Preface

It has been more than a decade since the publication of the fifth edition, and understandably numerous changes have come about, not the least of which are changes in authorship as well as rapid progress in the various fields of clinical scientific endeavor. First of all, we'd like to pay tribute to a number of our previous authors who have passed away since the publication of the fifth edition. Notably, they are Drs. Duane F. Brobst (Pancreas), Charles C. Capen (Calcium), Jens G. Hauge (Genetics), and Joseph E. Smith (Iron). All succumbed to cancers of various types except for Dr. Smith, who died in a tragic auto accident. Others have retired and chose not to contribute or to contribute in a secondary role. All of these authors contributed greatly to previous editions and are sorely missed as contributors at the forefront of their respective fields. It is to all these contributors that the editors of this current edition wish to dedicate this new volume. New lead authors have been identified and have contributed ably to this edition.

As in previous editions, this edition continues to promote the concept of the Systeme International d'Unites (SI units) with the hope and expectation that ultimately it may be universally accepted.

We would also like to take this opportunity to extend our heartfelt thanks to Melissa Turner and Kristi Anderson, who have ably shepherded us through the intricacies of dealing with a new publisher, Elsevier, who purchased Academic Press, the publisher for the first five editions. Our thanks also go to Julie Ochs who has ably guided us through the final steps of the printing and publication process. They have all been extremely diligent, having been almost at our beck and call for assistance, clarification, guidance, and encouragement at every step of the way. To all three of our publisher contacts, we are extremely grateful.

Finally, we must acknowledge and express our thanks to our families who have been incredibly supportive in our almost single minded effort to bring this current edition to fruition. Without their unqualified support, this work would have been most difficult to accomplish and perhaps not even possible.

J. Jerry Kaneko
John W. Harvey
Michael L. Bruss

Contributors

I. POPULATIONS AND THEIR DISTRIBUTIONS

A population is a collection of individuals or items having something in common. For example, one could say that the population of healthy dogs consists of all dogs that are free of disease. Whether a given dog belongs to the population of healthy dogs depends on someone's ability to determine if the dog is or is not free of disease. Populations may be finite or infinite in size.

A population can be described by quantifiable characteristics frequently called *observations* or *measures*. If it were possible to record an observation for all members in the population, one most likely would demonstrate that not all members of the population have the same value for the given observation. This reflects the inherent variability in populations. For a given measure, the list of possible values that can be assumed with the corresponding frequency with which each value appears in the population relative to the total number of elements in the population is referred to as the *distribution* of the measure or observation in the population. Distributions can be displayed in tabular or graphical form or summarized in mathematical expressions. Distributions are classified as discrete distributions or continuous distributions on the basis of values that the measure can assume. Measures with a continuous distribution can assume essentially an infinite number of values over some defined range of values, whereas those with a discrete distribution can assume only a relatively few values within a given range, such as only integer values.

Each population distribution can be described by quantities known as *parameters*. One set of parameters of a population distribution provides information on the center of the distribution or value(s) of the measure that seems to be assumed by a preponderance of the elements in the population. The mean, median, and mode are three members of the class of parameters describing the center of the distribution. Another class of parameters provides information on the spread of the distribution. Spread of the distribution has to do with whether most of the values that are assumed in the population are close to the center of the distribution or whether a wider range of values is assumed. The standard deviation, variance, and range are examples

of parameters that provide information on the spread of the distribution. The shape of the distribution is very important. Some distributions are symmetric about their center, whereas other distributions are asymmetric, being skewed (having a heavier tail) either to the right or to the left.

II. REFERENCE INTERVAL DETERMINATION AND USE

One task of clinicians is determining whether an animal that enters the clinic has blood and urine analyte values that are in the normal interval. The conventional method of establishing normalcy for a particular analyte is based on the assumption that the distribution of the analyte in the population of normal animals is the "normal" or Gaussian distribution. To avoid confusion resulting from the use of a single word having two different meanings, the "normal" distribution henceforth is referred to as the Gaussian distribution.

A. Gaussian Distribution

Understanding the conventional method for establishing normalcy requires an understanding of the properties of the Gaussian distribution. Theoretically, a Gaussian distribution is defined by the equation

$$y = \frac{1}{\sqrt{2\pi}\sigma} e^{-(x-\mu)^2 / 2\sigma^2}$$

where x is any value that a given measurement can assume, y is the relative frequency of x, μ is the center of the distribution, σ is the standard deviation of the distribution, π is the constant 3.1416, and e is the constant 2.7183.

Theoretically, x can take on any value from $-\infty$ to $+\infty$. Figure 1-1 gives an example of a Gaussian distribution and demonstrates that the distribution is symmetric around μ and is bell shaped. Figure 1-1 also shows that 68% of the distribution is accounted for by measurements of x that have a value within 1 standard deviation of the mean, and 95% of the distribution includes those values of x that are within 2 standard deviations of the mean. Nearly all of the distribution (97.75%) is contained by the bound of 3 standard deviations of the mean.

Most analytes cannot take on negative values and so, strictly speaking, cannot have Gaussian distributions. However, the distribution of many analyte values is approximated well by the Gaussian distribution because virtually all the values that can be assumed by the analyte are within 4 standard deviations of the mean and, for this range of values, the frequency distribution is Gaussian. Figure 1-2, adapted from the printout of MINITAB, Release 14.13,[1] gives an example of the distribution of glucose values given in Table 1-1 for a sample of 168 dogs from a presumably healthy population.

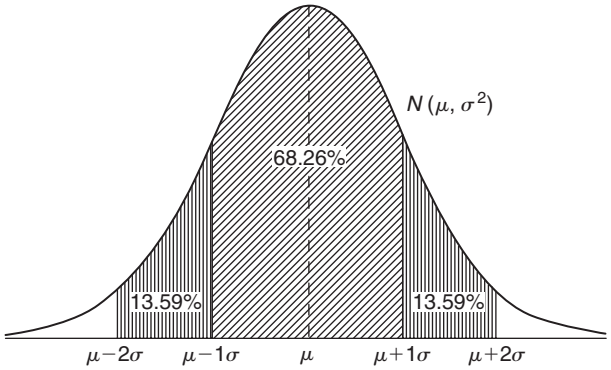

FIGURE 1-1 The Gaussian distribution.

[To produce this figure, place the glucose values for the 168 dogs in one column of a MINITAB worksheet and give the following commands:

Stat (from the main menu) → **Basic Statistics** → **Graphical Summary**

In the **Graphical Summary** dialog box, select the column of the worksheet containing the glucose values and place it in the **Variables:** box. Hit **OK**.

Though not perfectly Gaussian, the distribution is reasonably well approximated by the Gaussian distribution. Support for this claim is that the distribution has the characteristic bell shape and appears to be symmetric about the mean. Also, the mean [estimated to be 96.4mg/dl (5.34mmol/liter)] of this distribution is nearly equal to the median [estimated to be 95.0mg/dl (5.27mmol/liter)], which is characteristic of the Gaussian distribution. The estimates of the skewness and kurtosis coefficients are close to zero, also characteristic of a Gaussian distribution (Daniel, 2005; Schork and Remington, 2000; Snedecor and Cochran, 1989).

B. Evaluating Probabilities Using a Gaussian Distribution

All Gaussian distributions can be standardized to the reference Gaussian distribution, which is called the *standard*

Gaussian distribution. Standardization in general is accomplished by subtracting the center of the distribution from a given element in the distribution and dividing the result by the standard deviation of the distribution. The distribution of a standardized Gaussian distribution—that is, a Gaussian distribution that has its elements standardized in this form—has its center at zero and has a variance of unity. The elements of the standard Gaussian distribution are traditionally designated by the letter z so that it can be said that z is $N(0,1)$. That all Gaussian distributions can be transformed to the standard Gaussian distribution is convenient in that just a single table is required to summarize the probability structure of the infinite number of Gaussian distributions. Table 1-2 provides an example of such a table and gives the percentiles of the standard Gaussian distribution.

Example 1

Suppose the underlying population of elements is $N(4,16)$ and one element from this population is selected. We want to find the probability that the selected element has a value less than 3.0 or greater than 6.1. In solving this problem, the relevant distribution is specified: x is $N(4,16)$. The probability of observing $x < 3.0$ in the distribution of x is equivalent to the probability of observing $z < (3.0 - 4)/4 = -0.25$ in the standard Gaussian distribution. Going to Table 1-2, $z = 0.25$ is approximately the 60th percentile of the standard Gaussian distribution and by symmetry $z = -0.25$ is approximately the 40th percentile. Thus, the probability of observing a z value less than or equal to -0.25 is approximately 0.40. The probability of observing $x > 6.1$ is equivalent to the probability of observing $z > (6.1 - 4)/(4) = +0.525$. Table 1-2 gives the probability of observing a $z < 0.525$ as approximately 0.70, so the probability of observing a $z > 0.525$ approximately equals $1 - 0.70$ or 0.30. The desired probability of observing a sample observation less than 3.0 or greater than 6.1 is the sum of 0.40 and 0.30, which is approximately 0.7 or 7 chances in 10.

TABLE 1-2 Percentiles of the Standard Gaussian (z) Distribution[a,b]

$z_{0.50} = 0$	$z_{0.90} = 1.282$	$z_{0.975} = 1.960$
$z_{0.55} = 0.126$	$z_{0.91} = 1.341$	$z_{0.98} = 2.054$
$z_{0.60} = 0.253$	$z_{0.92} = 1.405$	$z_{0.99} = 2.326$
$z_{0.65} = 0.385$	$z_{0.93} = 1.476$	$z_{0.995} = 2.576$
$z_{0.70} = 0.524$	$z_{0.94} = 1.555$	$z_{0.999} = 3.090$
$z_{0.75} = 0.674$	$z_{0.95} = 1.645$	$z_{0.9999} = 3.719$
$z_{0.80} = 0.842$	$z_{0.96} = 1.751$	$z_{0.99999} = 4.265$
$z_{0.85} = 1.036$	$z_{0.97} = 1.881$	

[a] *This table was generated with* MINITAB *Release* 14.13 *as follows: The indicated cumulative probabilities* 0.5 *to* 0.99999 *were placed in a column of a* MINITAB *worksheet and the following commands given:* **Calc** *(from the main menu of* MINITAB) → **Probability Distributions** → **Normal Distribution**. *Within the* **Normal Distribution** *dialog box,* **Inverse cumulative probability** *was selected,* **Mean** *was set to* 0.0, **Standard deviation** *was set to* 1.0, *and the column of the worksheet containing the cumulative probabilities was selected and placed in the* **Input column**: *followed by hitting* **OK**.

[b] *Example: The 75th percentile, or the z value below, which is* 75% *of the Gaussian distribution, equals* 0.674, $z_{0.75} = 0.674$. *Percentiles smaller than the 50th percentile can be found by noting that the Gaussian distribution is symmetric about zero so that, for example,* $z_{0.30} = -0.524$.

C. Conventional Method for Determining Reference Intervals

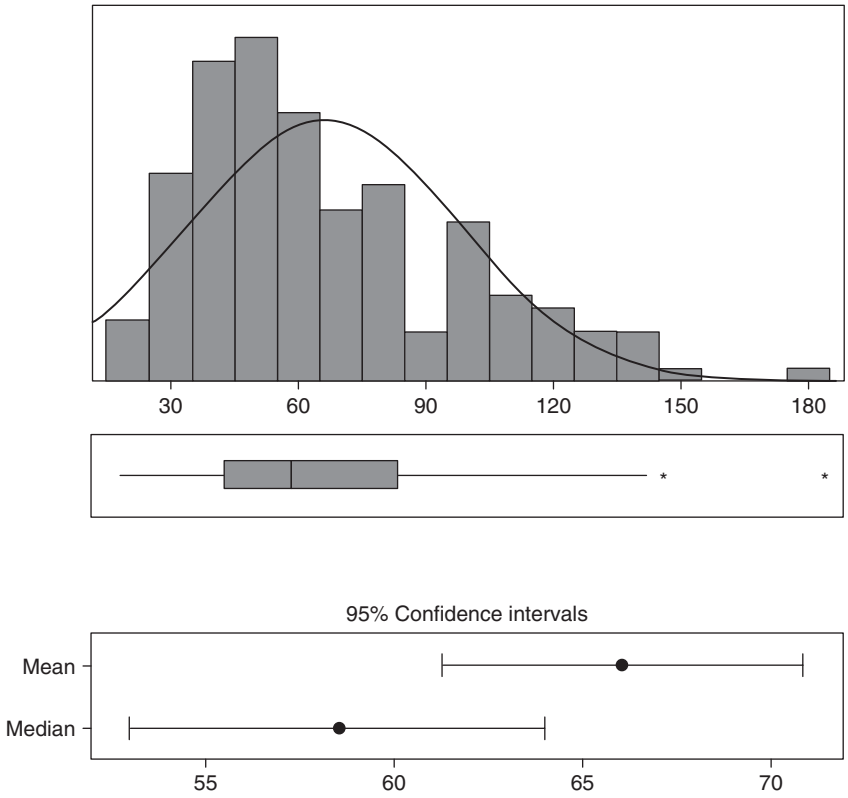
The first step in establishing a normal interval by the conventional method involves determining the mean and standard deviation of the distribution of the analyte. This can be accomplished by taking a representative sample (using a sampling design that has a random component such as simple random sampling) from the population of normal animals and computing the mean and standard deviation of the sample.

Once these estimates of μ and σ are obtained, an animal coming into the clinic in the future is classified as being normal for a particular analyte if its value for the analyte is within the bound of some multiple of the standard deviation below the mean and some multiple of the standard deviation above the mean. The multiple is determined by the degree of certainty that one desires to place on the classification scheme. For example, if the multiple chosen is 2, which is the conventional choice, any animal entering the clinic with an analyte value within 2 standard deviations of the mean would be classified as normal, whereas all animals with a value of the analyte outside this boundary would be classified as abnormal. Because 95% of the Gaussian distribution is located within 1.96 or approximately 2 standard deviations of the mean, with this classification scheme, 2.5% of the normal animals would have a value of the analyte that would be below 2 standard deviations below the mean, and 2.5% of the animals would have an analyte value above 2 standard deviations above the mean. So with this classification scheme, there is a 5% chance that a true normal animal would be classified as being abnormal. Clinicians, by choosing 2 as the multiple, are willing to designate normal animals with extreme values of a particular analyte as being abnormal as the trade-off for not accepting too many abnormal animals as normals. With this methodology, no consideration is given to the distribution of abnormal animals because in fact there would be multiple distributions corresponding to the many types of abnormalities. The assumption is that for those cases where an analyte would be useful in identification of abnormal animals, the value of the analyte would be sufficiently above or below the center of the distribution of the analyte for normal animals. The reference interval for glucose based on the distribution from the sample of 168 normal dogs is 96.42857mg/dl $\pm$ (1.96 $\times$ 14.61873mg/dl) or 67.8mg/dl (3.76mmol/liter) to 125.1mg/dl (6.94mmol/liter).

Solberg (1999) gave $1/\alpha$ as the theoretical minimum sample size for estimation of the 100α and $100(1 - \alpha)$ percentiles. Thus, a minimum of 40 animals is required to estimate the 2.5th and 97.5th percentiles but many more than 40 is recommended.

D. Methods for Determining Reference Intervals for Analytes Not Having the Gaussian Distribution

The conventional procedure for assessing normalcy works quite well provided the distribution of the analyte is approximately Gaussian. Unfortunately, for many analytes a Gaussian distribution is not a good assumption. For example, Figure 1-3 describes the distribution of alanine aminotransferase (ALT) values given in Table 1-1 for the same sample of 168 normal dogs. This distribution is visibly asymmetric. The distribution has a longer tail to the right and is said to be skewed to the right or positively skewed. The skewness value (0.93) exceeds the approximate 99th percentile of the distribution for this coefficient for random samples from a population having a Gaussian distribution. That the distribution is not symmetric and hence not Gaussian is also evidenced by the lack of agreement between the mean and median as shown in Figure 1-3. Application of the conventional procedure for computing reference intervals [$x \pm (1.96 \times \text{SD})$] reveals a reference interval of 4.4 to 127.7U/liter so that all the low values of the distribution fall above the value, which is 2 standard deviations below the mean of the distribution, and more than 2.5% of the high values fall above the value, which is 2 standard deviations above the mean. The following sections give two approaches that can be followed in such a situation to obtain reference intervals.



Anderson-Darling normality test	
A-squared	3.39
P-value <	0.005
Mean	66.042
StDev	31.447
Variance	988.902
Skewness	0.929303

FIGURE 1-3 Distribution and summary statistics for the sample of canine alanine aminotransferase values (U/liter) in Table 1-1. Printout of MINITAB, Release 14.13.

1. Use of Transformations

Frequently, some transformation (such as the logarithmic or square root transformation) of the analyte values will make the distribution more Gaussian (Kleinbaum *et al.*, 2008; Neter *et al.*, 1996; Zar, 1999). The boundaries for the reference values are two standard deviations above and below the mean for the distribution of the transformed analyte values. These boundaries then can be expressed in terms of the original analyte values by retransformation. Figure 1-4 describes the distribution of the ALT analyte values after transformation with natural logarithms. The reference boundaries in logarithmic units are equal to $4.08013 \pm (1.96 \times 0.47591)$ or (3.14734, 5.01292), which correspond to (23.3, 150.3U/liter), in the original units of the analyte.

2. Use of Percentiles

The second approach that can be followed in the situation where an assumption of a Gaussian distribution is not tenable is to choose percentiles as boundaries (Feinstein, 1977; Herrera, 1958; Mainland, 1963; Massod, 1977; Reed *et al.*, 1971; Solberg, 1999). For example, if we wanted to misclassify only 5% of normal animals as being abnormal, the 2.5th and 97.5th percentiles could be chosen as the reference boundaries. Thus, animals would be classified as abnormal when having analyte values either below the value of the analyte below which are 2.5% of all normal analyte values or above the value of the analyte below which are 97.5% of all normal analyte values. This method is attractive because percentiles are reflective of the distribution involved.

The 97.5th percentile is estimated as the value of the analyte corresponding to the $(n + 1) \times 0.975$th observation in an ascending array of the analyte values for a sample of n normal animals (Dunn and Clark, 2001; Ryan *et al.*, 2001; Snedecor and Cochran, 1989). For the ALT values from the sample of $n = 168$ animals, $(n + 1) \times 0.975 = 169 \times 0.975 = 164.775$. Because there is no 164.775th observation, the 97.5th percentile is found by interpolating between the ALT values corresponding to the 164th and 165th observation in the ascending array commonly referred to as the 164th and 165th order statistics (Ryan *et al.*, 2001; Snedecor and Cochran, 1989). The 164th order statistic is 138U/liter and the 165th order statistic is 140U/liter and the interpolation is $138 + 0.775(140 - 138) = 139.5$U/liter. The 2.5th percentile is estimated similarly as the $(n + 1) \times 0.025$th order statistic, which is the 4.225th order statistic for the sample of ALT values. In this case, the 4th and 5th order statistics are the same, 24U/liter, which is the estimate of the 2.5th percentile. Note that there is reasonable agreement between this reference interval and

that obtained using the logarithmic transformation. This method of using percentiles as reference values can also be used for analytes having a Gaussian distribution. The 2.5th and 97.5th percentiles for the sample of glucose values are 65.4mg/dl (3.63mmol/liter) and 126.3mg/dl (7.01mmol/liter), respectively. This interval agrees very well with that calculated earlier using the conventional method.

E. Sensitivity and Specificity of a Decision Based on a Reference Interval

As alluded to earlier, in addition to the "normal" or healthy population, several diseased populations may be involved, each with its own distribution. Figure 1-5 depicts the distributions of one analyte for a single diseased population and for a normal healthy, nondiseased population. Note that there will be some overlap of these distributions. Little overlap may occur when the disease has a major impact on the level of the analyte, whereas extensive overlap could occur if the level of the analyte is unchanged by the disease.

Using the upper limit of the reference interval for the normal dogs as the decision (threshold) point could lead to two types of mistakes in diagnosis of patients. First, diseased patients having values within the normal interval would be classified as nondiseased, the false negatives. Second, normal patients with values above the normal interval would be classified incorrectly as diseased and would be the false positives. The probabilities associated with making these two kinds of mistakes in classifying

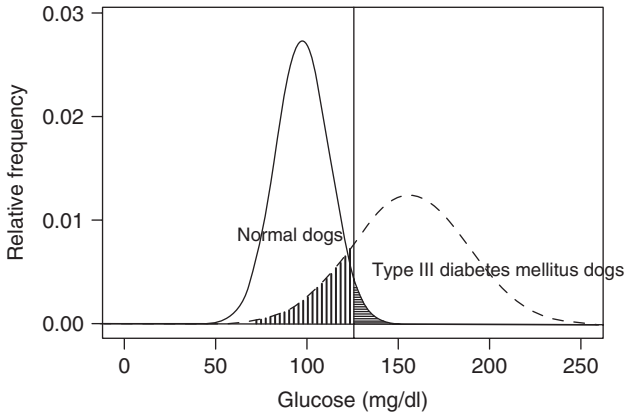

FIGURE 1-5 Overlapping Gaussian distributions of one analyte for a diseased dog population and a healthy, nondiseased dog population. Decision (threshold) point is the upper limit of the reference interval for the normal dogs. The magnitude of the vertically shaded area is the probability of misclassifying a diseased dog as being normal and the magnitude of the horizontally shaded area is the probability of misclassifying a normal dog as being diseased.

patients on the basis of analyte values, the error rates, are shown, respectively, as vertically and horizontally shaded areas in Figure 1-5. The *sensitivity* of the diagnostic or decision process using reference values is the probability of deciding that a truly diseased animal is diseased on the basis of the given reference value and is equal to 1 minus the vertically shaded area of Figure 1-5. The *specificity* of the decision process is the probability of deciding that a truly normal animal is normal and is equal to 1 minus the horizontally shaded area of Figure 1-5. It is possible to change the reference values to increase the sensitivity of the test, but such an action will also result in a reduction in the specificity of the test.

Example 2

Type III diabetic dogs have the chemical form of diabetes mellitus generally regarded as the first level of development of the disease offering the highest likelihood "for successful oral hypoglycemic therapy or dietary therapy" (Kaneko, 1977). Thus, it would be useful to distinguish type III diabetic dogs from normal dogs. Using the sample mean [155.6mg/dl (8.63mmol/liter)] and standard deviation [32.0mg/dl (1.77mmol/liter)] of the plasma glucose values given by Kaneko (1977) for five dogs with type III diabetes mellitus as reasonable estimates of the corresponding parameters for the population of dogs with type III diabetes mellitus, and assuming that this population distribution is approximately Gaussian, a comparison of this distribution of glucose values can be made with that for the population of normal dogs described by the approximately Gaussian distribution with parameter estimates given in Figure 1-2 [$\mu_x = 96.4$mg/dl (5.35mmol/liter) and $\sigma_x = 14.6$mg/dl (0.81mmol/liter)]. These two distributions are those shown in Figure 1-5; they have reasonably good separation with moderate overlap. Based on this information, a diagnostic procedure is proposed whereby a dog entering the clinic with a glucose value above 125.1mg/dl (6.94mmol/liter), the upper limit of the normal reference interval, will be flagged as possibly having type III diabetes mellitus thereby indicating need for more follow-up. (Note: This is an oversimplification of actual practice because a diagnostic decision of this type would be based on additional information, such as the animal's glucose tolerance and insulin response, making the decision rule and subsequent error calculations more complex.) This is an example of a one-sided diagnostic procedure because a dog with a glucose value below the lower limit of the reference interval would not be considered as having type III diabetes mellitus. If a dog actually having type III diabetes mellitus has a glucose value below the upper limit of the reference interval, the diagnostic procedure will make a mistake in deciding that the dog is normal. The probability of making this mistake is 0.170 or 17.0%, the area to the left of a glucose value of 125.1mg/dl in the distribution of glucose values for dogs having type III diabetes mellitus or the area to the left of the corresponding z-value, $z = (125.1 - 155.6)/32.0 \simeq -0.953$, for the standard Gaussian distribution (see Section II.B).

[This probability can be found by interpolating from Table D in Daniel (2005) or from MINITAB Release 14.13 using the reverse of the procedure described above for generating Table 1-2. The z-value -0.953 is placed in a column of a MINITAB worksheet and the following commands given:

Calc (from the main menu of MINITAB) → **Probability Distributions** → **Normal Distribution**. Within the **Normal Distribution** dialog box, **Cumulative probability** is selected, **Mean** is set to 0.0, **Standard deviation** is set to 1.0, and the column of the worksheet containing the z-value is selected and placed in the **Input column**: Hit **OK**.]

The clinician may be interested in determining the sensitivity and the specificity of the diagnostic procedure. The sensitivity is $1 - 0.170 = 0.830$ or 83.0%. A dog that actually is normal but has a glucose value greater than 125.1mg/dl would be incorrectly classified by the proposed diagnostic procedure as having type III diabetes mellitus. The probability of making this type of error is 0.025 or 2.5%, which is the area to the right of a glucose value of 125.1mg/dl in the distribution of glucose values for normal dogs or the area to the right of the corresponding z-value, $z = (125.1 - 96.4)/14.6 \simeq 1.96$, for the standard Gaussian distribution (from Table 1-2 or using MINITAB as shown earlier). The specificity of the diagnostic procedure is $1 - 0.025 = 0.975$ or 97.5%.

F. Predictive Value of a Decision Based on a Reference Interval

A useful quantity is the probability that a patient having a reference value outside the normal interval actually has the disease. This is known as the *predictive value of a positive diagnosis*, Prob(D | +). Interest could also be in determining the probability that a patient having a reference value within the normal interval is actually nondiseased or the *predictive value of a negative diagnosis*, Prob(D | −). The predictive value depends on the sensitivity, specificity, and prevalence (p) of the disease as is shown in the following equations:

$$\text{Prob}(\text{D}|+) = \frac{p \times \text{sensitivity}}{p \times \text{sensitivity} + (1-p) \times (1 - \text{specificity})}$$

$$\text{Prob}(\text{D}|-) = \frac{(1-p) \times \text{specificity}}{(1-p) \times \text{specificity} + p \times (1 - \text{sensitivity})}$$

Figure 1-6 demonstrates the extent to which the predictive value of a positive diagnosis changes with the prevalence. In general, larger changes are seen in the predictive value of a positive diagnosis for smaller changes in the

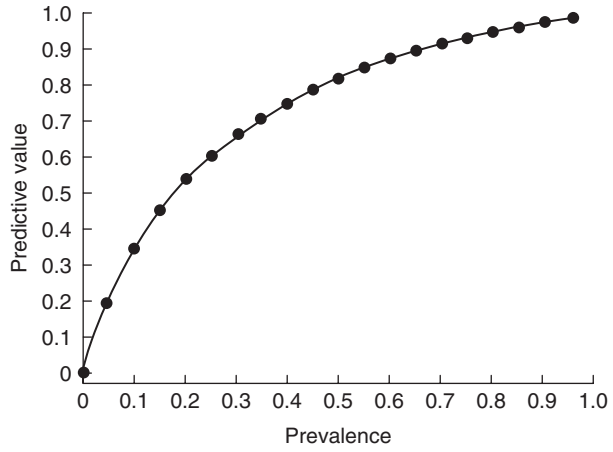

FIGURE 1-6 Impact of disease prevalence on the predictive value of a positive laboratory test having 95% sensitivity and 80% specificity.

TABLE 1-3 Sensitivity, Specificity, and False Positive Fraction (FPF)[a] Corresponding to Choices of a Decision (Threshold) Point in the Context of Example 2 and Used to Generate the ROC Curve in Figure 1-7

Decision Point	Sensitivity	Specificity	FPF
283.6	0.0000	1.0000	0.0000
132.9	0.7610	0.9938	0.0062
125.6	0.8257	0.9773	0.0227
118.3	0.8781	0.9332	0.0668
111.0	0.9183	0.8413	0.1587
38.0	0.9999	0.0000	1.0000

[a] FPF = 1 – *Specificity*.

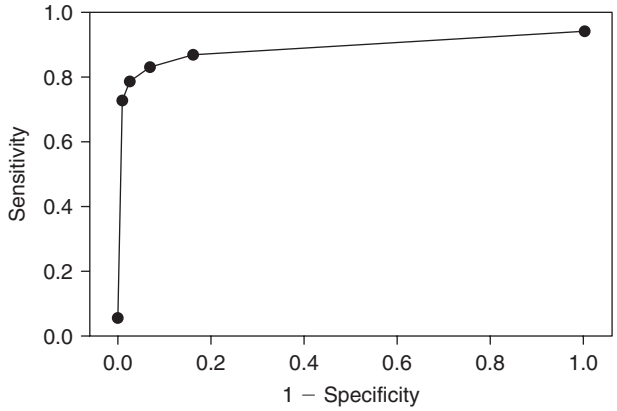

FIGURE 1-7 The empirical ROC curve for the data in Table 1-3.

prevalence for diseases with low prevalence, and smaller changes are seen in the predictive value for larger changes in the prevalence for diseases with high prevalence.

In the example of the diagnostic procedure given in the previous section, assuming the prevalence of type III diabetes mellitus in the dog population was 2%,

$$\begin{aligned}\text{Prob}(\text{D}|+) &= (0.02 \times 0.830) / \\ &\quad [(0.02 \times 0.830) + (0.98 \times 0.025)] \\ &= 0.404 \text{ or } 40.4\%, \text{ and}\end{aligned}$$

$$\begin{aligned}\text{Prob}(\text{D}|-) &= (0.98 \times 0.975) / \\ &\quad [(0.98 \times 0.975) + (0.02 \times 0.170)] \\ &= 0.996 \text{ or } 99.6\%\end{aligned}$$

To demonstrate how sensitivity and hence the predictive value of a positive test improves with greater separation of the populations, Kaneko (1977) gave estimates (based on a sample of 11 dogs) of the mean and standard deviation of the plasma glucose values of the population of dogs with type I diabetes mellitus (the juvenile or childhood form) as $\hat{\mu} = 415.1$mg/dl (23.02 mmol/liter) and $\hat{\sigma} = 114.3$mg/dl (6.34 mmol/liter). If we use these values in the preceding calculations with the diagnostic value remaining at 125.1mg/dl, the sensitivity improves to 99.4% and the predictive value of a positive test increases to 44.8%.

G. ROC Analysis

The receiver operating characteristic (ROC) curve is a classic graphic for visualizing the quality of diagnostic information (Hanley and McNeil, 1982; Metz, 1978). The conventional ROC curve is the plot of the sensitivity (y-axis) versus (1 − specificity), the false positive fraction (FPF) (x-axis). As alluded to previously, the sensitivity and specificity change with a change in the decision point. Table 1-3 gives the sensitivity, specificity, and FPF corresponding to some choices of a decision (threshold) point in the context of Example 2; Figure 1-7 gives the ROC curve generated by plotting the sensitivity versus the FPF using MINITAB's **Scatterplot** graphical option.

A nontechnical assessment of the usefulness of the diagnostic procedure can be made by comparing its ROC curve to that for the diagnostic procedure, which has no discriminating ability (DeLong *et al.*, 1988). The latter curve is the straight line diagonal extending from the coordinate (0,0) to the coordinate (1,1). The greater the separation of the ROC curve from the diagonal, the more discriminating the diagnostic procedure.

A quantitative assessment of the usefulness of the diagnostic procedure can be made by computing the area under its ROC curve. DeLong *et al.* (1988, page 838) gave the following interpretation of the area under the population ROC curve as "the probability that, when the variable is observed for a randomly selected individual from the abnormal population and a randomly selected individual from the normal population, the resulting values will be in the correct order (e.g., abnormal value higher than the normal value)."

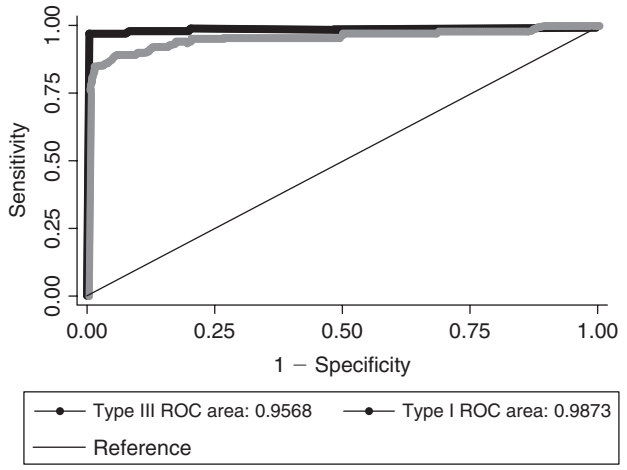

FIGURE 1-8 ROC curve comparison of the performance of glucose in distinguishing between normal dogs and dogs with type III diabetes mellitus and between normal dogs and dogs with type I diabetes mellitus.

This probability can be obtained as output from statistical software programs that perform ROC analysis such as STATA for Windows Release 9.2.[2]

As an example, we compare the performance of glucose in distinguishing between normal dogs and type III dogs and between normal dogs and type I dogs. A hundred random glucose responses were drawn from each of the type III and type I dog populations, and 1000 random glucose responses were drawn from the normal dog population. A STATA data file was made consisting of three columns. The first column (labeled **type III**) contained the 100 glucose responses from the type III dog population followed by the 1000 normal responses and the second column (labeled **type I**) contained the 100 glucose responses from the type I dog population followed by the 1000 normal responses. The third column (labeled **State**) contained "1" in the first 100 cells and "0" in the remaining 1000 cells indicating the true population membership (abnormal or normal) corresponding to the dogs in each of the first and second columns. The ROC analysis can be obtained using the following commands:

[**Graphics** (from the main menu of STATA) → **Roc analysis** → **Compare ROC curves**. Within the **Roccomp** dialog box, select **State** as the **Reference variable, type III** as the Classification variable and **type I** as the only **Additional classification variables**. Finally, select **Graph the ROC curves** and **Report the area under the ROC curves**. Hit **OK**.]

Figure 1-8 gives the results of the ROC analysis. It shows that glucose was a slightly better discriminator of type I dogs and normals dogs (the area under the ROC curve estimated to be 0.9873) than that of type III dogs and normal dogs (the area under the ROC curve estimated to be 0.9568). This difference was marginally statistically significantly ($p = 0.0345$) using a chi-square test (not shown).

III. ACCURACY IN ANALYTE MEASUREMENTS

Accuracy has to do with the conformity of the actual value being measured to the intended true or target value. An analytical procedure having a high level of accuracy produces measurements that on average are close to the target value. An analytical procedure having a low level of accuracy produces measurements that on average are a distance from the target value. Such a procedure in effect measures something other than is intended and is said to be *biased*. Failure of analytical procedures to produce values that on average conform to the target values is due to unresolved problems, either known or unknown, in the assay.

The degree of accuracy of an analytical procedure has been difficult to quantify because the target value is unknown. It is now possible for laboratories to compare their assay results with definitive results obtained by the use of isotope dilution-mass spectrometry (Shultz, 1994). Shultz (1994) reported the results of two large surveys of laboratories in the United States (Gilbert, 1978) and Sweden (Björkhem *et al.*, 1981) in which samples from large serum pools were analyzed for frequently tested analytes (calcium, chloride, iron, magnesium, potassium, sodium, cholesterol, glucose, urea-nitrogen, urate, and creatinine). The laboratory averages were compared with the target value obtained using definitive methods, and the results of these surveys indicated that, with the exception of creatinine, all averages expressed as a percentage of the target value were within the accuracy goals published by Gilbert (1975). Results from individual laboratories naturally would vary about the average, and many of these laboratories would not have met the accuracy goal.

IV. PRECISION IN ANALYTE MEASUREMENTS

Precision has to do with how much variability there is about the actual value being measured when the assay is replicated. If in a given laboratory a particular assay is run repeatedly on the same sample and the results obtained have little variability, the assay is said to have high precision. Large variability in the observed results indicates low assay precision. Note that precision is defined in reference to what is actually being measured and not to the target value. Clinical analysts have always had a goal of achieving the highest possible level of precision for a particular

[2] StataCorp, 4905 Lakeway Drive, College Station, TX 77845.

assay within a laboratory. Emphasis is presently placed on meeting an "average laboratory" level of precision (Shultz, 1994).

The level of precision is stated quantitatively in terms of the coefficient of variation (*cv*). The *cv* is the ratio of the standard deviation to the average of a series of replicated assays, and its magnitude depends on the concentration of the analyte. Elvitch (1977) and Harris (1988) provided the guidelines on the desired level of precision in terms of the *cv*. In the case where the analytical results are intended to assist in the diagnostic process or to assist in monitoring a patient's response to treatment, the level of laboratory precision of a given analyte in terms of the $cv(cv_a)$ needs only be a function of the within-day and day-to-day variability or intrasubject variation of healthy subjects. Specifically,

$$cv_a < ½\, cv_{\text{intrasubject}}$$

In the case where analytical test results were to be used to screen a population, the laboratory precision goal in terms of the *cv* should be a function of the variability in response among healthy subjects or intersubject variation. Specifically,

$$cv_a < ½\, cv_{\text{intersubject}}$$

Use of intrasubject variability as a goal for precision has appeal because this source of variability would be considered in decision processes relating to patients. Unfortunately, a given analysis reflects not only this intrasubject variability but also imprecision in the assay. Shultz (1994) summarized the results of a large national survey of laboratory precision. With the exception of high-density lipoprotein and thyroxine (T_4), the precision of the assay for the analytes evaluated from the "average" laboratory met or nearly met the precision goals based on the intrasubject variability. This result has to be regarded as encouraging, no doubt reflecting the tremendous emphasis that has been placed on quality control by laboratories as well as the use of automation in analytical work. On the other hand, there were some analytes for which the assay precision for the "average" laboratory was above the precision goal. It also must be remembered that many individual laboratories would not have assay precision profiles as good as the "average" laboratory. Assay precision in excess of the precision goal based on physiological variability makes it nearly impossible to rule out the possibility that very large changes in the level of an analyte reflect assay imprecision.

V. INFERENCE FROM SAMPLES

The basis for everything that has been discussed to this point is probability and distributional theory. No other theory is relevant unless one is operating at the level where inference is to be made on the basis of a sample from the underlying population. Most standard statistical theory assumes that the sample was obtained by simple random sampling.

A. Simple Random Sampling

Simple random sampling (SRS) is a method of sampling whereby, at each step of the sampling process, the elements available for selection have an equally likely chance of being selected. In most applications, it is assumed that the elements are selected without replacement, although the elements could be selected with replacement. If the number of elements to be selected is small relative to the number of elements in the population, then it is unlikely that an element will be selected more than a single time using replacement sampling, so that in such situations sampling replacement produces essentially the same results as sampling without replacement. It is only when a small finite population is being sampled that differences may be noted between the two methods.

Three steps are used to select a sample by SRS without replacement: all elements in the population must first be identified by a unique number from 1 to N, the population size. Then n numbers are selected from a table of random numbers or selected by a random number generator, which give the numbers 1 to N in random order. Numbers appearing more than once are ignored after their first use. Finally, those elements having numbers corresponding to the n numbers selected constitute the sample. There are other probability-based sampling procedures that should be considered in practice; these methods are found in texts on sampling (Cochran, 1977; Jessen, 1978; Levy and Lemeshow, 1999; Lohr, 1999; Murthy, 1967; Raj, 1968, 1972; Scheaffer *et al.*, 2006).

B. Descriptive Statistics

Once the data have been collected, so-called descriptive statistics can be computed. As the name suggests, these statistics are useful in describing the underlying populations. For example, because complete information for the entire population is not available, it is not possible to know the population mean, $\mu = \Sigma x_i/N$. (Here x_i designates the value of the ith element in the population and Σ indicates summation. Thus, the population mean μ is found by summing the values of all N elements in the population and then dividing the sum by N.) However, a sample mean based on the sample can be computed as $\bar{x} = \Sigma x_i/n$, the sum of the values of all n elements in the sample divided by n. If the sample has been selected in a manner that results in a small bias, $\bar{x}$ should be a reasonably good estimate of the population mean, μ, and will be a better estimate as the sample size increases. Other estimates of the measures of central

tendency of the population can be obtained from the sample, such as the sample median and the sample mode. Also, sample-based estimates of the measures of dispersion or spread for the population can be obtained. The sample variance is computed as $s^2 = \Sigma(\bar{x}_i - x)^2/(n-1)$, and the sample standard deviation, s, is obtained by taking the square root of s^2. The descriptive statistics are called *point estimates* of the parameters and represent good approximations of the parameters. An alternative to the point estimate is the *interval estimate*, which takes into account the underlying probability distribution of the point estimate called the sampling distribution of the statistic.

C. Sampling Distributions

In actual practice, only a single sample is taken from a population and, on the basis of this sample, a single point estimate of the unknown population parameter is computed. If time and resources would permit repeated sampling of the population in the same manner—that is, with the same probability-based sampling design—one point estimate would be obtained for each sample obtained. The estimates would not be the same because the sample would contain different elements of the population. As the number of such repeated sampling operations increases, a more detailed description emerges of the distribution of possible point estimates that could be obtained by sampling the population. This is the sampling distribution of the statistic.

Some fundamental facts relating to the sampling distribution of the sample mean follow: (1) The center of the sampling distribution of $\bar{x}$ is equal to μ, the center of the underlying distribution of elements in the population. (2) The spread of the sampling distribution of $\bar{x}$ is smaller than σ^2, the spread of the underlying distribution of elements in the population. Specifically, the variance of the sampling distribution of $\bar{x}$ (denoted $\sigma^2_{\bar{x}}$) *equals* σ^2/n, where n is the sample size. So increasing the sample size serves to increase the likelihood of obtaining an $\bar{x}$ close to the center of the distribution because the spread of the sampling distribution is being reduced. (3) The central limit theorem (Daniel, 2005; Schork and Remington, 2000; Zar, 1999) states that regardless of the underlying distribution of the population of elements from which the sample mean is based, if the sample size is reasonably large ($n \geq 30$), the sampling distribution of $\bar{x}$ is approximated well by the Gaussian distribution. So $\bar{x}$ drawn from any distribution has a sampling distribution that is approximately $N(\mu, \sigma^2/n)$ for $n \geq 30$. If the distribution of the underlying population of elements is Gaussian or approximated well by a Gaussian distribution, the sampling distribution of $\bar{x}$ will be approximated well by the Gaussian distribution regardless of the sample size on which $\bar{x}$ is based.

Probabilities of the sampling distribution of $\bar{x}$, $N(\mu, \sigma^2/n)$, can be evaluated using the method described in Section II.B.

Example 3

Suppose the underlying population of elements is $N(4,16)$ and a sample of size $n = 9$ is drawn from this population using SRS. It is desired to find the probability of observing a *sample mean* less than 3.1 or greater than 6.2. In solving this problem, the relevant sampling distribution is specified: $\bar{x}$ is $N(4,16/9)$. Note that the sampling distribution of $\bar{x}$ is Gaussian because the problem stated that the underlying population was Gaussian. (Otherwise the stated sample size would have needed to be 30 or larger to invoke the central limit theorem.) The probability of observing $\bar{x} < 3.1$ in the distribution of $\bar{x}$ is equivalent to the probability of observing $z < (3.1 - 4)/(4/3) = -0.675$ in the standard Gaussian distribution. Going to Table 1-2, $z = 0.675$ is approximately the 75th percentile of the standard Gaussian distribution, and by symmetry $z = -0.675$ is approximately the 25th percentile. Thus, the probability of observing a z value less than or equal to -0.675 is approximately 0.25. The probability of observing a sample mean greater than 6.2 is equivalent to the probability of observing $z > (6.2 - 4)/(4/3) = +1.65$. Table 1-2 gives the probability of observing a $z < 1.65$ as approximately 0.95 so the probability of observing a $z > 1.65$ equals $1 - 0.95$ or 0.05. The desired probability of observing a sample mean less than 3.1 or greater than 6.2 is the sum of 0.25 and 0.05, which is 0.3 or 3 chances in 10.

D. Constructing an Interval Estimate of the Population Mean, μ

This brief exposure to sampling distributions and their standardized forms provides the framework for generating an interval estimate for μ. Consider the probability statement $\text{Prob}(-2 < z < +2) = 0.9544$. Because $z = (\bar{x} - \mu)/(\sigma/\sqrt{n})$, this probability statement is equivalent to the statement $\text{Prob}(-2 < (\bar{x} - \mu)/(\sigma/\sqrt{n}) < +2) = 0.9544$. Some standard algebraic manipulation of the inequality within the parentheses gives $\text{Prob}(\bar{x} + (-2\sigma/\sqrt{n}) < \mu < \bar{x} + (2\sigma/\sqrt{n})) = 0.9544$. This is the form of the confidence statement about the unknown parameter μ. With repeated sampling of the underlying population, 95.44% of the intervals constructed by adding and subtracting $2\sigma/\sqrt{n}$ to and from the sample mean would be expected to cover the true unknown value of μ. The quantities of $\bar{x} - 2\sigma/\sqrt{n}$ and $\bar{x} + 2\sigma/\sqrt{n}$ are called the *lower* and *upper confidence limits*, respectively, and the interval bounded below by $\bar{x} - 2\sigma/\sqrt{n}$ and above by $\bar{x} + 2\sigma/\sqrt{n}$—that is, $(\bar{x} - 2\sigma/\sqrt{n}, \bar{x} + 2\sigma/\sqrt{n})$ is the 95.44% confidence interval for μ. In practice, only one sample is taken from the population, and thus there is a 95.44% chance that the one interval estimate obtained will cover the true value of μ. Note that 95.44% or 0.9544 is called the *confidence level*.

The degree of confidence that is to be had is determined by the amount of error that is to be tolerated in the estimation procedure. For a 0.9544 level of confidence, the error rate is $1 - 0.9544 = 0.0456$. The error rate is designated by alpha, α.

The size of α determines the magnitude of the value of z that is multiplied by $\sigma/\sqrt{n}$. The convention is to apportion half of α to the lower end and half of α to the upper end of the sampling distribution of $\bar{x}$ so that the relevant values of z are (1) the z-value, which has $\alpha/2$ area to its left, $z_{\alpha/2}$, and (2) the z-value, which has $\alpha/2$ to its right or equivalently (to conform to Table 1-2) the z-value, which has $1 - (\alpha/2)$ area to its left, $z_{1-(\alpha/2)}$. Therefore, the most general form of the interval estimate statement is $(\bar{x} - (z_{\alpha/2}\sigma)/\sqrt{n},\ \bar{x} + (z_{1-(\alpha/2)}\sigma)/\sqrt{n})$ or $\bar{x} \pm (z_{1-(\alpha/2)}\sigma)/\sqrt{n}$ because of the symmetry of the Gaussian distribution.

Example 4

Assuming the distribution in Example 3, construct a 90% confidence intervals for μ. A 90% level of confidence implies a tolerated error rate of 10% and the relevant z-values are (1) that which has 5% of the distribution of z to its left or $z_{0.05} = -1.645$ and (2) that which has 95% of the distribution to its left or $z_{0.95} = 1.645$. The 90% confidence interval for μ is therefore $(\bar{x} \pm (1.645 \times 4)/3)$ or $(\bar{x} \pm 2.1933)$, where $\bar{x}$ is the sample mean obtained by taking a sample of size 9 from the population.

The form of the interval estimate given earlier assumes that σ, the standard deviation of the underlying population, is also known.Frequently this parameter, like μ, is unknown and must be estimated from the sample drawn from the population using the estimator $s^2 = \Sigma(\bar{x}_i - x)^2/(n-1)$, the sample variance. The square root of s^2 is s, the sample standard deviation. For small samples ($n < 30$), the standardized form of $\bar{x}$, $(\bar{x} - \mu)/(s/\sqrt{n})$, does not have a standardized Gaussian distribution, $N(0,1)$, but rather has the t-distribution corresponding to the effective sample size, $n - 1$, the degrees of freedom. Table 1-4 gives the percentiles of several t-distributions. A given row of Table 1-4 pertains to the t-distribution with the indicated effective sample size or degrees of freedom. The entries in the row are percentiles or those points of the given t-distribution that have the indicated area to the left. For example, $t_{0.95,10}$ is 1.8125 meaning that the 95th percentile of the$t$-distribution with 10 degrees of freedom is 1.8125, which is equivalent to saying that 95% of the t-distribution with 10 degrees of freedom lies to the left of the t-value 1.8125. Note that the 5th percentile of the t-distribution with 10 degrees of freedom is -1.8125 because the t-distributions, like the standard Gaussian distribution, are symmetric about zero. Thus, for smaller sample sizes when the value of σ is unknown, the form of a confidence interval for μ is $\bar{x} \pm [(t_{1-\alpha/2;n-1}s)/\sqrt{n}]$.

As with the mean, interest also centers around estimating the variance, σ^2, and standard deviation, σ, of the population. The estimates for these parameters are s^2 and s, respectively. One might also be interested in constructing confidence intervals for these parameters. Because space does not permit further elaboration, the interested reader is referred to the several introductory statistics books for the relevant formulae and their derivation (Daniel, 2005; Dunn and Clark, 2001; Schork and Remington, 2000).

TABLE 1-4 Percentiles of the Student's t-distribution with 10 Degrees of Freedom[a,b]

$t_{0.50,10} = 0$	$t_{0.85,10} = 1.093$
$t_{0.55,10} = 0.129$	$t_{0.90,10} = 1.372$
$t_{0.60,10} = 0.260$	$t_{0.95,10} = 1.812$
$t_{0.65,10} = 0.397$	$t_{0.975,10} = 2.228$
$t_{0.70,10} = 0.542$	$t_{0.99,10} = 2.764$
$t_{0.75,10} = 0.700$	$t_{0.995,10} = 3.169$
$t_{0.80,10} = 0.879$	$t_{0.9995},10 = 4.587$

[a] *This table was generated with* MINITAB *Release* 14.13. *The indicated cumulative probabilities* 0.5 *to* 0.9995 *were placed in a column of a* MINITAB *worksheet and the following commands given:* ***Calc*** *(from the main menu of* MINITAB) → ***Probability Distributions*** → **t-*Distribution***. *Within the* **t-*distribution*** *dialog box,* ***Inverse cumulative probability*** *was selected with* ***noncentrality parameter*** *set to* 0.0, ***degrees of freedom*** *was set at* 10 *and the column of the worksheet containing the cumulative probabilities was selected and placed in the* ***Insert column****: followed by hitting* **OK**. *The same procedure is followed to obtain percentiles from* t*-distributions with other degrees of freedom.*

E. Comparing the Mean Response of Two Populations

1. Independent Samples

The presentation thus far has focused on estimation of parameters from a single population. Frequently, interest lies in two populations. For example, in a clinical trial, one group of animals might receive some treatment (t), whereas a second group of animals serves as a control receiving no treatment (c). Among the several points of interest could be that of estimating the difference in central response for the two populations—that is, $\mu_t - \mu_c$—where the subscripts designate the groups. The point estimate of $\mu_t - \mu_c$ is $\bar{x}_t - \bar{x}_c$. If we assume that the variances of the two populations, σ_t^2 and σ_c^2, are unknown but equal and the common variance designated as σ^2, then the estimate of σ^2 is $s_p^2 = [(n_t - 1)s_t^2 + (n_c - 1)s_c^2]/(n_t + n_c - 2)$ (called the *pooled variance*) and $[(\bar{x}_t - \bar{x}_c) - (\mu_t - \mu_c)]/s_p(1/n_t + 1/n_c)^{1/2}$ has a t-distribution with $n_t + n_c - 2$ degrees of freedom. A $100(1-\alpha)\%$ confidence interval for $\mu_t - \mu_c$ is $(\bar{x}_t - \bar{x}_c) \pm t_{1-\alpha/2;nt+nc-2}\ s_p (1/n_t + 1/n_c)^{1/2}$. If the interval so constructed covers zero, it may be that there is no difference between the central responses for the two distributions; otherwise, it could be concluded that the central responses differ significantly.

2. Nonindependent Samples

The procedure just discussed, in addition to assuming that the variances are homogeneous, also assumes that the two samples are drawn independently. An alternative design

for comparing two responses involves using each subject as its own control. For example, a pretreatment response in an individual might be compared with a posttreatment response. Clearly in this design, the pre- and posttreatment responses may not be and most likely are not independent so the procedure given earlier for comparing two groups would not be appropriate. Rather, the differences in response (pretreatment minus posttreatment response) are formed and the population of interest is the single population of differences having as one of its parameters the mean difference, μ_d. The quantity μ_d is estimated by the mean difference for the sample of n differences, $\bar{d} = \Sigma d_i/n$, and an interval estimate is formed by $\bar{d} \pm (t_{1-\alpha/2;n-1}s_d)/\sqrt{n}$ where s_d is an estimate of σ_d. If the interval so constructed covers zero, then it may be that there is no difference between the mean pre- and posttreatment values.

F. Comparing the Mean Response of Three or More Populations Using Independent Samples

1. By Extension of the 2-Sample t-Test

Comparison of more than two groups is the natural progression from the methodology discussed to this point. Consider the comparison of three independent groups. The approach that immediately comes to mind is that of estimating the three groups' means and standard deviations and then constructing three sets of confidence intervals (the first group versus the second group, the first group versus the third group, and the second group versus the third group) using the approach described earlier for two independent groups. However, some modifications need to be made. First, because we are assuming that all three groups have equal variances, pooling of the variances for the three groups provides a better estimate of the common variance than does pooling of just the variances for the two groups being compared. The form of the pooled variance is the natural extension of that for two groups, namely $s_p^2 = [(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2 + (n_3 - 1)s_3^2]/(n_1 + n_2 + n_3 - 3)$. When the group sample sizes are equal—that is, $n_1 = n_2 = n_3$—$s_p^2 = \Sigma s_i^2/3$. The quantity s_p^2 is used for all three interval estimates.

Second, the error rate of each comparison has to be adjusted so that the error rate over all three comparisons will be α. This is required because theoretically it turns out that the error rate over all three comparisons is larger than that for a single comparison. Several approaches are suggested in the literature for circumventing this problem. One such approach, based on the Bonferroni inequality (Neter *et al.*, 1996, Stevens, 2002), is called the Bonferroni/Dunn procedure (Zar, 1999). The Bonferroni/Dunn procedure involves making each single comparison in a "family" of comparisons with an error rate of α/m, where m is the total number of comparisons to be made. This approach gives an error rate of α over all comparisons—that is, over all members of the family of comparisons. In the context of comparing k groups in a pairwise manner, the form of the interval estimate is $(\bar{x}_i - \bar{x}_j) \pm [(t_{1-\alpha/2m;n1+n2+\ldots+nk-k})(s_p)(1/n_i + 1/n_j)^{1/2}]$, where m is the total number of comparisons to be made and k is the total number of groups, which in the present example is three. Intervals covering zero would indicate no difference in the central value of the groups being compared.

2. By One-Way Analysis of Variance

The process of deciding whether or not there are differences between groups in the central value of the response being evaluated can also be approached using the method of analysis of variance (ANOVA). ANOVA involves decomposing the total variability in a given set of data into parts reflective of the amount of variability attributable to various sources. One source of variability is that within the group. Because the groups are assumed to have the same spread, this source of variability is estimated as the pooling of the estimated variances for the k groups considered and is equal to s_p^2 defined earlier. The second source of variability results from the variability among groups means. If there is no difference in the groups' means, then the k samples can be thought of as being k independent samples from a common population and the k means, therefore, represent a sample of size k from the sampling distribution of $\bar{x}$. Their variance represents

TABLE 1-5 Analysis of Variance Table for Classification of Responses on Basis of One Factor, Equal Responses for Each Class[a]

Source of variation	Degrees of freedom	Sum of squares	Mean square	F value
Among group means	$k - 1$	$SS_A = (k - 1)MS_A$	$MS_A = \dfrac{n\sum_{i=1}^{k}[x_i - \sum_{i=1}^{k}(x_i/k)]^2}{k-1}$	MS_A/MS_W
Within group	$k(n - 1)$	$SS_W = k(n - 1)MS_W$	$MS_W = \dfrac{\sum_{i=1}^{k} s_i^2}{k}$	
Total	$kn - 1$	$SS_T = SS_A + SS_W$		

[a] *k is the number of classes of groups, n is the number of responses per group, constant over all groups, s_i^2 is the variability of the responses within the ith group.*

an estimate of the variance of the sampling distribution of $\bar{x}$—that is, $\hat{\sigma}^2 = \Sigma[x_i - \Sigma(x_i/k)]^2/(k-1)$, where $\hat{\sigma}$ denotes estimate. Because $\hat{\sigma}^2 = \hat{\sigma}^2/n$, where n is the common sample size, inflation of $\hat{\sigma}^2$ by n will produce a second estimate of the variance of the underlying population assuming no differences among the group means. These two estimates of σ^2 should be about equal and their ratio close to 1.

If there is significant separation among some or all of the group means, the second variance estimate, when computed as described, will be larger than the first estimate, indicating that a component of variance is being estimated beyond that embodied only in an estimate of the within-group variability. This additional variance component being estimated is the variance among group means. ANOVA in this example involves generating the two estimates of σ^2 (called *mean squares*) under the hypothesis that all of the group means are equal. The hypothesis is then tested by forming the ratio of the two mean squares (the second mean square divided by the first mean square) called the *F-statistic*. The *F*-statistic has a probability distribution called the *F*-distribution. If the computed *F*-value is greater than the tabled distributional value, then the hypothesis is rejected and subsequently confidence intervals are constructed as described earlier to determine which group means are different. If the hypothesis cannot be rejected, the process stops or perhaps, at most, the data from all the groups might be pooled together and the parameters of this single population estimated. Tables of the percentiles of the *F*-distributions can be found in all introductory texts on statistics (Daniel, 2005; Dunn and Clark, 2001; Schork and Remington, 2000), which also provide instruction on how to read the tables. Also, these texts give the generalization of the among group mean square when the sample size is not constant for all groups.

The results of an ANOVA are traditionally summarized in a table called the ANOVA table, and Table 1-5 is such an example. The first column of Table 1-5 shows the sources of variability into which the total variability is decomposed. In the present example, these sources are due to the variability within groups and that which is reflective of variability among group means. Column 4 gives the two independent (under a hypothesis of no difference in response among groups) estimates of σ^2 or mean squares, mean square among group means (MS_A), and mean square within groups (MS_W). Columns 3 and 2 give, respectively, the numerator (called the sum of squares) and the denominator (the effective sample size or degrees of freedom) of the corresponding mean square. The sums of squares provide a check on calculations when generating an ANOVA table because the total of the sum of squares attributable to the various sources of variability is equal to the sum of squared deviations of each observation across the k samples from the grand mean of all the observations in the k samples, called the *total sum of squares*. In other words, the total sum of squares is the numerator for estimating the total variability in the data ignoring group membership. Similarly, the degrees of freedom for the sources of variability sum to the effective sample size for estimating the total variability in the data ignoring group membership of the observations [here $kn - 1 = (k-1) + k(n-1)$].

Example 5

Suppose a study is designed to determine *in vivo* effects of cytokines on *in vitro* clonogenicity assays (expansion of CD34+ progenitor cells). To this end, a total of 30 monkeys (rhesus macaque) of the same age and gender were obtained and assigned randomly as follows: 10 monkeys were administered the traditional cytokine cocktail (TCC), 10 monkeys were administered a conditioned media with anti-CD3 (ACD3S), and 10 monkeys served as controls and were administered a placebo. Both cocktails were administered to induce production of progenitor cells expressing antigen CD34. Bone marrow samples were taken from the monkeys 10 days after administration, cultured for 14 days after which the number of colonies was determined. (Expression of CD34+ cells was monitored by flow cytometry and the response is the number of colonies detected *in vitro*.) Figure 1-9 gives the counts obtained for the three groups that were compared using ANOVA for the completely randomized design. The statistical software used was SPSS for Windows Release 11.[3]

FIGURE 1-10 Partial SPSS printout of the analysis of variance for comparing the three groups of Example 5 assuming a completely randomized design.

[Instructions for the SPSS data processing: The counts are placed in one column of an SPSS worksheet (labeled here as **count**) with the corresponding cocktail administered indicated in a second column (labeled here as **cocktail**). Figure 1-9 is the SPSS worksheet that was used for this example. The SPSS commands to obtain the ANOVA are: **Analyze** (from the main menu) ⇒ **General Linear Model** ⇒ **Univariate**. This opens the **Univariate** dialog box. The column containing the counts is placed in the **Dependent Variable:** box and the column containing the cocktail administered is placed in the **Fixed Factor(s):** box within the **Univariate** dialog box. Then the **Post Hoc…** tab is pressed, which opens the **Univariate Post Hoc Multiple Comparisons for Observed Means** dialog box. In this box the desired factor (here **exposure**) is moved from the **Factor(s):** box to the **Post Hoc Tests for:** box and the desired post hoc test(s) (here **Bonferroni**) selected. The **Continue** tab is hit to return to the **Univariate** dialog box. Finally, the **Options** tab is pressed to open the **Univariate: Options** box where the column containing the exposure is placed in the **Display Means for:** box and the **Display** of **Descriptive statistics** is selected. The **Continue** tab is hit to return to the **Univariate** dialog box and the **OK** tab is hit to get the output.]

Figure 1-10 gives a partial printout of the output. The ANOVA table shows that the total (**Corrected Total**) sum

of squares for the counts is 1948.8 with 29 degrees of freedom. This total has been decomposed into 1602.2 because of the **COCKTAIL** (reflective of the variability among exposure group means) with 2 degrees of freedom and 346.6 because of **Error** (reflective of the variability within exposure groups) with 27 degrees of freedom. The *F*-statistic is 62.405, considerably higher than 1, indicating highly significant separation among some or all of the group means. The column in the printout headed by *Sig.* gives the probability of observing such a large *F*-statistic under the hypothesis that the mean count for the three exposure groups is equal. This probability, commonly referred to as the *p-value*, is less than 0.0005 indicating that observing such a result is highly unlikely if the hypothesis is true.

Figure 1-10 also summarizes the multiple comparisons of the mean count for the three exposure groups. The mean count for monkeys exposed to ACD3S was significantly higher than that for monkeys exposed to TCC, which in turn was significantly higher than that for monkeys that received the placebo.

Note: The mean responses of two independent samples can be compared by using statistical software appropriate for performing a one-way analysis of variance as demonstrated earlier or by using the two-sample (independent-sample) *t*-test procedure available with most statistical software.

G. Efficiency in Experimental Designs

The One-way ANOVA does not represent a superior method to that of the Bonferroni/Dunn procedure in the context in which it was presented. In fact, if a significant group effect was noted by the ANOVA, the Bonferroni/Dunn procedure or any other appropriate multiple comparison procedure would be used to identify which group differences were contributing to the overall group effect. The reason analysis of variance has been introduced is that it is a convenient method for assessing the importance of various sources of variability encountered in the complex designs of clinical laboratories.

1. *Factorial Designs*

Suppose in the context of the previous example there was interest not only in evaluating cocktail effects but also age effects. The researchers would obtain 15 infant and 15 adult monkeys (rhesus macaque) and randomly assign 5 monkeys of each age to receive TCC, 5 monkeys of each age to receive ACD3S, and 5 monkeys of each age to receive the placebo. Otherwise the experimental design is exactly like that described in Example 5. The number of colonies of CD34+ progenitor cells counted per plate for the six combinations of cocktail and age are those given in Figure 1-11.

	cocktail	age	count
1	control	infant	45.00
2	control	infant	47.00
3	control	infant	39.00
4	control	infant	47.00
5	control	infant	51.00
6	control	adult	39.00
7	control	adult	40.00
8	control	adult	42 00
9	control	adult	35.00
10	control	adult	38.00
11	tcc	infant	52.00
12	tcc	infant	52.00
13	tcc	infant	53.00
14	tcc	infant	54.00
15	tcc	infant	49.00
16	tcc	adult	49.00
17	tcc	adult	48.00

30	acd3s	adult	60.00

FIGURE 1-11 SPSS worksheet for comparing the responses of the three groups of Example 5 using analysis of variance assuming a factorial design.

[Partial instructions for SPSS data processing: the SPSS worksheet is Figure 1-11, which includes one column providing the response (number of colonies of CD34+ progenitor cells counted per plate, **count**) information, one column providing the cocktail exposure information for each monkey (as done in Example 5), and one column providing the age of each monkey (labeled here as **age**). To get the SPSS analysis, the instructions are exactly those given in Example 5 for the One-way ANOVA with the exceptions that **age** in addition to **cocktail** is placed in the **Fixed Factor(s)** box within the **Univariate** dialog box and descriptive statistics are requested for **age** as well as for **cocktail** within the **Univariate: Options** dialog box. Note that in this particular case a post hoc multiple comparison for "age" is not requested as "age" has only two categories and thus a significant "age" effect would imply that infant and adult means are different.]

Figure 1-12 provides the ANOVA table resulting from a re-analysis of the count data for the 30 monkeys in Example 5 with their age taken into account. Note that the total (**Corrected Total**) sum of squares for the counts and

FIGURE 1-12 Partial SPSS printout of the analysis of variance for assessing both cocktail exposure and age effects assuming a factorial design.

the Sum of Squares and Mean Square for **COCKTAIL** are the same as those obtained with the One-way ANOVA. What has changed is that the Sum of Squares for **Error** from the One-way ANOVA (346.6) has been decomposed into the Sum of Squares for **AGE** (136.533), for the interaction between **COCKTAIL** and **AGE** (designated in the ANOVA table as **COCKTAIL * AGE**) (34.067), and for the new refined **Error** (176.0). Figure 1-12 also shows

that the 27 degrees of freedom for **Error** in the One-way ANOVA has been decomposed into 1 degree of freedom for **AGE**, 2 degrees of freedom for **COCKTAIL * AGE**, and 25 degrees of freedom for the new refined **Error**.

Two advantages of this factorial design are apparent from Figure 1-12. In addition to testing for the **COCKTAIL** main effect, it has become possible to test for the **AGE** main effect (statistically significant, $p < 0.0005$, with the infant monkeys having the higher count) and for the interaction between **COCKTAIL** and **AGE** main effects (not statistically significant, $p = 0.12$). Also, the refined error term should be more reflective of the unknown error term because the effects of **AGE** and the interaction between **COCKTAIL** and **AGE** in addition to the effect of **COCKTAIL** have been removed from the error. In this particular example, adjusting the effects of **COCKTAIL** for sources of variability because of **AGE** (the **AGE** main effect and the interaction between **COCKTAIL** and **AGE**) has resulted in a substantial reduction in the error (from 12.837 to 7.333) because of the highly significant age main effect. The smaller refined **Error**, as the denominator of the variance ratio for testing the significance of the main factor of interest, here cocktail, leads to a larger variance ratio. Thus, the chance of rejecting the hypothesis of equality of means for the main factor of interest is enhanced—that is, the *power of the test* for the main factor of interest is increased.

2. *Blocking Designs*

a. Basic Randomized Block Design

Assume that it is desired to evaluate **k** exposures in a study. Before assigning the exposure to each of the total of **n** animals available, the **n** animals are divided into **b** blocks of **k** animals each where the animals in each block are homogeneous with respect to the blocking factor. In the context of Example 5, suppose the researcher was interested in evaluating the impact of the cocktail effect only in infant monkeys but still wanted to adjust for any age effect. Here the blocking factor would be age. Thus, the 30 infant monkeys (rhesus macaque) would be placed in an array based on their birth date. Then the 3 youngest animals would form the first block, the 3 next youngest animals would constitute the second block, and so forth. Once the animals have been placed in blocks, each of the 3 exposures (TCC, ACD3S, and placebo) is assigned in a random manner to one animal within each block with each animal in a block receiving one assigned exposure. Here **k** equals 3 and b equals 10.

Examples of other blocking factors are breed, litter, and body weight. In the case of breed (or litter), each block consists of **k** animals of the same breed (or litter) that are as much alike as possible in all other respects. The blocking factor is a factor that represents a potentially large source of variability in terms of the response of interest. Blocking enables this source of variability to be isolated from the overall error. If indeed the response is highly variable across blocks, the resulting error should be considerably smaller than that which would be obtained from an experiment using the completely randomized design. This smaller error would enhance the chance of observing an exposure effect—that is, it would lead to a more powerful test for an exposure effect.

	monkey	placebo	tcc	acd3s
1	1.00	45.00	52.00	66.00
2	2.00	47.00	52.00	64.00

FIGURE 1-13 SPSS worksheet for comparing the responses of the three groups of Example 6 using analysis of variance assuming a repeated measures design.

b. Basic Repeated Measures Design

Repeated measures designs can be thought of as designs that involve blocking carried to its limit. In these designs, the sampling units, the animals, are the blocks with multiple responses taken on each animal. In the context of the previous examples, it may be possible to subject each monkey to a sequence of multiple exposures with an appropriate time interval between exposures to minimize the chance of a carryover effect. To obtain the same number of responses as from the previous designs (30), only 10 monkeys would be required rather than 30 monkeys. Besides this saving in the number of monkeys needed, if the response is highly variable across monkeys, the resulting error from this repeated measures design should be considerably smaller than that which would be obtained from an experiment using the completely randomized design. For the present example, it is assumed that all monkeys are given the placebo first, TCC second, and ACD3S third.

[Partial instructions for SPSS data processing: the SPSS worksheet that is appropriate for the data obtained from the basic repeated measures design described previously is shown in Figure 1-13. It consists of 10 rows, one for each monkey, and 4 columns, the first giving the animal identification (labeled here as **monkey**), the second giving the counts recorded often exposure to the placebo (labeled here as **placebo**), the third giving the counts recorded after TCC exposure (labeled here as **tcc**), and the fourth giving the counts recorded after ACD3S (labeled here as **acd3s**).

The SPSS commands to obtain the ANOVA are as follows:

Analyze ⇒ General Linear Model ⇒ Repeated Measures… This opens the **Repeated Measures Define Factor(s)** dialog box where a name, here **cocktail**, is

specified for the repeated measures factor in the **Within-Subject Factor Name** box. Then the number of categories of the Within-Subject Factor, here 3, is specified in the **Number of Levels** box. This information is registered [here as **cocktail(3)**] by hitting the **Add** tab. Hitting the **Define** tab opens the **Repeated Measures** dialog box where the columns of the worksheet corresponding to the levels of the repeated measures factor, here **placebo**, **tcc**, and **acd3s**, are moved into the **Within-Subject Variables** box. Hitting the **Options** tab opens the **Repeated Measures: Options** dialog box. In this dialog box, the repeated measures factor, here **cocktail**, is moved from the **Factor(s) and Factor Interactions:** box to the **Display Means for:** box. **Compare main effects** is selected, **Confidence interval adjustment** method (here **Bonferroni**) is specified, and other display options such as the **Descriptive statistics** are requested. The **Continue** tab is hit to return to the **Repeated Measures** dialog box and the **OK** tab is hit to get the output.]

A partial printout of the SPSS output for the example is presented in Figure 1-14. The variance ratio, $F = 82.3$, is larger than the 62.4 obtained from the One-way ANOVA of the data obtained assuming a completely randomized design. This is due the smaller error, 9.730, obtained with the analysis of the data obtained under the repeated measures design compared to that (12.837) obtained from the One-way ANOVA. This difference is because sizable variability due to animal, the block was removed from the error in the analysis of the data assuming the repeated measures design.

Note: The mean responses of two dependent samples can be compared by using this procedure for analyzing data obtained from the basic repeated measures design or by using the paired-samples *t*-test procedure available with most statistical software.

3. More Complex Experimental Designs

More complex experiments can be designed having one or more between subject factors and one or more within subject (repeated measures) factors. For example, the basic repeated measures design given previously could be modified where half of the monkeys used were infants and half were adults. Cocktail remains a within subject (repeated measures) factor, but age is included as a between subject factor because infant sampling units are distinct from adult sampling units.

The SPSS worksheet is exactly that described earlier for the example of the basic repeated measures design (see Fig. 1-13) with a column added giving the codes of the categories of the between subject factor (here **age**). The instructions for obtaining the SPSS analysis are the same

FIGURE 1-15 (Continued).

as those given previously for the example of the basic repeated measures design with the following additions:

1. In the **Repeated Measures** dialog box, **age** is added as a between subjects factor by moving "age" into the **Between-Subjects Factor(s):** box.

2. In the **Repeated Measures: Options** dialog box, both the repeated measures factor, here **cocktail**, and the between subjects factor, here **age**, are moved from the **Factor(s) and Factor Interactions:** box to the **Display Means for:** box for requesting options such as the display of descriptive statistics.

3. For between subject factors having more than 2 categories, pairwise multiple comparisons of means can be obtained by hitting the **Post-Hoc...** tab, which opens the **Repeated Measures Post Hoc Multiple Comparisons for Observe...** dialog box. In this dialog box all desired between subject factors can be moved from the **Factor(s):** box to the **Post Hoc Test for:** box and the desired pairwise multiple comparisons procedure(s) selected.

A partial printout of the SPSS output for the example is presented in Figure 1-15. Cocktail (**COCKTAIL**), the within subject main effect, is highly significant ($p < 0.0005$), age (**AGE**), the between subject main effect, is also highly significant ($p = 0.001$), but the interaction between cocktail and age (**COCKTAIL * AGE**) is nonsignificant ($p \geq 0.177$).

H. Nesting Designs

Frequently clinical studies are undertaken to quantify the magnitude of various sources of variability such as intra-animal and interanimal variability. An example of an experimental design that would provide estimates of intra-animal and interanimal variances is as follows: twenty ($n_a = 20$) dogs are randomly selected over a period of time from the population of dogs identified by a clinic as having pituitary-dependent hyperadrenocorticism. At the time the dog is selected, 3 days ($n_d = 3$) within the next 2 weeks are randomly selected for plasma cortisol samples to be taken at 11 A.M. from the dog. Plasma cortisol assays are replicated for each sample (n = 2). Because the animals are sampled across time, it is rather unlikely that many and perhaps any of the 3 days that samples are drawn will be common for the 20 dogs. If the 20 dogs had no sampling days in common, there would be 60 (20×3) different days that samples were taken. Thus, the factor "days" in this design is not crossed with the factor "animals" but is said to be nested within "animals." The total variability in this experiment can be decomposed by the method of ANOVA into three parts, that which will identify significant variability among animals and significant variability among days (nested within animals) and that which quantifies the residual variability.

Table 1-6 lists data that shall be assumed to have been generated from an experiment using the nested design described earlier. Table 1-7 gives the ANOVA table generated from these data. In addition to providing the standard entries of an ANOVA table (sum of squares, degrees of freedom, mean square and *F*-statistics with corresponding *p*-values), Table 1-7 also gives the expected mean squares, which are the quantities being estimated by the corresponding mean squares in the table. The expected mean squares are functions of the unknown population parameters. Note that each expected mean square involves one or more of the variance components of the design. The expected mean squares indicate which mean squares are appropriate as the denominator for computing the *F*-statistic to test the hypothesis for a given effect. For example, to test the hypothesis that the variance component giving the magnitude of the variability attributable to the effect of "days" is not significant—that is, to test H_o:$\sigma_{d/a}^2 = 0$, the test statistic is $F_{d/a} = MS_{d/a}/MS_e$. MS_e is the correct denominator for this test statistic because if the hypothesis is true and $\sigma_{d/a}^2 = 0$, the expected mean square for the effect of "days" reduces to σ_e^2 so that both $MS_{d/a}$ and MS_e would be estimating σ_e^2 and it would be expected that the ratio of $MS_{d/a}$ to $MS_e(F_{d/a})$ would not differ significantly from 1. This ratio

TABLE 1-7 Analysis of Variance of Canine Plasma Cortisol Level Data Assuming a Nested Experimental Design 2 ("Days" Nested within "Animals")

Source of variation	*df*	Sum of squares	Mean square	F-value	Expected mean square
Among Animals	19	70.8316	3.7280	38	$\sigma_e^2 + n n_d \sigma_a^2 + n\sigma_{d/a}{}^2$
Days/Animals	40	43.8333	1.0958	114	$\sigma_e^2 + n\sigma_d^2$
Error	60	0.5750	0.0096		σ_e^2
Total	119	115.2399			

differing significantly from 1 would indicate that $MS_{d/a}$ was estimating something additional to σ_e^2, namely, $n\sigma_{d/a}{}^2$, where n is the number of replications per sample. Based on the assumed data, the hypothesis $\sigma_{d/a}^2 = 0$ is rejected. $\sigma_{d/a}^2$ in this design is the true intradog variability for this response. The test result that the day effect is significant means that this intradog variability is larger than zero.

The second test is that the variance component for "animals" is equal to zero or $\sigma_a{}^2 = 0$. It can be determined by considering the expected mean squares of Table 1-14 that the test for no significant variability among animals (H_o:$\sigma_a^2 = 0$) is made using $MS_{d/a}$ in the denominator of the F-statistic. This test is also significant. This means that σ_a^2 is not equal to zero, indicating a significant source of variability among dogs in the plasma cortisol levels recorded in the experiment.

1. Estimating Variance Components

Once significance has been established for one or more of the variance components in an experimental design, interest focuses on estimating the variance component(s). Estimates are readily obtainable using the appropriate expected mean squares in conjunction with the mean squares obtained from the data. For example, Table 1-7 shows that an estimate of σ_e^2 is $MS_e(\hat{\sigma}_e^2 = 0.0096)$. An estimate of $\sigma_{d/a}{}^2$ can be obtained by noting that $MS_{d/a}$ estimates $\sigma_e^2 + n\sigma_{d/a}^2$; solving for $\sigma_{d/a}{}^2$ followed by substitution of MS_e for σ_e^2 yields $(MS_{d/a} - MS_e)/n$ as the estimate. Based on the data used in the example, $\hat{\sigma}_{d/a}^2 = (1.0958 - 0.0096)/2 = 0.5431$. An estimate of σ_a^2, obtained in a similar manner, is

$$(MS - MS_{d/a})/nn_d$$

where n_d is the number of days samples were taken (3). Based on the data an estimate of σ_a^2 is 0.4387. The term σ_a^2 is the estimate of the interanimal variability, whereas $\sigma_{d/a}^2$ estimates the intra-animal variability in plasma cortisol level for the underlying population of dogs. Interval estimates for these variance components can be obtained using these point estimates by methods described elsewhere (Harter and Lum, 1955; Mickey *et al.*, 2004; Satterthwaite, 1941).

2. Estimating the Variance of the Grand Mean Response

Another way to visualize the importance of these variance components is to analyze their impact on the estimate of the variance of interest. In some applications, there would be interest in estimating the grand mean (μ) of the response. In the present example, this would involve estimating the mean plasma cortisol level taking into account any random animal effect and day effect. The variance of $\hat{\mu}$, $\text{Var}(\hat{\mu})$, is given as $\sigma_a^2/n_a + \sigma_{d/a}^2/n_a n_d + \sigma_e^2/n_a n_d n$ (Little *et al.*, 1991; Neter *et al.*, 1996). In the present example, $\text{Var}(\hat{\mu})$ is estimated as $0.4387/20 + 0.5431/60 + 0.0096/120 = 0.0219 + 0.0091 + 0.0001 = 0.0311$, and by far the greatest contribution to this variance is that due to the variability among animals in their response. The intradog variance component, although slightly larger than the interdog variance component, makes a considerably smaller impact on $\text{Var}(\hat{\mu})$.

3. Estimating the Total Variability of a Single Response

In other applications, interest centers about the total variability ($\sigma_{\text{total}}{}^2$) associated with a single response. A single response is a linear combination of the terms in the response model and, using the assumption of the independence of terms in the model, has a variance equal simply to the sum of the variance components. Specifically, $\sigma_{\text{total}}{}^2 = \sigma_a^2 + \sigma_{d/a}^2 + \sigma_e^2$ (Kringle, 1994), which in this example is estimated as $0.4387 + 0.5431 + 0.0096 = 0.9914$. Here the total variability of a single response is divided nearly equally between "animals" and "days nested within animals."

Other possible designs could be considered. What has been demonstrated is that the method of analysis of variance in conjunction with experimental design can be useful in answering a variety of questions.

Nested designs are frequently used to assess sources of variability in an assay. For example, several laboratories could be involved in doing a particular assay, with several autoanalyzers in each laboratory and multiple technicians running these autoanalyzers. Inference in this context centers around being able to identify if there are significant sources of variation among the laboratories, among autoanalyzers within a given laboratory, and among technicians operating a given autoanalyzer. The goal of analyses of this sort is to identify large sources of variability. Once the larger sources of variability have been identified, changes are made in the system in an effort to reduce the variability associated with each source. The long-term objective is to have an assay with sources of variability that are as small as possible. Clinical analysts conventionally divide the square root of the estimates of the variance components (the sample standard deviations) resulting from such assay experiments by the grand mean to obtain coefficients of variation for each source of variability (Kringle, 1994). These coefficients of variability should be much smaller than those derived as intra-animal and interanimal variability. Interested readers are strongly encouraged to consult texts written on experimental design and ANOVA (Mickey *et al.*, 2004; Neter *et al.*, 1996).

I. INTRODUCTION

A. Genome Sequences

All the genetic information needed for the creation, maintenance, and reproduction of an organism is called the genome. For most organisms, this information is encoded in the DNA (deoxyribonucleic acid) or for some viruses in the RNA. A first step in the gigantic endeavor to understand this genetic information is to learn about the complete nucleotide sequence of a genome. Such genome projects have been or will be undertaken for many different organisms.

The progress made with the Human Genome Project around the turn of the century has not only produced an extraordinary resource for genetic research in human medicine, but it has also created the means for sequencing additional genomes. Following the completion of the high-density human genome sequence, these tools and sequencing capacities have been used for a variety of species, starting with that of model organisms. The mouse, as one of the most relevant models for genetic research, was the second mammal to be sequenced; however, genome sequences from rat, fruit fly, and zebra fish were soon to follow. The next group of genomes included those of domestic animals, such as the dog, cow, chicken, and pig, which were chosen because they also serve as model organisms and are of special interest as either companion or food animals. Genomes of other animals, including cat and horse, were chosen to help with the annotation of the human and other mammalian genomes (comparative annotation). They were sequenced at lower genome coverage and are expected to provide important information about genome evolution. Alignment and comparison of the available animal genomes to the human will help identify evolutionarily conserved regions, which mostly likely represent important functional elements. This is a critical step for the annotation of the human and animal genomes and the understanding of genomic function. Completed genome sequences for several domestic animals are now available (Table 2-1) and semiannual updates on the status of current sequencing projects are listed on the National Institutes of Health (NIH) website (www.genome.gov/10002154).

Many aspects of the canine genome and its impact on comparative and medical genetics are covered in *The Dog and Its Genome* (Ostander *et al.*, 2006). The knowledge about the genomes of companion animals will have an enormous impact on veterinary medicine by facilitating the identification of genes underlying breed characteristics including behavior, coat color, body type, disease predispositions, and the detection of disease-causing mutations. This knowledge will lead to great advances in genetic screening for desirable and disease-causing traits as well as breed-specific vaccine and drug development (custom drug design). It will also change livestock breeding and production through identification of productivity and disease-resistance genes.

B. Mapping the Genome

The nuclear genome is composed of a species-specific number of linear DNA molecules, which are packaged into chromosomes. The number of chromosomes varies greatly among eukaryotes (for haploid chromosome numbers, see Table 2-1) but appears to be unrelated to genome size and its biological features. During cell division, DNA is

TABLE 2-1 Genome Sequencing Projects

	Genome	Coverage	Size (Gb)	Haploid Chromosomes
Cat	Felis catus	1.9-fold	3	19
Chicken	Gallus gallus	6.6-fold	1.2	40
Cow	Bos Taurus	6-fold	3	30
Dog	Canis lupus familiaris	7.6-fold	2.4	39
Horse	Equus caballus	6.8-fold	2.1	32
Human	Homo sapiens	Finished	3	23
Mouse	Mus musculus	Finished	2.5	20
Pig	Sus scrofa	In process	2.8	19

duplicated and then condensed into the more compact forms of chromosomes. The varying sizes, location of centromeres, and the characteristic banding patterns revealed by staining techniques allow for the identification of individual chromosomes. For each organism, the arrangement of chromosomes by pairs (homologous chromosomes), according to standard classifications, is referred to as the karyotype (see the example in Fig. 2-1) and can also be depicted as a drawing called an ideogram.

The two types of genome maps (i.e., physical and genetic maps) are important tools for the sequencing and assembly of whole genome sequences. Once established, they are great resources for locating and sequencing genes, such as those involved in diseases. A *physical map* depicts the position of a specific DNA segment in a genome—for example, its location on a specific chromosome. A *genetic map* describes the order and distance between specific DNA sequences in terms of the rate of DNA recombination between homologous chromosomes during meiosis, and it is determined from breeding experiments and pedigree analyses. *Integrated maps* use DNA segments as markers that are mapped to both maps and display information from both.

1. *Physical Mapping*

Different techniques have been applied to construct physical maps as new techniques were made available.

a. Fluorescent *In Situ* Hybridization (FISH)

FISH enables the assignment of a DNA molecule directly to a chromosome. Hybridization of several DNA fragments simultaneously reveals not only their individual location but also their relative order to each other. To perform a traditional FISH experiment, cells are harvested in the metaphase stage of mitosis and their chromosomes are fixed onto a glass slide. Individual chromosomes can be distinguished by their distinct banding patterns and other cytological features. A specific DNA molecule (also referred to as a probe) is labeled with a fluorescent dye and hybridized to the denatured chromosomes. The single-stranded DNA probe anneals to its complementary strand in the chromosome in a sequence-specific manner, and the physical location of the probe is microscopically visible as

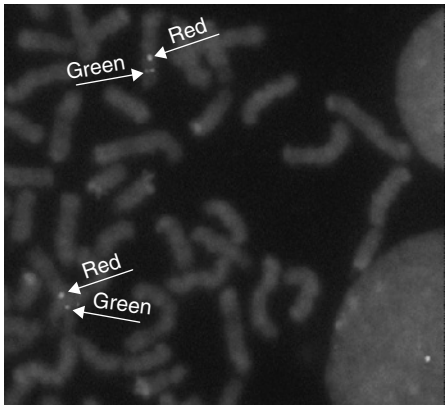

FIGURE 2-2 Fluorescent *in situ* hybridization. Two color FISH on canine metaphase chromosomes. Two loci labeled red and green are assigned to canine chromosome 9 (CFA9).

a bright fluorescent signal. With the development of fluorescent labels that have specific emission spectra, multiple DNA probes can be hybridized simultaneously to a single chromosome preparation, allowing their ordering on a chromosome (Fig. 2-2). Another useful application of multicolor FISH is called *chromosome painting*: multiple probes distributed throughout the length of one chromosome are labeled with the same color dye at a density such that the entire chromosome is covered by fluorescence. As chromosome-specific probe sets are hybridized with different colors, each chromosome reveals its unique color, which is particularly useful to examine chromosomal abnormalities like deletions, duplications, and translocations of chromosomal segments. Because FISH allows only low-resolution mapping (probes >1Mb apart), other techniques need to be applied for finer, high-resolution mapping.

b. Restriction Enzyme Mapping

Restriction endonucleases are enzymes isolated from various strains of bacteria that recognize and cleave specific double-stranded DNA sequences, called restriction sites, with the majority of sites consisting of only four to seven nucleotides (see the example in Fig. 2-3). A DNA segment, digested by a specific restriction enzyme, is cut into smaller DNA fragments of different sizes depending on the number and location of the recognition sites present within the DNA sequence. The differently sized fragments can be separated by agarose or polyacrylamide gel electrophoresis. A simple way to create a restriction map of a smaller genome is to first cut the DNA using two separate reactions, each with a different restriction enzyme, and then in an additional reaction simultaneously with both enzymes to compare the resulting fragment size patterns. This will allow one to assess the number of restriction sites for each enzyme by single digests and then the relative positions to each other by the double digest (Fig. 2-4). However, with an increasing size of the DNA segment to be mapped, the number, sizes, and order of resulting fragments become too complex. Then analysis requires cloning smaller fragments or other mapping techniques.

c. Sequence Tagged Site (STS) Mapping

STSs are short nonrepetitive DNA segments that are located at unique sites in the genome and can be easily amplified by the polymerase chain reaction (PCR). Common sources to obtain STSs represent expressed sequence tags (ESTs), microsatellites (discussed later), and known genomic sequences that have been deposited in databanks. ESTs are short sequences obtained by converting mRNA into complementary DNA (cDNA). They are unique and valuable sequences, because they represent parts of expressed genes of the cells or tissue used for the mRNA extraction. To construct a genome map using STSs, different DNA resources, sometimes called a mapping reagent, can be used. The most common resources are radiation hybrid panels or clone libraries, both of which can be constructed using either whole genome sequences or a single chromosome.

i. Radiation Hybrid (RH) Mapping Radiation cell hybrids are typically constructed using cells from two different species. Cells from the organism whose genome is to be mapped (donor) are irradiated with a lethal dose and then usually fused with rodent (recipient) cells. The irradiated chromosomes break at random sites and, after cell fusion with the recipient cells, the donor chromosome fragments are incorporated into the recipient chromosomes. Consequently each hybrid cell line derived from a single cell contains different parts of the donor's chromosomes, which were incorporated at random.

Radiation hybrid mapping is based on this artificially induced random breaking of the genomic DNA into smaller fragments. The original order of these fragments to each other is determined by ascertaining that specific DNA sequences are found to be in the same clones, which means that they segregate together because of their close physical proximity in the genome. For detailed mapping, fewer than 100 hybrid cell lines are necessary. For example, irradiated canine cells were fused with recipient hamster cells, and 88 cell lines were selected (Hitte *et al.*, 2005). To map the canine genome, DNA from each cell line is being tested for the presence or absence of unique canine markers, like STSs. If two markers are originally located closely on a chromosome, a break between the markers is unlikely, and, therefore, they will mostly be found together in the same cell line. In contrast, if they are farther apart or even on

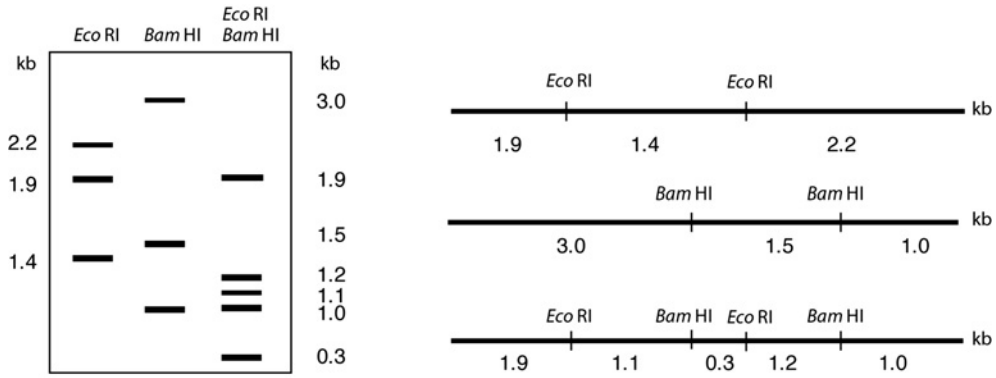

FIGURE 2-4 Restriction mapping. A 5.5kb DNA segment is cut with enzymes *Eco* RI and *Bam* HI to assess the number of restriction sites for each of the enzymes. (*Eco* RI and *Bam* HI single digests each produce three bands indicating two restriction sites for each of the enzymes) (as depicted as an agarose gel on the left). The double digest using both enzymes allows the inference of the relative location of the restriction sites to each other (schematic position of restriction sites on the right).

different chromosomes, the separation of the two markers into different cell lines is likely. Hence, the actual distance between two markers on a chromosome is proportional to the probability of the markers being separated and found in different cell lines. Analysis of hundreds to thousands of markers allows for the determination of the order and distance between markers. Higher resolution RH maps can be achieved by increasing the intensity of the initial radiation of the donor cells leading to increased chromosomal breaks and smaller average fragment sizes. The probability of separation between closely located markers increases, thereby permitting the ordering of more markers.

ii. Clone Library A *clone library* consists of DNA fragments, representing the total DNA from a specific chromosome or whole genome, inserted into some type of vector that can be grown in bacteria, yeast, or mammalian cells. To construct a library, the source DNA is cut into random fragments, usually by a restriction enzyme that has a 4bp recognition site and therefore cuts the DNA frequently. However, the digestion of the DNA is purposely prevented to go to completion, leaving randomly larger uncut fragments that partially overlap. These fragments are then cloned into vectors, for example, plasmids, which incorporate the DNA and allow for easy amplification and isolation in bacteria. Different types of vectors accommodate DNA fragments of different sizes, ranging from hundreds to thousands of base pairs (bp). As with the radiation hybrids, the individual clones are analyzed for the presence or absence of STSs, which allows the ordering of these markers depending on their common presence in the same clones. Again, the resolution of the STS map can be raised by decreasing the size of the DNA fragments used for construction of the library. The STS markers are also used to identify overlapping clones to build contigs (a number of overlapping clones representing a region of a particular sequence). Because sequences obtained from each clone can be precisely anchored to the physical map, clone libraries are critical in the assembly of whole genome sequences.

2. *Genetic Linkage Mapping*

Breeding experiments or pedigree analyses can be used to genetically map genes or molecular markers. The basis for genetic mapping is that the distance between two markers on a chromosome is directly correlated with the probability of *recombination* between them during meiosis. Because each diploid cell has two copies of each locus (two alleles), it is by chance that half the time the alleles of two different loci on different chromosomes are inherited together (Fig. 2-5a). In other words, in 50% of offspring (or meioses), the same alleles of the two loci are found together, although they are located on different chromosomes. However, if the two loci are located on the same chromosome, it is less likely that their alleles will be separated and, therefore, should segregate together in >50% of the offspring. If they are found separated in some of the individuals, then they are said to have recombined. The frequency of recombination is correlated with the distance between the two loci. If they are closely located, then recombination between the two markers will happen less often and will be <50%, and approaching 0% for very closely located markers (Fig. 2-5b). Markers are said to be linked if recombination between them is <50%.

