinogen enter the duodenum, where they are activated by intestinal enterokinase. This mechanism prevents autodigestion of pancreatic tissue (Duke, 1986).

There are two basic manifestations of exocrine pancreatic hormone disorders: (1) acute pancreatitis or acute pancreatic necrosis, and (2) chronic pancreatitis resulting in pancreatic fibrosis and pancreatic exocrine insufficiency.

The pathogenesis of acute pancreatitis involves the activation of pancreatic enzymes in and around the pancreas and bloodstream, resulting in coagulation necrosis of the pancreas and necrosis and hemorrhage of peripancreatic and peritoneal adipose tissue. Increased amylase and lipase activities in plasma have been reported from birds with active pancreatitis.

Reference values for plasma lipase and amylase have been established in a population of 87 African grey parrots (Van der Horst and Lumeij, unpublished observations). α-Amylase activity in plasma was determined with a kinetic *p*-nitrophenylmaltoheptaoside method (Sopachem α-Amylase kit # 003-0311-00 Sopar-biochem, 1080 Brussels) at 30°C. Values ranged from 571 to 1987 U/L (inner limits of $P_{2.5}$ to $P_{97.5}$ with a probability of 90%).

Lipase activity was measured at 30° C using a test based on the conversion of triolein by lipase to monoglyceride and oleic acid. The associated decreased turbidity was measured in the UV range (Boehringer Mannheim kit # MPR 3-1442651). Reference values ranged from 268 to 1161 U/L.

Hochleithner (1989b) reported reference values for plasma amylase in four different psittacine species using a dry chemistry system (Kodak Ektachem, Amylopectin, 25°C; Kodak Company, 1986). The values were considerably lower as compared to the ones just discussed: budgerigar ($n = 50$) 187 to 585 U/L, African grey parrot ($n = 68$) 211 to 519 U/L, Amazon parrot ($n = 30$) 106 to 524 U/L, and macaw 276 to 594 U/L.

In racing pigeons ($n = 24$), plasma amylase and lipase activities were determined with a Synchron CX chemistry analyzer (Beckman Coulter, Mijdrecht, The Netherlands) with reagents provided by the manufacturer. Lipase was measured by a time enzymatic rate method. Briefly, 1–2 diglyceride substrate is hydrolyzed by pancreatic lipase to 2-monoglyceride and fatty acid. The change of absorbance at 560 nm because of formation of the red quinone dimine dye after four consecutive chemical reactions is directly proportional to lipase activity. Amylase was measured by the rate of formation of maltose from maltotetraose through three coupled reactions. The change of absorbance at 340 nm is directly proportional to amylase activity. Reference values (inner limits of $P_{2.5}$ and $P_{97.5}$ with a probability of 90%) for plasma amylase and lipase activities in pigeons were 382 to 556 IU/L and 0 to 5 IU/L, respectively (Amann *et al.,* 2006).

Chronic pancreatitis may results in fibrosis and decreased production of pancreatic hormones. When insufficient pancreatic enzymes are available in the duodenum, maldigestion and passing of feces with excessive amylum and fat will occur. Affected animals have voluminous, pale, or tan greasy feces. Fat can be demonstrated by Sudan staining.

Fecal amylase and proteolytic activity were determined in African grey parrots ($n = 87$) by Van der Horst and Lumeij (unpublished observations), using radial enzyme diffusion as reported by Westermarck and Sandholm (1980). Reference values (inner limits of $P_{2.5}$ to $P_{97.5}$ with a probability of 90%) for fecal amylase were 6 to 18 mm and for fecal trypsin 14 to 19 mm. In racing pigeons ($n = 24$), these values were 13 to 16 mm and 11 to 14 mm, respectively (Amann *et al*., 2006). In a clinical case of exocrine pancreatic insufficiency in a racing pigeon, which was histologically confirmed at postmortem examination, values for fecal amylase and proteolytic activity were 0 and 2 mm, respectively, whereas plasma amylase and lipase activities were within the reference limits (Amann *et al.*, 2006).