To be able to follow the inheritance of different alleles of a genetic marker in a pedigree, they need to be polymorphic for a DNA variation (discussed later). Hundreds to thousands of these genetic markers are then analyzed in a number of families. Likelihood calculations for linkage based on the percentage of recombination between any two markers permit the ordering of the markers to each other into linkage groups and ultimately into a genetic map. The distance between markers on a genetic map is based on the recombination rate and expressed in centiMorgans (cM; 1cM = 1% recombination). The resolution of a

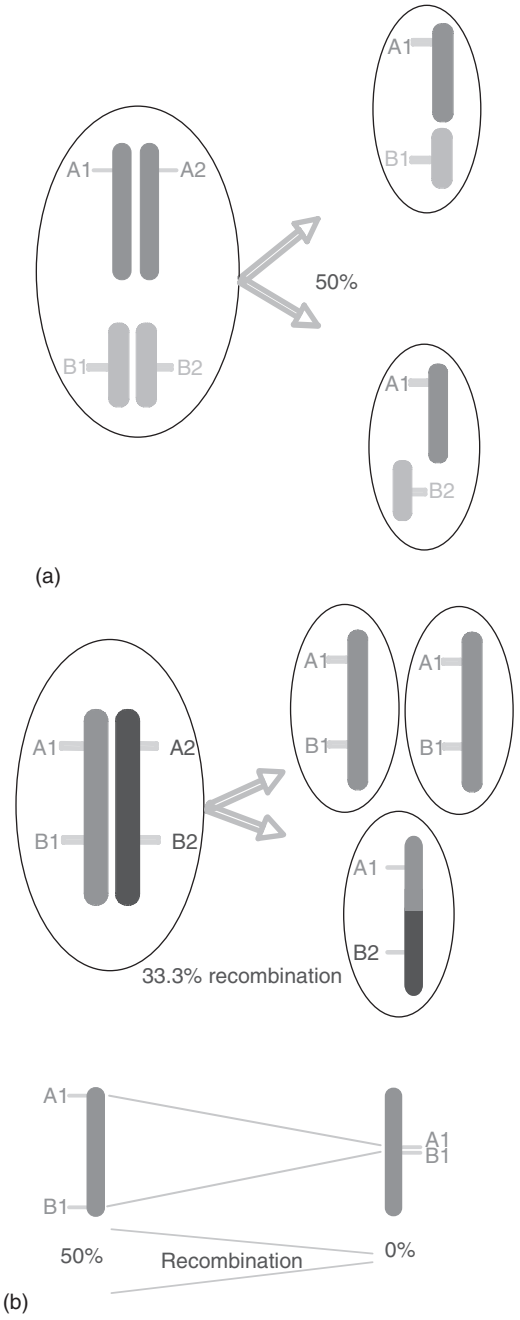

FIGURE 2-5 Schematic representation of recombination during meiosis. (a) Independent assortment. The chance for two alleles from two loci located on two different chromosomes to be inherited together is 50%. Therefore, the same alleles will be found together in 50% of the offspring, although the two loci are inherited independently of each other. (b) Recombination: If the loci are located on the same chromosome one would expect to find the same alleles together in all the offspring, but because of recombination the alleles rearrange in some of the offspring. For example, if one offspring out of three shows recombination, then the recombination is said to be 33.3%. The distance between the two loci on the chromosome is correlated with the probability of interchromosomal recombination between the two during meiosis. Although located on the same chromosome, recombination between two loci can reach 50% if the loci are far apart. In other words, the chance of the two loci being separated during meiosis is the same as if they were located on two different chromosomes. If the two loci are located very close together, few to no recombinant animals are found (recombination rate approaches 0) and the loci are said to be linked.

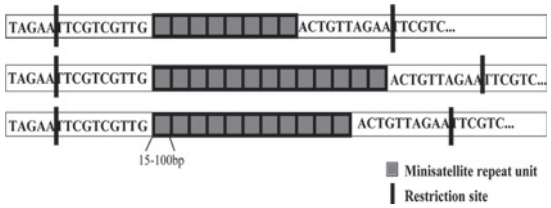
genetic map depends on the number of individuals as well as how informative the markers tested are.

a. Genetic Markers

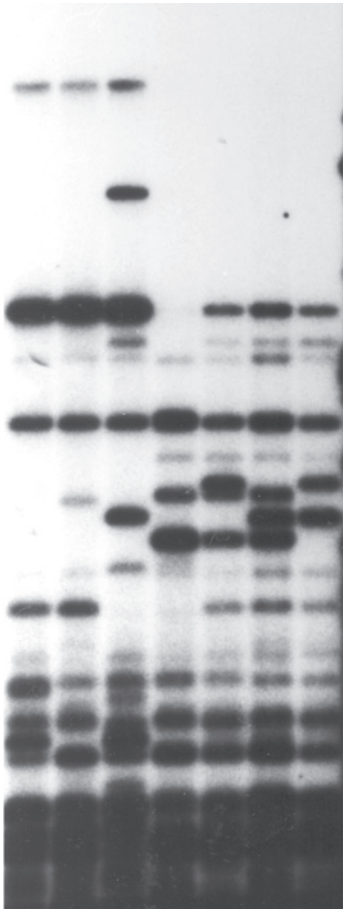
Although more than 99% of the DNA sequence is identical between individuals of any mammalian species, much variation remains. These sequence differences are known as polymorphisms, contribute to breed and individual differences, and have been useful for many practical applications, including genome mapping, screening for genetic diseases, and forensic applications such as DNA fingerprinting. Most variations are located outside of genes and generally do not affect any gene function. However, some of these polymorphisms may contribute toward physical characteristics or disease susceptibility. In contrast, polymorphisms within a regulatory or coding sequence of a gene can have deleterious effects on gene function. These polymorphisms have a lower frequency within a population and are referred to as mutations. Mutant alleles of genes are often associated with a genetic disease or disease predisposition and are referred to as disease genes or alleles.

***i. Restriction Length Polymorphisms* (RFLPs)** One of the first widely used techniques to detect DNA variations in a population was the analysis of RFLPs. Polymorphisms between individual DNAs can either destroy existing or create new endonuclease recognition sites and, thereby, lead to different fragment size patterns following restriction enzyme digestion. To test for a specific RFLP, a DNA region is amplified by PCR and subsequently digested with a particular restriction enzyme. The resulting DNA fragments can be separated by gel electrophoresis and visualized by staining with ethidium bromide. A difference in number or size of fragments between individuals tested indicates a polymorphism within the restriction site of the enzyme used. Before the advent of automated PCR, RFLP analysis methods included the extraction and digestion of genomic DNA of each individual tested, separation by gel electrophoresis, transfer of the DNA to a nylon membrane, and subsequent hybridization with a radioactively labeled DNA probe that bound to a known region in the genome. If a variation within a restriction site of the enzyme used was located within or close to the region of a locus binding to the probe, the labeled bands would differ either in size or number between individuals. Although extraordinarily laborious and not very informative, these RFLPs were used as markers to construct the first human genetic linkage map.

***ii. Minisatellite or Variable Number of Tandem Repeats* (VNTRs)** Minisatellites or VNTRs, succeeding the RFLPs, are noncoding DNA sequences of <20 kb long, containing a variable number of 15 to 100-bp long repeat units (Fig. 2-6a), and are distributed throughout the whole genome. If genomic



(a)



(b)

FIGURE 2-6 (a) Illustration of a single minisatellite location within the genome of three different animals depicting a varying number of repeat units. The sizes of the fragments differ depending on the number of repeat units when cut with a restriction enzyme, with restriction sites surrounding the minisatellite locus. (b) DNA fingerprints from Bernese mountain dogs. Each lane represents the banding pattern of one dog depicting the differently sized fragments of several locations of one specific minisatellite distributed throughout the genome. The DNA from each dog was digested with the same restriction enzyme and hybridized with a labeled probe binding to the minisatellite repeat unit.

DNA is cut by a restriction enzyme that has no recognition site within the repeat unit but cuts the remaining DNA fairly frequently, a large number of different-sized fragments can be identified. Because the numbers of the repeat units at most of the minisatellite loci vary among individuals, the resulting pattern of differently sized fragments is unique to each individual and is, therefore, called a *DNA fingerprint* (Fig. 2-6b). Although minisatellites are more informative than RFLPs, their analysis still is time consuming.

***iii. Microsatellites or Simple Tandem Repeats* (STRs)** With the advent of PCR, microsatellites soon replaced minisatellites as well as RFLPs as genetic markers. Microsatellites or STRs are composed of simple sequence repeats of 2 to 7 nucleotides. The number of repeat units may greatly differ among individuals resulting in alleles of varying lengths. PCR primers flanking the repeat are located in genome-wide unique sites and, therefore, allow for unique and easy amplification of one specific marker. Although initially radioactively labeled primers were used, fluorescent labels, automated DNA sequencers, and analysis software now allow for fast and inexpensive analyses. The abundance of STRs throughout the genome and ease of analysis greatly improved genetic maps in humans and animals with ever-increasing resolution.

***iv. Single Nucleotide Polymorphisms* (SNPs)** The most frequent, evenly distributed genome sequence variations (e.g., >4.5 million in humans) are SNPs, where a single nucleotide (A, T, G, or C) at a locus differs between individuals in a biallelic fashion. A small fraction of SNPs gave rise to the RFLPs described previously. However, current technologies allow for automated analysis of tens of thousands of SNPs per sample simultaneously, making it the preferred tool for genome-wide analysis in the search for mutations responsible for diseases. The commercially available high-density oligonucleotide *microarrays* or *DNA chips* contain thousands of different oligonucleotides representing different sequence variants. Hybridization of labeled sample DNA to the chip and subsequent analysis with a fluorescent scanner will result in a typical hybridization pattern. Because the representative genomic location of each oligonucleotide on the chip is known, the assessment of the pattern permits genotyping of several thousand SNPs per sample. SNP maps and chips, developed for humans and some domestic animals, are most useful to find the sequence variations that affect gene function associated with health, production, and disease.

3. *Integrated Maps*

Because some markers can be analyzed on both physical and genetic maps, they serve as anchors to compare and combine data from both maps. The resulting integrated map lists the order of the markers and gives their distances in both genetic and physical scales.

4. *Comparative Maps*

Comparative genomics, utilizing information about different genomes, is particularly important in the understanding

of genomes of various organisms. If two organisms have a recent ancestor, their genomes will be related. Comparative maps display similarities between two organisms by aligning genes and their order on a chromosome of one species and then comparing it to the location and order found in another species. This knowledge is useful for mapping, identifying and isolating genes, and gaining more information about principles of evolution. Comparison of the actual genome sequences of different species allows the detection of highly conserved regions within or around genes that, besides representing exonic sequences, most likely serve as important regulatory elements in gene expression and function.

C. Disease Gene Mapping

A major objective of genetic research is the identification of DNA mutations that is involved in disease or genetic predisposition. A small sequence change located within a gene can alter or eliminate gene or protein function. These mutations either arise during imperfect DNA replication or are caused by mutagens and are distinguished by the type of change in the nucleotide sequence. A replacement of a single nucleotide with another base is called a *point mutation*, which can either be silent (the amino acid remains unchanged), a *missense* (changes the amino acid), or *nonsense point mutation* (producing a stop codon). Insertion or deletions refer to varied numbers of nucleotides that are added or deleted, respectively. Nonsense point mutations and deletions or insertions unequal to an exact multiple of 3bp can result in an early stop codon and consequently in a shortened, unstable, or malfunctioning protein. Protein function can also be impaired by the change or addition/deletion of amino acids because of a mutation within the coding region (missense). Additionally, mutations within noncoding sequences that are necessary for correct gene regulation and function can also lead to a change in expression or nonfunctional proteins.

In single gene disorders such a specific mutation that is severe enough to cause disease by itself and often shows a *simple (Mendelian) inheritance* pattern. If the inheritance is said to be *dominant*, only one mutant allele is sufficient for the development of the disease in an affected individual. Because the second allele is a normal (wild-type) allele, the affected individual is considered to be heterozygous. If both alleles have to be mutated to cause clinical disease, then the inheritance pattern is said to be *recessive* and the affected animal is homozygous for the mutant allele. If the mutation is located on the X chromosome, the affected male is considered to be *hemizygous*. Complex or polygenic disorders are caused by sequence variations in only a few or numerous genes and are more difficult to evaluate. The influences of environmental factors are being recognized and explain some of the variation in disease presentations of simple and complex inherited traits. To identify mutant alleles, various methods have been applied.

1. *Candidate Gene Approach*

If the phenotype or metabolic basis of the disease to be studied is well characterized or previous research has been done in humans or in other animal species with a similar disease, there might be potential genes (known as *candidate genes*) that can be suspected to be involved based on the previous findings or known function. Candidate genes can be evaluated for their involvement by testing for linkage or association (discussed later) or direct sequencing of coding regions, exon/intron boundaries, and promoter regions from unaffected and affected animals. For example, symptoms seen in human patients with phosphofructokinase (PFK) deficiency closely resembled those in other glycogen storage diseases and extensive biochemical analyses revealed the deficiency of the key regulatory glycolytic enzyme muscle-type phosphofructokinase (PFK) (Tarui *et al.*, 1965). The gene was then cloned. Based on this information the canine PFK gene was sequenced in English springer spaniel dogs affected with PFK deficiency and a nonsense mutation identified (Smith *et al.*, 1996), which is different from published mutations responsible for PFK deficiency in humans (reviewed in Nakajima *et al.*, 2002). Protein-based functional assays are another common way to determine if a candidate gene is involved in the development of a disease. This approach led to the diagnosis of PFK deficiency in English springer spaniel dogs experiencing hemolysis and myopathy (Giger *et al.*, 1985).

If there is no candidate gene, a linkage approach involving a whole genome scan utilizing the molecular tools described earlier is an option to identify a chromosomal region or gene linked to the disease. This approach requires medical and pedigree information and a source to isolate DNA from a fairly large number of affected and nonaffected animals. Animal breeding data should make it possible to acquire the necessary data (pedigrees) and samples from three-generation pedigrees for linkage studies. If more than one breed is affected with the same disease, the different genetic background found in different breeds may further assist in narrowing the DNA region of interest. Generally, association studies require an equal number of affected and unaffected (control) animals from a population.

2. *Genetic Analysis*

The development of genome maps allowed for the mapping of genes without further knowledge of their function. Thousands of genetic markers mapped throughout the genome enable genome-wide linkage or association studies

looking for at least one of these markers to segregate with the disease. Because the location of the disease gene is initially not known, genetic markers, such as microsattelites and SNPs, covering the whole genome should be analyzed. The greater the number of markers analyzed, usually between several hundreds or thousands of markers, the higher the likelihood of finding one of these markers close to the disease locus. Most linkage or association analyses in animals are currently based on microsatellites, but with the increasing number of animal genomes sequenced and analyzed for SNP markers, faster and easier analysis with SNP microarray chips will soon be available for animals, as with the current human Genechip.

a. Linkage Analysis

Linkage analysis is based on the same principle of recombination used for genetic linkage mapping. However, unlike a genetic marker, the genotype of the disease locus is not known. Therefore, it is important to know the mode of inheritance of the disorder. Pedigree analysis or experimental breeding can help to identify how a disease is inherited. Single gene diseases are usually easier to evaluate and are commonly classified into Mendelian inheritance patterns as described earlier: autosomal recessive, autosomal dominant, and X-linked inheritance. More complex inheritance patterns are due to the involvement of two or more genes (polygenic) necessary to cause disease, variable penetrance, variable expressivity, and influences from the environment.

Once a mode of inheritance is established, the underlying genotype at the disease locus is inferred and analyzed for linkage with all genetic markers that were tested, which is mostly done with the help of computer programs. If a marker is located close to the disease locus, the result will show no or a very small recombination fraction between the marker and the disease locus. Based on this recombination fraction, a numeric value, called the LOD score, is calculated. This value expresses the likelihood that the result is due to linkage between the tested marker and the disease locus rather than by chance. For example, if the LOD score has a value of 3, this indicates that obtained results are a thousand times (10^3) more likely due to linkage between the tested marker and disease than by chance. In most cases, an LOD score ≥ 3 is statistically significant. Once linkage is established to a marker, the chromosomal region surrounding the marker can be analyzed for potential candidate genes (positional candidate gene approach). Frequently, more markers will have to be analyzed in that area to confirm and further narrow the genome region of interest.

b. Association Study

Genotyping data from hundreds of markers analyzed in groups of affected and unaffected animals can be evaluated for differences in allele frequencies in the two groups, thus demonstrating association between a genetic marker and the disease phenotype. If the marker and the disease locus are located close to each other, both loci will be inherited together, through several generations, and recombination between the two will be rare. Consequently, specific alleles of the marker and the disease locus will mostly be found together within the group of affected animals, which means they are associated (they are said to be in *linkage disequilibrium*). Therefore, an association study compares the frequency of marker alleles within the two groups, and an increased occurrence of a specific marker allele in the group of affected animals indicates that this marker is located at or close to the disease gene.

c. Positional Candidate Gene Approach

A major goal of a genome-wide linkage analysis is to find the gene or genes responsible for the development of the disease or phenotype that was used for the study. The markers found to be linked allow the assignment of the disease locus to a chromosomal area, and the more markers that are tested, the narrower the region will become. A small region is desirable to minimize the number of possible candidate genes that needs to be analyzed for mutations. Because the approximate location of the candidate gene is known, this method is called the positional candidate gene approach. Genes coding for products with a known function that could be involved in the development of the disease will be considered first for analysis.

3. *Genetic Tests*

a. Linked Marker Test

Once significant linkage to a disease has been found, a linked marker test can be offered to breeders using one of the polymorphic markers used to find or refine linkage. Because the actual disease locus is not known at this point, one has to keep in mind that genetic test results using a linked marker can in a few cases lead to an incorrect conclusion about the animal's genetic status at the disease locus as a result of possible recombination between the marker and the disease allele.

b. Mutation Test

A DNA-based test offered for a specific genetic disease that is based on the disease-causing mutation offers an accurate diagnosis and has the advantage that it is not age or phenotype dependent. Buccal (cheek) swabs or blood samples can be used for DNA extraction even from very young animals before any disease phenotype has developed. Deletions and insertions can readily be detected by size differences of the amplified DNA segment. A common method to detect single nucleotide changes is a restriction digest of a PCR-amplified DNA product, which requires

of the FVII protein, leaving affected animals with <4% of normal FVII plasma activity (Callan *et al*., 2006).

Furthermore, many enzyme functions depend on the availability of a vitamin or high-energy intermediate compound (which are also known as cofactors). Therefore, in addition to those diseases in which a mutation affects the protein function directly, alterations of the affinity of an enzyme for the cofactor or impairments in the normal absorption or conversion to the active form of the required cofactors can result in dysfunction (see the discussion of methylmalonic aciduria and cobalamin deficiency, presented later in this chapter). Of the metabolic disorders, these are the most amenable to therapeutic interventions (e.g., parenteral or megadose vitamin supplementation).

Because genetic alterations are possible at any gene locus, inborn errors of metabolism constitute a large heterogeneous group of monogenic (and in the future likely polygenic) disorders. Thus, any mutation affecting the expression or coding sequence in some way can produce any of a variety of malfunctions of the mature protein. Indeed, with the advanced biochemical and molecular characterization of hereditary disorders, most of the genetic defects could be considered to be "inborn errors of metabolism" including malformations and susceptibility to various simple and complex disease traits.

c. Genetic Predisposition to Disease

Increased susceptibility to disease has been recognized more recently to have a genetic basis. Single gene defects for a variety of genetic predispositions have been identified. For instance, mutations in the beta chain of the integrin leukocyte adhesion protein predispose to overwhelming bacterial infections in red Holstein calves and Irish and red and white setter puppies (Foureman *et al.*, 2002; Kijias *et al*., 1999; Shuster *et al.*, 1992). A single common mutation in the ryanodine receptor in various breeds of pigs is responsible for the development of malignant hyperthermia (Fujii *et al.*, 1991). A defect in the mutlidrug-resistant gene 1 is responsible for serious adverse drug reactions in collies and related dog breeds (Mealey *et al.*, 2001; Neff *et al.*, 2004). Moreover, predispositions caused by complex/polygenic traits are being currently characterized and include common predispositions to infections, inflammation, immune disorders, degenerative disorders, drug reactions (pharmacogenetics), and neoplasia.

2. *Inheritance of Genetic Diseases*

Genetic diseases are generally produced by defects in nuclear DNA and only rarely from anomalies in mitochondrial DNA (maternal pattern of inheritance such as with some myopathies). In contrast to humans where dominant traits seem to prevail, hereditary diseases are more often recessively inherited in domestic animals. Although inbreeding practices preserve and propagate desirable characteristics for meat and milk production in food animals or agility, behavior, and morphological traits in companion animals, they bear the risk of passing on deleterious mutations to their offspring and ending up with animals that are homozygous for the mutant allele and thus affected with a genetic disease. As there is pressure to increase health, fertility, and productivity in food animals, deleterious traits are rapidly eliminated with proper breeding practices. Furthermore, the diagnostic evaluations and characterizations of genetic diseases have been facilitated by the recent advances in medicine and comparative genetics, pet owner's interest, and financial support from the National Institutes of Health, other government sources, and foundations, as these animals may also serve as models of human disease. However, in companion animals, breeding is done less scientifically, emphasizing looks and character, leaving many animals at risk of carrying mutant alleles that may produce affected offspring in future generations. Because of these inbreeding practices, some mutations seem to be surprisingly prevalent in certain breeds of dogs and cats. Whereas a mutant allele frequency of 1% is considered to be high in humans, mutant allele frequencies of >10% have been reported for several diseases in several breeds of domestic animals, likely because of founder and popular sire effects. Moreover, X-chromosomal recessive traits such as hemophilia A and B, dystrophin deficiency, and X-linked severe combined immunodeficiency seen in different breeds may result from new mutations in oocytes and, thus, may well be limited to a particular family.

It is important to recognize that the Mendelian concepts of dominant and recessive modes of inheritance refer to the phenotypic presentation of heterozygous and homozygous animals for a particular trait. With recessive disorders, the presence of one normal/wild-type allele is sufficient to assure adequate activity to complete a certain function, whereas with a dominant trait the presence of one mutant allele is already deleterious. For instance, mutant and normal collagen strands will not make a functional fibril for normal joint, ligament, and skin structure. Furthermore, at the DNA level any polymorphism or disease-causing mutation is "codominant" and hence the terms dominant and recessive should be reserved for phenotypes and disorders and not be used for genes. Finally, it is being noted that single gene defects can exhibit variations in clinical signs and disease progression that are likely caused by yet to be determined modifying genes or environmental factors. Hence, simply inherited disorders may ultimately be found to have a more complex metabolic and molecular genetic basis.

3. *Screening for Hereditary Diseases*

Genetic screening generally requires more than clinical physical examination, routine blood and urine tests, and imaging studies to detect and definitively diagnose animals with genetic diseases. A variety of specific laboratory tests, such as hematological, biochemical/metabolic, and DNA

analyses, have been developed, some of which not only can identify affected/diseased animals but also can identify asymptomatic carriers of recessively inherited disorders (Giger and Jezyk, 1992; Sewell *et al.*, 2007).

a. Metabolic Genetic Testing

Inborn errors of metabolism may lead to the dysfunction of a biological system or pathway either under normal conditions or during more demanding situations, such as the presence of concurrent disease or during intense work loads, as many defects occur in catabolic pathways. Screening tests should lead to the detection of the failing biological system. Routine tests such as a complete blood count and a chemistry screen may reveal a specific metabolic problem such as inclusions in white blood cells (lysosomal storage disease) or hyperlipidemia (hyperchylomicronemia). Clinical imaging techniques, gastrointestinal and liver function investigations, as well as renal clearance function studies may more clearly define an organ failure, whereas for others the first clue is found only after pathological examination of tissues or at necropsy.

When a metabolic pathway is blocked by an enzyme deficiency, the substrate of that enzyme and other proximal metabolites either accumulate or divert into an alternate pathway (Fig. 2-8). In contrast, the products or distal metabolites subsequent to the enzyme deficiency will be reduced. In some cases, abnormal metabolites or excessive amounts of normal metabolites affect other metabolic pathways by acting as competitive substrates of another enzyme. Depending on the gene mutation, the deficiency can be complete or can lead to more or less severe clinical signs. One of the best examples of a common clinical diagnostic workup based on metabolic pathways is done clinically when suspecting a specific coagulopathy localizing the defect to the intrinsic (e.g., hemophilia A and B [FVIII and IX]), extrinsic (FVII deficiency), or common pathway (fibrinogen deficiency; see the chapter on hemostatic disorders).

The metabolic diagnosis of an enzyme deficiency can often be accomplished by detecting abnormal metabolites or metabolite concentrations in urine, serum, or cerebrospinal fluid. This was the basis of Garrod's initial urinary metabolite studies on alkaptonuria (homogentisic acid, a defect in the catabolism of phenylalanine and tyrosine), cystinuria, and pentosuria. Although more sophisticated techniques of analysis can now be used, examination of proximal and distal metabolites is still the mainstay of the efforts to diagnose and characterize novel metabolic diseases (Fig. 2-9).

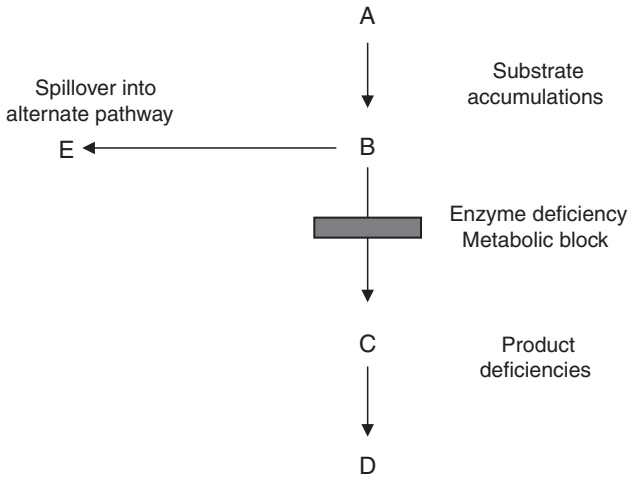


FIGURE 2-8 Metabolic consequences of an enzyme deficiency. Changes in substrates and product concentrations are shown when step B→C is dysfunctional.

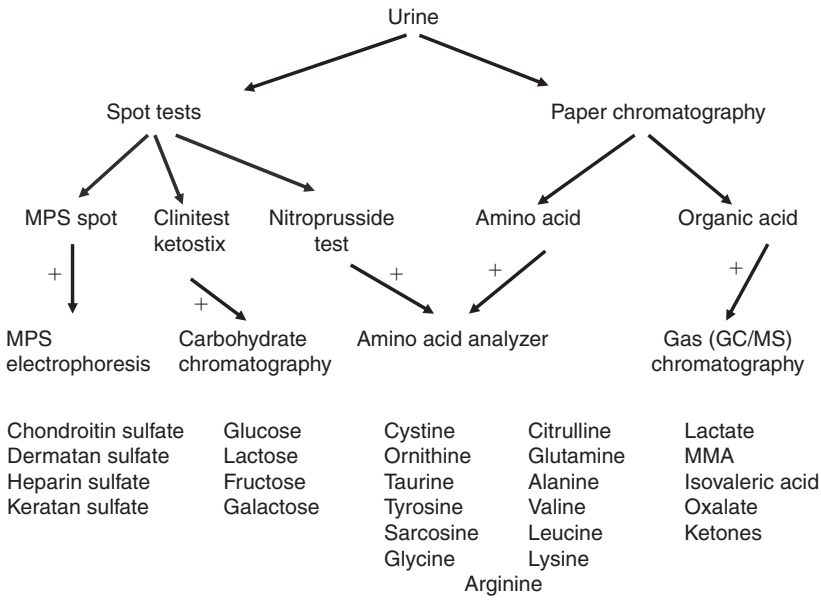

FIGURE 2-9 Metabolic Genetic Screening Scheme to detect inborn errors of metabolism involving amino and organic acids as well as carbohydrates.

One proceeds from metabolite identification to the demonstration of an enzyme or other gene product defect by assaying the functions of candidate proteins chosen based on the knowledge of metabolic pathways and the previous descriptions of metabolic diseases in the same or other species. Metabolic disorders are often named according to the aberrant substrate associated with the pathological condition rather than the truly defective (deficient) enzyme or cofactor (e.g., cystinuria, lactic aciduria, methylmalonic aciduria, porphyria, and mucopolysaccharidosis). Urine as a metabolic screening specimen is preferred, because abnormal metabolites in the blood will be filtered through the glomeruli but then fail to be reabsorbed, as no specific renal transport systems exist for most abnormal metabolites (Fig. 2-10). In those cases in which normal metabolites accumulate, their quantities usually exceed the renal threshold. As a consequence the amount of such compounds in a given volume of urine is often several fold greater than in blood. The renal tubules do not have the capacity to reabsorb abnormal metabolites or excess normal metabolites, and they become concentrated as water is conserved (Giger and Jezyk, 2000; Sewell *et al.*, 2007).

i. Examples of Amino Acidurias The cyanide nitroprusside reaction, which detects any compound containing a sulfhydryl group, is used to screen for cystinuria (and homocystinuria). Cystinuria and other aminoacidurias can be detected by simple spot (nitroprusside) test, paper chromatography using butanol/acetic acid/water as a solvent and ninhydrin stain, and high-pressure liquid chromatography. Cystinuria is caused by defects in renal basic amino acid transporters, which also affect the reabsorption of other amino acids, easily recalled as COLAs: cystine, ornithine, lysine, and arginine. Because cystine precipitates in acidic urine, cystine calculi are formed in the kidney, ureters, bladder, and urethra, leading to life-threatening urinary obstruction (Figure 2-10). The molecular defect has been defined in affected Newfoundland and Labrador retriever dogs, but in the many other dog breeds where the disease is milder and only appears to affect males, the molecular basis still needs to be elucidated. Cystinuria has been identified as a common renal transport defect in a variety of canine breeds, domestic shorthair cats, and also some wild carnivores (Henthorn and Giger, 2006). Interestingly in cats, which completely depend on arginine intake from their diet, the urinary loss in arginine can result in arginine deficiency and ensuing hyperammonemia and neuropathy. In addition, the most severe renal tubular defect involves glucosuria, lactic aciduria, and generalized amino aciduria and is known as Fanconi syndrome. Originally discovered and still common in Basenji dogs, it is now recognized in many other canine breeds, but can also be induced by dietary supplements.

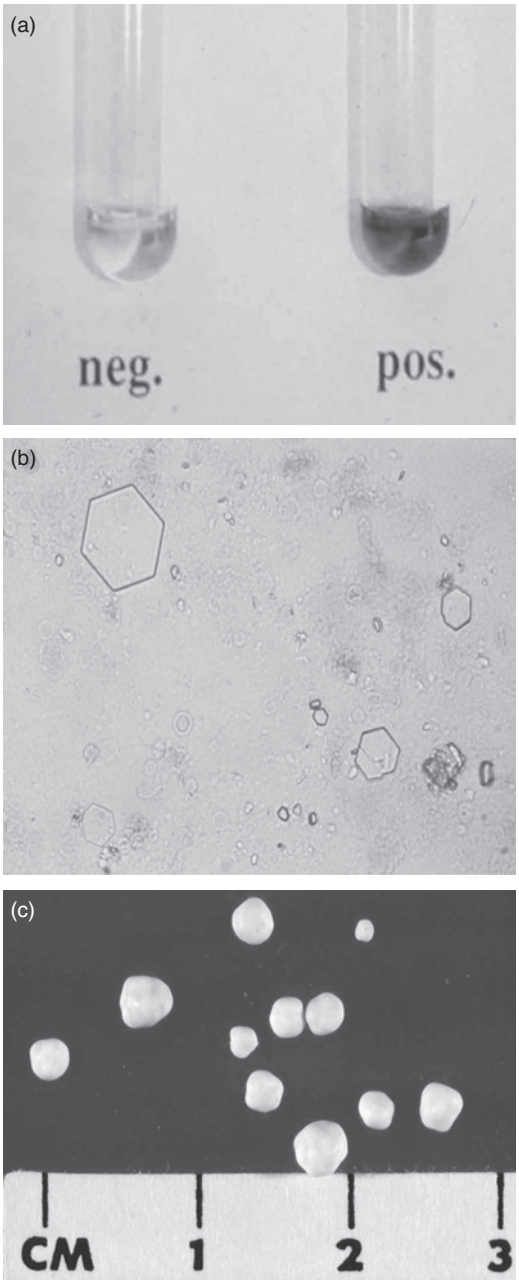

FIGURE 2-10 Cystinuria caused by renal amino acid transport defects. (a) Urinary nitroprusside screening test to detect cystine (magenta red discoloration indicates a positive reaction. (b) Characteristic hexagonal cystine crystals in urine sediment. (c) Cystine calculi removed from the urinary bladder.

ii. Screening for Organic Acids Methylmalonic aciduria is a prime example of an organic aciduria. Methylmalonic acid is a metabolite of an alternative pathway that only accumulates when there is a block in the catabolism of various amino acids, fatty acids, and cholesterol in the tricarboxic cycle. It may be caused by either an intermediary enzyme deficiency or cobalamin (vitamin B_{12}) deficiency, because cobalamin is a cofactor of the

intermediary mutase step. In several breeds of dog, a selective malabsorption of cobalamin has been identified because of a lack of expression of cubulin or amnionless, the intrinsic-cobalamin receptor on the surface of the brush border of the enterocytes in the ileum. Cobalamin is also involved in transmethylation reactions along with folate and its deficiency affects cell growth and hematopoiesis. Hence affected animals fail to thrive, and can become lethargic and cachectic. Fortunately, this serious metabolic disorder can be readily treated by regular parenteral supplementation of cobalamin, thereby circumventing the ileal resorption defect (Fyfe *et al.*, 2004; He *et al.*, 2005). There are several other organic acidurias described in animals, including lactic acidurias causing mitochondrial myopathies and primary hyperoxaluria with kidney calculi and renal failure.

b. Protein Function in Affected and Carrier Animals

Usually the biochemical phenotype of an enzyme deficiency is associated with the disease phenotype, and, as traits, they are inherited recessively, because most enzyme activities are present in excessive amounts than what is minimally necessary to process sufficient substrate for normal development and health. Enzyme activity is expressed in units or as a percentage of control, which is set at 100%. Generally, activity levels of at least 25% are still sufficient for most biological functions. The most immediate effects are seen with key regulatory enzymes in important intermediary pathways such as anaerobic glycolysis. One can often demonstrate the coexpression, or gene dosage effect, of the normal and mutant allele by measuring the activity or quantity of the protein (enzyme) in question in tissues of the affected individual, parent, and littermates compared to normal unrelated control animals. In autosomal recessively inherited diseases, the affected individuals will have enzyme activities of $<$20% and often 0% to 5% of the normal, whereas some littermates and possibly unrelated healthy appearing animals, and the (clinically unaffected) parents of affected animals will have an enzyme activity somewhere around half (30% to 75%) of normal control values. This forms the basis of many carrier detection programs for hereditary diseases. However, the efficiency of carrier detection by protein quantification or function can be seriously affected by various parameters (tissue-specific expression, labile activity, control samples, special shipping and handling). *In vitro* enzyme activity may also not really reflect the *in vivo* expression and function but may depend on substrate and cofactor availability and affinity and is usually measured using artificial substrates. Despite the lack of functional activity of a protein in a disorder, the dysfunctional protein may or may not be present and may be detected through immunological techniques. Thereby animals with and without a protein can be differentiated into cross-reacting material (CRM) positive and negative.

c. Molecular Genetic Testing

More recently, DNA testing for the disease-causing gene mutation can most accurately diagnose many metabolic diseases. Disease-causing mutations have been found in all domestic mammals. These tests are based on amplifying the DNA segment around the disease-causing mutation and differentiating the mutant from the normal by sequencing or identifying fragment size differences with a restriction enzyme digest (discussed previously). Such molecular tests can be accomplished with ethylene diamine tetraacetic acid (EDTA) blood or cheek swabs, and they readily permit the identification of normal, carrier, and affected animals for recessive traits as well as any dominant mutation in the heterozygous, hemizygous, and homozygous presentation. However, mutation-specific DNA tests are generally species and typically breed specific. For instance, different mutations have been found to cause pyruvate kinase deficiency in the basenji, West Highland white (and Cairn) terrier, and beagle breeds (Giger, in press; Skelly *et al.*, 1999; Whitney *et al.*, 1994). In contrast, a single missense mutation seems to be responsible for factor VII deficiency in beagles, Alaskan klee kai, and Scottish deerhounds (Callan *et al.*, 2006).

E. Gene Therapy

Gene therapy refers to the novel treatment of disease by introducing a new gene into a cell; usually the new gene provides a function that is missing because of a defective gene such as for the many hereditary diseases. In general, the defective gene remains, although techniques to repair defective genes are also possible. There are many reviews of gene therapy for metabolic diseases including both general and specific disease-related overviews (Biffi and Naldini, 2005; Brady, 2006; Hodges and Cheng, 2006; Pastores and Barnett, 2005; Sawkar *et al.*, 2006) and those involving large animals (Casal and Haskins, 2006; Ellinwood *et al.*, 2004). This section discusses gene therapy for lysosomal storage diseases (LSDs), primarily in domestic animals, as an example of the field. Clinicopathological and biochemical characteristics of LSDs are presented in a later chapter in this book (Haskins and Giger, in press). Guiding principles for treating LSDs and other inborn errors of metabolism include the following: (1) The earlier the treatment can be instituted, the better the outcome. Thus, prevention of central nervous system or bone disease is more successful than reversing existing lesions. (2) In those disorders with multiple organ involvement, some tissues respond better than others. Thus, in general, liver function is relatively easy to improve, whereas articular cartilage and bone functions are more difficult to change. Because of the blood-brain barrier, the brain and spinal cord present a unique set of challenges. (3) Novel approaches are being developed and assessed regarding efficacy and safety of gene therapy in dogs and

cats as an intermediate between the murine models and applications in humans. Hence, gene therapy, though promising for humans and animals alike and potentially simple to administer, is still an experimental approach for inborn errors of metabolism.

There are several ways to introduce a new gene into a cell. One of the more common current approaches uses viruses that act as vectors to target and transport DNA into a cell, often into the nuclear DNA. The viral vectors are modified to make them replication incompetent and contain additional genetic material, usually including at least a promoter in addition to the cDNA of the gene of interest. Many viruses have been used for gene transfer, including recombinant herpesviruses, lentiviruses, adeno-associated viruses (AAV), adenoviruses (Ad), and Sendai virus (reviewed in Verma and Weitzman, 2005). Although gene therapy is a promising technique for therapy for the LSDs, concerns remain, particularly those involving carcinogenesis. Integration can interfere with the normal function of nearby genes (Hacein-Bey-Abina *et al.*, 2003; Schmidt *et al.*, 2005) with ensuing deleterious effects. Thus, although recombinant retroviral vector gene therapy cured 80% of X-linked Severe-Combined Immunodeficiency (SCID) patients, the development of leukemia in some patients made real what had been a hypothetical risk since the early experiments in the 1990s. Also, the development of tumors in aged Mucopolysaccaridosis (MPS) VII mice that received recombinant adeno-associated viral vectors at birth have been reported (Donsante *et al.*, 2001). Other limitations have included an immune response to the vector or the transgenes they encode, particularly when individuals have a null mutation resulting in no protein production. In general, viral vectors are made replication incompetent by various techniques, such as removing genes encoding structural viral genes, limiting concerns about shedding vector for extended periods, and reducing the potential immune responses against the virus. However, readministration of a vector has a significant potential to induce an immune response. The search for new vectors and ways to modify existing vectors to reduce these limitations is ongoing. Three viral vectors currently in common use include the following:

1. Retroviruses are RNA viruses that reverse transcribe their single-stranded genome and can integrate into host chromosomes (Fields and Knipe, 1986). Some murine retrovirus vectors—for example, those based on murine leukemia viruses—transduce only dividing cells. Lentiviruses can also transduce nonreplicating cells (Fields and Knipe, 1986) and have been generated from the human immunodeficiency virus and feline immunodeficiency virus (Johnston *et al.*, 1999; Stein and Davidson, 2002) among others. The tropism of retroviruses can be modified by providing an alternative envelope glycoprotein during virus production, leading to broader cell-type targeting and enhanced stability upon enrichment (Stein *et al.*, 2005; Wong *et al.*, 2004).

2. Adenoviruses are nonenveloped double-stranded DNA viruses (Fields and Knipe, 1986), which can infect a variety of both quiescent and proliferating cells. The vectors have space for large transgenes; however, transgene expression is often transient because of host immune responses to the vector (Stein *et al.*, 1998; Yang *et al.*, 1996).

3. Adeno-associated viruses (AAV) are small single-stranded DNA viruses that do not produce disease but are, as the name implies, associated with adenoviruses (Fields and Knipe, 1986). This relationship renders AAV's replication incompetent without a helper virus, usually an adenovirus or a herpesvirus. Many serotypes have been developed (Chiorini *et al.*, 1997; Schmidt *et al.*, 2004), with most showing distinct tissue tropism (Gao *et al.*, 2005).

1. *Approaches for Gene Therapy Using Lysosomal Storage Diseases as Examples*

a. *Ex Vivo* Gene Therapy

The usual strategy in this approach is to modify autologous patient cells *in vitro*, returning them to the patient to create an "enzyme factory" to secrete a specific enzyme into the extacellular fluid to be taken up by other cells elsewhere in the body, thereby "cross-correcting" them. The most common therapeutic target is the pluripotent hematopoietic stem cell. Not only can these cells secrete enzyme into the circulation, they can repopulate fixed macrophages in liver, lung, brain, and elsewhere allowing widely distributed sites of local enzyme production. The rationale for this approach has been from the experience of heterologous bone marrow transplantation in animals and children (Birkenmeier *et al.*, 1991; Breider *et al.*, 1989; Consiglio *et al.*, 2004; Follenzi *et al.*, 2002; Hoogerbrugge *et al.*, 1988; Miranda *et al.*, 1998; Sands *et al.*, 1993; Taylor *et al.*, 1986; Walkley *et al.*, 1994; Yeager *et al.*, 1984). Gene therapy of autologous cells avoids the difficulties of finding a histocompatible bone marrow donor, and if engineered to have very high gene expression, the transduced cells will deliver substantially larger amounts of enzyme than normal cells (Biffi *et al.*, 2004).

Ex vivo transduction and transplantation into enzyme-deficient mouse models of LSDs has shown efficacy *in vivo* using murine retroviruses (Miranda *et al.*, 2000; Wolfe *et al.*, 1992). Thus, hematopoietic-directed gene therapy may be effective for the treatment of the systemic disease associated with a number of LSDs. However, thus far, this approach has not achieved the success in clinical trials that was seen in the animal models (Dunbar *et al.*, 1998), possibly because of a lack of conditioning to reduce resident bone marrow. Lentiviral vectors may be a better choice over murine retroviruses, because they transduce nondividing cells and show persistent *in vivo* expression.

b. Direct *In Vivo* Gene Therapy

As an alternative to *ex vivo* therapy, direct *in vivo* gene therapy is the injection of a gene transfer vector directly into a tissue or into the blood circulation. There are many examples in small and large animal models of LSD using a variety of vectors (Daly *et al.*, 1999a, 1999b, 2001; Gao *et al.*, 2000; Hartung *et al.*, 2004; Jung *et al.*, 2001; Ponder *et al.*, 2002, 2006; Xu *et al.*, 2005). As described earlier, each vector has advantages and disadvantages for tissue tropism, longevity of expression, and immune response and other side effects. Issues of long-term safety (greater than 10 years) have not been fully evaluated. The studies in neonates demonstrate the utility of early (disease prevention) rather than delayed (disease reversal) intervention for these progressive disorders. One of the most dramatic examples of neonatal, intravenous gene therapy in a large animal was reported in dogs with mucopolysaccharidosis VII, where the corneal clouding and mitral valve regurgitation were prevented and the dogs, now 6 years old, continue to be able to stand, walk, and run (albeit without a completely normal gait), whereas untreated dogs cannot stand by 6 months of age (Ponder *et al*., 2002).

Retinal degeneration is a relatively common clinical sign associated with a number of LSDs. Viral-mediated gene transfer by direct subretinal or vitreous injection has resulted in histological or functional improvements in mice and cats (Griffey *et al.*, 2005; Hennig *et al.*, 2004; Ho *et al.*, 2002).

The central nervous system (CNS) is a particularly challenging tissue. Over half of LSDs have CNS signs of mental retardation in children, and some also present with progressive ataxia in animals leading to early mortality. A large series of experiments have been performed using injections of a variety of vectors directly into the brain of mice with LSDs (Brooks *et al.*, 2002; Elliger *et al.*, 1999; Ellinwood *et al.*, 2004; Haskell *et al.*, 2003; Passini and Wolfe, 2001; Passini *et al.*, 2002, 2003; Stein and Davidson, 2002; Stein *et al.*, 2005; Vogler *et al.*, 1998). Selected areas of the brain have been injected with minute amounts of the gene construct, and the clinical, pathological, and biochemical effects have shown variable success. For instance, a remarkable reduction in neuronal storage and delayed onset of clinical signs was seen in cats with alpha-mannosidosis (Vite *et al.*, 2005). An alternate intravenous approach with a high dose of purified enzyme apparently crossed the blood-brain barrier in MPS VII mice (Vogler *et al.*, 2005) and is currently being tested in large animals.

As the examples for lysosomal storage diseases illustrate, gene therapy is moving forward with therapies for many metabolic diseases. Promising results have also been seen in dogs with hemophilia (Arruda *et al.*, 2005) and a form of progressive retinopathy (Acland *et al.*, 2001). As research continues into safe and effective approaches of providing genes with appropriate expression, a new era in therapeutics will begin.

Chapter 3

Carbohydrate Metabolism and Its Diseases

J. Jerry Kaneko
Department of Pathology, Microbiology, and Immunology
School of Veterinary Medicine
University of California, Davis
Davis, California

I. INTRODUCTION

The biochemical mechanisms by which the chemical energy contained in foodstuffs are made available to the animal are collectively described as metabolism. Thus, the description of the metabolism of a foodstuff encompasses the biochemical events that occur from the moment of ingestion to its final breakdown and excretion. Classically, these biochemical events have been divided into the metabolism of the three major constituents of food; carbohydrates, proteins, and lipids. The metabolism of the lipids and proteins is discussed in their individual chapters.

The major function of ingested carbohydrates is to serve as energy sources, and their storage function is relatively minor. Carbohydrates are also precursors of essential intermediates for use in synthetic processes. When the metabolic machinery of an animal is disrupted, a disease state prevails (e.g., diabetes). The literature of the biochemistry of metabolism and disease continues to expand as the minute details of individual and overall reaction mechanisms are continually clarified. Additionally, modern molecular approaches have significantly increased our understanding of disease mechanisms and remain fertile fields for investigations into the disease processes. This chapter presents a basis for the better understanding of the biochemical mechanisms underlying those diseases associated with carbohydrate metabolism. The intricate details of carbohydrate metabolic reactions may be found in the many books on fundamental biochemistry.

II. DIGESTION

The digestion of carbohydrates in the animal begins with the initial contact of the carbohydrates in their foodstuffs with the enzymes of salivary juice. Starch of plant foods and glycogen of meat are split into their constituent

monosaccharides by the action of amylase and maltase. This activity ceases as the food matter passes into the stomach, where the enzymatic action is destroyed by the hydrochloric acid. Within the stomach, acid hydrolysis may occur, but the stomach empties too rapidly for complete hydrolysis to take place. Thus, only a small portion of the ingested carbohydrate is hydrolyzed before passing into the small intestine. In the small intestine, digestion of carbohydrate takes place quickly by the carbohydrate splitting enzymes contained in the pancreatic juice and in the succus entericus. Starch and glycogen are hydrolyzed to glucose by amylase and maltase; lactose to glucose and galactose by lactase; and sucrose to glucose and fructose by sucrase. The monosaccharide products of enzymatic hydrolysis of carbohydrates, glucose, fructose, and galactose, are the principal forms in which absorption occurs in the monogastric animal.

III. ABSORPTION

The monosaccharides are almost completely absorbed through the mucosa of the small intestine and appear in the portal circulation as the free sugars. Absorption into the mucosal cell occurs by a sodium-dependent active transport mechanism using a glucose co-transporter. The absorbed glucose then leaves the mucosal cell by a facilitated diffusion process in the presence of a glucose transporter, GLUT-2. Glucose and galactose are absorbed rapidly, whereas fructose is absorbed at about half the rate of glucose with a portion being converted to glucose in the process. Other monosaccharides (e.g., mannose) are absorbed slowly at a rate consistent with a diffusion process. As a result, free sugars appear in the portal circulation for transport to the liver.

Glucose transporters (GLUT) are known to be involved in many tissues—for example, GLUT-1 is the hepatocyte/RBC transporter and is widely distributed; GLUT-2 is in hepatocytes, β cells, and mucosal cells; GLUT-3 is the brain transporter; GLUT-4 is the only insulin-responsive glucose transporter; GLUT-5 is in the intestine; GLUT-6 is not available; and GLUT-7 is within cell organelles (Winter and Signorino, 2002). Glucose transporters have been identified and numbered beyond GLUT-8 and up to GLUT-12 (Piroli *et al.*, 2004) but remain to be confirmed.

IV. METABOLISM OF ABSORBED CARBOHYDRATES

A. General

Liver cells are readily permeable to glucose. This process is facilitated by glucose transporter (GLUT) proteins within the plasma membrane, in particular, GLUT-2 is the transporter in the liver cell plasma membrane (Thorens *et al.*, 1988).

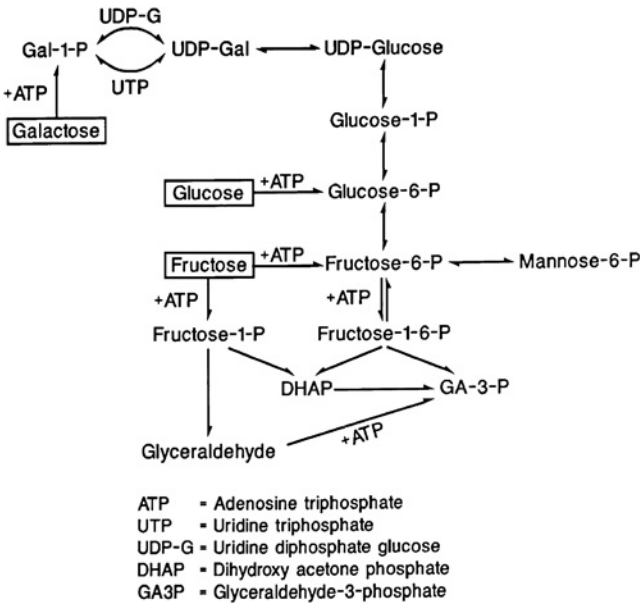

FIGURE 3-1 Pathways for hexose metabolism. Abbreviations: ATP, adenosine triphosphate; UTP, uridine triphosphate; UDP-G, uridine diphosphate glucose; DHAP, dihydroxy acetone phosphate; GA-3-P, glyceraldehyde-3-phosphate.

Within the liver, there are several pathways by which the immediate fate of the hexoses is determined. Glucose, fructose, and galactose first enter the general metabolic scheme through a series of complex reactions to form glucose phosphates (Fig. 3-1). The enzyme, galactose-1-P uridyl transferase, which catalyzes the reaction

$$\text{galactose-1-P} + \text{UDP-glucose} \rightarrow \text{UDP-galactose} + \text{glucose-1-P}$$

is blocked or deficient in congenital galactosemia of humans. The glucose phosphates are then converted to and stored as glycogen, catabolized to CO_2, and water or, as free glucose, returned to the general circulation. Essentially, intermediate carbohydrate metabolism of animals evolves about the metabolism of glucose, and the liver is the organ of prime importance.

B. Storage as Glycogen

Glycogen is the chief storage form of carbohydrate in animals and is analogous to the storage of starch by plants. It is found primarily in liver and in muscle, where it occurs at about 3% to 6% and about 0.5%, respectively (Table 3-1). Glycogen is composed solely of α-D-glucose units linked together through carbon atoms 1 and 4 or 1 and 6. Straight chains of glucose units are formed by the 1–4 links and these are cross-linked by the 1–6 links. The result is a complex ramification of chains of glucosyl units with branch

TABLE 3-1 Liver Glycogen Content of Animals

Species	Glycogen in Liver (%)	Reference
Dog	4.3	Barrett *et al.* (1994)
Sheep	3.82	Kaneta *et al.* (1991)
Cow (lactating)	1.0	Kronfeld *et al.* (1960)
Cow (nonlactating)	3.0	Kronfeld *et al.* (1960)
Baby pig	5.2	Morrill (1952)
Baby pig (newborn)	14.8	Swiatek *et al.* (1968)

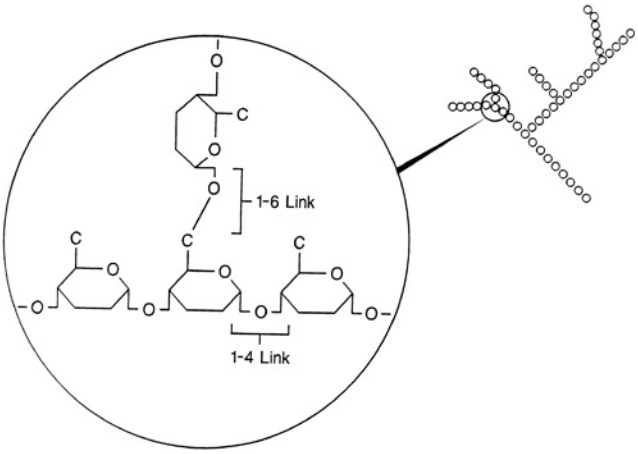

FIGURE 3-2 Glycogen structure. Note that hydrolysis of a 1–6 link by the debrancher enzyme yields a mole of free glucose.

points at the site of the 1–6 links (Fig. 3-2). The internal chains of the glycogen molecule have an average length of four glucosyl units. The external chains beyond the last 1–6 link are longer and contain between 7 and 10 glucose units. The molecular weight of glycogen may be as high as 4×10^6 Mr and contain about 20,000 glucosyl units.

In Table 3-2, the amount of carbohydrate available to meet the theoretical requirements of a hypothetical dog is shown. The amount present is sufficient for about half a day. It is apparent that the needs of the body that must be met continually are satisfied by alternate means and not solely dependent on continuous ingestion of carbohydrates. During and after feeding (postprandial), absorbed hexoses are converted to glucose by the liver and enter the general circulation. Excesses are stored as glycogen or as fat. During the fasting or postabsorptive state, glucose is supplied by the conversion of protein (gluconeogenesis) and by the breakdown of glycogen (glycogenolysis). The continued rapid synthesis and breakdown of glycogen, (i.e., turnover) is well illustrated by the biological half time of glycogen, which is about a day.

TABLE 3-2 Carbohydrate Content of a Dog[a]

Muscle glycogen (0.5%)	25.0g
Liver glycogen (6%)	18.0g
Carbohydrate in fluids 5.5mmol/l (100mg/dl)	2.2g
	45.2g
Caloric value (45.2 × 4kcal/g) = 181kcal	
Caloric requirement ($70kg^{3/4} = 70 \times 5.6$) = 392kcal/day	
$\frac{181}{392} \times 24$ hours = 11 hours	

[a] *Body weight, 10kg; liver weight, 300g; muscle weight, 5kg; volume of blood and extracellular fluid, 2.2 liters.*

C. Glycogen Metabolism

1. *Glycogenesis*

The initial reaction required for the entrance of glucose into the series of metabolic reactions, which culminate in the synthesis of glycogen, is the phosphorylation of glucose at the C-6 position. Glucose is phosphorylated with adenosine triphosphate (ATP) in liver by an irreversible enzymatic reaction catalyzed by a specific glucokinase (GK):

$$\text{glucose} + \text{ATP} \xrightarrow[\text{(HK-IV)}]{\text{GK}} \text{glucose-6-P} + \text{ADP (I)}$$

Glucokinase (GK) (also called hexokinase-IV [HK-IV]) is one of the four hexokinase isoenzymes that occurs in all tissues. Glucokinase (GK) or HK-IV, which is glucose specific, is the predominant isoenzyme found in liver. The nonspecific hexokinase-I (HK-I) is the isoenzyme found in red cells, brain, and nerve tissue.

Liver contains both GK (HK-IV) and HK-I, but GK is the predominant isoenzyme. GK has a high Michaelis constant ($Km = 2 \times 10^{-2}$mol G/l) indicating a low affinity for glucose. The rate of the phosphorylation reaction catalyzed by GK is therefore controlled by the glucose concentration. The activity of GK is increased by glucose feeding and by insulin and is decreased during fasting and in insulin lack (i.e., diabetes). In this regard, GK is an inducible enzyme whose activity is increased by glucose or by insulin. The nonspecific HK-I is found in all tissues including liver, brain, and erythrocytes and has a low Michaelis constant ($Km = 5 \times 10^{-5}$mol G/l), indicating a high affinity for glucose. HK-I catalyzes phosphorylation in all tissues, therefore, it is not controlled by glucose concentration. The activity of HK-I is not affected by fasting or by carbohydrate feeding, diabetes, or by insulin. Therefore, in contrast to GK, HK-I is not an inducible enzyme.

The initial unidirectional phosphorylation reaction permits the accumulation of glucose in the liver cells because phosphorylated sugars do not pass freely into and out of the cell in contrast to the readily transported free sugars. The glucose-6-phosphate (G-6-P) accumulated in the cell next undergoes a mutation in which the phosphate group is transferred to the C-1 position of the glucose molecule. This reaction is catalyzed by the enzyme, phosphoglucomutase (PGM) and involves glucose-1–6-diphosphate as an intermediate:

$$\text{gluocse-6-P} \rightarrow \text{glucose-1-P (II)}$$

Glycogen is synthesized from this glucose-1-phosphate (G-1-P) through a series of reactions involving the formation of uridine derivatives. Uridine-di-phosphoglucose (UDP-G) is synthesized by the transfer of glucose from G-1-P to uridine triphosphate (UTP). This reaction is catalyzed by the enzyme UDP-G-pyrophosphorylase (UDP-G-PPase):

$$\text{UTP} + \text{G-1-P} \rightarrow \text{UDP-G} + \text{PP (III)}$$

In the presence of a polysaccharide primer and the enzyme glycogen synthase (glucosyl transferase), the glucose moiety of UDP-G is linked to the polysaccharide chain by an α-1–4 link:

$$\text{UDP-G} + (\text{glucose 1–4})_n \xrightarrow[\text{synthase}]{\text{glycogen}} (\text{glucose 1–4})_{n+1} + \text{UDP(IV)}$$

Through repeated transfers of glucose, the polysaccharide chain is lengthened. When the chain length of the polysaccharide reaches a critical level between 11 and 16 glucosyl units, the brancher enzyme, α-glucan glycosyl 4:6 transferase, transfers the terminal 7 residue portion from an α-1–4 linkage to an α-1–6 linkage. The newly established 1–6 linkage thus becomes a branch point in the expanding glycogen molecule. The remaining stub can again be lengthened by the action of glycogen synthase. Approximately 7% of the glucose units of the glycogen molecule are involved in these branch points.

2. *Glycogenolysis*

The breakdown of liver glycogen to glucose (glycogenolysis) takes place via a separate pathway. The key initiating and regulating factor in glycogenolysis is the action of epinephrine on liver and muscle glycogen and of glucagon on liver glycogen only. The mechanism of action of glucagon and epinephrine is through a series of reactions that culminate in the phosphorolytic cleavage of the 1–4 glucosyl links of glycogen. In the liver cell, glucagon and epinephrine stimulate the enzyme adenylate cyclase to form 3′–5′ cyclic adenosine monophosphate (cAMP) from ATP. cAMP in turn activates a protein kinase, which in its turn activates liver phosphorylase (LP), the phosphorolytic enzyme. As with many enzymes, LP is present in an inactive form, dephospho-liver phosphorylase (dLP), which is converted to its active form, LP (Cherrington and Exton, 1976) by the protein kinase, phosphorylase kinase.

The action of the LP is to cleave the 1–4 glucosyl links of glycogen by the addition of orthophosphate in a manner analogous to a hydrolytic cleavage with water, hence the analogous term "phosphorolysis." Phosphate is added to the C-1 position of the glucose moiety while H^+ is added to the C-4 position of the other.

cAMP is also a key regulating factor in cellular processes in addition to LP activation. It is required for the conversion of inactive muscle phosphorylase b to active muscle phosphorylase a, again via phosphorylase b kinase. The actions of other hormones known to be mediated by activating adenylate cyclase and cAMP include ACTH, LH, TSH, MSH, T3, and insulin. From these findings, a general concept of hormone action has evolved in which the hormone elaborated by the endocrine organ is described as the first messenger and cAMP within the target cell is the second messenger.

Glucagon acts only on liver glycogen whereas epinephrine acts on both liver and muscle glycogen. In liver, glucagon promotes the formation and release of glucose by increasing glycogenolysis and decreasing glycogenesis. In liver, the hydrolysis of G-6-P is catalyzed by the enzyme glucose-6-phosphatase (G-6-Pase) to release free glucose, thus promoting hyperglycemia. Additionally, glucagon promotes hyperglycemia by stimulation of hepatic gluconeogenesis and thus glucagon is a potent hyperglycemic factor. With muscle glycogen, however, because the enzyme G-6-Pase is absent from muscle, glycogen breakdown in muscle results in the production and release of pyruvate and lactate rather than glucose. Mainly lactate and some pyruvate are transported to the liver where glucose is resynthesized via reverse glycolysis (Cori cycle; Section IV.D).

The continued action of LP on the 1–4 linkages results in the sequential release of glucose-1-P (G-1-P) units until a branch point in the glycogen molecule is reached. The residue is a limit dextrin. The debrancher enzyme, amylo-1-6-glucosidase, then cleaves the 1–6 linkage, releasing free glucose. The remaining 1–4 linked chain of the molecule is again open to attack by LP until another limit dextrin is formed. Thus, by the combined action of LP and the debrancher enzyme, the glycogen molecule is successively reduced to G-1-P and free glucose units.

G-1-P is converted to G-6-P by the reversible reaction catalyzed by phosphoglucomutase (PGM, Section IV.C.1, Reaction II). The G-6-P is then irreversibly cleaved to free glucose and phosphate by the enzyme G-6-Pase, which is found in liver and kidney. The free glucose formed can, unlike its phosphorylated intermediates, be transported

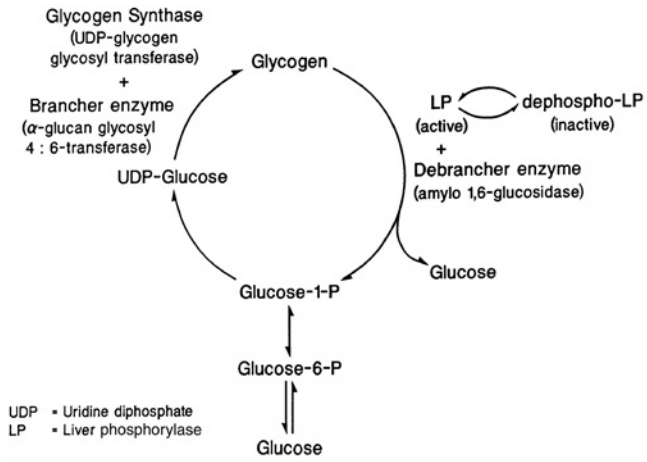

FIGURE 3-3 Summary of liver glycogen metabolism. In muscle, phosphorylase a is the active form and phosphorylase b is the inactive form. Abbreviations: UDP, uridine diphosphate; LP, liver phosphorylase.

out of the hepatic cell and enter the general circulation, thereby contributing directly to the blood glucose pool. In muscle tissue, there is no G-6-Pase, and muscle glycogen cannot supply glucose directly to the circulation by glycogenolysis. Muscle glycogen contributes to blood glucose indirectly via the lactate or Cori cycle (Section IV.D). The series of reactions described are illustrated schematically in Figure 3-3.

3. *Hormonal Influences on Glycogen Metabolism*

The biochemical basis of the glycogenolytic and hyperglycemic action of glucagon and epinephrine was discussed in Section IV.C.2. These hormone actions are the bases for the epinephrine and glucagon stimulation tests, which are used to assess the availability of liver glycogen and the sensitivity of the carbohydrate regulatory mechanisms to these hormones. Many other hormones influence carbohydrate metabolism to a greater or lesser degree in keeping with the concept that carbohydrate metabolism is a totally integrated metabolic mechanism.

One of the results of successful insulin therapy is a restoration of the depleted glycogen reserve. The mechanism of insulin action on carbohydrate metabolism continues to be a subject for intense study and is discussed more fully in Section VI. Briefly, the primary role of insulin is to promote glucose entry into peripheral cells, mainly muscle and fat cells, and to enhance glucose utilization by liver cells by its effect on enzyme systems at control points in the glycolytic pathways. In the presence of insulin, glucose removal from the blood is enhanced by shifting the direction of glucose metabolism toward utilization by increasing glycogen synthesis and glucose uptake and oxidation. The result is a hypoglycemia.

Promotion of liver glycogen storage is also one of the effects of the glucocorticoids. This effect may be attributed to their enhancement of gluconeogenesis, hyperglycemia, decreased glycogenolysis, and decreased glucose oxidation. A tendency toward a mild hyperglycemia is also present in hyperthyroid states, as the result of an overall increase in carbohydrate metabolism. Thyroxine is thought to increase the sensitivity of the liver cell to the action of epinephrine, thereby increasing glycogenolysis and promoting hyperglycemia. Increased glycogenolysis, gluconeogenesis, and the hyperglycemia may also be the compensatory result of an increased rate of tissue metabolism. In rats made hyperthyroid, hepatic G-6-Pase activities are increased, which would enhance hepatic glucose production and hyperglycemia in the hyperthyroid states. An additional factor contributing to the overall tendency for hyperglycemia is the stimulation of glucose absorption by the gastrointestinal tract by thyroxine.

4. *Glycogen in Disease*

In systemic disease, changes in glycogen concentrations in tissues or organs are generally observed as decreases. Depletion of liver glycogen stores is seen in diabetes mellitus, starvation, bovine ketosis, ovine pregnancy toxemia, or in any condition with nutritional carbohydrate deficiency or increased carbohydrate turnover. Pathological increases in liver glycogen occur in the rare glycogen storage diseases (GSD) and are described in Section IX.D.

D. Catabolism of Glucose

Carbohydrate in the form of glucose is the principal source of energy for the life processes of the mammalian cell. All cells require a constant supply of this indispensable nutrient, and only relatively small changes are tolerated without adverse effects on the health of the animal. Glucose is not oxidized directly to CO_2 and H_2O but rather through a series of stepwise reactions involving phosphorylated intermediates. The chemical energy of glucose is "stored" through the synthesis of "high-energy" phosphate bonds during the course of these reactions and used in other metabolic reactions. The details of the individual reactions in the pathways of glucose catabolism have been largely elucidated, but emphasis here is being placed on the interrelationships of the pathways rather than on the details of the individual reactions.

1. *Pathways of Glucose-6-Phosphate Metabolism*

The fundamental conversion required to initiate the oxidation of glucose by a cell is its phosphorylation to form G-6-P. This reaction has been described in Section IV.C.1.

The G-6-P formed as a result of the GK (HK-IV) catalyzed reaction is central to glucose catabolism. There are at least five different pathways that G-6-P can follow: free glucose, glycogenesis, glycolysis, hexose monophosphate, and glucuronate pathway.

a. Free Glucose

The simplest direction for G-6-P is a reversal of phosphorylation by a separate enzyme catalyzed reaction in which G-6-P is hydrolyzed to form free glucose and inorganic phosphate. This reaction is catalyzed by the enzyme G-6-Pase:

$$\text{glucose-6-PO}_{4^-} \xrightarrow{\text{G-6-Pase}} \text{glucose} + \text{P}_\text{i}$$

This is an irreversible reaction that opposes the previously described unidirectional GK (HK-IV) reaction. These two opposing and independently catalyzed enzyme reactions are the site of metabolic control for glucose because the balance of these enzyme activities regulates the net direction of the reaction. Significant amounts of G-6-Pase are found only in liver and to a lesser extent in the kidney. This is in accord with the well-known function of the liver as the principal source of supply of glucose for the maintenance of blood glucose concentration. The G-6-Pase activity is generally higher than the GK activity for most of a 24-hour day except for a few hours after each meal. This means that for most of the day, the liver is supplying glucose rather than using glucose.

Muscle G-6-P, however, because of the absence of G-6-Pase, does not contribute glucose from its glycogen to blood directly. Muscle G-6-P does, however, contribute glucose to blood indirectly via the lactate or Cori cycle. Lactate formed in muscle by glycolysis is transported to the liver, where it is resynthesized to glucose and its precursors as outlined in Figure 3-4.

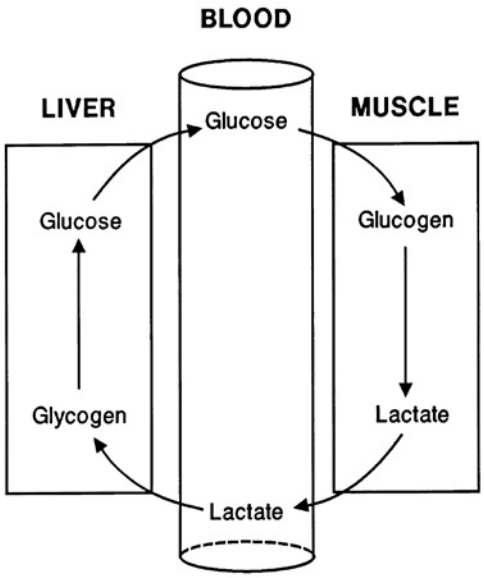

FIGURE 3-4 The lactate or Cori cycle. Muscle cells are devoid of glucose-6-phosphatase, therefore muscle glycogen contributes indirectly to blood glucose by this pathway.

b. Glycogenesis

This pathway for G-6-Pase leading to the synthesis of glycogen is discussed in Section IV.C.1.

c. Anaerobic Glycolysis

One of the three oxidative pathways of G-6-P is the classic anaerobic glycolytic or Embden-Meyerhof pathway (EMP). The intermediate steps involved in this pathway of breakdown of G-6-P into two three-carbon compounds are summarized in Figure 3-5. A mole of ATP is used to phosphorylate fructose-6-phosphate (F-6-P) to form fructose-1,6-diphosphate (F-1,6-P). This phosphorylation reaction is also irreversible and catalyzed by a specific kinase, phosphofructokinase (PFK). The opposing unidirectional reaction is catalyzed by a specific phosphatase, fructose-1,6-diphosphatase (F-1,6-Pase). These opposing PFK and F-1,6-Pase catalyzed reactions are a second site of metabolic control regulated by the activities of these two highly specific enzymes. At this point in the process, starting from glucose, a total of two high-energy phosphates from ATP have been donated to form a mole of F-1,6-P.

F-1,6-P is next cleaved to form two three carbon compounds as shown in Figure 3-5. The next step is an oxidative step catalyzed by the enzyme glyceraldehyde-3-phosphate dehydrogenase (GA-3-PD) with oxidized nicotinamide adenine dinucleotide (NAD^+) as the hydrogen acceptor. During the process, the molecule is phosphorylated. In the succeeding steps, the molecule is dephosphorylated at the points indicated, and a mole of ATP is generated at each point.

A third site of control of glycolysis is the irreversible formation of pyruvate catalyzed by the enzyme pyruvate kinase (PK). In the reverse direction, two enzymatic reactions operate. Pyruvate carboxylase (PC) first catalyzes the carboxylation of pyruvate to oxaloacetate (OAA), and the OAA is then converted to phospho-enol-pyruvate (PEP) by the enzyme PEP carboxykinase (PEP-CK) (Figs. 3-5 and 3-8).

Thus, the overall conversion of a mole of glucose to 2 moles of pyruvate requires 2 moles of ATP for the initial phosphorylations and a total of 4 moles of ATP are generated in the subsequent dephosphorylations. This net gain of 2 moles of ATP represents the useful energy of anaerobic glycolysis.

For repeated function of the glycolytic pathway, a supply of NAD^+ must be available for use in the oxidative (GA-3-PD) step. Normally in the presence of molecular O_2

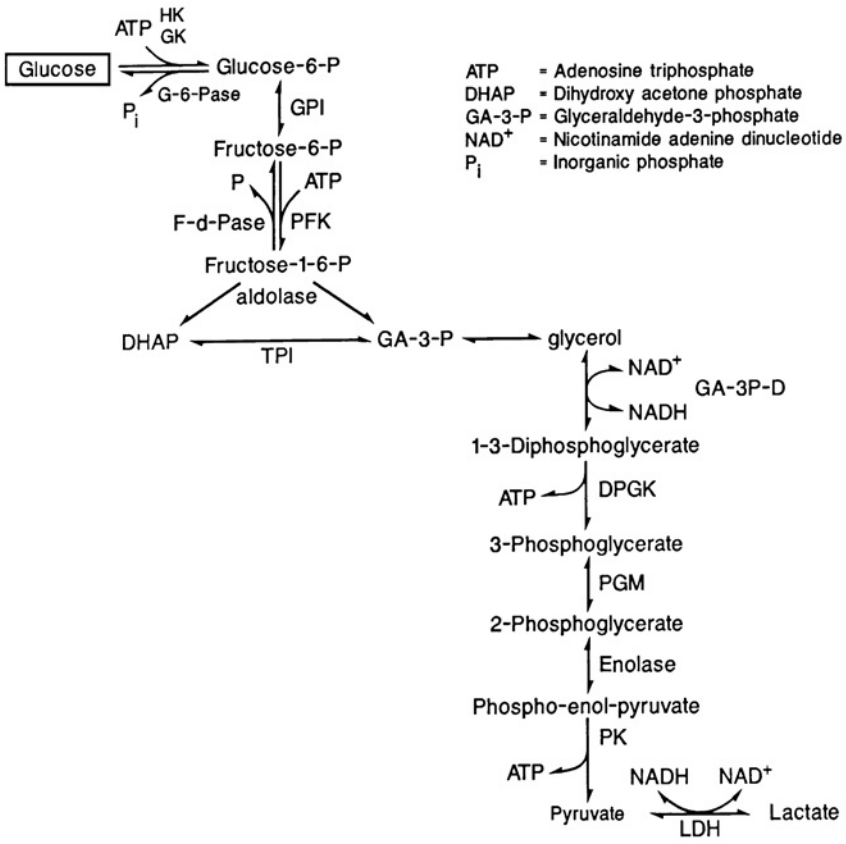

FIGURE 3-5 The glycolytic or classic Embden-Meyerhof pathway (EMP). Note that 2 moles of ATP are used and 4 moles of ATP are generated. Abbreviations: ATP, adenosine triphosphate; DHAP, dihydroxy acetone phosphate; GA-3-P, glyceraldehyde-3-phosphate; NAD^+, nicotinamide adenine dinucleotide; P_i, inorganic phosphate.

(i.e., aerobic glycolysis), reduced NADH is reoxidized via the cytochrome system:

$$\underset{\text{(cytochrome)}}{H^+ + NADH + \tfrac{1}{2}O_{2^-}} \rightarrow \underset{\text{(system)}}{NAD^+ + H_2O}$$

which provides a continuous source of NAD^+.

In the absence of O_2 (i.e., anaerobic glycolysis), NADH is reoxidized to NAD^+ in the reaction catalyzed by lactate dehydrogenase (LDH) where pyruvate is reduced to lactate and the NADH is the H^+ donor. Therefore, by this "coupling" of the LDH system to the GA-3-PD system, anaerobic breakdown of glucose to lactate proceeds in the absence of 02. As noted earlier, this anaerobic system generates only 2 moles of ATP and when compared to the 36 moles of ATP generated in aerobic glycolysis, anaerobic glycolysis is not very efficient.

d. Hexose Monophosphate Pathway

This alternate route of G-6-P oxidation has been variously referred to as the pentose phosphate pathway (PPP), direct oxidative pathway, Warburg-Dickens scheme, the hexose monophosphate pathway (HMP), or the hexose monophosphate shunt. The initial step of the shunt pathway involves the oxidation of G-6-P at the C-1 position to form 6-phosphogluconate (6-PG) as summarized in Figure 3-6. The reaction is catalyzed by glucose-6-phosphate dehydrogenase (G-6-PD) and in this pathway, oxidized nicotinamide adenine dinucleotide phosphate ($NADP^+$) serves as the hydrogen acceptor. In the second oxidative step, 6-P-G is oxidatively decarboxylated by 6-phosphogluconate dehydrogenase (6-P-GD) to yield a pentose phosphate, ribulose-5-phosphate (Rib-5-P), again in the presence of $NADP^+$. Thus, in the initial reactions, which are essentially irreversible, 2 moles of NADPH are formed. In this pathway, only the C-1 carbon atom of the glucose molecule is evolved as CO_2. By contrast, glucose catabolism via the glycolytic scheme results in the loss of both the C-1 and C-6 carbon atoms as CO_2 when pyruvate is oxidatively decarboxylated to form acetyl-CoA. This difference in CO_2 evolution is used to study partitioning of glucose metabolism through the glycolytic (EMP) pathway and the HMP shunt pathway in domestic animals. The subsequent metabolism of the Rib-5-P in the HMP shunt is also shown in Figure 3-6. As a result of the series of transformations, F-6-P and GA-3-P are formed, which serve as recycling links into the glycolytic pathway.

For continued functioning of the HMP shunt pathway, a supply of $NADP^+$ must be available to act as the hydrogen

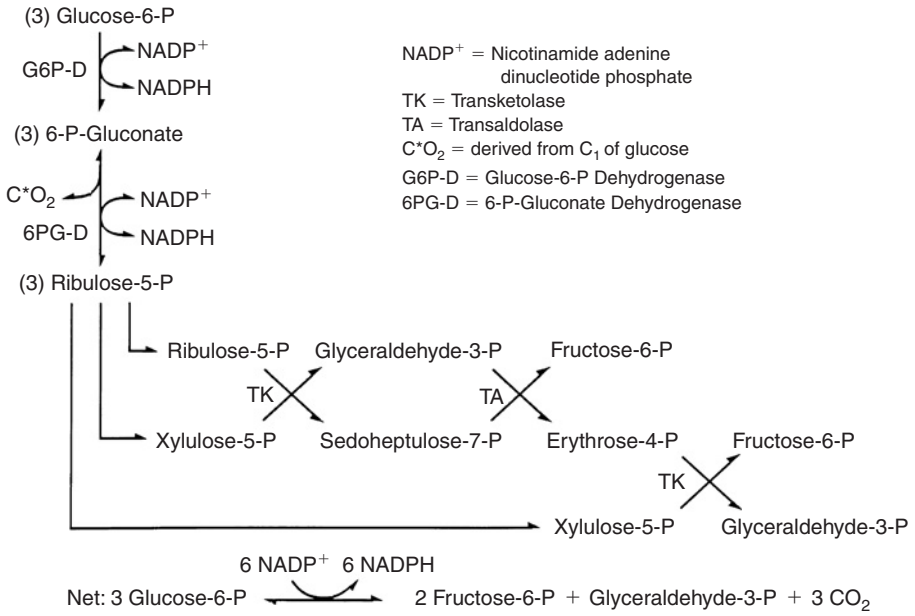

FIGURE 3-6 The pentose phosphate pathway (PPP) or the hexose monophosphate pathway (HMP). Abbreviations: $NADP^+$, nicotinamide adenine dinucleotide phosphate; TK, transketolase; TA, transketolase; TA, transaldolase; C^*O_2, is derived from C_1 of glucose.

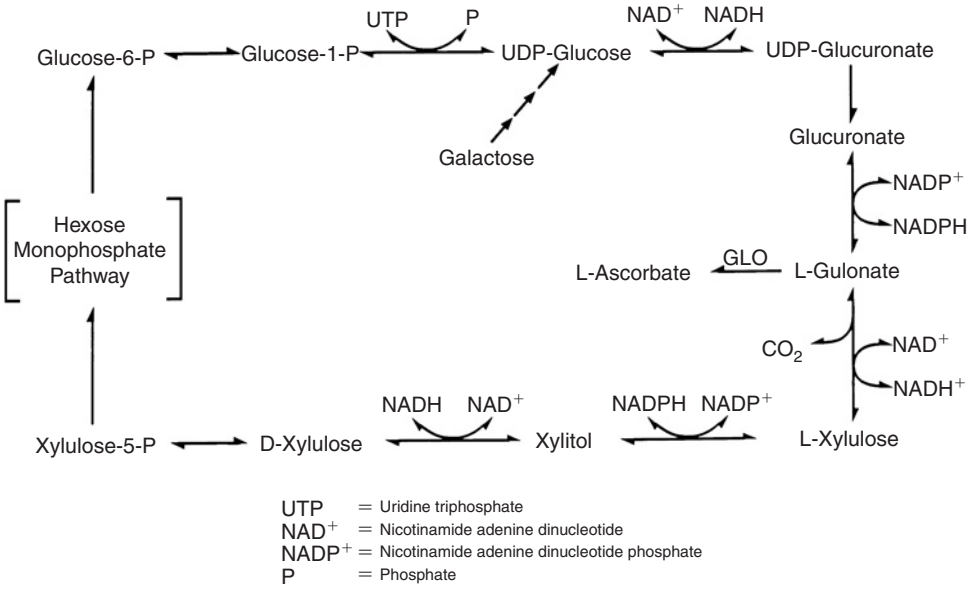

FIGURE 3-7 Glucuronate pathway or the C_6 oxidation pathway. Note that vitamin C is synthesized via this pathway.

acceptor. Oxidized $NADP^+$ is regenerated from NADPH via the cytochrome system in the presence of O_2 so the HMP pathway is an aerobic pathway of glucose oxidation. Reduced NADPH is also required as a hydrogen donor in the synthesis of fatty acids. Through generation of NADPH, the HMP shunt route of carbohydrate metabolism is linked to that of fat synthesis. Accordingly, glucose oxidation through the HMP shunt pathway is essential for the synthesis of fat. In general, the HMP pathway is the major source of the NADPH, which maintains the reductive environment for all biosynthetic processes using NADPH as a cofactor.

e. Glucuronate Pathway

This is an alternate pathway of G-6-P oxidation, which has been named the uronate pathway, the glucuronate pathway, or the C_6 oxidative pathway. This pathway is shown in Figure 3-7. The initial steps of this pathway involve the formation of uridine diphosphoglucose (UDPG), which, as noted earlier, is an intermediate in glycogen synthesis. G-6-P is first converted to G-1-P, which then reacts with uridine triphosphate (UTP) to form UDPG. This product is then oxidized at the C_6 position of the glucose moiety in contrast to the C_1 position, which is oxidized in the HMP

shunt pathway. This reaction requires NAD^+ as a cofactor and the products of the reaction are uridine diphosphoglucuronic acid (UDPGA) and NADH. This UDPGA is involved in a large number of important conjugation reactions in animals (e.g., bilirubin glucuronide formation, synthesis of mucopolysaccharides [chondroitin sulfate], which contain glucuronic acid, and generally in detoxification reactions). UDPGA is cleaved to release D-glucuronate and UDP.

D-glucuronate is next reduced to L-gulonate in a reaction catalyzed by the enzyme gulonate dehydrogenase (GUD), with NADPH as the hydrogen donor. The L-gulonate may be converted to a pentose, L-xylulose, or to vitamin C. When converted to L-xylulose, the C-6 carbon of L-gulonate is oxidatively decarboxylated and evolved as CO_2. The L-xylulose is then reduced to xylitol, catalyzed by the enzyme L-xylulose reductase. This is the enzyme that is deficient in pentosuria of humans. As shown in Figure 3-7, xylitol is converted to D-xylulose, which is then phosphorylated to D-xylulose-5-P and a cyclical pathway involving the HMP shunt pathway may occur. L-gulonate is also converted by enzyme-catalyzed reactions to L-ascorbate in those species that can synthesize their own vitamin C (i.e., all domestic animals). The enzyme, L-gulonolactone oxidase (GLO), is lacking in humans, nonhuman primates, and guinea pigs, and therefore vitamin C must be supplied in their diets. The enzyme is present only in the liver of the mouse, rat, pig, cow, and dog. In the dog, the liver GLO activity is low and the ascorbate hydrolytic activity is high so dogs may have additional needs for vitamin C during stress (e.g., wound healing, postsurgical stress). For vitamin C synthesis, D-galactose may be an even better precursor than D-glucose. This pathway is also included in Figure 3-7.

2. *Terminal Oxidation: Aerobic Glycolysis*

The metabolic pathways described thus far are those of the carbohydrates. In analogous fashion, the breakdown of fats and of proteins also follows independent pathways leading to the formation of organic acids. Among the organic acids formed from lipids are acetyl-CoA (AcCoA), acetoacetate (AcAc), and 3-OH-butyrate (3-OH-B) from the β-oxidation of fatty acids. From proteins, pyruvate, oxaloacetate (OAA), and α-ketoglutarate (α-KG) are formed from transamination of their corresponding α-amino acids. Direct deamination of amino acids is also a route of formation of organic acids. These organic acid intermediate metabolites are indistinguishable in their subsequent interconversions. Thus, the breakdown of the three major dietary constituents converges into a final common pathway, which also serves as a pathway for the interconversions between them.

a. Pyruvate Metabolism

The pathway for breakdown of glucose to pyruvate has been described in Section IV.D.1. Pyruvate, if it is not reduced to lactate, is oxidatively decarboxylated in a complex enzymatic system requiring the presence of lipoic acid, thiamine pyrophosphate (TPP), coenzyme A (CoA), NAD^+, and pyruvate dehydrogenase (PD) to form AcCoA and NADH. Pyruvate may follow a number of pathways as outlined in Figure 3-8. The conversion of pyruvate to lactate was described in Section IV.D.1. By the mechanism of transamination or amino group transfer, pyruvate may be reversibly converted to alanine. The general reaction for an amino group transfer is

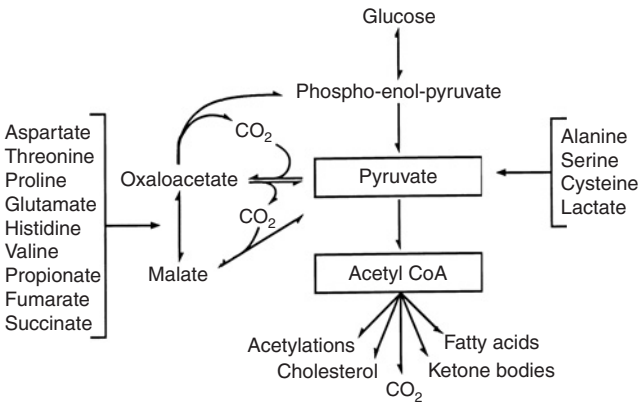

FIGURE 3-8 Pathways of acetate and pyruvate metabolism.

$$\begin{array}{l} R_1\text{-C-COO-} + R_2\text{-C-COO-} \rightarrow R_1\text{-C-COO-} \\ \qquad\qquad\qquad\qquad\qquad\qquad + R_2\text{-C-COO-} \\ \qquad\qquad\qquad\quad \| \;|\text{transferase}|\; \| \\ \qquad\qquad\qquad\quad O\;NH_2\;\;NH_2O \end{array}$$

α-keto acid α-amino acid α-amino acid α-keto acid

where the amino group of an amino acid is transferred to the α position of an α-keto acid and as a result, the amino acid is converted to its corresponding α-keto acid. This reaction requires the presence of vitamin B_6 as pyridoxal phosphate and is catalyzed by a specific transferase, in this case alanine aminotransferase (ALT). Serum levels of several of these transferases (e.g., ALT and aspartate aminotransferase [AST]) have been particularly useful in the diagnosis and evaluation of liver and muscle disorders, respectively. These aspects are discussed in the individual chapters on liver and muscle function.

The energetics of the reaction from phosphoenolpyruvate (PEP) to form pyruvate and catalyzed by pyruvate kinase (PK) are such that this is an irreversible reaction, as is the PD catalyzed conversion of pyruvate to AcCoA. A two-step separate pathway to reverse this process is present at this step so this is a fourth site of directional metabolic control. Through a CO_2 fixation reaction in the presence of $NADP^+$-linked malate dehydrogenase (MD), malate is formed from pyruvate. Malate is then oxidized to OAA in the presence of NAD^+-linked MD. OAA may also be formed directly from pyruvate by the reaction catalyzed

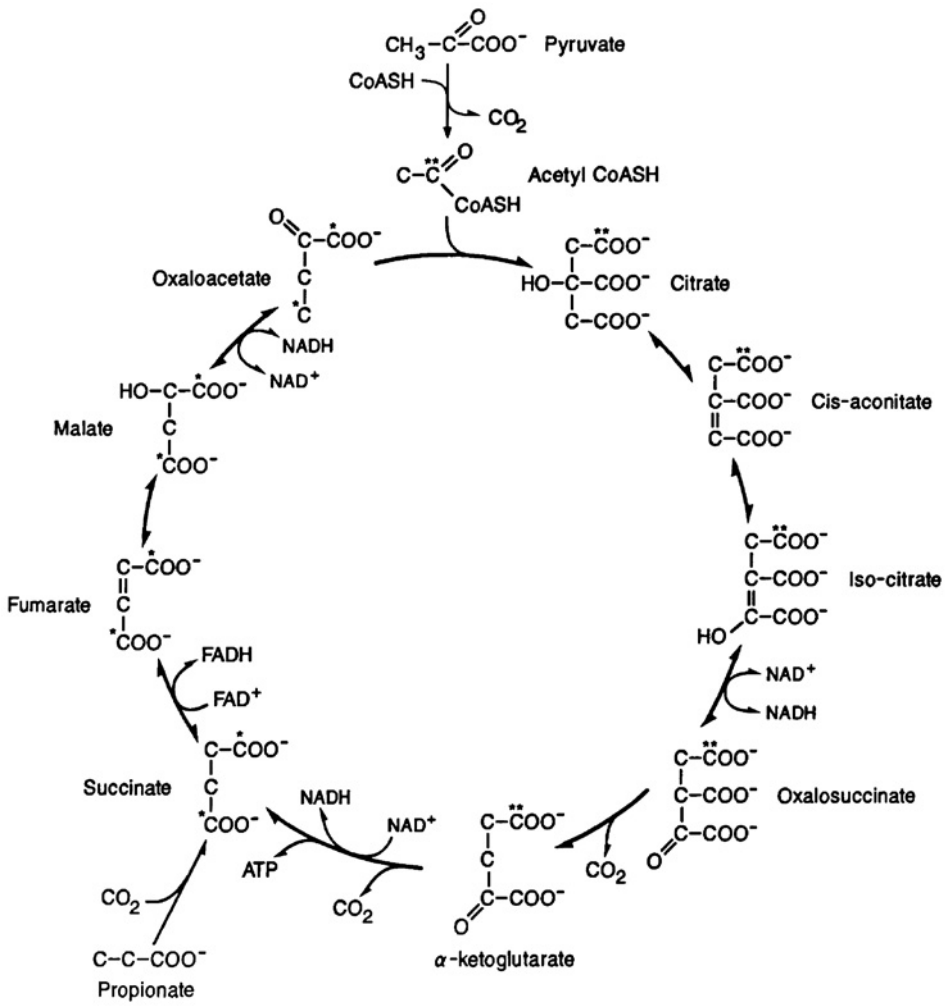

FIGURE 3-9 Tricarboxylic acid cycle. The pathway for the entry of propionate into the metabolic scheme is also included. The asterisks give the distribution of carbon in a single turn of the cycle starting with acetyl-CoA. Note the randomization of carbon atoms at the succinate step.

by pyruvate carboxylase (PC). OAA formed by either route may then be phosphorylated and decarboxylated to form PEP in a reaction catalyzed by PEP carboxykinase (PEP-CK). Thus, a pathway in the reverse direction of the PK reaction is present for gluconeogenesis from lower intermediates. These pathways for pyruvate metabolism are outlined in Figure 3-8, which includes the dicarboxylic acid cycle.

b. Tricarboxylic Acid Cycle

AcCoA formed by the oxidative decarboxylation of pyruvate also has a number of metabolic routes available. AcCoA occupies a central position in synthetic and in oxidative pathways as shown in Figure 3-8. The oxidative pathway leading to the breakdown of AcCoA to CO_2 and H_2O follows a cyclical pathway that is the tricarboxylic acid (TCA) cycle, citric acid cycle, or the Kreb's cycle. The major steps involved are given in Figure 3-9. In a single turn of the cycle, a mole of AcCoA enters, 2 moles of CO_2 are evolved, and a mole of OAA is regenerated. The regenerated OAA may then condense with another mole of AcCoA, and the cycle continues. Citric acid is a symmetrical molecule that behaves asymmetrically as shown in Figure 3-9. Also, the CO_2 that is evolved is derived from that portion of the molecule contributed by OAA during each turn of the cycle. The expected distribution of carbon atoms from AcCoA in one turn of the cycle is also given in Figure 3-9. During one turn of the cycle, a randomization of carbon atoms occurs at the succinate level such that CO_2 derived from the carboxyl group of acetate will be evolved during the next turn of the cycle.