XI. TOXICOLOGY

A. Lead

Lead (Pb) poisoning is common in birds (Dumonceaux and Harrison, 1994; Lumeij 1985b). A clinical diagnosis can be made by demonstrating elevated Pb concentrations in whole blood or by demonstrating secondary effects of Pb on various enzymes involved in heme synthesis. Blood Pb concentrations in clinically normal birds and in birds with signs of Pb poisoning can be much higher than in mammals (Lumeij, 1985b). Blood Pb in birds without clinical signs and without known exposure to Pb ranged between 2.5 and 180 μg/dl (100 μg/dl = 4.8 μmmol/L). Birds that had been exposed to Pb but showed no clinical signs had Pb concentrations ranging between 40 and 2000 μg/dl, whereas birds with clinical signs had blood Pb concentrations ranging from 52 to 5840 μg/dl. Dieter (1979) proposed that a blood Pb concentration of 20 μg/dl was physiologically detrimental in canvasback ducks, *Aythya valisaneria,* because a significant inhibition of δ-aminolevulinic acid dehydratase (ALA-D) activity, was observed at these Pb concentrations. The U.S. Fish and Wildlife Service (1986) accepted that blood Pb concentrations >20 μg/dl in 5% of hunter-killed or live-trapped waterfowl indicate that some type of Pb has been assimilated in tissues (U.S. Federal Register 29673, August 20, 1986). Draury *et al*. (1993) used the terms "detrimental" and "deleterious" in association with blood Pb of 20 μg/dl. Although a blood Pb of 20 μg/dl indicates increased exposure to Pb these values are not considered harmful to animals. The current clinical view is that blood Pb > 50 μg/dl (>2.4 μmol/L) is generally not associated with clinical signs and has a good prognosis, even without treatment. Lead between 50 and 100 μg/dl is associated with mild clinical signs and carries a good prognosis for recovery with treatment. Clinical signs and prognosis worsen when blood Pb exceeds 100 μg/dl. When concentrations exceed 200 μg/dl, the prognosis is guarded to poor (Degernes, 1995). When clinical signs are present, blood Pb > 35 μg/dl suggests of Pb toxicosis (Klein and Galey, 1989). In psittacines, blood Pb levels as low as 20 μg/dl are considered suggestive for Pb exposure (Dumonceaux and Harrison, 1994).

Most of the Pb in whole blood is associated with the red blood cells (Buggiani and Rindi, 1980). The nuclear inclusions which have been observed by electron microscopy in nucleated erythrocytes of pigeons with high blood Pb concentrations have led to the assumption that these could serve as storage sites, just like the Pb inclusion bodies that have been described in kidneys from Pb-poisoned rats. The capacity of birds to survive high blood Pb concentrations without overt toxicosis might be associated with these erythrocytic inclusion bodies (Barthalmus *et al*., 1977).

Lead interferes with two enzymes in the hemoglobin biosynthetic pathway: δ-aminolevulinic acid dehydratase (ALA-D) and heme synthetase (Fig. 28-19). In humans, ALA-D inhibition occurs even at normal blood Pb levels (McIntire *et al*., 1973). When there is an increase in Pb, ALA-D is uniformly low. A level > 600 IU/dl excludes Pb poisoning (Beeson *et al*., 1979). A significant negative correlation exists between blood Pb and ALA-D in pigeons, urban-dwelling humans, urban rats, and Pb dosed wildfowl, as long as the blood Pb concentrations are moderately elevated. If the blood Pb increases above a moderate level blood, ALA-D activity fails to decrease further. This has been observed in pigeons and humans (Hutton, 1980). The inhibition of ALA-D leads to accumulation of δ-aminolevulinic acid (ALA) and excessive amounts of ALA are excreted in the urine.

Because Pb inhibits heme synthetase, protoporphyrin IX also accumulates in the erythrocytes. In human Pb poisoning, free erythrocyte protoporphyrin (FEPP) is found in the range of 300 to 3000 μg/dl (reference range 15 to 60 μg/dl). If a fresh wet film of blood of a patient is examined under UV

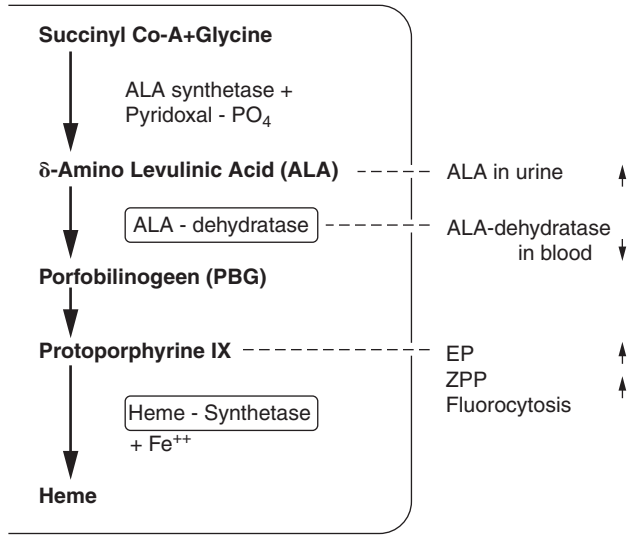

FIGURE 28-19 Schematic representation of heme synthesis. Lead interferes with the enzyme δ-aminolevulinic acid dehydratase (ALA-D), resulting in a lower activity of ALA-D in blood and a higher concentration of δ-aminolevulinic acid in the urine. Interference with the enzyme heme synthetase leads to an accumulation of protoporphyrin IX in the erythrocytes, which can be measured as FEPP or ZPP and leads to fluorocytosis. Reprinted with permission from Lumeij (1985b).

TABLE 28-4 Blood Protoporphyrin IX Concentrations Measured on the Hematofluorometer and Corresponding Clinical Signs of Pb Poisoning in Mallard Ducks

Blood Protoporphyrin IX	Clinical Signs
>801 μg/dl (14.4 μmol/L)	Death Inability to stand, walk, fly Loss of voice Green watery diarrhea
501–800 μg/dl (9.0–14.4 μmol/L)	Muscular weakness Easily fatigued Unsteady gait Slight tail drop Green watery diarrhea
201–500 μg/dl (3.6–9.0 μmol/L)	Hyperexcitability Green watery diarrhea
40–200 μg/dl (0.7–3.6 μmol/L)	Green watery diarrhea
0–39 μg/dl 0–0.7 μmol/L	No evidence of Pb poisoning

From Roscoe et al. (1979).

light (400 nm), 75% to 100% of the erythrocytes show a red fluorescence: fluorocytes. The accumulated protoporphyrin imparts the red fluorescence to fluorocytes (Beeson *et al*., 1979). The fluorocyte test has also been used successfully for the diagnosis of Pb poisoning in rabbits (Roscoe *et al*., 1975) and waterfowl (Barret and Karstad, 1971).

In humans, FEPP binds to zinc to form the fluorescent compound zinc protoporphyrin (ZPP), which can be measured fluorometrically in a single drop of whole blood (Roscoe *et al*., 1979). Roscoe *et al*. (1979) found that blood fluorescence spectra of Pb-poisoned mallards scanned on a fluorescence spectrophotometer were characteristic of metal-free protoporphyrin IX. They suggested that the reason for chelation of zinc by FEPP in human erythrocytes and not in duck erythrocytes might be due in part to the fact that duck erythrocytes contained only about one-third as much zinc as the human erythrocytes. By changing the factory-installed emission filter in a commercially available fluorometer used to screen humans for Pb intoxication by measurement of ZPP, they made the instrument suitable to measure FEPP. They found that FEPP concentrations were at their highest 8 days after Pb-shot ingestion in mallard ducks. The highest value they recorded was 2284 μg/dl. FEPP was rarely elevated (>40 μg/dl) in freshly drawn blood from Pb-poisoned ducks. However, when the same blood was oxygenated and refrigerated before testing, FEPP concentrations increased because of *in vitro* synthesis, which terminated within 2 days. No such increase was manifested by controls. They found that FEPP concentrations were related to the clinical signs of Pb poisoning in mallard ducks, and those with FEPP higher than 500 μg/dl began to show impaired motor function that could seriously affect their survival (Table 28-4).

In raptors, birds showing clinical signs of Pb toxicosis had consistently higher ZPP levels than other Pb-dosed birds with similar blood Pb values (Reiser and Temple, 1981). False-positive FEPP and ZPP elevations occur in humans with iron deficiency anemia or erythrocytic protoporphyria (Wijngaarden and Smith, 1982).

B. Zinc

Zinc poisoning has been reported in birds after ingesting (United States) pennies minted after 1983 (98% zinc) or metal fence clips (96% zinc). Galvanized wire is another well-known source of zinc poisoning in aviary birds (new wire disease). Clinical signs include weight loss, depression, anorexia, gastrointestinal signs, and posterior paresis. Pathological lesions are especially seen in the pancreas and include acinar atrophy and proliferation of pancreatic ductules (Howard, 1992; Labonde 1995; Lloyd, 1992; Morris, 1985; Reece, 1986; Wight *et al*., 1986; Zdziarski *et al*., 1994).

Serum zinc concentrations can be used to establish a diagnosis, but extreme care must be taken to exclude contamination from zinc containing grommets from plastic syringes or rubber stoppers from collecting tubes (Minnick *et al*., 1982). Serum zinc concentrations in an affected group of ducks were 1260 to 1660 μg/dl. Values in a reference

group ranged between 184 and 465μg/dl. In a group of normal cockatiels, the mean serum zinc concentration was 163μg/dl. It has been stated that in general blood zinc concentrations $>$1000μg/dl ($>$150μmol/L) are considered diagnostic and $>$200μg/dl ($>$30μmol/L) suggest zinc poisoning in psittacine birds (Labonde, 1995).

C. Organophosphate and Carbamate

Organophosphates (OPs) and carbamates (CBMs) are the most common causes of avian insecticide poisoning. Poisoning occurs through inhalation or ingestion. The mechanism of OP and CBM poisoning is acetylcholinesterase (AChE) inhibition. The LD-50 of this group of poisons is 10 to 20 times higher in birds than in mammals. Binding of CBM to AChE is reversible as opposed to OP. Clinical signs include acute anorexia, crop stasis, ptyalism, ataxia, wing twitching, star gazing, weakness, diarrhea, prolapsed nictitans, and muscular tremors or stiffness. Dyspnea and bradycardia may be observed as the toxicity progresses. In severe cases, the birds may be recumbent with varying degrees of paralysis or seizures. An organophosphorus ester-induced delayed neuropathy has been reported in mammals and birds. The onset occurs 1 to 3 weeks after exposure and is not associated with plasma cholinesterase (ChE) inhibition. With aging of some OP compounds, a metabolite can affect peripheral axons and myelin sheaths, resulting in sensory and motor neuropathy. Associated clinical signs include weakness, ataxia, and decreased proprioception in the limbs progressing to paralysis (LaBonde, 1992, 1995; Lumeij *et al*., 1993b; Porter, 1993).