In the process, 3 moles of NAD^+ and a mole of a flavin nucleotide (FAD) are reduced, and a mole of ATP is generated as noted in Figure 3-9. In animal tissues, there is a cytoplasmic $NADP^+$-linked isocitric dehydrogenase (ICD), which is not associated with the mitochondrial NAD^+-linked ICD or other enzymes of the TCA cycle. The $NADP^+$-ICD is another enzyme used as an aid to diagnose liver disease.

3. *Carbon Dioxide Fixation in Animals*

According to Figure 3-9, the TCA cycle is a repetitive process based on the regeneration of OAA at each turn. In addition, other metabolic pathways are available for intermediates in the cycle. Reversal of the transamination reactions previously described to form aspartate or glutamate would result in a withdrawal of OAA and α-KG, respectively, from the cycle. By decarboxylation, OAA may also be withdrawn to form PEP, and malate may form pyruvate and thence other glycolytic intermediates as shown in Figure 3-8. Continued losses of these intermediates into other metabolic pathways would theoretically result in a decrease in the rate of operation of the cycle. A number of metabolic pathways are known whereby the losses of cycle intermediates may be balanced by replacement from other sources and are shown in Figure 3-8. The amino acids, aspartate and glutamate, may function as sources of supply as well as routes for withdrawal. The CO_2 fixation reactions, which are the reversal of the reactions previously described,

$$\text{phosphoenolpyruvate} + CO_2 \rightarrow \text{oxaloacetate}$$
$$\text{pyruvate} + CO_2 \rightarrow \text{malate}$$
$$\text{pyruvate} + CO_2 \rightarrow \text{oxaloacetate}$$

may also function as important sources of supply. A fourth CO2-fixing reaction

$$\text{propionate} + CO_2 \quad \text{succinate}$$

is especially important in ruminants because propionate is a major product of rumen fermentation and is a major supplier of intermediates for the TCA cycle. Propionate is one of the three major fatty acids, with acetate and butyrate, involved in ruminant metabolism.

4. *Energy Relationships in Carbohydrate Metabolism*

The energy of carbohydrate breakdown must be converted to high-energy phosphate compounds to be useful to the organism; otherwise the energy is dissipated as heat. The total available chemical energy in the reaction

$$\text{glucose} \rightarrow 2\,\text{lactate}$$

is about 50kcal/mole or about 7% of the 690kcal/mole, which is available from the complete oxidation of glucose to CO_2 and water. The useful energy of anaerobic glycolysis is represented by the net gain of 2moles of ATP and the available energy of each is about 7kcal. Thus, the efficiency of glycolytic breakdown of glucose to pyruvate is 14kcal or 28% of the available 50kcal or only 2% of the total available 690kcal in glucose.

The major portion of the energy of glucose is generated in the further aerobic oxidation of pyruvate to CO_2 and H_2O. In the oxidative or dehydrogenation steps, NADH or NADPH (FAD in the succinate step) is formed. In the presence of molecular O_2, these compounds are reoxidized to NAD^+ or $NADP^+$ in the cytochrome system. In the sequence of reactions of this system, 3 moles of ATP are formed per mole of NADH or NADPH oxidized to NAD^+ or $NADP^+$. This transfer of energy to ATP is known as oxidative phosphorylation, or ox-phos. The yield of high-energy phosphate bonds in the form of ATP in the system per atom of oxygen consumed (½ O_2) is conventionally referred to as the P:O ratio, which in this case is 3.

TABLE 3-3 ATP Yield in Glucose Oxidation

Glucose	ATP
I ATP (2X)	−2
↓	
fructose-1-6-diphosphate	
I → NADH → 3 ATP (2X)	+6
ATP (4X)	+4
↓	
2 pyruvate	
NADH → 3 ATP (2X)	+6
↓	
2 acetyl-CoA	
NADH → 3 ATP (6X)	+18
ATP (2X)	+2
FADH → 2 ATP (2X)	+4
↓	
4 CO_2	
Net: Glucose → 6 CO_2	+38 ATP

Table 3-3 presents a balance sheet of the ATPs formed in the various steps, and 36 of the total 38 ATPs are generated in aerobic glycolysis. The complete oxidation of a mole of glucose to CO_2 and water yields 690kcal, and therefore the net gain of 38 ATPs in anaerobic plus aerobic glycolysis represents 266kcal for an overall efficiency of 38%. In comparison, the efficiency of the modern internal combustion engine is about 20%.

V. INTERRELATIONSHIPS OF CARBOHYDRATE, LIPID, AND PROTEIN METABOLISM

The pathways by which the breakdown products of lipids and proteins enter the common metabolic pathway have been described in previous sections. The principal points at which carbohydrate carbon may be interconverted between amino acids and fatty acids are outlined in Figure 3-10. Thus, certain amino acids (glycogenic) can serve as precursors of carbohydrate through the transamination reactions, and by reversal of these transaminations, carbohydrates can serve as precursors of amino acids.

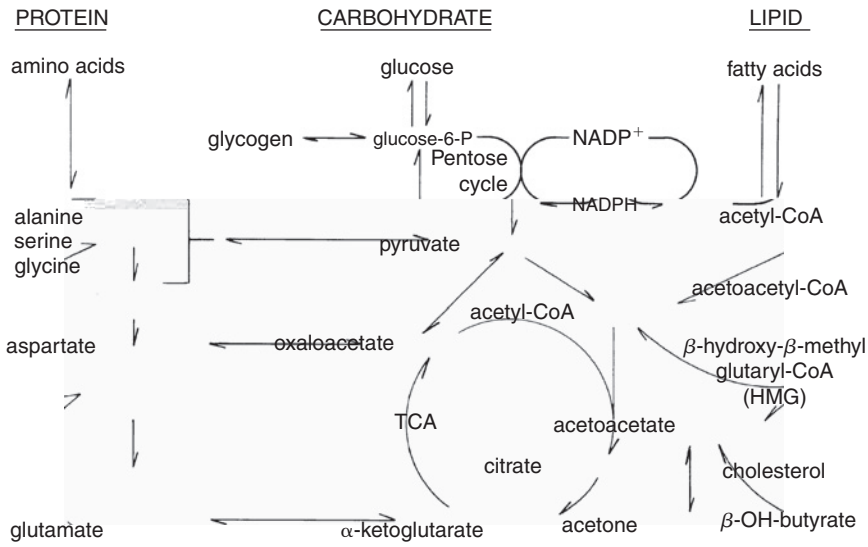

FIGURE 3-10 Interrelationships of carbohydrate, protein, and lipid metabolism.

The relationship between carbohydrate and lipid metabolism deserves special mention for the carbohydrate economy, and the status of glucose oxidation strongly influences lipid metabolism. A brief description of lipid metabolism follows, and greater detail may be found in the chapter on lipid metabolism.

A. Lipid Metabolism

1. *Oxidation of Fatty Acids*

Intracellular fatty acids are either synthesized in the cytoplasm or taken up as free fatty acids. Fatty acid oxidation begins in the cytoplasm with the activation of fatty acids to form fatty acyl-CoA. The activated fatty acyl-CoA is bound to carnitine for transport into the mitochondria where fatty acyl-CoA is released for intramitochondrial oxidation.

The classical β-oxidation scheme for the breakdown of fatty acids whereby two-carbon units are successively removed is a repetitive process involving four successive reactions. After the initial activation to form a CoA derivative, there is (1) a dehydrogenation, (2) a hydration, (3) a second dehydrogenation, and (4) a cleavage of a two-carbon unit. The result is the formation of AcCoA and a fatty acid residue shorter by two carbon atoms. The residue can then recycle to form successive AcCoA molecules until final breakdown is achieved. In the case of odd-chain fatty acids, propionyl-CoA is formed in the final cleavage reaction. The hydrogen acceptors in the oxidative steps are NAD^+ and FAD. The further oxidation of AcCoA to CO_2 and water proceeds in the common pathway of the TCA cycle. In the process, 2 moles of CO_2 are evolved per mole of AcCoA entering the cycle. Therefore, fatty acids could not theoretically lead to a net synthesis of carbohydrate. Net synthesis of carbohydrate from fatty acids would require the direct conversion of AcCoA into some glucose precursor (i.e., pyruvate). The reaction

$$\text{pyruvate} \rightarrow \text{acety1 CoA} + CO_2$$

however, is irreversible and the only route by which fatty acid carbon could theoretically appear in carbohydrate is through the TCA cycle intermediates, and this occurs without a net synthesis.

2. *Synthesis of Fatty Acids*

The pathway for fatty acid synthesis is separate from that of the β-oxidation mechanism for fatty acid breakdown. Malonyl-CoA is first formed by the addition of CO_2. Subsequently, two carbon units from malonyl-CoA are sequentially added to the growing chain with a loss of CO_2 at each addition. At each step, there is also a reduction, dehydration, and a final reduction to form a fatty acid that is two carbons longer than the previous one.

The synthesis of fatty acids also requires NADPH as the hydrogen donor rather than NADH or FADH. The major source of NADPH is during the oxidation of glucose in the HMP shunt pathway. NADPH concentration is also high in the cytoplasm of liver and adipose cells where HMP shunt activity is also high. The availability of this NADPH is the basis for the linkage of carbohydrate oxidation to lipid synthesis.

3. *Synthesis of Cholesterol and Ketone Bodies*

AcCoA is also the precursor of cholesterol and the ketone bodies: AcAc, 3-OH-B, and acetone. The synthesis of cholesterol proceeds through a series of reactions beginning with the stepwise condensation of 3 moles of AcCoA to

form β-hydroxy-β-methyl glutaryl-CoA (HMG-CoA). As shown in Figure 3-10, HMG-CoA is a common intermediate for the synthesis of cholesterol and ketone bodies in the liver cell. In liver, a deacylating enzyme is present, which cleaves HMG-CoA to yield AcCoA and free AcAc. This is the HMG-CoA cycle. The free AcAc then diffuses out of the cell and enters the general circulation. For further oxidations to occur, AcAc is "reactivated" with CoA in extrahepatic tissues (muscle) by the transfer of CoA from succinyl-CoA to form AcAcCoA. Increased ketogenesis and ketonemia are the net result of alterations in metabolic pathways or enzymes that favor the accumulation of AcAcCoA. Prime examples are diabetes mellitus and bovine ketosis.

The increased mobilization and utilization of fatty acids are a well-known requisite for ketogenesis under conditions of starvation and diabetes. Under these same conditions, lipid synthesis from AcCoA is also depressed. The net effect of either or both of these alterations favors the accumulation of AcCoA and thus ketogenesis.

Increased ketogenesis is always associated with an increased rate of gluconeogenesis in association with an increased activity of the key gluconeogenic enzyme, PEP-carboxykinase (PEP-CK). The increased rate of gluconeogenesis in turn depletes OAA. There is an increase in the NADH/NAD ratio, which would promote the conversion of OAA to malate, thereby depleting OAA. With the depletion of OAA and subsequent OAA deficiency, there is an insufficient condensing partner for AcCoA for the Kreb's cycle. The AcCoA is then readily diverted to ketone bodies.

Hepatic ketogenesis is regulated by the rate limiting transfer of FFA across the mitochondrial membrane. Carnitine acyl transferase, the enzyme system responsible for the mitochondrial uptake of FFA, is increased in diabetes and contributes to the ketogenesis.

B. Influence of Glucose Oxidation on Lipid Metabolism

In addition to the separation of the biochemical pathways for lipid oxidation and lipid synthesis, an anatomical separation of lipid metabolism is also present. The liver is the major site of fatty acid oxidation and the adipose tissue is the major site of lipid synthesis. Adipose tissue, *in vitro*, converts glucose carbons to fatty acids faster than does liver tissue.

It is well known that, with excessive carbohydrate feeding, fat depots in the body increase. Fasting, on the other hand, depresses the respiratory quotient (R.Q.) indicating that the animal is now using body fat as the energy source. During fasting, plasma FFA also increase, and when carbohydrate is supplied, they decrease. The presence of glucose both stimulates lipogenesis and spares fatty acid from oxidation. In diseases with an inability to utilize glucose (e.g., diabetes), depression of lipogenesis is a characteristic finding. When there is adequate glucose oxidation (e.g., successful insulin therapy in diabetes), lipid synthesis is restored and the animal regains its weight.

In those conditions with decreased glucose use or availability (e.g., diabetes, starvation, ruminant ketosis), there is an increased release of glucose precursors (amino acids) from muscle and FFA from adipose tissues mediated by activated hormone-sensitive lipases (HSL) (Khoo *et al*., 1973). The amino acids and FFA are transported to the liver where the amino acids follow gluconeogenic pathways. Fatty acids follow pathways toward oxidation and ketogenesis and, additionally, glucagon promotes hepatic ketogenesis. There is also an underutilization of ketones in the peripheral tissues of dogs (Balasse and Havel, 1971; Foster and McGarry, 1982). The net result is an overproduction of glucose and ketones in liver and an underutilization of both in the peripheral tissues.

VI. INSULIN AND CARBOHYDRATE METABOLISM

The internal secretions of the anterior pituitary, adrenal cortex and medulla, and the pancreas are closely associated with carbohydrate metabolism. The pituitary and adrenal factors were discussed in Section IV.C, together with glucagon. More detailed information is available in the chapters on pituitary and adrenal function. Since the successful extraction of insulin by Banting and Best in 1921, a vast amount of literature has accumulated on its role in carbohydrate metabolism and continues to this day. The fine details of insulin action are still being studied, and a basic understanding of the major biochemical events that occur in animals with and without insulin has evolved.

A. Proinsulin and Insulin

The elucidation of the insulin structure by Sanger in 1959 was soon followed by the discovery of its precursor, proinsulin, and its structure was quickly known. It has been the subject of many reviews (Raptis and Dimitriadis, 1985; Steiner, 2004). Proinsulin is a single-chain looped polypeptide linked by disulfide bridges (Fig. 3-11). It varies in length from 78 amino acid residues in the dog to 86 for the human, horse, and rat. Its m.w. is near 9000 daltons. Proinsulin is synthesized in the pancreatic β-cells on the rough endoplasmic reticulum (RER) and transported and stored in the secretory granules on the Golgi apparatus. There, the central connecting polypeptide or C-peptide is cleaved from the chain by proteolytic enzymes, and the two linked end fragments are the monomeric insulin molecule. C-peptide has an m.w. of 3600 daltons and is devoid of biological activity.

Insulin and C-peptide are released into the circulation in equimolar amounts but C-peptide's circulatory concentration is higher than that of insulin because of its slower clearance half-time of 20 min as compared to 5 to 10 min for insulin. C-peptide is primarily degraded by the kidney and a portion is excreted in the urine (Duckworth and Kitabchi, 1981).

In the pancreatic cells, as the insulin moiety is cleaved from the proinsulin, it crystallizes with zinc for storage in the β-cell granules. The dense central inclusions of these insulin secretory granules consist mainly of crystalline insulin. Insulin release is stimulated by glucose, amino acids, hormones (glucagon, gastrin, secretin, pancreozymin), and drugs (sulfonyl ureas, isoproterenol).

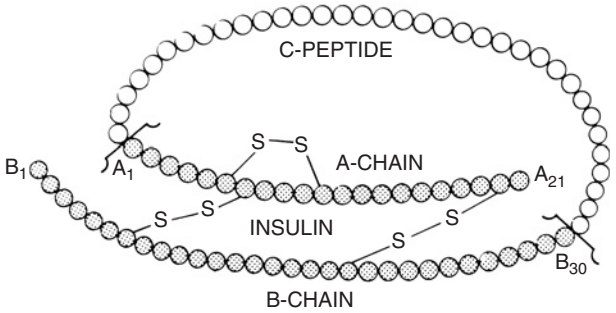

FIGURE 3-11 Insulin and proinsulin. Proinsulin is the coiled polypeptide. When the connecting C-peptide (open circle) is removed, the insulin molecule (solid circle) is released.

Insulin release is inhibited by hypoglycemia, somatostatin, and many drugs, such as dilantin and phenothiazines. The liver is the primary site of insulin degradation, and the kidney is a secondary site. The half-life of insulin in the circulation is between 5 and 10 min (Steiner, 1977).

The A chain of insulin consists of 21 amino acids and the B chain of 30 amino acid residues (Fig. 3-11). The m.w. of the insulin monomer is 6000 daltons and is the smallest unit possessing biological activity. Under physiological conditions, 4 molecules of insulin are linked together to form a tetramer, the active molecule. Insulin obtained from various species differs in amino acid composition in Chain A or Chain B or both (Table 3-4). Differences occur within species also as rats and mice (Markussen, 1971) have two nonallelic insulins. These structural differences among the various species of animals are not located at critical sites, however, because they do not affect their biological activity. They do, however, affect their immunological behavior.

The amount of insulin stored in the pancreata of various species also differs. The dog stores about 3.3 units per gram of pancreas, which amounts to about 75 I.U. in a 10-kg dog. This amount, if suddenly released, would be fatal.

Insulin release is affected by glucose, mannose, leucine, other amino acids, ketone bodies, and fatty acids. This release is mediated by glucagon, a hormone, which increases cAMP and potentiates the insulin response. The sulfonylureas are effective as pharmacological agents to release insulin, the basis for their therapeutic use.

TABLE 3-4 Species Variation in Amino Acid Sequences of Insulin[a]

Species	Position[a]						
	A Chain				B Chain		
	A-4	A-8	A-9	A-10	B-3	B-29	B-30
Human	Glu	Thr	Ser	Ileu	Asp	Lys	Thr
Monkey	Glu	Thr	Ser	Ileu	Asp	Lys	Thr
Dog	Glu	Thr	Ser	Ileu	Asp	Lys	Ala
Pig	Glu	Thr	Ser	Ileu	Asp	Lys	Ala
Sperm Whale	Glu	Thr	Ser	Ileu	Asp	Lys	Ala
Rabbit	Glu	Thr	Ser	Ileu	Asp	Lys	Ser
Horse	Glu	Thr	Gly	Ileu	Asp	Lys	Ala
Cow	Glu	Ala	Ser	Val	Asp	Lys	Ala
Sheep	Glu	Ala	Gly	Val	Asp	Lys	Ala
Sei Whale	Glu	Ala	Ser	Thr	Asp	Lys	Ala
Rat 1	Asp	Thr	Ser	Ileu	Lys	Lys	Ser
Rat 2	Asp	Thr	Ser	Ileu	Lys	Met	Ser

From Renold and Cahill (1966) *and Naithani* et al. (1984).

[a] *These are the sites of variation on the* A *chains and the* B *chains. Ala = alanine; Asp = aspartic acid; Glu = glutamic acid; Ileu = isoleucine; Met = methionine; Ser = serine; Thr = threonine.*

Blood glucose is the primary regulator of both insulin release and its biosynthesis. This is a highly selective process, and only insulin, C-peptide, and proinsulin are released and released rapidly. The insulin response curve to a glucose load (IVGTT) exhibits 2 peaks in humans, the early 5-min peak representing release and the second 10- to 30-min peak representing *de novo* insulin synthesis and release. This bimodal curve is not clear in dogs (see Fig. 3-14, presented later) but it is likely to occur.

During proinsulin hydrolysis, C-peptide also accumulates in the granules. Therefore, when the granule contents are released by glucose stimulation, insulin, C-peptide, and proinsulin all appear in plasma and each can be measured by radioimmunoassay (RIA). Whereas studies in humans have focused on all three, in animals, the focus has been on insulin, and little is known of proinsulin or C-peptide in health or disease.

The influence of the various gastrointestinal hormones on insulin secretion is of considerable interest because plasma insulin levels are higher at a given plasma glucose level after an oral glucose load as compared to an intravenous load. The oral glucose tolerance test (OGTT) is known to elicit larger total insulin response than the intravenous glucose tolerance test (IVGTT). A number of GI hormones are known to influence insulin secretion to varying degrees and are sufficient to form an entero-insular axis (Buchanan, 1975). The hormones implicated are secretin, cholecystokinin-pancreozymin (CCK-PZ), gastrin, glucagon-like activity (GLA) of the gut, and gastric inhibitory peptide (GIP). GIP is a powerful stimulator of insulin secretion in humans and dogs and this is associated with a rise in blood glucose (Ross *et al*., 1977). Thus, GIP is central to the entero-insular axis.

B. Insulin Transport

Insulin is transported in the circulation bound to a β-globulin. At a tissue, insulin binds to receptors on the cell membrane. The insulin receptor is a very large glycoprotein on the surface of virtually all cells, including liver, kidney, fat, muscle, erythrocytes, and monocytes. The receptor is a posttranslational derivative of a gene product and is a tetramer of 2 α and 2 β subunits. The internal β subunit of the receptor anchors the receptor to the membrane. As a result, insulin moves through the plasma membrane and into the cytoplasmic compartment, but the mechanism is unclear. All cells, in particular liver and kidney, are able to inactivate insulin by reductive cleavage of the disulfide bonds. Liver inactivates about 50% of the total insulin.

C. Glucose Transport

Insulin binding also activates receptors both on the plasma membrane surface and in the cytoplasm. This activation induces a variety of reactions—for example, phosphorylations—but the details and their implications are not yet known. However, the end result of these interactions—that is, glucose transport across the membrane and into the cell—is defined. Glucose transport proteins (glucose transporters [GLUT-1-7]) are characterized. They are small membrane proteins, 40 to 50kd, and the different transporters are distributed in different cells; GLUT-1 is widely distributed (brain, RBC, placenta, kidney), as are GLUT-2 (liver, pancreatic β cells, mucosal cells), GLUT-3, (brain), and GLUT-4 (skeletal muscle, heart muscle, fat). GLUT-5 is in the intestine, GLUT-6 is not available, and GLUT-7 is within cell organelles (Winter and Signorino, 2002). GLUT-4 is the only insulin-responsive glucose transporter, and for this reason has been studied extensively. Insulin mobilizes GLUT-4 to the membrane, thereby facilitating glucose transport into the cell. Glucose transport activity was studied in the erythrocytes of trained and untrained racehorses (Arai *et al*., 1994). Horses in training had glucose transport activities 2 to 3.5 times greater than those of untrained horses. The specific glucose transporter was not identified but presumably is GLUT-1 as in other animals.

D. Insulin Action on Biochemical Systems

The principal sites of insulin action are in the initial phases of glucose metabolism. Insulin first binds to insulin receptors of the target cell plasma membranes and then facilitates glucose entry into cells such as muscle and fat by activation of glucose transporters, in this case GLUT-4. There is also a high degree of stereo-specificity because D-glucose is transported but L-glucose is not. With increased accumulation of glucose in the cells, the movement of glucose into the metabolic scheme is enhanced and glucose utilization increases.

Insulin influences the metabolism of glucose by the liver cells, the central organ of glucose homeostasis, but with a slightly different focus. GLUT-2 is not significantly regulated by insulin, so the liver cell is freely permeable to glucose. Therefore, the major action of insulin in liver is after the initial transport step. The principal step is the first phosphorylation of glucose to form G-6-P in the reaction catalyzed by glucokinase (GK). This GK reaction is rate limiting and GK activity is influenced by insulin. Additionally, the effect of insulin on other key unidirectional phosphorylative steps directs glucose metabolism toward utilization and FA synthesis. An important effect of insulin is to increase the activity of the pyruvate dehydrogenase (PD) system, which increases AcCoA, thereby promoting increased FA synthesis and oxidation to CO_2 via the Krebs TCA cycle. These and other reactions are described in Section VII.C. Thus, there are two major roles for insulin, promoting (1) glucose transport across the membranes of muscle and fat cells and (2) glucose

utilization by increasing enzyme catalyzed reactions in liver cells.

In nerve cells, insulin binds to receptors and promotes membrane transport of glucose, but in this case, the membrane transport system itself appears to be the limiting factor. Thus, even though the HK system is operating maximally ($Km(G) = 5 \times 10^{-5}$), the limited glucose transport of about 1.5 mmols/l (27 mg glucose/dl) induces the symptoms of hypoglycemia: incoordination, disorientation, and weakness when there is insufficient glucose to compensate by mass action.

In other cells such as the red blood cell, which also has the HK system, insulin does not affect glucose metabolism or limit transport. The HK system is operating maximally and glucose utilization is sufficient to meet the needs of the blood cell at all times.

E. Physiological Effects of Insulin

The principal effects of insulin administration to an animal are summarized in Table 3-5. The most characteristic finding following insulin administration is a hypoglycemia. This occurs regardless of the nutritional state, age, and other characteristics of the animal and is a net result of the increased removal of glucose from the plasma into the tissues. The respiratory quotient (R.Q.) increases toward unity, indicating that the animal is primarily utilizing carbohydrate. The consequences of this increased utilization of glucose follow a pattern of an increase in those constituents derived from glucose and a decrease in those that are influenced by increased glucose oxidation. The conversion of glucose to glycogen, fat, and protein is enhanced, whereas gluconeogenesis and ketogenesis are inhibited. The decreases in serum phosphate and potassium levels that parallel those of blood glucose are presumably due to their involvement in the phosphorylating mechanisms.

F. Other Pancreatic Islet Hormones

Numerous hormones oppose the action of insulin and, by doing so, prevent or correct the hypoglycemic effects of insulin. Hypoglycemia stimulates a number of counterregulatory hormones including glucagon, epinephrine, and growth hormone. Norepinephrine and cortisol are less responsive than the three mentioned.

1. *Glucagon*

Glucagon is a polypeptide hormone (Mr = 3485 daltons) secreted by the α (A) cells of the islets. Release of glucagon is stimulated by hypoglycemia. Glucagon acts only in the liver where it stimulates glycogenolysis and gluconeogenesis, thereby increasing blood glucose. The most important physiological role of glucagon is to promote hyperglycemia in response to a hypoglycemia. Glucagon acts only on liver glycogen, unlike epinephrine, which acts on both liver and muscle glycogen. Like most hormones, glucagon is first bound to surface receptors on a cell, in this case, the hepatocyte. Acting through these receptors, adenylate cyclase is activated, which in turn increases the amount of cyclic AMP (cAMP). cAMP then activates a phosphorylase kinase, which activates phosphorylase A, which in turn hydrolyzes glycogen. Additionally, glucagon is an insulin secretagogue second only to glucose in the magnitude of the insulin response it elicits. This insulin-releasing action of glucagon is the basis for the glucagon stimulation test (GST), which has been used to evaluate diabetes in cats (Kirk *et al*., 1993).

2. *Somatostatin*

Somatostatin is secreted by many cells, including the hypothalamus, but its major source is the pancreatic δ (D) cells.

TABLE 3-5 Effects of Insulin on Animals

Tissue	Increase	Decrease
Whole animal	Anabolism Food intake Respiratory quotient	
Blood		Glucose Ketones Fatty acids Phosphate Potassium Amino acids Ketone bodies
Enzymes	Glucokinase Phosphofructokinase Pyruvate kinase Lipoprotein lipase AcCoA carboxylase	Glucose-6-phosphatase Fructose 1-6-diphosphatase Pyruvate carboxylase PEP-carboxykinase Carnitine acyltransferase Hormone-sensitive lipase
Liver	Glucose oxidation Glycogen synthesis Lipid synthesis Protein synthesis	Glucose production Ketogenesis
Muscle	(Skeletal/Heart) Glucose uptake Glucose oxidation Glycogen synthesis Amino acid uptake Protein synthesis Potassium uptake	
Adipose	Glucose uptake Glucose oxidation Lipid synthesis Potassium uptake	

Somatostatin has broad inhibitory effects on the release of many hormones, including growth hormone, glucagon, and insulin. Therefore, it has a modulating effect on the actions of these two hormones. Administration of somatostatin blocks the secretion of glucagon; in this way, somatostatin exacerbates an insulin-induced hypoglycemia.

VII. BLOOD GLUCOSE AND ITS REGULATION

A. General

The blood glucose concentration depends on a wide variety of factors and its concentration at any time is the net result of an equilibrium between the rates of entry and of removal of glucose in the circulation. As such, all the factors that exert influence on entry or removal become important in the regulation of blood glucose concentration. Furthermore, when the renal reabsorptive capacity for glucose is exceeded (renal threshold), urinary loss of glucose becomes an additional factor influencing the maintenance of the blood glucose concentration. The blood glucose levels at which this occurs vary between species and are listed in Table 3-6.

B. Glucose Supply and Removal

Glucose is supplied by intestinal absorption of dietary glucose or by hepatic glucose production from its precursors, for example, carbohydrates (glycogen, fructose, galactose) and amino acids (gluconeogenesis). The dietary sources of supply of carbohydrates are especially variable among the various species. The absorptive process varies with the degree of systemic hormonal activity (e.g., thyroid) and gastrointestinal hormone activity (e.g., secretin). All conditions affecting gastrointestinal digestive processes (e.g., gastrointestinal acidity, digestive enzymes, disease) substantially affect absorption of glucose. Hence, it is important to evaluate the blood glucose in virtually all diseases.

TABLE 3-6 Renal Thresholds for Glucose in Domestic Animals

	Species		Reference
	(mg/dl)	(mmol/l)	
Dog	180–220	10.0–12.2	Shannon *et al.* (1941)
Horse	180–200	10.0–11.1	Stewart and Holman (1940)
Cow	98–102	5.4–5.7	Bell and Jones (1945)
Sheep	160–200	8.9–11.1	McCandless *et al.* (1948)
Goat	70–130	3.9–7.2	Cutler (1934)

In the postabsorptive state, hepatic production is the major source of supply for maintaining blood glucose. The hormones epinephrine and glucagon promote the release of glucose from glycogen as described in Section IV.C.2. The glucocorticoids promote gluconeogenesis and oppose the hypoglycemic action of insulin.

Removal of glucose is governed by a variety of factors, most of which ultimately relate to the rate of utilization of glucose. All tissues constantly utilize glucose either for energy purposes or for conversion into other products (glycogen, pentoses, lipids, amino acids). Therefore, an outflow of glucose from the circulation, which is governed by the rate of utilization of glucose by a tissue, occurs at all times. The level of blood glucose itself partially governs the rate of utilization and therefore, in a sense, is autoregulatory. At high levels, the rate of glucose uptake by tissues such as muscle and liver increases because of mass action. The presence of insulin increases the rate of glucose utilization, either by increased transport via GLUT-4 (muscle, fat) or increased phosphorylation (liver). The action of insulin is opposed by the diabetogenic factors, growth hormone, glucagon, cortisol, and epinephrine.

The liver occupies a central position in the regulatory mechanism of blood glucose concentration because it supplies as well as removes glucose from the system. The major direction of liver glucose metabolism is directed toward supplying rather than using glucose. When liver takes up glucose, 25% is oxidized to lactate or CO_2 and the remainder forms glycogen. This glycogen is the source of the glucose supplied by the liver to the system during the better part of a day. Muscle, on the other hand, does not contain G-6-Pase, so it cannot provide free glucose and is therefore primarily a glucose-utilizing tissue.

C. Role of the Liver

The glucose transporter system (GLUT-4) across the membrane is rate limiting in peripheral tissues that are sensitive to insulin (muscle, fat). In the liver, however, glucose moves freely across the plasma membrane, so this process is not rate limiting at this point. At a blood glucose level of approximately 8.33 mmol/l (150 mg/dl), the liver does not take up or supply glucose to the circulation. This level is termed the "steady state" or the "glucostatic level" at which the mechanisms of normal supply and removal of glucose are operating at equal rates. Above 8.33 mmol/l (150 mg/dl), glucose removal is greater than supply, and below 8.33 mmol/l (150 mg/dl), glucose supply is greater than removal. But the fasting blood glucose level in most animals is about 5 mmol/l (90 mg/dl). This means that the liver supplies glucose throughout most of a day except for the few periods during the day when blood glucose is greater than the steady-state level of 8.33 mmol/l (150 mg/dl). These periods are the few hours after each meal during a day.

Insulin decreases liver glucose production, output, and glycogenolysis while increasing liver glucose utilization. The net result is an increase in glucose uptake by the liver with increased glucose oxidation, glycogenesis, and hypoglycemia. This directional control is due to the action of insulin on key enzymes of glucose metabolism.

Directional control for glucose production or utilization is governed by coupled sets of opposing and irreversible enzyme reactions at three control points of glucose metabolism. These "key enzyme" couples are GK/G-6-Pase, PFK/F-1-6-Pase, and PK/PEP-CK, PC. The kinases direct metabolism toward glycolysis utilization because they are phosphorylating enzymes and the opposing enzymes reverse the direction so they are gluconeogenic.

The insulin sensitivity of the rate limiting GK reaction in liver promotes glucose utilization. The opposing G-6-Pase reaction increases during fasting or starvation, which favors liver glucose production. In diabetes mellitus, even though there is a hyperglycemia >8.33 mmol/l (150 mg/dl), G-6-Pase is increased. Increases in the other key enzymes of gluconeogenesis, F-1-6-Pase, PEP-CK, and PC, are also observed in diabetes. Increases in activity of these gluconeogenic enzymes in insulin deficiency direct metabolic pathways toward excessive production of glucose by the diabetic liver.

The amelioration of diabetes in an experimental animal by hypophysectomy (Houssay animal) is well established. The pituitary factor, which opposes the action of insulin, is growth hormone. The glucocorticoids increase gluconeogenesis and intracellular G-6-P and, by their insulin opposing effect, increase free glucose. An increase also results from the glycogenolytic action of epinephrine and glucagon, and the equilibrium is shifted to favor of glucose production. Therefore, it is the balance of hormones that directly (insulin) or indirectly (epinephrine, growth hormone, glucagon, cortisol) affects glucose metabolism, which sets the "steady-state blood glucose" at which the liver neither uses glucose or produces glucose.

D. Glucose Tolerance

The regulatory events that occur in response to changes in blood glucose concentration are best summarized by a description of the events following ingestion of a test dose of glucose. When administered orally to a normal animal, a typical change in blood glucose concentration with time is observed as shown in Figure 3-12. During the absorptive phase, phase I, the rate of entry of glucose into the circulation exceeds that of removal and the blood glucose rises. As the blood glucose rises, hepatic glucose output is inhibited and the release of insulin from the pancreas is stimulated by the rising blood glucose. This release of insulin is also influenced by the insulin releasing effect of the GI hormones: secretin, cholecystokinin-pancreozymin (CCK-PZ), gastrin, and by pancreatic glucagon. In 30 to 60 min, the peak level of blood glucose is reached, after which it begins to fall. During this phase of falling blood glucose, phase II, the rates of removal now exceed those of entry and the regulatory mechanisms directed toward removal of glucose are operating maximally. At the same time, hepatic glucose output decreases and the blood glucose falls rapidly. When the blood glucose reaches its baseline level, it continues to fall below the original level for a short time and then returns to its baseline level. This hypoglycemic phase, phase III, is due to the inertia of the regulatory mechanisms because, in general, the higher the glycemia, the greater the subsequent hypoglycemia. Clinically, this postinsulin hypoglycemia can be marked if there is a defect in the secretion of glucagon.

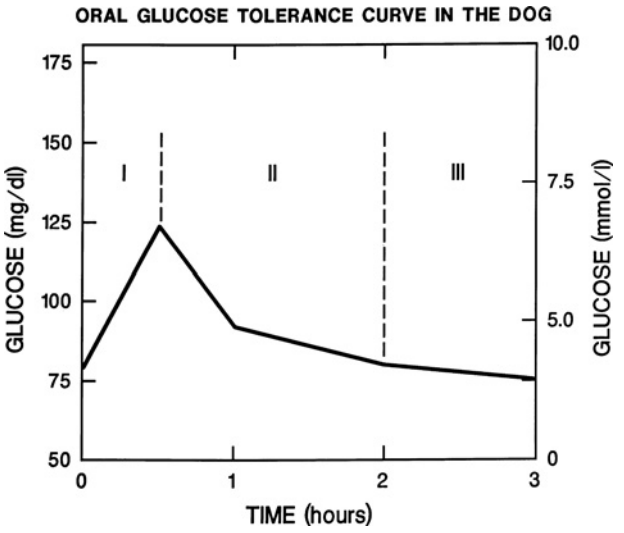

FIGURE 3-12 Oral glucose tolerance in the dog; I, II, and III are phases of the curve.

VIII. METHODOLOGY

A large number of tests have been devised to evaluate the status of the carbohydrate economy of animals but the principal focus continues to lie with the determination of blood glucose levels. The hexokinase (HK), glucose dehdrogenase (GD), and the glucose oxidase (GO) methods are currently the most widely used methods for blood glucose and are used in manual, automated, and in point-of-care testing modules.

A. Blood Glucose

1. *Methods*

Three glucose-specific enzyme methods are in use: the GO, HK, and the GD methods. The GO method is coupled with

peroxidase and a dye. GO catalyzes the conversion of glucose to gluconic acid:

$$\text{glucose} \xrightarrow{\text{GO}} \text{gluconic acid} + H_2O_2$$

The hydrogen peroxide, with peroxidase, oxidizes a dye to form a colored product. This principle is also used in the glucose-specific paper strips for urine glucose.

In the HK method, HK catalyzes the phosphorylation of glucose and the reaction is coupled to a reaction such as G-6-PD for assay:

$$\text{glucose} + \text{ATP} \xrightarrow{\text{HK}} \text{G-6-P} + \text{ADP}$$

$$\text{G-6-P} + \text{NADP} \xrightarrow{\text{G-6-PD}} \text{6-PG} + \text{NADPH}$$

Either NADP or NADPH is measured spectrophotometrically.

In the GD method, GD catalyzes

$$\text{glucose} + \text{NAD} \xrightarrow{\text{GD}} \text{gluconolactone} + \text{NADH}$$

and NAD or NADH is measured spectrophotometrically.

Of these enzymatic methods, the method of Banauch *et al*. (1975) was found to be best for the quantitative assay of urine glucose (Kaneko *et al*., 1978a).

No matter how accurate the method for blood glucose, it cannot compensate for loss of glucose in an improperly handled blood sample. Glucose breakdown (i.e., glycolysis) by red blood cells takes place very rapidly, about 10% per hour loss, at room temperature and is even more rapid if microorganisms contaminate the sample. For these reasons, the plasma or serum must be separated from the RBCs as quickly as possible, within the half hour; otherwise, the glucose in the blood sample must be protected from glycolysis. This is best accomplished through refrigeration or by the use of sodium fluoride (NaF) (10 mg/ml blood). The NaF acts both as an anticoagulant and a glucose preservative. The NaF can also be added to a blood sample vial containing an anticoagulant.

2. *Blood Glucose in Animals*

The reference ranges for blood glucose are given in Table 3-7 and in Appendices VII, VIII, and IX. A standard sampling procedure must be used to obtain optimum results and to minimize variations in blood glucose, especially those resulting from diet. This is best accomplished in the nonruminant and in the young ruminant by a standard overnight (12 to 16 h) fast before sampling. This is not necessary in the mature ruminant, because feeding elicits no blood glucose response. Methods for establishing statistically valid reference ranges for analytes such as blood glucose, with examples, are given in Chapter 1.

TABLE 3-7 Blood Glucose Levels in Domestic Animals[a]

	Glucose (Reference Range and Mean ± SD)	
Species	mmol/liter	mg/d
Horse	4.2–6.4 (5.3 ± 0.4)	75–115 (95 ± 8)
Cow	2.5–4.2 (3.2 ± 0.4)	45–75 (57 ± 7)
Sheep	2.8–4.4 (3.8 ± 0.3)	50–80 (68 ± 6)
Goat	2.8–4.2 (3.5 ± 0.4)	50–75 (63 ± 7)
Pig	4.7–8.3 (6.6 ± 0.9)	85–150 (119 ± 17)
Dog	3.6–6.5 (5.0 ± 0.4)	65–118 (90 ± 8)
Cat	2.8–4.2 (3.5 ± 0.4)	50–75 (63 ± 7)
Monkey (*Macaca* sp.)	4.7–7.3 (5.9 ± 0.7)	85–130 (107 ± 13)
Llama	5.7–8.9 (7.1 ± 0.9)	103–160 (128 ± 16)
Rabbit	2.8–5.2 (4.1 ± 0.5)	50–93 (73 ± 10)

B. Indirect Monitoring of Blood Glucose

The phenomenon of glucose molecules irreversibly binding to proteins is widespread in biological systems, and the products are known as glycated proteins. The glucose molecules are covalently bound to free amino groups of a protein (i.e., lysine) valine by a nonenzymatic glycation mechanism. The glycated intermediate in the reaction is unstable and immediately undergoes a classic Amadori rearrangement to form a stable ketoamine. The carbon backbone of this ketoamine is identical to fructose. When the protein of the protein-ketoamine complex is hemoglobin (Hb), the product is called hemoglobin A1c (HbA1c) because it was first identified as a fast-moving minor Hb component by electrophoresis. When the protein of the complex is albumin or total serum protein, the product is called fructosamine (FrAm) (Armbruster, 1987). When the albumin-ketoamine is specifically measured, the product is sometimes called glycoalbumin (Galb).

The binding of glucose to proteins occurs firmly and constantly over the life span of a particular protein. Therefore, these glycated proteins reflect the average blood glucose concentration over the half-life of the protein. Thus, they offer a means and are used to evaluate long-term average blood glucose levels in diabetics.

1. *Hemoglobin* A1*c*

In the case of canine HbA1c where the canine erythrocyte has a life span of 100 days and a half-life of about 60 days, HbA1c reflects the average blood glucose over the previous 2 months before sampling. In the cat, with an erythrocyte life span of 70 days and a half-life of about 40 days, HbA1c could be used as a measure of the average blood glucose over the previous 6 weeks. This means that bimonthly samplings for the dog and 6 weekly intervals in the cat for HbA1c could be used to monitor long-term blood glucose control. The use of HbA1c is a well-established means for monitoring long-term average blood glucose in human diabetics. The techniques for measuring HbA1c, however, have not been applicable to animals. The methods are complex as well as labor and equipment intensive. The methods all rely on the structural properties of HbA1c for their separation so that methods for human HbA1c are not directly applicable to animal HbA1c. Methods used for human HbA1c are affinity and ion-exchange high performance liquid chromatography (HPLC), electrophoresis, immunoassay, and colorimetrically to measure 5-hydroxymethylfurfural-thiobarbituric acid (HMF-TBA). Of these, the HPLC method is most widely used in humans. A report evaluating a number of methods for canine HbA1c indicated that the HMF-TBA method is the most promising (Hooghuis *et al*., 1994).

Because HbA1c is directly related to the amount of red cells, anemias or polycythemias must be ruled out. Also, bimonthly samplings may not detect the long-term changes in glucose in a timely manner.

2. *Fructosamine*

The total serum proteins or albumin have half-lives of 2 to 3 weeks and 7 to 9 days, respectively. This means that FrAm or Galb could be used as indicators of the average blood glucose over the previous 2 weeks. This biweekly time interval has the advantage of detecting changes in glucose control more quickly than HbA1c and allows for timely clinical intervention. Furthermore, the FrAm assay is a colorimetric assay based on its reducing properties, so it is an assay readily performed in any clinical laboratory. An improved version of the original kit is now available from the manufacturer (Roche Diagnostic Systems, Inc., Rahway, New Jersey). Using this improved version, Jensen and Aaes (1992) reported a reference range for FrAm of 259 to 344 μmol/l (301 $\pm$ 21.3 μmol/l). This result is lower than that originally reported by Kawamoto *et al*. (1992) for dogs by a factor of about 10. By extrapolation, the reference range for cats as reported by Kaneko *et al*. (1992) would be 219 to 347 μmol/l (283 $\pm$ 32 μmol/l).

In an extensive study of 253 diabetic dogs either treated or nontreated with insulins, Davison *et al*. (2005) found that FrAm and HbA1c concentrations compared similarly regardless of type of insulin, insulin injection regime, duration, or treatment or dose.

C. Tolerance Tests

1. *Glucose Tolerance Tests*

Glucose tolerance (GT) in its original definition referred to the amount of glucose that could be ingested by an animal without producing a glucosuria, hence, tolerance for glucose. Because, in the normal animal, the absence of a glucosuria indicates only a limited rise in blood glucose where the renal threshold is not exceeded, GT now refers to the blood glucose curve following glucose administration. Accordingly, an animal with an increased glucose tolerance is one that has a limited rise and rapid fall in blood glucose (i.e., can tolerate extra glucose). The animal with a decreased tolerance has an excessive rise and a slow return to its baseline level (i.e., cannot tolerate extra glucose). This is the typical diabetic type of GT curve.

It is important to ascertain the nature of the animal's diet, especially in the omnivores and carnivores, before performing this test. A carbohydrate-only diet favors a minimum rise in the tolerance curve, whereas a carbohydrate-free diet (meat only) favors a high or diabetic type of glucose tolerance curve. Therefore, for optimum results, the diet must be standardized by placing the dog on a standard diet of 100 to 200gm carbohydrate plus fat and protein per day for 3 days before performance of the test. The GT curve is also affected by the status of the intestinal absorptive process (i.e., inflammation, increased motility, thyroxine). Furthermore, the variations that result from absorption, the excitement attending intubation, or tranquilization can be avoided by use of the intravenous test.

a. Oral Glucose Tolerance Test

Section VII.D described the blood glucose curve following the oral administration of a test dose of glucose. The oral glucose tolerance test (OGTT) is ineffective in the ruminant because the ingested carbohydrate is almost totally fermented by the rumen microflora. The OGTT has been used in dogs by feeding of a test meal consisting of 4 gm glucose/kg b.w. mixed with a few grams of horse meat. A fasting blood sample is taken, the test meal is given, and blood samples are taken at 30-min intervals for 3 h. The OGTT curves in dogs receiving a standard daily diet of either glucose or galactose with meat had normal curves as described in Section VII.D. The maximum

level, 6.6 to 7.7 mmol/l (120 to 140 mg/dl) was reached at 1 h and returned to the fasting level, 3.6 to 5.3 mmol/l (65 to 95 mg/dl), in 2 to 3 h. The OGTT may be simplified by taking a single sample at 2 h after giving the glucose (i.e., 2 h postprandial glucose). A normal blood glucose level at 2 h postprandially indicates that diabetes is unlikely. A hyperglycemia at 2 h is indicative of a diabetic curve and should be confirmed with the complete GTT. The insulin response curve during the OGTT can also be evaluated. In the OGTT, for a given level of blood glucose, the total insulin secretion (TIS) is greater than in the IVGTT. This is most likely due to the insulin releasing effect of the gut hormones (Section VII.D).

b. Intravenous Glucose Tolerance Test and the Insulin Response

The intravenous glucose tolerance test (IVGTT) in animals must also be standardized for best results (Kaneko *et al.*, 1978a). This is necessary because glucose clearance half-times ($T_{1/2}$) and urinary glucose losses are directly proportional to the glucose dose. The recommended method gives optimal results because (1) it does not overload the animal with glucose, (2) the infusion can be given easily within the time limits, (3) the blood glucose level is high enough to give a maximal insulin response, and (4) urinary loss of glucose is minimal. After a standard overnight (12 to 16 h) fast (except for an adult ruminant), a zero-time heparinized blood sample is taken. Next, 0.5 gm glucose/kg b.w. is infused I.V. as a sterile 50% solution in 30 s. Timing of the test is begun at the midpoint or at 15 s after start of the injection. In large animals, the glucose is given within 2 to 3 min or more quickly if possible. Subsequent blood samples are taken at 5, 15, 25, 35, 45, and 60 min. The results are plotted on semilogarithmic coordinates from which the time required for the glucose concentration to fall by half, the $T_{1/2}$, is graphically estimated between 15 and 45 min postinfusion. From the $T_{1/2}$, the fractional turnover rate, k, can also be calculated:

$$k = \frac{0.693}{T_{1/2}} \times 100 \times \%/m$$

The fractional turnover rate, k, can also be calculated without graphing the data and using the relationships:

$$k = \frac{Ln\,1 - Ln\,2}{T_2 - T_1} \times 100 = \%/m$$

from the k value, the $T_{½}$ may be calculated:

$$T_{1/2} = \frac{0.693}{k} \times 100 = m$$

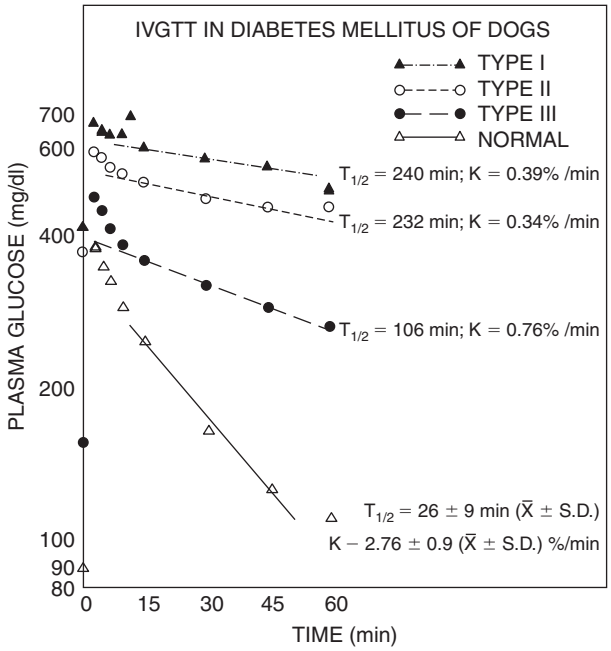

FIGURE 3-13 The intravenous glucose tolerance test (IVGTT) in normal dogs and in dogs with various types of diabetes mellitus. From Kaneko *et al.* (1977).

The fractional turnover rate has been variously expressed as the glucose turnover rate, the glucose disappearance rate, the glucose disappearance coefficient, or simply as the k-value. The normal $T_{½}$ and k in dogs are 25 ± 8 min and 2.76 ± 0.91%/min, respectively (Kaneko *et al.*, 1977). The diabetic animal with a decreased glucose tolerance has a longer $T_{1/2}$ and lower k.

The method is equally applicable to and the only practical method in large animals. The k-value in a spontaneously diabetic cow was 0.38%/m ($T_{1/2}$ = 182 m) as compared to a reference value of 1.98%/m ($T_{1/2}$ = 35 m) (Kaneko and Rhode, 1964) and was comparable to the k-values obtained using 14C-glucose (Kaneko *et al.*, 1966).

Standardization of the IVGTT as described also has the advantages that an adequate insulin response is provoked, the influence of urinary glucose loss is minimized, and reproducible clearance values are obtained (Fig. 3-13). Other areas of the IVGTT with diagnostic significance for diabetes are the 5-m peak, which is inordinately high, and the 60-m glucose level, which has not returned to the preinfusion level.

The insulin response curve to the glucose load is obtained from the same samples as for glucose (Fig. 3-14). In the normal response curve to a glucose load, the peak insulin response occurs at 5 min followed by a return to normal at 60 min (Kaneko *et al.*, 1977). The early 5-min peak is due to the stimulation of release of stored insulin by the beta cells by glucose. In humans, a second peak is seen at 20 to 30 min, which is attributed to the *de novo* synthesis of insulin by the beta cells. This peak has not been experimentally discernible in dogs (Kaneko *et al.*, 1978b).

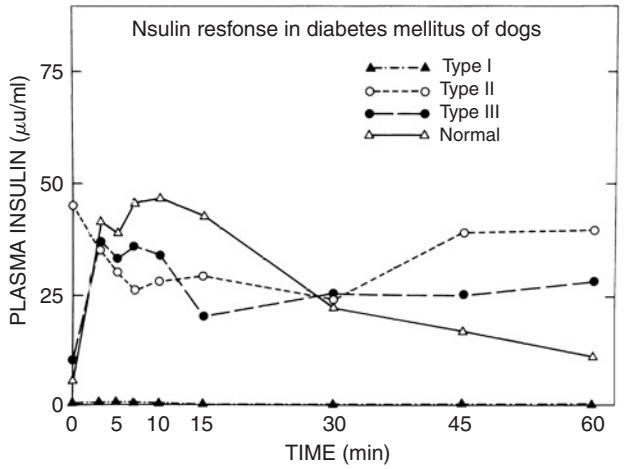

FIGURE 3-14 The insulin response during the IVGTT in normal dogs and in dogs with various types of diabetes mellitus. Key: ▲ type I; ❍, type II; ●, type III; Δ normal (Kaneko *et al.*, 1977).

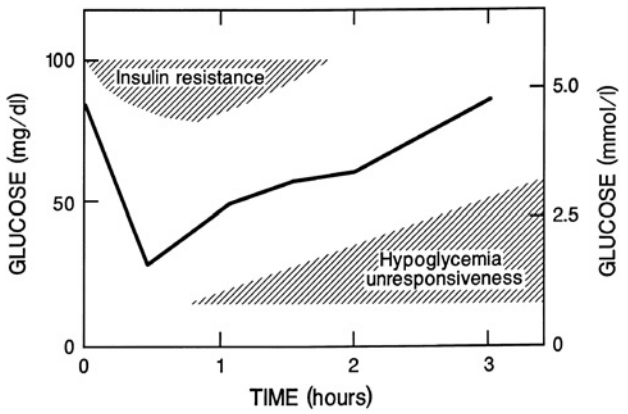

FIGURE 3-15 Insulin tolerance in the dog. Curves falling in the shaded areas are described as noted.

The IVGTT and the insulin response are of greatest value in the diagnosis of diabetes, particularly those cases with a mild hyperglycemia and without persistent glucosuria. Furthermore, the insulin response to the IVGTT allows for the accurate differentiation of the different types of diabetes. This has great significance because the type II diabetic can potentially respond to oral hypoglycemic therapy. Decreased tolerance is also observed, though less consistently, in hyperthyroidism, hyperadrenalism, hyperpituitarism, and in severe liver disease. An increased tolerance is observed in hypofunction of the thyroids, adrenals, pituitary, and in hyperinsulinism.

2. *Insulin Tolerance Test*

The blood glucose response of a normal animal after the administration of a test dose of insulin exhibits a characteristic response as shown in Figure 3-15. After obtaining a fasting blood sample, 0.1 unit of crystalline zinc insulin per kilogram body weight is injected intramuscularly or subcutaneously, and blood samples are taken every 30 min for 3 hours. The test measures (1) the sensitivity of the blood glucose level to a test dose of insulin and (2) the response of the animal to the insulin-induced hypoglycemia. Normally, the blood glucose level falls to 50% of its fasting level in 20 to 30 min and returns to its fasting level in 1½ to 2 h. Two types of abnormal responses are seen. If the blood glucose level does not fall by 50% or requires longer than 30 min to reach the maximum hypoglycemic level, the response is described as "insulin insensitive" or "insulin resistant." Insulin resistance is found, though inconsistently, in hyperfunction of the pituitary and adrenals. This test has not been used in the type II diabetic dog or cat but may be of value in evaluating insulin resistance in this type.

If the hypoglycemia is prolonged and fails to return to the fasting level in 2 h, the response is described as "hypoglycemia unresponsiveness." This type of response may be observed in hyperinsulinism, hypopituitarism, and hypoadrenalism and is most often used in suspected cases of the latter two diseases. An inability to secrete sufficient glucagon by the pancreatic delta cells may also be a significant factor in the unresponsiveness. In carrying out this test, because a hypoglycemia is being induced, a glucose solution should be readily available for injection.

3. *Glucagon Stimulation Test*

Glucagon via hepatic glycogenolysis and gluconeogenesis has a hyperglycemic effect, which in turn evokes an insulin response. In addition, glucagon is an insulin secretagogue second only to glucose. These are the bases for the glucagon stimulation test (GST), which has been used for the diagnosis of diabetes in cats (Kirk *et al.*, 1993). The test is performed by the I.V. injection of 30-μg glucagon/kg body weight. Samples for blood glucose and insulin are obtained before injection (0 time) and at 5, 10, 15, 30, 45, and 60 min after injection. In cats, the peak insulin response was observed at 15 min followed by a rapid decline to baseline levels at 60 min. The insulin response curve was flat in the type I diabetic cats whereas controls, obese, and type II diabetic cats had comparable 15-min peaks and declines to baseline at 60 min.

Samplings at half-hour intervals can be continued for up to 3 hours in suspected hyperinsulinism. An exaggerated 15-min insulin response followed by a marked hypoglycemia at 2 to 3 h or longer are characteristic of pancreatic islet cell tumors (Johnson and Atkins, 1977). However, Kruth *et al.* (1982) found that the GST was not diagnostic for these cases.

4. *Epinephrine Tolerance Test*

Epinephrine also has a postinjection hyperglycemic effect via hepatic glycogenolysis. The blood glucose level rises

to a maximum of 50% above the fasting level in 40 to 60 min and returns to the original level in 1½–2 h. The test is performed by obtaining a fasting blood sample (0 time), injecting 1 ml of 1:1000 epinephrine-HCL (in the dog) intramuscularly and obtaining blood samples every 30 min for 3 h.

The characteristic increase in blood glucose is used as an index of the availability of liver glycogen for the production of blood glucose. On the basis of a lowered response to epinephrine, liver glycogen can indirectly be shown to be depleted in bovine ketosis. This can be confirmed directly by measurement of glycogen in biopsy samples. A lowered glycemic response is also a characteristic response of the glycogen storage diseases where glycogenolysis is inhibited by enzyme deficiencies.

5. *Leucine-Induced Hypoglycemia*

The oral administration of L-leucine induces a marked and persistent hypoglycemia in hyperinsulinism because of pancreatic islet cell tumors. The hypoglycemia is associated with a rise in plasma insulin because of increased release of insulin by the tumorous islet cells. The test is performed by the oral administration of 150 mg L-leucine/kg body weight as an aqueous suspension to the fasting dog. A fasting blood glucose sample is taken before administration (0 time) and every 30 min for 6 h. A hypoglycemic effect is seen quickly at 30 min to 1 h and may persist for as long as 6 h in hyperinsulinism. The normal dog exhibits no hypoglycemic effect.

6. *Tolbutamide Test*

The intravenous administration of tolbutamide, an oral hypoglycemic agent, induces the release of insulin from the pancreas and is used as a test of the availability of insulin from the pancreas. The blood glucose curve during the test parallels the insulin tolerance test. This test has not been used in animals.

D. Ketone Bodies

The methodology and role of ketone bodies in the carbohydrate economy of animals in health and disease are discussed in the chapter on lipid metabolism. The major ketone bodies are acetone, acetoacetate (AcAc), and 3-OH-butyrate (3-OH-B). The 3-OH-B is the precursor of acetone and AcAc so that the measurement of any or all in body fluids is a standard method to evaluate ketosis and ketoacidosis. Additionally, 3-OH-B constitutes half or more of the total ketone bodies. The quantitative assay for 3-OH-B is based on the use of the enzyme 3-OH-B dehydrogenase (3-OHB-D). A point-of-care enzymatic and colorimetric method for the assay of plasma 3-OH-B is based on the enzyme 3-OH-B-D and nitroblue tetrazolium (NBT):

$$\text{3-OH-butyrate} + NAD^+ \xrightarrow{\text{3-OH-BD}} \text{acetoacetate} + NADH + H^+$$

$$NADH + NBT(ox) \xrightarrow{\text{diaphorase}} NAD^+ + NBT\,(red)$$

IX. DISORDERS OF CARBOHYDRATE METABOLISM

Although alterations in blood glucose levels occur in a wide variety of disease states, they are of particular importance in the endocrine disorders. Normal blood glucose levels are the result of a finely balanced system of hormonal interaction affecting the mechanisms of supply and removal from the circulation. When a hormonal imbalance occurs, a new equilibrium is established. Whether this equilibrium is clinically evident as a persistent hypoglycemia or hyperglycemia depends on the total interaction of the hormonal influences on carbohydrate metabolism. Further discussions concerning the disorders of the pituitary, adrenals, and the thyroids are presented in their respective chapters. The following sections discuss the conditions in which the principal manifestations are closely related to derangements in carbohydrate metabolisms.

A. Diabetes Mellitus

Although diabetes mellitus has been reported in virtually all laboratory animals (gerbils, guinea pigs, hamsters, mice, rats, nonhuman primates) and in horses, cattle, sheep, and pigs, it is most frequently found in dogs and cats. Estimates of the incidence of diabetes range as high as 1:66 (1.52%) for dogs and 1:800 for cats. Diabetes mellitus in animals has been frequently reviewed (Engerman and Kramer, 1982; Kaneko and Howard, 1989).

1. *Natural History of Diabetes*

The disease in dogs occurs most frequently in the mature or older female, often in association with estrus and in all breeds. In contrast, male cats appear to be more commonly affected than females. In the dog, it is frequently associated with obesity and it is now known that obesity is the single most important contributing factor to the development of diabetes (Mattheeuws *et al*., 1984). In the obese cat, the GTT is significantly impaired, suggesting that obesity also predisposes cats to diabetes (Nelson *et al*., 1990). The obese cat also has a GST response like that of the type II diabetic (Kirk *et al*., 1993). Little is known of the genetic aspects of diabetes in animals as compared to humans in which the

animal to utilize this inability is corrected by insulin glucose and is clearly shown in its inability to convert glucose-^{14}C to $^{14}CO_2$. This inability is corrected by insulin. The inability to utilize glucose is reflected in the clinical signs of diabetes, loss of weight, polyuria, polydipsia, and, in the advanced stages, ketoacidosis.

Several reports have suggested that the development of diabetes mellitus is the result of the interaction of several hormones, principally insulin and glucagon (Unger and Orci, 1975, 1976). Although excess glucagon is observed in diabetes and it can induce glucose intolerance or changes in diabetic control, it can do so only as long as insulin deficiency is present and pharmacological levels of glucagon are induced (Felig *et al*., 1976). Thus, insulin deficiency is sine qua non the cause of diabetes, and although glucagon may modify the consequences, it is neither necessary nor sufficient for the development of diabetes (Felig *et al*., 1976). The modifying action of glucagon on diabetes, however, has important implications because excess glucagon will tend to exacerbate the posthypoglycemic hyperglycemia (e.g., the Somogyi effect). A deficiency of glucagon will tend to increase the effect of insulin and contribute to a prolonged hypoglycemia after treatment. Thus, glucagon plays a significant role in the variability of diabetes.

The complex nature of the development of type II diabetes is further illustrated by the ongoing controversy as to the nature and value of the so-called metabolic syndrome as a clinical disease entity (Reaven, 2005) in an effort to link insulin resistance to increased risk of cardiovascular disease (CVD). Insulin resistance is a feature of type II diabetes and the metabolic syndrome in effect describes the interaction of the various hormones involved in carbohydrate metabolism. It's usefulness as a clinical disease entity is open to question (Reaven, 2006).

3. *Hyperglycemia*

A persistent fasting hyperglycemia is the single most important diagnostic criteria of diabetes mellitus. In the normal animal, the homeostatic level of blood glucose is maintained by the equilibrium between glucose supply and removal, which in turn is based on the endocrine balance. The effect of insulin tends to lower blood glucose, whereas the opposing effects of growth hormone, glucagon, and adrenal cortical hormones tend to raise it. In the diabetic animal with an absolute or relative lack of insulin, the equilibrium is shifted to a higher level of blood glucose. Glucose utilization in the peripheral tissues decreases while at the same time hepatic glucose production increases as a result of increases in their gluconeogenic enzyme activities.

In the diabetic, the hyperglycemia itself tends to compensate in part for the decrease in peripheral utilization. This occurs as a mass action effect that promotes the flow of glucose into the peripheral tissues. In this way, the diabetic can continue to use some glucose when insulin is decreased, but only at the expense of increased glucose production and hyperglycemia. As the deficiency of insulin progressively becomes more severe, the equilibrium level of blood glucose is established at higher and higher levels, and ultimately the equilibrium is never established without therapeutic intervention. Blood glucose levels in canine diabetics have reached 70 mmol/l (1260 mg/dl). When the renal threshold of 11.1 mmol/l (200 mg/dl) for glucose is exceeded, the diabetic is faced with excessive loss of glucose in the urine. It is evident that the blood glucose level is exquisitely sensitive to insulin and, conversely, the blood glucose level is the mainstay for monitoring the success of diabetes therapy. However, a marked posthypoglycemic hyperglycemia or the Somogyi effect has long been known to occur in humans after insulin therapy (Bolli *et al*., 1984), which indicates that glucose regulation by insulin is not complete. This hyperglycemic effect is thought to be due to an excess of glucagon, growth hormone, adrenal cortical hormones, or epinephrine. This phenomenon has been seen in diabetic cats given an inadvertent insulin overdose (McMillan and Feldman, 1986), which points to the need for effective monitoring of diabetes.

4. *Glycated Proteins*

The biochemical and physiological bases for using glycated proteins as a monitor for long-term glucose control are now commonplace in human diabetolgy (Section VIII.B). Successful management of diabetes depends on the reliable evaluation of blood glucose levels, and any blood glucose sample only reflects the blood glucose level at the moment of sampling. An effective method for estimating the average blood glucose over an extended time period offers a way of evaluating successful insulin therapy. This can be done by use of the glycated proteins, HbA1c or FrAm. Of these, FrAm offers the most cost effective method for evaluating the average blood glucose over the preceding 2 weeks. However, although HbA1c is the test of choice for indirect glucose monitoring by many academic programs, Davison *et al*. (2005) have found that either test is efficacious.

a. Hemoglobin A1c

The glycated hemoglobin, HbA1c, is known to reflect the average blood glucose level over the preceding 60 days and is now widely used to monitor human diabetics (Nathan *et al*., 1984). Several studies in diabetic dogs (Mahaffey and Cornelius 1982; Wood and Smith, 1980) have also shown that HbA1c is potentially useful for monitoring purposes. Although the reference values for % HbA1c differed in the two studies, 2.29% and 6.43%, the means for the diabetics were increased in each to 4.97% and 9.63%, respectively. Hooghuis *et al*. (1994), using thiobarbituric acid colorimetry

(HMF-TBA), reported a reference range of 1.4% to 3.2 % HbA1c (2.3 ± 1.96 SD). Previous assays for HbA1c have been time, labor, and equipment intensive as well as giving variable results. The colorimetric HMF-TBA method shows promise of being a clinically viable method.

b. Fructosamine

The fructosamines (FrAm) reflect the average blood glucose over the preceding 2 weeks in a manner analogous to HbA1c. This means that FrAm could be used to monitor the average blood glucose on a biweekly interval. This has the advantage that changes in blood glucose can be detected more quickly than with HbA1c and allows for timely clinical intervention. Furthermore, the FrAm assay is a colorimetric assay that can be readily performed in any clinical laboratory. An improved version of the original kit is now available from the manufacturer (Roche Diagnostic Systems, Inc., Rahway, New Jersey). Using this improved version, Jensen and Aaes (1992) reported a reference range for FrAm for dogs of 259 to 344 μmol/l (301 ± 21.3 SD). This result is 10-fold lower than that originally reported by Kawamoto *et al*. (1992) using the older method. By extrapolation, the reference range for cats as reported by Kaneko *et al*. (1992) is 219 to 347 μmol/l (283 ± 32 SD). In all cases, FrAm was shown to be significantly elevated in diabetes indicating that they can be of clinical value to monitor glucose control in treated diabetics. On occasion, especially in cats, hyperglycemia or glucosuria is seen on initial presentation and without other indications of diabetes. A FrAm sample taken at this time can be used to differentiate a transient from a persistent hyperglycemia.

5. *Glucose Tolerance and the Insulin Response*

The glucose tolerance test (GTT) is the most important test of carbohydrate function and is of particular value in those cases of diabetes in which the fasting blood glucose is only moderately elevated and the diagnosis is equivocal (Section VIII.C). The diabetic oral GGT curve is high and relatively flat, indicating a decreased tolerance for glucose (Fig. 3-12). The nature of the diabetic curve can be quantitated by using the intravenous GTT. The diabetic curve is characterized by a long $T_{1/2}$ or low k-value, which reflects the inability of the animal to use the test dose of glucose. The insulin response curve in type I (absolute insulin deficiency) diabetes clearly demonstrates the inability of the pancreas to release insulin in response to the glucose load. It is in the absence of an insulin response, which is responsible for the failure of the diabetic to utilize the added glucose, that the prolonged hyperglycemia occurs. An important factor adding to the hyperglycemia is the overproduction of glucose by the liver. The test dose of glucose is in effect added to the already existing oversupply of glucose. Because the steady-state level at which the liver ceases to supply or remove glucose is elevated in diabetes, the liver continues to oversupply glucose, which contributes to the slow return of the tolerance curve to its original level.

In types II and III diabetes (see the following discussion), there is also glucose intolerance, but this occurs in the presence of a normal to elevated insulin. This would mean that the insulin in the plasma of these types is unusable or ineffective (i.e., relative deficiency) because of a number of factors including insufficient receptors, receptor blockage, abnormal receptor structure, or antibody binding, all of which lead to the glucose intolerance and the phenomenon of insulin resistance. Therefore, glucose intolerance is seen in all types of diabetes whether there is an absolute (type I) or relative (types II, III) deficiency of insulin. The insulin response must be evaluated in order to establish the type of diabetes.

6. *Insulin and the Insulin Response*

Serum insulin is characteristically very low or absent in type I diabetes, whereas it is normal to very high in type II or III. Type I diabetes can be readily differentiated from the other types by an absent or low fasting insulin level. On the other hand, about 40% of diabetics have normal to very high insulins. The classification of these diabetic types is based on the nature of the insulin response curve in the IVGTT. Type II has a normal to high insulin with no increment of insulin response to the glucose load. Type III also has a normal to high insulin; the insulin response is inadequate and there is a delayed return to preinjection levels (Kaneko *et al*., 1977). Types II and III have been further subdivided on the basis of obesity or nonobesity (Mattheeuws *et al*., 1984), and their insulin levels are given in Table 3-9.

The classification of diabetes into types has important therapeutic and prognostic implications. Thus far, insulin replacement therapy is the only effective treatment for the type I and the type II nonobese diabetic, even though islet

TABLE 3-9 Insulin Concentrations in the Various Types of Canine Diabetes

	Serum Insulin (μU/ml)
Normal	5–20
Type	0–5
Type II nonobese	5–20
Type II obese	20–130
Type III nonobese	5–20
Type III obese	8–60

cell transplantation has corrected these diabetics for a short time. Type II obese and the type III dogs with even a small insulin reserve would be the most likely subjects for successful oral hypoglycemic therapy. The early detection of diabetes and being able to treat these patients using oral drugs would have obvious advantages. Nelson *et al*. (1993) have successfully treated cats with diabetes using oral hypoglycemic drugs. Prognostically, the severity of the diabetes can be assessed by the degree of glucose intolerance and the nature of the insulin response.

Atkins *et al*. (1979) identified diabetes in dogs less than 1 year of age, and Atkins and Chin (1983) examined their insulin responses to glucose loading. All dogs were glucose intolerant but could mount a minimal insulin response somewhat akin to the type II diabetic dogs. It could also be that these young diabetic dogs were identified during the early stages of their natural history of progression of their diabetes to type I or II.

7. *Glucagon Stimulation and the Insulin Response*

The GST has been used in humans and cats to differentiate type I from type II diabetes. Type I diabetic cats have a minimal or no insulin response to glucagon. Type II diabetic cats have a significant insulin response in the GST. Nondiabetic obese cats also have an insulin response that is similar to that observed in the type II diabetic cats. Thus, obesity is predisposing to the development of diabetes in animals as well as in humans. Type II diabetes is known to be characterized by various forms of insulin resistance (Section VIII.C.2).

8. *Ketonemia and Lipemia*

As the utilization of glucose progressively decreases in the diabetic, the utilization of fatty acids for energy purposes progressively increases to compensate. The supply of fatty acids for hepatic utilization is obtained by mobilization from the body fat depots. Mobilization of fatty acids progressively increases as insulin deficiency becomes more severe, and this is due to increases in hormone sensitive lipase. This enzyme is separate and distinct from the hepatic lipoprotein lipase.

In severe diabetes, lipid mobilization is so intense that the subsequent hyperlipemias are often so marked that the blood appears as tomato soup. A cream layer may separate out on storage overnight in the cold because of hyperchylomicronemia. The plasma is turbid due to the presence of lipoproteins (very low density lipoproteins [VLDLs]). On chemical analysis, total triglycerides and cholesterol are elevated (Rogers *et al*., 1975). Diabetic hyperlipemia appears to be caused by impaired lipolysis of chylomicra secondary to a deficiency of hepatic lipoprotein lipase rather than to an overproduction of VLDL.

Concurrently with increased fatty acid oxidation in liver, a progressive decrease in fatty acid synthesis occurs. The net effect of the alterations in hepatic fatty acid metabolism is that AcCoA is generated in excess by the liver because of the increased rate of fatty acid β-oxidation catalyzed by the increased activity of the enzyme carnitine acyltransferase. Fatty acyl-CoA from fat mobilization is also a strong inhibitor of citrate synthase, which removes another route for disposal of AcCoA. The accumulated AcCoA units are then diverted into alternate pathways as described in Section V.B, and with the activation of ketogenic mechanisms, excessive synthesis of ketone bodies (Kreisberg, 1978) and cholesterol results. In the peripheral tissues, there is an underutilization of ketone bodies in the diabetic dog (Balasse and Havel, 1971). Ketosis is thus the result of an overproduction of ketone bodies by the liver and an underutilization by the peripheral (muscle) tissues. The type I diabetic has a greater tendency to develop ketoacidosis than does the type II diabetic. The pathophysiology of the ketoacidosis in the type II diabetic remains unclear, but the most likely mechanism is the depth of the insulinopenia (Linfoot *et al*., 2005).

It has been suggested that the development of ketosis requires both a deficiency of insulin and an excess of glucagon (Foster and McGarry, 1982). Dobbs *et al*. (1975) and Unger and Orci (1975) proposed that diabetes develops as a result of a bihormonal interaction of insulin and glucagon because glucagon levels are high in insulin deficiency. The excess glucagon is thought to be caused by an abnormality in the alpha cell. There is also an excessive secretion of glucagon after protein ingestion or amino acid infusions (Unger, 1981). The excess glucagon may then exacerbate the insulin deficiency and lead to the ketoacidosis.

In the ketoacidotic state, marked cholesterolemias as high as 18mmol/l (700mg/dl) have been observed in clinical diabetes of the dog. Net gluconeogenesis from fatty acid does not occur, and the precursors for gluconeogenesis are the proteins. Excesses of glucagon, cortisol, and growth hormone in the diabetic also contribute to protein catabolism and gluconeogenesis. The cofactors that provide the reductive environment required for gluconeogenesis can be provided by the increased production of reduced cofactors during the increased fatty acid oxidation. This increase in the reductive environment of the cell is the mechanism that stimulates gluconeogenesis, which is corollary to the development of ketoacidosis.

8. *Electrolyte Balance and Ketoacidosis*

A mild glucosuria with only a few grams of glucose loss per day does not in itself precipitate the acidotic state because some compensation occurs. The liver increases its production and output of glucose even though there is a hyperglycemia, so glucose metabolism continues. However, with continued and severe loss of glucose, all

the attendant phenomena of attempts to compensate are exaggerated. Liver glycogen stores are depleted, but liver glucose production continues to be increased because of increased protein breakdown and gluconeogenesis. The oxidation of fatty acids is accelerated and, with it, the overproduction of the acidic ketone bodies, AcAc, 3-OH-B, and acetone occurs. The vapor pressure of acetone (b.p. 56.5°C) is high at body temperature, and thus this volatile compound is often detected in the breath of the severely ketotic animal. AcAc and 3-OH-B are acidic anions, which increase the "anion gap" and reduce the concentrations of HCO_3^-, Cl^-, Na^+, and K^+. Acidosis develops as the HCO_3^- is reduced and respiratory compensation is inadequate. In addition, there is an underutilization of ketone bodies in starvation (Garber *et al*., 1974) and a similar underutilization of ketone bodies occurs in diabetes (Sherwin *et al*., 1976). A rapid point-of-care method for quantifying 3-OH-B is now available and is useful in managing ketoacidosis (Section VIII.D).

In hyperketonemia, large amounts of ketones are wasted in the urine with the large losses of water and HCO_3^-. The acidic ketones are buffered by ammonium ions derived from glutamine in the renal tubules, but large amounts of ketones are ultimately lost with Na^+ and K^+ in the urine. Even without ketonuria, the loss of electrolytes in the polyuria of diabetes may be considerable. Thus, the acidosis of the diabetic is a primary base deficit fundamentally related to the ketonemia and to the loss of ketones and HCO_3^- in the urine.

Excess glucose in the glomerular filtrate provokes an osmotic diuresis leading to loss of water and dehydration. The progressively severe loss of water and electrolytes, the dehydration, and ketoacidosis ultimately lead to collapse, coma, and death. The condition is aggravated by renal impairment, which fortunately is not a common finding in diabetes of the dog. Not all the extracellular sodium deficit is due to urinary loss, however, because as H^+ increases, it enters the cells. In exchange, K^+ leaves the intracellular compartment and some Na^+ enters the cells. As the dehydration progresses, extracellular K^+ concentration may be very high even though there may be a total body deficit. This is an important consideration in the insulin, fluid, and electrolyte replacement therapy of diabetic ketoacidosis. The electrolyte replacement must include K^+ because correction of the acidosis and the rapid expansion of the extracellular fluid compartment lead to the reverse exchange of K^+, and this results in hypokalemia.

10. U*rinalysis*

The renal threshold for glucose in the dog is about 11.1mmol/l (200mg/dl) so that the detection of even trace amounts of glucose in the urine is an important finding and warrants further consideration. In virtually all cases of diabetes suspected on the basis of persistent glycosuria alone, the diagnosis can be later confirmed. Renal diabetes (i.e., low renal threshold for glucose) is an extremely rare occurrence and, if it does occur, can be detected by finding a normal blood glucose in the presence of the glucosuria. Transient glucosurias may occur for 1 to 1½h after a heavy carbohydrate meal, but a 2-h postprandial glucosuria is a strong indication of diabetes.

Currently, detection of glucosuria using the urinalysis sticks is the most common method of point-of-care evaluation of the clinical success of insulin therapy. There are disadvantages to this system because of owner difficulties, inconsistencies, and inaccuracies. The FrAm method, whereby only biweekly blood samplings need be taken, can have decided advantages in following the course of insulin therapy.

An elevated urinary specific gravity (SG) has in the past been considered to be a good indicator of glucosuria and, hence, of diabetes. SG is a measure of the concentration of solutes in the urine, principally the cations (Na^+, K^+, NH_4^+), anions ($PO_4^=$, $SO_4^=$, HCO_3^-, Cl^-), and urea. The observed SG of urine is the result of the additive effect of the contributions of all these solutes. It is for this reason that the osmolality of any fluid, urine or plasma, can be estimated by simply adding up the major anions and cations expressed in mmols/l (see the chapter on acid-base). Albumin in urine increases the SG by 0.003 units for each 10g/l (1g/dl), whereas glucose increases it by 0.004 units for each 55mmol/l (1g/dl). Even though the presence of glucose does increase the SG linearly, a 4^+ reaction, 140mmol/l (2.5g/dl) would increase the SG by only 0.010 unit, an insignificant value on the refractometer. Therefore, although SG is a valuable measure of renal function, it is of no value with respect to the glucosuria of diabetes or to proteinuria. Conversely, by subtracting the contributions of protein and glucose from the observed SG, a more accurate measure of renal function in diabetes may be obtained.

Proteinuria is a common sign of renal disease and is often observed in diabetes in dogs. There is doubt whether this is associated with chronic nephritis or whether it is due to renal failure as an aftermath of diabetes.

Diabetic nephropathies resulting from microangiopathies of the glomerular tufts and basement membrane injuries are frequent and serious complications of the chronic, poorly controlled, human diabetic. A degree of renal arteriosclerosis is common in diabetic dogs, but this lesion is not comparable to the Kimmelstiel-Wilson lesion seen in humans. Also, only 1 of 10 diabetic dogs at necropsy had a significant renal lesion although most had some degree of nephritis (Cotton *et al*., 1971). In renal function studies of experimental streptozotocin diabetes (Kaneko *et al*., 1978b) and in spontaneous diabetes (Kaneko *et al*., 1979), the urea, creatinine, and phosphate clearances were normal. The blood urea and creatinine concentrations were only slightly elevated, and it was concluded that renal disease is not a significant complication in the dog.

The ketone bodies are very low renal threshold substances, and their appearance in the urine is an early and significant sign of developing ketonemia and acidosis. They are not, however, diagnostic of diabetes because ketonuria is observed in starvation or any form of increased fat catabolism. Ketonuria is also absent in mild diabetes, but ketonurias of varying degrees are common in the advanced diabetic state. Therefore, ketonurias can be useful for prognostication. Generally, the type I diabetic is prone to ketonuria because there is an absence of insulin. In the type II diabetic, ketonuria occurs less frequently because there is ample insulin and ketonuria is seen only when the diabetes has advanced to the point of complete failure of production. Urine pH is of little value in detecting acidosis because only in extreme cases does the pH reflect acidosis.

11. *Summary*

The alterations in blood plasma that have been described are summarized in Figure 3-16. In the diabetic state, the uptake and hence utilization of glucose by muscle and adipose tissue is depressed. In these tissues, protein and lipid breakdown is enhanced, and increased amounts of their constituent amino acids and fatty acids are released to the circulation and carried to the liver. Increased hepatic urea production results from the catabolism of these amino acids. Increases in the key gluconeogenic enzymes of the liver, G-6-Pase, PEP-CK, and PC direct glucose metabolism toward an overproduction of glucose. Simultaneously, lipogenesis is suppressed and with the increased mobilization of fatty acids, AcCoA accumulates and is followed by increased cholesterogenesis and ketogenesis. In the peripheral tissues, there is an underutilization of ketones, all of which results in a net increase in blood ketones and subsequent ketoacidosis. Thus, diabetes mellitus is characterized by a fundamental overproduction of and an underutilization of both glucose and ketones as the result of the absolute or relative deficiency of insulin.

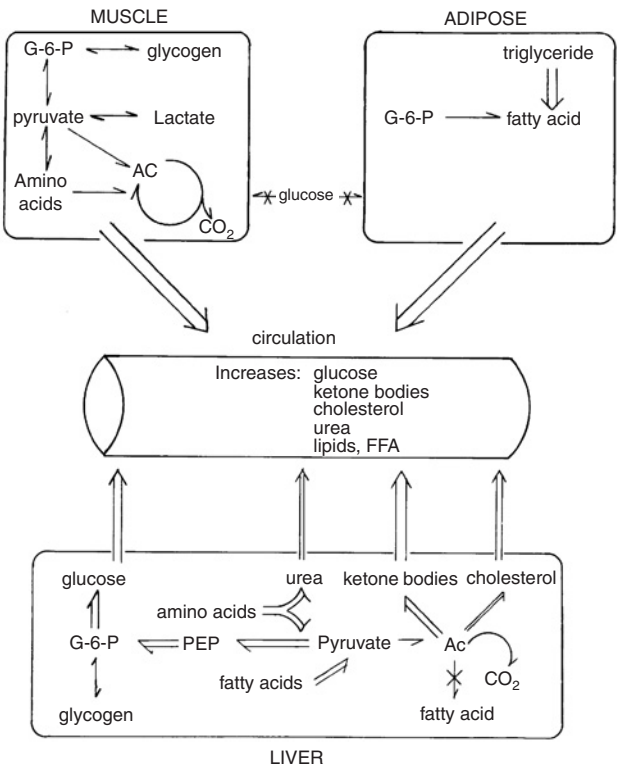

FIGURE 3-16 Summary of metabolic alternations in tissues of major importance in the diabetic animal. Increased flow in the metabolic pathways is noted by larger arrows. FFA = free fatty acids.

B. Hyperinsulinism

After the discovery of insulin, a clinical state with marked similarities to insulin overdosage was recognized as a disease entity in humans and named hyperinsulinism. The disease is now known to be due to a persistent hyperactivity of the pancreas as the result of insulin secreting islet cell tumors. Excess insulin can be extracted from metastatic foci in liver as well as from the pancreatic tumor. There are many reports on this disease in dogs (Hill *et al*., 1974; Mattheeuws *et al*., 1976). Priester (1974) and Kruth *et al*. (1982) reviewed pancreatic islet cell tumors in animals in the United States and Canada. In humans, more than 90% of insulinomas are said to be benign, and in those active tumors, complete surgical resection is required to effect a cure (deHerder, 2004).

Hyperinsulinism is characterized by a persistent hypoglycemia with periods of weakness, apathy, fainting, and during hypoglycemic crises, convulsions, and coma. A history relating the attacks to periods after fasting or exercise provides a clinical basis for further investigations. Establishment of the diagnosis depends on finding a hypoglycemia of <3 mmol/l (<55 mg/dl) at the time of symptoms and a hyperinsulinemia, usually $>20\,\mu$U/ml. The symptoms are also relieved by glucose administration. In mild cases, the fasting glucose level may be within the reference range, in which case, diagnostic hypoglycemia may be provoked by sequentially (1) placing on a low carbohydrate diet (meat only) with frequent feedings for 1 week, (2) placing on a 24-hour fast, and finally (3) adding moderate to stressful exercise (e.g., running on a lease for 15min). Blood glucose is determined at the end of each step, and if hypoglycemia is seen at any step, the provocation should be terminated. Serum insulin is determined at this time and a hyperinsulinemia is generally diagnostic of insulinoma. Calculations of ratios—insulin/glucose, glucose/insulin, amended insulin/glucose—do not offer any advantages over the individual insulin and glucose values.

The glucose tolerance curve is generally characteristic of an increased tolerance if the test is modified: (1) the dog

is on a standard carbohydrate diet for 3 days; (2) the intravenous test is used, and, most important; (3) blood sampling is continued for 6 to 8 hours. A prolongation of the hypoglycemic phase (phase III, Fig. 3-12) is the most significant portion of the curve.

A dog with a tendency toward persistent hypoglycemia is likely to have an abnormal response in the insulin tolerance test, but this is not a reliable test of insulinoma. The tolerance curve may have a minimal drop in blood glucose and remain below the original level for a prolonged length of time. Therefore, the curve has "insulin resistance" and "hypoglycemia unresponsiveness." Use of this test carries some risk for a hypoglycemic crisis, so a glucose solution for intravenous administration should be at hand. Similarly, the glucagon stimulation test has not been a reliable test for hyperinsulinism.

The hypoglycemia that follows oral administration of leucine in children has been used in human patients with islet cell tumors. Marked hypoglycemia occurs within 30 to 60 min after L-leucine administration. Leucine-induced hypoglycemia is also associated with a rise in plasma insulin. In patients with islet cell tumors, leucine sensitivity disappeared after surgical excision of the tumor, which indicates that the tumorous islet cells alone were being stimulated by the leucine. This test has been used successfully in pancreatic islet cell tumors of dogs.

Currently, the most useful tests are the serum insulin and the fasting plasma glucose taken as described earlier. There is an inappropriately high level of insulin ($>20\,\mu$U/l) with a hypoglycemia of $<$3mmol/l ($<$55mg/dl).

C. Hypoglycemia of Baby Pigs

Hypoglycemia of baby pigs occurs during the first few days of life and is characterized by hypoglycemias of $<$2.2 mmol/l ($<$40 mg/dl), apathy, weakness, convulsions, coma, and finally death.

The newborn baby pig is particularly susceptible to hypoglycemia. At birth, the blood glucose level is $>$6 mmol/l ($>$110 mg/dl) and, unless the pig is fed or suckles shortly after birth, its blood glucose drops rapidly to hypoglycemic levels within 24 to 36 hours. The liver glycogen, which is high (14.8%) at birth, is almost totally absent at death. In contrast, newborn lambs, calves, and foals are able to resist starvation hypoglycemia for more than a week. If the baby pig suckles, its ability to withstand starvation progressively increases from the day of birth. A 10-day-old baby pig can be starved up to 3 weeks before symptoms of hypoglycemia occur.

Gluconeogenic mechanisms are undeveloped in the newborn pig, which indicates that the gluconeogenic enzymes of the baby pig are inadequate at birth. This also indicates that these enzymes need to be induced by feeding so they can reach their maximal activities within 1 or 2 weeks after birth. The precise hepatic gluconeogenic enzymes and their inducibility by feeding have not yet been identified.

The association of baby pig hypoglycemia with complete or partial starvation is shown by the findings that their stomachs are empty at necropsy, and the syndrome itself is indistinguishable from experimental starvation of the newborn baby pig. Starvation of the newborn pig under natural conditions can occur because of factors relating to the sow (agalactia, metritis, etc.) or to the health of the baby pig (anemia, infections, etc.), either case resulting in inadequate food intake. The requirement for feeding to induce the hepatic gluconeogenic mechanisms in the newborn baby pig explains its inability to withstand starvation in contrast to the newborn lamb, calf, or foal, which is born with fully functioning hepatic gluconeogenesis.

D. Glycogen Storage Diseases

The glycogen storage diseases (GSD) are characterized by the pathological accumulation of glycogen in tissues. Based on their patterns of glycogen accumulation, their clinical pathological findings, their enzymes of glycogen metabolism, and the structural analyses of their glycogen, the GSDs in humans have been classified into types I through X and 0 and into their various subtypes (Shin, 2006). All have an autosomal recessive mode of inheritance except for GSD VIII, which is sex linked. Their glycogen structures are normal except in types III and IV.

Type I or classical von Gierke's disease is characterized by increased liver glycogen leading to a marked hepatomegaly. There is a marked hypoglycemia and the blood glucose response to epinephrine or glucagon is minimal or absent. The liver glycogen structure is normal. The defect in this disease is a deficiency of the enzyme G-6-Pase. Type II or Pompe's disease is a generalized glycogenosis with lysosomal accumulation of glycogen and early death. The defect in this disease is a deficiency of acid-α-glucosidase (AAGase). In type III or Cori's disease, the debrancher enzyme is deficient, which leads to the accumulation of glycogen of abnormal structure. The branches are abnormally short, and there are an increased number of branch points; it is a limit dextrin, and the disease is sometimes called a limit dextrinosis. There is a variable hypoglycemia, little or no response to epinephrine or glucagon, hepatomegaly, cardiomegaly, and early death. In type IV or Andersen's disease, the brancher enzyme is deficient, which leads to a glycogen with abnormally long branches and few branch points. It is clinically similar to type III. In type V or McArdle's disease, muscle phosphorylase (MPase) is deficient, whereas in type VI, it is liver phosphorylase (LPase) that is deficient. Type VII or Tarui's disease is characterized by a deficiency of muscle phosphofructokinase (PFK) with accumulation of glycogen in

muscle, and type VIII is deficient in leukocyte or hepatic phosphorylase b kinase (PBK). This disease is uniquely sex linked.

Of these 11 types in humans, only types I, II, III, and VIII are found in animals. Other forms of glycogen storage in animals are described as GSD-like based on their pathological patterns of glycogen accumulation. GSD in animals has been reviewed by Walvoort (1983).

There is an inherited PFK deficiency in the springer spaniel dog, but unlike human type VII GSD, there is no muscle pathology or glycogen accumulation in muscle. The deficiency in the dog is expressed as a hemolytic anemia caused by a deficiency of the PFK isoenzyme in the erythrocytes and is rightly considered to be an inherited erythrocyte enzyme deficiency rather than a GSD (Giger *et al*., 1985). Mammalian PFK is present in tissues as tetramers composed of combinations of three different subunits: PFK-M (muscle), PFK-L (liver), and PFK-P (platelets). Human and dog muscle and liver have homogenous tetrameric PFK-M4 and PFK-L4, respectively. Human erythrocyte PFK is a mixed tetramer, PFK-L2/PFK-M2, whereas the dog erythrocyte PFK is a mixed tetramer, PFK-M2/PFK-P2 (Vora *et al*., 1985). In PFK-M subunit deficiency in the dog erythrocyte, PFK-L replaces PFK-M; PFK-L2/PFK-P2. In the human erythrocyte, PFK-P replaces PFK-M; PFK-L2/PFK-P2. Although the substituted PFK in the erythrocyte is the same in dog or human, the deficiency in the human is expressed as a GSD, whereas in the dog it is expressed as an exertional hemolytic anemia. The anemia occurs after heavy exertional respiratory stress as in vigorous hunting or exercise. Hyperventilation induces a respiratory alkalosis, which in turn increases the fragility of the erythrocyte and the hemolytic anemia occurs (Giger *et al*., 1985).

A radiation induced type I GSD occurs as an autosomal recessive condition in the C3H mouse and is characterized by hypoglycemia, early death, and a deficiency of liver G-6-Pase (Gluecksohn-Welch, 1979).

Type II GSD has been described in Brahman cattle (O'Sullivan *et al*., 1981), the Lapland dog (Walvoort *et al*., 1982), and the Japanese quail (Murakami *et al*., 1980). In the Brahman cattle, type II is characterized by early death, generalized glycogen deposition, and a marked decrease in AAGase activity. It is inherited as an autosomal recessive. In the Lapland dog, there is also early death, generalized glycogen deposition, hepatomegaly, and cardiomegaly. There is also a marked decrease in heart and liver AAGase. The Japanese quail with type II is also characterized by early death; glycogen deposition in the heart, liver, and muscles; and decreased AAGase.

Type III occurs in the German Shepherd dog and is characterized by early death, little or no response to epinephrine or glucagon, hepatomegaly, and cardiomegaly with glycogen accumulation. The glycogen has a limit dextrin structure, and there is a very low debrancher enzyme activity in liver and muscle (Ceh *et al*., 1976; Rafaguzzaman *et al*., 1976).