Diagnosis of OP or CBM poisoning can be established by AChE activity in blood, plasma, or serum. There are a number of different test procedures, of which the results are not interchangeable. Besides AChE, another compound called pseudocholinesterase or butyrylcholinesterase (BChE, EC 3.1.1.8.) is found in sera. Although its physiological role has not been well defined, it is a useful indicator of exposure to OP and CBM compounds (Ludke *et al*., 1975; Sherman *et al*., 1964).

Because plasma BChE activity increases with age in nestling passerines, this might partially account for decreasing sensitivity in older birds to OP and CBM poisoning. Plasma BChE usually is inhibited more rapidly and to a larger degree than brain AChE and may be scavenging the active oxon forms of OP compounds that otherwise might inhibit brain AChE activity. Because of the lack of OP hydrolyzing enzymes in the plasma of many bird species or the low affinity of this class of enzymes for OP compounds in birds, the role of BChE in protecting individuals becomes important (Gard and Hooper, 1993).

It is important that results of ChE, AChE, or BChE determinations are compared with results of samples from nonexposed animals of the same species and age. Age-dependent changes in plasma ChE activities have been reported for many avian species. Furthermore, development patterns of plasma ChE differ between altricial and precocial species. In contrast to plasma BChE activities in nestlings of altricial species, plasma AChE and BChE activity decreased significantly with age in precocial species (Bennet and Bennet, 1991; Gard and Hooper, 1993).

Samples from cases of suspected CBM toxicity may show normal ChE activities because of rapid regeneration, and therefore these samples should be run as soon as possible to be accurate. Because CBMs are reversible ChE inhibitors in contrast to OP compounds, ChE inhibition followed by thermal reactivation has been employed to discriminate between these poisonings (Hunt and Hooper 1993; Hunt *et al*., 1993, 1995; Stansley, 1993).

Roy *et al.* (2005), after studying 729 European raptors of 20 species, reported age- and sex-related differences in ChE activities and found a negative correlation between ChE activity and body mass. They reported baseline values for these raptor species to evaluate the effect of anticholinesterase insecticides in the field.

XII. BLOOD COAGULATION

A. Introduction

Hemostatic disorders in birds have received less attention than those in mammals, but they can be considered clinically relevant. Although the knowledge of avian bleeding disorders lags behind that of mammals, it was already in 1929 in chickens that the role of vitamin K in blood coagulation was discovered in (Dam, 1935). Currently avian hemostasis research is still in its infancy, and the pathophysiology of many clinically intriguing bleeding disorders, such as the conure bleeding syndrome, awaits further clarification. Although blood coagulation in birds was addressed extensively in textbooks of avian physiology more than 30 years ago (e.g., Sturkie and Grimminger, 1976), inclusion of separate chapters on avian coagulation in clinical textbooks was only initiated at the beginning of this century (Espada, 2000; Powers, 2000). A brief synopsis of avian coagulation will be presented here, followed by diagnostic tests and a brief description of some known coagulation disorders.

B. Normal Hemostasis in Birds

When the vascular integrity in birds is disrupted, there are several mechanisms that prevent blood loss from the circulation, which are similar to those in mammals. In response to small vascular defects, thrombocytes aggregate to form a vascular plug. In larger defects, vasoconstriction reduces blood flow to the area and the blood starts to clot. Briefly, coagulation is a cascade of proteolytic reactions initiated through an extrinsic or intrinsic pathway and ending in a common pathway of which the end product is a solid fibrin plug.

Coagulation in birds is thought to be mainly initiated through the extrinsic pathway by the release of tissue thromboplastin (factor III) after vascular injury. Five proteases (factors VII, IX, X, protein C, and prothrombin) act with two cofactors (factors V and VII), Ca^{2+}, and phospholipids to form thrombin (factor IIa) from prothrombin (factor II), followed by the formation of fibrin (factor Ia) from fibrinogen (factor I).

The existence of an intrinsic pathway in birds (involving factors XII, XI, IX), which is initiated by the exposure to vascular subendothelium, is controversial. Although the intrinsic pathway is generally considered to be unimportant, Doerr and Hamilton (1981) did provide some evidence for the existence of such a pathway in chickens.

C. Diagnostic Tests

1. Sample Collection

Blood samples for coagulation studies in birds should be collected in plastic or siliconized tubes containing 3.8% sodium citrate. Samples should be fresh as freezing and thawing may interfere with the results. The principle of various tests is that clotting in the blood sample is inhibited by the binding of calcium by sodium citrate, and the presence of sufficient coagulation factors is examined by establishing the clotting time after the addition of calcium chloride and the missing factor. In the prothrombin test, where the extrinsic and common pathways are evaluated, tissue thromboplastin is added to initiate the clotting cascade (discussed later).

2. Whole Blood Clotting Time

The whole blood clotting time (WBCT), which evaluates the intrinsic and common coagulation pathways, should be performed in samples collected in nonsiliconized glass tubes or capillary tubes (discussed later), whereby contact with tissue thromboplastin should be avoided. Excessive contamination with tissue juices will reduce the WBCT considerably.