Type VIII is seen in the rat and the mouse. In the rat, the disease is inherited as an autosomal recessive, it appears healthy but is hypoglycemic, has hepatomegaly because of glycogen accumulation in the liver, and has a very low liver phosphorylase kinase activity (Clark *et al*., 1980). The affected mouse is apparently healthy but has increased glycogen accumulation in the muscle with a very low muscle PBK. The inheritance is sex linked (Gross, 1975).

X. DISORDERS OF RUMINANTS ASSOCIATED WITH HYPOGLYCEMIA

A. General

The principal disorders of domestic ruminants in which hypoglycemia is a salient feature are bovine ketosis and ovine pregnancy toxemia. Pregnancy toxemia characteristically is a widespread disease of high mortality occurring in the pregnant ewe just before term, the time when carbohydrate demands are highest, especially in those ewes carrying more than one fetus. Bovine ketosis, on the other hand, occurs in the high producing dairy cow, characteristically during the early stages of lactation when milk production is generally the highest. Abnormally high levels of the ketone bodies, acetone, AcAc, 3-OH-B, and isopropanol appear in blood, urine, and in the milk. The clinical signs of ketosis accompany these alterations: loss of appetite, weight loss, decrease in milk production, and nervous disturbances.

The energy metabolism of the ruminant is focused on the utilization of the volatile fatty acids produced by rumen fermentation rather than on carbohydrates as in the nonruminant. The carbohydrate economy of the ruminant is significantly different from that of the nonruminant, and an appreciation of these differences is important to the understanding of these metabolic disorders of the ruminant.

B. Carbohydrate Balance

1. *Glucose Requirements*

The heavy demands for glucose in early lactation and in late pregnancy are well known. Kleiber (1959) calculated that about 60% of the lactating cow's daily glucose requirement is for the production of milk. The balance sheet (Table 3-10) indicates a total daily glucose requirement of 1140g of which 700g appear in the milk. For sheep in late pregnancy, the fetus utilizes about one-third to one-half of the daily glucose turnover of 100g.

A good approach to assess the glucose requirements of an animal is to measure its turnover rate or the rate at which glucose enters or leaves the circulation. This is best

TABLE 3-10 Carbohydrate Balance Sheet[a]

A. Cow's daily glucose flux	
1. In 12.5 kg milk:	Carbohydrate carbon
610 g lactose	257 g C/day
462 g milk fat with 58 g glycerol	23 g C/day
Carbohydrate carbon in milk/day	280 g C/day
2. Daily glucose catabolism	
Cow produced daily 3288 liters CO_2 = 1762 g C	
Transfer quotient plasma glucose → CO_2 is 0.1	
Thus glucose to CO_2/day = 176 g C/day	
1 + 2 = daily flux of glucose	456 g C/day
$\frac{180}{72} \times 456 = 1140$ g glucose/day	
B. Cow's glucose sources	
Cow secreted daily in urine 34 g N,	
indicating catabolism of 213 g protein	= 100 g C/day
Less C in urea	= 14 g C/day
Maximum available for glucose synthesis from protein	= 96 g C/day
Glucose flow in milk and respiration	= 456 g C/day
Thus glucose flow from nonprotein sources	= 360 g C/day
$\frac{180}{72} \times 360 = 900$ g glucose daily must have been supplied from a nonprotein source	

[a] *From Kleiber* (1959).

measured by the use of isotopically labeled glucose and has been used in lactating cows. It has been estimated to be 1440 g/day (60 g/h) in cows and about 144 g/day (6 g/h) in normal pregnant ewes just before term.

2. *Glucose Sources*

The large amounts of indigestible carbohydrates ingested by ruminants are fermented to volatile fatty acids by the rumen microflora. Little, if any, of the digestible carbohydrates (starch, glucose) in the diet escapes this fermentation, so that glucose absorption from the digestive tract accounts for virtually none of the daily glucose requirement of ruminants. However, if any glucose escapes rumen fermentation (e.g., in gastrointestinal disease), it is readily absorbed.

An indirect source of blood glucose is ruminal lactic acid. Lactic acid is a product of many fermentation reactions, and ruminal lactate can be absorbed. The blood lactate can be a source of blood glucose via the lactic acid cycle (Fig. 3-4). However, the principal source of blood lactate is the breakdown of muscle glycogen. Therefore, some of the ruminant's glucose requirement may be met by lactate, but this is minimal because excess lactic acid in the rumen is toxic.

The carbohydrate balance sheet (Table 3-10) provides the contribution of protein as a source of carbohydrate for the lactating cow. Because glucose absorption in the ruminant is minimal, the balance sheet also illustrates the importance of an alternate nonprotein source of carbohydrate carbon. These sources are the ruminal volatile fatty acids. The principal products of rumen fermentation are the volatile fatty acids, acetate, propionate, and butyrate. These acids are absorbed across the rumen wall and are the major source of nutriment for the ruminant. Various authors have used a variety of techniques to estimate the amounts of production and absorption of these acids. These fatty acids are found in blood in approximately the following proportions: acetate, 65; propionate, 20; and butyrate, 10. Further details of fatty acid production and absorption by the ruminant may be found in the chapter on lipid metabolism. In general, carbon atoms of acetate, although they appear in carbohydrate (blood glucose, milk lactose) through the mechanism of rearrangement in the TCA cycle (Fig. 3-9), cannot theoretically contribute to the net synthesis of carbohydrate. Thus, acetate is not a glucogenic compound. The large amounts of acetate provided by rumen fermentation are utilized for energy purposes and for the synthesis of fat. A possible mechanism for the direct incorporation of acetate into a glucose precursor is the so-called glyoxylate pathway, which occurs in plants but not in animals.

Propionate, on the other hand, is a well-known precursor of carbohydrate. The pathway leading to a net synthesis of glucose from propionate is available via the reaction

$$\text{propionate} + CO_2 \rightarrow \text{succinate}$$

as shown in Figure 3-9. According to the scheme, two moles of propionate are required for the synthesis of a mole of glucose, so 1g of propionate theoretically can provide 1.23g of glucose. The amounts of propionate available from rumen fermentation can theoretically supply the glucose requirements not accounted for by protein sources.

Butyrate, the third major fatty acid of rumen fermentation, influences glucogenesis but does not contribute carbon directly to glucose. Butyrate stimulates glucose production by liver by increasing phosphorylases and gluconeogenesis. The AcCoA derived from β-oxidation of butyrate also activates pyruvate carboxylase, a key gluconeogenic enzyme, which further promotes gluconeogenesis.

3. *Utilization of Glucose*

The overall utilization of glucose by the ruminant has significant differences from that of other animals. Acetate

oxidation rather than glucose plays the important role in energy metabolism of the ruminant. Only about 10% of the respiratory CO_2 arises from glucose oxidation, which is considerably less than the 25% to 60% for the rat, dog, and human. The glucose tolerance of the cow, however, is the same as in other animals. The plasma clearance $T_{1/2}$ of 33 min in the cow is similar to that of dogs (Kaneko *et al*., 1977) and humans.

About 60% of the glucose oxidized in the mammary gland of the lactating cow occurs via the HMP pathway (Fig. 3-6), the same as in the rat mammary gland. HMP pathway activity in the ruminant mammary gland is also evidenced by the high activities of the HMP enzymes, G-6-PD and 6-P-GD, in sheep and cows mammary glands. Thus, even though overall glucose utilization is lower in ruminants, their pathways of glucose catabolism are the same as in other animals. As in other animals, the HMP pathway is the major provider of the reductive atmosphere for the synthetic processes of the mammary gland.

Through the TCA cycle pathway, carbons from acetate, from whatever source, appear in milk products (Fig. 3-17). Glucose carbon atoms may be given off as CO_2, appear in the amino acids of milk protein via transamination of oxaloacetate and α-ketoglutarate, or appear in milk fat. The short chain fatty acids of butterfat are synthesized from acetate in the mammary gland, whereas the long chain acids of butterfat are derived from blood lipids. The synthetic pathway for fatty acids in the gland is the same as that in other animal tissues (see Section IX).

The major portion of the glucose uptake by the mammary gland provides for the biosynthesis of milk. The glucose and galactose moieties of lactose are derived from blood glucose. The rate of lactose synthesis is also constant over a wide range of blood glucose concentrations of 1.1 to 4.4 mmol/l (20–80 mg/dl), which indicates that lactose synthesis is maximal even under hypoglycemic conditions.

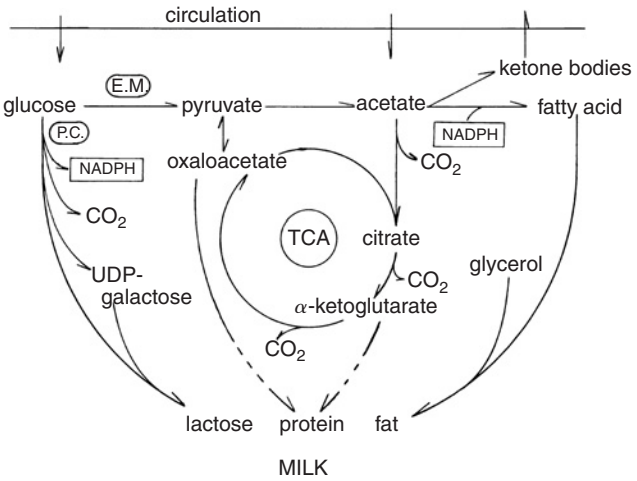

FIGURE 3-17 Summary of some metabolic pathways in the mammary gland.

The mammary gland, therefore, is a glucose-utilizing tissue, principally for biosynthesis and considerably less is oxidized. The principal metabolic pathways involved are summarized in Figure 3-17.

Ruminant nervous tissue (i.e., brain) is also similar to that of other animals in being an obligatory glucose-utilizing tissue. The HK activity of sheep brain, however, is significantly lower than that of rat brain. This means that even though there is the same obligatory glucose requirement between the ruminant and nonruminant, glucose utilization by ruminant nervous tissue is lower than in the nonruminant. Similarly, ruminant intestine and muscle use less glucose than nonruminants.

With regard to organ distribution of gluconeogenic enzymes, highest G-6-Pase activities are found in ruminant livers as compared to other organs of ruminants and are generally equal to or slightly lower than the activities found in nonruminant livers. During early lactation, the period when a cow's glucose requirement is highest, hepatic G-6-Pase does not increase. Similarly, cow liver PEP-CK, a key gluconeogenic enzyme, is already very high in comparison to that of rat liver. All of this is in keeping with the concept that liver is primarily a glucose producing tissue. This also means that the high producing dairy cow that has been genetically selected for these qualities is already synthesizing glucose maximally under normal conditions. It follows that any additional demands for glucose from physical stress, disease, and so on are unlikely to be met by increased glucose production. This glucose shortage leads to ketosis, the primary form from excess milk production or secondary form from the stress of a disease.

To summarize, the ruminant appears to be an animal well adapted to a carbohydrate economy based on the endogenous synthesis of glucose from noncarbohydrate sources (gluconeogenesis). The enzymatic mechanisms for gluconeogenesis are already operating at near maximal levels in the high producing dairy cow. Glucose oxidation by individual tissues as well as by the intact animal is lower in ruminants than in nonruminants. Although overall partitioning of glucose oxidation may be different in ruminants, the pathways by which this oxidation is accomplished are similar to those of other animals (Fig. 3-17). The endocrine relationships of ruminants are also qualitatively similar to those of nonruminants so that the normally low blood glucose concentrations of ruminants are a reflection of their degree of influence or balance rather than their type of action.

C. Biochemical Alterations in Body Fluids

1. *Hypoglycemia and Ketonemia*

Hypoglycemia is such a consistent finding in bovine ketosis and in ovine pregnancy toxemia that "hypoglycemia"

has been suggested as another name for bovine ketosis. This hypoglycemia has played an important role in ketosis, as a rationale for therapy and as a basis for the concept of ketosis and pregnancy toxemia as manifestations of a carbohydrate deficiency, which occurs under conditions of excessive and insurmountable demands.

The ketone bodies are the same as those previously mentioned (Section V.3): AcAc, 3-OH-B, and acetone. A fourth compound, isopropanol, is included for the ruminant, and interconversions can occur between these ketone bodies. The fundamental mechanism and pathogenesis of ketosis are covered in the lipids and ketones chapter.

Chapter 4

Lipids and Ketones

Michael L. Bruss

University of California, Davis
Davis, California

I. INTRODUCTION

This chapter covers the biochemistry and clinical chemistry of long chain fatty acids, triacylglycerols, phospholipids, cholesterol, and ketones, a list that includes the majority of lipids found in vertebrates. The only remaining major classes are sphingolipids and waxes, which are not discussed here. Although lipids have many functions, two of the most important are energy storage and membrane structure. Triacylglycerols are by far the most important lipid with regard to energy storage, and phospholipids and cholesterol are the most important lipid membrane constituents. Lipids serve other functions, including being precursors for steroids and bile acids (cholesterol), thermal insulation (triacylglycerols), and electrical insulation (various lipids). Virtually all lipids are insoluble in water, which greatly complicates their handling in the body. Because of their insolubility, lipids must rely on proteins for transport for any significant distance in the body, and various proteins have evolved to provide this function. The insolubility of lipids is an asset as well as a liability. Because of their insolubility, lipids generate no osmotic force, so large amounts of triacylglycerol can be stored in adipose without the weight gain from water that would accompany it if it were soluble. The insolubility of lipids is vital to many of their functions in membranes.

II. LONG CHAIN FATTY ACIDS

A. Structure, Properties, and Assay of Long Chain Fatty Acids

Long chain fatty acids (LCFA), frequently called free fatty acids or nonesterified fatty acids, are straight chain fatty acids containing twelve or more carbon atoms. Because LCFA are usually synthesized in animals or plants from acetyl-CoA and are then degraded two carbons at a time via β-oxidation in animals, the LCFA found most commonly in animals have an even number of carbon atoms. LCFA having

carbon chain lengths of 16 and 18 constitute the greatest bulk of fatty acids in animal tissues and most animal diets. The saturated 16-carbon LCFA is palmitic acid, and the saturated 18-carbon LCFA is stearic acid. Unsaturated 18-carbon LCFA are common, with double bonds occurring at C_9—C_{10} (oleic acid); at C_9—C_{10} and C_{12}—C_{13} (linoleic acid); and at C_9—C_{10}, C_{12}—C_{13}, and C_{15}—C_{16} (linolenic acid). The double bonds found in fatty acids in nature are mostly of the cis configuration. Ruminant fat contains more trans-LCFA than that of nonruminants because rumen microbes isomerize some plant cis-LCFA to trans isomers. Unsaturated LCFA have a lower melting point than saturated LCFA with the same number of carbons and are more susceptible to spontaneous oxidation (Gurr *et al*., 2002). The 20-carbon polyunsaturated fatty acids, arachidonic acid (double bonds at C_5—C_6, C_8—C_9, C_{11}—C_{12}, C_{14}—C_{15}) and eicosapentaenoic acid (also called timnodonic acid), which is arachidonic acid with an additional double bond at C_{17}—C_{18}, are the precursors of the eicosanoids (prostaglandins, leukotrienes, thromboxanes).

Long chain fatty acids are relatively insoluble in water at physiological pH. They dissolve readily in highly alkaline solutions, forming soaps. LCFA are amphiphilic, being quite polar (hydrophilic) at their carboxyl end and quite nonpolar (hydrophobic) at the methyl end. All LCFA must bind to proteins in order to be transported for any significant distance, and albumin is the primary transport protein in plasma (Gurr *et al*., 2002).

Plasma LCFA concentrations can be determined spectrophotometrically with a specific enzymatic reaction, which involves direct reaction of plasma LCFA to form LCFA-CoA. Then, LCFA-CoA is oxidized using LCFA-CoA oxidase, which produces hydrogen peroxide. The hydrogen peroxide is used to produce a colored product under the catalysis of peroxidase (Demacker *et al*., 1982; Shimizu *et al*., 1980). If a sample contains triacylglycerol and lipase, which is not uncommon, LCFA may be released if the sample is allowed to stand. Falsely high LCFA may be avoided by centrifuging blood samples and freezing the plasma immediately after collection or by adding paraoxon, a lipase inhibitor (Degen and Van der Vies, 1985).

B. Synthesis of Long Chain Fatty Acids

LCFA may be synthesized in most tissues, but only liver, adipose, or mammary tissue does it on a large scale. Synthesis occurs in the cytosol from acetyl-CoA. The precursor of the acetyl-CoA used for LCFA synthesis is usually acetate or glucose, with the former being important in ruminants and the latter being important in nonruminant mammals. When acetate is the acetyl-CoA precursor, it is formed from plasma acetate in the cytosol, the same cellular location as the enzymatic machinery needed to manufacture the LCFA. However, when glucose is the precursor, it must go through glycolysis, which has its terminal enzyme, pyruvate dehydrogenase, located in the mitochondria. Thus, the acetyl-CoA is produced in the mitochondria, which is a problem if it is to be used for LCFA synthesis because the inner mitochondrial membrane is relatively impermeable to acetyl-CoA (Rangan and Smith, 2002).

This problem has been solved by a mechanism known as the citrate shuttle, which is shown in Figure 4-1. Acetyl-CoA in the mitochondria combines with oxaloacetate under the catalysis of citrate synthase to form citrate. Citrate is translocated across the mitochondrial membrane where it is cleaved into acetyl-CoA and oxaloacetate by ATP-citrate lyase. Thus, acetyl-CoA has been effectively transported from mitochondrion to cytosol. What remains is for the oxaloacetate to reenter the mitochondria to complete the cycle. However, the inner mitochondrial membrane is also impermeable to oxaloacetate, so it is first converted to malate-by-malate dehydrogenase or aspartate-by-aspartate aminotransferase in the cytosol. The malate or aspartate is translocated into the mitochondrion where it can be converted back to oxaloacetate by reversal of the reactions that occurred in the cytosol. Alternately, malate in the cytosol can be converted to pyruvate by malic enzyme, and the pyruvate can enter the mitochondrion and be converted to oxaloacetate by pyruvate carboxylase (Rangan and Smith, 2002).

Once acetyl-CoA reaches or has been formed in the cytosol, it must be carboxylated to produce malonyl-CoA via acetyl-CoA carboxylase if it is to be used for LCFA synthesis. This biotin-containing enzyme catalyzes the following reaction:

Acetyl-CoA Carboxylase

$$CH_3CO\text{-}CoA + CO_2 + ATP \rightarrow {}^{-}OOCCH_2CO\text{-}CoA + H^+ + ADP + P_i$$

Acetyl-CoA carboxylase is the main regulatory site in the synthesis of LCFA, which makes sense because the cell has little use for malonyl-CoA other than the synthesis of LCFA. The enzyme is activated by citrate, which is logical because citrate will be abundant only when there is a plentiful supply of mitochondrial acetyl-CoA. In addition, acetyl-CoA carboxylase is directly inhibited by LCFA-CoA, which can be derived from the synthetic process itself or from uptake and activation of plasma LCFA. Acetyl-CoA carboxylase is also regulated by hormones via phosphorylation of the enzyme itself. Glucagon and LCFA-CoA stimulate phosphorylation, which inhibits the enzyme. Insulin activates the enzyme quickly by stimulating dephosphorylation (Rangan and Smith, 2002). These controls make sense in that a fasting or exercising animal will have its capacity for LCFA synthesis suppressed by increased plasma glucagon and LCFA levels, decreased plasma insulin, and increased intracellular LCFA-CoA. Conversely, in a recently fed animal, these controls will all be reversed to promote LCFA synthesis.

Malonyl-CoA is used as the building block for LCFA in the cytosol by a large, complex, multiunit enzyme called

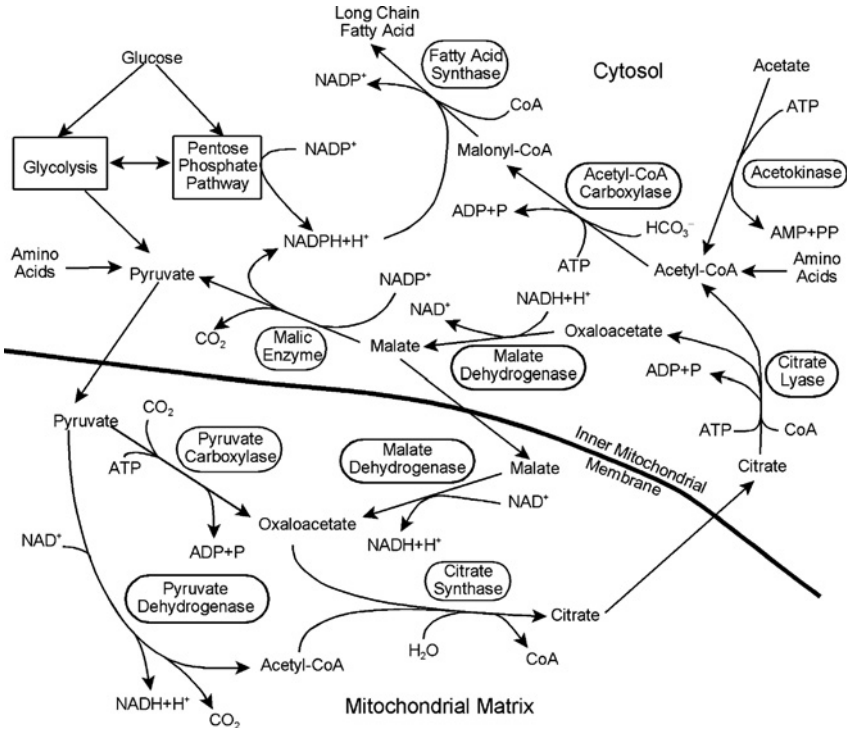

FIGURE 4-1 Fatty acid synthesis. Acetyl-CoA is generated in the mitochondria from pyruvate but cannot penetrate the mitochondrial membrane to reach fatty acid synthesizing enzymes in the cytosol. Citrate is formed from acetyl-CoA and oxaloacetate and migrates to the cytosol where it is cleaved to regenerate acetate and oxaloacetate. The acetyl-CoA is converted into malonyl-CoA and used for fatty acid synthesis. The oxaloacetate cannot penetrate the mitochondrial membrane but must be converted to malate or pyruvate, which can penetrate the membrane and be converted back to oxaloacetate in the mitochondria. NADPH needed for fatty acid synthesis is generated by the pentose phosphate pathway and malic enzyme.

fatty acid synthase. Fatty acid synthase uses malonyl-CoA to add two carbon units at a time to a growing LCFA chain that is attached to the enzyme itself, and it uses NADPH to reduce the oxygen that was attached to what was the end carbon of the old LCFA chain. The reaction proceeds in a series of distinct steps, which all occur on the same enzyme complex. The overall reaction is as follows:

$$CH_3\text{-}(CH_2)_n\text{-CO-enzyme} + {}^{-}OOCCH_2CO\text{-CoA} + 2\ NADPH + 3\ H^{+}$$

$$CH_3\text{-}(CH_2)_{n+2}\text{-CO-enzyme} + CO_2 + H_2O + 2\ NADPH^{+}$$

The subscript, *n*, in the structural formula for the growing LCFA is an even number ranging from zero (i.e., the starting acetyl group) to usually no more than eight (stearate). The process begins when an acetyl group binds to the enzyme complex and usually ends when a palmityl (16-carbon) group has been formed on the enzyme, at which point the LCFA is detached from the enzyme. New carbons are added to the carboxyl end, not the methyl end, of the growing LCFA. The carbon atom in the carbon dioxide produced in the fatty acid synthase reaction is the same carbon atom in the carbon dioxide used to form malonyl-CoA from acetyl-CoA.

Cellular synthesis of the enzymes directly involved in LCFA synthesis (acetyl-CoA carboxylase and fatty acid synthase) and the enzymes involved in the generation of NADPH and acetyl-CoA translocation is stimulated by diets that are high in carbohydrate and low in fat and suppressed by fasting, high-fat/low-carbohydrate diets, and diabetes. These changes appear to be brought about, in part, by alterations in plasma insulin and glucagon that accompany diet changes or diabetes (Gurr *et al*., 2002; Rangan and Smith, 2002).

Fatty acid synthesis is expensive energetically. To add a single acetyl-CoA to a growing LCFA chain, one ATP is used directly and six more are used indirectly (each of the two NADPH is equivalent to three ATP). Because fatty acid synthesis occurs in the cytosol and requires NADPH, there must be a generous source of that cofactor when fatty acid synthesis is active. The main source of NADPH for fatty acid synthesis is the hexose monophosphate pathway in the cytosol. This pathway utilizes plasma glucose in the case of adipose or mammary tissue, whereas in the liver, it can use plasma glucose, glycogen, or gluconeogenesis as the hexose source. Another source of NADPH in the cytosol is the malic enzyme reaction. These sources of NADPH are illustrated in Figure 4-1.

Although the most common length for nascent LCFA when they are released from fatty acid synthase is 16 carbons, they can be 18 carbons or, in the case of fat synthesis in the mammary gland, as short as 4 carbons. When LCFA are detached from fatty acid synthase, they are rapidly thioesterified to CoA by LCFA-CoA synthetase, an enzyme found in the endoplasmic reticulum and outer mitochondrial membrane. Most of the palmitate produced by fatty acid synthase will be elongated to produce stearate by fatty acid elongase, an enzyme found mainly in the endoplasmic reticulum but also in mitochondria. This enzyme adds

2 new carbons at the carboxyl end of the existing LCFA. Fatty acid elongase uses the same substrates (malonyl-CoA and NADPH) as fatty acid synthase, but it is located in a different part of the cell and prefers palmityl-CoA as its substrate. However, fatty acid elongase can use longer LCFA-CoA as substrates to a limited degree to produce LCFA-CoA with a length of as great as 24 carbons (Cook and McMaster, 2002).

Nonruminant mammals synthesize LCFA in liver, adipose, and mammary tissue. Ruminants synthesize LCFA primarily in adipose and mammary tissue with acetate being the most important precursor. Ruminants generally have a low capacity for LCFA synthesis in liver, but after eating large amounts of high-starch diets, they may synthesize some LCFA in the liver from acetate and propionate (Hanson and Ballard, 1967; Ingle, 1972a, 1972b; Liepa 1978).

C. Catabolism of Long Chain Fatty Acids

1. *Desaturation*

Most animals are capable of desaturating LCFA only at the Δ^4, Δ^5, Δ^6, and Δ^9 positions (counting from the carboxyl end). Animals are able to desaturate palmityl-CoA and stearyl-CoA between C_9 and C_{10} by means of Δ^9 desaturase system located in the endoplasmic reticulum to produce palmitoleyl-CoA and oleyl-CoA, respectively. However, animals are not able to create additional double bonds beyond C_9 in these products to any significant extent, so linoleic and linolenic acids must be absorbed from the intestinal tract (Cook and McMaster, 2002). By a combination of the actions LCFA elongase and Δ^4, Δ^5, and Δ^6 desaturase systems, the livers of most mammals can synthesize arachidonic acid and eicosapentaenoic acid from linoleic and linolenic acids, respectively. However, the cat has very low levels of Δ^6 desaturase in its liver and must have arachidonic acid in its diet (MacDonald *et al*., 1984).

2. β-Oxidation

The main catabolic route for LCFA is β-oxidation. Most tissues can perform β-oxidation (erythrocytes are an exception), but those most adept at it are liver, skeletal muscle, and heart. In addition, the liver can partially oxidize LCFA to ketones, an important process that will be discussed extensively later. Before LCFA can be subjected to β-oxidation, they must be esterified to CoA, which is accomplished by the following reaction:

$$\text{LCFA} + \text{ATP} + \text{CoA} \rightleftharpoons \text{LCFA-CoA} + \text{AMP} + \text{PP}$$

The reaction is catalyzed by LCFA-CoA synthetase, an enzyme bound to the endoplasmic reticulum and the outer mitochondrial membrane. The pyrophosphate (PP) is rapidly hydrolyzed, so the reaction effectively consumes two ATP. The activation of LCFA is not rate limiting for β-oxidation (Pande, 1971).

For LCFA-CoA to be catabolized, it must pass into the mitochondrion, which is a problem because the inner mitochondrial membrane is impermeable to it. The CoA must be exchanged for a carnitine moiety, a reaction catalyzed outside the mitochondrion by carnitine acyltransferase I (Fig. 4-2):

$$\text{LCFA-CoA} + \text{carnitine} \rightleftharpoons \text{LCFA-carnitine} + \text{CoA}$$

LCFA-carnitine passes readily through the inner mitochondrial membrane and is acted on by carnitine acyltransferase II, which converts the LCFA-carnitine back to LCFA-CoA (Kopec and Fritz, 1973).

Carnitine acyltransferase I appears to be controlled by inhibition by malonyl-CoA (McGarry *et al*., 1977), and it is logical that when lipogenesis is stimulated, the LCFA that are produced should be prevented from entering the mitochondrion where they will be catabolized.

In the mitochondrion, the process of β-oxidation per se cleaves the LCFA into acetyl-CoA units. The reaction sequence is as follows:

$$\text{R-CH}_2\text{-CH}_2\text{-CO-CoA} + \text{FAD} \xrightarrow{\text{acyl-CoA dehydrogenase}} \text{R-CH=CH-CO-CoA} + \text{FADH}_2$$

$$\text{R-CH=CH-CO-CoA} + \text{H}_2\text{O} \xrightarrow{\Delta^2\text{-enoyl-CoA hydratase}} \text{R-C(OH)H-CH}_2\text{CO-CoA}$$

$$\text{R-C(OH)H-CH}_2\text{-CO-CoA} + \text{NAD}^+ \xrightarrow{\text{L(+)-3-hydroxyacyl-CoA dehydrogenase}} \text{R-CO-CH}_2\text{-CO-CoA} + \text{NADH} + \text{H}^+$$

$$\text{R-CO-CH}_2\text{-CO-CoA} + \text{CoA} \xrightarrow{\text{thiolase}} \text{R-CO-CoA} + \text{CH}_3\text{-CO-CoA}$$

The resulting acyl-CoA is two carbons shorter and can recycle through the pathway. Each trip of an acyl-CoA through the pathway generates one $FADH_2$ and one NADH + H 1 , which can generate 5 ATP via oxidative phosphorylation. If the LCFA has an odd number of carbons, which is rare, the final product of β-oxidation will be propionyl-CoA. The double bond produced by the acyl-CoA dehydrogenase reaction is of trans configuration, not the cis configuration occurring in unsaturated LCFA found free or esterified to glycerol.

Unsaturated LCFA can proceed through β-oxidation to within three carbons of the double bond. As this point, Δ^2-enoyl-CoA hydratase cannot act because it requires a trans, rather than a cis, configuration in its substrates, and it requires that the double bond be between C_2 and C_3 rather than between C_3 and C_4. At this point, Δ^3, Δ^2-enoyl-CoA isomerase will convert the Δ^3-cis double bond to a Δ^2-trans double bond, which will allow β-oxidation to proceed

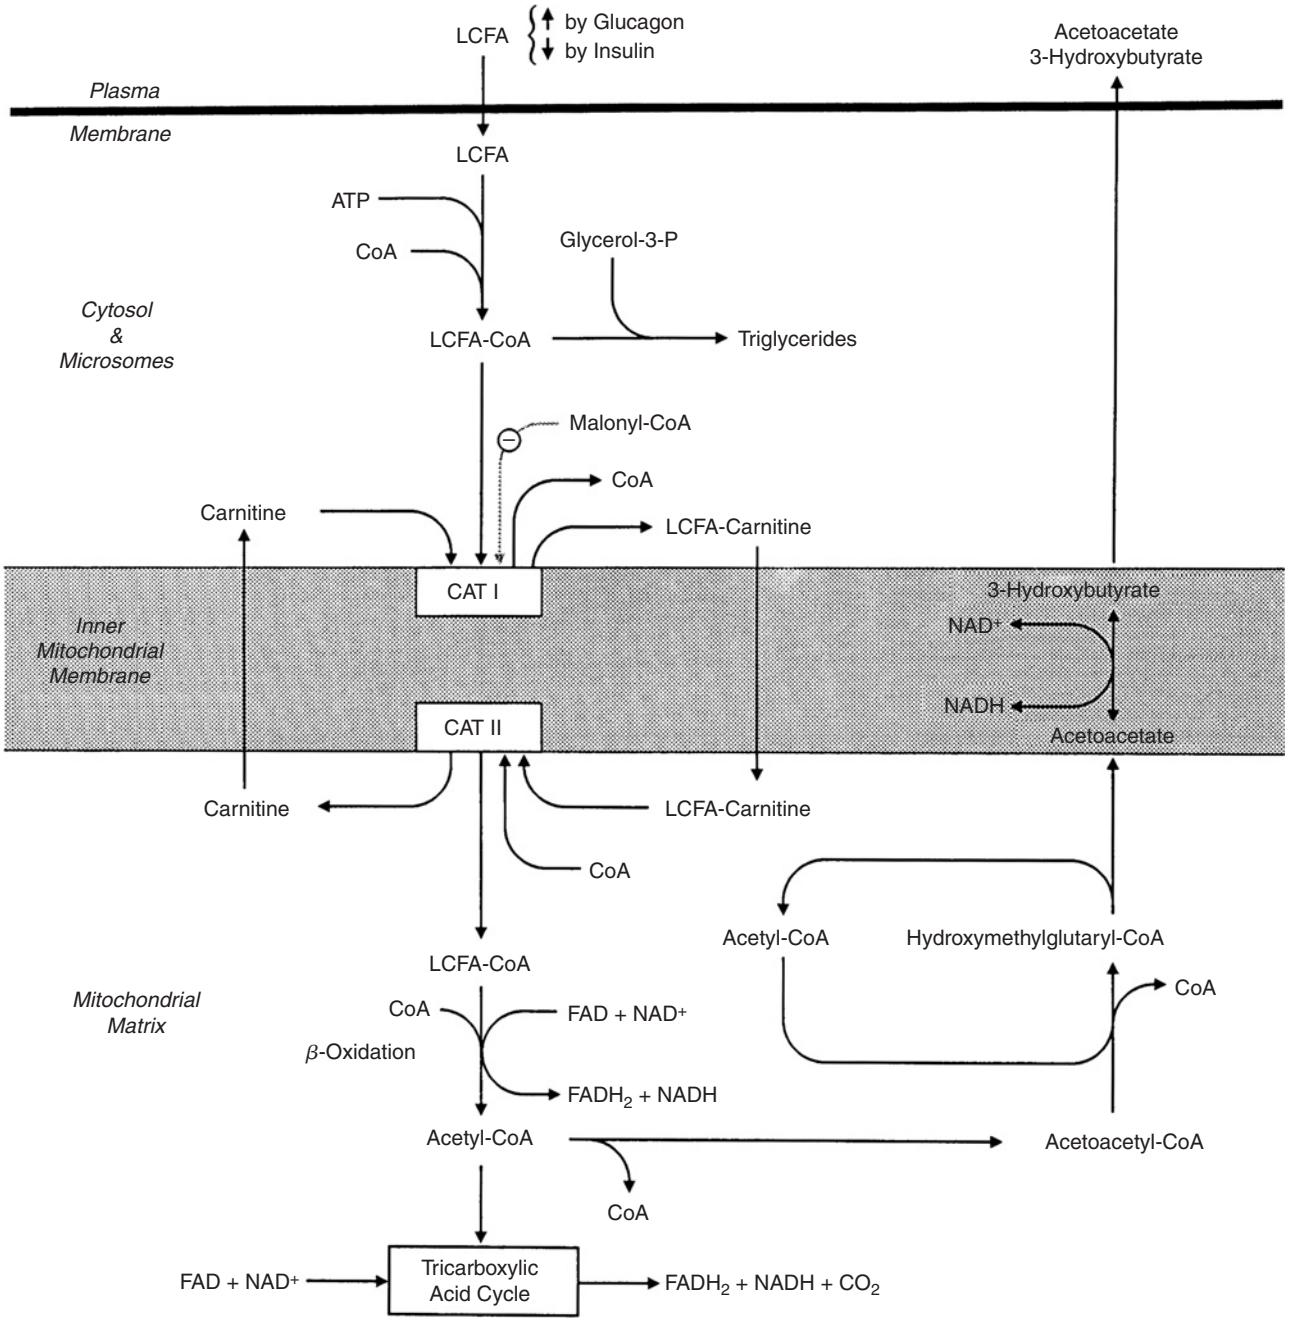

FIGURE 4-2 Long chain fatty acid (LCFA) oxidation and ketogenesis in the liver. Abbreviations: CAT, carnitine acyltransferase.

(Kilponen *et al*., 1991). Polyunsaturated LCFA require an additional enzyme, 2,4-dienoyl-CoA reductase, because after enoyl-CoA isomerase acts, the new trans double bond will still have the second cis double bond in close proximity, which will prevent Δ^2-enoyl-CoA hydratase from acting. 2,4-Dienoyl-CoA reductase effectively eliminates the second double bond by reducing it with NADPH (Roe *et al*., 1990).

β-Oxidation in the mitochondria appears to be controlled mainly by substrate availability. The acetyl-CoA units can be oxidized in the citric acid cycle provided there is sufficient oxaloacetate to condense with them to form citrate. Alternatively, acetyl-CoA units can be recondensed to form ketones, which will occur when there is not sufficient oxaloacetate for citrate formation or when citrate synthase is inhibited by high levels of citrate. Although β-oxidation occurs mostly in mitochondria, the process occurs to a minor extent in peroxisomes as well (Wanders *et al*., 1992).

Although the main catabolic route for LCFA is β-oxidation, there are two quantitatively minor alternatives.

α-Oxidation, in which carbons are removed one at a time from the carboxyl end of the LCFA, is used by brain tissue to produce LCFA of varying lengths for synthesis of complex lipids. ω-Oxidation, which is oxidation that occurs at the methyl, rather than at the carboxyl, end is conducted to a limited extent by the cytochrome P-450 system in the endoplasmic reticulum of liver. The resulting dicarboxylic acid can then undergo β-oxidation to a chain length of six carbons (adipate), most of which will be excreted in the urine (Gurr *et al*., 2002; Mortensen, 1990).

III. TRIACYLGLYCEROL

A. Structure, Properties, and Assay of Triacylglycerol

The main storage forms of LCFA are the triacylglycerols (also called triglycerides), in which three LCFA are esterified to glycerol. Triacylglycerols are even less soluble than LCFA and also must be bound to proteins in complexes called lipoproteins for transport through plasma.

Assay of triacylglycerol in plasma or serum is best accomplished by enzymatic hydrolysis using lipase followed by enzymatic determination of the released glycerol (Klotzsch and McNamara, 1990; McGowan *et al*., 1983). If high plasma glycerol levels are likely, as it is in animals that have not eaten lately, a plasma blank must be run. Older methods that use alkaline hydrolysis require caustic reagents, consume more time, and may assay phospholipids plus triacylglycerol. Contamination of samples with glycerol, which is sometimes used to lubricate stoppers of blood collecting tubes, or with soap, which may contain glycerol or fatty acids, will lead to falsely elevated values. If the sample contains lipase, which is not uncommon, triacylglycerol levels will decrease if it is allowed to stand. Prompt centrifugation of blood samples followed by rapid analysis or freezing of the plasma will prevent falsely low triacylglycerol levels.

B. Synthesis of Triacylglycerol

Although most cells can synthesize triacylglycerols, liver, adipose, mammary gland, and small intestine are particularly adept at it. LCFA-CoA are the building blocks for triacylglycerol synthesis, and it should be realized that there are two sources of LCFA-CoA for triacylglycerol synthesis: LCFA in the plasma and LCFA synthesized locally. Generally, physiological or pathological circumstances, such as starvation or diabetes, which promote high plasma levels of LCFA, suppress LCFA synthesis. Physiological circumstances that promote LCFA synthesis, such as eating a carbohydrate meal, also inhibit lipolysis in adipose, so plasma LCFA levels are not elevated.

To form triacylglycerols, LCFA-CoA are esterified to glycerol-3-P. Glycerol-3-P can be produced in the liver from glycerol, which is absorbed from the plasma, and ATP in a reaction catalyzed by glycerol kinase:

$$\text{glycerol} + \text{ATP} \rightarrow \text{glycerol-3-P} + \text{ADP}$$

Glycerol is normally plentiful in plasma only when there is active lipolysis occurring in adipose tissue.

When glucose is plentiful in the plasma and LCFA are being synthesized from glucose via acetyl-CoA, glycerol-3-P is also synthesized from glucose in liver, mammary gland, and adipose. This process occurs via glycolysis to dihydroxyacetone-P followed by a reduction catalyzed by glycerol-3-P dehydrogenase:

$$\text{dihydroxyacetone-P} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{glycerol-3-P} + \text{NAD}^+$$

LCFA-CoA is esterified to glycerol-3-P by glycerol-P acyltransferase:

$$\text{glycerol-3-P} + \text{LCFA-CoA} \rightarrow \text{1-acyl-glycerol-3-P} + \text{CoA}$$

This reaction occurs in both mitochondria and smooth endoplasmic reticulum, but the smooth endoplasmic reticulum enzyme is more plentiful and most important in triacylglycerol synthesis. Next, another LCFA-CoA is esterified by the enzyme, acylglycerol-P acyltransferase, which is located in the smooth endoplasmic reticulum:

$$\text{1-acyl-glycerol-3-P} + \text{LCFA-CoA} \rightarrow \text{phosphatidate} + \text{CoA}$$

Phosphatidate (the ionized form of phosphatidic acid) is 1,2-diacyl-glycerol-3-P. Next, the phosphate is hydrolyzed from phosphatidate by phosphatidate phosphohydrolase to produce a diacylglycerol:

$$\text{phosphatidate} \rightarrow \text{diacylglycerol} + \text{P}$$

This reaction occurs in the smooth endoplasmic reticulum and cytosol. Finally, a last LCFA-CoA is esterified by the enzyme diacylglycerol acyltransferase, an enzyme located in the smooth endoplasmic reticulum (Bernlohr *et al*., 2002):

$$\text{diacylglycerol} + \text{LCFA-CoA} \rightarrow \text{triacylglycerol} + \text{CoA}$$

If the triacylglycerol has been synthesized in adipose, it will migrate into the large storage vesicle that each adipocyte possesses. Most of the triacylglycerol synthesized in liver normally will be incorporated into and exported from the liver as part of very low density lipoproteins (VLDL). However, if triacylglycerol synthesis exceeds hepatic export capacity, triacylglycerol will accumulate in vesicles in hepatocytes, leading to fatty liver. If the triacylglycerol has been synthesized in mammary gland, the resulting triacylglycerols will accumulate in vesicles of secretory cells, and the vesicles will be extruded into the lumina of the gland acini.

The regulation of triacylglycerol synthesis is not fully understood and differs among tissues. In small intestine, substrate availability is most important because triacylglycerol synthesis in that organ is an integral part of triacylglycerol absorption. In mammary gland, substrate availability and the hormones that support lactation regulate triacylglycerol synthesis.

In liver, the limiting enzyme in the pathway appears to be phosphatidate phosphohydrolase. This enzyme is subject to an interesting control mechanism in which it is switched between a less active and more active state by the enzyme itself being translocated between the cytosol and endoplasmic reticulum, respectively. Intracellular cAMP, which increases with high plasma glucagon or low plasma insulin levels (e.g., fasting or diabetes), inhibits binding of the enzyme to the endoplasmic reticulum, whereas LCFA or LCFA-CoA promote binding of the enzyme to the endoplasmic reticulum (Bernlohr *et al*., 2002; Gurr *et al*., 2002). The role of LCFA and LCFA-CoA in promoting synthesis of triacylglycerols in the liver is important and explains how fat synthesis and fatty liver can occur in the fasting state when hormonal changes would oppose triacylglycerol synthesis.

In adipose tissue, the synthesis of triacylglycerol is very much regulated by hormones, especially glucagon, catecholamines, and insulin. The first two hormones increase intracellular cAMP, and the latter tends to decrease it, although insulin probably has effects independent of cAMP. In conditions in which glucagon would be elevated and insulin would be decreased (e.g., fasting), hormone-sensitive lipase will be activated and lipolysis will be occurring. It is important that fat synthesis not be operative during lipolysis, so as not to waste energy. Low insulin and elevated catecholamine or glucagon levels decrease the level of lipoprotein lipase (LPL) in adipose tissue. Fat cells need LPL in order to hydrolyze plasma triacylglycerol so that the resulting LCFA can be absorbed and used for triacylglycerol synthesis. Decreased plasma insulin levels will decrease entry of glucose into adipocytes, which will result in less glycerolphosphate being synthesized. Increased intracellular cAMP in adipose tissue decreases the activity of several key enzymes in fat synthesis, including fatty acyl-CoA synthetase, glycerolphosphate acyltransferase, phosphatidate transferase, and diacylglycerol acyltransferase; however, the mechanism of inhibition is uncertain (Saggerson, 1988).

C. Catabolism of Triacylglycerol

Catabolism of triacylglycerol involves the action of lipases, which are specialized esterases that hydrolyze glyceride bonds. The major lipases are pancreatic lipase, hepatic lipase, hormone-sensitive lipase of adipose, lipoprotein lipase found on endothelial cells, and lysosomal lipases contained in most cells. Pancreatic lipase is the essential lipase for digestion of triacylglycerol in the GI tract and is discussed later. Hepatic lipase is synthesized in hepatocytes from where it migrates to the surface of hepatic endothelial cells. Hepatic lipase primarily attacks triacylglycerol in the plasma, which are part very low density lipoprotein (VLDL) remnants to produce low-density lipoproteins (LDL), and it attacks triacylglycerol in high-density lipoproteins (HDL) as well.

Lipoprotein lipase attacks triacylglycerol in chylomicrons and VLDL in plasma and is found on the endothelium of many organs and tissues, but it is in greatest quantity in adipose, heart, skeletal muscle, and mammary gland. Lipoprotein lipase is synthesized by the underlying tissue and migrates to the capillary endothelium where it is anchored on the cell surfaces to glycoproteins, which have polysaccharide chains structurally similar to heparin. If heparin is injected into an animal, lipoprotein lipase can switch its attachment from cell surface glycoproteins to the free injected heparin and, thus, appears in the plasma. If the animal had a lipemia before injecting the heparin, the large amount of lipoprotein lipase released into the plasma will clear the lipemia. Phospholipids and apolipoprotein C-II must be present for lipoprotein lipase to have full activity (Fielding and Fielding, 2002).

IV. PHOSPHOLIPIDS

A. Structure and Properties of Phospholipids

Most of the phospholipids found in the body consist of a core of glycerol, which has LCFA esterified to its 1 and 2 carbons and phosphate esterified to its 3 carbon, a compound called phosphatidate. In addition, the phosphate is often esterified to a hydroxyamino compound such as choline, ethanolamine, or serine to produce phosphatidylcholine (also called lecithin), phosphatidylethanolamine, and phosphatidylserine, respectively. Inositol may be esterified to the phosphate to produce phosphatidylinositol. Because of the phosphate group, phospholipids are very polar on one end but are nonpolar on the other end and still must be part of lipoproteins for transport through the plasma. Phospholipids are constituents of all cellular membranes, lipoproteins, and bile micelles. The fatty acid portion of the molecule is oriented toward the center of the membrane or micelle, and the phosphatidyl group is oriented toward the outer surface (i.e., toward the aqueous medium). In micellar structures, like lipoproteins and bile micelles, the surface coating of the polar ends of constituent phospholipids provides a surface charge that helps to keep the micelles in suspension.

B. Synthesis of Phospholipids

Phospholipids are synthesized either from phosphatidate (e.g., phosphatidylinositol) or diacylglycerol (e.g., phosphatidylcholine and phosphatidylethanolamine), both of

which are intermediates in the synthesis of triacylglycerol. In all cases, cytidine triphosphate (CTP), a high-energy organophosphate that derives its phosphates from ATP, plays an important role. In the case of phosphatidylinositol, CTP reacts with phosphatidate to form CDP-diacylglycerol, which then reacts with inositol to form phosphatidylinositol and CMP. In the case of choline or ethanolamine, it must first be phosphorylated by reaction with ATP. Then the phosphocholine or phosphoethanolamine reacts with CTP to form CDP-choline or CDP-ethanolamine, respectively, which then reacts with diacylglycerol to produce phosphatidylcholine and phosphatidylethanolamine, respectively. Phosphatidylserine is formed by serine replacing ethanolamine in phosphatidylethanolamine. In the endoplasmic reticulum of the liver, a methyl group from S-adenosylmethionine can be transferred to phosphatidylethanolamine to produce phosphatidylcholine (Vance, 2002a). Figure 4-3 illustrates the synthesis of phospholipids.

The enzymes that synthesize CDP-choline and CDP-ethanolamine (cytidylyltransferases) appear to be rate limiting for the synthesis of phosphatidylcholine and phosphatidylethanolamine, respectively. Phosphocholine cytidylyltransferase is subject to regulation similar to that of phosphatidate phosphohydrolase, the control enzyme in triacylglycerol synthesis. When phosphocholine cytidylyltransferase is bound to the endoplasmic reticulum, it is relatively active, but when it is free in the cytosol, it is relatively inactive. Factors that increase binding of the enzyme to the endoplasmic reticulum are decreased levels of phosphatidylcholine, increased levels of diacylglycerol or LCFA, and dephosphorylation of the enzyme. Opposite changes in these factors inhibit binding of the enzyme to the endoplasmic reticulum forcing it to remain inactive (Vance, 2002a).

C. Catabolism of Phospholipids

Phospholipids are hydrolyzed by phospholipases, which can be found in lysosomes of most tissues and in pancreatic secretion. Mammalian phospholipases are primarily of the A type, meaning that they hydrolyze the glycerol-LCFA ester bond at either position 1 (A_1 type) or 2 (A_2 type), but not both (Gurr *et al*., 2002; Waite, 2002). Phospholipase types B, C, and D, which hydrolyze at other locations in the molecule, exist in mammalian tissues, but with lower activities.

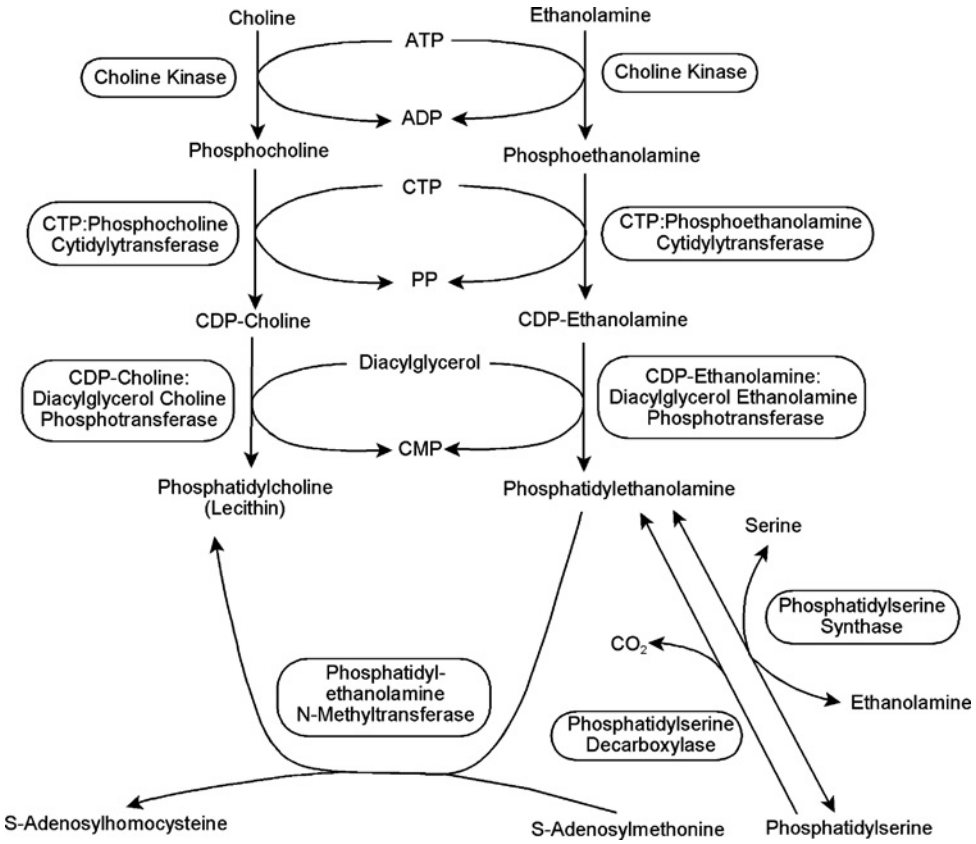

FIGURE 4-3 Synthesis of phospholipids. Diacylglycerol is the lipid to which organic bases and phosphate are transferred via CDP derivatives. Abbreviations: CTP, CDP, CMP, cytidine tri-, di-, and mono-phosphate, respectively.

V. CHOLESTEROL

A. Structure, Properties, and Assay of Cholesterol

Structurally, cholesterol is composed of a core of phenanthrene to which a cyclopentane ring is attached, and there is an eight-carbon side chain attached to the cyclopentane ring (Fig. 4-4). Cholesterol is found only in animals and is not present in plants or microorganisms. Cholesterol is the precursor of steroid hormones, vitamin D, and the bile acids, and is a constituent of cell membranes and bile micelles. Cholesterol can be obtained from the diet if it contains animal products, or it can be synthesized.

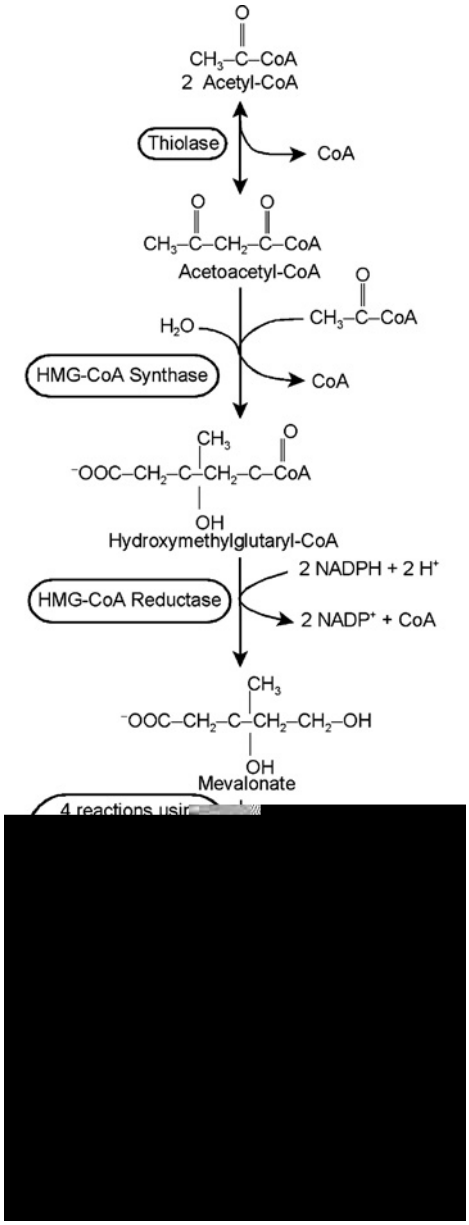

FIGURE 4-4 Synthesis of cholesterol. The first two reactions occur in the cytosol and the remainder in the smooth endoplasmic reticulum.

The chief synthetic and catabolic organ for cholesterol is the liver. Steroidogenic endocrine organs (adrenal cortex, testis, ovary, placenta) can synthesize small amounts of cholesterol; however, these organs utilize hepatically synthesized cholesterol for most of their steroid synthesis (Pedersen, 1988). Pure cholesterol and cholesterol esters are insoluble waxy white solids and must be transported through plasma as part of lipoproteins.

Enzymatic methods are used almost universally for assay of cholesterol (Stein and Meyers, 1994). Older nonenzymatic methods used harsh reagents and lack specificity. The key enzymes in the assay are cholesterol esterase, which hydrolyses cholesterol esters, and cholesterol oxidase. The latter enzyme is of microbial origin and has an action analogous to that of glucose oxidase (i.e., it uses dissolved oxygen to oxidize cholesterol to produce cholest-4-ene-3-one and hydrogen peroxide). In the presence of added peroxidase, hydrogen peroxide will oxidize an added organic dye (e.g., dianisidine, ABTS, 4-aminoantipyrine plus phenol) to generate a colored product that can be quantified spectrophotometrically. If cholesterol esterase is included in the reagent, then total cholesterol will be determined. If cholesterol esterase is omitted from the reagent, then only nonesterified (i.e., free) cholesterol will be determined. If the assay is done with and without cholesterol esterase, then cholesterol ester concentration can be determined by subtraction.

Because virtually all of the cholesterol and cholesterol esters in plasma are part of lipoproteins, they must be liberated before they can be acted on by the enzymes of the reagent. This liberation can be accomplished by extracting cholesterol and its esters with an organic solvent before the assay or, more conveniently, by including small amounts of detergents (bile acids or artificial detergents) in the reagent (Stein and Meyers, 1994).

B. Metabolism of Cholesterol

As is the case for LCFA and ketones, the substrate for cholesterol synthesis is acetyl-CoA. The beginning site of cholesterol synthesis is in the cytosol, so acetyl-CoA, which is generated primarily in the mitochondria, must be transferred to the cytosol via the citrate shuttle mechanism discussed earlier. The process of cholesterol synthesis is shown diagrammatically in Figure 4-4. In the cytosol, the first two steps of cholesterol synthesis are identical to the first two steps of ketone synthesis except that the process occurs in the cytosol rather than in the mitochondria. The enzymes that catalyze the first two steps are acetyl-CoA: acetoacetyl-CoA thiolase and hydroxymethylglutaryl-CoA (HMG-CoA) synthase:

$$2 \text{ acetyl-CoA} \rightleftharpoons \text{acetoacetyl-CoA} + \text{CoA}$$

$$\text{acetoacetyl-CoA} + \text{acetyl-CoA} \rightleftharpoons \text{HMG-CoA} + \text{CoA}$$

The remaining enzymes of cholesterol synthesis are located in the endoplasmic reticulum, perhaps because of decreasing solubility of succeeding products formed in the pathway. Next, HMG-CoA is reduced to mevalonate under the catalysis of HMG-CoA reductase:

$$\text{HMG-CoA} + 2\ \text{NADPH} + 2\ \text{H}^+ \rightarrow \text{mevalonate} + 2\ \text{NADP}^+ + \text{CoA}$$

HMG-CoA reductase is the primary control point for cholesterol synthesis, and its control mechanisms will be discussed later. Next, via three steps, isopentenylpyrophosphate is formed. Six of these molecules, often called the active isoprenoid units, are linked to form cholesterol in a long and complex pathway, which is only partially understood (Faust *et al*., 1988; Liscum, 2002).

The control of HMG-CoA reductase is complex and not completely understood. Artificially increasing plasma cholesterol levels *in vivo* decreases the activity of the enzyme in liver. However, cholesterol does not inhibit the enzyme directly, but represses synthesis of the enzyme mRNA (Liscum, 2002). Thus, if the amount of cholesterol consumed in the diet increases, the amount synthesized by the liver will decrease. This reciprocal relationship between cholesterol consumed and hepatic synthesis limits the extent to which plasma cholesterol levels can be decreased by restricting the amount of cholesterol in the diet.

Hepatic HMG-CoA reductase is inhibited by phosphorylation of the enzyme and reactivated by dephosphorylation. The protein kinase system responsible for the phosphorylation of HMG-CoA reductase is stimulated by intracellular cAMP (Liscum, 2002). Hepatic intracellular cAMP levels are controlled in part by plasma glucagon, which increases it, and by insulin, which decreases it. Thus, conditions that increase insulin (e.g., eating) will increase cholesterol synthesis, and conditions that decrease insulin (e.g., diabetes) or increase glucagon (e.g., fasting) will decrease cholesterol synthesis. Other hormones that affect hepatic HMG-CoA reductase activity, but probably not by altering intracellular cAMP levels, are thyroid hormones (increase HMG-CoA reductase activity) and glucocorticoids (decrease HMG-CoA reductase activity). Some drugs, such as lovastatin and mevastatin, used in humans to decrease plasma cholesterol levels, operate by inhibiting HMG-CoA reductase (Brown and Goldstein, 1990).

Once cholesterol has been synthesized in the hepatocyte, it can be secreted into the plasma as part of lipoproteins (mostly in VLDL), it can be secreted into the canaliculi and become part of bile micelles, it can be degraded to bile acids, or it can be esterified to an LCFA by acyl-CoA:cholesterol acyltransferase (ACAT), which is located in the smooth endoplasmic reticulum. Cholesterol esters are even less soluble than cholesterol and are found in membranes and micelles wherever cholesterol itself is found. Cholesterol ester can be exported as part of lipoproteins, or it can be converted back to cholesterol plus LCFA by cholesterol ester hydrolases, which are found in the cytosol, endoplasmic reticulum, and lysosomes. De-esterification is mandatory before cholesterol can be catabolized to bile acids. Because enzymes for the final steps of cholesterol synthesis and the first steps of its degradation are colocated in the endoplasmic reticulum, it might seem that most newly synthesized cholesterol would be immediately degraded. However, the negative feedback of bile acids on cholesterol degradation keeps this process in check.

HDL contains lecithin:cholesterol acyltransferase (LCAT), which esterifies cholesterol by transferring an LCFA moiety from lecithin (phosphatidylcholine). The cholesterol to be esterified by LCAT can be then secreted with HDL at the time of its synthesis, or it can be cholesterol from other lipoproteins or cell membranes that come in contact with HDL at a later time.

VI. LIPOPROTEINS

A. Structure, Properties, and Assay of Lipoproteins

Lipoproteins are very large noncellular conglomerations (micelles) of lipids and proteins, which are suspended in plasma or lymph. Their main function is to transport most lipids (steroid hormones and LCFA being notable exceptions) among tissues. Another function of lipoproteins is the esterification of cholesterol. Lipoproteins have a micellar structure in which the least polar molecules (triacylglycerol and cholesterol) occupy the center and more polar molecules (proteins and phospholipids) coat the exterior. Lipoproteins are synthesized almost exclusively by liver and the small intestine.

The main classes of lipoprotein are defined by their density as determined by ultracentrifugation and are chylomicrons ($d < 0.94$ g/ml), very low density lipoproteins (VLDL, $d = 0.94$ to 1.006 g/ml), low-density lipoproteins (LDL, $d = 1.006$ to 1.063 g/ml), and high-density lipoproteins (HDL, $d = 1.063$ to 1.21 g/ml). Less commonly considered are very high density lipoproteins (VHDL, $d > 1.21$g/ml), which are usually very low in concentration in plasma. It is common to designate the lighter LDL ($d = 1.006$ to 1.019g/ml) as intermediate density lipoproteins (IDL), and some schemes subdivide the HDL into HDL_1, HDL_2, and HDL_3. (Chapman, 1986; Gotto *et al*., 1986).

The lipid component of lipoproteins is less dense than the protein component, but the lipids have similar densities, and the proteins have similar densities. Therefore, the density of a lipoprotein is almost entirely dependent on its ratio of lipid to protein, with the chylomicrons having the

TABLE 4-1 Composition of Lipoproteins of Domestic Animals[a]

highest ratio and, on the other end of the spectrum, the HDL having the lowest ratio (Table 4-1). More than one-half of the lipid in chylomicrons and VLDL is triacylglycerol, whereas in LDL and HDL the majority of the lipids are not triacylglycerol (Table 4-2). In domestic species, HDL is normally the most abundant plasma lipoprotein in the fasting state.

Chylomicrons and VLDL particles are large enough to refract light significantly, so they make plasma appear turbid or creamy if in high enough concentration (lipemic plasma). The chylomicrons have a low enough density that they will rise to the top of an undisturbed refrigerated plasma sample in 6 to 12 hours. This phenomenon is the basis of the "chylomicron test," in which a milky plasma sample is placed in the refrigerator overnight. If a "cream layer" has formed at the top, then hyperchylomicronemia is present, and if the bottom portion of the plasma is turbid, then elevated levels of VLDL are present.

Because of the expense, time, and complexity involved with ultracentrifugation, electrophoresis in an alkaline medium has been used as an alternate method of lipoprotein classification. A variety of electrophoretic supports, ranging from paper to acrylamide gels, have been used. The sample is applied at the cathode end of the support, voltage is applied for a variable time, and the proteins are fixed and stained with a lipid stain such as oil red O. A densitometer is used to quantify the lipoprotein fractions on the stained electrophoretogram.

Typically, three to five bands of lipoproteins can be discerned; however, additional bands may be present depending on the species of animal, electrophoretic technique, and presence of abnormal lipoproteins. The fastest moving band is HDL, which is designated as α-lipoprotein. The next fastest moving band is VLDL, which is designated pre-β-lipoprotein followed by the LDL band, which is designated as β-lipoprotein. The slowest moving band, which is still at the origin and seen primarily in the postprandial period, is composed of chylomicrons. With some electrophoresis systems, a separate IDL band, designated as slow pre-β-lipoproteins, can be discerned between the VLDL and LDL bands, and sometimes subbands of the HDL can be discerned. The correlation of electrophoretic and ultracentrifuge fractions established for humans does not always apply to animals. For example, bovine LDL can appear as α- or β-bands on electrophoresis (Puppione, 1983). Usually, two HDL bands can be discerned for dog plasma (Rogers, 1977). Figure 4-5 illustrates the distribution of lipoproteins in dog plasma.

Although easier and cheaper to perform than ultracentrifugation, lipoprotein electrophoresis still requires considerable time and expense. Consequently, methods have been developed that involve precipitation of one or more lipoprotein classes followed by analysis of a particular lipid, usually cholesterol, in the remaining supernatant. For example, chylomicrons can be removed by low-speed centrifugation (they rise to the top), and then precipitation of VLDL and LDL in human plasma can be accomplished by treatment with magnesium and dextran sulfate. The main lipoprotein remaining in the supernatant will be HDL, and if cholesterol is determined, it will mostly be HDL

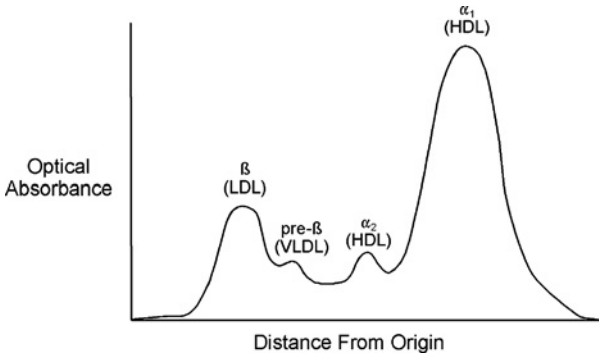

FIGURE 4-5 Densitometric scan of an electrophoretogram of canine plasma lipoproteins. The scan is typical of a fasted dog. In a fed dog, an additional peak as a result of chylomicrons would be present at the origin. Abbreviations: HDL, LDL, and VLDL, high-, low-, very low density lipoproteins, respectively.

cholesterol (Stein and Meyers, 1994). Such empirical methods may be species specific. For example, the preceding method, though valid for human plasma, does not work for dog plasma (Rhodes *et al*., 1992).

B. Apolipoproteins

The protein components of lipoproteins are called apolipoproteins. Some apolipoproteins are found in only one class of lipoproteins, whereas others can be found in multiple classes. Although there are species variations in the amino acid sequences of apolipoproteins, individual apolipoproteins in the domestic species are quite similar. The main classes of apolipoproteins are designated with a letter (A through E), sometimes followed by a number to indicate a distinct subclass. The main classes and subclasses of apolipoproteins found in domestic animals are A-I, A-II, A-IV, B_{48}, B_{100}, C-I, C-II, C-III, C-IV, and E. Characteristics of these apolipoproteins are listed in Table 4-2.

The B_{100} apolipoprotein, synthesized in the liver and part of VLDL, is one the largest polypeptide chains in mammals, having a molecular weight of 527,000 in horses (Watson *et al*., 1991). B_{48} apolipoprotein is about one-half the size of B_{100} and contains a subset of the B_{100} amino acid sequence (i.e., they are probably coded by the same gene); however, B_{48} is synthesized in the small intestine and is part of chylomicrons. The origin of the "48" and "100" designations stems from the fact that human B_{48} is exactly 48% of the mass of human B_{100}. Both B_{48} and B_{100} are glycoproteins and have a variety of carbohydrates attached to them (Chapman, 1986).

In addition to apolipoproteins, HDL contains an additional protein in the form of the enzyme lecithin:cholesterol acyltransferase (LCAT), which esterifies cholesterol esters by transferring an LCFA moiety from phosphatidylcholine (lecithin) to cholesterol. LCAT is activated by lipoprotein A-I.

C. Digestion of Fat and Formation of Chylomicrons

The largest lipoproteins are the chylomicrons, and to understand their formation, the digestion of triacylglycerol must be discussed. The main site of digestion and absorption of triacylglycerol is the small intestine, and the chief enzyme involved is pancreatic lipase. The pancreas not only supplies lipase to attack triacylglycerol but also supplies cholesterol esterase to hydrolyze cholesterol esters and phospholipase A_2 to attack phospholipids. For any of these enzymes to be effective, the lipids in food must first be emulsified with bile. Bile contains micelles composed mostly of bile acids, phospholipids, and cholesterol. Fats in food become part of these micelles, and then the enzymes can attack them on the outer surface of the micelles. The fatty acids, monoacylglycerols, and cholesterol resulting from the attack of the enzymes become part of the lipids of the brush border of the intestinal cells. The intestinal cells then use the monoacylglycerols and fatty acids to resynthesize triacylglycerol. Globules of triacylglycerol coated with protein are extruded from the basolateral membranes into the interstitium as chylomicrons. The lymphatic capillaries of the microvilli are called lacteals and have many large openings between the endothelial cells that line them. Consequently, the chylomicrons can enter the lymphatics, but not the blood capillaries. From the small intestine, the lymph flows to larger abdominal ducts to the thoracic duct and enters the right atrium. Thus, unlike most other nutrients, most of the absorbed fat bypasses the portal system and liver (Gurr *et al*., 2002; Vance, 2002b).

The main apolipoproteins in chylomicrons are A-series, B_{48}, C-series, and E. The A-series and B_{48} apolipoproteins are added by the small intestine, but the C-series and E apolipoproteins, which are synthesized in the liver, appear to transfer from HDL to nascent chylomicrons soon after they are released into the circulation.

Chylomicrons are attacked by lipoprotein lipase, which resides on the surface of endothelial cells and hydrolyses triacylglycerol. Most of the resulting LCFA are absorbed by the tissue cells. As the chylomicron diminishes in size, some of the apolipoproteins, mostly A-series and C-series, transfer to HDL. Finally, a much diminished chylomicron remnant is left and will attach to an apolipoprotein-E receptor on hepatocytes. The remnant will be absorbed and its components hydrolyzed within the hepatocytes (Fielding and Fielding, 2002; Schneider, 2002). The transport and metabolism of chylomicrons are illustrated in Figure 4-6.

D. Very Low Density Lipoprotein: Synthesis, Export, and Metabolism

Secretion of very low density lipoproteins (VLDL) into the plasma is the main method by which hepatocytes export

TABLE 4-2 Apolipoproteins of Domestic Animals[a]

Major				
Molecular			Synthetic Lipoprotein	Constituent of Special Properties
Apolipoprotein	Weight	Organ		
A-I	28 kd (all species)	Small intestine	Chylomicrons, HDL	Activates lecithin: cholesterol acyltransferase
A-II (monomer)	8.5 kd (cattle, dog)	Small intestine	Chylomicrons, HDL	Exists mostly as a dimer 6.5 kd (horse)
A-IV	43 kd (cattle, dog)	Small intestine	Nascent chylomicrons, HDL	Activates lecithin: cholesterol acyltransferase?
B_{48}	270 kd (cattle, horse)	Small intestine	Chylomicrons	
B_{100}	534 kd (cattle, horse)	Liver	VLDL, LDL	Binds to LDL receptor 325 kd (swine)
C-I	8.0 kd (cattle)	Liver	VLDL, LDL, HDL, chylomicrons	
C-II	9.5 kd (cattle, pig)	Liver	VLDL, LDL, HDL, chylomicrons	Activator of lipoprotein lipase
	14 kd (horse)			
C-III	8.0 kd (cattle) 12 kd (horse)	Liver	VLDL, LDL, HDL	
C-IV	10 kd (cattle)	Liver	VLDL, LDL, HDL, chylomicrons	
E	37 kd (all species)	Liver	VLDL, LDL, HDL, chylomicrons	Binds to LDL and chylomicron remnant receptor

triacylglycerol. Its main apolipoproteins are B_{100}, C-series, and E, but some A-series is present as well. The A-series apolipoproteins, which are synthesized in the small intestine, transfer from HDL to VLDL soon after its secretion. Some C-series and E apolipoprotein may transfer from HDL to newly secreted VLDL as well. Like chylomicrons, the main lipid component of VLDL is triacylglycerol (see Table 4-1). VLDL and chylomicrons both serve as a means to distribute triacylglycerol to tissues. In the case of chylomicrons, the triacylglycerol is a product of fat digestion, whereas in the case of VLDL, the triacylglycerol is synthesized in the liver.

The assembly process for VLDL is complex (Fig. 4-7). Final steps in the synthesis of triacylglycerol, phospholipid, and cholesterol occur in the smooth endoplasmic reticulum. Microdroplets containing these three lipids and cholesterol esters move toward the confluence of the rough and smooth endoplasmic reticulums where they are joined by apolipoproteins synthesized on the rough endoplasmic reticulum to form the nascent VLDL.

The nascent VLDL particles move through microtubular membranes to the Golgi apparatus where the apolipoproteins are glycosylated. In the Golgi apparatus, the nascent VLDL particles reach final composition and are surrounded by membranes to form secretory granules. The secretory granules merge with the plasma membrane and spill their contents into the plasma (Alexander, 1976; Vance, 2002b).

The capacity of the liver to synthesize the protein components of VLDL is stimulated by a diet high in carbohydrate. It has been hypothesized that this stimulation is due to increased insulin and decreased glucagon levels in plasma. Most studies have shown that glucagon partially inhibits hepatic VLDL secretion, whereas insulin stimulates it (Gibbons, 1990). Estrogens (Crook and Seed, 1990; Haffner and Valdez, 1995; Sacks and Walsh, 1994) and glucocorticoids (Gibbons, 1990; Martin-Sanz *et al*., 1990) stimulate VLDL secretion.

The inherent capacity of the liver to synthesize the lipid components exceeds its inherent capacity to synthesize the protein components, a fundamental factor in the development of fatty liver. In addition, phosphatidylcholine is essential for lipoprotein assembly, so animals having a deficiency of choline tend to develop fatty livers (Vance, 2002a, 2002b).

Triacylglycerol in plasma VLDL is hydrolyzed by lipoprotein lipase just like triacylglycerol of chylomicrons, and most of the released LCFA is absorbed by the underlying tissue cells. As the VLDL shrink, some of the apolipoproteins (C-series and E) transfer to HDL. Finally, the shrinking VLDL becomes an IDL and then an LDL. The LDL will attach to an apoprotein B_{100} or E receptor on hepatocytes or extrahepatic tissues and be taken into the cell where its component parts will be hydrolyzed. The transport and metabolism of VLDL are illustrated in Figure 4-8.

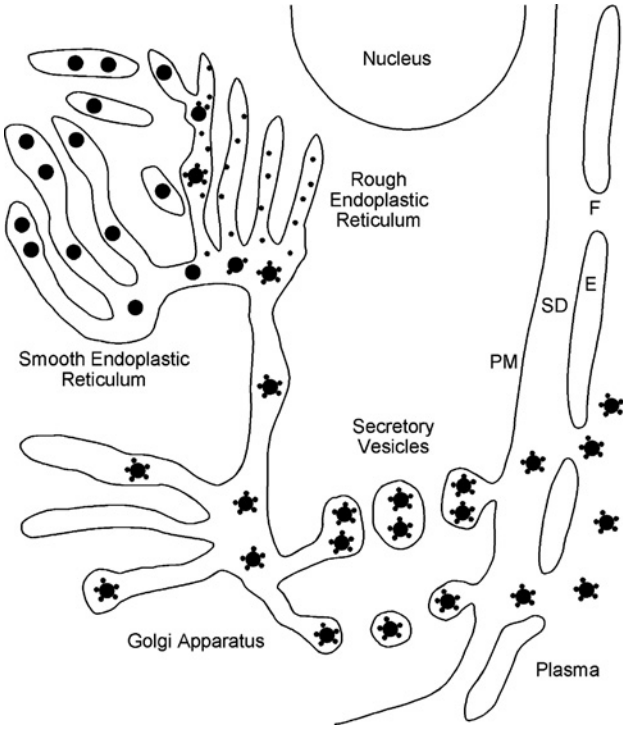

FIGURE 4-7 Synthesis of very low density lipoprotein (VLDL) in liver. Triacylglycerol and phospholipid synthesis occurs in the smooth endoplasmic reticulum to generate lipid particles (large dots), which acquire small amounts of cholesterol and its esters as well. Apolipoproteins (small dots) are synthesized on the rough endoplasmic reticulum. Lipid particles acquire apolipoproteins at the convergence of the rough and smooth endoplasmic reticulum or by merging of sections of the two organelles. The nascent VLDL move through tubular membranes to the Golgi apparatus where apolipoproteins are glycosylated, and the nascent VLDL are collected in secretory vesicles. The secretory vesicles migrate to and merge with the plasma membrane (PM) and spill VLDL into the space of Dissé (SD). The VLDL migrate through the fenestrae (F) between endothelial cells (E) to enter the plasma in hepatic sinusoids.

E. Metabolism of High-Density Lipoproteins

HDL is synthesized by both liver and small intestine. Nascent HDL produced in the small intestine has only A-series apolipoproteins and gains C-series and E apolipoproteins and LCAT, which are synthesized in the liver, from other lipoproteins after it enters the circulation. Nascent HDL produced in the liver gains its A-series apolipoprotein, which is synthesized in the small intestine, from other lipoproteins after it enters the circulation. HDL serves two main functions. It is a repository for A-series, C-series, and E apolipoproteins, and it transports cholesterol from peripheral tissues to liver. LCAT is important in this latter function. The conversion of cholesterol-to-cholesterol ester within HDL creates a favorable concentration gradient from tissue cell to HDL, which promotes migration of cholesterol from tissue cells to HDL (Fielding and Fielding, 2002; Gurr *et al*., 2002).

FIGURE 4-8 Metabolism and transport of very low density lipoprotein (VLDL). Abbreviations: A, B_{100}, C, E, apolipoproteins; HDL, IDL, and LDL, high-, intermediate-, and low-density lipoproteins, respectively; LCAT, lecithin:cholesterol acyltransferase; LCFA, long chain fatty acid; TAG, triacylglycerol.

HDL is removed from the circulation primarily by the liver, and its component parts can be metabolized within the hepatocyte or some of its lipid components can be incorporated into VLDL and enter the plasma again. Cholesterol can migrate from HDL into hepatocytes without the entire HDL being removed, and as mentioned earlier, apolipoproteins can migrate from HDL to chylomicrons, VLDL, and other HDL.

In summary, chylomicrons and VLDL distribute triacylglycerol, cholesterol, and phospholipids from the small intestine and liver, respectively, to other tissues. IDL and LDL are effectively remnants of VLDL. HDL is a reservoir of some apolipoproteins and transports cholesterol from peripheral tissues to liver.

VII. HYPERLIPIDEMIA

A. Introduction

Hyperlipidemia refers to increased plasma levels of cholesterol (hypercholesterolemia) and triacylglycerols (hypertriacylglycerolemia or hypertriglyceridemia). Note that increased plasma levels of LCFA alone do not constitute hyperlipidemia. Because cholesterol and triacylglycerols must reside within lipoproteins in plasma, hyperlipidemia is synonymous with hyperlipoproteinemia. *Lipemia* is a term denoting that hyperlipidemia is severe enough that the plasma looks milky (i.e., lactescent). If lipemia is marked, whole blood may have a light red color or "tomato soup" appearance. The most common form of hyperlipidemia is postprandial hyperlipidemia, which is observed after an animal consumes a meal containing fat and is due primarily to increased chylomicron levels. For evaluation of possible abnormalities in lipid metabolism, it is important that blood samples be taken from fasting animals to avoid confusion caused by postprandial hyperlipidemia. One exception is adult ruminants, which are usually on a very low fat diet and, because of the volume of the rumen and fermentative nature of digestion there, have absorption spread over a considerable time period.

B. Canine Fasting Hyperlipidemias

Healthy dogs normally do not develop significant hyperlipidemia upon fasting. Therefore, fasting hyperlipidemia in a dog usually is an abnormal sign with potential causes being hypothyroidism, diabetes, pancreatitis, hyperadrenocorticism, hepatic disease, nephrotic syndrome, and inherited defects in lipid metabolism. Hyperlipidemia is commonly observed in dogs with hypothyroidism, whether of congenital or acquired origin (Barrie *et al*., 1993; DeBowes, 1987; Liu *et al*., 1986; Manning *et al*., 1973; Medaille *et al*., 1988; Watson and

Barrie, 1993). The main lipid that is increased is cholesterol, but triacylglycerol may be increased too, and most of the increased lipid is in LDL and HDL, but some animals have increased VLDL or chylomicron levels as well (Rogers, 1977; Whitney, 1992). The mechanism by which hypothyroidism causes hyperlipidemia in dogs is unknown; however, a similar phenomenon occurs in humans, and in that species, it appears that hypothyroidism decreases lipoprotein lipase and hepatic lipase activities (Valdemarsson *et al*., 1983). The prolonged hypercholesterolemia associated with chronic hypothyroidism in dogs may lead to atherosclerosis (Liu *et al*., 1986; Patterson *et al*., 1985), although other factors may be involved as well.

Dogs with naturally occurring pancreatitis frequently have hyperlipidemia (Hardy, 1992; Whitney *et al*., 1987). Because the pancreatitis in some of these animals causes diabetes, the hyperlipidemia in those individuals may be due to diabetes. Plasma lipid levels of dogs with pancreatitis induced by injecting bile into or ligating the pancreatic duct are comparable to control dogs (Bass, 1976; Whitney *et al*., 1987; Zieve, 1968). In some cases, hyperlipidemia may play a role in the pathogenesis of pancreatitis rather than being a result of pancreatitis. This proposition is supported by the fact that humans with some forms of hyperlipidemia have increased risk of pancreatitis (Cameron *et al*., 1974; Greenberger, 1973). One proposed mechanism is that increased lipids, especially chylomicrons, entering the pancreatic capillaries will be hydrolyzed by pancreatic lipase, and the resultant LCFA may injure endothelial or acinar cells (Havel, 1969). Once the initial damage occurs, there is a positive feedback in which more lipase enters the circulation and hydrolyses more triacylglycerol leading to more LCFA release and more damage. In support of this theory, when dog pancreata were perfused with a medium containing high levels of triacylglycerol or LCFA, they became edematous and hemorrhagic and released large amounts of amylase compared to pancreata perfused without these additions (Saharia *et al*., 1977). In a related proposed mechanism, large amounts of chylomicrons or VLDL may impede the microcirculation of the pancreas, leading to partial stasis, which allows blood lipids and their hydrolysis products more contact with pancreatic cells (Hardy, 1992).

Dogs with uncontrolled diabetes frequently have hyperlipidemia (Medaille *et al*., 1988; Rogers, 1977; Whitney, 1992). In naturally occurring cases, plasma triacylglycerol levels are increased with concomitant increases in VLDL levels and often hyperchylomicronemia is present as well (DeBowes, 1987; Ford, 1995; Rogers, 1977; Rogers *et al*., 1975b). The increase in VLDL is due in part to increased mobilization of LCFA from adipose. The liver removes LCFA from plasma and reissues some of them to the plasma as triacylglycerol in VLDL. In addition, synthesis of lipoprotein lipase by peripheral tissues is partially dependent on insulin, so less of this enzyme is available to remove triacylglycerol from the circulation (Brown and Goldstein, 1994).

Hyperlipidemia with increases in plasma triacylglycerol and cholesterol levels have been noted in dogs with cholestasis (Bauer *et al*., 1989; Meyer and Chiapella, 1985). The increase in cholesterol can be explained in part by the inability of the liver to remove and catabolize cholesterol. However, there is evidence of production of an abnormal LDL, called lipoprotein-X, which is rich in cholesterol (Bauer *et al*., 1989; Blomhoff *et al*., 1978; Danielsson *et al*., 1977; Meyer and Chiapella, 1985).

Dogs with hyperadrenocorticism (Cushing's disease) often have hyperlipidemia with increased total plasma cholesterol levels (Barrie *et al*., 1993; Feldman, 1995; Ling *et al*., 1979; Medaille *et al*., 1988; Scott, 1979). Most of the increased plasma cholesterol is associated with LDL, and although the mechanism of the hyperlipidemia is unclear, it may be related to a decrease in activity of hepatic LDL receptors (Barrie *et al*., 1993).

Dogs with nephrotic syndrome often have hyperlipidemia (Ford, 1995; Lewis and Center, 1984; McCullagh, 1978; Medaille *et al*., 1988). Hypercholesterolemia is present most commonly, but hypertriacylglycerolemia may be present as well, especially in more severe cases (McCullagh, 1978). In humans with nephrotic syndrome, the hyperlipidemia appears to be related to the loss of albumin or regulatory factors in the urine, and infusion of albumin or dextran into afflicted patients lowers lipid levels (Glassock *et al*., 1991). Albumin or regulatory factors may inhibit VLDL production by the liver, and without this inhibition, more VLDL will be released to the plasma increasing VLDL and LDL levels (Glassock *et al*., 1991).

Idiopathic hyperlipidemia, which is probably inherited, occurs in some miniature schnauzers (Ford, 1993; Richardson, 1989; Rogers *et al*., 1975a). Animals present with abdominal pain, diarrhea, and vomiting, and sometimes with seizures and pancreatitis. Affected animals have hypertriacylglycerolemia, hypercholesterolemia, and increased chylomicron levels and often have increased levels of other lipoproteins as well. The animals often have elevated liver enzymes as well (Xenoulis *et al*., 2008). It has been proposed that these animals may have low levels of lipoprotein lipase or perhaps deficient apolipoprotein C-II, the activator of lipoprotein lipase. However, some dogs have shown clearing of the plasma following heparin injection, so the mechanism remains unknown. The primary treatment is to place the animal on a low-fat diet. A similar syndrome has been reported in mixed-breed dogs (Baum *et al*., 1969; Rogers *et al*., 1975a) and in Brittany spaniels (Hubert *et al*., 1987). Hypercholesterolemia, which is probably inherited, has been reported in rough collie dogs (Jeusette *et al*., 2004) and Shetland sheepdogs (Sato *et al*., 2000). Corneal lipidosis, which responded to dietary manipulation, was observed in the former, and

possibly increased incidence of atherosclerosis was observed in the latter.

C. Feline Fasting Hyperlipidemias

Not surprisingly, some of the same diseases that are associated with hyperlipidemia in dogs are associated with hyperlipidemia in domestic cats, including diabetes and nephrotic syndrome (Jones, 1995; McCullagh, 1978; Watson and Barrie, 1993). Some cats, however, have a well-characterized familial hyperlipidemia because of lipoprotein lipase deficiency (Brooks, 1989; Jones, 1993, 1995; Jones *et al*., 1983; Watson *et al*., 1992b; Whitney, 1992). There is lipemia with hyperchylomicronemia and increases in plasma levels of cholesterol and triacylglycerol (Jones, 1993, 1995; Whitney, 1992). The high plasma levels of lipids lead to deposition in tissues (xanthoma formation) in the skin, nerve sheaths, and other locations (Jones, 1993; Whitney, 1992). Pressure on spinal or other nerves from xanthomas or subsequent granulomas may lead to peripheral neuropathy (Jones *et al*., 1986). The disease appears to be autosomal recessive, and homozygotes apparently manufacture a defective lipoprotein lipase and do not have a defective or missing apolipoprotein C-II activator (Peritz *et al*., 1990; Watson *et al*., 1992b).

D. Equine Fasting Hyperlipidemia

The phenomenon of equine hyperlipidemia was reported in horses with maxillary myositis (Hadlow, 1962) and equine infectious anemia (Gainer *et al*., 1966). It is likely that the hyperlipidemia described in these early reports was due to anorexia, and it has been shown that fasting alone causes hyperlipidemia in horses and that pregnancy, lactation, and obesity accentuate the effect (Eriksen and Simesen, 1970; Schotman and Kroneman, 1969; Schotman and Wagenaar, 1969; Schotman and Wensing, 1977). Total plasma triacylglycerol may increase from a normal fed value of less than 500 mg/l to more than 2000 mg/l (Morris *et al*., 1972; Naylor *et al*., 1980) and, in severe cases, may exceed 10,000 mg/l (Freestone *et al*., 1991; Naylor *et al*., 1980; Schotman and Wensing, 1977). Although most horses are susceptible to this effect of calorie deprivation, it is harmless for the majority, and only becomes pathological for a few. Ponies and females are more susceptible to the pathological syndrome, which can be fatal (Hughes *et al*., 2004). Survival rates are inversely proportional to plasma triacylglycerol concentrations (Schotman and Wagenaar, 1969), and severe fatty liver and increased plasma levels of liver enzymes have been reported (Schotman and Wagenaar, 1969). Like in other mammals, fasting increases plasma levels of LCFA in horses and ponies (Baetz and Pearson, 1972; Naylor *et al*., 1980; Watson *et al*., 1992a), and the hyperlipidemia in horses and ponies is due to increased VLDL levels (Bauer, 1983; Morris *et al*., 1972; Watson *et al*., 1992a). Presumably, horse liver is removing LCFA from plasma and reesterifying them into triacylglycerol, which are released to the plasma as VLDL. It appears that the liver of fasting horses has a high capacity for reesterification of LCFA into triacylglycerol, which is exported as VLDL. Horses do have increased plasma ketone levels when fasting (Rose and Sampson, 1982), so some of the LCFA removed from plasma by liver are converted to ketones, but additional LCFA are reesterified to glycerol and are recycled to the plasma as triacylglycerol in VLDL.

The mechanism of fasting equine lipemia is uncertain; it could be increased secretion or decreased uptake of VLDL or a combination thereof. In one study, fasting horses were injected with Triton WR 1339, a compound shown to inhibit lipoprotein lipase in rats, and the rate of increase in plasma triacylglycerol levels was observed (Morris *et al*., 1972) and compared with the preinjection level of triacylglycerol. The authors claimed that the rate of increase was not related to the level of triacylglycerol concentration. However, only four horses were used, which may not have been enough given the high variation in fasting triacylglycerol levels observed among them. On close examination of the data, it is apparent that three horses showed a perfect rank correlation of fasting triacylglycerol level and rate of triacylglycerol increase after Triton injection, with the fourth being a considerable outlier to the trend. In addition, the dose of Triton was such that all the horses developed anemia because of intravascular hemolysis. Thus, elucidation of the mechanism of fasting equine lipemia will have to await additional kinetic or enzyme studies.

There are reports of apparent therapeutic success with intravenous glucose and oral carbohydrates (Dunkel and McKenzie, 2003; Durham, 2006; Hallebeek and Beynen, 2001; Mogg and Palmer, 1995; Watson and Love, 1994). This therapy makes sense in that increasing plasma glucose levels should lead to increased insulin and decreased glucagon levels, which should inhibit lipolysis in adipose which is generating plasma LCFA used for triglyceride synthesis. In addition, the hormonal changes may stimulate lipoprotein lipase activity. Although supplemental insulin has been used with carbohydrate therapy, its efficacy and safety have not been adequately evaluated, and one report indicates that hyperlipemic horse have hyperinsulinemia as well (Oikawa *et al*., 2006).

VIII. KETOGENESIS AND KETOSIS

A. Introduction

The ketones or ketone bodies, which are composed of acetoacetic acid, 3-hydroxybutyric acid (also known as

β-hydroxybutyric acid), and acetone, are important compounds in the metabolism of birds and mammals. Ketosis simply means that ketones are present in body fluids in elevated concentrations. Ketones are important clinically and have a rather sinister reputation because of the ketoacidosis that is often present when their plasma levels are high. In recent years though, the survival value of ketogenesis has become clearer, and although increased levels of ketones in biological fluids will continue to be regarded as a pathological sign in many situations, perhaps the beneficial aspects of ketogenesis will be more widely appreciated.

B. Chemistry of Ketones

1. *Structure and Properties*

The ketones, acetone, 3-hydroxybutyric acid, and acetoacetic acid, are relatively simple chemical structures. Of the three, only 3-hydroxybutyric acid can exist as stereoisomers, having L-(+) and D-(−) forms. Only the D-(−) form is produced in a free state in intermediary metabolism. The L-(+) form exists only as its CoA thioester produced and destroyed in β-oxidation (Newsholme and Leach, 1983). Acetone is relatively volatile, whereas the other two ketones are not. Acetone has a characteristic organic solvent odor that may be detectable in the exhaled breath of animals with elevated blood ketone levels. Anecdotal evidence indicates that people vary greatly in their olfactory sensitivity for acetone.

Acetone does not ionize appreciably, whereas 3-hydroxybutyric acid and acetoacetic acid do readily ionize. Acetoacetic acid has a pKa of 3.58, and 3-hydroxybutyric acid has a pKa of 4.41 (Dean, 1985). Consequently, at normal plasma pH of 7.40, 99.9% of either compound exists in its ionized form. Therefore, the compounds will usually be referenced by the names of their ions whenever their metabolism is discussed. Acetoacetic and 3-hydroxybutyric acids are more powerful acids than the volatile fatty acids (VFA; acetic, propionic, and butyric acids), which have pKa's of 4.76 to 4.87 (Dean, 1985). Acetoacetic acid is more powerful, and 3-hydroxybutyric acid is less powerful as an acid than lactic acid, which has a pKa of 3.86 (Dean, 1985).

Acetone and acetoacetic acid are miscible in water in all proportions, and 3-hydroxybutyric acid is exceedingly soluble, but not in all proportions (Dean, 1985). The common metallic salts of acetoacetic acid and 3-hydroxybutyric acid are soluble in water. Acetone and 3-hydroxybutyric acid and its salts are relatively stable compounds. Acetoacetic acid spontaneously decomposes to acetone and carbon dioxide. This reaction occurs readily without catalysis, and its rate is accelerated by increased temperature and hydrogen ion concentration. Apparently, there can be some nonspecific catalysis of acetoacetate decarboxylation by cellular proteins (Williamson, 1978). The lithium, sodium, and potassium salts of acetoacetic acid are relatively stable if stored in dry form below 0°C.

2. *Detection and Assay*

a. Qualitative

The most common qualitative test for ketones is the alkaline nitroprusside test, which is also known as the Rothera test (Rothera, 1908). This test has been used for decades in clinical practice and is still exceedingly useful today. The test relies on the reaction of nitroprusside with acetone or acetoacetate to produce a purple chromogen. The nitroprusside test has been used for virtually every body fluid imaginable including whole blood, serum, plasma, urine, and milk. The test is most sensitive for acetoacetate (0.5 mmol/l can be detected), gives only a slight response to acetone, and is completely insensitive to 3-hydroxybutyrate.

The nitroprusside test is available commercially in the form of strips, tablets, and powders. The maximum sensitivity of all three forms is approximately 0.5 mmol/l, although specific formulations may have a sensitivity less than this value. The strip form is commonly used for urine. The powder form and strips are both commonly used for milk. The tablet form is used for serum, plasma, and whole blood and can be used for milk and urine as well. The test is often used in a semiquantitative manner with the result expressed in adjectival form (negative, weak, strong) or as a series of pluses (−, +, + +, etc.).

A number of drugs or other substances may appear in urine and give a false positive with the nitroprusside test. Some compounds react with nitroprusside to yield a purple or near purple color. Included in this group are phenylketones, levodopa, methyldopa, acetaldehyde, paraldehyde (Caraway and Kammeyer, 1972), cysteine, cysteamine, penicillamine, and mesna (Csako, 1987). In general, substances with keto, aldehyde, or sulfhydryl groups have the potential for reacting with nitroprusside. Because the nitroprusside test is performed in an alkaline medium, some substances, like sulfobromophthalein and phenolsulfonphthalein, which may exist in urine and are otherwise colorless, may yield a purple or near purple color simply because of the alkaline pH (Caraway and Kammeyer, 1972).

More recently a semiquantitative color test for 3-hydroxybutyrate in milk has been used for diagnosis of clinical and subclinical ketosis in dairy cows (Gutzwiller, 1998; Jorritsma *et al*., 1998). This test, which is quite specific, is based on the same enzymatic method used for quantitative determination of 3-hydroxybutyrate (see the next section) except that a color visible to the human eye is produced.

b. Quantitative

Commonly used means of quantitative assay for ketone concentrations in biological fluids include microdiffusion methods, used primarily for assay of acetone, and enzymatic methods, used primarily for assay of acetoacetate and 3-hydroxybutyrate. Regardless of the method to be used for analysis, proper handling of the samples before

analysis is crucial for obtaining representative results. In particular, the volatility of acetone and instability of acetoacetate must be respected.

Blood samples should be cooled immediately after collection. Ketones can be determined on whole blood or plasma. Serum is not recommended because of losses, particularly of acetoacetate, that may occur during the time required for clotting. Any of the common anticoagulants (heparin, fluoride, oxalate, citrate, or EDTA) may be used. If whole blood is to be used, it should be mixed with perchloric acid immediately after collection to precipitate proteins. The tube should be chilled on ice until centrifuged, which should be performed within a few hours. The supernatant should be frozen until analyzed. If plasma is to be used, the red cells should be spun down within a few hours, and the plasma proteins precipitated with perchloric acid. The supernatant should be frozen until analyzed.

The microdiffusion method can be used to determine the concentration of acetone or acetone plus acetoacetate in any biological fluid. The reagents are relatively simple and inexpensive although rather corrosive. The diffusion step requires specialized, but inexpensive, apparatus and adds to the complexity and time to complete the assay. The method relies on the reaction of acetone with vanillin (Henry *et al*., 1974) or salicylaldehyde (Nadeau, 1952) to produce a colored product that can be quantified in a spectrophotometer. In the author's experience, vanillin provides more sensitivity than salicylaldehyde, but variability in the purity of vanillin batches from commercial sources makes salicylaldehyde the reagent of choice. Salicaldehyde must be stored under nitrogen or argon to preserve its purity.

The method as described by Henry *et al*. (1974) was shown to determine acetone, and there was speculation that it would also detect acetoacetate simultaneously. In fact, the method as described by Henry *et al*. (1974) is specific for acetone. It has been found in the author's laboratory that to use the method for acetone plus acetoacetate, it is necessary to preincubate the sample with an equal volume of 10 N sulfuric acid for 4 hours at 50°C in a sealed container to decarboxylate all of the acetoacetate. The method can be adapted to measure 3-hydroxybutyrate as well by introducing a step in which 3-hydroxybutyrate is oxidized to acetoacetate with potassium dichromate (Procos, 1961). However, if the primary interest is the determination of acetoacetate or 3-hydroxybutyrate, rather than acetone, the enzymatic method described later should be used. For determination of acetone on large numbers of samples, flow injection analysis (Marstorp *et al*., 1983) or infrared spectroscopy (Hansen, 1999) has been used.

The enzymatic method for assay of acetoacetate or 3-hydroxybutyrate in biological fluids is accurate and precise (Williamson *et al*., 1962) and is probably the most common method used for quantitative assay of ketone concentrations. The method has been successfully adapted to a variety of automated analysis systems (Harano *et al*., 1985; Ozand *et al*., 1975; Työppönen and Kauppinen, 1980) and is a relatively straightforward spectrophotometric or fluorometric method. For a detailed step-by-step practical description of the method, see Mellanby and Williamson (1974) and Williamson and Mellanby (1974).

The method relies on the reversible reaction catalyzed by 3-hydroxybutyrate dehydrogenase:

$$\text{3-hydroxybutyrate} + \text{NAD}^+ \rightleftharpoons \text{acetoacetate} + \text{NADH} + \text{H}^+$$

The reaction is run in the forward direction by including an excess of NAD 1 in the reaction mixture to assay 3-hydroxybutyrate and in the backward direction by including an excess of NADH in the reaction mixture to assay acetoacetate. The equilibrium constant of the reaction is 1.42×10^{-9} and therefore, is highly favorable toward the reduction of acetoacetate at pH 7.0 (Krebs *et al*., 1962). To force the reaction to completion in the direction of oxidizing 3-hydroxybutyrate, hydrazine is used as a trapping agent to remove acetoacetate as it is formed, and the reaction mixture is buffered at an alkaline pH. The change in NADH concentration is measured by the change in absorbance at 340 nm in either case. Alternately, a fluorometer can be used to measure the change in NADH concentration. To avoid interference from lactate or pyruvate in the sample, the 3-hydroxybutyrate dehydrogenase should be free of lactate dehydrogenase, or alternately, the lactate dehydrogenase inhibitor, oxamic acid, can be added to the reaction mixture (Harano *et al*., 1985).

Table 4-3 lists normal blood and plasma ketone concentrations for several domestic species. The values are for healthy fed animals. It is assumed that plasma and blood ketone concentrations should be similar because of the generally high permeability of cell membranes to ketones and lack of protein binding of ketones; however, reports of definitive studies on this problem are not apparent in the literature. For clinical purposes, there is no lower normal limit for ketone concentrations.

C. Synthesis of Ketones

Ketones are primarily products of intermediary metabolism. Only under unusual circumstances would more than trace amounts be absorbed from the contents of the gastrointestinal tract. The real source of ketones is fatty acids including those with short (1 to 4 carbons), medium (5 to 11 carbons), and long (>11 carbons) chains. Of course, any compound (glucose, lactate, glycerol, amino acids, etc.) that can be converted to fatty acids can be considered as a source of ketones, but for the purposes of this discussion, the origin of ketones will be considered to be fatty acids, either esterified or nonesterified.

TABLE 4-3 Blood and Plasma Ketone Concentrations of Domestic Animals[a]

Species	3-Hydroxy-Butyrate (mmol/l)	Acetoacetate (mmol/l)	Sample	Reference
Cow (lactating)	0.41 ± 0.03	0.043 ± 0.00	plasma	Hibbit *et al.*, 1969
	0.95 ± 0.18	0.13 ± 0.03	blood	Gröhn, 1985
Cow (nonlactating)	0.27 ± 0.04	0.011 ± 0.003	plasma	Baird *et al.*, 1968
Dog	0.033 ± 0.015	0.018 ± 0.010	blood	Balasse, 1970
	0.030 ± 0.006	—	plasma	Lammerant *et al.*, 1985
Goose	0.042 ± 0.015	0.023 ± 0.003	plasma	Maho *et al.*, 1981
Horse	0.11 ± 0.01	—	blood	Snow and Mackenzie, 1977
	0.064 ± 0.006	0.029 ± 0.003	plasma	Rose *et al.*, 1980
Sheep	0.27 ± 0.04	0.051 ± 0.005	blood	Brockman, 1976
	0.55 ± 0.04	0.030 ± 0.002	blood	Heitman *et al.*, 1986

[a] *Values are means ± standard errors for healthy fed animals. Ketone concentrations were determined by the method of* Williamson et al. (1962) *or a modification thereof.*

The predominant source of ketones in healthy animals is long chain fatty acids (LCFA) released during lipolysis in adipose tissue. When plasma insulin levels decrease and plasma glucagon levels increase, cAMP levels in adipose cells increase. Increased cAMP levels lead to activation of hormone-sensitive lipase, which hydrolyses triacylglycerols to LCFA and glycerol. The LCFA bind to plasma albumin for transport to other tissues, whereas glycerol freely dissolves in plasma water (McGarry, 1979; Newsholme and Leach, 1983; Spector and Fletcher, 1978).

1. *Ketogenesis by Liver*

The liver has an enormous capacity to remove LCFA from plasma. LCFA unbind from albumin, diffuse through the hepatocyte plasma membrane, and bind to fatty acid binding protein in the cytosol (Burnett *et al*., 1979). In the cytosol, LCFA are converted to LCFA-CoA as discussed earlier. The LCFA-CoA can be used to synthesize triacylglycerol or can go through β-oxidation to acetyl-CoA in the mitochondrion, a process discussed earlier. Mitochondrial acetyl-CoA can have a number of fates, but under circumstances that elevate plasma LCFA levels, the two main fates are combustion in the TCA cycle or conversion to ketones. Two acetyl-CoA units can be recondensed to form ketones, which will occur when there is not sufficient oxaloacetate for citrate formation or when high levels of citrate inhibit citrate synthase.

There are four enzymes involved in ketogenesis from acetyl-CoA: acetoacetyl-CoA thiolase, hydroxymethylglutaryl-CoA (HMG-CoA) synthase, HMG-CoA lyase, and D-3-hydroxybutyrate dehydrogenase. These four enzymes catalyze the following four reactions, respectively:

$$2\ \text{acetyl-CoA} \rightleftharpoons \text{acetoacetyl-CoA} + \text{CoA}$$

$$\text{acetoacetyl-CoA} + \text{acetyl-CoA} \rightarrow \text{HMG-CoA} + \text{CoA}$$

$$\text{HMG-CoA} \rightarrow \text{acetoacetate} + \text{acetyl-CoA}$$

$$\text{acetoacetate} + \text{NADH} + \text{H}^+ \rightleftharpoons 3\text{-hydroxybutyrate} + \text{NAD}^+$$

Thiolase occurs in both cytosol and mitochondria, whereas the other three enzymes are mainly restricted to the mitochondrion. However, there is some HMG-CoA synthase in the cytosol, which is involved in cholesterol synthesis. The first three enzymes are in the mitochondrial matrix, whereas 3-hydroxybutyrate dehydrogenase is in the inner membrane of the mitochondrion, and membrane lipids are required for full activity of the enzyme. Interestingly, livers of ruminants have lower apparent activities of 3-hydroxybutyrate dehydrogenase than the livers of other species (Nielsen and Fleischer, 1969; Watson and Lindsay, 1972), a situation that has not been explained adequately. Because ruminant liver is continuously presented with 3-hydroxybutyrate synthesized by the rumen epithelium, the low hepatic activity of 3-hydroxybutyrate dehydrogenase may be beneficial because more of the

compound will reach peripheral tissues in an unoxidized state.

Acetoacetyl-CoA thiolase and 3-hydroxybutyrate dehydrogenase catalyze reactions that are at or near equilibrium (i.e., the rates of these reactions are controlled by the concentrations of the substrates and products). HMG-CoA synthase and lyase catalyze reactions that are far removed from equilibrium, and these enzymes may be subject to regulatory controls other than the concentrations of substrates and products. The synthase is considered to be the rate-limiting enzyme and appears to be restricted almost exclusively to the liver (Duee *et al*., 1994; McGarry and Foster, 1969; Valera *et al*., 1994). Physiological controls of the enzyme are not completely understood; however, the concentration of enzyme molecules in the mitochondria is increased by cAMP, so fasting and diabetes increases it, and refeeding decreases it (Serra *et al*., 1993). In addition, succinyl-CoA inhibits the enzyme (Quant *et al*., 1990). Glucagon usually decreases mitochondrial succinyl-CoA, whereas an abundance of glucose or glucose precursors, like propionate, increases it. A summary of ketogenesis in the liver is depicted diagrammatically in Figure 4-1.

Ketogenesis can occur from VFA and medium chain fatty acids. Medium chain fatty acids are normally in quite low concentration in the diet or in triacylglycerols of mammals and, therefore, are not usually quantitatively important in ketogenesis. Except in unusual circumstances, nonherbivores do not absorb large quantities of VFA from the gastrointestinal tract. Among the herbivores, the metabolism of VFA has been studied most thoroughly in ruminants. Propionate is the major gluconeogenic precursor and is not an important precursor of ketones, and, in fact, propionate inhibits ketogenesis in ruminant liver (Faulkner and Pollock, 1991). The propionate inhibition probably is due to inhibition of carnitine acyltransferase I in ruminant liver by methylmalonyl-CoA, a metabolite of propionate (Brindle *et al*., 1985). Without active carnitine acyltransferase I, LCFA cannot enter mitochondria and be oxidized to ketones.

Butyrate is converted to 3-hydroxybutyrate by the rumen epithelium and will be discussed later. Acetate must be covalently bound to CoA under the catalysis of acetokinase before it can be catabolized further. Acetokinase is found in the cytosol and mitochondria of most cells in most organs. In ruminants, the liver has a relatively low concentration of acetokinase, and most absorbed acetate passes through the liver and is removed from the plasma by other tissues, particularly heart, skeletal muscle, kidney, and mammary gland (Bauman and Davis, 1975; Cook *et al*., 1969).

2. *Ketogenesis by the Alimentary Tract*

Butyrate, which is produced during fermentation of feedstuffs in the rumen, is readily absorbed by the rumen wall (Stevens, 1970). The rumen epithelial cells possess high activities of butyryl-CoA synthetase, which can convert butyrate to butyryl-CoA (Cook *et al*., 1969). By β-oxidation, butyryl-CoA is converted to L-3-hydroxybutyryl-CoA, which is oxidized to acetoacetyl-CoA followed by cleavage of the CoA and reduction of the resulting acetoacetate to 3-hydroxybutyrate (Emmanuel, 1980). Rumen epithelium does have HMG-CoA synthase, HMG-CoA lyase and 3-hydroxybutyrate dehydrogenase activities, although in lesser concentration than in liver (Baird *et al*., 1970; Emmanuel, 1980). It is possible that rumen epithelium can cleave CoA from acetoacetyl-CoA directly because it contains acetoacetyl-CoA deacylase (Bush and Milligan, 1971). In addition, rumen epithelium possesses 3-ketoacid CoA-transferase, an enzyme to be discussed later when ketone oxidation is discussed (Bush and Milligan, 1971). This enzyme can catalyze the transfer of CoA from acetoacetyl-CoA to succinate, thus liberating acetoacetate. This latter route may be the predominant pathway in rumen epithelium (Bush and Milligan, 1971).

3-Hydroxybutyrate appears in portal blood (Katz and Bergman, 1969; Stevens, 1970). At least 50% of absorbed butyrate is oxidized to ketones in the rumen wall, and of the butyrate that does appear in portal blood, nearly all of it is removed on the first pass through the liver (Bergman *et al*., 1965; Bergman and Wolfe, 1971; Fell and Weekes, 1975; Ramsey and Davis, 1965). Ruminal production of 3-hydroxybutyrate is probably the main reason why fed ruminants normally have a higher plasma concentration of this compound than fed nonruminants (see Table 4-3).

3. *Ketogenesis by Other Organs*

It has been claimed that mammary gland may synthesize appreciable ketones in ketotic dairy cows; however, the evidence is weak. Arteriovenous concentration differences and mammary blood flow have been used to estimate mammary ketone production and uptake in dairy cows (Kronfeld *et al*., 1968). It was found that the mammary gland utilized small quantities of acetoacetate and larger quantities of 3-hydroxybutyrate in healthy cows, whereas the mammary gland of ketotic cows produced large quantities of acetoacetate. The increased uptake of 3-hydroxybutyrate by mammary in ketotic cows equaled almost exactly mammary production of acetoacetate. There was no significant difference in mammary uptake of acetate between healthy and ketotic cows.

In yet another study on ketotic cows (Schwalm *et al*., 1969), arteriovenous concentration differences across the mammary glands of acetoacetate and 3-hydroxybutyrate were observed. A positive AV difference was noted for 3-hydroxybutyrate, which was almost equal in magnitude to the negative AV difference noted for acetoacetate. The foregoing results point toward mammary conversion of 3-hydroxybutyrate to acetoacetate, which increases in ketosis. This process cannot really be called ketogenesis; perhaps *ketoconversion* would be the appropriate term.

D. Catabolism of Ketones

1. Reduction and Oxidation

Reduction is a possibility for acetoacetate, and, of course, the reduction product is 3-hydroxybutyrate. 3-Hydroxybutyrate is a metabolic cul de sac because it can be metabolized only by being reconverted to acetoacetate. In comparison to acetoacetate, 3-hydroxybutyrate should be viewed as a means by which the liver can export reducing power (hydrogen) to the peripheral tissues for combustion and energy generation there.

Both acetoacetate and 3-hydroxybutyrate can be reduced by being converted to LCFA. This fate is more likely to occur in mammary gland than in adipose tissue. Plasma 3-hydroxybutyrate has been shown to be a milk fat precursor in cows (Palmquist *et al*., 1969), goats (Linzell *et al*., 1967), and rabbits (Jones and Parker, 1978). A substantial portion of 3-hydroxybutyrate used for milk fat synthesis in ruminants is incorporated as a four-carbon unit (Kinsella, 1970; Palmquist *et al*., 1969).

Ultimately, the fate of most 3-hydroxybutyrate and acetoacetate is oxidation in the peripheral tissues. Once 3-hydroxybutyrate has been oxidized to acetoacetate, the acetoacetate is converted to acetoacetyl-CoA by the following reaction:

$$\text{acetoacetate} + \text{succinyl-CoA} \rightleftharpoons \text{acetoacetyl-CoA} + \text{succinate}$$

This reaction is catalyzed by 3-ketoacid CoA-transferase, and viewed from the point of converting succinyl-CoA to succinate, it effectively bypasses the succinyl-CoA synthetase reaction of the citric acid cycle. Because the reaction catalyzed by succinyl-CoA synthetase produces one GTP from GDP, the 3-ketoacid CoA-transferase reaction effectively consumes 1 mole of ATP. The reaction also pushes succinyl-CoA toward oxaloacetate in the citric acid cycle, and oxaloacetate will be needed to form citrate from the acetyl-CoA derived from the acetoacetyl-CoA.

3-Ketoacid CoA-transferase is found in spleen, skeletal muscle, brain, adipose, heart, lung, and kidney of rodents and sheep although the activities are very low in sheep heart and brain (Williamson *et al*., 1971). In general, though, the highest activities are in the heart and kidney. Activity of 3-ketoacid CoA-transferase is absent in liver (Williamson *et al*., 1971). The absence of the enzyme from liver is logical because if there were a need for NADH for combustion in the liver, it could be obtained directly from acetyl-CoA in the citric acid cycle rather than shunting the acetyl-CoA units into ketones and back again.

Acetyl-CoA is produced from acetoacetyl-CoA via the acetoacetyl-CoA thiolase reaction, which was discussed under ketogenesis. All tissues have thiolase, and it is in greatest activity in heart, liver, and kidney (Williamson *et al*., 1971). Heart and brain of sheep have significantly less thiolase than in rodents. The activities of 2-ketoacid CoA-transferase and acetoacetyl-CoA thiolase are relatively stable in fasting, fed state, high-fat diet, and diabetes except that in rodents, thiolase increases upon feeding a high-fat diet (Williamson *et al*., 1971). In general, it appears that the ketone utilizing capacity of the body is relatively constant, and ketone availability controls ketone oxidation.

For many years, acetone was viewed as a metabolic dead end, a substance destined to be excreted in the urine or exhaled in the breath. Although much acetone does indeed wind up in the breath and urine, evidence has accumulated that indicates that some acetone is metabolized (Kalapos *et al*., 1994; Luick *et al*., 1967; Owen *et al*., 1982; Vander Jagt *et al*., 1992). Furthermore, evidence for the catabolic pathway for acetone metabolism indicates that it is metabolized to pyruvate, apparently via hydroxyacetone and pyruvaldehyde (Vander Jagt *et al*., 1992). Thus, by this mechanism, it is possible that small amounts of fat can be converted to glucose.

Labeling patterns of milk glutamate carbons following injection of 2-^{14}C-acetone into cows, indicated that acetone was metabolized via pyruvate (Black *et al*., 1972; Luick *et al*., 1967). Labeling patterns of glucose in humans injected with radiolabeled acetone also indicate metabolism via pyruvate (Owen *et al*., 1981). In rats, however, labeling patterns of glucose following radiolabeled acetone injection indicate that acetone can be metabolized via pyruvate and acetate, but that the latter pathway predominates (Kosugi *et al*., 1986). Thus, there appear to be real species differences in acetone metabolism. In humans, at least, the fraction of acetone that is metabolized versus excreted varies inversely with acetone concentration (Owen *et al*., 1982), so it appears that the catabolizing pathways for acetone are not capable of handling large quantities.

2. Renal Metabolism and Excretion

The kidney cannot synthesize ketones to any appreciable extent (Lynen *et al*., 1958; Weidman and Krebs, 1969) but is a voracious consumer of ketones as an energy source in ruminants (Kaufman and Bergman, 1971, 1974) and nonruminants (Baverel *et al*., 1982; Weidman and Krebs, 1969). It is interesting though that in fasting sheep, the kidney removes from the plasma and catabolizes both acetoacetate and 3-hydroxybutyrate (Kaufman and Bergman, 1974), whereas in fasting humans, there is substantial removal of 3-hydroxybutyrate and a slight production of acetoacetate (Owen *et al*., 1969).

Ketones are freely filterable in the glomerulus. There appears to be in humans and dogs, at least, a direct or indirect energy-consuming tubular transport system for acetoacetate and 3-hydroxybutyrate, which approaches saturation at relatively low plasma concentrations of ketones such as encountered in the fed state or a one day

fast. Neither ketone is excreted at these lower concentrations, but they do begin to appear in the urine as plasma levels begin to rise (Sapir and Owen, 1975; Schwab and Lotspeich, 1954; Visscher, 1945; Wildenhoff, 1977). However, as the ketone concentrations increase in the glomerular filtrate, the primary mode of reabsorption is by diffusion down a concentration gradient as water is reabsorbed from the tubular lumen. Acetone begins to appear in the urine as soon as it begins to appear in the plasma (Widmark, 1920); presumably, this effect is due to great lipid solubility of acetone, which allows it to penetrate cell membranes with relative ease.

Renal excretion and reabsorption of ketones is approximately proportional to their filtration rates (or plasma concentrations if glomerular filtration rate remains constant) at concentrations found after more than a 1-day fast in humans and in ruminants (Kaufman and Bergman, 1974; Wildenhoff, 1977). At least some parts of the nephron, probably beyond the proximal tubule, are less permeable to ketones than to water because when plasma ketone levels are substantially increased, the urinary concentration exceeds the plasma concentration.

The dual mode of ketone reabsorption has an advantage in that none of this valuable energy source is lost at lower plasma concentrations; however, there is no transport maximum for the kidney as a whole, so 80% to 90% of filtered ketones are reabsorbed regardless of how concentrated ketones become in the plasma during pathological conditions or prolonged starvation. Mammals presumably could have evolved a greater activity of the energy-consuming ketone transport system. However, the energy cost of continuously maintaining the system at a higher activity probably outweighed the survival value of having the system available during rare periods of prolonged starvation.

E. Pathophysiology of Ketonemia

As discussed earlier, the acetoacetate and 3-hydroxybutyrate are more powerful acids than the VFA, and in the case of acetoacetate, they are more powerful than lactic acid. Not surprisingly, then, a high concentration of ketones in the plasma results in a metabolic acidosis known as ketoacidosis. The most significant ketoacidoses commonly encountered in domestic animals are in diabetes mellitus and ovine pregnancy toxemia. The ketoacidosis encountered in these syndromes may cause plasma bicarbonate to be below 10 mmol/l (Ling *et al*., 1977; Reid, 1968) and is a chief contributor to mortality.

The ketoacidosis in diabetes of dogs and cats can be severe with blood pH being 7.2 or less (Edwards, 1982; Ling *et al*., 1977; Schaer, 1976). Because plasma ketone concentrations in diabetic dogs have been reported to average 3.2 mmol/l with some individuals having levels of 7 to 8 mmol/l (Balasse *et al*., 1985), the base deficit in extracellular fluids would be greater than that concentration for two reasons. First, the distribution space of the ketones is greater than that of extracellular fluid; second, some acetoacetate and 3-hydroxybutyrate anions may have been lost in the urine without equal losses of hydrogen ion (a mineral ion such as sodium or potassium would have balanced the electrical charge). Base deficits of more than 15 mmol/l have been reported in spontaneously diabetic dogs (Edwards, 1982; Ling *et al*., 1977).

As the metabolic acidosis of diabetes progresses in dogs, there is increased catabolism of muscle protein (Balasse *et al*., 1985). Much of the nitrogen from protein degradation is diverted into ammonia rather than urea, and it is ammonium ion that balances most of the electrical charge on excreted acetoacetate and 3-hydroxybutyrate.

Ketones are really an alternate form of lipid, comparable to triacylglycerols, LCFA, or VFA, and should be considered as such in caloric balance (Williamson, 1971). VFA and ketones are effectively water-soluble forms of lipids; however, only the ketones can be produced in large quantities in tissue metabolism.

In fed animals, only a nominal caloric production is derived from oxidation of ketones; however, in fasted animals or in some pathological conditions, ketone oxidation accounts for a substantial quantity of expended calories. For example, only 3% to 4% of expired carbon dioxide is derived from 3-hydroxybutyrate in fed cows (Palmquist *et al*., 1969), whereas 30% of expired carbon dioxide is derived from ketones in fasted pregnant ewes (Pethick and Lindsay, 1982).

It has been demonstrated in canine perfused liver (Shaw and Wolfe, 1984) and *in vivo* in humans (Binkiwicz *et al*., 1974; Mebane and Madison, 1964; Miles *et al*., 1981) and dogs (Balasse *et al*., 1967; Paul *et al*., 1966) by infusing acetoacetate or 3-hydroxybutyrate that both ketones inhibit gluconeogenesis. In most of these experiments, there has been evidence of increased plasma insulin concentrations, which could account for the diminution in plasma glucose concentration. The survival value of having ketones inhibit gluconeogenesis is that in starvation, as ketone concentrations increase and become available for tissue energy needs, the rate at which body protein must be catabolized to supply glucose precursors can decrease.

Not surprisingly in view of the increased insulin levels usually observed, decreased levels of LCFA were noted during ketone infusions in some of the experiments mentioned previously. Thus, increased ketone levels may serve a negative feedback on rate of lipolysis in adipose and, therefore, on the plasma levels of ketones themselves.

F. Fasting Ketosis

During fasting, hormonal changes occur that promote lipolysis. Most important, as less glucose is available from the gut or from gluconeogenesis in the liver, plasma glucose concentrations will decrease. Responding to the hypoglycemia,

pancreatic islet cells will release less insulin and more glucagon, so that plasma insulin concentrations will decrease and plasma glucagon concentrations will increase. These hormonal changes will increase cAMP concentrations in adipose cells, which leads to the activation of hormone-sensitive lipase.

Through the action of hormone-sensitive lipase, triacylglycerols are hydrolyzed with release of LCFA and glycerol. LCFA are utilized directly by tissues for energy but are also taken up by the liver in proportion to their plasma concentration. During fasting, hepatic concentrations of malonyl-CoA and methylmalonyl-CoA are relatively low, so carnitine acyltransferase I activity is relatively high, and LCFA-CoA are quickly converted to LCFA-carnitine, which is translocated into the mitochondrion (McGarry *et al*., 1977). Once in the mitochondrion LCFA-carnitine is converted to LCFA-CoA again.

Following β-oxidation of ketones, some acetyl-CoA is combusted in the citric acid cycle. However, during fasting, gluconeogenesis is quite active in the liver, and much of the mitochondrial oxaloacetate is used for that purpose and is unavailable for citrate formation with acetyl-CoA; consequently, large quantities of acetyl-CoA are shunted into ketogenesis.

Acetoacetate and 3-hydroxybutyrate can be utilized by most extrahepatic tissues. Because peripheral tissues can also use LCFA, the utility of hepatic production of ketones from LCFA was not clear originally. However, many tissues have as great or greater capacity for utilizing plasma ketones as for utilizing plasma LCFA. Among these tissues are heart and kidney (Hall, 1961; Little *et al*., 1970; Owen *et al*., 1969; Williamson and Krebs, 1961). In some species, such as the rat (Hawkins *et al*., 1971) and human (Owen *et al*., 1967), ketones constitute a major energy source for the brain during fasting. In some other species though, it appears that the brain prefers glucose and utilizes only small quantities of ketones in the fed or fasted state in the sheep (Jones *et al*., 1975; Lindsay and Setchell, 1976; Pell and Bergman, 1983), the dog (Wiener *et al*., 1971), and the pig (Tildon and Sevdalian, 1972). Resting skeletal muscle utilizes ketones preferentially as a fuel during short-term starvation (Owen and Reichard, 1971); however, LCFA are preferred during long-term starvation (Owen and Reichard, 1971) or exercise (Hagenfeldt and Wahren, 1968a, 1968b).

Ketones are quite soluble, require no protein carrier, and diffuse (in their un-ionized form) or are transported rapidly through biological membranes including the blood-brain barrier (Hawkins *et al*., 1971; Persson *et al*., 1972). The liver has an advantage over other tissues regarding uptake of LCFA from plasma albumin because of its unique sinusoidal vascular system. Therefore, the liver can be regarded as a machine that can rapidly remove LCFA from plasma and convert them to a form, the ketones, that other tissues can utilize rapidly.

Because they must be bound to albumin if they are to be nontoxic, the maximum safe plasma concentration of LCFA is fixed by the albumin concentration. Furthermore, in prolonged fasting, albumin concentration decreases, which lessens the number of LCFA carriers. Generally, LCFA concentrations do not rise above 2 mmol/l in fasting, whereas ketone concentrations can increase to 3 to 4 mmol/l or more. Thus, ketones can have a greater concentration gradient to allow their entry into the cell.

Although the acid nature of ketones has received much attention in the clinical literature, less well recognized is the toxic potential of LCFA. If LCFA are released into the plasma in excess of hepatic uptake, albumin-binding capacity will be exceeded (Spector and Fletcher, 1978). Unbound fatty acids may damage endothelial cells, perhaps because of detergent action, oxidation of unsaturated LCFA, or changes in cell metabolism (Ramasamy *et al*., 1991). Such damage to endothelial cells has been proposed as a mechanism in the development of atherosclerotic plaque (Zilversmit, 1973). There is some evidence in humans and guinea pigs that high levels of LCFA within the heart may predispose it to arrhythmias (Cowen and Vaughn-Williams, 1977; Oliver *et al*., 1968). The possible role of LCFA in causing some cases of pancreatitis was discussed earlier.

Ketogenesis in fasting should be viewed as an evolved mechanism with specific survival value for peripheral tissues and not a burden that the liver is placing on the rest of the body. It is important to remember that fasting animals should be expected to have a degree of ketonemia, ketonuria, and ketolactia. Thus, any disease condition which causes anorexia will usually be accompanied by increased ketone levels in body fluids that have no significance other than the fact that the animal has a subnormal caloric intake.

G. Diabetic Ketosis

Although diabetes mellitus is covered in more depth elsewhere in this book, no discussion of ketones would be complete without a mention of this disease. Diabetes is diagnosed more frequently in dogs and cats than other domestic species, and the ketoacidosis that occurs can be fatally severe and was discussed under acid-base balance above.

In experimental diabetes in dogs, plasma total ketone concentrations are 3.2 mmol/l as compared with 0.1 mmol/l in healthy dogs (Balasse *et al*., 1985). Diabetes is accompanied by hyperglycemia, whereas most other ketotic syndromes occurring in domestic animals are usually accompanied by normoglycemia or hypoglycemia. The ketonemia in diabetes is due to increased lipolysis in adipose plus accelerated hepatic gluconeogenesis, both brought about by a lack of insulin. Thus, there are abundant plasma LCFA as ketogenic substrates and metabolic conditions in the liver that favor ketone synthesis.

H. Ketosis Associated with Pregnancy and Lactation

These ketoses are most commonly observed in ruminants although they have been documented in dogs and humans. Before specific syndromes are discussed, a general picture of ketogenesis in pregnancy and lactation will be presented.

Fetal demands for glucose are high, and the placenta can transport glucose from maternal to fetal plasma (Setchell *et al*., 1972; Warnes *et al*., 1977). When an imbalance occurs between the maternal ability to synthesize or absorb glucose and fetal consumption, hypoglycemia results. Under these circumstances, hypoglycemia will lead to lipolysis in adipose tissue and release of LCFA as discussed earlier. The LCFA will be taken up by the liver and converted to ketones with resulting ketosis.

Ketosis in lactation is somewhat more complex than ketosis occurring during pregnancy. The volume of milk produced is almost totally dependent on the rate of lactose synthesis by the mammary gland because milk volume formation is an osmotic phenomenon, and lactose is the predominant molecular species in milk (Peaker, 1977). There is virtually only one precursor of lactose, and that precursor is plasma glucose (Bickerstaffe *et al*., 1974; Kleiber *et al*., 1955). Therefore, a female that is in heavy lactation will have a heavy drain on plasma glucose. There are two sources of plasma glucose: absorption from the gut and gluconeogenesis.

In ruminants, little glucose is absorbed from the gut, so the overwhelming bulk of it is synthesized (Lindsay, 1959; Otchere *et al*., 1974). Most (approximately 90%) of this synthesis occurs in the liver with the remainder occurring in the kidney (Bergman, 1982). The chief substrates are propionate and amino acids, with the former being most important in animals on a high-grain diet. Other precursors are branched chain VFA and lactate absorbed from the rumen and glycerol released during lipolysis (Bergman, 1975). If there is a mismatch between mammary drain of glucose for lactose synthesis and gluconeogenesis in the liver, hypoglycemia will result. Under these circumstances, hypoglycemia will lead to ketosis as explained in the discussion on fasting ketosis.

1. *Bovine Ketosis*

Bovine ketosis is actually at least three different syndromes that occur in cows during lactation (Kronfeld, 1980; Kronfeld *et al*., 1983). The syndromes are characterized by anorexia, depression (usually), ketonemia, ketolactia, ketonuria, hypoglycemia, and decreased milk production. The three syndromes are underfeeding ketosis, alimentary ketosis, and spontaneous ketosis.

Underfeeding ketosis occurs when a dairy cow receives insufficient calories to meet lactational demands plus body maintenance. This version of ketosis can be conveniently divided into nutritional underfeeding ketosis and secondary (or complicated) ketosis. The former occurs when the cow has a normal appetite but is given an insufficient quantity of feed or a diet with low metabolic energy density. The latter occurs when a cow has some other disease, such as hypocalcemia, mastitis, and metritis, which suppresses appetite and causes the cow to consume insufficient nutrients. In most respects, underfeeding ketosis resembles starvation ketosis explained earlier, except that there is the additional caloric and glycemic burden of milk production.

Alimentary ketosis occurs when cattle have been fed spoiled silage that contains excessive amounts of butyric acid (Adler *et al*., 1958; Brouwer and Kijkstra, 1938). As discussed previously, the rumen epithelium has a high capacity to activate butyrate to acetoacetate and 3-hydroxybutyrate. Under conditions where excessive butyrate is presented to the rumen epithelium, large amounts of 3-hydroxybutyrate will be produced and released to the circulation with resulting ketosis. Alimentary ketosis then is really butyrate toxicosis.

Spontaneous ketosis is probably the most common, the most researched, the most controversial, and the least understood form of bovine ketosis. It occurs in high producing dairy cows that are near the peak of lactation, that have access to abundant high-quality feed, and that have no other disease (Baird, 1982; Kronfeld, 1980). The disease is not accompanied by severe acidosis (Sykes *et al*., 1941), and spontaneous recovery is common although there is a large decrease in milk production (Baird, 1982; Kronfeld, 1980). There are several schemes proposed for the molecular pathogenesis of the syndrome. As these schemes are discussed, it will become evident that they are not necessarily mutually exclusive, and more than one of them may be correct and may be present simultaneously in the same animal.

The most widely accepted theory of bovine ketosis is the hypoglycemia theory (Baird, 1982). In this theory, hypoglycemia is the driving force in the syndrome and ultimately causes the ketonemia. Dairy cows are selected for remaining in the herd more for milk production that for any other factor. Thus, dairy cows have been selected for many generations to have a metabolically aggressive mammary gland. This selection criterion has dictated that the mammary produce a maximum amount of milk with secondary regard for the metabolic consequences for the rest of the animal. It is not surprising, therefore, that occasionally the mammary gland might withdraw glucose from the plasma more rapidly than the liver can resupply it, which leads to hypoglycemia even in a well-fed animal. The hypoglycemia will lead to ketonemia by mechanisms discussed earlier and later in this discussion. The hypoglycemia and ketonemia may cause the cow to be ill enough that she will decrease her feed intake. At this point, the syndrome will resemble underfeeding ketosis.

As explained previously, high milk production equates to a high rate of plasma glucose utilization by the mammary gland, which equates to a high rate of hepatic

gluconeogenesis. In a lactating cow, plasma glucose concentration represents the balance point between hepatic glucose production and peripheral glucose utilization, with the mammary gland being the chief user. If peripheral glucose utilization should leap ahead of hepatic glucose production, hypoglycemia will result. In theory, hypoglycemia under these circumstances should lead to a decrease in plasma insulin and an increase in plasma glucagon levels. Lower plasma insulin and higher plasma glucagon should increase the activity of hormone-sensitive lipase in adipose tissue, which will lead to increased plasma levels of LCFA. Consequently, more LCFA will reach the liver and exceed its capacity to oxidize them completely or to reesterify them, and increased ketogenesis will result.

What evidence supports this theory? First, the vast majority of cows with clinical spontaneous ketosis are indeed hypoglycemic (Baird *et al*., 1968; Gröhn *et al*., 1983; Schwalm and Schultz, 1976). Second, cows with spontaneous ketosis usually are hypoinsulinemic (Hove, 1974; Schwalm and Schultz, 1976). Third, compared to the prelactation period, postparturient dairy cows have been found to have elevated levels of plasma immunoreactive glucagon (De Boer *et al*., 1985; Manns, 1972), which is even greater in cows with ketosis (Sakai *et al*., 1993). Fourth, ketotic cows have elevated levels of plasma LCFA (Baird *et al*., 1968; Ballard *et al*., 1968; Schwalm and Schultz, 1976).

Some investigation of molecular mechanisms of ketogenesis in the liver ketotic cows has been performed (Baird *et al*., 1968; Ballard *et al*., 1968). In particular, there has been interest in hepatic mitochondrial oxaloacetate levels. In the discussion of ketogenesis presented earlier, it was noted that when increased levels of plasma LCFA occur, the liver can reesterify them or can oxidize them to acetyl-CoA. The acetyl-CoA can be oxidized to carbon dioxide provided there is sufficient oxaloacetate to permit entry into the citric acid cycle as citrate. For the citric acid cycle to operate, there must also be a sufficient amount of ADP available for phosphorylation as well, or accumulation of NADH will slow the cycle. If acetyl-CoA accumulates, the excess will be diverted into ketogenesis.

Two studies have attempted to investigate oxaloacetate concentrations in the livers of ketotic cows (Baird *et al*., 1968; Ballard *et al*., 1968). Different methodologies were used to estimate oxaloacetate concentrations; one study (Ballard *et al*., 1968) concluded that there was no change in oxaloacetate concentration during ketosis, and the other concluded that oxaloacetate concentrations were lower in ketotic than in healthy cows (Baird *et al*., 1968). Actually, both studies measured total hepatic oxaloacetate rather than mitochondrial oxaloacetate, which may be critical in ketogenic control. However, there has been no evidence to indicate that the ruminant liver should be any different from the nonruminant liver with regard to the concept that if the liver is presented with sufficient LCFA, ketogenesis will result. There has been insufficient research on the control of lipolysis in adipose in ruminants. In particular, there has been insufficient research in differences in plasma levels of lipogenic and lipolytic hormones and sensitivity of adipose to these hormones in cow populations that are susceptible and nonsusceptible to ketosis. No matter how low mitochondrial oxaloacetate levels might be in the liver, ketogenesis will not occur at a significant rate without a sufficient precursor in the form of LCFA, and conversely, ketogenesis could occur with normal oxaloacetate levels if the liver were presented with a sufficiently high concentration of LCFA.

It has been noticed, however, that dairy cattle can become ketonemic without the presence of significant hypoglycemia (Ballard *et al*., 1968; Gröhn *et al*., 1983). This is often the case with subclinical ketosis in which ketonemia exists without other signs of ketosis. It has been postulated that there is a lipolytic signal of unknown identity for lipolysis to meet mammary demand for LCFA, which is independent of plasma glucose concentration (Kronfeld, 1982; Kronfeld *et al*., 1983). The increased plasma LCFA lead directly to increased hepatic ketogenesis.

When it was first observed that glucocorticoids appeared to be an effective treatment for spontaneous ketosis, it was hypothesized that the disease was due to adrenal cortical insufficiency (Shaw, 1956). This theory has fallen into disfavor because it has been shown that ketotic cows have higher plasma levels of glucocorticoids than healthy cows (Robertson *et al*., 1957). Glucocorticoids are efficacious and probably have their effect by stimulating proteolysis and inhibiting glucose use in muscle, thereby providing gluconeogenic precursors and glucose (Bassett *et al*., 1966; Braun *et al*., 1970; Reilly and Black, 1973; Robertson, 1966; Ryan and Carver, 1963).

The efficacy of glucose or glucose precursors as ketosis treatments favors the hypoglycemic theory. Parenteral glucose provides nearly immediate relief although relapses are common (Kronfeld, 1980). Gluconeogenic precursors, such as propylene glycol, glycerol, and sodium propionate, have been shown to be efficacious (Emery *et al*., 1964; Kauppinen and Gröhn, 1984; Schultz, 1952; Simesen, 1956). Treatment of cows with bovine somatotropin in one lactation appears to decrease the likelihood of ketosis in the next lactation (Lean *et al*., 1994). Cows treated with somatotropin appear to have less body fat and more skeletal muscle, so after calving, there is less fat to mobilize to LCFA and more protein to mobilize as a glucose precursor. Therefore, hypoglycemia and subsequent fatty acidemia and ketonemia are less likely to occur.

2. *Ovine Pregnancy Toxemia*

This syndrome occurs in pregnant ewes that are carrying more than one fetus and that have been subjected to caloric deprivation or stress. Because of intense genetic selection for twinning, the syndrome is, to a large extent, a man-made disease. Susceptibility increases as ewes approach

term because fetal glucose demands increase with increasing body size. The ovine placenta is capable of extracting glucose from maternal plasma at concentrations below 1mmol/l and readily does so. It might seem biologically useless for the fetuses to cause a fatal hypoglycemia in the ewe, which will also lead to their own demise, but the fetuses are highly dependent on glucose as a caloric and synthetic source and would expire without it anyway.

Fetal lambs normally maintain a very low plasma glucose concentration of approximately 0.6 mmol/l compared to 2.7 mmol/l in a ewe (Warnes *et al*., 1977). Thus, the transplacental glucose gradient greatly favors movement from dam to fetus. Curiously, the most concentrated carbohydrate in fetal sheep plasma is fructose (5.1mmol/l), which is synthesized from glucose in the placenta by reducing glucose to sorbitol followed by oxidation to fructose (Hers, 1960; Warnes *et al*., 1977). Despite the abundance of fructose in the plasma of the fetal sheep, glucose constitutes its primary energy supply (Lindsay and Pethick, 1983; Warnes *et al*., 1977), and the fetuses normally consumed 60% to 70% of maternal glucose production (Prior and Christenson, 1978; Setchell *et al*., 1972).

The ovine placenta appears to have a low permeability for acetoacetate. When acetoacetate loads have been infused into pregnant sheep, the concentrations in fetal blood have remained low. Further, *in vitro* experiments with perfused sheep placenta have also demonstrated a low permeability for acetoacetate (Alexander *et al*., 1966, 1969). Thus, it appears that maternal acetoacetate, and perhaps 3-hydroxybutyrate, cannot be a major energy source for the ovine fetus.

The disease is characterized by depression and weakness in the ewes, which are associated with hypoglycemia, ketonemia, and ketonuria (Henze, 1998; Reid, 1968). The ketonemia is severe enough to cause acidosis, which can be severe (Holm, 1958; Reid, 1968). There is also considerable fatty deposition in the liver to the extent that it may interfere with liver function (Cornelius *et al*., 1958; Snook, 1939). Eventually, the ewes are unable to rise, become comatose, and die if untreated.

Mild cases respond to intravenous glucose, glucocorticoids, glucose precursors such propylene glycol or glycerol coupled with removal of stress, and improved nutrition (Henze *et al*., 1998; McClymont and Setchell, 1955a, 1955b; Thompson, 1956). Severe cases, in which the ewes are unable to rise, usually respond only to delivery of the lambs, and even then, a high mortality will occur (Holm, 1958; Reid, 1968).

3. *Syndromes in Other Species*

Ketosis associated with lactation can occur in dairy goats (Morand-Fehr *et al*., 1984). The syndrome has also been reported in beef cows with caloric deprivation and nursing two calves (Khan *et al*., 1986). Pregnancy toxemia has been reported in goats carrying multiple fetuses (East, 1983; Morand-Fehr *et al*., 1984; Rindsig, 1980; Thedford, 1983). The syndrome can be produced with calorie deprivation, particularly if coupled with stress, and almost always occurs in does carrying more that one fetus. Obesity also may be a predisposing factor in does (Morand-Fehr *et al*., 1984; Thedford, 1983). Generally, the syndrome in does appears entirely similar to that in ewes.

Pregnancy toxemia has been reported in beef cows in the last 2 months of gestation (Caple *et al*., 1977; Kingrey *et al*., 1957; Sampson *et al*., 1945; Tyler *et al*., 1994). The disease occurs predominantly in cows that are carrying twins. The cows may be in good or even obese body condition, but sudden food deprivation or decrease in quality or imposition of stress such as water deprivation may precipitate the syndrome. The disease resembles pregnancy toxemia in sheep in most respects. Pregnancy toxemia has been reported in pregnant bitches (Irvine, 1964; Jackson *et al*., 1980) and appears similar to the disease in sheep. Hypoglycemia is severe in canine cases, and the animals respond readily to intravenous glucose. If the animals will eat a carbohydrate-containing diet, a relapse is unlikely; otherwise, removal of the fetuses is required for a cure. There is a report of diabetic ketosis developing in pregnant dogs, which may resolve after delivery; however, these dogs are hyperglycemic and are treated with fluids and insulin (Norman *et al*., 2006). Pregnancy toxemia occurs in pregnant guinea pigs and, like in pregnant ewes, the syndrome can be precipitated by inadequate calories and stress (Bergman and Sellers, 1960; Wagner, 1976). The syndrome in guinea pigs is similar to that in sheep. There is marked ketonemia and acidosis, and the animals become weak and depressed with eventual coma (Wagner, 1976).

I. Postexercise Ketosis

Postexercise ketosis, which was first documented in 1909 (Forssner, 1909), has been investigated most extensively in humans and rats. Neither trained nor untrained humans or rats show much increase in ketones during exercise, but only untrained individuals exhibit a significant ketonemia and ketonuria after exercise (Johnson *et al*., 1969; Koeslag, 1982; Winder *et al*., 1975). The experiments of Winder *et al*. (1975) demonstrated a greater enzymatic capacity of muscles of trained rats to catabolize ketones. It also appears that trained athletes have a greater capacity to oxidize LCFA in muscle than nonathletes (Johnson *et al*., 1969). A high-carbohydrate diet in conjunction with training also decreases the magnitude of postexercise ketosis (Koeslag *et al*., 1980).

From the foregoing, it appears that a number of factors are involved in postexercise ketosis. During exercise, all forms of fuel, including LCFA, ketones, and glucose, are oxidized. Postexercise, there is a diminution of LCFA release from adipose tissue; however, plasma LCFA concentrations decrease little at first because of an even greater

diminution in LCFA oxidation, and more LCFA may be converted to ketones. Ketone oxidation by muscle is decreased postexercise, which will allow ketones to accumulate. In the postexercise period, there is gluconeogenesis as lactate is cycled back into glucose and glycogen, which may lead to decreased mitochondrial oxaloacetate levels and increased ketogenesis. Finally, compared to the exercise period, in the postexercise period, relatively more of the cardiac output will flow through the portal system, and the rate at which LCFA are presented to the liver may increase.

Postexercise ketosis undoubtedly occurs in most mammalian species, but among the domestic species, it has been best documented in dogs and horses. Postexercise increases in plasma levels of ketones have been observed in racing sled dogs (Hammel *et al*., 1977). Postexercise ketosis has been reported several times in the horse (Dybdal *et al*., 1980; Lucke and Hall, 1980; Rose and Sampson, 1982). In these studies, horses were subjected to endurance rides of 80 to 160 km. Plasma 3-hydroxybutyrate concentrations increased two- to three-fold 5 to 60 minutes postexercise compared to preexercise levels. Plasma LCFA concentrations increase five-fold or more in horses during exercise (Lucke and Hall, 1980; Rose and Sampson, 1982) and decrease little during 30 to 60 minutes postexercise. Thus, abundant LCFA are available to the liver postexercise when muscle utilization of LCFA and ketones is decreased, a situation that results in ketonemia.

I. INTRODUCTION

Protein is the most abundant component of plasma. There is in the region of 6 to 7 g/dl (60 to 70 g/liter) of protein in plasma in comparison to 0.1 g/dl (1.0 g/liter) of glucose (5.5 mmol/liter) or 0.35 g/dl (3.50 g/liter) of sodium (150 mmol/liter). However, this large mass of protein consists of many different individual protein molecules. Complete analysis of this complex mixture of different proteins is not possible at present in the diagnostic laboratory. Proteins contain approximately 95% of all nitrogenous material in blood in the form of chains of amino acids linked by peptide bonds. Protein can be separated from the nonprotein nitrogen (NPN) component of plasma by precipitation with reagents such as trichloracetic acid. The NPN consists of nucleic acids along with low molecular weight compounds such as urea (50% of NPN), free amino acids (25% of NPN), glutathione, and creatinine.

Analysis of serum protein is an area of clinical biochemistry of domestic animals, which has seen a rapid advance since the 1990s, and with current developments in analytical technology and interpretation, the rate of advance is likely to accelerate rather than decline. At the forefront of these advances in the diagnostic application of serum protein analysis has been the development of specific assays for individual proteins. In particular, it has been recognized that quantification of a group of serum protein called the acute phase proteins (APP) can greatly assist the assessment of infection, inflammation, and trauma in animals. These advances are now being applied in clinical biochemistry laboratories for the immediate benefit in the diagnosis, prognosis, and monitoring of treatment of domestic animals.

In the future, technology may be developed to characterize all proteins (the proteome) of serum, which would

make a major contribution to the diagnosis of disease. However, it is a salutary lesson that currently only a limited number of the many plasma proteins are used for diagnostic analysis (Anderson and Anderson, 2002).

This chapter focuses on the biochemistry, the diagnostic methodology, and use in disease diagnosis of measuring the concentration of serum or plasma proteins, but it will exclude a number of groups of proteins where the interpretation of results is more appropriate for other chapters. Immunoglobulins and complement will be covered in Chapter 6, lipoproteins in Chapter 4, and fibrinogen in Chapter 10. Studies on the proteins of blood have been performed on serum or plasma. Where appropriate, a distinction is made between these fluids, although apart from the absence of fibrinogen in serum, most diagnostic investigations can be applied to either. Nevertheless serum is the preferred sample for most of the diagnostic assays used to investigate the proteins of blood.

II. CLASSIFICATION OF PROTEINS

A. Structural Classification

The structure of proteins is defined by increasing levels of complexity. The primary structure of a protein is the sequence of amino acids that makes up the unique composition of the individual protein. The amino acids are joined together by peptide bonds linking the carboxylic acid group of one amino acid to the amino group of the neighboring amino acid in the chain. With 20 different amino acids occurring in proteins and with the possibility of more than a hundred or more amino acids making up the primary structure of each protein, there are an almost infinite number of potential proteins that could be present in cells and tissues. However, the sequence of the amino acids in a particular protein is predetermined by the order of nucleotide bases in nuclear DNA, which contains the genetic code for that protein.

Secondary structure is the presence in protein of regular structures formed by the linked amino acids giving identifiably similar three-dimensional conformations. These may be repeated at intervals in the three-dimensional molecular structure of the protein. The most important of these structures are the α-helix and the β-sheet. The α-helix is a right-handed helix stabilized by hydrogen bonds between the C = O group of one amino acid residue and the N-H group of another amino acid located four residues along the peptide chain. The β-sheet is also stabilized by hydrogen bonds between carboxyl and amino groups of amino acid residues, but the interacting residues are at different parts of the same chain. An example of the α-helix is shown by the structure of albumin (Section IV.A), whereas the contribution of β-sheets to protein structure is illustrated by the structure of C-reactive protein (CRP) (Section IV.B.1). The α-helices and β-sheets can associate together into supersecondary structures forming recognized motifs among which the β-meander, Greek key, and β-barrel structures have been described (Walsh, 2002)

The tertiary structure of proteins is the three-dimensional structure of the protein and is dependent on its primary and secondary structures. This native conformation of the protein is essential for its activity and depends on the correct folding of the protein after synthesis. Most proteins above a certain size can be subdivided into domains, which are independent folding units. The conformation of the protein is held together by weak forces between amino acid side chains such as hydrogen bonds, electrostatic and hydrophobic interaction, and also by covalent disulphide bonds between cysteine residues. Great strides have been made in determining the structure of proteins using X-ray crystallography and nuclear magnetic resonance (NMR). Structures of many proteins, including serum protein, can be obtained from online, open-access databases such as the Research Collaboratory for Structural Bioinformatics Protein Data Base located on the Internet at www.rcsb.org/pdb. The structures can be manipulated by protein modeling software, among which Protein Explorer or RasMol can be downloaded from www.umass.edu/microbio/rasmol.

The quaternary structure of proteins is the combination of protein subunits to create a multisubunit complex. Thus, hemoglobin requires the combination of four subunits (two α-chains and two β-chains) into a tetramer for the fully functional protein. Examples of serum proteins that have quaternary structure include immunoglobulins, formed from two light chains and two heavy chains, and CRP, in which five subunits combine to form a pentameric structure.

A further classification of protein based on their structure is between "fibrous" and "globular" proteins. The former adopt elongated three-dimensional shapes in their quaternary structure and are usually involved in structural roles in biological systems such as α-keratin, collagen, and elastin. Apart from fibrinogen (Section VI.B.5), which has as its function the formation of fibrin, fibrous proteins are not found in plasma protein. Thus, the majority of plasma proteins are globular proteins, adopting complex three-dimensional shapes by folding of the polypeptide chain.

B. Chemical Classification

Proteins are also classified as "simple" or "conjugated." Simple proteins contain only a polypeptide chain of linked amino acids, whereas conjugated proteins contain nonamino acid components. These can be carbohydrate residues (glycoprotein and proteoglycan), metal ions such as Fe^{2+} or Ca^{2+} (metalloproteins), phosphate (phosphoproteins), lipid (lipoproteins), and nucleic acids (nucleoproteins such as histones). Many plasma proteins are conjugated to carbohydrate and are present in the circulation as glycoproteins.

C. Physical Classification

Proteins can be classified by physical properties and behavior, by their size (relative molecular mass, M_r), or by the charge on the protein. The charge on a protein results from a combination of the acidic and basic groups on free side chains of the amino acids of the protein and is dependent on the pH of the aqueous environment. For every protein, there is a specific pH where the protein has an equal number of negative and positive charges on its side chains and the protein has a net charge of zero. This is the isoelectric point of the protein (pI). The higher the proportion of basic amino acids, such as lysine or arginine, the higher the pI of the protein will be, whereas with more acidic amino acids, such as glutamate or aspartate, the protein will have a low pI. The proportion of aromatic amino acids tyrosine, tryptophan, or phenylalanine contained by a protein influences its spectral properties because these amino acids absorb light at 280nm, which can be measured in a spectrophotometer. The spectral property can also be influenced by factors such as the presence of heme groups and the binding of metal ions. The proportion of hydrophobic amino acids defines the hydrophobicity of a protein, which can be predicted from the primary sequence. Chemical composition in terms of the primary structure and the physical properties of proteins that have been sequenced are available from online databases such as the UniProt database at www.ebi.uniprot.org.

TABLE 5-1 Natural Amino Acids

Essential Amino Acids		
Histidine	Lysine	Threonine
Isoleucine	Methionine	Tryptophan
Leucine	Phenylalanine	Valine
Nonessential Amino Acids		
Alanine	Cysteine	Proline
Arginine	Glycine	Serine
Asparagine	Glutamate	Tyrosine[a]
Aspartate	Glutamine	

[a] *By conversion from phenylalanine.*

III. METABOLISM OF PROTEINS

A. General

The metabolism of nitrogenous compounds in animals is largely related to the processes of anabolism and catabolism of amino acids and proteins. Proteins in the diet are broken down by protease digestion to yield free amino acids and small peptides, the latter being finally degraded in the intestinal cells during absorption. The products of protein digestion enter the portal vein as amino acids. In the healthy animal, an equilibrium is established between intake and synthesis of amino acids, on the one hand, and breakdown and excretion of excess nitrogenous material, in the form of urea, on the other. Excessive loss of nitro-genous material can occur in illness because of cellular breakdown, lactation with production of milk protein, and in urinary or gut losses. During growth, pregnancy, and recovery from disease, there is a positive nitrogen balance as amino acids and other nitrogenous compounds are supplied to meet the body's requirements.

B. Synthesis of Proteins

Proteins are made from amino acids in the cytoplasm of cells when the appropriate mix of amino acids is present. Among the 20 naturally occurring amino acids found in protein, nearly half cannot be synthesized by mammalian cells. These are the essential amino acids that have to be obtained in the diet (Table 5-1). The nonessential amino acids can be synthesized by transamination reactions in which the amino group of glutamate is transferred to a carbon skeleton in the form of an α-ketoacid. An example of this is the action of alanine transaminase, which catalyzes the transfer of the amino group of glutamate to the α-ketoacid, pyruvate, with the formation of alanine and α-ketoglutarate. Alanine transaminase (ALT; EC 2.6.1.2) is an important diagnostic enzyme, used as a marker of liver damage (Chapter 12) in small animals. The nonessential amino acids can be synthesized in animals from components of the central metabolic pathways, whereas the essential amino acids have to be present in the diet. However, in ruminants, the symbiotic relationship with ruminant microbes allows production of the full range of amino acids so that these species do not require all the essential amino acids in their dietary intake.

The intricate process of synthesis of protein in the ribosomes of the rough endoplasmic reticulum, under the instruction of messenger ribonucleic acid (mRNA), is a major part of the discipline of molecular biology and will not be described here in detail as authoritative texts are devoted to the subject (Alberts *et al.*, 2002). The primary structure of the protein is determined by the gene sequence of nuclear DNA on a chromosome in the nucleus. The genetic code, which is the sequence of nucleotides in DNA (adenine, cytosine, guanine, thymine), controls the sequence of amino acids in the protein. During protein synthesis, the code is transcribed from DNA to mRNA, which moves from the nucleus to the ribosomes in the cytoplasm. Here, specific amino acids are added to the growing peptide chain following linkage to a specific transfer RNA (tRNA). The specificity of production of the amino acid chain during this process of translation is dependent on the triplet of nucleic acids in the mRNA (codon) binding accurately to the anticodon of the tRNA. By this means, the

genetic code in nuclear DNA directs the primary sequence of amino acids during protein synthesis. Formation of the peptide bonds between the amino acids of the protein is followed by folding of the protein into its natural conformation. With up to 20 different amino acids in protein chains of 100 residues or more, several million structural arrangements are feasible for any one protein. It is essential for protein function that they form the correct native conformation, and protein folding is an essential process following synthesis. Folding is the responsibility of chaperones, which guide the growing protein chain to produce the single structure that will ensure its full activity (Walsh, 2002).

TABLE 5-2 Albumin Turnover in Animals

Species	$T_{1/2}$ (days)	Reference
Mouse	1.9	(Allison, 1960)
Rat	2.5	(Allison, 1960)
Dog	8.2	(Dixon *et al.*, 1953)
Sheep	14.3	(Campbell *et al.*, 1961)
Cow	16.5	(Cornelius *et al.*, 1962)
Human	19.0	(Putnam, 1975)
Horse	19.4	(Mattheeuws *et al.*, 1966)

C. Catabolism of Proteins

1. *Turnover of Proteins*

Throughout an animal's body, proteins are continually being synthesized and broken down, resulting in a continuous turnover of protein. In a healthy animal, the rates of synthesis and degradation are in equilibrium, but during disease these can alter. Plasma proteins are subject to the same process, and a function of albumin, the most abundant plasma protein, is to provide amino acid for the natural turnover of protein in peripheral tissues. Albumin is taken up by pinocytosis into tissues where lysosomal proteases hydrolyze the protein, releasing the amino acids for utilization by the cells for synthesis of their own proteins (Evans, 2002). There is no storage capability in the body for protein. As a result, amino acid in excess of requirement for cellular protein synthesis is utilized for the central pathways of metabolism. The carbon skeleton of amino acids can be used for provision of energy via the tricarboxylic acid cycle and oxidative phosphorylation or may be converted to glucose or lipid and stored for later use. Carnivores derive as much as 40% to 50% of their energy from dietary protein, whereas omnivores and herbivores derive from 10% to about 20% from this source.

The rate of degradation of the plasma proteins is expressed as their turnover, fractional clearance, or as their half-life, which is the time taken for their concentration to fall by 50%. Plasma half-lives were originally determined by measurement of the rate of disappearance of radioisotope labeled protein. More recently, proteins labeled with stable isotopes and measured by mass spectrometry have been used for this purpose (Preston *et al.*, 1998; Prinsen and de Sain-van der Velden, 2004). Clearance half-lives for cellular proteins range from a few hours (enzymes) to as long as 160 days for hemoglobin in bovine red cells. The clearance half-life for plasma protein can be as long as 3 weeks. Plasma albumin in humans has a normal half-life of 19 days, α_1-acid glycoprotein has a half-life of 5.5 days (Putnam, 1975), and γ-globulins have a half-life of 7 days (Andersen *et al.*, 1963). The plasma half-life of albumin shows considerable variation between species (Table 5-2). It is associated with the size of the species with murine albumin having a $T_{1/2}$ of 1.9 days, whereas equine albumin has a $T_{1/2}$ of 19.4 days.

2. *Urea Cycle*

During digestion, protein is not only broken down to amino acid, but gut bacteria can degrade the amino acids releasing ammonia, which is absorbed along with the amino acids. This is an important consideration in the management of liver disease, as sterilization of the gut by antibiotics can reduce the ammonia load on the liver. Once absorbed, amino acids, along with ammonia, are transported in the portal vein to the liver and then to other tissues where the amino acids are utilized for protein synthesis.

The liver is the central processing organ for nitrogen metabolism, and approximately 75% of the amino acid (and ammonia) absorbed from the intestine is transported into the hepatocytes. Transaminase reactions facilitate the transfer of amino groups to appropriate α-ketoacids in the formation of the required balance of nonessential amino acids. If not required for protein synthesis, amino acids undergo deamidation by mitochondrial enzymes including glutamate dehydrogenase and glutaminase. Amino groups are also transferred to oxaloacetate, with the formation of aspartate, which along with an ammonium ion and a carbonate group are the precursors of urea. In this way, amino groups from excess amino acids are transferred into urea for safe excretion.

In the urea cycle (Fig. 5-1), which takes place in hepatocytes, the initial step is the formation of carbamoyl phosphate in the mitochondria from an ammonium ion, a carbonate ion, and ATP. This step, which is under metabolic control and is activated by an increase in the cellular arginine concentration, occurs when there is an excess of amino acids in the hepatocyte. The carbamoyl phosphate combines with ornithine to form citrulline. This metabolite

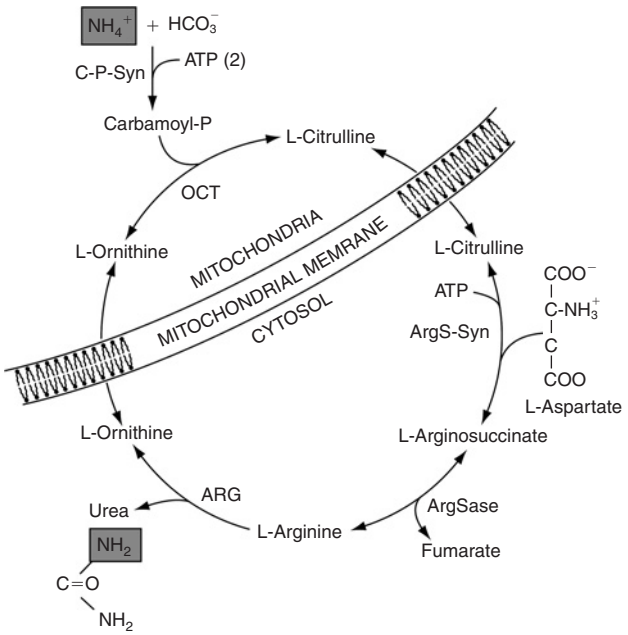

FIGURE 5-1 The urea cycle. Formation of urea from precursors of aspartate, NH_4^+, and COO^- with part of the cycle taking place in the cytoplasm and part in the mitochondria. Abbreviations: C-P-Syn, carbamoyl phosphate synthase; OCT, ornithine citrulline transferase; ArgS-Syn, argininosuccinate synthase; ArgSase, argininosuccinase; ARG, arginase.

leaves the mitochondria and combines with aspartate to form arginosuccinate, which separates into arginine and fumarate. Urea is then released from arginine leaving ornithine, which reenters the mitochondria and the cycle repeats. There is a close link between the urea cycle and the tricarboxylic acid (TCA) cycle as the fumarate released from arginosuccinate is converted to malate and then oxaloacetate in reactions of the TCA cycle. Aspartate transaminase catalyses the transfer of an amino group for production of aspartate from the oxaloacetate, thus providing the amino group for further urea production. Division of the urea cycle between mitochondria and cytoplasm aids in coordination between cycles. The urea produced in the liver is transported in the circulation to the kidney where it is excreted by the kidney tubules and eliminated in urine. Other routes for the excretion of nitrogenous material, such as uric acid or nucleic acid, are relatively minor in mammalian species.

All animals are quite intolerant of free ammonia (NH_3), but at physiological pH the protonated ammonium ion form predominates:

$$NH_3 + H^+ \rightarrow NH_4^+$$

The ammonium ion does not readily transfer across membranes unlike free ammonia, which readily enters cells where it is reconverted to the ammonium ion. Ammonia is particularly toxic to cells of the central nervous system where it acts by reducing the activity of the TCA cycle by removing a critical intermediate, α-ketoglutarate. Increased ammonia leads to the production of glutamate from α-ketoglutarate by the action of glutamate dehydrogenase. The α-ketoglutarate is lost to the TCA cycle, causing ATP production in the neurons to be restricted. Ammonia may also be directly toxic as it can decrease neurotransmitter concentrations. Ammonia is associated with hepatic encephalopathies of humans, horses (Hasel *et al.*, 1999), and dogs (Reisdesmerie *et al.*, 1995), possibly by affecting the expression of neuron proteins such as glial fibrillary acidic protein, glutamate transporters, and peripheral-type benzodiazepine receptors (Butterworth, 2002).

IV. PLASMA PROTEINS

A. Sites of Synthesis

Apart from the immunoglobulins, produced by B-lymphocytes, the major plasma proteins are synthesized and secreted from hepatocytes. Control of secretion is exerted by varied mechanisms. The secretion of albumin is stimulated by a fall in osmotic pressure (Evans, 2002) but can also be affected by pathophysiological changes such as during infectious or inflammatory disease when the secretion is reduced. This is caused by proinflammatory cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor-α (TNF). These cytokines are simultaneously responsible for the increased synthesis and secretion of the APP (see Section VI.B). The immunoglobulins are produced by B-lymphocytes in the spleen, lymph nodes and bone marrow following stimulation by the presence of pathogen in the circulation or tissues.

Use of molecular biological techniques such as Northern blots and the polymerase chain reaction (PCR) has revealed that nonhepatic tissues have the capability to synthesize some of the plasma proteins and that in certain circumstances the expression of their mRNA is up-regulated. Thus, in tissues such as intestine, lung, and adipose tissue, the mRNA for the plasma proteins haptoglobin and serum amyloid A are increased during infections and inflammation (Friedrichs *et al.*, 1995; Vreugdenhil *et al.*, 1999; Yang *et al.*, 1995). The proportion of the proteins in the circulation derived from these nonhepatic sources has not been determined. A further site of nonhepatic synthesis is the mammary gland, which has been shown to produce a mammary associated serum amyloid A and haptoglobin during mastitis. However, the protein produced in the mammary gland does not appear in plasma but is secreted in the milk during the disease (Eckersall *et al.*, 2001; Jacobsen *et al.*, 2005b).

The origin of low-abundance plasma proteins is varied. They may be made and secreted for specific functions such as the protein and peptide hormones. For example, the gonadotropins and adrenocorticotropin are released into the circulation from the pituitary gland, insulin and glucagon

from the pancreas, and parathyroid hormone and calcitonin from the parathyroid gland. Similarly, the adipose tissue releases adiponectin and leptin, peptides affecting the appetite and nutritional status, whereas the cytokines are derived from cells of the immune system. The plasma also contains tissue proteins lost during normal turnover of cells, which can be valuable biomarkers of disease in identifying when pathological events occur. For example, enzymes determined in clinical enzymology for liver or muscle damage and the troponins released from cardiac or skeletal muscle are minor plasma proteins.

B. Functions of the Plasma Proteins

The functions of proteins in the body of animals are innumerable and include forming the basis of structure of cells, organs, and tissues; maintaining colloid osmotic pressure; catalyzing biochemical reactions; and buffering acid-base balance. The proteins are also multifunctional in plasma. The functions of specific plasma proteins will be described later in this chapter, but main functions of protein in blood are in blood coagulation (fibrinogen), in host defenses against pathogens (immunoglobulins, complement), in transport of metabolites (transferrin, albumin), in regulation of cellular metabolism (hormones), in prevention of proteolysis (α_1-antitrypsin), in provision of nitrogen balance for nutrition (albumin), and in maintaining osmotic pressure (albumin). The biological activities of the plasma proteins in these functions depend ultimately on their primary, secondary, tertiary, and quaternary structures.

C. Factors Influencing the Plasma Proteins

1. Age

At birth, plasma proteins of most species are low because of minimal quantities of immunoglobulins. As the newborn animal ingests colostrum, a rapid rise in immunoglobulins occurs as a result of absorbed maternal immunoglobulins. As the maternal immunoglobulins reduce in concentration because of natural turnover, the neonate rapidly gains immunocompetence and begins to synthesize its own immunoglobulins. Upon reaching young adulthood, adult levels of globulins are reached. In contrast to this general trend, α_1-acid glycoprotein is elevated in serum at birth in piglets but declines over the first few months of life (Itoh *et al.*, 1993b). With increasing age, the plasma protein concentration increases as a result of a small decrease in albumin and a progressive increase in globulins.

2. Hormones, Pregnancy, and Lactation

In some species, the total plasma protein concentration in the maternal blood decreases during gestation because of a decline in albumin, even though there is a slight increase in globulins. In a number of species pregnancy associated proteins have been observed during pregnancy. The only one in regular diagnostic use is equine chorionic gonadotropin (formerly pregnant mare serum gonadotropin) used to confirm pregnancy in mares (Henderson *et al.*, 1998). In pregnant bitches, an acute phase reaction occurs about 21 days after fertilization and acute phase proteins, especially C-reactive protein, increase in the maternal serum (Eckersall *et al.*, 1993; Vannucchi *et al*., 2002). In cattle approaching term, there is a rise in γ-globulins and a corresponding rise in total plasma protein, but at term a fall occurs in this fraction because of transfer to colostrum (Weaver *et al.*, 2000). The acute phase protein, serum amyloid A (SAA), also increases in the maternal plasma around parturition in cows (Alsemgeest *et al.*, 1993). During lactation, the total plasma protein decreases in some species because of albumin decrease.

Some hormones (testosterone, estrogens, growth hormone) promote an increase in total plasma protein because of their anabolic effects, whereas others (thyroxine, cortisol) tend to decrease the total plasma protein because of their catabolic effects.

D. Handling and Identification of Proteins

Protein denaturation is the net effect of alterations in the biological, chemical, and physical properties of the protein by mild disruption of its structure. When blood samples are taken for protein analysis, it is important that they are handled correctly so that no artifacts are introduced that could affect the investigation and its interpretation. If the protein is allowed to even partially degrade, the assay will not be accurate. Therefore, it is essential that denaturation is avoided. The ability of plasma proteins to resist denaturation in a blood sample taken for diagnostic analysis varies between proteins; consequently, the sample should be handled according to the analysis required. Fortunately, most major plasma proteins are relatively resistant to denaturation and can be assayed in samples that have been handled carefully and have been kept away from elevated temperatures. However, separation of plasma or serum from the blood cells by centrifugation should be performed as early as possible. Thereafter, many proteins are stable at 4°C for several days and at –20°C for much longer (months to years). Some proteins are less stable, with enzymes being particularly susceptible to loss of activity with time, while the stability of the peptide hormone ACTH is so low that samples should be snap-frozen immediately to preserve the intact peptide.

For identification and quantification of serum protein, the protein component in serum must either be separated or individual proteins must be measured independently. The primary separation of the proteins in serum is between albumin and the globulins. Albumin is a water-soluble, globular protein that is usually identifiable as a single discrete

molecule. The globulins are also globular proteins, but many of them, in contrast to albumin, precipitate in pure water and require salts to maintain their solubility. The globulins are a mix of proteins of various types, which migrate in groups in an electric field (electrophoresis) as families of proteins identified as α-, β-, or γ-globulins. The nomenclature of the globulin fractions is based on their location during separation by electrophoresis. Albumin has the most rapid migration of the major proteins (in some species it is preceded by prealbumin), followed by the α-globulin, β-globulin, and γ-globulin fractions, respectively. The γ-globulins are largely composed of immunoglobulins, the antibodies that bind to invading pathogens or other foreign matter. In contrast, the α- and β-globulin fractions contain a great variety of different proteins.

Electrophoresis is a well-established diagnostic method that was first introduced to the clinical biochemistry laboratory with cellulose acetate as the support medium for the separation. This has largely been replaced with agarose, so that serum protein electrophoresis (SPE) in agarose gels, followed by protein staining and densitometry to quantify the protein in each of the main fractions, is common in clinical biochemistry laboratories. This has evolved into an extremely useful technique because aberrations are observed in many disease states though there are only a few diseases where the electrophoretic pattern can provide a definitive diagnosis.

Interest has advanced the investigation armory for serum protein analysis with the development of specific analytical methods for individual proteins. Though specific assays have been used for a long time for determination of proteins such as albumin and fibrinogen, it is only relatively recently that specific assays for other diagnostically useful proteins such as haptoglobin, CRP, SAA, and α_1-acid glycoprotein (AGP) have become commonly available. In most cases, this has been achieved by the use of immunoassays, which has often required the development and validation of species-specific methodology.

V. METHODOLOGY

A. Total Protein

Assays for total protein can be performed on serum or plasma. The method employed to measure the total amount of protein in solution varies with the amount of dissolved protein and is therefore chosen according to the biological fluid under investigation. The technology used to measure total protein can be based on chemical or physical measurements. In the diagnostic laboratory, chemical methodologies are used because they can be readily adapted to automated analyses. On the other hand, point-of-care determination of total protein, for instance, in a veterinary practice, can be performed by use of refractometry, which depends on the physical properties of protein in solution.

1. *Chemical Methods*

a. Biuret Reaction

The biuret reaction, in which protein forms a complex with copper (Cu^{2+}) in alkaline solution, has become the standard chemical test for total serum or plasma protein. This complex, which is dependent on the presence of peptide bonds, is blue-purple in color. This method is used in automated wet biochemical analyzers and is also the basis for total protein assays in dry chemistry analyzers. The biuret method is highly accurate for the range of total protein found in serum (1 to 10 g/dl, 10 to 100 g/liter) but is not sensitive enough for the protein concentrations found in other body fluids where the concentration range is lower, for example, cerebrospinal fluid. More sensitive protein assays should be used for these fluids.

b. Precipitation Methods

Proteins in solution are sensitive to changes in the pH of the environment that result in alteration of the ionization of the side groups of acidic and basic amino acids. This distorts the electrostatic forces between residues, which normally keep the protein in its native conformation. Changing the pH, especially to the extremes of the pH range, therefore disrupts the tertiary and quaternary structures of proteins leading to reduced solubility and causing precipitation of the protein from solution. Reagents such as trichloroacetic acid, sulphosalicylic acid, and tungstic acid cause the precipitation of protein and are used to quantify the total protein concentration in biological fluids when the protein concentration is in a range of 0.1 to 1g/dl (1 to10 g/liter).

c. Sensitive Chemical Methods

For measurement of total protein in fluids at concentrations less than 0.1 g/dl (1 g/liter), more sensitive protein assays have to be used. For many years, the Phenol-Folin-Ciocalteau method (Lowry *et al.*, 1951) was the method of choice to measure low concentrations of protein. This method is based on the reaction of the phenolic group of tryptophan and tyrosine with the Folin-Ciocalteau reagent yielding a blue chromogen. A less laborious modification of this method, which is even more sensitive, has been developed using bicinchonic acid (Smith *et al.*, 1985), whereas methods based on the binding of the dye, Coomassie blue to protein in acidic solution, are also useful in quantifying dilute protein solutions (Bradford, 1976). These sensitive methods are conveniently performed in microtiter plates, but their use is mainly restricted to the research laboratory. These sensitive methods depend on the reactions between reagent and a number of specific amino acids in the proteins, such as with the phenolic group of aromatic amino acids. Results vary depending on the proportion of these amino acids in the proteins being measured. The protein used to calibrate the assay may have a significant effect on results. Conventionally, bovine serum albumin is used as calibrant.

2. Physical Methods

a. Refractometric

Light is refracted when it passes from air to liquid, and if the liquid contains dissolved proteins, the degree of refraction (refractive index) changes in proportion to the concentration of protein. With appropriate instruments and careful use, determination of the refractive index of serum can give an accurate assessment of total protein concentration. The use of hand-held refractometers allows rapid determination of protein in serum, plasma, or other body fluid and is one of the most widespread point-of-care methods in use. It is important to frequently check the calibration of the refractometer, as this may be a source of error. Most refractometers are scaled to read directly both total serum protein and urine-specific gravity. Studies have shown that results for protein estimates from hand-held refractometers correlate well with results from the biuret method, though there are reports of major discrepancies in samples from avian species (George, 2001). Because of the dependence on the transmission of light, it is important that the sample is clear, nonturbid, nonlipemic, and nonhemolyzed. In a comparison of refractometry to the biuret method for the determination of the total protein in plasma from dogs and cats, the correlation coefficients were high, but there were differences between the methods of 0.6g/dl (6g/liter) and 0.2g/dl (2g/liter) for dog and cat plasma, respectively (Briend-Marchal *et al.*, 2005). Although the internal scales on most refractometers limit the measurement of protein to a minimum of 2.5g/dl (25g/liter), it has been shown that a close correlation to total protein determined by the biuret method can be obtained to concentrations as low as 0.6g/dl (6g/liter), allowing the use of the method to estimate the protein content in most body fluid samples (George and O'Neill, 2001).

b. Fibrinogen

Refractometry can be used to determine the concentration of fibrinogen in plasma. This large protein (340 kDa) constitutes about 5% of the total plasma protein, and its concentration can be estimated from the difference in protein content before and after heat treatment of plasma at 56°C for 3 minutes, which causes fibrinogen to precipitate. A refractometer is used to determine the protein concentrations before and after heating with the fibrinogen being estimated from the difference between the two readings. Fibrinogen has also been estimated by measurement of the height of fibrin clot in microhematocrit tubes or the assessment of the weight or the protein content of fibrin clots (Davey *et al.*, 1972). Monitoring the fibrin formation spectrophotometrically via enzymic action of thrombin or the snake venom, batroxobin, on fibrinogen allows the assay to be automated (Messmore *et al.*, 1997; Oosting and Hoffmann, 1997) and has been used to monitor canine fibrinogen (Mischke *et al.*, 2005). Thrombin time, as described in Chapter 10 on hemostasis, is also used to estimate fibrinogen concentration.

B. Fractionation of the Serum Proteins

The total protein content of serum is made up of a large number of individual proteins, and diagnostic information can be obtained by detecting changes in the component proteins or in different fractions of proteins. It has been suggested (Anderson and Anderson, 2002) that virtually all diseases affect the proteins found in serum and that diagnosis would be advanced by using proteomics methods (Section V.C.4) to monitor change in many serum proteins at the same time. This is likely to be in the distant future for routine applications in veterinary clinical pathology laboratories. Nevertheless, considerable valuable diagnostic information can be obtained using current methods to fractionate serum to determine the concentration of its major proteins or groups of proteins.

Most of these methods require the initial determination of the total serum protein concentration, which is then used in calculation of the protein content of different fractions. In its simplest form, the globulin fraction can be estimated if the total protein and albumin concentrations are known. The globulin concentration is the difference between the total protein and albumin concentrations. For quantitative estimation of the subdivided globulin fractions (α-, β-, or γ-globulins), the percentage of each fraction in a serum sample can be determined by electrophoresis and the concentration of each fraction calculated from the total protein by proportion.

1. Salt, Acid, and Glutaraldehyde Fractionation

The weak bonds that hold together the secondary, tertiary, and quaternary structures of proteins can be disrupted by a variety of changes in the aqueous environment leading to reduced solubility. Because of the different amino acid composition of proteins, alterations in the environment have differential effects on individual proteins, and salt fractionation of serum protein exploits this property. The addition of salts to serum increases the ionic concentration causing the flocculation and precipitation of the globulins (particularly γ-globulins), whereas albumin is more resistant to increased ionic charge and remains in solution. Precipitation with ammonium sulphate is a widespread technique used in the purification of serum (and other) proteins.

For diagnostic test use in animals, the most common application of salt precipitation is in assessment of the transfer of antibody (γ-globulins) from colostrum to the serum of the neonate (Weaver *et al.*, 2000). The optimal concentrations of sodium sulphite (Pfeiffer and Mcguire, 1977) or zinc sulphate (McEwan *et al.*, 1970) have been determined, which, when added to a serum sample, will only precipitate the γ-globulin fraction. Thus, serum from calves or foals in which passive transfer of immunoglobulin

has occurred will show an increase in turbidity, whereas a sample from a neonatal animal that has not absorbed colostral antibody will remain clear. The simplicity of these methods has allowed their use as point-of-care methods. A recent reevaluation of the use of sodium sulphite found that a concentration of 18% (w/v) provided the optimal diagnostic value. With zinc sulphate as the precipitant, a similar diagnostic value was found, but it was affected by hemolysis and the test solution was not stable when exposed to atmospheric carbon dioxide (Tyler *et al.*, 1999).

An alternative approach to assessment of antibody transfer, which also causes the precipitation of the γ-globulin fraction, is the glutaraldehyde coagulation test (Sandholm and Kivisto, 1975). Glutaraldehyde reacts with free amino groups on proteins causing cross-links to form between protein chains and, if sufficient numbers are produced, will cause aggregation of the proteins and visible precipitate formation. γ-Globulins have the highest proportion of the basic amino acids (lysine, arginine), which have free amino groups available for reaction with glutaraldehyde. Therefore when mixed with glutaraldehyde at a predetermined concentration, a serum sample with a high γ-globulin concentration will form cross-links and precipitate formation will be visible, whereas a sample with low γ-globulin will not produce a precipitate. However, fibrinogen can also form cross-links with glutaraldehyde (Liberg *et al.*, 1975) and can cause interference with the test when it is used for antibody detection in plasma, especially in cases of hyperfibrinogenemia. Indeed, though the glutaraldehyde test was deemed to have poor sensitivity and specificity for detection of failure of passive transfer in calves (Tyler *et al.*, 1996), it was found to be a useful screening test able to distinguish between acute and chronic disease in horses (Brink *et al.*, 2005) because of this reaction with fibrinogen in plasma.

The seromucoid fraction of serum is a group of highly soluble glycoproteins that have the ability to remain in solution in the presence of perchloric acid while other proteins are precipitated. Methods have been developed to estimate this "acid soluble glycoprotein" fraction by addition of perchloric acid to aliquots of serum (Nagahata *et al.*, 1989). As most of the glycoproteins in the seromucoid (acid soluble glycoprotein) fraction are APP, this was an early means for monitoring the acute phase reaction.

2. Dye Binding and the Albumin:Globulin Ratio

Albumin has the highest concentration of any of the individual serum proteins, and valuable diagnostic information can be obtained by measurement of its concentration. Various dyes have been found that, after binding to albumin, change their absorbance and are used as a means to measure the protein in a spectrophotometer, in automatic analyzers, or in dry chemistry systems. The dyes used most widely for this procedure are bromocresol green (BCG) and bromocresol purple (BCP). BCG has become the favored dye to utilize in dye-binding assays for albumin (Keay and Doxey, 1983), although BCP has been recommended for equine serum albumin (Blackmore and Henley, 1983). Accuracy of the dye-binding methods is generally acceptable within the albumin concentration reference ranges found in animals. However, the accuracy decreases outside the reference ranges and may be unacceptable at very low or very high albumin concentrations. With heparinized canine plasma, it is possible that interference from fibrinogen can lead to overestimation of the albumin concentration when using BCG (Stokol *et al.*, 2001).

Once the albumin and total protein concentrations have been determined, the globulin fraction can be calculated by subtraction of the albumin from the total protein concentrations. The albumin:globulin ratio can then be calculated (albumin concentration/globulin concentration). This provides a means of assessing the relative contribution of the albumin or the globulins to the total serum protein, which complements the analysis of either analyte alone (Section VII.B).

C. Electrophoretic Fractionation of the Serum Proteins

Electrophoresis is the method of choice for analytical separation of protein. Serum protein electrophoresis (SPE) is currently regarded as the standard of reference for fractionation of serum protein. Serum rather than plasma is used as the sample for electrophoretic separation because it reduces the complexity of interpretation by the removal of fibrinogen. Many modifications have been made to the basic principles of electrophoresis since the separation of protein in an electric field was first pioneered by Tiselius (Tiselius, 1937). Many of these methods have been applied to serum proteins, but only a few have been employed in clinical biochemistry. A major difference between methods is the nature of the support material for the protein separation. From the mid-20th century, the cellulose acetate membrane was utilized for this purpose for SPE (Kohn, 1957). Toward the end of the century, electrophoresis on agarose gel was introduced and has become more popular in diagnostic laboratories. In contrast, biochemical research laboratories almost universally use polyacrylamide gel as the separation medium. Major advances have been made in the ability to separate protein with the introduction of two-dimensional electrophoresis (2DE) and associated proteomic techniques. Whereas SPE on agarose can separate serum into seven or eight fractions, it is claimed that proteomic methodologies can separate and also identify several hundred proteins simultaneously. Although these new methods have not been validated for use in domestic animal clinical biochemistry, it is valuable to be aware of the possibilities that could be available by application of these methods.

1. *Principle of* Electrophoresis

The principle for all protein electrophoresis is based on the movement of charged protein molecules in an electric field. In original studies in the early 20th century, electrophoresis was carried out in solution. This "free electrophoresis" was subsequently replaced by methods in which the proteins are separated in the matrix of a support medium in which the charged proteins and buffer ions are still able to move. The use of support medium has the benefit of reducing interfering problems and allows greater reproducibility. The choice of support can have direct consequences on the separation obtained during electrophoresis. As well as the nature of the support media, the migration of proteins depends on their size and charge, the pH and ionic composition of the buffer, and the strength of the electric field. The charge on the protein is dependent on the balance of acidic and basic amino acids in its primary structure and varies with pH. Thus, at a neutral pH, protein with a high proportion of acidic amino acids will have an overall negative charge, whereas a protein with a preponderance of basic amino acids will have an overall positive charge. SPE is usually performed at a basic pH (pH 8.6) so that most protein will have a negative charge. Molecules with a negative charge move toward the anode (positive electrode) when an electric current is passed through the solution. A side effect of agarose electrophoresis is that electroendosmosis occurs because of impurities in the agarose, causing the migration of the more basic (γ-globulins) proteins to the cathode (negative electrode).

Interestingly, one of the most recent innovations in electrophoretic separation has been to revert to electrophoresis in the absence of support media, but in this case using a very narrow bore capillary column. This "capillary zone electrophoresis" has the benefit of providing more rapid and reproducible analyses for individual samples, but the equipment is more specialized than that for SPE. These methods have been applied to canine serum protein fractionation (Martinez-Subiela *et al.*, 2002b) with results analogous to conventional SPE, though hemolysis and lipemia were found to cause interference in the β and α regions, respectively. Specific proteins such as haptoglobin can also be measured using capillary zone electrophoresis (Pirlot *et al.*, 1999).

2. *Cellulose Acetate and Agarose* Electrophoresis

For several decades, cellulose acetate was the method used in diagnostic laboratories for SPE, but the easier use, greater reproducibility, and commercial availability of agarose gels specifically produced for SPE have meant that use of the latter method is now more common. Agarose is a polysaccharide-based material derived from seaweed. When used for electrophoresis at a concentration of ~1% (w/v), the agarose forms a gel through which serum protein can move relatively freely. The introduction of plastic backed previously prepared gels meant that the handling, staining, and quantification of results could be easily undertaken.

Typically in an SPE run, serum samples are diluted 1:5 in buffer, and 5 µl are placed close to the center of the gel, slightly on the cathodal side; after the sample has diffused into the agarose, a voltage is applied across the agarose and the proteins are allowed to separate. The mobility of the proteins is based on a mix of their charge at the pH of the buffer (usually pH 8.6) and the size of the protein. Albumin has a high negative charge under these conditions and is also relatively small, so it is one of the most mobile proteins in moving toward the anode. At the other extreme the immunoglobulins (especially γ-globulins) have the least negative charge and are affected by electroendosmosis and migrate toward the cathode. The α- and β-globulins have intermediate mobility between albumin and the γ-globulins. Agarose SPE allows the subdivision of these groups, and α_1, α_2, β_1, β_2, γ_1, and γ_2 fractions of proteins may be observed (Trumel *et al.*, 1996), though this can vary between samples and between species. Following electrophoresis the proteins are fixed in the gel and visualized by staining with a stain such as amido black. Usually 10 samples will be run on one agarose gel with each sample in a different "track." After staining and clearing the gel, the proportion of proteins in each fraction can be estimated by densitometry. In most instruments a computer-generated printout will provide a graphical representation of the absorbance readings from the densitometer and will also calculate the percentage of protein per fraction. This allows the calculation of the protein content of each fraction based on the total serum protein concentration. Examples of agarose SPE and densitometer scans of the major domestic animal species are illustrated in Figures 5-2 and 5-3.

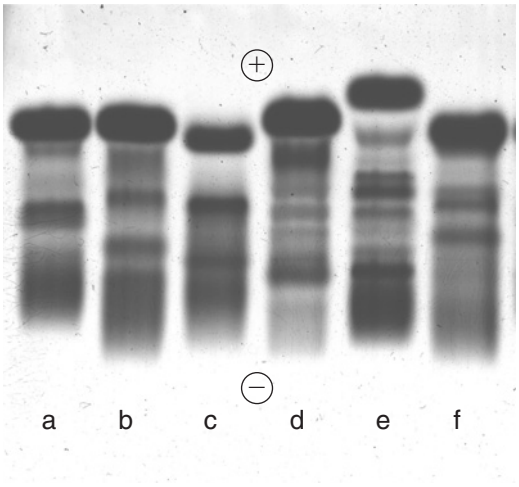

FIGURE 5-2 Agarose gel serum protein electrophoresis showing the separation of normal serum protein from healthy animals. Samples are from (a) sheep, (b) cow, (c) pig, (d) dog, (e) cat, and (f) horse.