3. Blood Smears for Thrombocyte Counts

In birds in which there is a clinical suspicion of a coagulation disorder, a thrombocyte count should be estimated from a peripheral blood smear. The best-quality blood smears for an estimated thrombocyte count can be obtained from whole fresh blood without an anticoagulant, using the two-slide wedge technique with bevel-edged microscope slides.

Avian thrombocytes are oval nucleated cells that are smaller and more rounded than avian erythrocytes. Because thrombocytes tend to clump in a peripheral blood smear, an actual thrombocyte count is difficult. In normal birds, one or two thrombocytes are expected to be seen in an average monolayer oil immersion field. The estimated number of thrombocytes in a bird with a normal hematocrit is equal to the average number of thrombocytes in five monolayer fields multiplied by 3500 and should normally range between 20,000 and 30,000/ul.

4. Prothrombine Time

The single most useful coagulation test in birds is establishment of the prothrombine time (PT) or tissue thromboplastin time. PT is a measure of the extrinsic and common coagulation pathways. It should be stressed that PT in birds should be performed with homologous brain thromboplastin, as PT significantly increases when heterologous avian or even mammalian thromboplastin is used. The use of the PT in birds has been considered inconvenient because of the unavailability of species-specific brain thromboplastin. Reportedly, commercially available Russels's viper venom (RVV) may be used instead of homologous brain thromboplastin (Powers, 2000). PT times using RVV are considerably shorter compared to those using mammalian brain thromboplastin, but they are longer than those using a homologous brain thromboplastin (Timms, 1977). Details of performing a prothrombin test in chickens have been reported by Doerr *et al.* (1975).

5. Modified Russels's Viper Venom Test (MRVVT)

Russels's viper venom, in the presence of Ca^{2+} and phospholipids, is a powerful coagulant of normal plasma and plasma from humans deficient in factors VII, VIII (antihemophilic factor A), and IX (antihemophilic factor B, Christmas factor). It is an activator of the common coagulation pathway by activation of factor X. In humans with factor V or X deficiency, the RVVT is prolonged. The conventional RVVT cannot be used in birds because the phospholipids in the rabbit-brain cephalin inhibits coagulation in the presence of raw RVV. However, use of purified factor X activating enzyme (RVV-X) eliminates this interference. It has been shown that experimental infection of turkeys with *Pasteurella multocida* increases MRVVT, indicative of a consumptive coagulopathy, possibly caused by increased consumption of factors X, V, II, or I (Friedlander and Olson, 1995).

6. Fibrinogen Estimation

Fibrinogen is formed and stored in the liver and is important for the final stage of blood coagulation where it is transformed into fibrin. Plasma fibrinogen concentrations decrease when there is severe liver damage. A variety of inflammatory, suppurating, traumatic, and neoplastic diseases can increase fibrinogen concentrations in humans and domestic animals (Schalm *et al.*, 1975). Hawkey and Hart (1988) concluded that fibrinogen estimation in conjunction with a heterophil count was a useful screening test for birds to detect infections.

Fibrinogen can be measured by the micro heat-precipitation test at 56°C. This test is based on the principle that fibrinogen

will precipitate at 56°C, while the other plasma proteins remain in solution. EDTA rather than heparin should be used as an anticoagulant when this test is performed (Hawkey and Hart, 1988; Schlam *et al.*, 1975). Protein concentrations can be estimated in the plasma column of two hematocrit tubes, one of which has been placed in a water bath at 56°C to 58°C for 3 min. Fibrinogen concentration is the difference between the protein concentration of the two plasma columns (Schalm *et al*., 1975). See also Section IV.B.

Because the difference between plasma and serum is the absence of fibrinogen in the latter, it is possible to locate the fibrinogen fraction in the electrophoretic gel of a particular species by performing a comparative protein electrophoresis in serum and plasma from the same sample of this particular avian species (Roman *et al*., 2006).

D. Hemostatic Disorders

1. *Bacterial and Viral Infections*

A variety of bacterial and viral diseases in a variety of avian species have caused hemostatic disorders. Examples are circovirus and polyomavirus in psittacines. Reasons for the increased bleeding tendency seen with these infections may include thrombocytopenia, liver failure leading to a lack of clotting factors, vasculitis, and disseminated intravascular coagulation (DIC). In DIC, the chain of events is initiated by exogenous or endogenous procoagulants, which stimulate the formation of fibrin, which is followed by fibrinolysis. The combination of consumption of thrombocytes and clotting factors and the inhibition of fibrin formation by fibrin degradation products may result in consumptive coagulopathy.

2. *Vitamin K Deficiency*

Because vitamin K is essential for the formation of prothrombin and factors VII, IX and X, both the extrinsic and the common coagulation pathway is affected in vitamin K deficiency, leading to a prolonged PT in birds. Vitamin K deficiency is well known in birds and has been reported in chickens fed a diet low in fat (Dam, 1935). A syndrome resembling the disease in chickens has been reported in a pigeon with exocrine pancreatic insufficiency by Amann *et al*. (2006), supposedly because of malabsorption of the fat-soluble vitamin K. Intoxication with anticoagulant rodenticides interferes with the formation of active vitamin K and produces similar clinical effects. Clinical signs are widely reported (Powers, 2000) but depend on species, susceptibility and the type of anticoagulant used, poultry being 10-fold more sensitive than pigeons and quail (Towsend and Tarrant, 1997). History, clinical signs, prolonged PT, and toxicological investigation of gastrointestinal contents can confirm the diagnosis. It has also been suggested that Vitamin K deficiency in birds is caused by oversupplementation with vitamin E, causing a competitive inhibition of vitamin K by α-tocopherol (Nichols *et al*., 1989). A similar antagonism has been reported with the use of sulphonamides in birds (Griminger and Donis, 1960).

3. *Fatty Liver Hemorrhagic Syndrome*

It has been suggested that alterations in the composition of the phospholipids that are essential cofactors in the thrombin formation may be a contributing factor in the development of fatty liver hemorrhagic syndrome (FLHS) in laying hens (Thomson *et al.*, 2003).

4. *Aflatoxicosis*

Aflatoxins originating from Aspergillus fungi can be found on moldy feed and are a well-known cause of fatty liver degeneration and bile duct proliferation in poultry. In experimental aflatoxicosis, the increase of the PT was dependent on the aflatoxin dose. The specific activity of clotting factors I, II, V, VII, and X was reduced (Fernandez *et al*., 1995).

ACKNOWLEDGMENTS

The author is grateful to the publishers of the journals *Avian Diseases*, *Avian Pathology*, *Seminars in Avian and Exotic Pet Medicine*, and *The Veterinary Quarterly* for permission to use illustrations that were published previously in these journals and to Wingers Publishing Inc. (Lake Worth, Florida) for using material previously published in *Avian Medicine: Principles and Application* (B. W. Ritchie, G. J. Harrison, and L. R. Harrison, Eds.), 1994. The respective sources have been indicated in the text were appropriate. The critical remarks on the draft document from various diplomats of the European College of Avian Medicine and Surgery were highly appreciated: Dr. Med. Vet. Petra Zsivanovits, MRCVS; Brian Coles, BVSc, FRCVS; Brian Speer, DVM, Dip ABVP-certified in avian practice; Prof. Dr Med. Vet. Marina Krautwald-Junghanns and Frank Verstappen, DVM.

Appendix I

SI Units

The Systeme International d'Unites (SI), or the International System of Units, was recommended for use in the health professions by the World Health Assembly (WHA 30.39) in May of 1977. The SI is the culmination of more than a century of effort to develop a universally acceptable system of units of measure. Since the 1990s, the use of SI has been rapidly gaining acceptance with many nations now mandating its use and many others strongly recommending its use. Furthermore, many scientific journals now require that units be expressed in SI along with the conventional units, if used. The following tables in this appendix briefly describe the basis of SI and provide factors for the conversion of conventional units to SI.

TABLE A SI Base Units

Quantity	Name of Unit	Symbol
Length	meter (metre)	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol

TABLE B SI Derived Units

Quantity	Name of Unit	Symbol
Area	square meter	m^2
Volume	cubic meter	m^3
Speed, velocity	meter per second	m/s
Acceleration	meter per second squared	m/s^2
Substance concentration	mole per cubic meter	mol/m^3
Pressure	pascal	Pa
Work, energy	joule	J
Celsius temperature	degree Celsius	°C

TABLE C SI Prefixes

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{18}	exa	E	10^{-1}	deci	d
10^{15}	peta	P	10^{-2}	centi	c
10^{12}	tera	T	10^{-3}	milli	m
10^{9}	giga	G	10^{-6}	micro	μ
10^{6}	mega	M	10^{-9}	nano	n
10^{3}	kilo	k	10^{-12}	pico	p
10^{2}	hector	h	10^{-15}	femto	f
10^{1}	deca	da	10^{-18}	atto	a

TABLE D Non-SI Units Still in General Use

Quantity	Unit	Symbol	Value in SI
Time	minute	m	60 s
	hour	h	3,600 s
	day	d	86,400 s
Volume	liter (litre)	l[a]	$10^{-3}\,m^3$
Mass	tonne	t	1,000 kg
Length	angstrom	Å	10^{-10} m (0.1 nm)
Pressure	bar	bar	10^5 Pa
	atmosphere	atm	101,325 Pa
	mmHg	mmHg	1.333×10^{-4} Pa
Radioactivity	curie	Ci	3.7×10^{10} Bequerel(Bq)
	roentgen	R	2.58×10^{-4} Ci/kg
	rad	rad	10^{-2} gray(Gy)
	rem	rem	10^{-2} sievert(Sv)

[a] *Liter is often spelled out or symbolized by* L *to avoid confusion.*

TABLE E SI Conversion Factors

Chemical Constituent	Conventional "Old Unit"	×	Factor	=	New SI Unit
Acetoacetate	mg/dL		0.098		mmol/L
Acetone	mg/dL		0.172		mmol/L
Albumin	g/dL		10.0		g/L
Ammonia	μg/dL		0.5872		μmol/L
Bicarbonate	mEq/L		1.0		mmol/L
Bilirubin	mg/dL		17.10		μmol/L
Bromsulfophthalein	mg/dL		11.93		μmol/L
Calcium	mg/dL		0.2495		mmol/L