Although attempts have been made to classify the serum protein peaks in an electrophoretogram into more fractions (Keay, 1982; Keay and Doxey, 1982), it is the division into albumin, α_1-, α_2-, β_1-, β_2-, γ_1-, and γ_2-globulin fractions (Trumel *et al.*, 1996) that is predominantly used in the diagnosis of the dysproteinemias (Section VII.B). Agarose gel electrophoresis can therefore separate serum protein into several fractions, but apart from albumin, each of these is composed of a number of different proteins. This produces a frustrating limit to the usefulness of SPE in disease diagnosis. More advanced methods of protein separation have been developed but are not at present practical for a routine clinical biochemistry laboratory because of cost, reproducibility, and the ability to analyze the amount of data that can be generated. However, if these obstacles could be overcome, protein separation would become even more useful than at present.

A recently introduced modification to the commercially available agarose gel allows high-resolution electrophoresis (HRE) to be employed for SPE. This method has been applied to canine serum and was able to localize specific serum proteins within the different subfractions. Thus, haptoglobin and α_2-macroglobulin were identified in the α_2 fraction, β-lipoprotein and complement C3 were located in the β_1 region, and transferrin and IgM were located in the β_2 region (Abate *et al.*, 2000). The use of HRE may become more widespread as it is as user-friendly as conventional agarose electrophoresis.

3. *Polyacrylamide Gel Electrophoresis and Isoelectric Focusing*

The most widely used support medium for protein electrophoresis outside the diagnostic laboratory is polyacrylamide gel (PAGE). The use of this medium brings a further factor to the electrophoretic separation of protein. During the polymerization of acrylamide to form the gel used in electrophoresis, the proportion of cross-links between polymer chains can be controlled, and the gel forms a molecular sieve that slows the migration of proteins depending on size. In its original version of discontinuous polyacrylamide gel electrophoresis (Davis, 1964), a strategic use of different buffer systems in the gel, in the sample, and in running buffer caused the proteins in the sample to focus into a sharp band before entering the gel. Once in the gel, separation was based on a balance of mass and charge on the protein. The most widely used modification of this system is to pretreat the proteins by heating in a solution of detergent (sodium dodecyl sulphate, SDS) and a reducing agent such as β-mercaptoethanol. These have the effect of separating any subunits held together by disulphide bonds and coating all the proteins with negative charge so that separation, with the same detergent also in the gel and buffers, is based on size alone as all protein will move to the anode because of their negative charge. This is the SDS-PAGE system introduced by Laemmli (Laemmli, 1970). Separation of serum protein on SDS-PAGE increases the complexity for interpretation of the electrophoretogram. The proteins are no longer grouped in the familiar globulin regions but are in a series of bands defined by relative molecular mass (M_r). The treatment and breakdown of complex proteins into their component subunits complicate interpretation. The high abundance of just a few of the proteins, such as albumin and the immunoglobulins, causes further difficulty in interpretation. Added to this are the more technically demanding methods required for SDS-PAGE such that this method is largely confined to the research laboratory. Nevertheless, separation of serum protein by SDS-PAGE has revealed disease-related changes in protein bands (Fagliari *et al.*, 1998; Kiral *et al.*, 2004), but there has not been a widespread application of the method in diagnostic biochemistry.

A further separation technique for electrophoretic fractionation of protein mixtures, introduced in the 1970s (Righetti and Drysdale, 1971), is isoelectric focusing (IEF). This technique, which can be performed in agarose or polyacrylamide gels, differs from other forms of electrophoresis by separating the proteins solely on the basis of their charge. The presence of special reagents, called ampholytes, in the buffer creates a pH gradient once an electric voltage is set up across the gel. Proteins in the gel move because of their relative charge, but once they reach their isoelectric point (pI) on the pH gradient, they become stationary, as they now have zero charge. Thus, an acidic protein with a negative charge will move toward the anode, but as it moves down the pH gradient the protein becomes less charged until it reaches the point where it has no net charge and it is "focused" at their pI. This method has a high resolution and can separate protein isoforms that have only slight charge differences caused, for instance, by glycosylation or phosphorylation of proteins. This greatly increases the potential number of bands that can be seen on IEF gels, but the method has not been adopted by diagnostic clinical biochemistry laboratories for separation of serum proteins, possibly because of this great complexity. However, IEF has been used in examination of enzyme isoforms (Eckersall and Nash, 1983) and can be used to identify microheterogeneity in specific serum proteins, for instance, being able to differentiate multiple forms of AGP that are caused by different degrees of glycosylation (Itoh *et al*., 1993a; Yoshida *et al.*, 1997).

4. *Proteomics*

Protein analysis is currently going through rapid evolution that could impact the veterinary diagnostic laboratory in the not-too-distant future and is being driven by advances in proteomics. Technological developments in different disciplines have converged to produce an approach to the separation, identification, and quantification of individual proteins within a complex mixture. The objective of a proteomic investigation is to be able to identify all proteins in a tissue or fluid and to detect even small changes taking place in its composition. Although this goal is still beyond the reach of all but the best-funded research laboratories, it is probable that proteomic techniques will eventually be used in diagnosis of disease. Analysis of serum or plasma protein will be at the forefront of these advances. It has been suggested that the human plasma proteome could be used to detect virtually all pathological processes because every diseased tissue is in contact with the circulation and interchanges material with plasma (Anderson and Anderson, 2002). As many as 1175 distinct gene products have been reported in human plasma by a combination of methods (Anderson *et al.*, 2004), whereas 289 proteins have been directly detected. However, only 117 of these have been registered in the Untied States by the Food and Drug Administration under the Clinical Laboratory Improvement Amendment for use in diagnostic investigation of plasma (Anderson and Anderson, 2002). Investigation of the diagnostic potential of animal serum or plasma proteomes is at a much earlier stage, but it has the potential to yield many novel diagnostic applications.

a. Two-Dimension Gel Electrophoresis

The new science of proteomics (James, 1997) initially developed from methods in which the electrophoretic techniques of IEF and SDS-PAGE were combined into two-dimensional electrophoresis (2DE) (O'Farrell, 1975). Combination of these methods leads to a protein map,

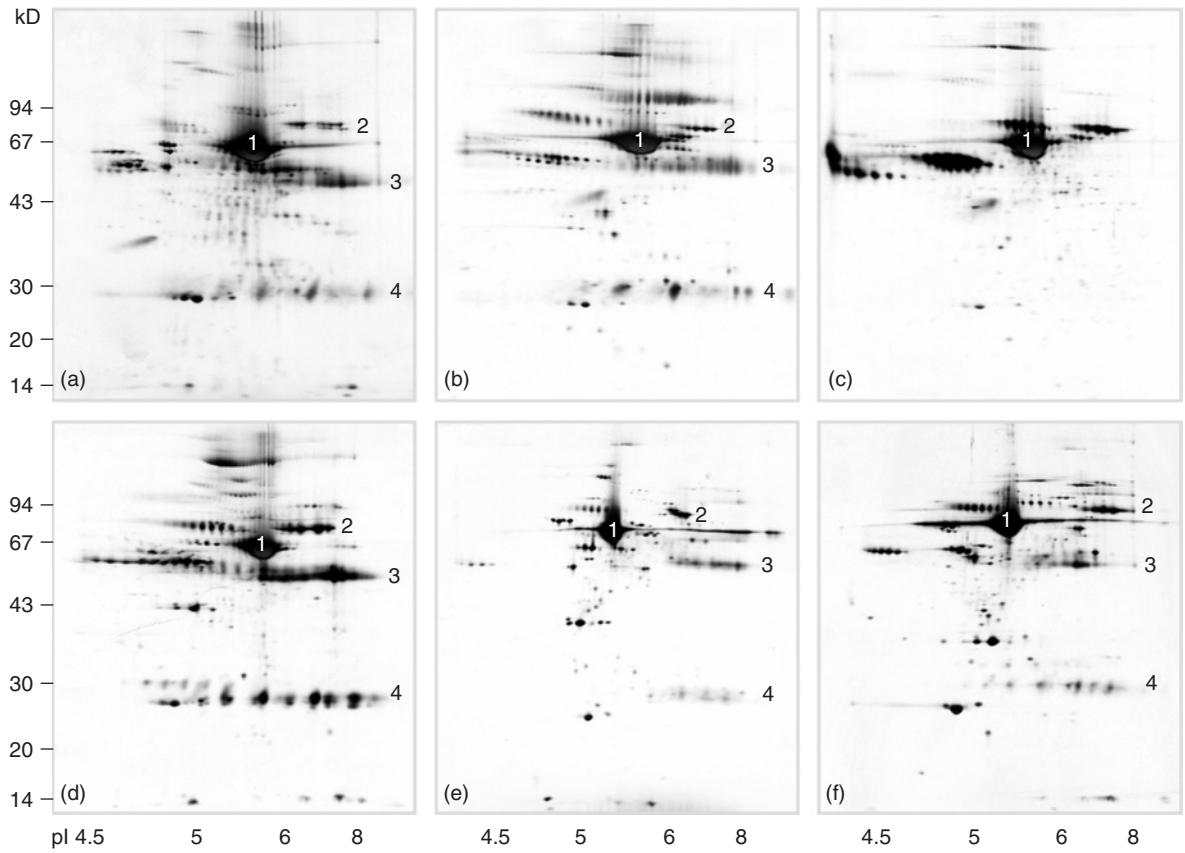

FIGURE 5-4 Two-dimensional electrophoresis of serum protein from (a) horse, (b) cow postcolostrum, (c) cow precolostrum, (d) sheep, (e) cat, and (f) dog. Labeled proteins are 1: albumin, 2: transferrin, 3: IgG heavy chain, and 4: IgG light chain. Gels were run on an IPG gradient from pH 4-10 (nonlinear) and then on SDS-PAGE. Gels courtesy of Ingrid Miller, Institute of Medical Chemistry, Department of Natural Sciences, University of Veterinary Medicine, Vienna, Austria.

where a protein mixture is separated horizontally by charge (IEF) and vertically by molecular mass (SDS-PAGE) yielding a two-dimensional map with each protein present as a single spot. An innovation that meant that these protein maps were much more reproducible was the introduction of immobilized pH gradients for use in the IEF step (Gorg *et al.*, 2000, 2004). In 2DE, the protein sample is subjected to IEF in a gel strip containing the immobilized pH gradient, and then the strip with the focused protein is placed on the top of an SDS-PAGE gel. After electrophoresis, the separated proteins are stained, using either Coomassie blue or the more sensitive silver or fluorescent stains. The amount of data generated by a 2DE gel can be vast, and a computer program is required to handle the analysis.

The serum proteomes of a number of domestic animals are illustrated in Figure 5-4. It is noticeable that albumin is the most abundant protein in adult serum and that the IgG spots are missing in serum from a precolostral calf (Fig. 5-4c). The serum proteomes of cattle and horse have been more fully determined with 30 and 50 proteins identified, respectively (Miller *et al.*, 2004; Wait *et al.*, 2002). Identification of protein spots following 2DE was originally performed with antibody detection, specific stains (e.g., for lipoprotein), or by comparison to the proteins of other species. A further advance that greatly facilitated proteomic research was the use of mass spectrometry to identify protein spots on gels.

b. Mass Spectrometry for Protein Identification

Mass spectrometry has been used for many years in investigations to measure the mass of molecules to a high degree of accuracy, but for a long time it was restricted to low-molecular-weight compounds. In the 1980s and 1990s, methods were introduced to determine the mass of larger molecules such as peptides and smaller protein. This was achieved with the introduction of electro spray ionization (ESI) (Fenn *et al.*, 1989) and matrix-assisted laser desorption/ionization (MALDI) (Karas and Hillenkamp, 1988). These methods are central to alternative approaches to identify the protein on 2DE gels and have accelerated the development

of proteomics. Mass spectrometry actually measures the mass-to-charge ratio (m/z) of ions under vacuum. To perform this process, a means of generating the necessary ions, a mass analyzer and a detector are required (Patterson and Aebersold, 1995). In proteomic investigation, the most widespread approach is the MALDI time-of-flight (TOF) mass spectrometer, which is used in combination with database searches to identify the protein in a specific spot on 2DE protein maps.

Protein identification by MALDI-TOF mass spectrometry is based on some prior knowledge of the amino acid sequences of likely proteins to be identified or of equivalent proteins in other species. It is dependent on enzymic cleavage of the protein into shorter peptides, the size of which is defined by their component amino acids. Before mass spectrometry, the protein spot to be identified is cut out of the polyacrylamide gel and subjected to hydrolysis by a specific protease, usually trypsin. The site of action of trypsin is at the peptide bond of the basic amino acids lysine and arginine. The trypsin digest products of any proteins whose primary structure is held on international protein databases such as UniProt (www.ebi.uniprot.org) or NCBI (www.ncbi.nlm.nih.gov) can be predicted from the position along the protein sequence of the arginine or lysine residues. The tryptic digest product of any protein whose primary structure can be derived from genetic (DNA) databases can also be determined. These tryptic digest "fingerprints" are characteristic of each protein and identify protein spots after 2DE.

The trypsin-digested sample is mixed with a matrix compound and dried on a metal slide, which is inserted into the mass spectrometer. Bombardment of the slide by a laser results in the ionization of the peptides and application of a high voltage causes the ions to travel rapidly to the detector with smaller ions having a greater velocity. Thus, small peptides have a shorter time of flight than larger peptides, and from this the mass of each peptide is determined to a high degree of accuracy. The data generated by the MALDI-TOF are thus the mass of each of the peptides produced by the trypsin digest of the protein excised from the 2DE gel.

Identification of the protein is completed by comparison of the masses of all the peptides produced by trypsin digest to the protein and gene databases. This is especially useful in species where the whole genome has been sequenced such as human or mouse. There are means to identify proteins by this peptide fingerprint approach even where the genome has not been determined (Wait *et al.*, 2002), though a number of genomes of the domestic species (cow, dog, chicken) are close to being fully sequenced, which will simplify the proteomic investigation of samples from these species. More advanced mass spectrometry using ESI in tandem MS with quadruple instrumentation can directly determine sequences of peptides, but these methods are more time consuming. An advantage of MALDI-TOF is that it can be used in robotic systems where computer-controlled workstations can excise multiple spots from a 2DE gel and automatically perform the trypsin digest, transfer the hydrolysate to the mass spectrometer, and identify the protein as a probability score of the most likely candidate protein.

c. Non-Gel-Based Proteomic Analysis

When first developed, proteomics combined protein separation on 2DE and mass spectrometry. However, for use in diagnostic investigations, 2DE is an expensive, time-consuming, and difficult technique to reproduce precisely. It is likely to remain a research tool unless major advances are made in the robustness of the methodology. Interest is shifting to non-gel-based approaches to proteomics in which alternatives to 2DE are used for protein and peptide separation but with mass spectrometry still being used for identification. These methods have a greater potential for automation, throughput, precision, and accuracy, which may in the future allow their use in disease diagnosis.

One such approach is surface enhanced laser desorption ionization mass spectrometry (SELDI-MS). In this method, a sample such as serum is preincubated with a "protein chip," which has one of a variety of surfaces to which proteins bind with differing affinity. These surfaces are designed to bind with protein by ion-exchange, hydrophobic, or metal chelate interaction. After washing away unbound protein, the protein chip is placed in the SELDI-MS instrument and subjected to mass spectrometry. The system is optimized to identify biomarkers for disease by contrasting samples from healthy and diseased animals. This approach can identify peptide or protein peaks in the mass spectrogram that have potential as biomarkers and has been used to identify biomarkers for ovarian cancer and other diseases in humans (Petricoin *et al.*, 2002). A drawback of the current SELDI-TOF system is that identification of the protein biomarkers requires further investigation by traditional protein biochemistry methods.

Another approach to non-gel-based proteomics is nano liquid chromatography coupled to mass spectrometry. Native proteins are in general too large for mass spectrometry, so before separation the sample is treated with trypsin, producing shorter peptides. The peptides are separated by high-pressure liquid chromatography (HPLC) with the output coupled to an ESI mass spectrometer (Gaskell, 1997; Mehlis and Kertscher, 1997). The results can be plotted with elution volume from the HPLC against the mass/charge (*m/z* ratio) of the peptide and the size of the peptides compared to protein and gene databases.

An interesting finding from a number of proteomic investigations using gel and nongel approaches designed to identify cancer biomarkers has been that many of the identified candidate biomarkers have already been identified with many of them being APP (Diamandis and van der Merwe, 2005). It will be fascinating over the next few years to see if these advanced techniques can earn a role in the veterinary diagnostic laboratory.

D. Specific Protein Analysis

Serum protein is composed of many different individual proteins with current electrophoretic fractionation in routine diagnostic use (SPE) only providing a guide to the disease-related changes affecting serum proteins as only a small number of protein fractions can be consistently characterized. Undoubtedly the ideal diagnostic approach would be to monitor the changes in concentration of most if not all serum proteins, and this is the ultimate objective of proteomic investigation. However, until the technology advances sufficiently, the only means to measure changes in individual serum proteins is to use assays that directly measure the specific proteins. In recent years, there has been increasing success in identifying proteins with sufficient diagnostic value to develop suitable assays to perform routine analysis. Some serum proteins can be measured by methods where physical, chemical, or biological activities can be exploited (Sections V.A.2.b and V.B.2). However, most serum proteins are measured by immunoassay requiring a specific antibody raised against the target serum protein. Though there is cross reactivity between species for a number of serum proteins, it is advisable to use species-specific antiserum or to thoroughly validate assays developed with antisera to species other than the one under investigation.

1. *Immunoassays for Serum Proteins*

Immunoassays have become an established weapon in the arsenal of the clinical biochemistry laboratory, especially where the exquisite specificity of antibody can be harnessed for diagnostic procedures. Antibodies for use in immunoassays for serum proteins can be polyclonal or monoclonal. They are usually raised against the proteins purified from serum, though a recombinant protein may be produced if the gene sequence is known. There are several ways in which antibodies can be incorporated in immunoassays to provide qualitative or quantitative data with the choice of method being dependent on several factors. The range of analyte concentration, time taken to run an assay, and ease of automation are among the considerations taken into account when setting up an immunoassay for a specific serum protein.

a. Radial Immunodiffusion

One of the simplest methods for measurement of specific serum protein is radial immunodiffusion (RID). This method requires polyclonal antibody. The method is based on the precipitation in agarose gel of antigen-antibody complexes, and this does not occur with monoclonal antibodies as more than one binding site on the antigen is required for complex formation. The RID plates are prepared with agarose gel containing antibodies to the protein antigen at an optimized concentration. Sample is placed in a well in the agarose and allowed to diffuse for 24 to 48 hours. A precipitin ring forms because of the antibody-antigen reaction, the diameter of which is dependent on the analyte concentration. The concentration of the protein in the sample is determined by comparison to standards. Radial immunodiffusion assays have been used to measure immunoglobulin and complement in serum and can distinguish between the different classes of antibody (see Chapter 6), and RID assays for acute phase proteins have also been developed (Ohwada and Tamura, 1995; Tamura *et al.*, 1989).

b. Immunoturbidimetry

Immunoturbidimetry (IT) and the related method of immunonephelometry also make use of the formation of antigen-antibody complexes, but in solution rather than in agarose gel. With the correct balance of antigen and antibody, the formation of antigen-antibody complexes can be followed in a spectrophotometer as flocculation occurs and absorbance increases. As the reaction takes as little as a few minutes, this is the method of choice for automation of analysis, but it is only suitable for protein concentrations above 0.5 to 1.0 mg/dl (5 to 10 mg/liter). This method is widely used in human clinical biochemistry for determination of protein such as CRP, but availability of suitable reagents has held back applications in veterinary medicine. However, IT methods for canine CRP (Eckersall *et al.*, 1991) and feline AGP (Bence *et al.*, 2005) have been described. Although commercial kits for human CRP based on IT have been validated for use in serum from some animal species (Kjelgaard-Hansen *et al.*, 2003), care has to be taken in their use, especially as antiserum batches may have differing cross-reactivities with animal protein so that batch-to-batch variation may occur. Immunonephelometry is a related method where reflected rather than absorbed light is measured, which aids in reducing interference. Another modification of the IT test is to make use of antibody-coated latex particles, which can make assays more sensitive as well as stabilizing the antibodies. A method using latex particles coated with antibody to human serum amyloid A has been validated to detect this protein in horses (Jacobsen *et al.*, 2005a; Stoneham *et al.*, 2001).

c. Enzyme-, Luminescent-, and Fluorescent-Linked Immunosorbent Assays

Enzyme-linked immunosorbent assay (ELISA) are a common format for many immunoassays and are used to detect or measure a wide variety of serum analytes including steroid and protein hormones, drug residues, immunoglobulins, and pathogen antigens. They can be performed in a number of formats with antigen or antibody absorbed onto the plastic surface of microtiter plate wells and with primary or secondary antibody being conjugated to a variety of labels to allow sensitive detection. Labels that have been used include enzymes such as horseradish peroxidase or alkaline phosphatase, whereas more recent developments have replaced enzyme labeling with fluorescent

or luminescent labels (Parra *et al.*, 2005a, 2005b). These labels extend the sensitivity and reproducibility of assays. Most immunoassays for specific serum proteins are based on ELISA formats and include assays for canine CRP, porcine and bovine Hp and a cross-species SAA immunoassay that can be used in most species as the antibody shows cross-species specificity for SAA (Eckersall *et al.*, 1989; Eckersall *et al.*, 2001; Hiss *et al.*, 2003; Sheffield *et al.*, 1993; Yule *et al.*, 1997). Immunoassays based on ELISA or related formats have been developed for low-abundance proteins found in serum that are used as biomarkers for disease in particular tissues. Thus, assays have been developed for biomarkers such as troponin I (Spratt *et al.*, 2005) as a cardiac biomarker and trypsin-like immunoreactivity as a biomarker for pancreatic disease and intestinal malabsorption (Fetz *et al.*, 2004; Steiner *et al.*, 2000; Williams and Batt, 1988).

d. Immunochromatography

Attempts have been made to produce immunoassays in formats that can be used in practice or on a farm as point-of-care assays. Latex agglutination has been used in tests in which visible agglutination can be observed and has been used in assays for IgG for confirmation of transfer of antibody from colostrum. A more recent innovation has been the development of immunochromatography in which application of a sample to a test slide leads to diffusion of a sample and reagent along a membrane and appearance of a colored line for a positive result. A test method based on this principle for canine CRP has been produced and was assessed for identification of animals with an acute phase response (McGrotty *et al.*, 2004). This technology should be able to produce rapid, in practice, testing for proteins, particularly when there is a large difference in concentration between health and disease states.

2. *Biochemical Assays*

Apart from albumin and fibrinogen (see Sections V.A and V.B), assays for a number of other serum proteins have been developed based on their chemical, physical, or biological activity. These generally have the advantage that they can be performed on automated biochemical analyzers, do not need the instrumentation required for the more sensitive immunoassays, and are usually applicable in all species.

Haptoglobin, an acute phase protein, can be measured by making use of its high affinity for hemoglobin and subsequent preservation of the peroxidase activity of this protein at low pH. Interference by albumin in this assay was eliminated by use of a novel reagent, which also incorporated the chromogen (Eckersall *et al.*, 1999). Ceruloplasmin, a copper-containing acute phase protein, can be estimated by measuring its endogenous oxidase activity (Ceron and Martinez-Subiela, 2004). Methods have been described for measuring the protease inhibitors, α_1-antitrypsin and α_1-antichymotrypsin (Conner *et al.*, 1988a, 1988b, 1989), based on the specificity of their action, though these assays have not been automated.

3. *Quality Assurance and Quality Control*

An impediment to the greater use of specific protein assays is the lack of primary reference standards for calibration, quality control material, and the availability of quality assurance schemes. None of these is presently available from commercial sources. However, the European Union has funded a project to establish reference material for bovine and porcine serum proteins and to establish a quality assurance scheme, but at the time of the project too few laboratories were running specific protein assays to enable a scheme to be viable (Skinner, 2001). As more interest in the use of specific assays expands, this could be reactivated. Laboratories running the tests routinely should prepare their own material for internal quality control.

VI. NORMAL PLASMA AND SERUM PROTEINS

Although 289 proteins have been reported in human plasma (Anderson and Anderson, 2002), only 70 assays have been validated to the extent of reporting reference intervals. Of these, only about 10 are currently employed for diagnostic testing in domestic animals. Table 5-3 gives an overview of serum proteins, but as proteins are under genetic control, variations occur between individuals and especially between species. Biochemical and pathophysiological features of albumin and several globulins that are being used for diagnosis of disease are described next, grouped by their function(s).

A. Albumin

1. *Biochemistry*

Albumin is the major single protein found in serum and constitutes 35% to 50% of the total serum protein. Bovine serum albumin, when synthesized and secreted by the hepatocytes, is a nonglycosylated protein of 583 amino acids with a molecular weight of 66.4 kDa and a pI of pH 5.6 (accession number P02769, UniProt database at www.ebi.uniprot.org). Based on X-ray crystallographic studies on human serum albumin, the structure is a heart-shaped protein with three homologous domains (Fig. 5-5) (Nakajou *et al.*, 2003) containing 67% of the protein as α-helix with no β-sheet (Curry *et al.*, 1998). A notable feature of the primary structure of albumin is that there is an odd number of cysteine residues (35 in total) so that, after the formation of 14 cysteine-cysteine internal disulfide

TABLE 5-3 Common Serum Proteins, Their Functions, and Changes in Disease

Protein	M_r (Da)	Function	Change in Disease
Prealbumin/Transthyretin	54,500	Thyroxine transport	Increase: nephrotic syndrome, Decrease: liver disease, protein deficiency, acute phase
Albumin	66,400	Osmotic pressure regulation, general transport	Increase: dehydration, Decrease: liver, kidney, gastrointestinal disease, acute phase response, malnutrition, blood, and plasma loss
α-Globulins (α_1 and α_2)			
Thyroxine-binding globulin (TBG)	54,000	Thyroxine transport	Increase: pregnancy
α_1-Fetoprotein	65,000	Unknown	Increase: hepatoma, pregnancy, Decrease: liver disease, chronic pulmonary disease
α_1-Protease inhibitor	45,000	Protease inhibitor	Increase: acute phase response, Decrease: liver disease, chronic pulmonary disease
α_1-Acid glycoprotein (orosomucoid, seromucoid)	43,000	Immunomodulator, binds ligands, and drugs	Increase: acute phase response, Decrease: liver disease, nephrotic syndrome, malnutrition
α_1-Antithrombin III	65,000	Thrombin inhibitor	Increase: possible acute phase response in cats Decrease: disseminated intravascular coagulation, protein-losing nephropathies, and enteropathies sepsis
α_1-Lipoprotein (HDL, α-lipoprotein)	200,000	Lipid transport	Decrease: acute phase response
α_2-Lipoprotein (VLDL, pre-β-lipoprotein)	1,000,000	Lipid transport	Increase: nephrotic syndrome, diabetes mellitus, hypothyroidism, steroid therapy
α_2-Macroglobulin	62,000	Insulin binding, protease inhibitor	Increase: nephrotic syndrome, chronic active liver disease
Ceruloplasmin	151,000	Copper transport, ferroxidase	Increase: acute phase response
Haptoglobin	100,000	Hemoglobin binding	Increase: acute phase response, glucocorticoids in dogs Decrease: intravascular hemolysis
Protein C	62,000	Protease, anticoagulant	Increase: acute phase response
β-Globulins (β_1 and β_2)			
β_2-Lipoprotein (LDL, β-lipoprotein)	2,750,000	Lipid transport	Increase: nephrotic syndrome, hypothyroidism, hepatocanalicular disease
Transferrin	76,000	Iron transport	Increase: iron deficiency, acute liver disease, nephrotic syndrome, chronic hepatopathy, Decrease: iron storage disease, acute phase response, inflammatory disease
Ferritin	465,000	Iron transport	Increase: iron storage disease, acute phase response Decrease: iron deficiency
Hemopexin	80,000	Heme transport	Decrease: hemolytic anemia, chronic active liver disease
C3 complement	75,000	Complement C3 factor	Increase: acute inflammatory disease, atopic dermatitis Decrease: autoimmune disease
C-reactive protein	100,000	Activate complement	Increase: acute phase response
C4 complement		Complement C4 factor	Increase: acute phase respons, Decrease: autoimmune disease
Plasminogen		Proenzyme of plasmin, fibrinolysis	Increase: disseminated intravascular coagulation
Fibrinogen	340,000	Fibrin precursor, coagulation	Increase: acute phase response, Decrease: disseminated intravascular coagulation, hereditary afibrinogenemia

(continued)

TABLE 5-3 Continued

Protein	M_r (Da)	Function	Change in Disease
γ-Globulins (γ_1 and γ_2)			
Immunoglobulin G (IgG)	150,000	Major antibody formed in response to infective agents, toxins	Increase: infectious disease, connective tissue disease, liver disease, myelomas and other lymphoid tumors Decrease: fetuses, newborn animals before intake of colostrum, immune deficiency disease, hereditary agammaglobulinemia
Immunoglobulin A (IgA)	150,000	Secretory antibodies in the fluids of the respiratory, gastrointestinal, and the genitourinary tracts	Increase: infectious disease, connective tissue disease, liver disease, myelomas and other lymphoid tumors Decrease: fetuses, newborn animals before intake of colostrum, immune deficiency diseases
Immunoglobulin E (IgE)	200,000	Antibodies in allergy	Increase: allergies, anaphylaxis
Immunoglobulin M (IgM)	900,000	Antibody formed early in response to infective agents, cold agglutinin, initiator	Increase: inflammatory disease, primary cell reactions, macroglobulinemia (Waldemstrom's)
Light chains (Bence-Jones protein)	30,000	Part of the immunoglobulin molecule	Increase: myeloma

FIGURE 5-5 The molecular structure of human serum albumin (Curry *et al.*, 1998). Note the high proportion of α-helices. Figure generated by Rasmol from UniProt Accession number P02768 and protein database entry 1N5U.

bonds, there is a free cysteine residue, which is important for certain functions of the protein.

Following SPE, albumin is the most prominent band and has the most anodal mobility of the serum proteins in most species resulting from its high proportion of acidic amino acids and a relatively small size. There is variation between species in the mobility of albumin on agarose SPE (see Fig. 5-2), which does correspond to their proportion of

acidic and basic amino acid residues. Porcine albumin has 97 acidic and 83 basic amino acid residues, whereas feline albumin has 100 acidic and 75 basic amino acid residues, and these proportions result in a relatively high mobility for feline albumin and low mobility for porcine albumin.

Albumin is synthesized in the cytoplasm of the hepatocyte, being transferred from bound ribosomes to rough membrane to cisterna, then via the smooth endoplasmic reticulum to the Golgi complex, and through the membrane to the sinusoid (Prinsen and de Sain-van der Velden, 2004). The rate of albumin synthesis is controlled by the colloid osmotic pressure, although it can be influenced by hormones such as insulin, thyroxine, and cortisol (Evans, 2002). Only about 30% to 40% of albumin is in the blood; the remainder is in the interstitial space. Once secreted into the circulation, albumin is modified by covalent, irreversible, but nonenzymic glycation of lysine residues such that 6% to 10% of albumin is in reality glycoalbumin following conjugation to glucose or galactose. This can rise to 20% to 30% in (human) hyperglycemic patients (Nakajou *et al.*, 2003). Catabolism of albumin occurs in various tissues where it enters cells by pinocytosis at a rate related to atrial natriuretic peptide concentration (Evans, 2002) and is then degraded by protease action. Muscle, liver, and kidney are the main contributors to albumin catabolism with 40% to 60% of the total albumin being broken down in these tissues (Prinsen and de Sain-van der Velden, 2004). The turnover of albumin differs with species but is related to the body size (see Table 5-2). The half-time for clearance of albumin varies from 1.9 days in the mouse to 19.4 days in the horse. Whereas originally radioactive isotopes such as I^{131} were required for studies on protein turnover, a new generation of markers based on stable isotopes (Preston *et al.*, 1998; Prinsen and de Sain-van der Velden, 2004) have been introduced, and it could be that diagnostic applications of serum protein turnover rates will prove to be valuable in the future.

2. *Function and Physiology*

Maintaining the colloid osmotic pressure and the blood volume is an important action for albumin and is a function that is disproportionate to its serum concentration. Although albumin is only about 50% of the total protein mass in the circulation, it is responsible for 80% of the colloid osmotic pressure. This is because it has a lower molecular mass (67 kDa) than the mean of the globulins (170 kDa) and also because of its contribution to the Donnan effect from its high net negative charge (Prinsen and de Sain-van der Velden, 2004). Another major function of albumin is as a transport protein. A number of metabolites circulate in blood bound to this protein. Binding to albumin assists the transport of substances that are sparingly soluble in aqueous media and also prevents loss through the kidney of important small molecules. Thus, fatty acids, cholesterol, bilirubin, nitric oxide, and metal ions circulate bound to albumin (Evans, 2002). As well as metabolites, a variety of pharmacological compounds bind to albumin and four discrete sites have been identified on the molecule. Drugs such as phenytoin, digoxin, nonsteroidal anti-inflammatories, and antibiotics interact via these binding sites (Evans, 2002). The exposed cysteine residue of albumin, which does not form an internal disulfide bond, has an important role in the action of albumin as an antioxidant. The free cysteine is an avid scavenger of reactive oxygen and peroxynitrite radicals such that albumin may actually be the major and predominating antioxidant in the circulation (Anraku *et al.*, 2001). Albumin is a negative acute phase protein and its concentration falls gradually during infectious and inflammatory disease.

B. Acute Phase Proteins

Studies on individual serum proteins of domestic animals have expanded greatly since the 1990s (Ceron *et al.*, 2005; Murata *et al.*, 2004; Paltrinieri, in press; Petersen *et al.*, 2004). This has largely been caused by the realization that monitoring the levels of the acute phase proteins (APP) can provide a means to assess the innate immune system's response to disease and in the ability of the APP to provide a "molecular thermometer." As these proteins change their serum concentration by $>25\%$ in response to inflammation, infection, and trauma, many conditions can cause their elevation or decrease. Therefore, as quantitative markers for disease they can be used for prognosis and monitoring responses to therapy, for general health screening, as well as for diagnosis of disease. The APP are highly sensitive for the presence of pathological lesions while having a low specificity for a particular disease. The APP are now recognized as having an important role to play in the diagnosis of disease in animals, but there are major differences between species in the pathophysiological change in their concentrations during an acute phase reaction. Furthermore, although initial interest focused on proteins that increase in concentration during this response (positive APP), a number of serum proteins decrease in concentration and can be considered to be negative APP.

In any one species, positive APP have been found that have major, moderate, or minor responses. A major APP has a low concentration in the serum of healthy animals, often at $<0.1\mu$g/dl ($<1\mu$g/liter) but with the concentration increasing over 100- or 1000-fold on stimulation, reaching a peak 24 to 48 hours after the insult and falling rapidly during recovery. A moderate APP is present in the blood of healthy animals, but on stimulation the concentration will increase 5- to 10-fold, reach a peak concentration 2 to 3 days after stimulation, and decrease more slowly than the major APP. A minor APP shows a gradual increase and only increases in concentration by 50% to 100% of the

TABLE 5-4 Acute Phase Protein: Major and Moderate Responders in Various Animal Species

Species	Major APP	Moderate APP
Cat	SAA	AGP, Hp
Cow	Hp, SAA	AGP
Dog	CRP, SAA	Hp, AGP, Cp
Horse	SAA	Hp
Mouse	SAA	Hp, AGP
Pig	CRP, MAP	Hp, Cp
Rat	α_2-macroglobulin	Hp, AGP

resting level. The major and moderate APPs for domestic species are given in Table 5-4.

Production of APP is controlled by cytokines, with the proinflammatory cytokines interleukin-1, interleukin-6, and tumor necrosis factor–α released from the site of pathogenic or inflammatory damage stimulating the production of the APP. The mechanism of production has been elucidated (Jensen and Whitehead, 1998; Moshage, 1997) and involves cytokine receptor, signaling pathways, and induction of mRNA for the APP, which are released 6 to 12 hours after stimulation. The liver is the main site of synthesis of the APP, but there have been recent reports of nonhepatic tissues such as lung, adipocyte, and intestine increasing expression of mRNA for APP following stimulation (Friedrichs *et al.*, 1995; Urieli-Shoval *et al.*, 1998; Vreugdenhil *et al.*, 1999; Yang *et al.*, 1995). The mammary gland has been shown to be the source of significant amounts of the APP haptoglobin and mammary-associated serum amyloid A during infection of the gland in cattle (Eckersall *et al.*, 2001; Gronlund *et al.*, 2003; Hiss *et al.*, 2004).

The functions of the APPs are varied but generally relate to the defense of the animal to pathological damage and restoration of homeostasis. Indeed the acute phase response is an integral component of the innate immune response (Beutler, 2004) forming the first reaction of the host to pathogens and tissue damage. The innate response and the APP predate the acquired immune response during evolution. Though varied, the functions of many APP can be grouped together. A number of the APP (α_1-antitrypsin, α_2-macroglobulin) have antiprotease activity designed to inhibit proteases released by phagocytes and other cells of the immune system to minimize damage to normal tissues. A number of APP (haptoglobin, SAA, CRP) have scavenging activities and bind metabolites released from cellular degradation so they can reenter host metabolic processes rather than be utilized by pathogen. Other APP actions include antibacterial activity and the ability to influence the course of the immune response (AGP, SAA, CRP).

1. C-R*eactive P*rotein

a. Biochemistry

C-reactive protein (CRP) was the first acute phase protein to be recognized (Pepys, 1981). It is named from its ability to bind to C-polysaccharide of Gram + bacteria, but it has since been shown that CRP has a high affinity for phosphorylcholine and related membrane lipids as well as for DNA (Marnell *et al.*, 2005). The protein is a pentraxin, being composed of five subunits ($\sim$20 kDa) combining in the same plane to form a pentametric structure (Fig. 5-6), which can be seen as a distinct structure using an electron microscope (Thompson *et al.*, 1999). Each subunit of CRP contains a binding site for ligand. Human CRP is nonglycosylated and the subunits migrate as a single band on SDS-PAGE, whereas canine CRP migrates as a double band and two of the five subunits are glycosylated (Caspi *et al.*, 1987).

b. Function and Pathophysiology

Following bacterial infection, CRP binds to pathogen and activates the classical complement pathway leading to the opsonization of the bacteria. Binding of CRP to pathogen also interacts with specific receptors on phagocytes, induces anti-inflammatory cytokine production, and modulates neutrophil function (Du Clos and Mold, 2001).

There is considerable species variation in the pathophysiology of CRP. In a number of species such as dog and pig, CRP is a major APP, and its serum concentration can increase rapidly from $<$0.5 mg/dl ($<$0.5 mg/liter) to more than 10 mg/dl (100 mg/liter). In other species such as cow and cat, CRP has been reported to be a constitutive serum protein with only a minor increase during disease. A number of infectious diseases lead to an increase in CRP in the dog including babesiosis, leishmaniasis, leptospirosis, parvoviruses, trypanosomiasis, and infection with *Bordetella bronchiseptica*, *Ehrlichia canis*, and *Escherichia coli* sepsis (Ceron *et al.*, 2005). Relatively moderately raised levels of CRP have been found in inflammatory bowel disease (Jergens *et al.*, 2003) and in hematological and neoplastic diseases of the dog (Tecles *et al.*, 2005). Elevated levels of canine CRP have been observed in serum from midgestation of pregnant bitches with its appearance coinciding with the implantation of the embryo in the endometrium (Eckersall *et al.*, 1993; Vannucchi *et al.*, 2002). It has been postulated that sufficient damage is caused to the endometrium by this process to stimulate the acute phase response in the maternal circulation.

In the pig, CRP concentration increases following aseptic inflammation (Lampreave *et al.*, 1994) and with experimental infection with *Actinobacillus pleuropneumoniae* where plasma

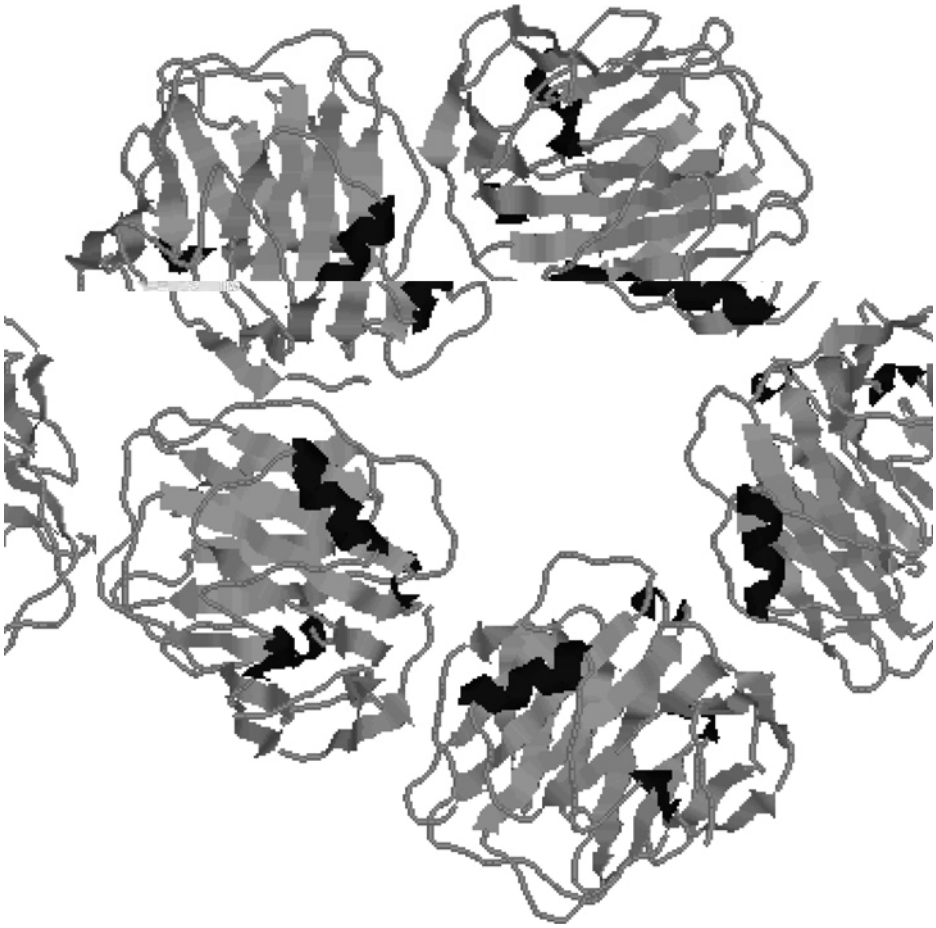

FIGURE 5-6 The molecular structure of C-reactive protein (Thompson *et al.*, 1999). It is a pentraxin with five identical subunits, each of which has a binding site for ligands such as phosphorylcholine. Figure generated by Rasmol from UniProt accession number P02741 and protein database entry 1B09.

levels also correlated with clinical findings and were reduced following antibiotic treatment (Lauritzen *et al.*, 2003).

2. H*aptoglobin*

a. Biochemistry

Haptoglobin is a glycoprotein composed of 2α and 2β subunits with the α subunit having a molecular weight of 16 to 23 kDa and the β subunit 35 to 40 kDa. The subunits combine in the form of a β–α–α–β chain. Human Hp has three subtypes known to be genetic polymorphisms (Hp 1-1, Hp 1-2, Hp 2-2). Canine Hp is thought to be similar to human Hp 1-1, whereas bovine Hp has closer similarities to Hp 2-2. Bovine and ruminant Hp in general have noticeable species differences from the Hp in carnivores and omnivores. In the ruminants, Hp tetramers form polymers with other Hp tetramers and a macromolecular complex with a molecular mass of 1000 to 2000 kDa is formed (Morimatsu *et al.*, 1991). The mechanism of polymer formation in ruminant serum is thought to depend on the presence of a gene duplication in the α-chain, which results in a free cysteine residue capable of forming disulfide bridges between Hp tetramers as occurs in the human Hp 2-2 phenotype (Bowman, 1992). Another difference between Hp in ruminants and many other species is that this protein is not present in serum from healthy animals, only appearing during the acute phase response.

b. Function and Pathophysiology

The primary function of Hp is to bind free hemoglobin in the blood. The affinity of Hp for hemoglobin is one of the highest among transport proteins (Bowman, 1992), and by removing from the circulation any free hemoglobin, which has inherent peroxidase activity, Hp prevents it causing oxidative damage to tissues (Yang *et al.*, 2003). The Hp-hemoglobin binding also reduces the availability of the heme residue and its iron from bacterial use, and therefore Hp has an indirect antibacterial activity (Eaton *et al.*, 1982). The Hp-hemoglobin complex is recognized by CD163, a surface receptor on macrophages, which leads to its rapid removal from the circulation (Graversen *et al.*, 2002). A number of immunomodulatory activities have been ascribed to haptoglobin (Murata *et al.*, 2004). In knockout mice, in which the Hp gene was removed, the

major lesions were related to hemoglobin-derived lipid peroxidation (Lim *et al.*, 1998), confirming that Hp has a role in the antioxidant defenses of the body.

The acute phase profile of Hp differs between species. In ruminants, it is a major APP with circulating levels below 2 mg/dl (20 mg/liter) but it can increase in concentration to reach 0.2 g/dl within a couple of days of infection. In dogs, cats, horses, and pigs, the normal level is in the range of 0.10 g/dl to 0.2 g/dl (1 to 2 g/liter), whereas during infectious or inflammatory disease this may rise to 5g/liter or more. Haptoglobin has been the main APP studied in ruminants because of its reaction during the acute phase response and also because of its ease of analysis. In cattle, it has been shown to be an effective marker for the presence, severity, and recovery in cattle with mastitis, enteritis, peritonitis, pneumonia, endocarditis, and endometritis, and for monitoring processes such as tail docking and surgical castration (Murata *et al.*, 2004; Petersen *et al.*, 2004). Elevations have also been reported in cows with fatty liver syndrome, at parturition, during starvation, and following the stress of road transport (Ametaj *et al.*, 2005; Bionaz *et al.*, 2007; Katoh and Nakagawa, 1999; Nakagawa *et al.*, 1997; Uchida *et al.*, 1993). Increases of APP during noninfectious disease that involve lipid metabolism may be explained by the release of cytokines from adipose tissue or adipose tissue macrophages that have been implicated in human obesity-related diseases (Tilg and Moschen, 2006).

In pigs, raised Hp was found to be associated with clinical signs of lameness, respiratory disease, diarrhea, tail bite, and ear necrosis, and at slaughter it was found to be related to the presence of lesions and chronic abnormalities. Experimental or natural infection with *Actinobacillus pleuropneumoniae*, *Mycoplasma hyorhinis*, *Toxoplasma gondii*, *Bordetella bronchiseptica*, *Pasteurella multocida*, and porcine reproductive and respiratory syndrome virus leads to increased Hp concentration in serum (Petersen *et al.*, 2004).

Haptoglobin is a moderate APP in dogs and responds to inflammatory and infectious disease. However, canine Hp is particularly sensitive to glucocorticosteroids, and elevated levels of Hp are found both after treatment with glucocorticosteroids and during naturally occurring hyperadrenocorticism (Harvey and West, 1987; Martinez-Subiela *et al.*, 2004; McGrotty *et al.*, 2005). This is a disadvantage in monitoring inflammatory disease with canine Hp, but a full understanding of this process may reveal novel uses for the Hp assay, possibly as a screening method for Cushing's syndrome. The glycosylation of canine Hp alters during the acute phase reaction (Andersson and Sevelius, 2001; Andersson *et al.*, 1998), but methodology is currently too cumbersome to allow such changes to be used for diagnostic purposes. In horses, Hp has been found elevated in animals with systemic inflammatory responses, alimentary laminitis, and grass sickness (Fagliari *et al.*, 1998; Hulten *et al.*, 2002; Milne *et al.*, 1991). Little information is available on the pathophysiology of Hp in cats. It is removed from blood within a few hours after binding free hemoglobin in plasma (Harvey and Gaskin, 1978), and levels are elevated in feline infectious peritonitis and other inflammatory disorders (Duthie *et al.*, 1997).

3. *Serum Amyloid* A

a. Biochemistry

Serum amyloid A (SAA) is a small hydrophobic protein (9 to 14 kDa) that is found in serum associated with high-density lipoprotein (HDL). In humans, four isoforms have been identified that are separate gene products (Jensen and Whitehead, 1998). Of these, SAA1 and SAA2 respond to an acute phase reaction with increasing production from the liver. In contrast, SAA4 is a constitutive protein that is produced normally at a low level and is not affected by the acute phase response. The SAA3 is expressed in nonhepatic tissues during the acute phase response with increases found in lung (Wilson *et al.*, 2005), adipose tissue (Fasshauer *et al.*, 2004), ovarian granulosa (Son *et al.*, 2004), and in the mammary gland (Weber *et al.*, 2006). This isoform has also been detected in bovine colostrum (McDonald *et al.*, 2001). Serum amyloid A is the precursor of amyloid A and is therefore implicated in the pathogenesis of amyloidosis (Uhlar and Whitehead, 1999).

b. Function and Pathophysiology

A number of functions have been ascribed to SAA including reverse transport of cholesterol from tissue to hepatocytes, inhibition of phagocyte oxidative burst, platelet activation, and a number of *in vitro* immune responses (Petersen *et al.*, 2004). A direct antibacterial action of SAA was described in which SAA was found to bind to Gram-negative bacteria leading to opsonization of the target bacteria (Hari-Dass *et al.*, 2005). It has been demonstrated that the M-SAA3 isoform found in colostrum stimulates the production of mucin from intestinal cells assisting the initiation of secretions from the neonatal intestine and helping to prevent bacterial colonization (Larson *et al.*, 2003; Mack *et al.*, 2003).

It is only relatively recently that immunoassays became available for measuring the concentration of SAA, but it is already apparent that this analyte will be of great value in monitoring the acute phase response, especially in species in which CRP is not a major APP. Therefore, in ruminants, horses, and cats, SAA assay may become a routine analysis included in the assessments of infection and inflammation. In cattle, SAA has been identified as a marker of inflammation being elevated more in acute rather than chronic conditions (Horadagoda *et al.*, 1999). It was raised also by experimental infection with *Mannheima haemolytica*, with bovine respiratory syncytial virus, and in experimental and natural cases of mastitis (Eckersall *et al.*, 2001; Gronlund

et al., 2003; Heegaard *et al.*, 2000; Horadagoda *et al.*, 1994). The mammary isoform of SAA (M-SAA3), which is expressed and secreted in milk from mammary glands of dairy cows with mastitis (Eckersall *et al.*, 2001; Jacobsen *et al.*, 2005b; Nielsen *et al.*, 2004; Winter *et al.*, 2003), is also found in milk from ewes with this condition (Winter *et al.*, 2003).

In the horse, SAA is a major APP with a large dynamic range between the resting level in the healthy animal and the concentrations obtained in serum from horses with infection or inflammation (Jacobsen and Andersen, 2007; Pepys *et al.*, 1989; Stoneham *et al.*, 2001). Increased SAA concentrations have been observed in horses following surgery, with aseptic inflammation or arthritis, septicemia, enteritis, pneumonia, and diarrhea (Petersen *et al.*, 2004). Measurement of the SAA concentration was found to be of value in diagnosis of horses with colic, especially where inflammation was the primary component of the pathogenesis (Vandenplas *et al.*, 2005). Experimental infections with equine herpesvirus and influenzavirus have also resulted in an increase in the SAA concentration (Hulten *et al.*, 1999; Pepys *et al.*, 1989).

Determination of the SAA concentration may be similarly useful in cats as it was shown to be the most rapidly responding APP in a variety of inflammatory and infectious conditions (Kajikawa *et al.*, 1999), and the cat is another species where CRP does not show a major response. In the dog, the circulating concentration of SAA does increase during an acute phase response and has been observed in experimental parvovirus infection (Yule *et al.*, 1997) and in leishmaniasis (Martinez-Subiela *et al.*, 2002a). However, with CRP becoming the primary canine APP, it is likely that SAA will be used in a secondary role in monitoring the acute phase response in this species. The relationship of serum concentration of SAA with familial amyloidosis as encountered in Siamese and Abyssinian cats and Chinese shar-pei dogs remains to be fully elucidated (Johnson *et al.*, 1995; Niewold *et al.*, 1999).

4. α-1 *Acid Glycoprotein*

a. Biochemistry

Alpha-1 acid glycoprotein (AGP) is one of the most highly glycosylated proteins in serum with a molecular mass of around 43kD, of which approximately 45% is covalently linked carbohydrate. These branched carbohydrate side chains are composed of linked monosaccharides such as mannose, galactose, and glucose with the final group in the chain usually being sialic acid (N-acetyl-neuraminic acid). Thus, negatively charged groups are located at the end of each chain leading to the low pI of AGP of 2.8 to 3.8. The sialic acid residues are also important for the structure of the protein. Studies on feline AGP have revealed that its branching degree was very low and that a decrease in sialic acid expression occurred during infection with feline infectious peritonitis virus (Ceciliani *et al.*, 2004). In feline leukemia virus infections, the degree of sialylation was reduced in cats diagnosed with lymphoma (Pocacqua *et al.*, 2005). In contrast, feline AGP from cats with feline immunodeficiency virus infection showed a wide range of variation of the glycan chains.

b. Function and Pathophysiology

Though the precise role of AGP is not clear, it does bind to a number of endogenous metabolites such as heparin, histamine, serotonin, steroids, and catecholamines (Israili and Dayton, 2001). A related action of AGP is its ability to bind to pharmacological compounds. This ability to bind to drugs may have therapeutic implications as the amount of drug bound can affect the free concentration of drug, which is the metabolically active fraction. Increased AGP because of an acute phase response may reduce the concentration of free drug and could therefore affect pharmokinetics (Ikenoue *et al.*, 2000). The ability of AGP to bind low-molecular-weight ligands may also have a general protective role as it binds to toxic lectins and endotoxins. AGP also has several putative roles in the innate defense against infection and modulating the immune reaction. It can inhibit the attachment of *Mycoplasma pneumoniae* to alveolar macrophages and can inhibit some strains of influenza-virus. Furthermore, phagocytosis, neutrophil activation, and platelet aggregation are inhibited by AGP, and it may have a role in the maturation of T- and B-lymphocytes. (Israili and Dayton, 2001). A biologically important alteration of the glycosyl residue on AGP is the expression during inflammatory disease of the sialyl Lewis-X antigen, which is one of the major groups expressed on leukocytes and is involved in leukocyte migration across the endothelium (Degraaf *et al.*, 1993).

In most species, AGP is a moderate APP increasing more slowly but also remaining elevated for longer than the major APP such as canine CRP or bovine SAA and Hp. However, this may be advantageous in diagnosis in that inclusion of AGP in an acute phase profile would provide information on conditions as they move from acute to chronic. In a study of inflammatory disease in cattle, serum from animals with chronic conditions had a higher proportion of raised AGP than either SAA or Hp (Horadagoda *et al.*, 1999). Indeed the term "acute phase protein" is in some ways a misnomer as it is not just acute conditions that lead to the elevation of APP. Continued production of at least some APP in chronic or subclinical disease may be of equal importance to their appearance in acute conditions, which can be more obvious to diagnose.

Feline AGP was found to be raised, though not as rapidly as SAA, in a variety of inflammatory and infectious diseases as well as postsurgery (Kajikawa *et al.*, 1999). The measurement of AGP in feline serum and peritoneal fluid has become a recognized differential test for the identification of feline infectious peritonitis (Duthie *et al.*, 1997;

Giordano *et al.*, 2004). Raised levels of AGP have also been reported in tumor-bearing cats (Selting *et al.*, 2000) including those with lymphoma (Correa *et al.*, 2001), though in the latter study the AGP concentration was not prognostic for survival.

In the pig, AGP has been the subject of contrasting experience. AGP concentration was shown to be raised in pigs with naturally occurring pneumonia and meningitis (Itoh *et al.*, 1993b), but in studies where aseptic inflammation caused an acute phase reaction, the AGP concentration was not significantly affected (Eckersall *et al.*, 1996; Lampreave *et al.*, 1994). Furthermore, an experimental model of porcine reproductive and respiratory syndrome virus showed no increase in serum concentration of AGP, whereas Hp increased (Asai *et al.*, 1999). However, AGP was elevated and negatively correlated to body weight in a study of the effects of stress and immune function (Grellner *et al.*, 2002). In the newborn pig, AGP is present at 40 times the adult level with the concentration falling more rapidly in specific pathogen-free animals than in animals exposed to the normal pathogens encountered in production (Itoh *et al.*, 1993b). It is important to interpret AGP levels in the pig with regard to age as the elevated levels found at birth take about 20 weeks to fall to adult levels.

5. Fibrinogen

Fibrinogen is a large protein of 340 kDa that constitutes nearly 5% of the total plasma protein and migrates with a β mobility, though it is usually excluded from electrophoretic analysis as serum is the preferred sample. It is composed of three domains linked by disulfide bridges and contains 3% to 5% carbohydrate (Doolittle *et al.*, 1998) (Fig. 5-7). Fibrinogen is a moderate APP such that in a study of arthritis in the horse, the rise in fibrinogen was 0.87 times the baseline concentration, whereas Hp was increased by 1.14 times and SAA by 227 times (Hulten *et al.*, 2002). However, in terms of mass of protein it

FIGURE 5-7 The molecular structure of D-fragment of fibrinogen (Doolittle *et al.*, 1998). Fibrin formation occurs with formation of bonds between adjacent chains following removal of fibrinopeptides by thrombin action. Figure generated by Rasmol from UniProt accession number P02671 and protein database entry 1FZA.

represents the greatest proportion of plasma protein synthesized during an acute phase response. Calculations have been made in human medicine that during an acute phase reaction approximately 12 g of muscle tissue has to be degraded to provide the amino acids for 1 g of fibrinogen, which, in common with most APP, has a higher proportion of aromatic amino acids than muscle protein (Preston *et al.*, 1998). Assays for plasma fibrinogen have been available for a long time. It is more consistently increased during inflammation in horses and cattle than it is in dogs and cats. The measurement of low plasma fibrinogen supports a diagnosis of disseminated intravascular coagulation (Mischke *et al.*, 1998), but it is not consistently decreased in disseminated intravascular coagulation.

6. Pig Major Acute Phase Protein (Inter-Alpha-Trypsin Inhibitor Heavy Chain 4)

During the acute phase response in pigs, a major acute phase protein (pig MAP) can be detected (Lampreave *et al.*, 1994) and has been identified as porcine inter-alpha-trypsin inhibitor heavy chain 4 by comparison to the equivalent human protein (Gonzalez-Ramon *et al.*, 2000). This protein of molecular mass 120 kDa is inducible by IL-6 in hepatocyte culture. In serum during the acute phase response, its concentration can increase by a factor of 30 compared to healthy levels. Increases have been shown during infection with *A. pleuropneumonia* (Heegaard *et al.*, 1998), in post-weaning multisystemic wasting disorder (Segales *et al.*, 2004), and following transport (Saco *et al.*, 2003). A bovine equivalent of this protein has been described that also displays an acute phase response (Pineiro *et al.*, 2004).

7. Negative Acute Phase Proteins

Negative acute phase proteins are serum proteins that decrease in concentration by greater than 25% during the acute phase in response to infection, inflammation, and trauma. The mechanism for the decrease in concentration is not clear, but it can be rapid with significant reduction found after 24 hours or it may be a more gradual decrease over a period of days. Serum albumin is a negative acute phase protein, and the concentration of this protein falls gradually with the reduction in concentration being more noticeable in chronic inflammatory disease. Transferrin, the iron transport protein of serum (Gomme and Mccann, 2005), has also been described as a negative APP, but the major diagnostic application of measuring its serum concentration is in relation to its role in diseases of iron metabolism (Chapter 9). Its analogue in chickens, ovatransferrin, is a positive APP (Tohjo *et al.*, 1995; Xie *et al.*, 2002a, 2002b).

More rapidly reacting negative APP have been identified. Porcine apolipoprotein A-1 (Navarro *et al.*, 2004) decreased in concentration by 50% to 80% within 2 to 5 days of experimental infection with *Streptococcus suis or A. pleuropneumoniae* (Carpintero *et al.*, 2005). As this apolipoprotein is associated with HDL, it appears to have a reverse relation with SAA (which also binds to this lipoprotein). Transthyretin (TTR) and retinal binding protein (RBP) are related transport proteins, which in rats show a decrease during the acute phase reaction (Rosales *et al.*, 1996), but their pathophysiology has not been fully elucidated in domestic animals. In addition, the interpretation of a fall in serum concentration of these proteins is complicated because they are also affected by nutritional status. TTR is a thyroxine binding protein, which in human serum has a higher electrophoretic mobility than albumin and was therefore originally known as prealbumin. However, in most domestic species, TTR has a lower mobility and no prealbumin is observed (see Fig. 5-2). In the circulation it forms a complex with RBP, which in turn binds to retinol (vitamin A). Infection of pigs with *S. suis* caused a significant reduction of the TTR concentration in serum, showing that it was a negative APP in this species (Campbell *et al.*, 2005).

C. Complement Proteins

Complement is a group of interacting serum proteins that participate in a cascade of reactions, resulting in opsonization of foreign cells and particles (Gorman and Halliwell, 1989a). Complement is activated by the "classical" or "alternative" pathways, terminology based on the time frame of discovery rather than on the relative importance of the pathway concerned. The complement proteins are a series of zymogens, which on activation are able to specifically activate another member of the cascade by proteolytic cleavage. Activation of the classical pathway occurs by binding of complement C1q to initiating factors such as antigen-antibody complexes or C-reactive protein bound to bacterial pathogen. The alternative pathway does not need antibody for activation but can be stimulated by mediators such as parasites, viruses, bacteria, and tumor cells. Both pathways lead to the formation of a membrane attack complex composed of components C5, C6, C7, C8, and C9, which cause lysis of cell membranes. More than a dozen complement proteins have been identified, but apart from a minor positive acute phase response that has been observed for component C3, the most use in diagnosis of disease is in assessment of complement deficiency in relation to immune function. These are covered in Chapter 6 as part of the discussion on clinical immunology.

D. Immunoglobulins

On SPE, most immunoglobulins are found in the γ-globulin fraction, which can be differentiated into γ_1 and γ_2. Of

the immunoglobulins observed in animals, IgA, IgM, and IgE are found primarily in the γ_1 region (and to some extent in the β_2 region), and IgG is found primarily in the γ_2 region. The specific identification and quantification of the immunoglobulins require the use of immunochemical techniques (Section V.D.1). A brief description of the immunoglobulins is given here as a basis for understanding the interpretation of dysproteinemias visualized on SPE. More thorough coverage is given in Chapter 6 on clinical immunology.

1. *Source of Immunoglobulins*

Immunoglobulins act as antibodies and are produced in response to antigens. They are highly specific if only one antigenic determinant is involved. In nature, however, multiple antigenic determinants are usually involved. The lymphocytic cell line plays the central role in the immune system. There are two subpopulations, the B lymphocytes (bursa) and the T lymphocytes (thymus), which can be identified by special immunological means. The T cells are found in blood and in lymph nodes in the deep cortical areas and paracortical sinuses. They are associated with cell-mediated immunity. The B cells were originally identified in the bursa of Fabricius of the chicken. In the adult, they are found in the blood and in the germinal centers of lymph nodes. The B cells respond to antigenic stimuli with the proliferation of plasma cells that produce the specific antibody against the stimulating antigen. Five immunoglobulin classes, IgG, IgA, IgM, IgD, and IgE, have been identified in humans but in most domestic animal species only IgG, IgA, IgM, and IgE are evident, although IgD may be rarely expressed (Gorman and Halliwell, 1989b).

A specific plasma cell population of defined genetic origin—a clone—produces a specific immunoglobulin. Uncontrolled growth of a single B-cell clone (malignancy) results in the overproduction of a single chemical species of immunoglobulin, which appears as a sharp "monoclonal" spike or monoclonal gammopathy on an electrophoretogram. Occasionally, a "biclonal" or "triclonal" gammopathy can be identified. A group of clones, each of a different genetic origin, can also overproduce a heterogeneous mixture of immunoglobulins, which appears as a diffuse or broad hyperglobulinemic region on the electrophoretogram. This region is described as a "polyclonal" gammopathy.

2. *Structure of Immunoglobulins*

The immunoglobulins are glycoproteins whose basic structure is comprised of two heavy (H) and two light (L) chains linked by disulphide bridges with a molecular mass of 150 kDa. The structure of the H chain governs the class of immunoglobulin and is named by corresponding Greek letters: γ in IgG, μ in IgM, α in IgA, ε in IgE, and δ in IgD. The structure of the L chain is either kappa (κ) or lambda (λ) and denotes type. Structural variations in the variable regions of H or L chains provide a basis for further subdivision into subtypes and subclasses. To date, four subclasses of IgG have been identified in humans (IgG1, IgG2, IgG3, and IgG4), with two identified in cattle (IgG1 and IgG2), four in dogs (IgG1, IgG2a, IgG2b, and IgG2c), and three in horses (IgGa, IgGb, and IgGc). The horse also has IgG(T). This was originally recognized in horses used to produce antitetanus toxoid, and although it has a higher mobility than γ-globulins, its amino acid sequence showed it was more closely related to IgG (Gorman and Halliwell, 1989b).

IgG, IgD, and IgE are monomers; IgA is a dimer; and IgM is a pentamer. Most viral, bacterial, and toxin antibodies are of the IgG type and are present in all animals. IgE is involved in allergic and anaphylactic reactions, whereas IgA is found in the secretions of the respiratory, genitourinary, and gastrointestinal tracts. IgA is a dimer of two basic units joined by a secretory piece. IgM is a cyclic pentamer of five basic units that forms a high-molecular-weight unit. These are the macroglobulins or "M" components.

The Bence-Jones proteins are light-chain units, and their presence reflects the asynchronous synthesis of H chains so that excess L chains appear and are secreted in urine. They are not detected on SPE, but they can be detected by immunochemical techniques and are often found to accompany gammopathies (Solomon, 1976), especially multiple myelomas.

E. Lipoproteins

A significant amount of protein in serum is associated with lipid in the form of lipoproteins. These microscopic particles are composed of a lipid core containing hydrophobic molecules such as triglyceride and cholesterol ester with a phospholipid monolayer on the surface. The apolipoproteins are proteins that help to stabilize the structure of the lipoproteins and also have biological activity related to their function of transporting the immiscible lipids through the aqueous environment of the circulation. Lipoproteins can be characterized according to their electrophoretic mobility (α-, β-lipoprotein) but are now mainly classified by their density as determined by ultracentrifugation. The main classes are very low density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). These are involved with lipid transport between the liver and peripheral tissues. There is a further class of lipoprotein, the chylomicrons, which are involved in the transport of dietary lipid from the intestine. Lipoproteins are the subject of extensive research in human medicine, especially in relation to diagnosis of diseases of the cardiovascular system, but in domestic animals their analysis is not a frequently requested test. The lipoprotein profile in horses and dogs has been established (Watson, 1996; Watson and Love, 1994) and can be altered in disease,

but these aspects are more fully explored in Chapter 4 lipids.

F. Other Serum Proteins

A number of other serum proteins of domestic animals have been studied but have not been fully investigated for diagnostic purposes.

The antiproteases, α_1-antitrypsin and α_1-antichymotrypsin have moderate acute phase responses in cattle and dogs, and an antielastin was also identified in dogs (Conner *et al.*, 1988b). Ceruloplasmin, a copper-containing serum protein that has inherent oxidase activity, is involved in iron metabolism and is also a moderate APP (Ceron and Martinez-Subiela, 2004; Martinez-Subiela *et al.*, 2002b).

Among the collectins (Gabius, 1997), mannan-binding protein, conglutinin, and collectin-43 have been investigated in cattle (Kawai *et al.*, 1997; Krogh-Meibom *et al.*, 2004a, 2004b). A low level of conglutinin was found to be associated with reduced resistance to disease and could be used as a breeding trait to produce animals with increased resistance (Holmskov *et al.*, 1998). Lipopolysaccaride-binding protein, which as its name suggests is able to bind to bacterial endotoxin (lipopolysaccharide), has been shown to be a moderate APP in cattle (Horadagoda *et al.*, 1995; Schroedl *et al.*, 2001).

G. Multiplex Assays, Protein Arrays, and Acute Phase Index

Advances in proteomics and in genomics have stimulated investigations of multiple analytes in an organism, cell, tissue, or biological fluid. Gene arrays have been developed that can monitor the expression of several thousand genes in a tissue sample at the same time. An objective of proteomics is to be able to perform a similar feat for protein, but the technology is still some distance from use in the clinical biochemistry laboratory (Anderson and Anderson, 2002). A step toward the examination of the complete serum proteome would be made if it were possible to measure the concentration of a number of proteins in the same aliquot of sample. To achieve this goal, multiplex assay systems are being developed in which numerous immunoassays can be run simultaneously. One such system uses fluorescently labeled beads with differing emission characteristics for different proteins, which can be quantified simultaneously (Pang *et al.*, 2005). Another novel multiplex system uses an array of antibody-based reagents for different protein analytes immobilized on a biochip surface (Molloy *et al.*, 2005). These multiplex assays may find a role in the clinical biochemistry of domestic animals if they can be developed and validated for individual species.

Interpretation of data from multiple assays will be a challenge for the clinical biochemist involved in serum protein analysis. It is possible that the relative change in concentrations of groups of proteins will provide more useful diagnostic information than that obtained by simply interpreting the changes in concentration of individual proteins. Advanced statistical methods—for instance, using neural network analysis (Chen *et al.*, 2004)—may be needed for implementation of such analysis, but bioinformatics is exploiting the application of mathematics, statistics, and computing to biological systems. However, combination of results from individual analyte tests is not new. Use of the albumin-globulin ratio to improve diagnosis is a simple example of this approach. Combination of results from individual acute phase proteins can increase the diagnostic value of the tests involved. This has been developed as an "acute phase index" with a formula proposed of (major positive APP) × (moderate positive APP) divided by (major negative APP) × (moderate negative APP), which increased the sensitivity and specificity of analysis (Toussaint *et al.*, 1995)

VII. INTERPRETATION OF SERUM PROTEIN PROFILES

The determinations of serum proteins and their SPE profiles are important diagnostic aids in clinical biochemistry, even though a specific diagnosis can seldom be made with SPE. Abnormal serum protein profiles can be identified with general types of disease processes and in this way provide the rationale for further definitive studies of the patient. Various electrophoretograms illustrating some common applications in different species are given in Figures 5-8 and 5-9. Inclusion of total protein and albumin assays in automated systems to provide the albumin-to-globulin ratio (A:G) enhances the analysis. A change in the A:G ratio is often the first signal of a protein dyscrasia, which leads to further study of the proteins by SPE. Reference values for total serum protein and its fractions in animals and birds are given in Appendices VIII, IX, and X.

A. Physiological Influences

Abnormalities of SPE must be interpreted in light of the many influences not associated with disease. However, normal physiological variations within an individual are relatively constant over a considerable period of time; therefore, even minor changes in the SPE profile can be of significance and warrant close scrutiny.

1. *Influence of* Age, Development, *and* Breed

In the fetus, the concentration of total protein and albumin progressively increases with little change in total globulins and an absence of γ-globulin. After birth, and with colostral uptake during the first 24 hours, the SPE changes to reflect

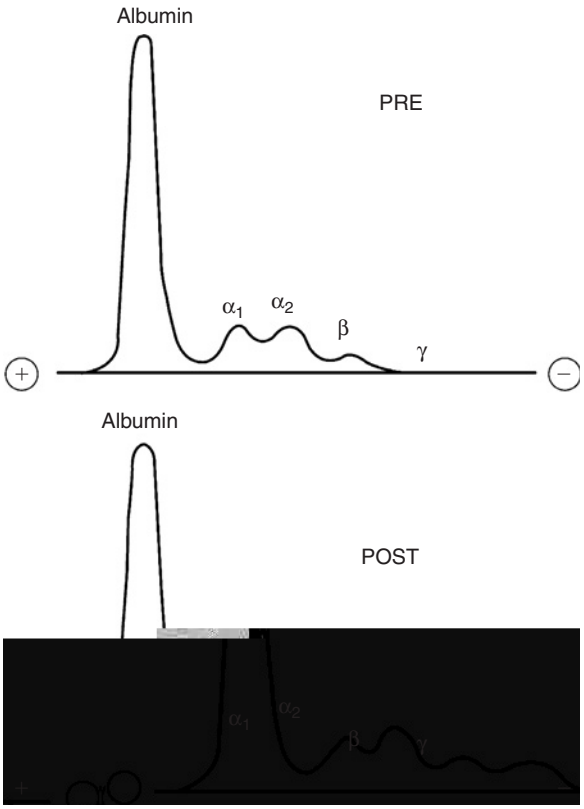

FIGURE 5-8 Densitometer trace of serum protein electrophoresis on agarose gel from calf before feeding with colostrum (upper) and after feeding with colostrums (lower).

the absorption of immunoglobulins. Baby pigs acquired large amounts of γ-globulin, which progressively decreased to 5% of the total serum protein by 4 weeks of age (Rutqvist, 1958). In the calf, precolostral serum normally contains no γ-globulin, but within a few hours after ingestion of colostrum, γ-globulin appears in serum (see Fig. 5-8) and absorption continues for up to 36 hours after birth after which closure occurs (Weaver *et al.*, 2000). In colostrum-deprived calves, immunoglobulins increase only minimally. In the developing foal from birth to 12 months of age, progressive increases in albumin, globulins, and total proteins are also seen (Bauer *et al.*, 1984; Rumbaugh and Adamson, 1983).

Over the life span of animals, there is a general increase in total protein, a decrease in albumin, and an increase in globulins with advancing age. However, in the very old, the total plasma proteins again decline. Thus, age is an important consideration in the interpretation of the SPE. Breed may also affect serum proteins. Retired greyhounds were found to have significantly decreased α- and β-globulins in comparison to age- and gender-matched nongreyhound controls (Fayos *et al.*, 2005).

2. Hormonal and Sexual Influences

Hormones can have anabolic or catabolic effects on serum proteins. Testosterone and estrogens are generally anabolic in all species. Growth hormone is another well-known anabolic hormone with similar effects. On the other hand, thyroxine decreases total serum protein, most likely because of its catabolic effect. The glucocorticoids have not been reported to have a major effect on SPE except in the dog where prednisolone injection was shown to cause an increase in α_2-globlins with the rise shown to be due to the induction of haptoglobin (Harvey and West, 1987). Otherwise hormonal effects of serum proteins are slight even though their effects on weight gains or body composition may be quite marked.

3. Pregnancy and Lactation

During gestation, maternal albumin decrease and the globulins increase in some species. In ewes, albumin decreases to a minimum at midgestation and returns to near normal at term, whereas globulins and the total serum protein progressively decrease throughout gestation (Dunlap and Dickson, 1955). In cows, the total serum protein and γ_1-, and β_2-globulins begin to increase at 2 months before term, reach maximum values at 1 month, and then rapidly decline toward term (Larson and Kendall, 1957). This reflects the transport of immunoglobulins from serum to the mammary gland that begins several weeks before parturition, reaching a peak 1 to 3 days before birth of the calf (Weaver *et al.*, 2000). Lactation and egg production impose further stresses on protein reserves, and metabolism and changes similar to pregnancy may also occur. However, no changes in serum albumin or total globulin concentrations were measured in horses during gestation or lactation (Harvey *et al.*, 2005).

4. Nutritional Influences

The plasma proteins are sensitive to nutritional influences, but the changes are often subtle and difficult to detect and interpret. In a study in Holstein heifers, increasing the proportion of crude protein in the diet from 8% to 15% increased total serum protein and albumin, but the albumin: globulin ratio stayed the same at 1.09 (Hoffman *et al.*, 2001). Increases in α-globulin and decreases in γ-globulin fractions were found in ostriches fed a high-protein diet (Polat *et al.*, 2004). In contrast, total serum protein was not affected in pregnant mares by substantial differences in dietary protein quantity and quality, even though the foal mass decreased by 25% (vanNiekerk and vanNiekerk, 1997).

5. Stress and Fluid Loss

Temperature stress, either fever or hypothermia, is associated with nitrogen loss, increased adrenal activity, and increased protein turnover. These stresses cause a decrease in total serum protein and albumin, but they often cause an increase in α_2-globulin associated with the acute phase response. Similar findings are observed in crushing injuries, bone fractures, and extensive surgery. In the inflammatory

process, fluids and proteins move into the tissues, inducing edema and contributing to a decrease in plasma albumin. Hemorrhage or massive exudation with large external losses of plasma is followed by a rapid movement of interstitial fluid (without protein) into the plasma compartment to induce an acute hypoproteinemia. Conversely, dehydration leads to hemoconcentration through reduction in fluid volume and consequent hyperproteinemia. During splenic contraction in the horse, a large mass of erythrocytes moves into the circulation with little or no change in the serum protein.

B. The Dysproteinemias

The current method of choice for the overall evaluation of protein status remains SPE on cellulose acetate or agarose gel. The SPE profile and the absolute values of the individual fractions provide an excellent basis for presumptive diagnoses and for additional studies of the patient. The A:G ratio derived from chemistry panels or from the SPE is the basis on which the SPE can be interpreted.

Classification of the SPE profile in conjunction with the A:G ratio provides a systematic approach to the interpretation of protein dyscrasias. Table 5-5 gives such a classification of the SPE results based on the A:G ratio and the nature of the profile. This table provides a useful vehicle for alerting the clinical biochemist and the clinician to the underlying significance of the specific dysproteinemia.

1. N*ormal* A:G—N*ormal* P*rofile*

a. Hyperproteinemia

Simple dehydration with water loss is essentially the only instance when a simple hyperproteinemia without change in profile or A:G occurs. In this case, all protein fractions increase proportionately, including albumin, because only water has been removed from the system.

b. Hypoproteinemia

Overhydration through vigorous fluid therapy or excess water intake is a common cause of simple hypoproteinemia. This is simply a dilution of the system. In other instances, for example, after acute blood loss, interstitial fluid moves rapidly into the plasma compartment, thus diluting the system. This dilution may be further intensified by the ingestion of water to satisfy the thirst commonly seen in acute blood loss. Similarly, after acute plasma loss, whether internal or external, by exudation or extravasation, simple hypoproteinemia occurs because movement of interstitial water into the plasma compartment rapidly replaces the water losses.

2. D*ecreased* A:G—A*bnormal* P*rofile*

a. Decreased Albumin

Decreased albumin is a common form of dysproteinemia. Fundamentally, the decrease can be attributed to either albumin loss or failure of albumin synthesis. Depending on the stage of the disease, it can be associated with either slight hyperproteinemia (acute stage), normoproteinemia (progressive stage), or, in its advanced stages, hypoproteinemia. Therefore, the total serum protein is not a reliable index of albumin status and albumin must be determined.

Because of its small size and osmotic sensitivity to fluid movements, albumin is selectively lost in renal disease (Grauer, 2005), gastrointestinal disease, (Kaneko *et al.*, 1965; Meuten *et al.*, 1978), and in intestinal parasitism (Dobson, 1965). The hypoalbuminemia of intestinal parasitism is aggravated by increased albumin catabolism (Cornelius *et al.*, 1962; Halliday *et al.*, 1968; Holmes *et al.*, 1968). Furthermore, because of the sensitivity of albumin synthesis to protein and nitrogen loss such as that occurring in some forms of gastrointestinal disease, albumin loss impairs albumin synthesis and further compounds the hypoalbuminemia. Because of this same sensitivity of albumin synthesis to protein and nitrogen availability, decreased albumin concentration precedes the development of generalized hypoproteinemia in dietary protein deficiencies. Classic human protein-calorie malnutrition, kwashiorkor, is characterized by hypoalbuminemia and hypoproteinemia.

The liver is the only site of albumin synthesis, and hypoalbuminemia is an important feature of chronic liver disease and when accompanied by marked decrease in total protein is indicative of terminal liver cirrhosis (Sevelius and Andersson, 1995). In the horse, a unique postalbumin shoulder with or without a hypoalbuminemia suggests liver disease. Additionally, albumin is a negative APP and extensive inflammation accompanying any of the aforementioned conditions may compound the hypoalbuminemia.

b. Increased Globulins

i.* α-*Globulins α_1-Globulin but mainly α_2-globulin increases are commonly found and are of diagnostic significance. Many of the APPs (Section VI.B) migrate in the α_1- and α_2-globulin regions (Table 5-5) so that increases in these globulins are a common finding in acute inflammatory diseases and represent an acute phase response. Increases in α-globulins can be accompanied by increased β- or γ-globulins (Fig. 5-9a and 5-9c). In the nephrotic syndrome, α_2-globulins increase due in part to increases in α_2-macroglobulin and the lipoproteins. The triad of azotemia, hypoalbuminemia, and hypercholesterolemia is a characteristic of the nephrotic syndrome. Increased α-globulin, identified as α_1-antitrypsin, and Hp have been described in dogs with chronic liver disease, many of which recovered (Sevelius and Andersson, 1995).

ii.* β-*Globulins Increases in β-globulins alone are infrequent in most species and found in association with active liver disease, suppurative dermatopathies, and in the

TABLE 5.5 Classification of the Dysproteinemias Based on the Albumin-to-Globulin Ratio and the Serum Protein Electrophoretic Profile

A. Normal A:G—normal SPE profile
   1. Hyperproteinemia: dehydration
   2. Hypoproteinemia
      a. Overhydration
      b. Acute blood loss
      c. External plasma loss: extravasation from burns, abrasions, exudative lesions, exudative dermatopathies, external parasites; gastrointestinal disease including parasites
      d. Internal plasma loss: vasculitis

B. Decreased A:G–abnormal SPE profile
   1. Decreased albumin
      a. Selective loss of albumin: glomerulonephritis, nephrosis, nephrotic syndrome, gastrointestinal disease including parasites
      b. Decreased synthesis of albumin: chronic liver disease, malnutrition, chronic inflammatory disease
   2. Increased globulins
      a. Increased α_1-globulin
         i. Acute inflammatory disease: α_1-antitrypsin, α_1-acid glycoprotein (orosomucoid, seromucoid)
      b. Increased α_2-globulin
         i. Acute inflammatory disease: α_2-macroglublin, ceruloplasmin, haptoglobin
         ii. Severe active hepatitis: α_2-macroglobulin
         iii. Acute nephritis: α_2-macroglobulin
         iv. Nephrotic syndrome: α_2-macroglobulin, α_2-lipoprotein (VLDL)
         v. Glucocorticoids: haptoglobin in dogs
      c. Increased β-globulin
         i. Acute hepatitis: transferrin, hemopexin
         ii. Nephrotic syndrome: β_2-lipoprotein (LDL), transferrin
         iii. Suppurative dermatopathies: IgM, C3
      d. Bridging
         i. Chronic active hepatitis: IgA, IgM
      e. Increased γ-globulin (broad increase)—polyclonal gammopathies: IgG, IgM, IgA
         i. Chronic inflammatory disease, infectious disease, collagen disease
         ii. Chronic hepatitis
         iii. Hepatic abscess
         iv. Suppurative disease: feline infectious dermatitis, suppurative dermatitis, tuberculosis
         v. Immune-mediated disease: autoimmune hemolytic anemia, autoimmune thrombocytopenia, Aleutian disease of mink, equine infectious anemia, systemic lupus erythematosus, autoimmune polyarthritis, autoimmune glomerulonephritis, autoimmune dermatitis, allergies
         vi. Lymphoid tumors
      f. Increased γ-globulin (sharp increase)—monoclonal gammopathies: IgG, IgM, IgA
         i. Lymphoid tumors
         ii. Plasma cell dyscrasias: multiple myeloma, Aleutian disease of mink
         iii. Macroglobulinemia
         iv. Canine ehrlichiosis (usually polyclonal)
         v. Benign

C. Increased A:G—abnormal profile
   1. Increased albumin: does not occur except in dehydration
   2. Decreased globulins
      a. Fetal serum
      b. Precolostral neonate
      c. Combined immunodeficiency of Arabian foals
      d. A gammaglobulinemia

nephrotic syndrome. Transferrin appears to be a major component that rises in active liver disease together with hemopexin and complement, but as transferrin is a negative acute phase protein, it may decrease during infectious or inflammatory disease. IgM can also rise in active liver disease in response to the antigenic stimulus of infectious agents. In the suppurative dermatopathies, a similar antigenic stimulus is thought to account for the IgM and complement increases in the β fraction. In the nephrotic syndrome, increases in β-globulins are associated with increases in transferrin. Most increases in β-globulins are polyclonal with accompanying increases in γ-globulins (Fig. 5-9b)

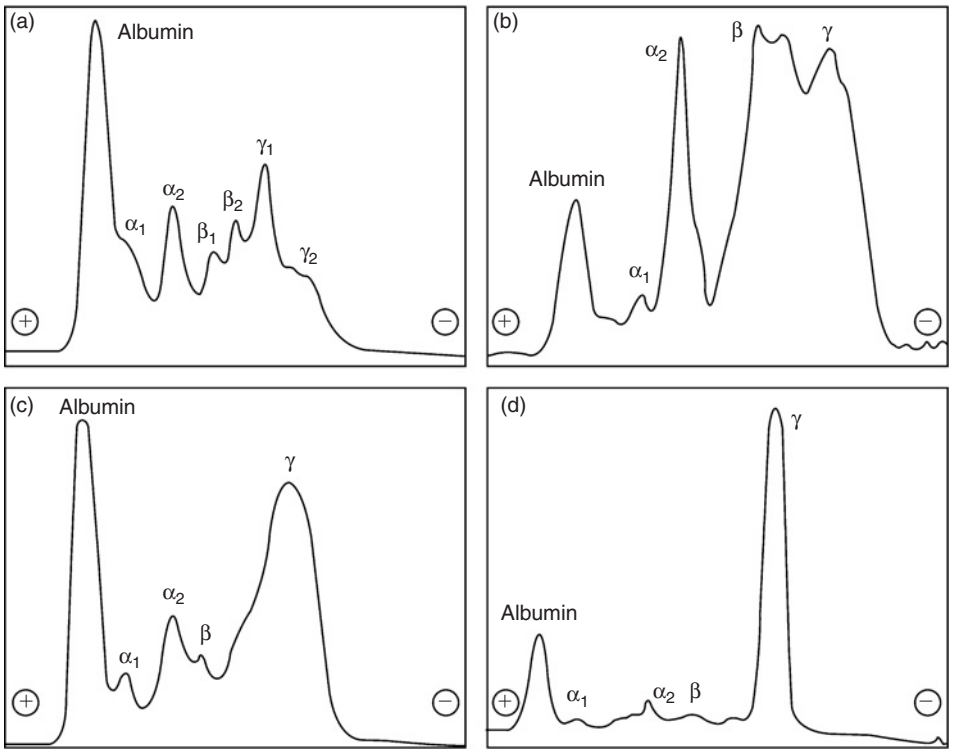

FIGURE 5-9 Densitometer trace of serum protein electrophoresis on agarose gel from (a) a dog with malignant lymphoma showing increases in α-, β-, and γ-globulins, A:G ratio 0.67; (b) a dog with B cell tumor showing hypoalbuminemia, a spike in α_2-globulins, increased β-globulins, and a polyclonal immunoglobulinemia, A:G ratio 0.15; (c) a cat with feline infectious peritonitis showing increased α_2-globulins and a polyclonal gammopathy, A:G ratio 0.36; (d) a cat with hypoalbuminemia and an IgG monoclonal gammopathy A:G ratio 0.20.

and only occasionally the sharp monoclonal spikes of multiple myeloma, Waldenstrom's macroglobulinemia, or lymphoma are seen (Macewen *et al.*, 1977). Waldenström's-type macroglobulinemia with hyperviscosity and IgM monoclonal spikes have been reported in dogs (Hurvitz *et al.*, 1971; Macewen *et al.*, 1977).

In the horse, increased levels of β-globulins have been observed on SPE of serum from animals infected with the intestinal parasites *Strongylus vulgaris* and *Strongyloides westeri*. The peak can appear as a monoclonal gammopathy in which an equine-specific immunoglobulin, IgG(T), is produced (Mair *et al.*, 1993). This immunoglobulin may also migrate in SPE with an α_2 mobility (Kent and Roberts, 1990).

iii. β-γ Bridging The phenomenon of β-γ bridging suggests chronic active hepatitis. In this case, there is no clear separation between the β_2 and γ_1-fraction, which results from an increase of IgA, IgM, or both. Rarely a low-grade gammopathy of lymphoma may result in a β-γ bridge.

iv. Increased γ-Globulin (Broad Increase): Polyclonal Gammopathy The diffuse or broad increases in the γ-globulins that characterize polyclonal gammopathies are a result of the heterogeneity of the clones of B lymphocytes and plasma cells, which produce a heterogeneous mix of immunoglobulins. Any one or all of the immunoglobulins IgM, IgG, or IgA can be present, but a preponderance of one is usually observed.

The chronic inflammatory disease profile may be manifested by a variety of disease states such as malignancies in general (Fig. 5-9b), chronic infections (Fig. 5-9c), and collagen diseases. There is a concomitant decrease in albumin as a result of decreased synthesis (Fig. 5-9b).

Chronic hepatitis, hepatic abscesses, and suppurative disease processes also exhibit changes characteristic of chronic disease (Rumbaugh *et al.*, 1978). In these cases, the polyclonal increase is more marked and the hypoalbuminemia more severe than in other chronic inflammatory diseases. This phenomenon may reflect the severity of the disease process and the more intense antigenic response generated.

Immunologically mediated disease processes are also characterized by polyclonal increases. These may be immune processes directed against "self," that is, autoimmune disease, or against external antigenic stimuli. In either case, a multiple immunological response is elicited, one or more organs may be affected, and polyclonal increases are observed on the electrophoretogram. Immune complexes trapped in the glomeruli and reacting with antigens are thought to be involved in the glomerulonephritis often seen with heartworms, pyometra, and systemic lupus erythematosus (SLE). SLE is a multifaceted disease in the dog often found in association with autoimmune hemolytic anemia, thrombocytopenia, glomerulonephritis, and polyarthritis. The basic abnormality in SLE is the LE factor, an antinuclear antibody, and the widespread dissemination of nuclear–antinuclear complexes throughout highly vascular structures.

Lymphomas can elicit either a polyclonal or monoclonal hyperglobulinemia. The hyperglobulinemic peaks can occur anywhere between the β_1 and γ_2 regions and range from very broad, diffuse peaks to very sharp, monoclonal spikes. The polyclonal peaks of lymphoma are thought to be the result of a tumorous group of distantly related clones in contrast to the single discrete clones, which give rise to the monoclonal spikes.

v. Increased γ-Globulin (Sharp Increases): Monoclonal Gammopathy The monoclonal forms are characterized by sharp spikes of immunoglobulin. They may occur in the β region, but are frequently limited to the γ region (Fig. 5-9d). A useful guideline for interpretation is to compare visually the sharpness of these spikes to the albumin peak. One or the other slope of the monoclonal spike is as steep or steeper than one of the slopes of the albumin peak. The monoclonal spike is the result of a single clone producing a single class of immunoglobulin usually abnormal in nature. Thus, the monoclonal immunoglobulins are of identical structure and move as one on the SPE. These immunoglobulins have been described as "paraproteins." The characteristic monoclonal spike in the γ region, Bence-Jones proteinuria, and plasma cell tumors have been general findings in multiple myelomas reported in the horse (Geelen *et al.*, 1997; Pusterla *et al.*, 2004), dog (Giraudel *et al.*, 2002), and cat (Farrow and Penny, 1971; Patel *et al.*, 2005). Light-chain disease with Bence-Jones proteins in the plasma and urine has been observed in dogs (Hurvitz *et al.*, 1971).

Lymphomas may present with monoclonal spikes depending on the degree of cloning of the tumor cells. The dominant monoclonal protein was identified as IgM in a case of lymphocytic leukemia in a dog (Braund *et al.*, 1978). A biclonal gammopathy has been observed in a dog with a combined myeloma and cutaneous lymphoma (Jacobs *et al.*, 1986).

A retrospective study of 18 cases of monoclonal gammopathies in the dog confirmed that most were associated with lymphoproliferative tumors, including multiple myelomas, Waldenström's macroglobulinemia, lymphoma, chronic lymphocytic leukemia, and mucocutaneous plasmacytoma (Giraudel *et al.*, 2002). However, nonmyelomatous monoclonal gammopathies were identified in cases of leishmaniasis and ehrlichiosis in this and other studies (Breitschwerdt *et al.*, 1987). Monoclonal gammopathies have also been reported in canine amyloidosis (Schwartzman, 1984).

Generally, the clinical characteristics of the monoclonal gammopathies are referable to the magnitude of lymphocyte or plasma cell proliferation, the extent of organ infiltration, and production of abnormal protein. Thus, immunologically associated diseases tend to be multifaceted and can present with bleeding tendencies, glomerulonephritis, polyarthritis, arteritis, hepatitis, and SLE. All monoclonal gammopathies are not necessarily pathological, however, because they can be benign. Consequently, care must be exercised in the final evaluation of a monoclonal gammopathy.