Enzymes[a]	U/L		16.67		nkat/L

[a] *There is yet no general agreement nor recommendation for the use of the katal (1 kat = 1 mol/s) in place of the widely used international unit (1 U = 1 μmol/m). The U/L should continue to be used for all enzyme activities.*

Conversion Factors of Some Non-SI Serum Enzyme Units to SI International Enzyme Units[a]

Serum Enzyme	Non-SI Unit	×	Factor	=	SI
Aldolase (ALD)	Sibley-Lehninger Unit (SLU) (mg DNP/hr/mL)		0.75		U/L
Amylase (AMYL)	Somogyi Unit (SU) (mg G/30 m)		1.85		U/L
Glutamic-oxalacetic Transaminase (SGOT, AST)	Sigma-Frankel Unit (SFU) Karmen Unit (KU) Wroblewski-LaDue Unit (WLU) Reitman-Frankel Unit (RFU) (0.001 OD/m/mL)		0.48		U/L
Glutamic Pyruvic Transaminase (SGPT, ALT)	Sigma-Frankel Unit (SFU) Karmen Unit (KU) Wroblewski-LaDue Unit (WLU) Reitman-Frankel Unit (RFU) (0.001 OD/m/mL)		0.48		U/L
Isocitric Dehydrogenase (ICD)	Wolfson-Williams-Ashman Unit (WWAU) (nmol/h/mL)		0.0167		U/L
Lipase	Roe-Byler Unit (RBU) (μmol/h/mL) Cherry-Crandall Unit (CCU) (50 μmol/3 h/mL)		16.7 2.77		U/ U/L
Phosphatase, acid	King-Armstrong Unit (KAU) (mg Phenyl-P/30 m)		1.85		U/L
Phosphatase, Alkaline (AlP)	King-Armstrong Unit (KAU) (mg Phenyl-P/30 m) Bodansky Unit (BU) (mg P/hr)		7.10 5.4		U/L U/L
Sorbitol (Iditol) Dehydrogenase (SDH, IDH)	Sigma-Frankel Unit (SFU) (nmol/hr/mL)		0.0167		U/L

[a] U = 1 *International Unit* = 1 $\mu mol/m$ = 16.67 *nmol/s* = 16.67 *nkatal/s* = 0.01667 μ*katal/s*.

Appendix III

Temperature Correction Factors (Tf) for Some Common Enzymes

Assay Temperature (EC)	ALP	CK	LDH	SDH	ALT/AST
20	2.61	2.05	2.10	1.48	2.29
21	2.37	1.82	1.96	1.42	1.85
22	2.15	1.70	1.80	1.37	1.71
23	1.95	1.59	1.67	1.32	1.59
24	1.77	1.49	1.55	1.27	1.45
25	1.61	1.39	1.45	1.22	1.37
26	1.46	1.31	1.33	1.17	1.29
27	1.33	1.23	1.26	1.12	1.21
28	1.21	1.15	1.16	1.08	1.12
29	1.10	1.07	1.07	1.04	1.05
30	1.00	1.00	1.00	1.00	1.00
31	0.90	0.93	0.93	0.96	0.95
32	0.81	0.87	0.86	0.93	0.89
33	0.73	0.81	0.80	0.89	0.85
34	0.66	0.75	0.74	0.85	0.80
35	0.59	0.70	0.68	0.82	0.77
36	0.53	0.65	0.64	0.79	0.73
37	0.48	0.50	0.59	0.76	0.70

Abbreviations: ALP, *alkaline phosphatase*; CK, *creatine kinase*; LDH, *lactate dehydrogenase*; SDH, *sorbitol (iditol) dehydrogenase*; ALT, *alanine aminotransferase*; AST, *aspartate aminotransferase*.

Examples of Use

A. To correct an enzyme activity to a standard temperature of 30EC, multiply the assay value at any temperature by the Tf of that temperature:

AlP activity at 27EC = 48 U/L; correct it to 30EC

$$48 \times 1.33 = 63.8 \text{ U/L}$$

B. To correct an enzyme activity at any one temperature to another temperature, multiply the assay value at the first temperature by the ratio of the Tf of the first temperature to the Tf of the second temperature:

AlP activity at 22EC = 38 U/L; correct it to 37EC

$$38 \text{ U/L} \times 2.15/0.48 = 170.2 \text{ U/L at 37EC}$$

Stability of Serum Enzymes under Various Storage Conditions[a]

Enzyme	25EC	4EC	−25EC
Acid phosphatase	4 h[b]	3 d[c]	3 d[c]
Alkaline phosphatase	2–3 d[d]	2–3 d	1 month
Aldolase	2 d	2 d	Unstable[e]
Amylase	1 month	7 months	2 months
Cholinesterase	1 wk	1 wk	1 wk
Creatine kinase	2 d	1 wk	1 month
γ-Glutamyl transferase	2 d	1 wk	1 month
Glutamate dehydrogenase	1 d	2 d	1 d
Aspartate aminotransferase	3 d	1 wk	1 month
Alanine aminotransferase	2 d	1 wk	Unstable[e]
Hydroxybutyrate dehydrogenase	Unstable	3 d	Unstable[e]
Isocitrate dehydrogenase	5 h	3 d	3 wk
Leucine aminopeptidase	1 wk	1 wk	1 wk
Lactate dehydrogenase	1 wk	1–3 d[f]	1–3 d[f]
Malate dehydrogenase	Unstable	3 d	3 d
Sorbitol (Iditol)dehydrogenase	Unstable	1 d	2 d

[a] *No more than 10% of the original activity lost during the specified time.*
[b] At *p*H 5–6.
[c] *With added citrate or acetate.*
[d] *Activity may increase.*
[e] *Enzyme does not tolerate thawing well.*
[f] *Depends on the isoenzyme profile.*

Appendix V

Temperature Conversions among Degrees Celsius, Degrees Fahrenheit, and Degrees Kelvin

$EC = 5/9 \times (EF - 32)$
$EF = (9/5 \times EC) + 32$
$EK = EC + 273.15$
$EC = EK - 273.15$
$EF = (9/5 \times EK) - 459.67$
$EK = (5/9 \times EF) + 255.37$

Nomogram for Computing Relative Centrifugal Forces (RCF)

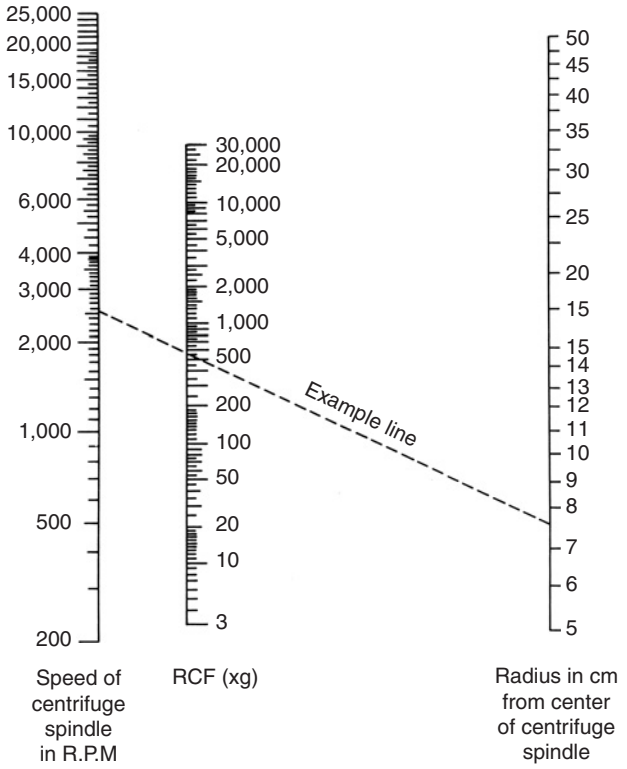

FIGURE VI-1 To calculate the RCF value at any point along the tube, measure the radius in cm from the center of the centrifuge spindle to the point. Draw a line from this radius value on the right-hand column to the centrifuge speed on the left-hand column. The RCF value is the point where the line intersects the center column. The nomogram is based on the following formula:

$$\text{RCF} = 0.00001118 \times \text{radius} \times \text{RPM}^2.$$

Appendix VII

Conversions of Body Weight to Square Meters of Body Surface Area for Dogs and Cats[a]

Kg	M^2	Kg	M^2
0.5	0.06		
1.0	0.10	26.0	0.89
2.0	0.16	27.0	0.91
3.0	0.21	28.0	0.93
4.0	0.26	29.0	0.95
5.0	0.30	30.0	0.98
6.0	0.33	31.0	1.00
7.0	0.37	32.0	1.02
8.0	0.40	33.0	1.04
9.0	0.44	34.0	1.06
10.0	0.47	35.0	1.08
11.0	0.50	36.0	1.10
12.0	0.53	37.0	1.12
13.0	0.56	38.0	1.14
14.0	0.59	39.0	1.16
15.0	0.62	40.0	1.18
16.0	0.64	41.0	1.20
17.0	0.67	42.0	1.22
18.0	0.69	43.0	1.24
19.0	0.72	44.0	1.26
20.0	0.74	45.0	1.28
21.0	0.77	46.0	1.30
22.0	0.79	47.0	1.32
23.0	0.82	48.0	1.33
24.0	0.84	49.0	1.35
25.0	0.86	50.0	1.37

[a] *Calculated from*: $A = k\ W^{0.667} \times 10^{-4}$, *where* A = *body surface area in square meters* (M^2); *k* = *constant* 10.1 *for dogs*; W = *body weight in grams*. *For cats, the constant, k, is* 10.0 *so the conversion to body surface area closely approximates that for the dog and may be used interchangeably.*

Appendix VIII Blood Analyte Reference Values in Large Animals[a]

Analyte[b]	Unit	Horse	Cow	Sheep	Goat	Llama	Pig
Acetylcholinesterase (AcChE): R	U/L	450–790	1270–2430	640	270		930