3. *Increased* A:G—*Abnormal Profile*

a. Increased Albumin

True overproduction of albumin does not occur in any animal. Therefore, any rise in albumin is only a relative hyperalbuminemia because of hemoconcentration as a result of water loss and dehydration.

b. Decreased Globulins

The absence of γ-globulins in fetal serum or in serum from precolostral or colostrum-deprived neonatal animals (Weaver *et al.*, 2000) can be readily demonstrated on SPE (see Fig. 5-8). Hypo-γ-globulinemia occurred in about 15% of foals less than 2 weeks of age and was attributed to failure of colostral transfer even though most had nursed (Mcguire *et al.*, 1975a; Sellon, 2000). Combined immunodeficiency of Arabian foals is thought to be an inherited autosomal recessive disease. The disease is characterized by lymphopenia, failure to synthesize IgG, IgM, and IgA and early death (Davis and Jones, 2003; Mcguire *et al.*, 1975b; Perryman, 2000). A selective IgM deficiency has been reported (Perryman *et al.*, 1977).

University of California, Davis
Davis, California

I. INTRODUCTION

The field of clinical immunology has evolved from serological testing for the presence of antibodies to infectious agents to a multifaceted discipline that utilizes some of the traditional techniques in addition to many newer more sensitive assay systems. Yet it is still involved with evaluation of the immune system of patients and the ability of the immune system to respond to antigenic stimuli. Assays developed to target specific parts of the immune system enable the clinician not only to determine if a patient has normal immune responsiveness but also to target those parts of the immune system that are suspect of inadequate function. Serology has historically been used to determine retrospectively if a patient were infected with a particular disease agent; antibody titers continue to have importance in diagnostics.

Current technologies have created expanded opportunities to diagnose infectious, autoimmune, and allergic diseases with new tools. Diagnostic quantitative reverse transcriptase polymerase chain reaction (RT-PCR) has shifted the focus from the immunology laboratory for the identification of infecting pathogens. Yet growing concern that veterinarians may be overvaccinating their patients has provided a new incentive for the development of sensitive and specific immunoassays to measure the immune response to vaccine antigens. Another increasing trend since the previous edition of this book is the use of diagnostic flow cytometry. This technique can evaluate multiple parameters on cells using multicolor analysis. The current availability of antibodies to many cytokines makes it now possible to determine not only cell phenotype but also the intracellular cytokines being made. Production of monoclonal antibodies specific to some leukocyte antigens expressed on leukemic cells has allowed diagnosis of these conditions to be achieved through flow cytometry. Flow cytometry is currently being used for detection of autoantibodies to platelets and erythrocytes. The traditional antinuclear antibody

test is often supplemented with more specific assays for evaluation of the presence of autoantibodies in animal patients. Diagnosis of allergic conditions is now commonplace because of the development of reagents and assays to measure IgE in dogs, horses, and cats.

This chapter reviews some basic principles of immunology and presents current methodologies used in the clinical immunology laboratory.

II. INNATE IMMUNITY

Entry into the body of a pathogen is the first stimulus for immunity. Pathogens contain pattern recognition receptors called pathogen associated molecular patterns (PAMP), which are recognized by Toll-like receptors (TLR) on the surface of host cells. There are at least 10 such receptors, each recognizing a different motif. For example, TLR 2 recognizes the peptidoglycan of the Gram-positive bacterial cell wall, TLR 4 recognizes lipopolysaccharide from the Gram-negative bacterial cell wall, TLR 6 recognizes flagella protein present on motile bacteria, and TLR 9 recognizes DNA containing cytosine-guanine repeating motifs (CpG). The binding of these TLRs with their ligands stimulates production of proinflammatory cytokines that jumpstart the immune response (Takeda, 2005).

The immune response is generally divided into innate and acquired responses. This division is based on the need for the host to have previously been exposed to the antigen/pathogen in order to rapidly mount a protective response. Innate immunity does not require previous exposure to a pathogen for it to be effective. It is thus not an antigen-specific response. Innate immunity is a broad category that includes protective barriers such as skin and mucosa. Reflexes are included, such as the cough coupled with the anatomical/physiological function of the mucociliary apparatus, which moves inhaled material out of the respiratory system. Dogs with inherited ciliary dyskinesis have nonfunctional cilia and suffer from repeated respiratory infections because of their inability to remove inhaled particles (such as bacteria) from the lung.

Phagocytes are important components of innate immunity. The initial responder to infection is usually the polymorphonuclear leukocyte or neutrophil. These cells participate in phagocytosis and killing of bacteria. Dogs with inherited cyclic neutropenia develop cyclic bouts of bacterial disease that coincide with the episodes during which the bone marrow shuts down its production of these essential phagocytes. Other defects, such as that seen in calves with bovine leukocyte adhesion deficiency (BLAD), occur when production is good, but the neutrophils lack the CD18 part of the adhesion molecule that allows them to adhere to blood vessel endothelium and then exit into the tissue by diapedesis. These animals develop even more critical disease because their defect is not cyclic, but constant. These calves generally succumb to overwhelming bacterial disease within the first 6 months of life. These experiments in nature demonstrate the importance of the innate defense provided by the neutrophil.

The other population of phagocyte is the macrophage. This cell plays a role not only as a phagocyte, generally entering an area of inflammation after the neutrophil, but also as a vital link to the acquired immune response. Macrophages function as antigen-presenting cells. As such they engulf a pathogen, digest it within a vacuole, and then display peptides generated from the engulfed organism on their cell surface. This antigen presentation function relies on the presence of a cell surface molecule called major histocompatibility complex antigen class II (MHC II). Lymphoid cells of the CD4+ T cell lineage then bind to the peptide and to the MHC II for initiation of the immune response. This is a critical step in immune responses. However, there is another cell type, the dendritic cell, that performs the antigen presentation function more efficiently than the macrophage. These cells are pivotal to induction of the acquired immune response and serve as an effecter for innate immunity.

The need for acquired immunity is demonstrated by certain bacterial species that are able to live and divide after being ingested by a macrophage. These organisms, called facultative intracellular bacteria, are able to overcome the macrophage and prevent their own digestion in the phagosome. To overcome the infection, the macrophages infected with these bacteria require signals from cytokines that are secreted by T cells stimulated in an acquired immune response. Infection of cattle with *Mycobacterium bovis subspecies paratuberculosis* causes a chronic wasting disease because of the ability of the bacteria to overcome the killing function of the macrophages. The acquired immune response required for killing these organisms is discussed with cellular immunity.

There is a population of lymphocytes that are neither T nor B cells; they lack the receptors for antigen recognition. These cells are natural killer cells (NK cells). The NK cells have the ability to recognize cells that lack or have depressed levels of the MHC class I molecule on the cell surface. Many tumor cells and some viral infected cells fall into this category. It is an evasion technique employed by some viruses to down-regulate the expression of the MHC molecules, which are required for recognition of the effector cells of the immune system. These NK cells are part of the innate immune system, because they are available to act on target cells without prior exposure.

III. ACQUIRED IMMUNITY

Acquired immunity is specific for the stimulatory antigen; and the acquired response has memory. Thus, once a host has encountered an antigen and initiated an immune response, the next time the antigen is encountered by that host, the response is more rapid and more robust. The antigen can be from a pathogen (bacteria, virus, parasite, fungal) or it can

be a protein (as in an injected biological or an ingested or inhaled protein). Initially an antigen is taken up by a dendritic cell and is carried in the lymph to a local lymph node. In that site it is presented to the T cells in the body to initiate the response. When the T cell with the appropriate receptor recognizes the antigenic peptide on the surface of the antigen-presenting cell, it binds and begins a process of activation. Ultimately the activated T cell secretes cytokines that enhance the development of the T cell response and others that stimulate the growth and differentiation of B lymphocytes. There are multiple signals involved in antigen stimulation of T and B lymphocytes; these are receptor binding, cytokine binding, and binding of co-stimulatory molecules. Once this has been accomplished, a B cell can differentiate into a plasma cell to make antibody with the same specificity as that which stimulated the original B cell.

There are two major types of T cells: CD4+ helper T cells and CD8+ cells, usually called cytotoxic T cells. This latter group has the capacity to kill target cells that are infected with antigens, such as viruses. There are two main subsets of CD4+ T helper cells: T helper 1 and T helper 2. The Th1 cells assist in cellular immune responses, such as activation of the macrophages infected with facultative intracellular bacteria. The Th2 cells provide "help" to B cells by provision of cytokines and co-stimulatory molecules (as described earlier). This T cell help initiates clonal expansion into mature B cells and ultimately into memory B cells and plasma cells. The plasma cells are the end cell that makes the immunoglobulin (antibody) that is so important in humoral immunity.

These Th1 and Th2 cells are primarily identified by the cytokines that they produce. Th1 cells make IL-2, IL-12, and interferon γ. The former activates T cells to divide and proliferate, and the latter activates macrophages to become more efficient killers. Cytokines produced by the Th2 subset include IL-4, IL-5, and IL-13. IL-4 is a B cell growth factor; and in conjunction with IL-13, they can facilitate development of an allergic type response (in which plasma cells produce lots of IgE). The T helper cell subsets were originally described in the inbred mouse, where the division between the two is distinct. However, in many of out bred species, such as humans and cattle, the distinction is less clear, with a T helper 1 or 2 skew more commonly identified than a complete polarization of the immune response.

One additional T cell subset that is described is the regulatory T cell (T reg). These cells are CD4+ and CD25+ and contain the nuclear activation factor FoxP3. T regs produce IL-10 and TGF-β, which depress the T helper 2 response. These cells may have a role in control of autoimmunity and allergy.

A. Humoral Immunity

Electrophoretic separation of serum proteins separates the proteins into four broad categories: albumin, alpha globulins, beta globulins, and gamma globulins. The antibody activity is present in the gamma globulin fraction, with a slight amount in the beta fraction. These immunoglobulins are heterogeneous, having different molecular weights and functional properties.

There are five classes (isotypes) of immunoglobulins: IgG, IgM, IgA, IgD, and IgE. They share a basic structure, which consists of four polypeptide chains bound together by disulfide bonds. Two of these chains are called light chains, because with a molecular weight of about 22K each they are lighter than the other two heavy chains (approximately 55K each). At the nitrogen terminal of the polypeptide chains on all four chains is a portion of variable amino acid sequences. This is the antigen-binding end of the immunoglobulin. The hinge region of the immunoglobulin provides for flexibility of the molecule for binding to antigenic epitopes.

In the serum, IgG is the antibody class with the greatest concentration, approximately 1 to 2 g/100 ml, with some species differences (Tizard, 2008). Subclasses of IgG are recognized in most species. IgG has a four polypeptide-chain structure with a total molecular weight of 180,000 daltons. The heavy chains in IgG are called gamma chains and are unique to IgG. Immunoglobulin G is important in host defense because it can exit the vascular system and distribute throughout the extravascular tissue fluid where it has many protective functions. For example, IgG can agglutinate bacteria, causing them to clump; it can opsonize bacteria, by binding to the bacteria by the Fab fragment and to the phagocyte by receptors for the Fc fragment, thereby facilitating engulfment of the bacteria by the phagocyte. The complement system (a series of serum proteins to be discussed later in this chapter) can be activated by two IgG molecules bound near each other on a cell membrane and target cells can be lysed by this mechanism. In addition, IgG can participate with several different effector cells in antibody-dependent cellular cytotoxicity (ADCC). This mechanism allows destruction of virus-infected cells by lymphocytes that lack specific antigen receptors. The ability of IgG to neutralize toxins, such as those produced by *Clostridium tetani*, is an important protective mechanism for bacterial diseases.

Immunoglobulin M (IgM) is the first antibody to be synthesized in response to an immunogenic stimulus and is the first antibody seen in ontogeny. In serum, IgM is present in the second greatest concentration, generally between 100 and 400mg/100ml (species dependent). The structure of IgM consists of five of the basic four polypeptide units held together by a J chain. The large size of IgM (900,000 daltons) keeps it confined to the intravascular space. There are a total of 10 potential antigen-binding sites on IgM. Even though in reality, because of steric hindrance, only five to seven of the antigen-binding sites are functionally active, this large capacity to bind antigens makes IgM an efficient antibody at agglutination, precipitation, opsonization, complement fixation, and virus neutralization.

Immunoglobulin A exists primarily in two forms, as a monomer (160,000 daltons) in the blood-vascular compartment and in a dimeric secretory form (390,000 daltons).

Less commonly, polymers of greater number occur. The dimeric form consists of two monomers, each containing a heavy chain (alpha) and a light chain. These are held together by J chain and include an additional component called secretory piece. The secretory piece is produced by mucosal epithelial cells and functions to assist in transport of IgA dimers from the lamina propria of the intestine through into the lumen where it then protects the IgA dimer from proteolysis by intestinal enzymes. In domestic animals, IgA is important as a secretory antibody both within the intestinal tract and the lung. It is capable of neutralizing virus and preventing adherence of bacterial pathogens to target tissues. It does not function as an opsonin and is unable to fix complement.

IgD is the is usually of not generally quantitated in the serum, although serum levels are reported for humans are greater than those measured for IgE. IgD is a four-polypeptide chain configuration (heavy chains are called δ) with a molecular weight of 180,000 daltons. IgD serves as a B cell receptor for antigen. Early in an immune response, immature B cells express IgD. As the cell matures in response to antigen, the IgD is replaced with monomeric IgM. Although IgD has been demonstrated in humans, mice, pigs, horses, cattle, dogs, and chickens, information is lacking in the cat. The existence of IgD in the animal species (other than the mouse) is based primarily on genome sequencing.

Immunoglobulin E is recognized and characterized in dogs, cattle, sheep, pigs, horses, and functionally recognized in cats. IgE has never been documented in avian species. IgE occurs normally in very small amounts in the serum (nanogram quantities). In allergic or parasitized individuals, the serum concentration of IgE is greatly increased. The basic four-polypeptide chain structure of IgE, with epsilon heavy chains that contain one additional domain, has a molecular weight of 196,000 daltons. Functions of IgE are mediated through its ability to bind via the high affinity Fcε receptors on tissue mast cells and blood basophils. When an antigen cross-links these cell-bound antibodies, the cell degranulates, releasing vasoactive amines, stimulating leukotriene synthesis, and resulting in potent pharmacological effects. IgE can also bind to the low-affinity IgE receptor, CD23. Binding of IgE to the CD23 stimulates a regulatory function. IgE can participate in parasite killing by binding to low-affinity IgE receptors on eosinophils and then to the parasite by specific Fab regions. This allows the eosinophils to deposit their toxic granule contents on the cuticle of the worm.

B. Cellular Immunity

The cellular immune response is important for viral pathogens, tumor immunity, and for defense against bacterial pathogens that are able to evade killing by macrophages (these are facultative intracellular bacteria). The T cell response is important for cellular immunity. The CD8+ T cells are cytotoxic cells. They are able to recognize peptides derived from antigens that grow in an intracellular location and are processed and "presented" on the cell surface with the major histocompatibility molecule (MHC class I). Once the T cell has recognized the peptide from the antigen, it is able to respond by killing the infected cell and others infected with the same pathogen. The killing is mediated by interaction of surface molecules called "death receptors," Fas and Fas-ligand to initiate apoptosis. The polymerization of perforins from the T cell onto the surface of the infected target cell allows for the entry of granzymes, which are molecules that are able to initiate cell death. This mechanism of immunity is particularly effective for viruses such as herpesviruses that are primarily cell associated and therefore not very accessible to antibodies.

The immune response to the facultative intracellular pathogens is primarily mediated by the T helper 1 subset of CD4+ T cells. These cells make interferon γ, which activates the macrophage and helps it to become a better killer. It does this by increasing a variety of metabolic activities, such as synthesis of cytokines (tumor necrosis factor α, IL-1α, IL-12), by increasing the ruffled membrane activity and increasing nitric oxide production.

IV. EVALUATION OF THE IMMUNE RESPONSE

When the clinician is concerned that there may be some defect in the innate immune system of a patient, the concern is usually initiated by repeated infection in the patient. If the infection is primarily bacterial, the focus of the immune system investigation will be on phagocytes and humoral immunity. Other types of innate defenses that may be perturbed, such as the ciliary dyskinesis described earlier, require other diagnostic assays such as bronchial biopsy and radio isotopic clearance studies.

A. Evaluation of Neutrophil Function

Evaluation of neutrophil function includes number, expression of adhesion molecules, response to chemotactic factors, and phagocytosis (engulfment and killing). There are assays available to examine each of these functions. In addition to assessment of neutrophil function, the importance of appropriate opsonins cannot be ignored. Hence, the presence of antibody specific for the pathogen to be engulfed or C3b is required for optimum engulfment. Table 6-1 lists the functions of neutrophils that should be evaluated and the assays available.

B. Evaluation of Complement

The components of complement can be activated by innate mechanisms as well as by antibody. The multiple pathways

of complement activation diminish the effect of deficiency of some components. However, the importance of the third component of complement C3 to all pathways means that a deficiency in C3 can affect overall complement function. One assay for complement function is called the *CH50* (hemolytic complement 50). This assay measures the ability of the patient's plasma to participate in completion fixation and the terminal lytic pathway.

C. Evaluation of Humoral Immunity

The acquired immune response generates antibodies after stimulation with antigen. Each animal species has a normal range for each antibody class. There may be some interlaboratory variation in normal ranges, but they should be generally similar. Normal concentrations of immunoglobulin classes for each species are shown in Table 6-2 (Tizard, 2008). The method used for quantitative evaluation of total levels of IgG, IgM, and IgA concentration is the single radial immunodeficiency assay (SRD). In single radial diffusion, the antisera is placed into the agar and the serum sample is placed into a well. This assay requires a serum sample, and it takes 2 days for results to be available. Known standards are compared with patient samples by generation of a standard curve. A typical SRD test for IgA in dog serum is shown in Figure 6-1.

It is sometimes useful to evaluate the antibody response to a specific antigen. It is usually possible to use one of the common vaccine antigens to accomplish this goal. In species that are routinely vaccinated for tetanus, tetanus toxoid is a good antigen to use because it elicits a strong immune response in all normal vaccinates. Failure to respond to a dose of tetanus toxoid indicates a problem with humoral immunity and potentially performance of T helper lymphocytes.

Immunoelectrophoresis (IEP) is another technique used to visualize in a semiquantitative manner the immunoglobulin molecules in serum. This technique combines electrophoretic separation with gel diffusion. The serum is first separated in the gel according to charge; next antiserum is added to the trough followed by its diffusion and formation of precipitin arcs with the antibodies in the serum. A normal IEP pattern is shown in Figure 6-2a. It is easy to detect an agammaglobulinemia (Fig. 6-2b), and an abundant amount of identical immunoglobulin as seen with a myeloma protein (Fig. 6-2c).

TABLE 6-1 Evaluation of Neutrophil Function

Neutrophil Function	Assay
Adhesion	Flow cytometry, RT-PCR
Chemotaxis	Chemotaxis assay: agarose gel or Boyden chamber
Engulfment	Phagocytic index
Oxidative killing	Nitroblue tetrazolium, chemiluminescence
Killing (oxidative and nonoxidative)	Bacteriocidal assay

D. Evaluation of Cellular Immunity

Cellular immunity is generally considered to encompass both the T helper cell type 1 response that activates macrophages and the T cytotoxic cell response that performs killing of virus infected cells. The Th1 response can most easily be evaluated by *in vitro* detection of interferon gamma production after antigen stimulation. For most species, ELISA is possible for measurement of IFNγ in the supernatant. Detecting the presence of CD8+ cytotoxic lymphocytes (CTL) is more difficult. A chromium release assay can be performed, but this requires preparation of virus infected target cells from the patient. This technique is often used in research situations, but it is rarely practical in the hospital setting. As an alternative, cell-mediated responses are most often evaluated by lymphocyte stimulation tests.

TABLE 6-2 Normal Ranges for Immunoglobulin Concentrations (mg/dl)

Species	IgG	IgM	IgA	IgE
Bovine	1700–2700	250–400	10–50	NA
Canine	1000–2000	70–270	20–150	2.3–4.2
Equine	1000–1500	100–200	60–350	8.4–9.09
Feline	400–2000	30–150	30–150	NA
Ovine	1700–2000	150–250	10–50	NA
Porcine	1700–2900	150–250	10–50	NA

Data from Takeda and Akira (2005).

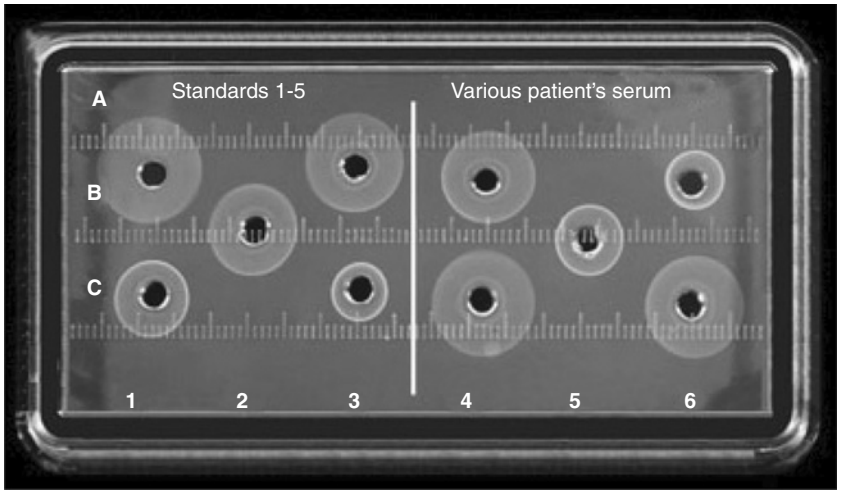

FIGURE 6-1 Single radial immunodiffusion test for determination of IgA levels in serum.

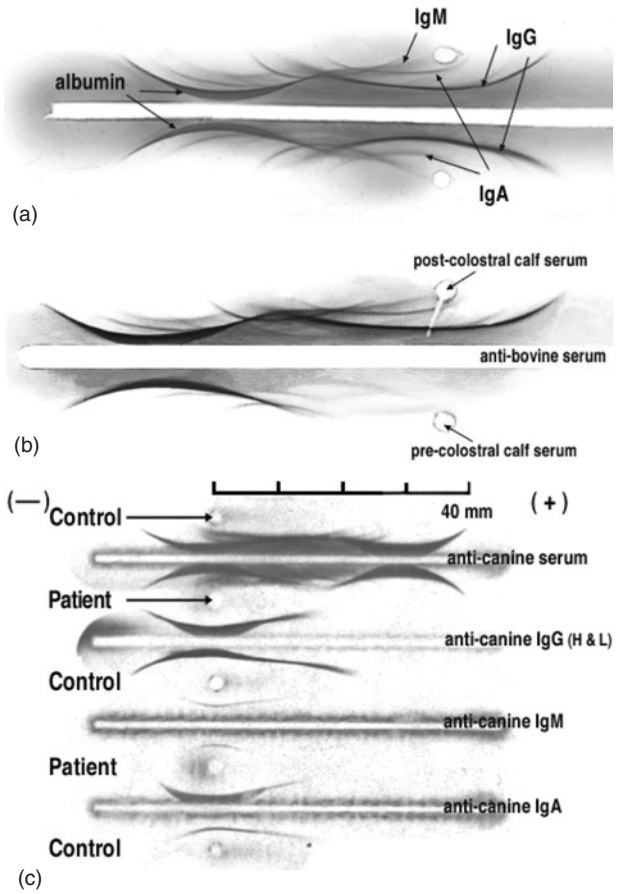

FIGURE 6-2 (a) Normal serum immunoelectrophoresis (IEP) showing IgG, IgM, and IgA. (b) IEP showing lack of gamma globulins. (c) IEP demonstrating an IgA myeloma protein in patient's serum.

This technique is performed by incubating peripheral blood lymphocytes with mitogens or specific antigen for several days. The addition of tritiated thymidine or a nonradioactive dye that incorporates into dividing cells provides a signal that is commensurate with the degree of cell division. Comparison of the stimulated cells with unstimulated cells from the same animal provides a stimulation index, which indicates the amount of responsiveness inherent in the cells of the patient. Usually the assay is used to determine whether or not a patient has suppressed or diminished T cell function in general. In can be used to measure the T cell response to specific antigen.

Multicolor flow cytometry can be used to demonstrate the presence of T cells making either Th1 or Th2 cytokines. This technique utilizes surface staining to distinguish CD4 or CD8 T cell populations followed by permeabilization, incubation with a reagent that prevents newly synthesized protein from leaving the Golgi apparatus, and staining for intracellular cytokine using antibodies conjugated with different fluorochromes.

V. METHODS FOR EVALUATION OF THE IMMUNE RESPONSE TO INFECTIOUS AGENTS

A. Agglutination and Passive Agglutination

The antibody response to a specific antigen can be evaluated by a variety of assays. For a particulate antigen, an agglutination test can be performed. In this test, serum is serially diluted, and the dilutions are then mixed with an antigen suspension. The tubes are observed for agglutination. The titer is the inverse of the dilution in the last tube that shows a positive agglutination response. This is a traditional assay that is still used for detection of antibodies to a variety of bacterial antigens. It is possible to use this method to evaluate titers for soluble antigens by binding them to latex particles. Figure 6-3 shows a tube agglutination test used to measure the titer of antibodies against *Brucella canis* in canine serum. When a soluble antigen is linked to a particle, it becomes a passive agglutination test. The microagglutination test for antibodies to *Toxoplasma gondii* is performed this way. Figure 6-4 shows an example of the Toxotest, run in microtiter plate wells. Both of these assays

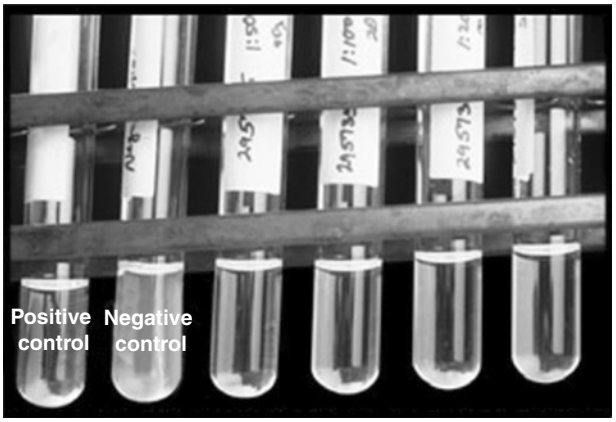

FIGURE 6-3 Tube agglutination test for antibodies to *Brucella canis*. Serial dilutions of patient serum are compared with positive and negative sera.

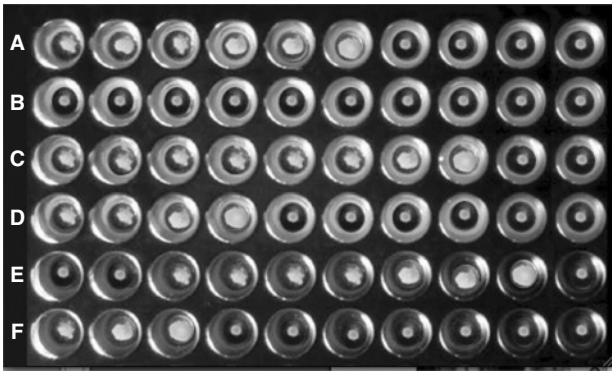

FIGURE 6-4 Microagglutination test for antibodies *Toxoplasma gondii*, performed using latex agglutination. Serum is diluted serially beginning at 1:16.

measure a titer of antibody and require serial dilution of the test serum. A simple positive or negative is sufficient for some purposes, such as the test for canine rheumatoid factor shown in Figure 6-5.

B. Hemagglutination and Hemagglutination-Inhibition

Some viruses have receptors for erythrocytes and when incubated in their presence cause them to agglutinate. This phenomenon is called hemagglutination. Specifics of the erythrocyte source, mammalian or avian, and optimum temperature and time for reaction vary depending on the virus of interest. Myxoviruses, paramyxoviruses, enteroviruses, and adenoviruses are several virus groups with members of veterinary interest that are capable of hemagglutination. The hemagglutination procedure is itself of little immunological interest. However, the ability of antiserum to inhibit the hemagglutination caused by virus receptors for erythrocytes has been utilized to develop a serological test called hemagglutination inhibition (HI). The antibodies bind to receptor sites for erythrocytes and thus block the hemagglutination reaction. The test is used to measure antibody titers to the virus. Alternatively, with a known source of antiserum, one can use the HI test as a preliminary step in viral identification.

To perform the hemagglutination-inhibition test, serial two-fold dilutions of heat-inactivated serum are prepared in saline. A 0.25-ml aliquot of each dilution is then mixed with a similar amount of viral suspension that contains 4 hemagglutinating units. These are mixed and incubated. Next 0.25 ml of a 1% erythrocyte suspension is added, and the tubes are mixed again and incubated at the appropriate temperature and time for the virus of interest. The agglutination or absence thereof is read, and the HI titer of the serum is assigned as the reciprocal of the highest serum dilution that completely prevents hemagglutination. Alternatively, one can perform the test by making serial dilutions of the virus suspension and using a standard amount of serum. Test sera are then compared with known negative and positive sera. The former HI test is called the alpha procedure, and the latter is called the beta procedure. Appropriate controls must be included in either procedure, particularly to prevent false positive results from the presence of hemagglutinating substances in test sera.

C. Virus Serum Neutralization Assay

Evaluation of the protective antibody response to viral agents is most often done using a serum virus neutralization assay. This assay is performed by incubation of serum dilutions with virus followed by inoculation of cell culture with the virus/serum mixture. The cells are observed for the development of cytopathic effect (CPE). Control cells inoculated with virus that has been incubated with a negative serum will show positive CPE and serve as a basis for comparison with the test sera. Performance of dilutions allows for the determination of a titer. Because the antibodies that are active in this assay prevent viral entry to the cell, they are protective. This is not necessarily true for antibodies detected by enzyme-linked immunosorbent assay (ELISA) or indirect immunofluorescence assay (IFA).

D. Agar Gel Double Immunodiffusion

Agar gel immunodiffusion has been used routinely to identify horses infected with the equine infectious anemia virus has been demonstrated by the "gold standard" Coggin's test. In this assay, serum samples from positively infected horses are alternated with samples to be tested around the outside wells. In the center well, EIA antigen is placed. The development of a line showing continuity with the adjacent lines of precipitation between viral antigen and positive control sera (called identity) confirms that the serum is from an infected horse. Although this assay is extremely reliable, it is much less sensitive than other methods (such as ELISA). Sometimes a horse newly infected will not be positive on an initial sample but on retesting will demonstrate the appropriate line of identity. The same horse would

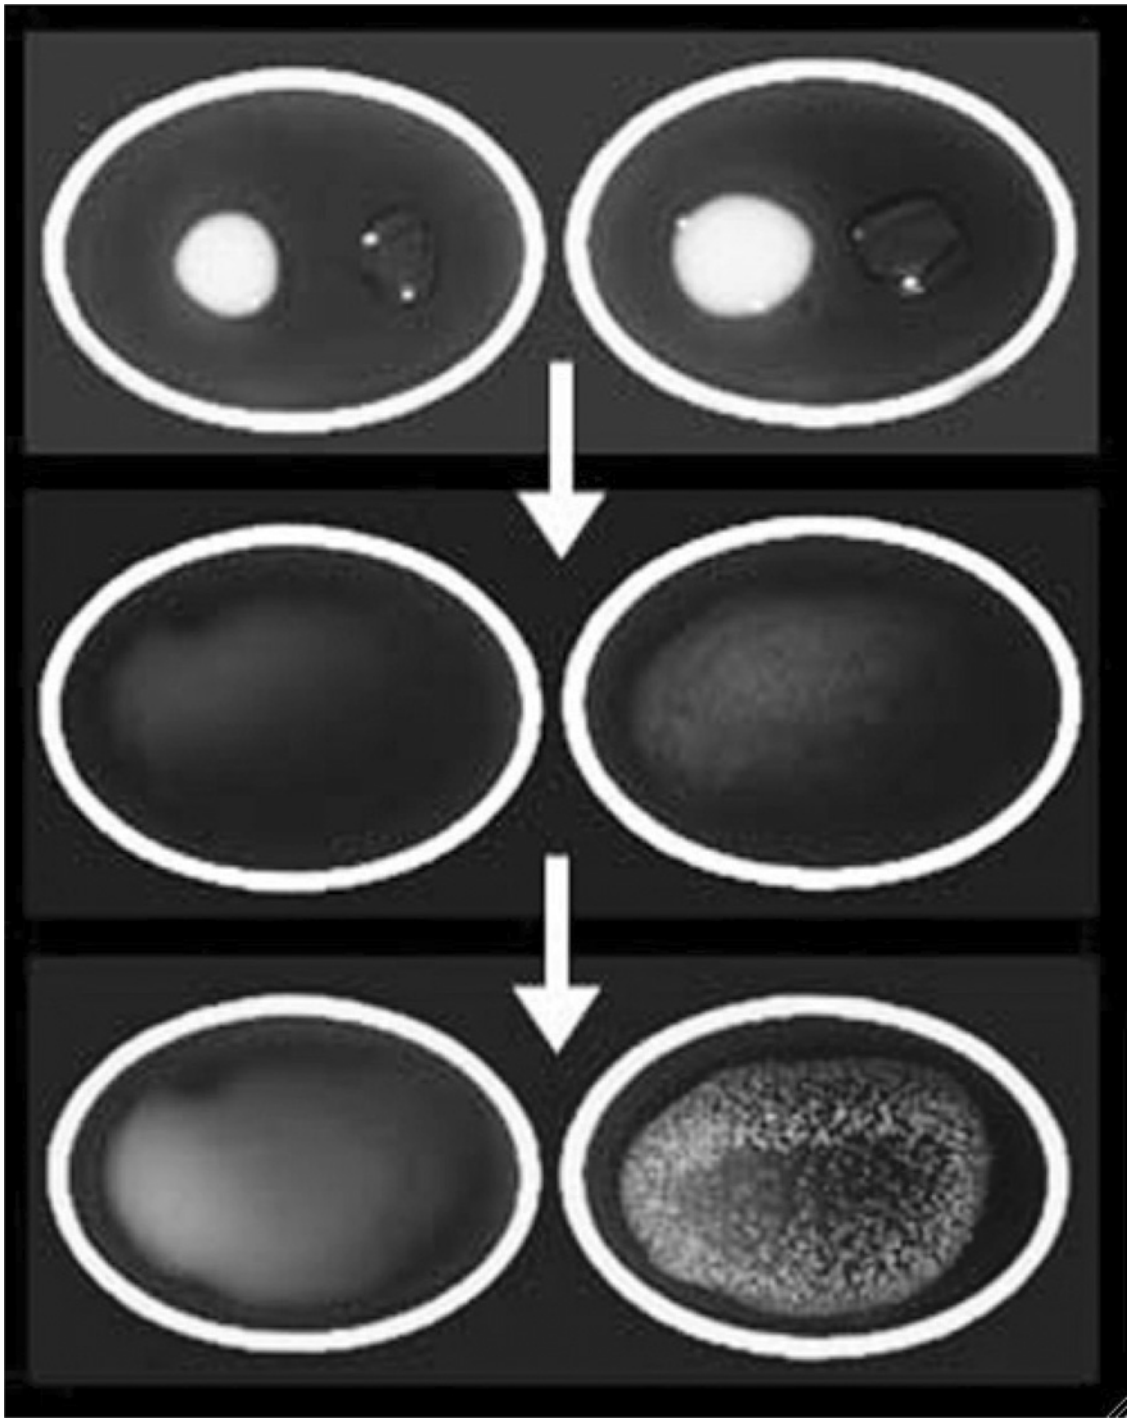

FIGURE 6-5 Plate agglutination test for rheumatoid factor, using a test kit that couples IgG to latex beads. Serum is mixed with beads and examined for agglutination and compared with controls.

likely show up as positive on the ELISA because of the increased sensitivity of the latter assay. This type of double immunodiffusion (Ouchterlony) is also used in the demonstration of precipitating antibodies against some fungal pathogens, such as *Aspergillus fumigatus* and *Coccidioides immitis*. In both cases, positive control sera are used to demonstrate identity with potentially positive sera.

E. Indirect and Direct Immunofluorescence (IFA) Test

The indirect immunofluorescence assay (IFA) is a technique that is used to diagnose some protozoan and viral diseases. It is also the basis of the antinuclear antibody test, used to diagnosis autoimmune disease. It is useful when

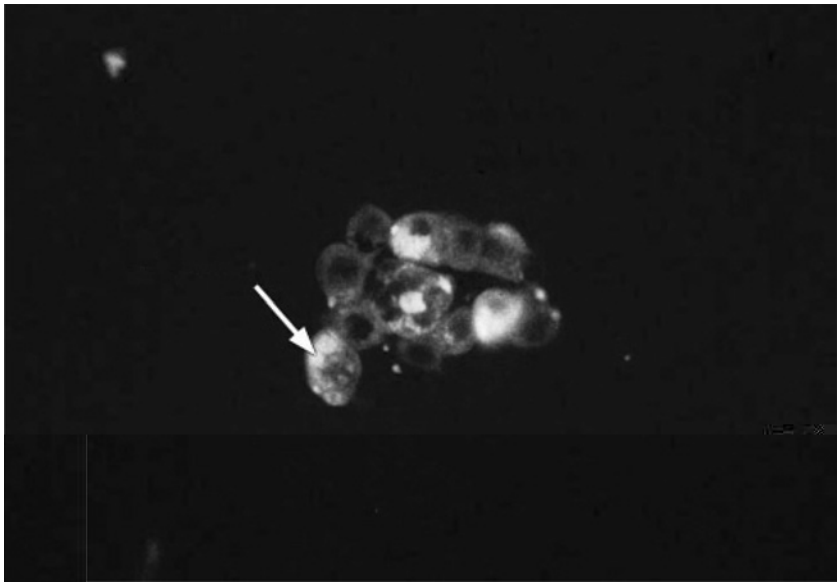

FIGURE 6-6 Direct immunofluorescence demonstrates herpesvirus in a feline conjunctival smear. Arrow shows fluorescent intracellular virus.

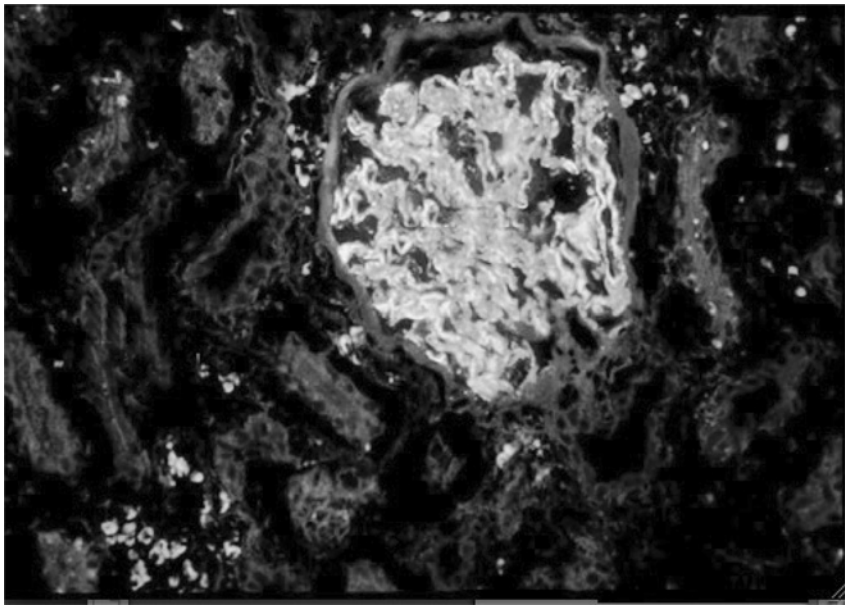

FIGURE 6-7 Direct immunofluorescence demonstrates deposition of IgG in a glomerulus of a dog with immune complex mediated kidney disease.

a pathogen is intracellular and can easily be propagated in culture. Indirect immunofluorescence is performed to detect and quantitate titer of antibodies specific for these cell-associated antigens. When IFA is used, it is not necessary to purify the antigen. Cell-associated antigen, such as pathogens that are intracellular or nuclear antigen (in the case of the antinuclear antibody test), are present in cells that are fixed onto slides. The serum to be evaluated is then diluted serially and applied to wells containing the cells. The application of a fluorescein-conjugated secondary antibody then allows binding of the conjugate to antibodies present in the serum that have recognized epitopes present on the antigen. Several washing steps must be properly performed for this technique to yield reliable information.

The technique of direct immunofluorescence also has diagnostic application. In direct immunofluorescence, the sample comes from the patient and consists of cells or tissues rather then serum. A known fluorochrome-conjugated serum is used to detect the antigen of interest. For example, conjunctival cells or transitional epithelial cells from the bladder of canine distemper-infected dogs can be stained with FITC-antidistemper antibodies to demonstrate viral infection. Another application of this technique involves diagnosis of autoimmune disease and is included under the discussion of autoimmunity. Figure 6-6 shows conjunctival cells from a cat infected with herpesvirus (direct FA). For detection of IgG or C3, deposition in blood vessels of patient's that have immune complex disease direct FA is often used. Deposition of IgG in a kidney glomerulus is shown in Figure 6-7. Indirect immunofluorescence is used to demonstrate the presence and measure the titer of antinuclear antibodies, as shown in Figure 6-8.

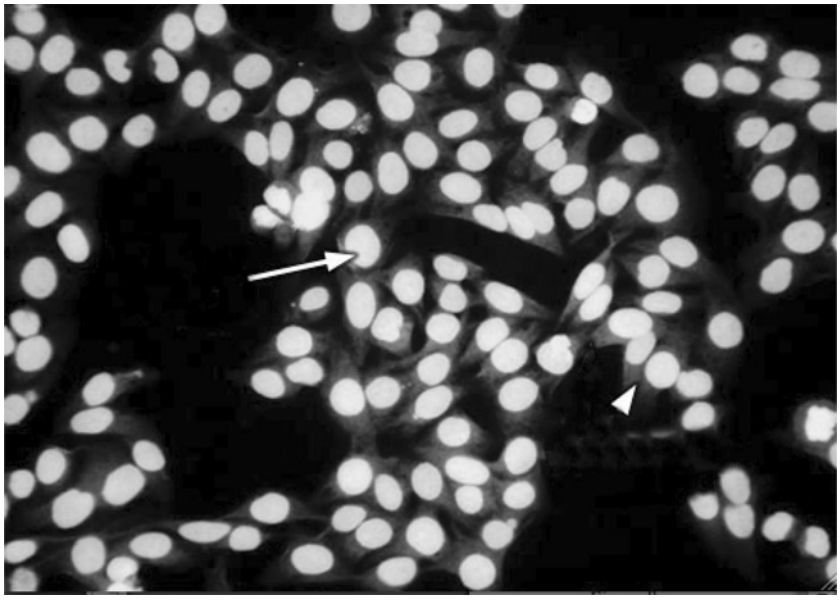

FIGURE 6-8 Indirect immunofluorescence demonstrates the presence of antinuclear antibodies in serum of a dog with systemic lupus erythematosus. Arrow points to nuclear fluorescence in HEP-2 cells; arrowhead shows nonfluorescence of cytoplasm.

F. Flow Cytometry

Flow cytometry uses fluorochromes conjugated to specific antisera to identify and quantitate cells of various types. This is an application of immunofluorescence. It is most commonly used to identify populations of cells, such as T cells and dendritic dells. The availability of antisera specific for activation markers, such as CD25 (IL-2 receptor), makes it possible to evaluate activated versus resting cells. This technique has broad application for diagnosis of a variety of immunological, neoplastic, and infectious diseases. Diagnosis of viral immunodeficiency (SAIDS, FIV) often utilizes flow cytometry to determine ratios of CD4+ to CD8+ cells. An example of data from flow cytometry is shown in Figure 6-9.

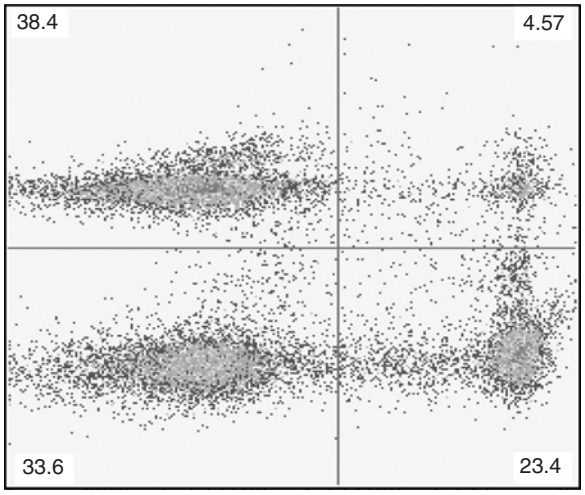

FIGURE 6-9 Plot from flow cytometry analysis. The plot shows cells stained for CD4 and CD8. The y-axis shows cells stained for CD4 with the fluorochrome FITC, and the x-axis shows cells stained to detect CD8+ cells with another fluorochrome, Alexa 647. These cells are from bovine afferent lymph. This sample has 38.4% CD4+ cells and 23.4% CD8+ cells. A population of cells (33.6%) is neither CD4 nor CD8 cells.

G. Enzyme-Linked Immunosorbent Assay (ELISA)

Enzyme-linked immunosorbent assay (ELISA) is the primary binding assay that has become a standard for many diagnostic tests since the 1980s. It is used both as a quantitative assay for serum antibodies to a variety of antigens and as a quick test for a simple positive or negative answer to the question of whether or not a patient is infected with a particular pathogen. Because the ELISA is a primary binding assay, it is very sensitive. The specificity of each ELISA depends on the quality and specificity of the reagents used. The technique has the ability to be both very specific and very powerful if appropriately configured. There are two main configurations, one for detection of antibody and the other for detection of antigen (Fig. 6-10a). In the indirect form of ELISA, antigen is detected using a "catching" antibody attached to a solid substrate, most often a microtiter plate. The sample is added and it is detected after a series of incubation and wash steps by another antibody specific for the antigen, either conjugated with an enzyme, or another variation, such as biotin (which is followed with addition of an enzyme attached to avidin). Addition of the substrate for the enzyme produces a colored product, whose optical density is determined by spectrophotometry. In the direct format, the antigen coats the solid substrate and serum is added to that. Antibodies present bind the antigen and are then detected by specific antisera recognizing the species-specific antibody. This technique has the advantage of allowing for selection of a particular class of antibody, such as IgM or IgE, by using heavy

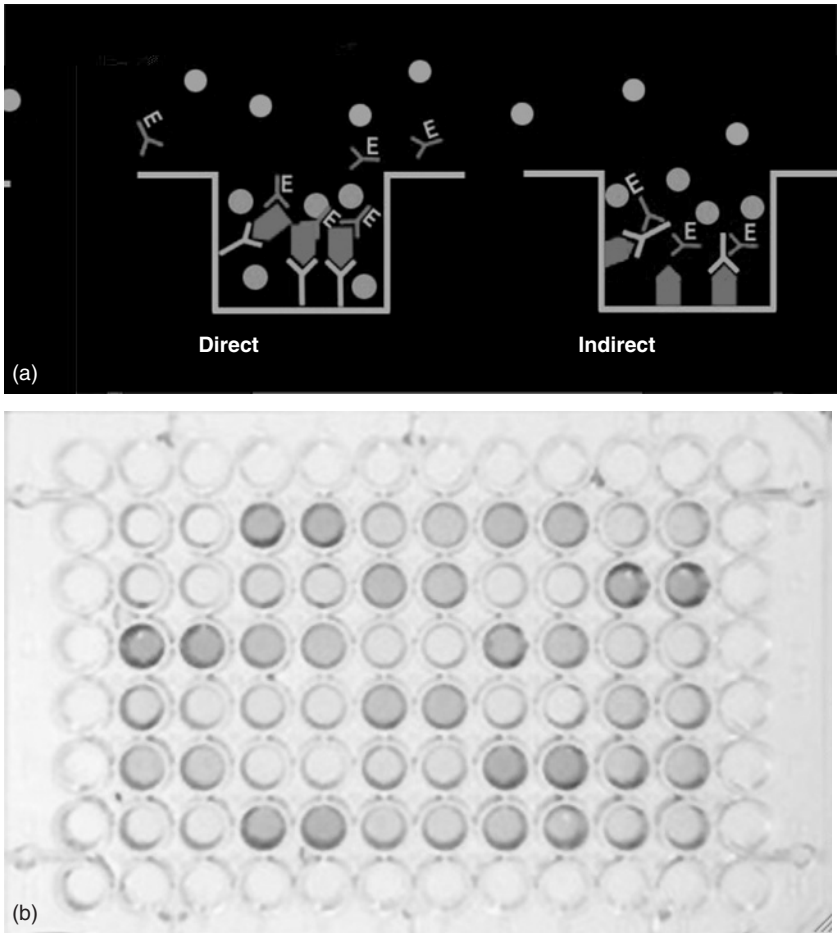

FIGURE 6-10 (a) Schematic demonstrating direct and indirect ELISA. Direct ELISA measures antigen-specific antibody; indirect ELISA measures antigen. (b) Photograph of 96 well ELISA plate: darkest color indicates most positive reaction. Quantitation is performed by measuring optical density of well contents.

chain-specific antisera as detection reagents. The appearance of both direct and indirect ELISA in which intense color equates with a positive result is shown in Figure 6-10b. A less commonly used configuration of ELISA is the competitive ELISA. This type of ELISA can be constructed to detect either antigen or antibody. It utilizes an enzyme-labeled ligand (antigen or antibody), which then competes with its unlabeled counterpart in the patient's serum. Such an assay shows color (higher O.D.) when the sample is negative. Thus, it is important for those interpreting ELISA to fully understand what constitutes a negative and a positive sample. The use of appropriate controls makes this of minor concern.

H. Immunohistochemistry/ Immunoperoxidase Techniques

Just as immunofluorescence can be used to evaluate serum antibodies or antigen present in tissue or on cells, the technique of enzyme immunoassay is also applied to tissue sections for identification of cell populations and demonstration of antigens in tissues. Immunoperoxidase detection of antigens has the advantage that the tissue sections can be examined with a standard microscope, whereas the immunofluorescence-based testing requires utilization of mercury lamps, dichroic mirrors, and special filters for excitation of the fluorochrome and for visualization of the emitted fluorescence. For immunoperoxidase evaluation of tissue antigens, an enzyme tagged antiserum is used to bind the antigen, then the substrate for the enzyme is added. The substrate is chosen so that it changes color when hydrolyzed by the enzyme. Thus, a colored product is deposited permanently in the tissue. In general, direct immunofluorescence and immunohistochemistry can be used for the same type of determinations. Figure 6-11 shows a canine lung section infected with canine distemper virus using immunoperoxidase staining with anti-canine distemper virus (CDV) antibody.

I. Western Blot Analysis

Western blot immunoassay is performed when it is desirable to determine which antigens in a mixture are binding with antibodies in test sera. It has great value when it is necessary to discriminate between antibodies produced in response to vaccination and those produced as a result of infection. If a subunit vaccine is used, this technique can be successfully applied. Some of the newer "designer" vaccines use only one or two protective epitopes to immunize.

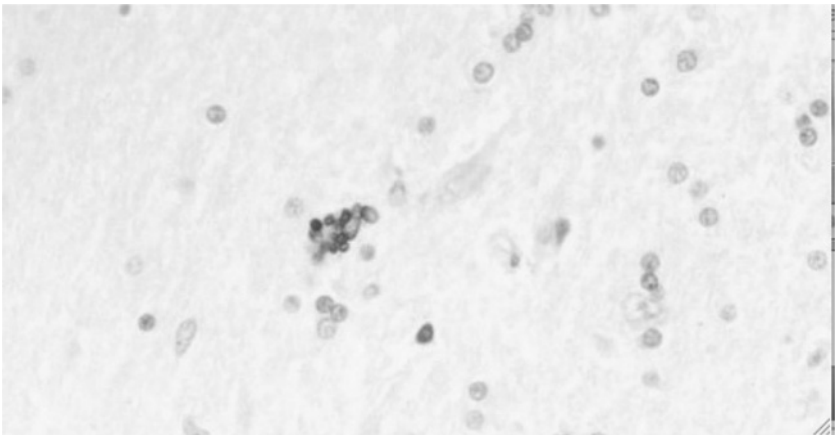

FIGURE 6-11 Immunoperoxidase staining of dog lung infected with canine distemper virus. Brown staining indicates the presence of intracellular virus as shown with horseradish peroxidase conjugated anti-CDV and substrate.

In this case, it is possible to evaluate serum using the Western blot method to identify to which of multiple proteins present in a pathogen a patient has responded. For example, in the vaccine for Lyme disease, if a dog has bands on Western blot for numerous *Borrelia burgdorferi* proteins, it is likely to be infected. However, the presence of only antibodies to Osp A (the protein containing protective epitopes that is present in the vaccine) indicates a vaccinated uninfected dog. The Western blot has also been used to differentiate between *Sarcocystis neurona* exposed and infected horses in patients suspected of having equine protozoal myelitis (EPM). Figure 6-12 shows an EPM Western blot.

To perform a Western blot assay, the antigen preparation must first be separated into its protein components using polyacrylamide gel electrophoresis (PAGE). This technique denatures the disulfide bonds and causes proteins to move through the gel according to their molecular weight. After the antigen is separated, the gel is blotted electrophoretically onto a nitrocellulose membrane, which is then probed with the patient sera and ultimately an enzyme-conjugated secondary antibody and substrate to visualize the bands representing proteins recognized by antibodies in the patient's serum. It is possible, by using specific conjugated antisera, to identify which antibody isotypes are binding (IgM, IgG, IgA, or IgE).

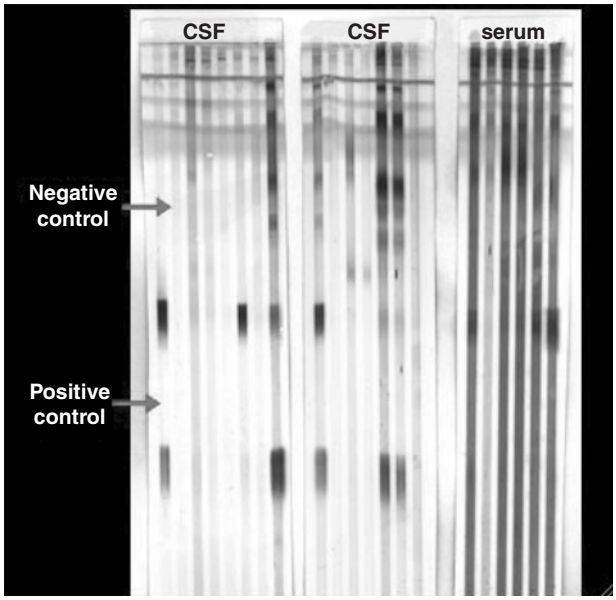

FIGURE 6-12 Western blot for equine protozoal myelitis. *Sarcocystis neurona* antigen was separated by SDS-PAGE, blotted to nitrocellulose, and probed with either sera or CSF. Bands on positive and negative control strips are compared to those on test strips.

J. How Do the Sensitivities of Different Immunoassays Compare?

Generally the gel diffusion-based assays such as double and single radial diffusion are much less sensitive that the primary binding assays like ELISA. This is because the former require not only binding of antigen to antibody but also the formation of an appropriate size insoluble precipitate for detection visually. Recently an ELISA kit has been developed to test for antibodies to equine infectious anemia. The traditional gold standard EIA assay is based on gel diffusion. The use of these two tests represents an interesting comparison in sensitivity between test methods, as the gel diffusion-type tests are far less sensitive than the primary binding assays like ELISA. Generally a negative ELISA for EIA is an acceptable result, but a positive is tested again by the Coggin's test to avoid false positives in the diagnosis of this important reportable equine infectious disease. The agglutination assays are generally between the gel diffusion and ELISA-type assays in sensitivity, and the immunofluorescence assays are less sensitive than ELISA but more sensitive than the gel diffusion-type assays. These comments are generalities, and each test will depend on the quality of the reagents used for both sensitivity and specificity.

K. Interpretation of Immune Responses to Pathogens

Diagnosis of infection with viral, bacterial, or parasitic pathogens can be determined by isolation of the agent, identification of pathogen nucleic acid using PCR methods, or by examination of the immune response to the suspected pathogen. The assays performed to detect an immune response to pathogens utilize the immunological principles described previously in this chapter. When immunological methods are used, it is most often necessary to obtain paired serum samples. These are acute and convalescent; samples are taken when the animal is first presented to the veterinarian and again in 2 to 3 weeks. Performance of the assay on both samples at the same time eliminates much variation from day-to-day fluctuations. Generally an increase in titer that is greater than two dilutions is evidence for induction of an immune response and hence (in the absence of recent vaccination) infection. When the initial sample is negative for antibodies to the pathogen and then becomes strongly positive, the patient is said to have undergone seroconversion.

Evaluation of the immune response to vaccination is currently of particular interest because immunologists are advising against routine vaccination annually. Yet it is important that immunity to diseases for which vaccination is performed is present. Thus, monitoring the titer of the antibody response has become more common (Schultz, 2006). When evaluating the immune response to virus, the ELISA is often used and so is the serum neutralization test. These assays evaluate different aspects of the immune response. The ELISA is a primary binding assay, which evaluates antibody levels without regard to function. The serum neutralization assay measures functional antibody and is better suited to determine protective levels of antibody to viral pathogens. Thus, for determination of protective antibody in response to vaccination, use of the serum neutralization (SVN) assay is most likely to equate to protection.

Many reference laboratories now have data that allow for a prediction for immune status based on serological titers.

Determination of antibody levels against *Sarcocystic neurona* is done using a combination of Western blot on serum and cerebrospinal fluid and indirect immunofluorescence with patient serum for diagnosis of equine protozoal myelopathy. For this disease, the presence of antibodies against *S. neurona* in the serum indicates exposure but not necessarily infection. Evaluation of the cerebrospinal fluid for the presence of antibody is preferable to detect infection.

VI. LABORATORY DIAGNOSIS OF DISEASES WITH AN IMMUNOLOGICAL PATHOGENESIS

A. Autoimmune Diseases

The use of the diagnostic clinical immunology tools is generally focused on the diagnosis or prevention of infectious disease, diagnosis of immune deficiency, detection of autoimmune responses, and diagnosis of hypersensitivity conditions. A variety of immune tests are used to help establish a diagnosis of autoimmune disease. Several examples follow.

Autoimmune hemolytic anemia is characterized by the presence of a Coombs' positive anemia. The Coombs' test evaluates the presence of autoantibody bound to patient erythrocytes by provision of a cross-linking antibody to facilitate agglutination of the antibody-bearing cells. This assay allows for the detection of so-called incomplete antibody. In the indirect Coombs' test, the patient's serum is examined for the presence of antibody that will bind to erythrocytes and agglutinate them when a secondary antiglobulin is added. Both tests can be employed to evaluate immune-mediated anemia.

The often-related disease autoimmune thrombocytopenia (AITP) can be tested for by staining a bone marrow biopsy with fluorescein-conjugated antisera specific for immunoglobulin (from the species of interest). The stained section is then observed for fluorescence of megakaryocytes, indicating the presence of antimegakaryocyte antibodies.

The systemic autoimmune disease systemic lupus erythematosus (SLE) requires a positive antinuclear antibody test diagnosis. Although the ANA test is sensitive, it is not specific. Nevertheless, antinuclear antibody titers of greater than 50 are present in SLE. Sometimes a lupus erythematosus (LE) cell may be observed; these are neutrophils that have engulfed opsonized nuclei. Such an observation is essentially pathognomic for SLE. In human medicine, a variety of other measurements for the presence of antinuclear antibodies are made. Some of these have been occasionally reported in domestic animal species (Gershwin, 2005; Smee, 2007).

Development of autoantibodies against components of the thyroid gland is associated with hypothyroidism caused by autoimmune thyroiditis, although sensitized T lymphocytes are also important in pathogenesis of the disease. Recognition of the antithyroid antibodies using indirect immunofluorescence with serum from the patient and normal thyroid tissue has been used to demonstrate the presence and titer of these antibodies. Similar assays can be performed on pancreas to detect the presence of anti-islet cell antibodies in patients with type I diabetes mellitus. One form of the neuromuscular disease myasthenia gravis develops as a result of immune destruction of the acetylcholine receptor at the neuromuscular junction. Detection of autoantibodies binding these receptors can be accomplished using patient sera in indirect immunofluorescence or immunohistochemistry.

B. Primary Immune Deficiency Diseases

Primary immune deficiency diseases are caused by a genetic defect that creates a malfunction or absence of a component or components of the immune system. Several such diseases were discussed previously in this chapter. Clinical signs of the disease generally in the young animal

TABLE 6-3 Evaluation of Cell Mediated Immunity

Function	Assay	Description
General T cell responsiveness	Lymphocyte stimulation	Peripheral blood lymphocytes (PBL) are stimulated *in vitro* with T cell mitogens or antigen
T cell subset enumeration	Flow cytometry	CD4 and CD8 specific monoclonal antibodies label PBL; intracellular cytokine production is measured with anti-IL-4 and anti-IFN γ
I*n vitro* production of interferon γ	ELISPOT or ELISA for IFN γ	Cells are evaluated for production of TH1 cytokine IFN γ after *in vitro* incubation with antigen
NK cell assay	Chromium release assay	Chromium^{51}-labeled tumor cell line is incubated with patient's lymphocytes with tumor cell line (not from patient)

provide the stimulus for initiation of testing to determine the nature of the problem. For diseases such as bovine leukocyte adhesion deficiency (BLAD), the use of flow cytometry on patient cells can demonstrate the lack of the CD18 molecule (Gu, 2004).

Other primary deficiencies requiring laboratory diagnosis include the combined immunodeficiency disease severe combined immunodeficiency (SCID) that occurs in Arabian horses. This disease results from a defect in the DNA-dependent protein kinase gene caused by a mutation (Perryman, 2000). This mutation prevents the production of a functional enzyme that is required for formation of the B and T cell antigen receptors. Without these receptors, foals are unable to respond to antigenic stimuli. Clinical signs begin to appear as the maternal immunity wanes, usually at about 8 weeks of age. Immunological diagnosis requires SRD testing of serum for IgM levels and enumeration of lymphocytes in the peripheral blood. Confirmation of the genetic defect can be accomplished using polymerase chain reaction (PCR) to detect the five-base-pair deletion. The homozygous condition is present in clinically affected foals. A similar defect has been identified in the Jack Russell terrier breed of dogs.

Other primary immune defects such as selective immunodeficiencies are recognized in various animal species. These include selective immunoglobulin deficiencies, such as IgA deficiency, seen in German shepherd and shar-pei dogs, or IgM deficiency in horses. Single radial diffusion quantitation is the assay of choice for diagnosis of these conditions. The patient with selective complete or partial deficiency of IgA will have levels of IgA less than normal (see Table 6-1).

T cell deficiencies have also been reported in several species. Functional T cell defects are most commonly identified using the lymphocyte stimulation assay (Table 6-3). Stimulation of patient and control peripheral blood lymphocytes with plant mitogens, such as concanavalin A or phyto- hemagglutinin, cause proliferation, which is measurable either by incorporation of tritiated thymidine or with a colorimetric readout. Comparison of the stimulated cells of the patient with unstimulated cells of the patient yields a stimulation index. The same data are collected from the normal control for comparison. Although it is a fairly crude measure of T cell function, this assay has been successfully used to demonstrate diminished T cell function in animal patients.

Another method for evaluation of the T cell response involves incubation of the patient's T cells with specific antigen, or mitogen, *in vitro.* ELISA is later used to evaluate the supernatant from the cultured cells for the presence of interferon γ. This technique was initially introduced as a kit for diagnosis of *Mycobacterium paratuberculosis* infection (Johne's disease), but it is easily adaptable to other antigens.

C. Secondary Immunodeficiencies

Secondary immunodeficiency is not a genetic disease. Patients that develop secondary immunodeficiency are often adult at onset. A common cause of secondary immunodeficiency is viral infection. Immunodeficiency viruses, such as feline immunodeficiency virus, cause a loss of CD4+ helper T cells, which prevents the patient from mounting a normal immune response. Infection with a variety of organisms that are not normally important as pathogens is common for immunosuppressed patients. Other viruses such as canine distemper and bovine viral diarrhea virus cause lymphocyte depletion and depressed immunity. Other causes of secondary immunodeficiency include parasitism, poor nutrition, and neoplasia. Diagnosis of depressed immune function can be accomplished using lymphocyte stimulation for T cell function and response to antigen challenge (such as increase in titer following routine vaccination). Depression of total immunoglobulin levels may not be helpful for short-term immunosuppression because of the relatively long half-life of IgG.

Failure of passive antibody transfer is a form of immune deficiency, albeit temporary. When a foal, calf,

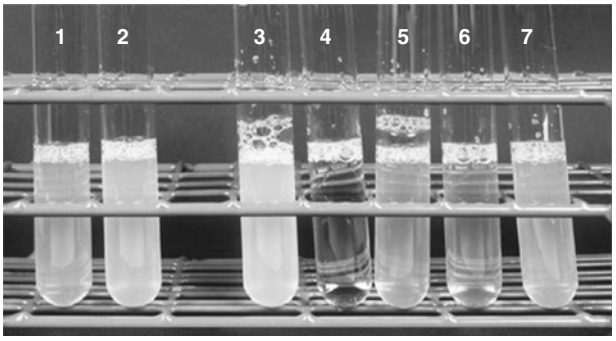

FIGURE 6-13 Tubes containing a solution of zinc sulfate are incubated with serum from neonatal foals to evaluate the quantity of passively transferred maternal IgG. Increased turbulence correlates with more IgG.

or piglet fails to suckle or obtains insufficient antibody, it will be susceptible to disease during the neonatal period. It is imperative to determine if sufficient antibody has been acquired. If this is done before the intestinal epithelium closes (before 18 hours of age), oral supplementation can be used. There are several tests to evaluate serum IgG levels in a semiquantitative but quick way. Several companies make kits based on ELISA technology, but a simple method that uses zinc sulfate turbidity is adequate. Serum of the foal is mixed with a solution of zinc sulfate. This test relies on binding of the sulfate to the IgG and formation of a precipitate. The more IgG in the serum, the greater the opacity of the mixture in the tube. An example is shown in Figure 6-13. The SRD is far more accurate, but the zinc sulfate test provides a rough estimate within less than an hour, thereby allowing oral supplementation of colostrums to occur within the window of time that it can be effective. An example of this method is shown in Figure 6-13.

D. Hypersensitivity Diseases

The diseases known collectively as hypersensitivities are grouped into four categories based on the mechanism that causes the pathology. These are types I to IV (Gell and Coombs). Type I hypersensitivity is the classic allergy, characterized by clinical signs ranging from systemic anaphylactic shock to allergic rhinitis and asthma. The mechanism involved in the pathogenesis of type I disease is IgE mediated. IgE antibodies, having a high affinity for mast cell receptors, bind to these cells and release mediators, such as histamine, upon contact with antigen/allergen. Arachidonic acid metabolism is also initiated through phospholipase activation and leukotriene and prostaglandin mediator synthesis occurs subsequent to the allergic stimulation. Laboratory diagnosis of type I hypersensitivity relies on testing serum for allergen-specific IgE, generally by ELISA. The availability of anti-IgE reagents for the various domestic animal species has made this diagnostic tool available in recent years. In addition, there is a commercially available service that uses a cloned alpha chain of the human IgE receptor to detect IgE bound to allergen in an ELISA format. Traditionally, intradermal skin testing has been used to determine which allergens are causing the allergic response. Many veterinary dermatologists use this method with good success.

Type II hypersensitivity occurs when IgG or IgM antibodies bind to a cell surface and fix complement. When the cell is an erythrocyte, the ultimate result is immune-mediated anemia. The *Coombs' test* described on page 169 for antibody bound to erythrocyte surfaces is the standard agglutination-type assay used to detect incomplete antibodies causing erythrocyte destruction. Erythrocyte destruction in the affected patient results from either complement-mediated lysis or removal by fixed phagocytes lining splenic sinusoids. Other type II hypersensitivities that do not involve erythrocytes include the skin diseases of the pemphigus complex and the neuromuscular disease, myasthenia gravis (both are autoimmune). For laboratory diagnosis of these diseases, immunofluorescence or immunohistochemistry is often used to demonstrate the deposition of immunoglobulin or complement within the lesion of affected skin (pemphigus) or on cells with acetylcholine receptors within the neuromuscular junction (myasthenia gravis).

Type III hypersensitivities are caused by immune complex formation. The antigens involved are soluble. Most commonly immune complexes form in chronic diseases in which antigen persists in the circulation despite a vigorous immune response (e.g., equine infectious anemia) and in certain autoimmune diseases (e.g., systemic lupus erythematosus) in which antinuclear antibodies are made and bind to various nuclear components from cell debris. In these cases, deposition of immune complexes within the small blood vessels, such as the kidney glomerulus as shown in Figure 6-7, is common. Detection of immune complex deposition by immunofluorescence is diagnostic for their presence.

Type IV hypersensitivity, unlike the previously discussed types I to III, is not mediated by antibody but is caused by development of sensitized T lymphocytes specific for the antigen. The classic example is the intradermal skin test for tuberculosis, which shows an erythemic-indurated lesion at the site of injection of tuberculin after 48 to 72 hours in infected individuals. The ELISA for interferon gamma can be used to evaluate T cell reactivity to antigens thought to be responsible for a type IV response.

VII. MODULATION OF THE IMMUNE RESPONSE

Adjuvants in vaccines have been used for many years to increase the immune response to vaccine antigen. In recent years, increased understanding of the immune response has resulted in the emergence of new modalities for immune modulation, not only for responses to vaccine antigens but

also for therapy of disease. Toll-like receptors (specifically TLR 10), described previously in this chapter, bind to nucleotides. The oligonucleotides containing cytocine-quaninemotifs in the unmethylated form as they occur in bacteria modulate the immune response toward the T helper type 1 response. Thus, recent experiments have been performed using these synthetic CpG oligonucleotides to either alter the response in a vaccine toward cellular rather than humoral immunity or in some cases to attempt to alter the strong T helper cell type 2 response that occurs in allergy (Wilson, 2006).

Another recent advance in immune modulation is the use of recombinant cytokines or their receptors to alter the immune response. For example, inclusion of the gene for interferon γ in a vectored viral vaccine facilitates the development of a cellular immune response to the antigens expressed by the vaccine. Therapy for tumor patients has utilized recombinant IL-2 (the cytokine that stimulates growth and proliferation of T cells) to enhance development of T cells specific for tumor antigens. This technique usually involves *in vitro* incubation of the patient's T cells with the recombinant IL-2 then readministration of the cells to the patient (Tizard, 2008).

The field of immune modulation is advancing rapidly and should be expected to yield useful prophylactic and therapeutic regimens for the future. Receptor antagonists, such as for interleukin 4, may diminish the progress of type 1 hypersensitivity. Similarly antagonists for some of the proinflammatory cytokines show promise for control of arthritic conditions.

VIII. SUMMARY

The current status of clinical immunology in veterinary medicine is better than it has ever been. The availability of species-specific reagents has made it possible to develop and apply a variety of immune assays previously only possible in humans and laboratory mice. These advances facilitate recognition of previously undiagnosable diseases in domestic animals and further the understanding of the pathogenesis of immune-mediated, neoplastic, and infectious diseases of domestic animals.

Gainesville, Florida

I. INTRODUCTION

Mammalian erythrocytes or red blood cells (RBCs) are anucleate cells that normally circulate for several months in blood despite limited synthetic capacities and repeated exposures to mechanical and metabolic insults. Their primary purpose is to carry hemoglobin (Hb), a heme-containing protein that accounts for more than 90% of the protein within RBCs (Quigley *et al.*, 2004). The benefits of having Hb contained within cells, as opposed to free in plasma, include the much slower turnover in blood (free Hb has a half-life of only a few hours), the metabolic capability of RBCs to maintain iron in Hb in the functional ferrous state, and the ability to control Hb oxygen affinity by altering the concentrations of organic phosphates, especially 2,3-diphosphoglycerate (2,3DPG). In addition, the presence of free Hb in plasma in concentrations normally found in whole blood would exert an osmotic pressure several times greater than that normally exerted by plasma proteins, profoundly affecting the movement of fluid between the vascular system and tissues.

A. Species Differences in Erythrocyte Shape

Most RBCs in normal dogs, cats, horses, cattle, and sheep occur in the shape of biconcave disks (discocytes). The degree of biconcavity is most pronounced in dogs and less so in cats and horses. RBCs from goats generally have a flat surface with little surface depression; a variety of irregularly shaped RBCs (poikilocytes) may be present in clinically normal goats (Jain, 1986). The apparent benefit of the biconcave shape is that it gives RBCs high surface area-to-volume ratios and allows for deformations that must take place as they circulate.

Marked acanthocytosis is reported to occur in young goats (Holman and Drew, 1964) and some young cattle (McGillivray *et al.*, 1985; Sato and Mizuno, 1982). Acanthocytosis of young goats reportedly occurs as a result of the presence of HbC at this stage of development (Jain *et al.*, 1980). Normal adult angora goats (Jain *et al.*, 1980; Jain and Kono, 1977) and some breeds of British sheep (Evans, 1968) have variable numbers of fusiform or spindle-shaped RBCs that resemble sickle cells (drepanocytes) in normal deer and people with sickle cell anemia (Taylor, 1983). Drepanocyte formation in deer depends on the Hb types present. It is an *in vitro* phenomenon that occurs when oxygen tension is high and pH is between 7.6 and 7.8 (Taylor, 1983). The proportion of fusiform cells in angora goats varies depending on the individual and *in vitro* alterations in temperature, pH, and oxygenation, but the tendency to form fusiform cells could not be attributed to differences in Hb type (Jain and Kono, 1977). Echinocytosis is a consistent artifact in stained blood films from pigs (Harvey, 2001).

B. Functions of RBCs

The RBC functions of oxygen transport, carbon dioxide transport, and hydrogen ion buffering are interrelated. Each Hb tetramer can bind four molecules of oxygen when fully saturated, forming oxyhemoglobin (OxyHb). Assuming a normal arterial pO_2 of 100mmHg and an Hb concentration of 150g/l (15g/dl) in blood, the presence of Hb-containing RBCs increases the oxygen carrying capacity of blood approximately 70 times that which could be transported dissolved in plasma (West, 1985).

Approximately 10% of CO_2 is transported dissolved in blood, 5% to 10% is transported bound to amine groups of blood proteins, and 80% to 85% is transported in the form of bicarbonate in normal individuals (Hsia, 1998; Jensen, 2004). Carbonic acid is formed when dissolved CO_2 combines with water. This reaction occurs nonenzymatically but is accelerated by the presence of the carbonic anhydrase (CA), also called carbonate dehydratase, enzyme in RBCs. Bicarbonate is formed by the rapid spontaneous dissociation of carbonic acid as shown:

$$H_2O + CO_2 \xleftrightarrow{CA} H_2CO_3 \longleftrightarrow H^+ + HCO_3^-$$

Hb potentiates the formation of bicarbonate by buffering hydrogen ions and shifting the equilibrium of the reaction to the right. Carbamino groups are formed by the combination of CO_2 with the terminal groups of proteins. The globin of Hb is the most important blood protein in this regard. The transportation of CO_2 from the tissues to the lungs as carbamino groups is potentiated because deoxyhemoglobin (DeoxyHb) binds twice as much CO_2 as OxyHb. The formation of carbamino groups can be represented as follows:

$$Hb\text{-}NH_2 + CO_2 \leftrightarrow Hb\text{-}NHCOOH \leftrightarrow Hb\text{-}NHCOO^- + H^+$$

Hb is the most important protein buffer in blood because it occurs in high concentration, has a relatively low molecular weight, and has a large number of histidine residues with pK_a values close to 7.4, enabling them to function as effective buffers. It has about six times the buffering capacity of the plasma proteins. An additional factor of importance in contributing to the effectiveness of Hb as a blood buffer is the fact that DeoxyHb is a weaker acid than OxyHb. As a result, most of the H^+ produced in the tissues under normal conditions is buffered as a direct result of the H^+ uptake by DeoxyHb owing to an increase in effective pK_a of Hb following release of oxygen to the tissues (West, 1985).

II. HEMATOPOIESIS

A. Stem Cells and Progenitor Cells

Primitive hematopoietic stem cells (HSCs) appear to develop in the embryo from a common precursor cell for both endothelial and hematopoietic lineages. The first HSCs appear to develop as clusters of cells in the wall of the dorsal aorta, with subsequent development in the yolk sac, placenta, and fetal liver (Baron and Fraser, 2005). Beginning in midgestation and continuing throughout postnatal life, mammalian blood cells are produced continuously from HSCs within extravascular spaces of the bone marrow. HSCs are capable of proliferation, life-long self-renewal, and differentiation. HSCs replicate only once every 8 to 10 weeks (Abkowitz *et al.*, 2002). The term *hematopoietic progenitor cell* (H*P*C) refers to cells that form colonies in bone marrow culture like HSCs but do not have long-term self-renewal capacities. HSCs and HPCs are mononuclear cells that cannot be distinguished morphologically from lymphocytes. The presence of a transmembrane glycoprotein termed *cluster of differentiation antigen 34* (CD34) has been used to identify HSCs and early HPCs, but some HSCs (possibly inactive ones) lack CD34 (Gangenahalli *et al.*, 2006). In addition, CD34 is also present on the surface of nonhematopoietic stem cells and vascular endothelial cells (Kucia *et al.*, 2005; Wu *et al.*, 2005). CD34 is believed to play a role in cell adhesion (Gangenahalli *et al.*, 2006).

The most primitive HSC has the capacity to differentiate into HPCs of all blood cell lineages and several cell types in tissue. The frequency of HSCs in the marrow is estimated to be $<0.01\%$ of nucleated marrow cells in adult mice and $<0.0001\%$ of nucleated marrow cells in adult cats (Abkowitz *et al.*, 2002). HSCs produce HPCs that can give rise to one or more blood cell types. HPCs are much more numerous in marrow than are HSCs. Less than 2% of nucleated bone marrow cells in adult dogs are $CD34^+$, but up to 18% $CD34^+$ cells have been reported in neonatal pups (Faldyna *et al.*, 2003; Suter *et al.*, 2004). A common lymphoid progenitor cell is believed to give rise to B lymphocytes, T lymphocytes, lymphoid dendritic cells, and natural killer cells (Blom and Spits, 2006). A common myeloid

progenitor cell is believed to give rise to all nonlymphoid blood cells, as well as macrophages, myeloid dendritic cells, osteoclasts, and mast cells (Kaushansky, 2006a). HPCs proliferate with higher frequency than do HSCs, but the self-renewal capabilities of HPCs decrease as progressive differentiation and cell lineage restrictions occur. When measured in an *in vitro* cell culture assay, HPCs are referred to as colony-forming units (CFUs). HPCs that rapidly proliferate, retain their ability to migrate, and form multiple subcolonies around a larger central colony in culture are called burst-forming units (BFUs). Colony-forming unit-granulocyte, RBC, macrophage, megakaryocyte (CFU-GEMM) is a tetrapotential HPC that has been studied extensively *in vitro*. The existence of a bipotential HPC (CFU-GM) that is the precursor of both neutrophils (and possibly other granulocytes) and monocytes is well established, and recent studies indicate the likelihood of a bipotential HPC for RBCs and megakaryocytes (Kaushansky, 2006a).

B. Hematopoietic Microenvironment

Blood cell production occurs throughout life in the bone marrow of adult animals because of the unique microenvironment present there. The hematopoietic microenvironment is a complex meshwork composed of stromal (fibroblast-like) cells, endothelial cells, adipocytes, macrophages, subsets of lymphocytes, natural killer cells, and osteoblasts; extracellular matrix components; and glycoprotein growth factors that profoundly affect HSC and HPC engraftment, survival, proliferation, and differentiation (Abboud and Lichtman, 2006).

Stromal cells and endothelial cells produce components of the extracellular matrix (ECM), including collagen fibers, basement membranes of vessels and vascular sinuses, proteoglycans, and glycoproteins. In addition to providing structural support, the ECM is important in the binding of hematopoietic cells and soluble growth factors to stromal cells and other cells in the microenvironment so that optimal proliferation and differentiation can occur by virtue of these cell-cell interactions.

Collagen fibers produced by stromal cells may not have direct stimulatory effects on hematopoiesis but rather are permissive, promoting hematopoiesis by forming an inert scaffolding around which the other elements of the microenvironment are organized. Hematopoietic cells can adhere to collagen types I and VI.

Adhesion molecules (most importantly β_1-integrins) on the surface of hematopoietic cells bind to ECM glycoproteins such as vascular cell adhesion molecule-1 (VCAM-1), hemonectin, fibronectin, laminin, tenascin, vitronectin, and thrombospondin. The spectrum of expression of adhesion molecules on hematopoietic cells that will differentially bind to these ECM glycoproteins varies with the type, maturity, and activation state of the hematopoietic cells. In addition to anchoring cells to a given microenvironmental niche, binding of adhesion molecules on hematopoietic cells also plays a role in cell regulation by direct activation of signal pathways for cell growth, survival, and differentiation or by modulating responses to growth factors.

Proteoglycans consist of a protein core with repeating carbohydrate glycosaminoglycans (GAGs) attached. Major proteoglycans in the marrow include heparan sulfate, chondroitin sulfate, hyaluronic acid, and dermatan sulfate. Proteoglycans enhance hematopoiesis by trapping soluble growth factors in the vicinity of hematopoietic cells and by strengthening the binding of hematopoietic cells to the stroma.

Hematopoietic cells develop in microenvironmental niches within the marrow. HSCs are concentrated near trabecular bone where osteoblasts help regulate their numbers (Yin and Li, 2006). Erythroid cells develop around macrophages, megakaryocytes form adjacent to sinusoidal endothelial cells, and granulocyte development is associated with stromal cells located away from the vascular sinuses (Abboud and Lichtman, 2006; Kaushansky, 2006a).

C. Hematopoietic Growth Factors

Proliferation of HSCs and HPCs cannot occur spontaneously but requires the presence of specific hematopoietic growth factors (HGFs) that may be produced locally in the bone marrow (paracrine or autocrine) or produced by peripheral tissues and transported to the marrow through the blood (endocrine). All cells in the hematopoietic microenvironment, including the hematopoietic cells themselves, produce HGFs or inhibitors of hematopoiesis. Some HGFs have been called poietins (erythropoietin and thrombopoietin). Other growth factors have been classified as colony-stimulating factors (CSFs) based on *in vitro* culture studies. Finally, some HGFs have been described as interleukins (ILs) (Kaushansky, 2006b).

Hematopoietic cells coexpress receptors for more than one HGF on their surface. The number of each receptor type present depends on the stage of cell activation and differentiation. Binding of an HGF to its receptor results in a series of enzymatic reactions that generate signals that promote the synthesis of molecules that inhibit apoptosis, the formation of cell-cycle regulators (cyclins), and the synthesis of additional HGFs and their receptors (Kaushansky, 2006b).

HGFs vary in the type(s) of HSCs or HPCs that they can stimulate to proliferate. Factors are often synergistic in their effects on hematopoietic cells. In some instances, an HGF may not directly stimulate the proliferation of a given cell type but may potentiate its proliferation by inducing the expression of membrane receptors for HGFs that do stimulate proliferation. Some glycoproteins such as IL-1 and tumor necrosis factor-α (TNF-α) can modulate hematopoiesis indirectly by stimulating marrow stromal cells,

endothelial cells, and T cells to produce HGFs. Different combinations of HGFs regulate the growth of different types of HSCs or HPCs (Kaushansky, 2006a).

Early-acting HGFs are involved with triggering dormant (G_O) primitive HSCs to begin cycling. Stem cell factor (SCF), flt3 ligand (FL), and thrombopoietin are important early factors that act in combination with one or more other cytokines such as IL-3, IL-6, IL-11, and granulocyte-CSF (G-CSF).

Intermediate-acting HGFs have broad specificity. IL-3 (multi-CSF), granulocyte-macrophage-CSF (GM-CSF), and IL-4 support proliferation of multipotent HPCs. These factors also interact with late-acting factors to stimulate proliferation of a wide variety of committed progenitor cells. Late-acting HGFs have restricted specificity. Macrophage-CSF (M-CSF), G-CSF, erythropoietin, thrombopoietin, and IL-5 are more restrictive in their actions. They have their most potent effects on committed progenitor cells and later stages of development when cell lines can be recognized morphologically (Kaushansky, 2006b).

D. Erythropoiesis

1. *Primitive Erythropoiesis*

Primitive RBC production begins and predominates in the yolk-sac but also occurs later in the liver and bone marrow. Primitive RBCs are large (>400 fl in humans) generally nucleated cells with high nuclear-to-cytoplasmic ratios. Their nuclei have open (noncondensed) chromatin, and their cytoplasm contains predominantly embryonal Hb with high oxygen affinity (Segel and Palis, 2006; Tiedemann, 1977; Tsuji-Takayama *et al.*, 2006). Like nonmammalian species, primitive RBCs enter blood as nucleated cells, but in contrast to nonmammalian species, enucleation can eventually occur in the circulation (Kingsley *et al.*, 2004). Primitive RBCs appear to be generated in an erythropoietin (Epo)-independent manner, but their expansion and survival require Epo (Tsuji-Takayama *et al.*, 2006). A switch to definitive erythropoiesis occurs during fetal development. Definitive erythropoiesis results in the production of smaller cells that generally extrude their nuclei before entering blood, produce fetal Hb (in some species) and adult Hb, and are highly dependent on Epo (Tsuji-Takayama *et al.*, 2006).

2. *Definitive Erythropoiesis*

Oligopotent progenitor cells (including CFU-GEMM cells) are stimulated to proliferate and differentiate into BFU-E by SCF, IL-3, and GM-CSF in the presence of Epo. BFU-E proliferation and differentiation into CFU-E results from the presence of these same factors and may be further potentiated by additional growth factors. Epo is the primary growth factor involved in the proliferation and differentiation of CFU-E into rubriblasts, the first morphologically recognizable erythroid cells. CFU-E cells are more responsive to Epo than are BFU-E cells because CFU-E cells exhibit greater numbers of surface receptors for Epo (Sawada *et al.*, 1990).

Marrow macrophages are important components of the hematopoietic microenvironment involved with erythropoiesis. Both early and late stages of erythroid development occur with intimate membrane apposition to central macrophages in so-called blood islands. Several adhesion molecules are important in forming these blood islands (Chasis, 2006). These central macrophages may regulate basal RBC production by producing both positive growth factors, including Epo, and negative factors such as IL-1, TNF-α, transforming growth factor-β, and interferon-α, -β, and -γ (Chasis, 2006; Weiss and Goodnough, 2005; Zermati *et al.*, 2000). The finding that Epo can also be produced by erythroid progenitors suggests that these cells may support erythropoiesis by autocrine stimulation (Stopka *et al.*, 1998). Although some degree of basal regulation of erythropoiesis occurs within the marrow microenvironment, humoral regulation is important, with Epo production occurring primarily within peritubular interstitial cells of the kidney and various inhibitory cytokines being produced at sites of inflammation throughout the body.

3. *Erythropoietin*

Epo is a 34 kDa glycoprotein hormone that exhibits a high degree of sequence homology among mammals (Wen *et al.*, 1993). It is the principal HGF that promotes the viability, proliferation, and differentiation of erythroid progenitor cells expressing specific cell surface Epo receptors. The main mechanism used to achieve these effects is inhibition of apoptosis. The binding of Epo to its receptor results in autophosphorylation of the receptor and the activation of several kinases that initiate multiple signaling pathways (Eckardt and Kurtz, 2005). Early BFU-E cells do not express Epo receptors, but more mature BFU-E cells express Epo receptors and are responsive to Epo. Epo receptor copies on cell surfaces increase to maximum values in CFU-E cells and then decline in rubriblasts and continue to decrease in later stages of erythroid development (Porter and Goldberg, 1993; Prchal, 2006). Because of their Epo receptor density, CFU-E cells readily respond to Epo, promoting their proliferation, differentiation, and transformation into rubriblasts, the first morphologically recognizable erythroid cell type. High concentrations of Epo may accelerate rubriblast entry into the first mitotic division, shortening the marrow transit time and resulting in the early release of stress reticulocytes (Prchal, 2006).

In the presence of Epo, other hormones including androgens, glucocorticoid hormones, growth hormone, insulin, and insulin-like growth factors (IGFs) can enhance the growth of erythroid progenitor cells *in vitro* (Leberbauer *et al.*, 2005; Miyagawa *et al.*, 2000). However, growth factors may have additional effects *in vivo*. For example,

growth hormone and IGF-1 are reported to decrease Epo synthesis in rat kidneys (Sohmiya and Kato, 2005). Glucocorticoids promote the differentiation of embryonic stem cells to hematopoietic cells and prolong the proliferation of erythroid progenitor cells but reduce the rate of spontaneous differentiation and terminal maturation of erythroid cells (Leberbauer *et al.*, 2005; Srivastava *et al.*, 2006). Glucocorticoids appear to be important in stress erythropoiesis (e.g., following hemorrhage or increased RBC destruction) when a substantial increase in erythropoiesis is required (Bauer *et al.*, 1999). The thyroid hormone 3,5,3′-triiodothyronine (T3) promotes the differentiation and maturation of erythroid cells toward enucleated RBCs (Leberbauer *et al.*, 2005). Thyroid hormones may also promote the synthesis of Epo in the kidney (Ma *et al.*, 2004).

Epo production in adult mammals occurs primarily within peritubular interstitial cells that are located within the inner cortex and outer medulla of the kidney. The liver is an extrarenal source of Epo in adults and the major site of Epo production in the mammalian fetus (Jelkmann, 2007). Bone marrow macrophages and erythroid progenitor cells themselves have also been shown to produce Epo, suggesting the possibility of short-range regulation of erythropoiesis (Stopka *et al.*, 1998; Vogt *et al.*, 1989).

The ability to deliver oxygen to the tissues depends on cardiovascular integrity, oxygen content in arterial blood, and Hb oxygen affinity. Low oxygen content in the blood can result from low partial pressure of oxygen (pO_2) in arterial blood, as occurs with high altitudes or with congenital heart defects in which some of the blood flow bypasses the pulmonary circulation. Low oxygen content in blood can also be present when arterial pO_2 is normal, as occurs with anemia and methemoglobinemia. An increased oxygen affinity of Hb within RBCs results in a decreased tendency to release oxygen to the tissues (McCully *et al.*, 1999).

Epo production is stimulated by tissue hypoxia, which is mediated by hypoxia-inducible factors (HIFs) that are heterodimers consisting of α and β subunits. An α subunit denoted 2α is most important in Epo production, at least for definitive erythropoiesis. Both α and β subunits are continuously translated, but α subunits are labile and regulated by tissue oxygen levels. At normal tissue oxygen levels in tissue ($pO_2 > 36$ mmHg), α subunits are hydroxylated by prolyl hydroxylases, polyubiquitinated, and removed by proteasomal degradation. When tissue oxygen levels are low ($pO_2 < 36$ mmHg), α subunits are no longer hydroxylated and degraded, allowing them to translocate into the nucleus and combine with β subunits to form heterodimeric transcription factors. These HIF heterodimers activate the transcription of the Epo gene, and many other target genes, by binding to the hypoxia responsive elements (HREs) in their promoter/enhancer regions. Binding to the Epo gene results in increased Epo synthesis when tissue hypoxia is present (Gruber *et al.*, 2007; Jelkmann, 2007).

Other tissues also exhibit Epo receptors, and Epo also stimulates nonhematopoietic actions including promoting proliferation and migration of endothelial cells, enhancing neovascularization, stimulating the production of modulators of vascular tone, and exerting cardioprotective and neuroprotective effects (Jelkmann, 2007).

III. DEVELOPING ERYTHROID CELLS

A. Morphological and Metabolic Changes

Rubriblasts are large cells (approximately 900 fl in humans) that are continuously generated from progenitor cells in the extravascular space of the bone marrow. The division of a rubriblast initiates a series of approximately 5 divisions over a period of 3 to 5 days to produce about 32 metarubricytes that are no longer capable of division (Prchal, 2006). These divisions are called maturational divisions because there is a progressive maturation of the nucleus and cytoplasm concomitant with the divisions. Each division yields a smaller cell with greater nuclear condensation and increased Hb synthesis. An immature RBC, termed a *reticulocyte*, is formed following extrusion of the nucleus (Harvey, 2001).

Early precursors have intensely blue cytoplasm, when stained with Romanowsky-type bloodstains, owing to the presence of many basophilic ribosomes and polyribosomes that are actively synthesizing globin chains and smaller amounts of other proteins. As the cells are nonsecretory, rough endoplasmic reticulum is scant and limited to early erythroid precursors (Bessis, 1973). Hb progressively accumulates in these cells, imparting a red coloration to the cytoplasm. Cells with both red and blue coloration are described as having polychromatophilic cytoplasm (Harvey, 2001). Kinetics of erythroid cells and changes in biochemical and metabolic pathways are depicted in Figure 7-1; time intervals were determined for cattle (Rudolph and Kaneko, 1971).

B. Iron Metabolism

Erythroid precursors have iron requirements that far exceed the iron requirements of any other cell type because of the need for Hb synthesis. Developing erythroid cells generally extract about 75% of the iron circulating in plasma (Smith, 1997).

1. *Transferrin and Transferrin Receptors*

Plasma iron is bound to apotransferrin, a beta globulin that can maximally bind two atoms of ferric iron per molecule. The proportion of apo-, mono-, and diferric forms of transferrin present in serum depends on the percentage saturation of transferrin with iron. Diferric transferrin is more efficient than monoferric transferrin in delivering iron

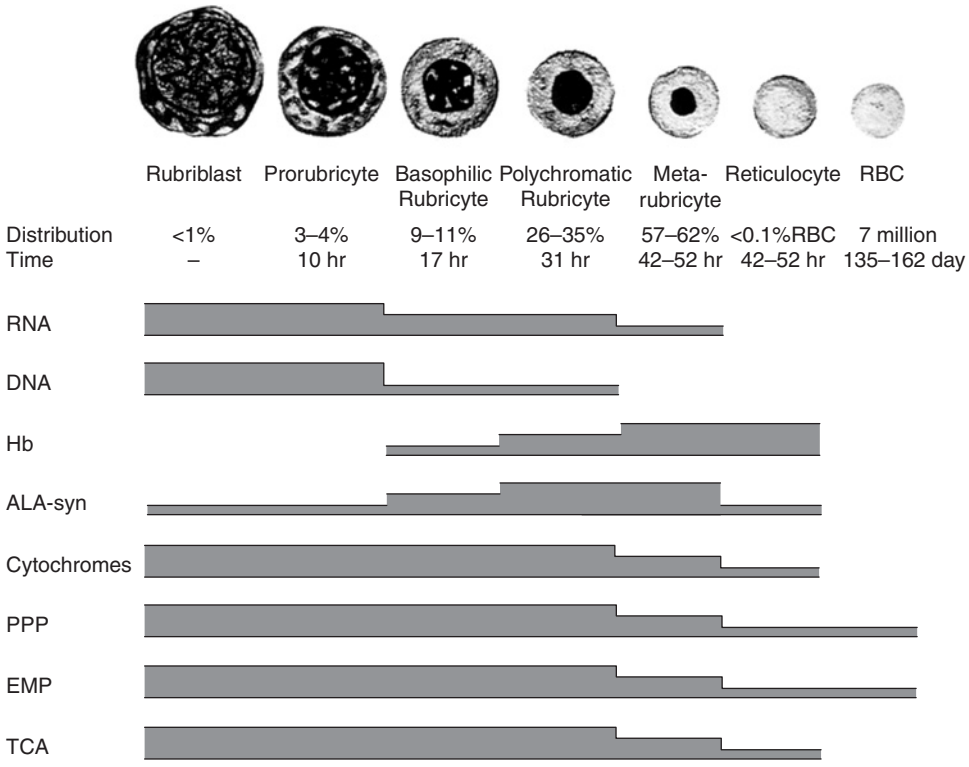

FIGURE 7-1 Summary of metabolic activities of the erythroid series. Maturation progresses from left to right. The time intervals indicated are for cattle. From Kaneko, 1980, with permission.

to cells, because it binds with higher affinity to receptors and can deliver twice the iron per molecule of transferrin incorporated (Huebers *et al.*, 1985). Transferrin molecules transport iron to erythroid cells and bind to transferrin receptor-1 (TfR1) on cell surfaces. Transferrin-TfR1 complexes localize to clathrin-coated pits, which invaginate to initiate endocytosis (Beutler, 2006). After the complexes are internalized as endosomes, a proton pump decreases the pH in the endosome, resulting in conformational changes in the proteins and subsequent release of Fe^{+3} ions from transferrin. Following reduction with NADPH-dependent ferrireductase, Fe^{+2} is exported from the endosome using divalent metal transporter-1 (Ohgami *et al.*, 2005). The resultant apotransferrin-TfR1 complex is recycled to the cell membrane, where apotransferrin is released from the cell, and the receptor is again available for binding additional transferrin molecules.

2. Intracellular Iron Transport

A direct interorganelle transfer of iron occurs between endosomes and mitochondria (Sheftel *et al.*, 2007). Most iron within mitochondria is incorporated into protoporphyrin IX to form heme, but some mitochondrial iron is used to synthesize iron-sulfur complexes that are important prosthetic groups for numerous proteins involved in electron transfer, metabolic, and regulatory processes (Lill *et al.*, 2006). Some iron is presumably released from endosomes into a cytoplasmic labile iron pool (LIP). Various chaperone molecules have been proposed, but the nature of the iron in the LIP remains enigmatic (Beutler, 2006).

3. Ferritin

Iron not required for iron-sulfur complex or heme synthesis is stored as ferritin within the cytoplasm. Each ferritin molecule is composed of a protein shell of 24 apoferritin subunits surrounding a central core containing as many as 4000 iron atoms as ferric hydroxide (Arosio and Levi, 2002). Individual ferritin molecules can be visualized by electron microscopy, and large aggregates of ferritin molecules can be visualized by light microscopy when stained for iron using the Prussian blue reaction. When membrane bound, ferritin aggregates have been called siderosomes (Bessis, 1973). Iron stored as ferritin is not available for Hb synthesis in erythroid cells (Ponka *et al.*, 1998).

4. Iron Regulation of Transferrin Receptor and Ferritin Expression

Apoferritin, TfR1, and erythroid-specific 5-aminolevulinic acid synthase (eALAS) synthesis are regulated by the LIP concentration. An increase in the LIP stimulates apoferritin synthesis and inhibits TfR1 expression to minimize the potential of iron toxicity to the cell. A decrease in the cytoplasmic LIP results in decreased apoferritin synthesis and increased TfR1 expression on cell surfaces to maximize iron uptake and use for heme synthesis (Beutler, 2006). RBCs

coordinate protoporphyrin IX formation with the availability of iron by increasing the synthesis of eALAS (rate limiting enzyme in porphyrin synthesis) when the LIP is high and decreasing eALAS synthesis when the LIP is low.

5. *Siderotic Inclusions in Erythroid Cells*

Anucleated RBCs containing siderotic (iron-positive) inclusions are called siderocytes. Nucleated siderocytes have been called sideroblasts in human hematology, in which terminology used for RBC precursors is generally different from that conventionally used in veterinary hematology (Bottomley, 2004). Siderotic inclusions in erythroid cells may consist of cytoplasmic ferritin aggregates or iron-loaded mitochondria. Ferritin aggregates can occur normally in nucleated erythroid cells of humans (Cartwright and Deiss, 1975), dogs (Feldman *et al.*, 1981), and pigs (Deiss *et al.*, 1966), but the presence of iron-loaded mitochondria is a pathological finding (Cartwright and Deiss, 1975). Electron microscopy is used to definitively identify the nature of siderotic inclusions (Fresco, 1981; Hammond *et al.*, 1969); however, the location of iron-positive inclusions in a ring around the nucleus of a nucleated siderocyte (termed *ringed sideroblast* in human hematology) strongly suggests the presence of iron-loaded mitochondria (Bottomley, 2004). Conditions resulting in the pathological iron accumulation in mitochondria may induce the synthesis of a novel mitochondrial ferritin (Torti and Torti, 2002).

Except for iron deficiency, disorders in heme synthesis have the potential to cause excess iron accumulation in mitochondria (Beutler, 1995b; Fairbanks and Beutler, 1995). Experimental pyridoxine deficiency and experimental chronic copper deficiency have both resulted in mitochondrial iron overload in nucleated erythroid cells in bone marrow of deficient pigs (Hammond *et al.*, 1969; Lee *et al.*, 1968a). Drugs or chemicals reported to cause siderocytes or nucleated siderocytes in dogs include chloramphenicol (Harvey *et al.*, 1985), lead, hydroxyzine, zinc (Harvey, 2001), and an oxazolidinone antibiotic (Lund and Brown, 1997).

Siderotic inclusions in erythroid cells have been recognized in some dogs and cats with myeloproliferative disorders (Blue *et al.*, 1988; Weiss and Lulich, 1999). Acquired dyserythropoiesis with siderocytes have been reported in dogs in which specific etiologies could not be determined, although some of these animals had inflammatory disorders (Canfield *et al.*, 1987; Weiss, 2005). Congenital anemias with ringed nucleated siderocytes have been reported in humans (Bottomley, 2006). Persistent siderotic inclusions have been recognized in microcytic hypochromic erythrocytes from an English bulldog. Erythrocytes also contained Heinz bodies and rare hemoglobin crystals (Harvey *et al.*, 2007). A congenital defect resulting in mitochondrial iron overload and secondary oxidant injury was suspected, but not identified. Refer to Chapter 9 for more information concerning iron metabolism.

C. Hb Synthesis

Hb is a tetrameric protein consisting of four polypeptide globin chains each of which contains a heme prosthetic group within a hydrophobic pocket. The molecule consists of two identical alpha and two nonalpha chains that are generally classified as beta chains in adults.

1. *Heme Synthesis and Metabolism*

Heme is a planar molecule composed of the tetrapyrrole protoporphyrin IX, containing a central ferrous molecule. The initial rate-controlling step in heme synthesis, the eALAS reaction, occurs within mitochondria (see Chapter 8). Glycine and the Krebs cycle intermediate succinyl-CoA are utilized as substrates, and vitamin B_6, as pyridoxal phosphate, is required as a cofactor. The ALA formed is transported to the cytoplasm where a series of reactions results in the formation of coproporphyrinogen III, which must enter the mitochondria, presumably using an ATP-binding cassette transporter ABCB6 (Krishnamurthy *et al.*, 2006) for the final steps in heme synthesis. The final reaction, catalyzed by heme synthetase, involves the insertion of ferrous iron into protoporphyrin IX.

Following synthesis, heme must be transferred from mitochondria to the cytoplasm for combination with globin chains to complete the synthesis of Hb. The mitochondrial heme exporter has not been identified at this time. Free heme is poorly soluble in water and can bind to and damage cellular components (Kumar and Bandyopadhyay, 2005). It apparently is bound to cytosolic proteins for transport to sites of globin chain synthesis (Kumar and Bandyopadhyay, 2005; Taketani *et al.*, 1998). Sometime after its synthesis, the iron moiety of heme is oxidized (presumably spontaneously) to the ferric state and is then more specifically called ferriheme (Schulman *et al.*, 1974).

Heme affects erythroid cell metabolism in different ways depending on the stage of maturation. It stimulates iron uptake and heme synthesis in early erythroid cells, but it inhibits iron uptake and heme synthesis in reticulocytes (Abraham, 1991; Battistini *et al.*, 1991). A cellular heme exporter termed *feline leukemia virus subgroup C cellular receptor* (FLVCR) is up-regulated on colony-forming units-erythroid (CFU-E) progenitor cells. It may provide a safety mechanism to prevent the accumulation of toxic amounts of cytoplasmic heme before globin synthesis is initiated.

2. *Globin Synthesis*

The synthesis of polypeptide globin monomers occurs in association with ribosomes and polyribosomes in the cytoplasm. Evidence has been provided indicating that binding of a partially unstructured apo-β chain to a tightly folded holo-α chain to form a heme-deficient dimer is the initial step of Hb assembly. Such binding locks the β chain in a highly ordered conformation, which allows for an efficient

heme acquisition by the β chain. (Griffith and Kaltashov, 2003). Free α globin chains are highly unstable and tend to aggregate within the cell and generate reactive oxygen species through chemical reactions catalyzed by their heme-bound iron molecules. Fortunately, free α globin chains are stabilized by binding to alpha Hb stabilizing protein (AHSP) until they combine with free β globin chains to form stable α-β dimers (Weiss *et al.*, 2005). Two like α-β dimers spontaneously combine in a readily reversible manner to form Hb tetramers (Bunn, 1987). Newly synthesized Hb is in the form of methemoglobin (MetHb) (Schulman *et al.*, 1974).

3. Control of Hb Synthesis

Even though three different pathways are required for Hb synthesis in RBC precursors and reticulocytes, minimal intermediates (iron, globin chains, or heme) accumulate in the cytoplasm of these cells. Several positive and negative feedback mechanisms account for the balanced production of these Hb components. As already discussed, an increase in the LIP limits the uptake of additional iron by decreasing TfR1 synthesis. The availability of iron also limits and, thereby controls, heme synthesis. Free "uncommitted" heme inhibits iron uptake by erythroid cells and consequently heme synthesis. In addition, free heme is essential for the synthesis of globin chains at both the transcriptional and translational levels (Koury and Ponka, 2004). Consequently, globin synthesis does not occur in the absence of heme.

4. Hb Types in Animals

Hb types are different in animal and human embryos than in fetuses or in adults. Embryonal Hbs are composed of either one or two pairs of peptide chains not found in adult Hbs (Kitchen and Brett, 1974). In higher primates, embryonal Hbs are replaced by fetal Hb composed of 2 α chains and 2 γ chains (HbF) in the fetus, followed by Hbs with 2 α chains and 2 β chains (HbA) or 2 α chains and 2 δ chains (HbA_2) after birth. The γ globin gene was deleted during evolution in artiodactyls (even-toed ungulates). The γ globin gene functions as an embryonic gene in other nonartiodactyl mammals. Among nonprimate mammals, a specific fetal globin gene is expressed only in artiodactyls. In this lineage, a duplicated β globin gene (β^F) is expressed in the fetus, rather than a γ globin gene. The entire β globin gene locus was duplicated in cattle and HbB sheep and triplicated in goats and HbA sheep during evolution (Gumucio *et al.*, 1996). Most fetal Hb in cattle ($\alpha_2\beta_2^F$) is replaced by adult Hb types during the first 3 weeks after birth (Lee *et al.*, 1971). Embryonal Hbs are replaced by adult Hb types during the fetal period in cats, dogs, horses, and pigs. Consequently, Hb types present in fetuses are identical to those found in adults in these species (Bunn and Kitchen, 1973; Kitchen and Brett, 1974).

In addition to expressing fetal Hb ($\alpha_2\beta_2^F$) in the fetus, most goats and some sheep express a juvenile Hb ($\alpha_2\beta_2^C$) called HbC during the neonatal period that is subsequently replaced with adult Hb types. Sheep that produce adult HbA ($\alpha_2\beta_2^A$) express variable amounts (generally less than 10%) of HbC during the neonatal period, but sheep that produce adult HbB ($\alpha_2\beta_2^B$) do not express HbC in the neonatal period (Huisman *et al.*, 1969; Yu *et al.*, 2005). Fetal Hb in the newborn goat is replaced almost entirely by HbC during the first 40 days of life (Fig. 7-2), and then HbC is gradually replaced by adult Hbs (Huisman *et al.*, 1969).

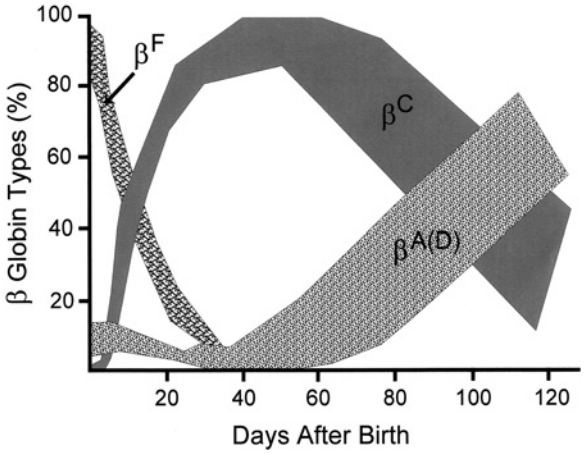

FIGURE 7-2 Changes in proportion of β globin types in Hb from five newborn goats during the first 120 days of life. Fetal Hb contains β^F. HbC contains β^C. HbD differs from HbA by a single amino acid substitution in position 21 of their β chains, β^D and β^A, respectively. Modification of a figure by Huisman *et al.*, 1969.

The switch from production of fetal Hb to the production of adult Hb appears to result from an inherent programming of hematopoietic stem cells (Wood *et al.*, 1985). In contrast, HbC synthesis appears to be mediated by Epo, which is low at birth and increases after birth as the hematocrit decreases (see Section V.C) (Barker *et al.*, 1980; Huisman *et al.*, 1969). Adult sheep RBCs contain little or no HbC, but adult goat RBCs may have as much as 10% HbC (Huisman *et al.*, 1969). Sheep and goats that synthesize HbC during the neonatal period will also increase HbC synthesis in anemic adults and in nonanemic adults treated with Epo (Vestri *et al.*, 1983; Yu *et al.*, 2005). Most goats and sheep with HbA have 12 genes in the β-globin locus, including the β^C gene. Cattle and sheep with HbB have 8 genes in the β-globin locus and lack the β^C gene (Garner and Lingrel, 1988). HbC was not reported to occur in three breeds of Omani goats after birth even though they were reported to be either homozygous for HbA or heterozygous for HbA and HbB (Johnson *et al.*, 2002). The composition of the β-globin locus was not investigated in these animals.

The α-globin genes have been duplicated in humans and other mammals. Triplication of α-globin genes is relatively common in sheep and quadruplication of genes also occurs. There is an expression gradient of α-globin protein and α-globin mRNA levels produced by duplicated and triplicated

α-globin genes, based on their location in the α-globin gene cluster. Gene expression progressively decreases from 5′ to 3′ (Vestri *et al.*, 1994). Compared to sheep with duplicated α-globin genes, sheep with triplicated α-globin genes produce excess α-globin, resulting in an unbalanced alpha/beta ratio and larger RBCs with increased osmotic fragility (Pieragostini *et al.*, 2003).

Considerable heterogeneity of Hb types occurs in adult animals. Two or more Hb types are reported to occur in domestic animal species (Braend, 1988; Kitchen, 1974; Kohn *et al.*, 1998, 1999; Pirastru *et al.*, 2003; Rando and Masina, 1985). Most polymorphism of animal Hbs is determined genetically and is usually caused by multiple amino acid interchanges (Kitchen, 1974). Hb types were initially classified based on electrophoretic mobility in gels. Electrophoretic differences can result from differences in α or β chain structure. For example, HbA and HbB in sheep are attributable to differences in β chains (Garner and Lingrel, 1988), but HbA and HbB in goats are attributed to differences in α chains (Huisman and Kitchens, 1968; Pieragostini *et al.*, 2005). Electrophoretic mobility in gels is not sensitive enough to identify many α and β chain variants, and distinctly different Hb tetramers can migrate with similar mobilities, resulting in misleading information. For example, HbB ($\alpha_2^B\beta_2^A$) and HbD ($\alpha_2^A\beta_2^D$) in goats have almost the same mobility at alkaline pH (Pieragostini *et al.*, 2005).

Nongenetic alterations in Hb structure can also contribute to apparent Hb heterogeneity. Examples include the N-acetylation of beta chains in cat HbB (Taketa *et al.*, 1972) and glycosylation of Hb, a function of intracellular glucose concentration and RBC life span (Higgins *et al.*, 1982; Rendell *et al.*, 1985). Increased glycosylation of Hb has been reported in diabetic dogs and cats (Elliott *et al.*, 1997, 1999). Similar to the glycosylation of Hb by glucose, cyanate combines spontaneously and irreversibly with Hb to form carbamylated Hb. Cyanate forms spontaneously from urea. Dogs with chronic renal failure and long-term increases in urea concentration have larger amounts of carbamylated Hb than dogs with acute renal failure (Heiene *et al.*, 2001).

D. Reticulocytes

1. Formation

Most reticulocytes are formed from metarubricytes within the extravascular space of the bone marrow by a process of nuclear extrusion that requires functional microtubules (Chasis *et al.*, 1989) and is likened to mitosis (Bessis, 1973; Simpson and Kling, 1967). The erythroblast macrophage protein (Emp) associates with F-actin and is important in denucleation of metarubricytes, as well as blood island formation (Soni *et al.*, 2006). Extruded nuclei quickly expose phosphatidylserine on their surfaces, which promotes their binding to, and phagocytosis by, blood island macrophages (Yoshida *et al.*, 2005).

Reticulocyte cytoplasm contains ribosomes, polyribosomes, and mitochondria necessary for the completion of Hb synthesis. Reticulocytes derive their name from a network or reticulum that appears when stained with basic dyes such as methylene blue and brilliant cresyl green. That network is not preexisting but is an artifact formed by the precipitation of ribosomal ribonucleic acids and proteins. As reticulocytes mature, the amount of ribosomal material decreases until only a few basophilic specks can be visualized with reticulocyte staining procedures. These mature reticulocytes have been referred to as type IV (Houwen, 1992) or punctate reticulocytes (Alsaker, 1977; Perkins *et al.*, 1995). To reduce the chance that a staining artifact would result in misclassifying a mature RBC as a punctate reticulocyte using a reticulocyte stain, the cell being evaluated should have two or more discrete blue granules that are visible without requiring fine focus adjustment of the cell to be classified as a punctate reticulocyte.

2. Metabolism

Reticulocyte metabolism and maturation have been reviewed by Rapoport (1986) and are summarized here. Immature reticulocytes continue to synthesize protein (primarily globin chains) with residual mRNA, tRNA, and rRNA formed before denucleation. About 30% of total Hb is synthesized after nuclear extrusion (Geminard *et al.*, 2002). Synthesis of fatty acids is minimal, but phospholipids are synthesized from preformed fatty acids. Substrates for protein and lipid synthesis and for energy metabolism are provided from endogenous sources (breakdown of mitochondria and ribosomes) as well as from plasma. The reticulocyte can synthesize adenine and guanine nucleotides *de novo* (Rapoport, 1986).

Most ATP is generated in reticulocytes by oxidative phosphorylation in mitochondria. Glucose is the major substrate, but amino acids and fatty acids can also be utilized for energy (Rapoport, 1986).

3. Maturation into RBCs

Reticulocyte maturation into mature RBCs is a gradual process that requires a variable number of days depending on the species involved. Consequently, the morphological and physiological properties of reticulocytes vary with the stage of maturation. Early reticulocytes have polylobulated surfaces. The cell surface undergoes extensive remodeling with loss of membrane material and ultimately the formation of the biconcave shape of mature RBCs (Bessis, 1973). The loss of membrane protein and lipid components requires ATP and involves the formation of intracellular multivesicular endosomes that fuse with the plasma membrane releasing vesicles (exosomes) extracellularly (Geminard *et al.*, 2002). This is a highly selective process in which some proteins (e.g., TfR1 and fibronectin receptor) are lost and cytoskeletal proteins (e.g., spectrin) and firmly bound transmembrane

proteins (e.g., the anion transporter and glycophorin A) are retained and concentrated (Geminard *et al.*, 2002; Ponka *et al.*, 1998). The heat shock protein 70 (Hsp70) is concentrated in exosomes and may promote the formation of exosomes during reticulocyte maturation (Jeong *et al.*, 2005). Some membrane proteins such as the nucleoside transporter, glucose transporter, Na,K-ATPase, insulin receptor, and adrenergic receptors decrease to variable degrees depending on the species involved (Chasis *et al.*, 1989; Geminard *et al.*, 2002). Examples of reticulocytes from a species that exhibit a complete or nearly complete loss of a protein that is retained in mature RBCs from other species include the adenosine transporter in sheep (Jarvis and Young, 1982), the glucose transporter in pigs (Zeidler and Kim, 1982), and Na,K-ATPase in dogs (Maede and Inaba, 1985).

Although loss of membrane components accounts for much of the change in membrane protein composition during reticulocyte maturation, certain proteins such as protein 4.1 and glycophorin C increase because they are still being synthesized in reticulocytes (Chasis *et al.*, 1989). These membrane alterations result in increased mechanical stability of blood reticulocyte and RBC membranes compared to marrow reticulocyte and nucleated erythroid cell membranes (Waugh *et al.*, 2001).

Mitochondria undergo degenerative changes in a programmed death phenomenon (mitoptosis) owing to 15-lipoxygenase attack and subsequent ATP-dependent proteolysis (Geminard *et al.*, 2002). Degenerating mitochondria are either digested or extruded following entrapment in structures resembling autophagic vacuoles (Simpson and Kling, 1968). The polysomes separate into monosomes and decrease in number and disappear as reticulocytes mature into RBCs. The degradation of ribosomes appears to be energy dependent; it presumably involves proteases and RNAases (Rapoport, 1986).

4. *Species Differences in Marrow Release*

Reticulocyte maturation begins in the bone marrow and is completed in the peripheral blood and spleen in dogs, cats, and pigs. As reticulocytes mature, they lose the surface receptors needed to adhere to fibronectin and thrombospondin components of the extracellular matrix, presumably facilitating their release from the bone marrow (Telen, 2000). Residual adhesion molecule receptors on newly released reticulocytes may explain their tendency to concentrate in the reticular meshwork of the spleen (Patel *et al.*, 1985).

Reticulocytes become progressively more deformable as they mature, a characteristic that also facilitates their release from the marrow (Waugh *et al.*, 2001). To exit the extravascular space of the marrow, reticulocytes press against the abluminal surfaces of endothelial cells that make up the sinus wall. Cytoplasm thins and small pores (0.5 to 2 μm) develop in endothelial cells, which allow reticulocytes to be pushed through by a small pressure gradient across the sinus wall (Lichtman and Santillo, 1986; Waugh, 1991). Pores apparently close after cell passage.

Relatively immature aggregate-type reticulocytes are released from canine bone marrow; consequently, most of these cells appear polychromatophilic when viewed following routine blood film staining procedures (Laber *et al.*, 1974). Absolute reticulocyte counts oscillate with a periodicity of approximately 14 days in some dogs, suggesting that canine erythropoiesis may have a homeostatically controlled physiological rhythm (Morley and Stohlman, 1969). Reticulocytes are normally not released from feline bone marrow until they mature to punctate-type reticulocytes; consequently, few or no aggregate reticulocytes ($<$0.4%), but up to 10% punctate reticulocytes, are found in blood from normal adult cats (Cramer and Lewis, 1972). The high percentage of punctate reticulocytes results from a long maturation time with delayed degradation of ribosomes (Fan *et al.*, 1978). Reticulocytes are generally absent in peripheral blood of healthy adult cattle and goats, but a small number of punctate types (0.5%) may occur in adult sheep (Jain, 1986). Based on microscopic examination of blood films stained with new methylene blue, equine reticulocytes are absent from blood normally and rarely released in response to anemia. However, low numbers of reticulocytes have been reported in the blood of normal and anemic horses using an Advia 120 (Siemens Medical Solutions Diagnostics, Tarrytown, New York) automated analyzer (Cooper *et al.*, 2005). Either the instrument is more sensitive than microscopic evaluation, or values reported in normal horses represent "noise" in the instrument.

5. *"Stress" Reticulocytes*

Except for horses, increased numbers of reticulocytes are released in response to anemia, with better responses to hemolytic anemia than to hemorrhage. When the degree of anemia is severe, basophilic macroreticulocytes, or so-called stress reticulocytes, may be released into blood. It is proposed that a generation in the maturation sequence is skipped and immature reticulocytes, about twice the normal size, are released (Rapoport, 1986). Increased Epo results in a diminution in the adventitial cell and endothelial cell barrier separating marrow hematopoietic cells from the sinus, thereby potentiating the premature release of stress reticulocytes from the marrow (Chamberlain *et al.*, 1975). Although a portion of these macroreticulocytes apparently is rapidly removed from the circulation (Noble *et al.*, 1990), it is clear from studies in cats that some can mature into macrocytic RBCs with relatively normal life spans (Weiser and Kociba, 1982).

E. Abnormalities in Erythroid Development

1. *Ineffective Erythropoiesis*

Ineffective erythropoiesis is a term used to describe the destruction of developing erythroid cells in marrow.

Normally, few die within the marrow (Odartchenko *et al.*, 1971), but ineffective erythropoiesis is prominent in disorders of nucleic acid, heme, or globin synthesis. Examples include folate deficiency, iron deficiency, vitamin B_6 deficiency, lead poisoning, and thalassemia in humans (Jandl, 1987). Ineffective erythropoiesis also occurs in association with myeloproliferative and myelodysplastic disorders (Meyer and Harvey, 2004) and congenital dyserythropoiesis (Holland *et al.*, 1991; Steffen *et al.*, 1992).

2. *Vitamin and Mineral Deficiencies*

Folate is required for normal DNA synthesis. Folate deficiency impairs the activity of the folate-requiring enzyme thymidylate synthase (Jandl, 1987). Not only is deoxythymidylate triphosphate (dTTP) synthesis decreased, but deoxyuridylate triphosphate (dUTP) accumulates secondarily in the cell such that some becomes incorporated into DNA in place of dTTP. Cycles of excision and attempts to repair these copy errors, with limited thymidine available, result in chromosomal breaks and malformations and slowing of the S phase in the cell cycle. Consequently, erythroid precursors are often large with deranged-appearing nuclear chromatin; such cells are classified as megaloblastic cells. Folate deficiency in people causes macrocytic anemia because fewer divisions occur as a result of retarded nucleic acid synthesis in the presence of normal protein synthesis (Jandl, 1987). Possible causes of folate deficiency include dietary deficiency, impaired absorption, and drugs that interfere with folate metabolism.

Macrocytic anemias resulting from folate deficiency are rarely reported in animals. A possible case was reported in a dog on anticonvulsant therapy (Lewis and Rebar, 1979), but serum folate was not measured. Megaloblastic precursors were present in bone marrow of cats with experimental dietary folate deficiency, but hematocrits and mean cell volumes (MCVs) remained normal (Thenen and Rasmussen, 1978). However, macrocytic anemia with dyserythropoiesis was reported in a cat that appeared to have both a folate-deficient diet and defective folate absorption (Myers *et al.*, 1996). Macrocytic anemia has been reported in folate-deficient pigs (Bush *et al.*, 1956), but not lambs (Stokstad, 1968).

Vitamin B_{12} (cobalamin) deficiency in people causes hematological abnormalities similar to folate deficiency because vitamin B_{12} is necessary for normal folate metabolism in humans (Chanarin *et al.*, 1985). In contrast, vitamin B_{12} deficiency does not cause macrocytic anemia in any animal species (Chanarin *et al.*, 1985). Anemia has been reported in some experimental animal studies, but RBCs were of normal size (Stokstad, 1968; Underwood, 1977), although slight increases in MCV have been reported in B_{12}-deficient goats fed diets deficient in cobalt (Mgongo *et al.*, 1981). Cobalamin deficiency has been reported secondary to an inherited malabsorption of cobalamin in giant schnauzer dogs (Fyfe, 2000). Affected animals have normocytic, nonregenerative anemia with increased anisocytosis and poikilocytosis, neutropenia with hypersegmented neutrophils, and giant platelets. Megaloblastic changes in the bone marrow were particularly evident in the myeloid cell line. The malabsorption of cobalamin in these dogs apparently results from the absence of an intrinsic factor-cobalamin receptor in the apical brush border of the ileum. No blood or bone marrow abnormalities were recognized in kittens fed a B_{12}-deficient diet for several months (Morris, 1977), but a normocytic nonregenerative anemia was present in a cobalamin-deficient cat that probably had an inherited disorder of cobalamin absorption (Vaden *et al.*, 1992).

A number of disorders exhibit macrocytic anemias with megaloblastic abnormalities in the marrow that mimic findings in human folate or cobalamin deficiency but have had normal serum levels of these vitamins when measured. Examples include cats infected with the feline leukemia virus (Dunn *et al.*, 1984; Weiser and Kociba, 1983a), cattle with congenital dyserythropoiesis (Steffen *et al.*, 1992), and myelodysplastic syndromes (Harvey, 2001). In addition, some miniature and toy poodles exhibit macrocytosis without anemia and variable megaloblastic abnormalities in the bone marrow with normal serum folate and cobalamin values (Canfield and Watson, 1989).

Abnormalities in heme or globin synthesis can result in the formation of microcytic hypochromic RBCs. Cellular division is normal, but Hb synthesis is delayed; consequently, one or more extra divisions occur in RBC development, resulting in smaller cells than normal.

Pyridoxine, vitamin B_6, is required for the first step in heme synthesis. Although natural cases of pyridoxine deficiency have not been documented in domestic animals, microcytic anemias with high serum iron values have been produced experimentally in dogs (McKibbin *et al.*, 1942), cats (Bai *et al.*, 1989; Carvalho da Silva *et al.*, 1959), and pigs (Deiss *et al.*, 1966) with dietary pyridoxine deficiency. Erythroid cells with iron-loaded mitochondria, secondary to impaired heme synthesis, have been demonstrated in pigs fed a pyridoxine-deficient diet (Hammond *et al.*, 1969).

With the exception of young growing animals, iron deficiency in domestic animals usually results from blood loss. Milk contains little iron; consequently, nursing animals can easily deplete their body iron store as they grow (Furugouri, 1972; Harvey *et al.*, 1987; Holter *et al.*, 1991; Siimes *et al.*, 1980). Microcytic RBCs are produced in response to iron deficiency (Holman and Drew, 1966; Holter *et al.*, 1991; Reece *et al.*, 1984), but a low MCV may not develop postnatally in species where the MCV is above adult values at birth (Weiser and Kociba, 1983b). The potential for development of severe iron deficiency in young animals appears to be less in species that begin to eat food at an early age.

Chronic iron deficiency anemia with microcytic RBCs is common in adult dogs in areas where hookworm and flea infestations are severe (Harvey *et al.*, 1982; Weiser and O'Grady, 1983). Severe iron deficiency appears to be

rare in adult cats (French *et al.*, 1987; Fulton *et al.*, 1988) and horses (Smith *et al.*, 1986), but it occurs frequently in ruminants that are heavily parasitized with blood-sucking parasites such as *Haemonchus contortus*. Much more information concerning iron deficiency is given in Chapter 9.

Prolonged copper deficiency generally results in anemia in mammals (Auclair *et al.*, 2006; Brewer, 1987; Lahey *et al.*, 1952), although anemia was not a feature of experimental copper deficiency in the cat (Doong *et al.*, 1983). The anemia is generally microcytic hypochromic; however, normocytic anemia has been reported in experimental studies in dogs, and normocytic or macrocytic anemias have been reported in cattle and adult sheep (Brewer, 1987). Copper deficiency results in impaired iron metabolism (Lee *et al.*, 1968b). In experimental studies in pigs, serum iron concentration is low in early copper deficiency when iron stores are normal (Lahey *et al.*, 1952; Lee *et al.*, 1968b). Functional iron deficiency occurs because copper-containing proteins hephaestin and ceruloplasmin are required for normal iron transport (Lee *et al.*, 1968a; Wessling-Resnick, 2006).

If experimental copper deficiency is prolonged in pigs, hyperferremia occurs and nucleated erythroid cells with cytoplasmic siderotic (iron-positive) inclusions increase in bone marrow (Lee *et al.*, 1968a). Reticulocyte mitochondria from copper-deficient pigs are unable to synthesize heme at the normal rate using Fe^{+3} (Williams *et al.*, 1976). A deficiency in copper-containing cytochrome oxidase within mitochondria may slow the reduction of Fe^{+3} to Fe^{+2} within mitochondria. That would limit heme synthesis, which requires iron in the Fe^{+2} state (Porra and Jones, 1963).

3. Deficiencies in Globin Synthesis

Hereditary deficiencies in synthesis of the globin α chain (α-thalassemia) and β chain (β-thalassemia) cause microcytic hypochromic anemias in humans with variable degrees of poikilocytosis (Weatherall, 2006). Both α- and β-thalassemia occur in mice, but thalassemias have not been reported in domestic animals.

4. Aplastic Anemia

Aplastic anemia is generally used to describe anemias where granulocytic, megakaryocytic, and erythrocytic cell lines are markedly reduced in the bone marrow. When only the erythroid cell line is reduced or absent, terms such as *pure red cell aplasia*, *selective erythroid aplasia*, or *selective erythroid hypoplasia* are used.

Many drugs have been incriminated in the production of aplastic anemia in humans (Shadduck, 1995). Drug-induced causes of aplastic anemia or generalized marrow hypoplasia in animals include estrogen toxicity in dogs, phenylbutazone toxicity in dogs and possibly a horse, trimethoprim-sulfadiazine administration in dogs, bracken fern poisoning in cattle and sheep, trichloroethylene-extracted soybean meal in cattle, albendazole toxicity in dogs and cats, griseofulvin toxicity in cats, various cancer chemotherapeutic agents, and radiation. Thiacetarsamide, meclofenamic acid, and quinidine have also been incriminated as potential causes of aplastic anemia in dogs. In addition to exogenous estrogen toxicity, high levels of endogenous estrogens, produced by estrogen secreting tumors and functional cystic ovaries in dogs and prolonged estrus in ferrets, can result in aplastic anemia (Harvey, 2001). Parvovirus infections can cause erythroid hypoplasia, as well as myeloid hypoplasia in canine pups (Potgieter *et al.*, 1981; Robinson *et al.*, 1980), but animals may not become anemic, because of the long life spans of RBCs. Although some degree of marrow hypoplasia or dysplasia often occurs in cats with feline leukemia virus (FeLV) infections (Cotter, 1979), true aplastic anemia is not a well-documented sequela (Rojko and Olsen, 1984). Hypocellular bone marrow has been reported in cats experimentally co-infected with FeLV and feline parvovirus (Lutz *et al.*, 1995). Dogs with acute *Ehrlichia canis* infections may spontaneously recover or develop chronic disease that generally exhibits some degree of marrow hypoplasia. Although rare, aplastic anemia may develop in association with severe chronic ehrlichiosis in dogs (Neer, 1998).

A retrospective review of cats with aplastic anemia identified 13 cases in which the clinical diagnoses included chronic renal failure (n = 5), FeLV infection (n = 2), hyperthyroidism treated with methimazole (n = 1), and idiopathic aplastic anemia (n = 5). The author suggested that starvation may have played a role in the development of marrow aplasia in some of these cats (Weiss, 2006). Idiopathic aplastic anemia has also been reported in dogs and horses (Harvey, 2001). CFU-E were not detected in bone marrow culture from a dog with an idiopathic aplastic anemia (Weiss and Christopher, 1985).

Other potential causes of aplastic anemia include congenital defects and primary immune-mediated disorders. Most cases of aplastic anemia in adult humans are immune mediated, with activated type 1 cytotoxic T cells implicated in the pathogenesis (Young *et al.*, 2006). The aberrant immune response may be triggered by environmental exposures, such as to chemicals and drugs or viral infections, and possibly by endogenous antigens generated by genetically altered bone marrow cells (Young, 2002).

5. Selective Erythroid Aplasia

Selective erythroid aplasia (pure red cell aplasia) occurs as either a congenital or acquired disorder in people. Acquired erythroid aplasia is often associated with abnormalities of the immune system. Erythroid aplasia may also occur secondary to disorders such as B-19 parvovirus infection, lymphoid malignancies, and drug or chemical toxicities (Erslev and Soltan, 1996).

Acquired erythroid hypoplasia or aplasia occurs in dogs (Stokol *et al.*, 2000; Weiss, 1986). Some cases have

immune-mediated etiologies based on positive responses to immunosuppressive therapy and the presence of antibodies that inhibit CFU-E development in marrow cultures (Weiss, 1986). Acquired, presumably immune-mediated, erythroid aplasia has also been reported in FeLV-negative cats (Stokol and Blue, 1999).

Selective erythroid aplasia occurs in cats infected with FeLV subgroup C (FeLV-C), but not in cats infected only with subgroups A or B (Riedel *et al.*, 1986). CFU-E numbers are markedly decreased but BFU-E numbers are normal in infected cats, indicating that FeLV-C inhibits differentiation of BFU-E into CFU-E (Abkowitz, 1991). The cell surface receptor for FeLV-C is called FLVCR. This receptor has recently been demonstrated to be a heme exporter (Quigley *et al.*, 2004). Free heme is toxic to cells, and it is hypothesized that the binding of FeLV-C to FLVCR on CFU-E progenitor cells inhibits heme export from these cells, resulting in their destruction (Quigley *et al.*, 2004).

High doses of chloramphenicol cause reversible erythroid hypoplasia in some dogs (Watson, 1977) and erythroid aplasia in cats (Watson and Middleton, 1978). Marked erythroid hypoplasia has been reported in dogs, cats, and horses given recombinant human erythropoietin (Cowgill *et al.*, 1998; Piercy *et al.*, 1998; Woods *et al.*, 1997). Antibodies made against this human recombinant glycoprotein apparently cross-react with the animals' endogenous erythropoietin.

IV. MATURE RBC

Values for RBC glucose utilization, ion concentrations, and survival times in normal animals are given in Table 7-1. Enzyme activities are given in Tables 7-2 and 7-3, and chemical constituents in RBCs are given in Tables 7-4 and 7-5. These are not, however, comprehensive lists. Other values are provided by Friedemann and Rapoport (1974) and in various chapters of a reference book edited by Agar and Board (1983). Anemia induced by phlebotomy or by hemolytic drugs produces changes in many of the previously stated values owing to the influx of young RBCs into the circulation in response to the anemia (Agar and Board, 1983). Methods for enzyme assays vary considerably; consequently, each laboratory will need to establish its own reference intervals if enzyme studies are to be done.

A. Membrane Structure

The RBC membrane is composed of a hydrophobic lipid bilayer with a protein skeletal meshwork attached to its inner surface by binding to integral (transmembrane) proteins (Fig. 7-3). Membrane proteins from RBCs have been numbered by their migration location (Smith, 1987) on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE); some have also been given one or more

names. Electrophoretic patterns of membrane proteins on SDS-PAGE are species variable (Gillis and Anastassiadis, 1985; Kobylka *et al.*, 1972; Smith *et al.*, 1983a; Whitfield *et al.*, 1983).

1. *Lipids*

The lipid bilayer and associated transmembrane proteins chemically isolate and regulate the cell interior. The bilayer consists of phospholipids arranged with hydrophobic hydrocarbon chains of fatty acids to the center of the bilayer and the polar ends of the molecules in contact with both intracellular and extracellular aqueous environments. Molecules of unesterified cholesterol are intercalated between fatty acid chains in molar concentrations approximately equal to the sum of the molar concentrations of phospholipids. Phospholipids are asymmetrically arranged, with anionic amino-containing phospholipids (phosphatidylserine and

most of the phosphatidylethanolamine) located in the inner layer or leaflet of the bilaminar membrane. After uptake from plasma, these phospholipids are shuttled (flipped) from the outer leaflet to the inner leaflet by an ATP-dependent aminophospholipid-specific translocase or flippase (Zwaal *et al.*, 1993). Most of the cationic choline-containing phospholipids, phosphatidylcholine (lecithin) and sphingomyelin, are located in the outer layer (Delaunay, 2007). These choline-containing phospholipids are readily exchangeable with plasma phospholipids, whereas the aminophospholipids are not (Reed, 1968). RBCs also contain a Ca^{+2}-dependent phospholipid scramblase that is activated by a protein kinase C catalyzed phosphorylation. This scramblase accelerates the bidirectional transbilayer movement of phospholipids. The inhibition of the flippase or the activation of the scramblase can result in increased phosphatidylserine in the outer layer, which promotes coagulation and erythrophagocytosis (Delaunay, 2007; Mandal *et al.*, 2005).

Species vary in RBC membrane phospholipid compositions (Garnier *et al.*, 1984; Nelson, 1967; Wessels and Veerkamp, 1973). Cattle, sheep, and goat RBCs are unique in that their membranes contain little or no phosphatidylcholine

and high sphingomyelin levels (Nouri-Sorkhabi *et al.*, 1996). Another anomaly recognized in bovine RBCs is an extreme asymmetry of phosphatidylethanolamine, with only 2% of the total present in the outer leaflet (Florin-Christensen *et al.*, 2001). Although RBC cholesterol/phospholipid ratios remain relatively constant, differences occur in membrane phospholipid composition between neonate and adult RBCs (Marin *et al.*, 1990).

A small amount of glycolipid is also located in the outer layer. Species differ in the dominant glycolipids of RBCs (Eberlein and Gercken, 1971; Yamakawa, 1983). Based on studies of human blood group antigens, it is assumed that many animal blood group antigens are also glycolipids and that specificity resides in the carbohydrate moieties.

2. *Integral Membrane Proteins*

Integral membrane proteins penetrate the lipid bilayer. These glycoproteins express carbohydrate residues on the outside surface of the cell. They contribute negative charge to the cell surface, function as receptors or transport proteins, and carry RBC antigens (Chasis and Mohandas, 1992; Mohandas and Chasis, 1993; Schrier, 1985). Band 3 (anion exchanger 1) is the major integral protein. It accounts for approximately one-fourth of the total membrane protein, with about 10^6 copies/RBC (Delaunay, 2007; Schrier, 1985). It is important as an anion transporter and provides a site for binding of the cytoskeleton internally. Additional transmembrane glycoproteins called glycophorins also help anchor and stabilize the cytoskeleton (Chasis and Mohandas, 1992).

3. *Membrane Skeletal Proteins*

The membrane skeleton appears as a dense sweater-like meshwork bound to the inner surface of the lipid bilayer. It is a major determining factor of membrane shape, deformability, and durability (Mohandas and Chasis, 1993). A simplified cross section of the RBC membrane is shown in Figure 7-3. Spectrin is a heterodimer of long, flexible alpha and beta chains twisted around one another. Heterodimers are bound together by self-association at their head ends

[a] *Given in nmole/ml* RBC, *except lactate and pyruvate, which are given in nmole/ml whole blood. Mean values have been recalculated at times to permit direct comparisons between species. Standard deviation values are given where indicated. Abbreviations*: G6P, *glucose 6-phosphate*; F6P, *fructose 6-phosphate*; FDP, *fructose 1,6-diphosphate*; DHAP, *dihydroxyacetone phosphate*; 3PG, *3-phosphoglycerate*; 2PG, *2-phosphoglycerate*; PEP, *phosphoenolpyruvate*; AMP, *adenosine monophosphate*; ADP, *adenosine diphosphate*; ATP, *adenosine triphosphate*; 2,3-DPG, *2,3-diphosphoglycerate*; Pi, *inorganic phosphate*; GSH, *reduced glutathione*; GSSG, *oxidized glutathione*. *Figures in parentheses are the references cited as follows*: (1) *Zinkl and Kaneko*, 1973*b*; (2) *Noble* et al., 1983; (3) *Agar and Smith*, 1974; (4) *Magnani* et al., 1983; (5) *Agar* et al., 1983; (6) *Harkness* et al., 1969; (7) *Agar* et al., 1974*a*; (8) *Travis* et al., 1985; (9) *Battaglia* et al., 1970; (10) *Srivastava and Beutler*, 1969.

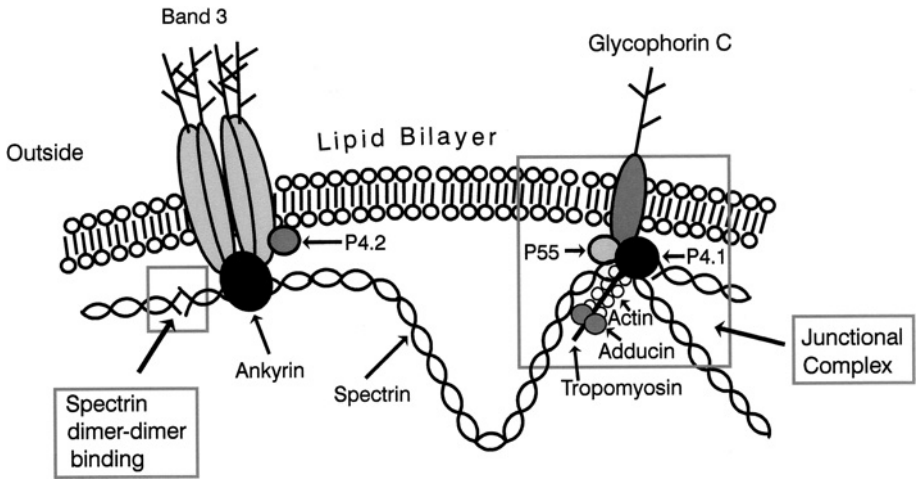

FIGURE 7-3 Schematic model of the organization of the RBC membrane skeleton.

to form tetramers. Multiple spectrin tail ends (an average of six) are joined together by binding to common short filaments of actin and a variety of other proteins, including tropomyosin and adducin, to form an anastomosed meshwork of polygons (Fig. 7-4). These junctional complexes with actin are stabilized by other proteins, including protein 4.1 and protein 55. Protein 4.1 binds the meshwork to one or more integral membrane glycophorins (Delaunay, 2007). The meshwork is also bound to transmembrane band 3 by ankyrin in regions of spectrin self-association, and protein 4.2 may strengthen the ankyrin to band 3 linkage (Mohandas and Chasis, 1993; Rybicki *et al.*, 1996).

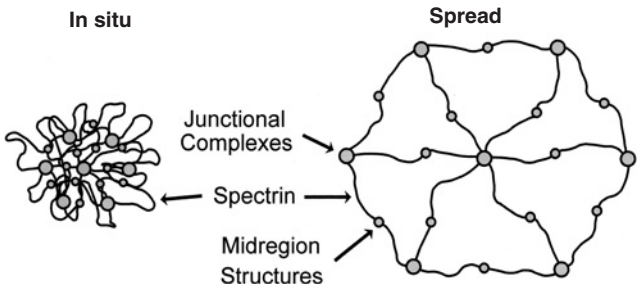

FIGURE 7-4 Schematic model of a hexagon of condensed and fully extended (spread) cytoskeletal meshwork. Spectrin dimer-dimer interactions and binding to band 3 occur in the midregions. See Figure 7-3 for components of junctional complexes.

Band 4.2 has not been demonstrated in some species including horses (Guerra-Shinohara and Barretto, 1999).

The cytoskeletal meshwork assumes a condensed configuration in nondeformed discocytes, with spectrin tetramer fibers existing in folded or coiled states (Fig. 7-4). When fully extended (accomplished by removal of lipid from the membrane), the cytoskeleton meshwork extends over an area several times the normal RBC surface area (Liu and Derick, 1992; Palek and Sahr, 1992). Because of the spectrin structure, membrane skeletons have extensional elasticity and can be stretched more than twice the normal RBC diameter without rupture.

B. Shape and Deformability

The normal biconcave shape of most mammalian RBCs (discocytes) represents the resting unstressed geometry of the cell. The biconcave shape results in a large surface area-to-volume ratio compared to that of a sphere, allowing RBCs to undergo marked deformation while maintaining a constant surface area (Lenard, 1974). This is important because an increase of 3% to 4% of surface area results in cell lysis (Mohandas and Chasis, 1993).

The RBC spends little time in a discoid shape in the microcirculation. Except for goats, RBCs from domestic animals have diameters (Jain, 1986) greater than those of capillaries (approximately 4 μm) (Henquell *et al.*, 1976; Sobin and Tremer, 1972); consequently, they must be deformable to flow through capillaries. RBCs must pass through even smaller spaces in the sinus wall of the spleen (Chen and Weiss, 1973). The biconcave shape is generally more pronounced in species with larger RBCs (Harvey, 2001), presumably because the degree of deformation required to flow through capillaries is greater. RBC deformability also reduces bulk viscosity of blood in large vessels (Smith, 1991).

RBC deformability is a function of surface-to-volume ratio, viscosity of intracellular contents (determined primarily by intracellular Hb concentration), and viscoelastic properties of the membrane (Mohandas and Chasis, 1993). RBC shape and viscoelastic properties result from interactions between the fluid lipid bilayer and the underlying cytoskeleton, which stabilizes the lipid bilayer and provides both rigid support and elasticity. Membrane lipid fluidity varies with the cholesterol composition, concentration of phospholipids present, and the degree of saturation of fatty acids and length of acyl chains (Yawata *et al.*, 1984). Comparisons of RBC deformability among various animal species using ektacytometry have been reported (Smith *et al.*, 1979). Large RBCs are generally more deformable than small ones. RBCs from species in the family Camelidae are flat, thin, and not deformable; they apparently flow through vessels by orienting to the direction of flow.

In addition to mechanically induced deformations, a wide variety of chemical perturbations, genetic defects, and oxidative injury can result in shape changes (Mohandas and Chasis, 1993; Smith, 1987). Small changes in the surface areas of the inner or outer lipid monolayers can result in transformations of discocytes into echinocytes or stomatocytes. Biochemical abnormalities associated with certain RBC shape abnormalities follow in this text. Consult a reference text for additional information about these and other RBC shape abnormalities (Harvey, 2001).

1. *Echinocytes*

Echinocytes are spiculated RBCs in which the spicules are relatively evenly spaced and of similar size. When observed in stained blood films, echinocytosis is usually an artifact that results from excess EDTA, improper smear preparation, or prolonged sample storage before blood film preparation. Echinocytes form when the surface area of the outer lipid monolayer increases relative to the inner monolayer. Echinocytic transformation occurs in the presence of fatty acids, lysophospholipids, and amphiphatic drugs that distribute preferentially in the outer half of the lipid bilayer (Mohandas and Chasis, 1993; Smith, 1987). Transient echinocytosis occurs in horses with *Clostridium perfringens* infection and in dogs following coral snake (Marks *et al.*, 1990) and rattlesnake (Brown *et al.*, 1994a; Hackett *et al.*, 2002) envenomation, presumably secondary to the action of phospholipases present in venom (Walton *et al.*, 1997). Echinocytes also form when RBCs are dehydrated (Weiss and Geor, 1993), pH is increased, intracellular calcium is increased (Smith, 1987), and RBC ATP is depleted (Backman *et al.*, 1998; Jacob *et al.*, 1973). Echinocytes are the predominant RBC shape abnormality in human burn patients (Harris *et al.*, 1981).

Echinocytosis occurs in horses in which total body depletion of cations has occurred. Increased numbers have been reported in horses during endurance exercise (Boucher *et al.*, 1981), following furosemide-induced electrolyte depletion (Weiss *et al.*, 1992b), and in ill horses with systemic electrolyte depletion and hyponatremia (Geor *et al.*, 1993).

Echinocyte formation in sheep RBCs after ATP-depletion has been attributed to the degradation of membrane phosphoinositides (Backman *et al.*, 1998). Echinocytes and other shape abnormalities have been recognized in dogs with RBC pyruvate kinase deficiency, which results in a decreased ability to generate ATP (Chandler *et al.*, 1975; Muller-Soyano *et al.*, 1986; Schaer *et al.*, 1992).

Although the mechanism(s) is unknown, ATP is required for maintenance of normal shape and deformability of RBCs (Jacob *et al.*, 1973). Because ATP concentrations must be depleted for a number of hours to demonstrate changes in shape and deformability *in vitro*, the concentration does not directly control these properties; rather, the processes occurring secondary to ATP depletion alter the shapes of cells (Feo and Mohandas, 1977).

ATP is required for a number of reactions involving the RBC membrane (Cohen and Gascard, 1992). It is used as the phosphoryl donor in a wide variety of phosphorylation reactions involving membrane proteins and for the phosphorylation of membrane phosphoinositides. It provides the energy needed to pump Ca^{+2} out of cells. Increased Ca^{+2} activates neutral proteases (calpains), which can degrade membrane skeletal proteins, and phospholipase C, which cleaves phosphoinositides. ATP is required for the transport of aminophospholipids to the inner half of the lipid bilayer, presumably assisting in the maintenance of the asymmetry of membrane phospholipids. The relative importance of each of these ATP-dependent reactions to the maintenance of RBC shape and deformability remains to be determined (Cohen and Gascard, 1992).

2. *Acanthocytes*

Acanthocytes (spur cells) are RBCs with irregularly spaced, variably sized spicules. They can form when RBC membranes contain excess cholesterol compared to phospholipids. If cholesterol and phospholipids are increased to a similar degree, codocyte formation is more likely than acanthocyte formation (Cooper *et al.*, 1972). Alterations in RBC membrane lipids can result from increased blood cholesterol content (Cooper *et al.*, 1980) or the presence of abnormal plasma lipoprotein composition (Ulibarrena *et al.*, 1994). Another possible contributing factor is the defective repair (acylation of lysophospholipids) of oxidant-damaged RBC phospholipids reported in human patients with cirrhosis and acanthocytosis (Allen and Manning, 1994). Acanthocytes have been recognized in animals with liver disease, possibly because of alterations in plasma lipid composition, which can alter RBC lipid composition (Christopher and Lee, 1994; Shull *et al.*, 1978). They have also been reported in dogs with disorders such as hemangiosarcoma and disseminated intravascular coagulation that result in RBC fragmentation (Weiss *et al.*, 1993).

Marked acanthocytosis is reported to occur in young goats (Holman and Drew, 1964) and some young cattle (McGillivray *et al.*, 1985; Sato and Mizuno, 1982). Acanthocytosis of young goats has been attributed to the presence of HbC at this early stage of development (Jain *et al.*, 1980).

Acanthocytosis in blood is associated with a heterogeneous group of inherited neurodegenerative disorders in humans (neuroacanthocytosis), resulting in defects of at least four different proteins (Stevenson and Hardie, 2001). Deficient proteins appear to be important in membranes of neural or muscular tissues in addition to RBCs.

3. *Stomatocytes*

Cup-shaped RBCs that have oval or elongated areas of central pallor when viewed in stained blood films are called stomatocytes. They most often occur as artifacts in thick blood film preparations. Stomatocytes form when pH is decreased (Gedde *et al.*, 1997) and when amphiphatic drugs are present that distribute preferentially in the inner half of the lipid bilayer (Smith, 1987; Suwalsky *et al.*, 1999, 2000). Stomatocytes also form when RBC water content is increased, as occurs in hereditary stomatocytosis in dogs (Giger *et al.*, 1988a; Paltrinieri *et al.*, 2007; Pinkerton *et al.*, 1974; Slappendel *et al.*, 1994).

4. *Eccentrocytes*

Eccentrocytes are RBCs in which the Hb is localized to part of the cell, leaving an Hb-poor area visible in the remaining part of the cell. Other terms used to refer to eccentrocytes include hemighosts, irregularly contracted cells, double-colored cells, and cross-bonded RBCs (Arese and De Flora, 1990; Chan *et al.*, 1982). They are formed by the adhesion of opposing areas of the cytoplasmic face of the RBC membrane (Fischer, 1986). Denatured spectrin is believed to be of primary importance in the cross bonding of membranes (Arese and De Flora, 1990; Fischer, 1988). Eccentrocytes that have become spherical with only a small tag of cytoplasm remaining may be called pyknocytes. Eccentrocytes have been seen in animals ingesting or receiving oxidants (Caldin *et al.*, 2005; Harvey, 2001; Harvey *et al.*, 1986; Harvey and Rackear, 1985; Lee *et al.*, 2000; Reagan *et al.*, 1994) and in horses with severe burns (Norman *et al.*, 2005). Eccentrocytes have also been seen in horses with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Stockham *et al.*, 1994) and glutathione reductase deficiency secondary to RBC flavin adenine dinucleotide (FAD) deficiency (Harvey *et al.*, 2003). Both of these disorders decreased the ability of RBCs to protect against endogenous oxidants.

5. *Spherocytes and Elliptocytes*

Defects in ankyrin, band 3, protein 4.2, and certain defects is α-spectrin and β-spectrin result in hereditary spherocytosis in mice and humans (Delaunay, 2007). A complete

absence of band 3 results in hereditary spherocytosis in Japanese black cattle (Ban *et al.*, 1995; Inaba *et al.*, 1996). Hereditary spherocytosis has been reported in golden retriever dogs with reductions in RBC membrane spectrin (Slappendel, 1998). RBCs from these dogs exhibited increased osmotic fragility, but spherocytes were not recognized in stained blood films (Slappendel *et al.*, 2005).

Hereditary elliptocytosis occurs with certain defects in α-spectrin, β-spectrin, band 3, and protein 4.1 deficiency in humans (Bruce, 2006; Delaunay, 2007). Hereditary elliptocytosis has been reported in a dog with protein 4.1 deficiency (Smith *et al.*, 1983a) and in a dog with mutant β-spectrin (Di Terlizzi *et al.*, 2007).

C. Blood Group Isoantigens

Large numbers of protein and complex carbohydrate antigens occur on the external surface of RBCs. Some antigens are present on RBCs from all members of a species, and others (including blood group isoantigens) segregate genetically, appearing in some but not all members of a species. Blood group isoantigens are detected serologically on the surface of RBCs using agglutination or hemolysis tests. With detailed genetic studies, these isoantigens can be placed into blood groups (RBC isoantigen systems). Blood groups have individual chromosomal loci, and each locus has from two to many allelic genes. Most blood groups (such as the ABO system in humans) derive their antigenicity from the carbohydrate composition of membrane-associated glycolipids and glycoproteins. The amino acid sequence of membrane proteins accounts for the antigenic determinants in other blood groups, such as the complex Rh system in humans (Agre and Cartron, 1991). Most isoantigens are produced by erythroid cells, but some, such as the J group in cattle, the DEA-7 (Tr) group in dogs, the R group in sheep, and the A and O groups in pigs, are produced by other tissues and adsorbed from plasma (Andrews, 2000; Penedo, 2000).

Blood groups in domestic animals have been reviewed (Andrews, 2000; Bowling, 2000; Penedo, 2000). They have been most extensively characterized in horses and cattle, in which blood typing was routinely used for animal identification and parentage testing. Blood typing for these purposes is being phased out in favor of assays based on DNA sequence.

1. *Blood Group Isoantigens of Clinical Significance*

Isoantigens vary in their potential to cause transfusion reactions when mismatched blood is given. Many isoantigens are weak (do not induce antibodies of high titer) or induce antibodies that do not act at normal body temperature. Fortunately only a few isoantigens appear to be important in producing hemolytic disease in animals. More than 13 canine blood groups have been described. DEA 1.1 antibody-antigen interactions result in most of the acute hemolytic transfusion reactions in dogs (Andrews, 2000), but transfusion reactions have been reported against DEA 1.2 (Hale, 1995), DEA 4 (Melzer *et al.*, 2003), and an unclassified common antigen (Callan *et al.*, 1995) on dog RBCs. A new blood type termed *Dal* has been reported in a low percentage of Dalmatian dogs (Blais *et al.*, 2007). Dalmatians lacking the *Dal* antigen develop alloantibodies after being transfused with *Dal*-positive RBCs. Sensitized animals are likely at risk for delayed or acute hemolytic reactions when transfused again with *Dal*-positive RBCs.

Incompatibilities in the AB blood group of cats have been recognized to cause transfusion reactions and neonatal isoerythrolysis (Auer and Bell, 1983; Giger and Akol, 1990; Giger and Bücheler, 1991; Hubler *et al.*, 1987). The A and B isoantigens (blood types) result from the action of two different alleles at the same gene locus, with A being dominant over B (Andrews, 2000). Type A cat RBCs have glycolipids with terminal N-glycolyneuraminic acid (NeuGc) on their surface, whereas type B cat RBCs have glycolipids with terminal N-acetylneuraminic acid (NeuAc) on their surface (Andrews *et al.*, 1992). Because the enzyme CMP-N-acetylneuraminic hydroxylase converts NeuAc to NeuGc, it has been proposed that type B cats lack this enzyme. Cats rarely express both type A and type B antigens (type AB) on RBCs. The frequency of blood types varies with location and breed of cat. From 0.3% (northeast) to 4.7% (west coast) of domestic short- and long-hair cats in the United States are type B, but up to 50% of purebred cats in certain breeds in the United States are type B (Andrews, 2000). In contrast to the low prevalence of type B in mixed-breed cats in the United States, about one-third of the mixed-breed cats in Australia are type B (Malik *et al.*, 2005). A new blood group antigen, termed *Mik*, has been reported in domestic shorthair cats that is capable of inducing a hemolytic transfusion reaction when *Mik*-positive RBCs are transfused into a *Mik*-negative recipient cat that has naturally occurring anti-*Mik* alloantibodies in its plasma (Weinstein *et al.*, 2007).

Horse RBC isoantigens are recognized to occur at seven blood group loci. The frequency of expression of RBC isoantigens varies by breed of horse (Bowling, 2000). Historically, Aa and Qa have been the most common antigens associated with neonatal isoerythrolysis in foals. Mares negative for one of these antigens develop antibodies against them and transfer these antibodies to their foals through colostrum. Hemolysis occurs when the foal inherits the respective antigen from the sire (Bowling, 2000). Other isoantigens associated with neonatal isoerythrolysis in foals include Db, Dg, Pa, Qb, Qc, and a combination of Qa, Qb, and Qc (Boyle *et al.*, 2005; MacLeay, 2001). Neonatal isoerythrolysis has been reported in mule foals because of an RBC antigen not found in horses but present in some donkeys and mules (Boyle *et al.*, 2005; McClure *et al.*, 1994).

Pig RBC isoantigens are recognized to occur in 16 blood groups numbered A to P (Penedo, 2000). A-negative pigs exhibit intravascular hemolysis when transfused with A-positive blood. Neonatal isoerythrolysis has been recognized in pigs, with antibodies usually directed against isoantigens of the E blood group (Tizard, 2000).

Naturally occurring neonatal isoerythrolysis has not been reported in cattle, but it occurs in some calves born to cows previously vaccinated for anaplasmosis or other bovine origin vaccines containing RBC membranes (Dimmock and Bell, 1970; Luther *et al.*, 1985). Several blood group isoantigens have been incriminated, but the most important blood group isoantigens involved in this disorder are uncertain (Dimmock and Bell, 1970). Based on experimentally produced disease, the B isoantigen group appears to generate potent hemolysins (Dimmock *et al.*, 1976).

2. Natural Antibodies

Some blood group systems, such as the ABO group in humans, the AB group and *Mik* group in cats, and the A group in pigs, are characterized by "naturally occurring" antibodies (i.e., antibodies occur in plasma in the absence of prior exposure to blood from another individual) (Tizard, 2000; Weinstein *et al.*, 2007). In other blood groups, such as the Rh system in humans and most blood groups in animals, antibody formation results from prior exposure to different RBC isoantigens via transfusion, pregnancy, or vaccination with products containing blood group antigens (Stormont, 1982). Fortunately, naturally occurring antibodies of clinical significance seldom occur in animals; consequently, adverse transfusion reactions to unmatched RBCs generally do not occur at the time of the first blood transfusion. However, exceptions may occur as in the case of the AB group in cats where B-positive cats have naturally occurring anti-A antibodies with high hemolytic titer (Bücheler and Giger, 1993).

D. Membrane Transport

The lipid bilayer is impermeable to most molecules. Consequently, various membrane protein transport systems are utilized for movement of molecules into and out of RBCs.

1. Anions and Water

Water and CO_2 are transported across RBC membranes using water channels called aquaporins (Endeward *et al.*, 2006; Kuchel and Benga, 2005). Band 3 appears to function as a channel for the movement of anions, especially bicarbonate and chloride, certain nonelectrolytes, and probably cations to some extent (Bruce, 2006; Solomon *et al.*, 1983). Gruber and Deuticke studied phosphate as a model for anion exchange in RBCs from several species. There was a positive correlation between phosphate influx and the proportion of phosphatidylcholine in membrane phospholipids (Gruber and Deuticke, 1973).

2. Sodium and Potassium

Major interspecies, and in some cases intraspecies, differences occur in cation transport and subsequently in intracellular Na^+ and K^+ concentrations (Ellory and Tucker, 1983). There is a strong positive correlation between intracellular K^+/Na^+ ratio and ATP concentration when RBCs of different species are compared. The cause of this relationship is unknown, but it is not related to differences in glucose utilization (Miseta *et al.*, 1993).

Like humans, those animal species with high intracellular K^+ concentrations, horse, pig, and some ruminants, have an active Na^+,K^+-pump that exchanges intracellular Na^+ for extracellular K^+ with the hydrolysis of ATP. This Na^+,K^+-activated ATPase activity is often used as a measure of Na^+,K^+-pump activity. In addition to individuals with high potassium (HK^+) RBCs, some sheep, goats, buffalo, and most cattle have relatively low potassium (LK^+), and consequently high sodium, RBCs. These LK^+ RBCs have low Na^+,K^+-pump activity and high passive K^+ permeability (i.e., high K^+-Cl^- cotransport) (Dunham and Blostein, 1997; Tosteson and Hoffman, 1960). Studies in sheep and goats have demonstrated that HK^+/LK^+ polymorphism is determined by a single autosomal genetic locus with 2 alleles, the LK^+ allele being dominant (Tunon *et al.*, 1987; Xu *et al.*, 1994). In sheep, this polymorphism is associated with an M and L blood group antigen polymorphism. The HK^+ cells exhibit M antigens and the homozygous LK^+ cells exhibit L antigens, with heterozygous LK^+ sheep exhibiting M and L antigens. There are two classes of L antigen (Lp and Ll) that assort together. The Lp antigen inhibits the Na^+,K^+-pump, mainly by promoting nonspecific inhibition by intracellular K^+. This antigen also modulates pump differentiation in immature cells. In contrast, the Ll antigen stimulates K^+-Cl^- cotransport (Dunham and Blostein, 1997).

RBCs from cats, ferrets, and most dogs do not have Na^+,K^+-pump activity and have Na^+ and K^+ concentrations near, but not at, those predicted for the Donnan equilibrium with plasma (Mairbaurl and Herth, 1996; Parker, 1977). Some clinically normal Japanese Akita dogs (Degen, 1987), mongrel dogs from Japan (Inaba and Maede, 1984), and Korean Jindo dogs (Yamato *et al.*, 1999) have HK^+ RBCs. RBCs from the HK^+ mongrel dogs have substantial Na^+,K^+-ATPase activity and altered amino acid metabolism which are discussed later. Dog, ferret, and bear RBCs have a unique Na^+-Ca^{+2} countertransport system that can remove sodium (Parker, 1992). The calcium that enters the cell is subsequently pumped out by an ATP-dependent calcium pump.

Other pathways of sodium and potassium transport occur to variable degrees in certain species. These pathways include passive diffusion, Na^+,K^+,Cl^- cotransport, $Na^+ \times Na^+$ countertransport, band 3 anion transport as $NaCO_3^-$, Na^+-dependent amino acid transport, K^+,Cl^- cotransport, Na^+,H^+ exchange, and a calcium-dependent K^+ channel (Contreras *et al.*, 1986; Ellory and Tucker, 1983; Haas, 1989; Maher and Kuchel, 2003). A negative linear correlation between internal sodium concentration and membrane protein-to-lipid ratio was found by comparison of RBC values from nine mammalian species, the significance of which is unknown (Garnier *et al.*, 1984).

RBC volumes influence cation fluxes. Sodium flux increases when cells are shrunken, and potassium flux increases when cells are swollen. The Na^+,K^+,Cl^- cotransport and Na^+-H^+ exchange are activated by cell shrinkage and K^+-Cl^- cotransport is activated by cell swelling (Dunham, 2004; Haas, 1989; Mairbaurl and Herth, 1996). Volume changes are believed to be detected from alterations in cytoplasmic macromolecules (Parker, 1992).

Early nucleated erythroid precursors in dog bone marrow have HK^+ content, whereas mature RBCs are of the LK^+ type. The switch from HK^+ to LK^+ content occurs during the maturation from early to late nucleated erythroid cells (Kirk *et al.*, 1983). When erythropoiesis is dramatically stimulated in response to a hemolytic anemia, much of the HK^+ to LK^+ transition does not occur until after denucleation. Consequently, stress reticulocytes, produced in response to anemia, have potassium contents much higher than reticulocytes normally released into blood. The high potassium concentration in canine stress reticulocytes results from membrane Na^+,K^+-ATPase activity that is lost during maturation into RBCs, possibly by ATP-dependent proteolysis (Inaba and Maede, 1986). Stress reticulocytes produced by LK^+-type ruminants (Israel *et al.*, 1972; Kim *et al.*, 1980; Tucker and Ellory, 1971) also have high potassium concentrations as a result of high Na^+,K^+-ATPase activities (Blostein and Grafova, 1990). The decline in the number of Na^+,K^+ pumps on LK^+ sheep reticulocytes during maturation is modulated by the Lp antigen (Xu *et al.*, 1994). Fetal and neonatal RBCs examined from mammals with LK^+ RBCs have higher potassium concentrations than adult RBCs, but the difference in dogs was not as dramatic as that in ruminants (Coulter and Small, 1973; Ellory and Tucker, 1983).

3. *Calcium*

Excessive intracellular Ca^{+2} is deleterious to RBCs; consequently, they actively extrude Ca^{+2} using a calcium pump having Ca^{+2}-activated, Mg^{+2}-dependent ATPase activity. A calcium-binding protein called calmodulin activates the calcium pump (Bababunmi *et al.*, 1991; Hinds and Vincenzi, 1986). This pump, working in conjunction with a Na^+-Ca^{+2} countertransport system, appears to be important in RBC volume regulation in dogs (Parker, 1992).

4. *Amino Acids*

Amino acid transport in RBCs provides amino acids for synthesis of reduced glutathione (GSH). In addition, amino acid transporters may be responsible for efflux of amino acids during reticulocyte maturation (Tunnicliff, 1994).

Several amino acid transport systems have been recognized in mammalian RBCs, each with its own characteristic species distribution, ion requirements, and substrate specificity (Fincham *et al.*, 1987; Young, 1983). In addition, the band 3 anion transporter can transport glycine and some other amino acids (Fincham *et al.*, 1987). A y+ transport system that transports cationic amino acids has been described in human RBCs. This system is distinct from that of the y + L system, which is a cationic amino acid transporter that also accepts neutral amino acids with high affinity in the presence of Na^+ (Rojas and Deves, 1999). A Na^+-independent C amino acid transporter has been described in sheep whose optimal substrates are cationic amino acids and small neutral amino acids (Young, 1983). Sheep deficient in this transporter have low RBC GSH, because of impaired cysteine transport (Tucker *et al.*, 1981). A similar asc transport system occurs in most equine RBCs, and deficient horses are predisposed to GSH deficiency (Fincham *et al.*, 1987, 1988). A transport system for cationic amino acids in cat RBCs has been called the Ly^+ system (Young, 1983). Dog and cat RBCs have a Na^+-dependent acidic amino acid transporter that optimally transports glutamate and aspartate. The transport of 1 glutamate into dog RBCs is accompanied by 2 Na^+ and by the countertransport of 1 K^+ and 1 anion (Sato *et al.*, 1994). A Na^+-dependent anionic amino acid transporter, termed *excitatory amino acid carrier* 1 (EAAC1), has been reported in rat RBC membranes (Novak *et al.*, 2002).

5. *Glucose*

Species vary in their permeability to glucose, with human RBCs being very permeable and pig RBCs being poorly permeable (McManus, 1967). RBCs of other domestic animals appear to be intermediate between these extremes (Arai *et al.*, 1992; Bolis, 1973; Widdas, 1955). Facilitative glucose transporter 1 (GLUT-1) mediates the passive diffusion of glucose into RBCs (Jiang *et al.*, 2006). Glucose movement into RBCs is not regulated by insulin (Baldwin, 1993). RBCs from adult pigs lack a functional glucose transporter (Craik *et al.*, 1988) and, therefore, have limited ability to utilize glucose for energy (Kim and McManus, 1971; Magnani *et al.*, 1983). In contrast, RBCs from neonatal piglets and pig reticulocytes have the transporter (Craik *et al.*, 1988) and, consequently, exhibit substantial glucose transport (Kim and Luthra, 1977). A similar phenomenon

occurs in chickens, in which erythroid cells in bone marrow transport glucose, but circulating RBCs do not (Johnstone *et al.*, 1998). With the exception of cats, fetal and neonatal RBCs studied from humans and animals have higher glucose transport than RBCs from adults (Mooney and Young, 1978; Widdas, 1955).

6. *Adenine, Adenosine, and Inosine*

RBC membranes from most animal species have a nucleoside transporter (Young, 1983). The adenosine transporter from human and pig RBCs migrates in the band 4.5 region on SDS-PAGE (Kwong *et al.*, 1986). Rabbit, pig, and human RBCs exhibit substantially more adenosine uptake than those of other species studied (Van Belle, 1969). RBCs from dogs exhibit more adenosine uptake than cats, goats, or cattle, and RBCs from horses and most sheep appear to be nearly impermeable to adenosine. A low percentage of sheep have RBCs with a high affinity nucleoside transport system with a broad specificity for both purine and pyrimidine nucleosides (Young, 1983). RBCs from most horses have a Na^+-dependent hypoxanthine transporter. Although dog RBCs are permeable to adenosine, they are impermeable to inosine (Duhm, 1974). Dog and cat RBCs exhibit adenine uptake and incorporation into nucleotides, but values are much lower than those of human, rabbit, or rodent RBCs (Lalanne and Willemot, 1980).

E. Metabolism of Adenine Nucleotides

Adenine nucleotides in RBCs contain adenine, ribose, and one or more phosphate groups. Mature RBCs cannot synthesize adenine nucleotides *de novo* but can produce these compounds utilizing so-called salvage pathways (Brewer, 1974; Eaton and Brewer, 1974). AMP can be synthesized from adenine or from adenosine, both of which may be supplied to RBCs as they pass through the liver. One molecule of ATP interacts with one molecule of AMP to generate two molecules of ADP in the adenylate kinase reaction. ATP is generated from ADP in glycolysis.

AMP is synthesized from adenine and phosphoribosyl pyrophosphate (PRPP), utilizing the adenine phosphoribosyltransferase enzyme. Adenine is converted to ATP at a slower rate in dog and cat RBCs than in those of humans, rodents, or rabbits (Lelanne and Willemot, 1980). AMP degradation to inosine monophosphate and ammonia is catalyzed by AMP-deaminase. The activity of this enzyme is generally lower in mammalian RBCs compared to nucleated RBCs from birds, reptiles, amphibians, and fish (Kruckeberg and Chilson, 1973).

Adenosine can be phosphorylated to AMP using ATP in the adenosine kinase reaction. A competing reaction, adenosine deaminase, converts adenosine to inosine, which cannot be incorporated into AMP. The uptake or deamination of adenosine varies considerably by species (Van Belle, 1969). Not only are dog, cat, and cattle RBCs poorly permeable to inosine, but inosine produced by adenosine deamination cannot be readily used for energy in these species because of low purine nucleoside phosphorylase activity, which converts inosine to ribose 1-phosphate and hypoxanthine (Duhm, 1974).

NAD and NADP can apparently be synthesized from nicotinate by way of a series of reactions in RBCs (Eaton and Brewer, 1974). In addition to ATP, PRPP and NH_3, or glutamine, are required. Comparative studies of the synthesis of these compounds in domestic animals have not been reported.

F. Carbohydrate Metabolism

RBCs require energy in the form of ATP for maintenance of shape and deformability, phosphorylation of membrane phospholipids and proteins, active membrane transport of various molecules, partial synthesis of purine and pyrimidine nucleotides, and synthesis of GSH (Nakao, 1974; Reimann *et al.*, 1981). Reducing potential in the form of NADH and NADPH is needed to counteract oxidative processes. Although substrates such as ribose, fructose, mannose, galactose, dihydroxyacetone, glyceraldehyde, adenosine, and inosine may be metabolized to some extent, depending on the species, glucose is the primary substrate for energy needs of RBCs from all species except the pig (Agar and Board, 1983; Kim, 1983).

RBCs from adult pigs utilize glucose at lower rates than other species (Magnani *et al.*, 1983) because they lack a functional glucose transporter (Craik *et al.*, 1988; Zeidler and Kim, 1982). Inosine appears to be the major substrate for pig RBCs; its production by the liver is sufficient to meet their energy requirements (Young *et al.*, 1985; Zeidler *et al.*, 1985). Inosine can be used because nucleoside phosphorylase converts it to ribose 1-phosphate and hypoxanthine (Sandberg *et al.*, 1955). Ribose 1-phosphate is converted to ribose 5-phosphate, an intermediate of the pentose phosphate pathway (PPP), by phosphoribomutase (Brewer, 1974).

Glucose utilization rates of RBCs vary by species (Table 7-1). Factors such as pH, phosphate concentration, temperature, and leukocyte and platelet contamination of RBC incubations can have substantial effects on glucose utilization rates measured *in vitro*. Consequently, species comparisons of values determined in different laboratories may be misleading. Harvey and Kaneko (1976a) approximated physiological conditions *in vitro* and measured mean glycolytic rates of 0.64, 0.94, 1.33, and 1.48 μmoles/hour/ml RBC for the horse, cat, dog, and human, respectively. Once glucose enters the cell, it is phosphorylated to glucose 6-phosphate (G6P) utilizing the hexokinase (HK) enzyme. The G6P is then metabolized through either the Embden-Meyerhof pathway (EMP) or the pentose phosphate pathway (PPP) as shown (Fig. 7-5).

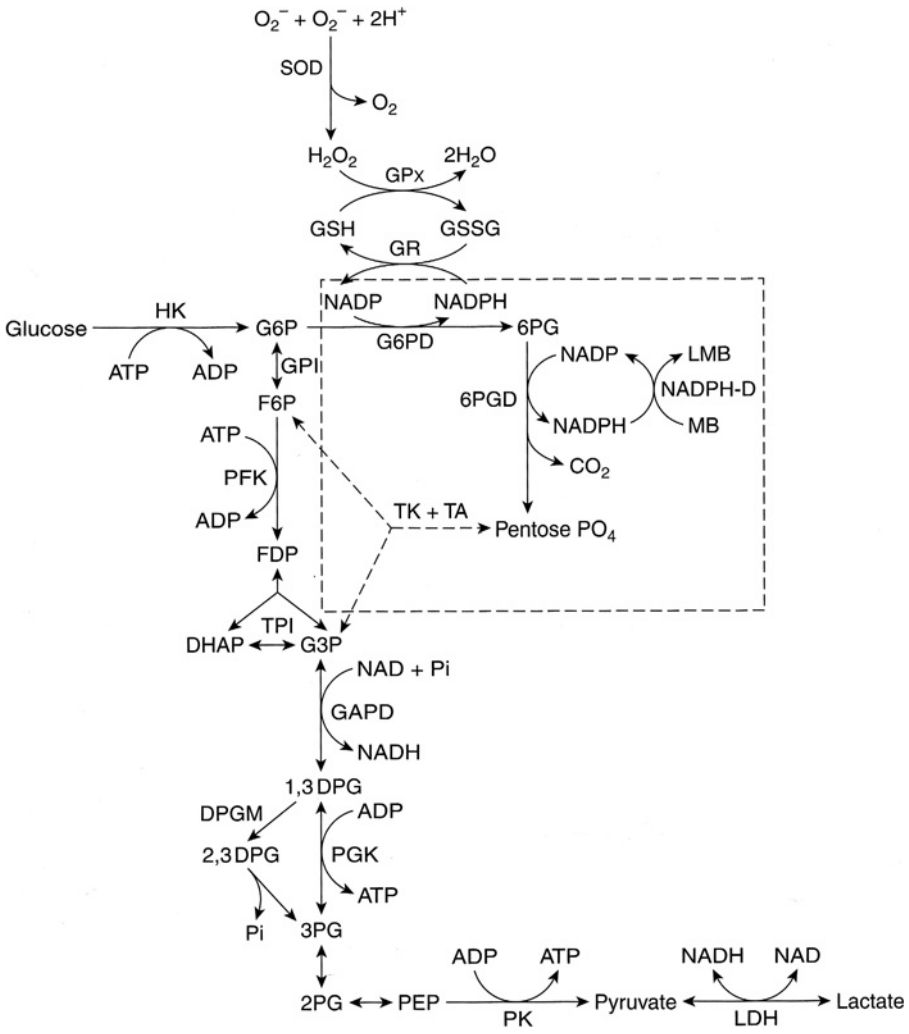

FIGURE 7-5 Metabolic pathways of the mature erythrocyte. Abbreviations: HK, hexokinase; GPI, glucose phosphate isomerase; PFK, phosphofructokinase; TPI, triosephosphate isomerase; GAPD, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; MPGM, monophosphoglycerate mutase; DPGM, diphosphoglycerate mutase; PK, pyruvate kinase; G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; LDH, lactate dehydrogenase; LMB, leukomethylene blue; MB, methylene blue; GR, glutathione reductase; GPx, glutathione peroxidase; TK, transketolase; TA, transaldolase; GSSG, oxidized glutathione; G6P, glucose 6-phosphate; F6P, fructose 6-phosphate; FDP, fructose 1,6-diphosphate; DHAP, dihydroxyacetone phosphate; GAP, glyceraldehyde 3-phosphate; 1,3-DPG, 1,3-diphosphoglycerate; 2,3-DPG, 2,3-diphosphoglycerate; 3PG, 3-phosphoglycerate; 2PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate; NADPH-D, reduced nicotinamide adenine dinucleotide phosphate diaphorase; GSH, reduced glutathione; P_i, inorganic phosphate; SOD, superoxide dismutase.

G. Embden-Meyerhof Pathway

Most of the species variations in glucose utilization appear to result from variations in EMP metabolism, with PPP metabolism being relatively constant when not stimulated by oxidants (Harvey and Kaneko, 1976a). In addition to the phosphorylation of glucose, one molecule of ATP is used to phosphorylate fructose 6-phosphate, and one molecule of ATP is generated for each three-carbon molecule metabolized through the phosphoglycerate kinase (PGK) and pyruvate kinase (PK) reactions (Fig. 7-5). Consequently a net of two molecules of ATP is produced for each molecule of glucose metabolized to two molecules of lactate in the EMP. Because mature RBCs lack mitochondria, the EMP is the only source of ATP production in these cells.

In human RBCs, reactions catalyzed by HK, phosphofructokinase (PFK), and PK appear to be rate-limiting steps in glycolysis, because these reactions are far displaced from equilibrium (Minakami and Yoshikawa, 1966). Under physiological steady-state conditions, the PFK enzyme reaction controls glycolysis through the EMP (Rapoport, 1968). Its activity is influenced by a variety of effectors, with ATP being the most important inhibitor and AMP and

inorganic phosphate (P_i) being the most influential activators. ADP is a less potent activator (Jacobasch *et al.*, 1974). Most of the adenine nucleotide pool in RBCs is maintained as ATP under normal conditions, with less as ADP and even less as AMP (Tables 7-4 and 7-5). Glycolysis is ultimately controlled by the demand for production of ATP. As ATP is utilized, concentrations of ADP, AMP, and P_i increase. These changes result in the activation of PFK and increased EMP metabolism. Other potential activators of PFK include ammonium ions (Debski and Rynca, 1985; Shimizu *et al.*, 1988), glucose 1,6-bisphosphate (Accorsi *et al.*, 1985; Harvey *et al.*, 1992b), fructose 2,6-bisphosphate (Gallego and Carreras, 1990; Harvey *et al.*, 1992b; Sobrino *et al.*, 1987), and K^+ (Ogawa *et al.*, 2002).

When PFK is activated, HK is activated secondarily because the concentration of G6P is reduced, and G6P competitively inhibits HK (Rapoport *et al.*, 1976). Although the HK reaction is normally not a rate-controlling step in glycolysis of human RBCs, conceivably it is more important in animal species with lower HK activity (Rapoport, 1968). The glycolytic rate is correlated with HK activity when RBCs of various species are compared at pH values above 8.0. Comparisons may be less reliable when measurements are made at pH 7.4 (Harvey and Kaneko, 1976a). In human RBCs, the PK reaction becomes limiting when the PFK reaction is markedly stimulated (i.e., at pH values above 7.6) (Jacobasch *et al.*, 1974). The pH values listed earlier are external values. The pH within RBCs is generally about 0.2 units lower than the external pH (Waddell and Bates, 1969).

In addition to ATP/ADP and ADP/AMP ratios, various other factors influence EMP metabolism. Alterations in pH of plasma or *in vitro* buffers affect glycolysis. As pH is increased above 7.2, PFK is activated and glucose utilization and EMP metabolism increase (Burr, 1972; Rapoport, 1968).

At physiological pH values, high concentrations of P_i stimulate glycolysis through the EMP by reducing the ATP inhibition of PFK. Conversely, glycolysis is inhibited by short-term phosphate deficiency, primarily by decreasing intracellular P_i for glyceraldehyde-3-phosphate dehydrogenase (GAPD) (Jacobasch *et al.*, 1974; Ogawa *et al.*, 1989; Wang *et al.*, 1985). Decreased glycolytic rates result in decreased RBC ATP concentrations and hemolytic anemia in experimental dogs made severely hypophosphatemic by hyperalimentation (Jacob *et al.*, 1973; Yawata *et al.*, 1974). Hemolytic anemia associated with hypophosphatemia has also been reported in diabetic cats and a diabetic dog following insulin therapy (Adams *et al.*, 1993; Perman and Schall, 1983; Willard *et al.*, 1987), in a cat with hepatic lipidosis (Adams *et al.*, 1993), and in postparturient cattle in which decreased RBC ATP concentrations have been measured (Ogawa *et al.*, 1987, 1989). In addition to having low ATP concentrations, dog RBCs might hemolyze as a result of decreased RBC 2,3DPG concentration, because dog RBCs with low 2,3DPG are more alkaline fragile than those of normal dogs and may hemolyze at physiological pH values (Harvey *et al.*, 1988).

Several glycolytic enzymes, including PFK, GAPD, and aldolase, bind to the cytoplasmic domain of band 3, forming multimeric complexes on the inner RBC membrane. Other enzymes, including PK and lactate dehydrogenase (LDH), are associated with these complexes but do not directly bind to band 3 (Campanella *et al.*, 2005; Chu and Low, 2006). The binding of enzymes to the cytoplasmic domain of band 3 results in their inhibition, which presumably also has an inhibitory effect on RBC glycolysis (Weber *et al.*, 2004). The assembly of these glycolytic enzyme complexes appears to be regulated by band 3 phosphorylation and Hb oxygenation. The phosphorylation of tyrosine in the cytoplasmic domain of band 3 by protein tyrosine kinases prevents the binding of glycolytic enzymes, which presumably enhances glycolysis (Campanella *et al.*, 2005). The deoxygenation of RBCs also dislodges the glycolytic enzymes from the membrane, consistent with the established ability of DeoxyHb, but not OxyHb, to bind the NH_2 terminus of the band 3, which may contribute to the increased glycolytic rate present in deoxygenated RBCs compared to oxygenated RBCs (Weber *et al.*, 2004).

There is a strong positive correlation between intracellular Mg^{+2} and ATP concentrations in RBCs from various species because of the presence of the Mg^{+2}-ATP complex within cells (Miseta *et al.*, 1993). RBCs of rats and dogs with short-term magnesium deficiency have lowered glycolytic rates, because adenine nucleotide substrates in four glycolytic kinase reactions (HK, PFK, PGK, and PK) must be complexed with Mg^{+2} (Rapoport, 1968). Dogs and rats on magnesium-deficient diets become anemic (Elin and Alling, 1978; Kruse *et al.*, 1933), owing to shortened RBC life spans.

The saturation of Hb with oxygen has an effect on glucose utilization. Human RBCs utilize more glucose when incubated anaerobically under nitrogen than under aerobic conditions (Asakura *et al.*, 1966). OxyHb is a stronger acid than DeoxyHb; consequently, the intracellular pH of human RBCs is lower in oxygenated blood than in deoxygenated blood (Takano *et al.*, 1976). The PFK reaction is inhibited as blood is oxygenated due to the pH effect. In human RBCs, 2,3DPG is bound to DeoxyHb and released on oxygenation. Based on studies of glycolytic intermediates, the increased unbound 2,3DPG in oxygenated RBCs may have additional inhibitory effects on glycolysis (Hamasaki *et al.*, 1970). The effect of oxygenation on glycolysis of RBCs from domestic animals remains to be determined. It may not be important in ruminants because oxygenation results in insignificant decreases in intracellular pH values (Takano *et al.*, 1976). As discussed earlier, deoxygenation of RBCs dislodges certain glycolytic enzymes from the cytoplasmic domain of band 3, which may contribute to the increased glycolytic rate present in deoxygenated RBCs compared to oxygenated RBCs (Weber *et al.*, 2004).

2,3DPG inhibits glycolysis in part because of its reduction of intracellular pH as a consequence of the Donnan effect of this nonpenetrating anion (Duhm, 1975). 2,3DPG

also inhibits glycolysis by inhibiting HK, PFK, and PK in a manner different from its pH effect on these enzymes (Duhm, 1975; Jacobasch *et al.*, 1974). In addition, 2,3DPG inhibits 6-phosphofructokinase-2-kinase, the enzyme responsible for the synthesis of the positive PFK effector fructose-2,6-bisphosphate (Sobrino *et al.*, 1987).

The RBC glycolytic rate is higher in dogs with HK^+ RBCs compared to dogs with LK^+ RBCs. Glycolysis was stimulated by increasing intracellular K^+ concentration in both types of RBCs, at least in part by the activation of PFK and PK by K^+ (Ogawa *et al.*, 2002).

Glycolysis increases in human RBCs with increasing temperature to a maximum at 45°C, with a Q_{10} of 2 (Rapoport, 1968). Based on measurements of glycolytic intermediates, the major effect of temperature appears to be on the PFK reaction (Jacobasch *et al.*, 1974).

H. Diphosphoglycerate Pathway

Molecules of 1,3-diphosphoglycerate (1,3DPG), produced by the GAPD reaction, may be utilized by the PGK reaction in the EMP or may be converted to 2,3DPG by the diphosphoglycerate mutase (DPGM) reaction (Fig. 7-5). 2,3DPG degradation to 3-phosphoglycerate (3PG) is catalyzed by diphosphoglycerate phosphatase activity (DPGP). A single protein is responsible for both the DPGM and DPGP activities (Sasaki *et al.*, 1977). The DPG pathway or shunt (Rapoport-Luebering cycle) bypasses the ATP-generating PGK step in glycolysis; consequently, no net ATP is generated when glucose is metabolized through this pathway (Brewer, 1974).

Normally, from 10% to 30% of triose phosphate metabolism in human RBCs is shunted through this pathway (Jacobasch *et al.*, 1974; Mulquiney *et al.*, 1999; Oxley *et al.*, 1984). The proportion of 1,3DPG metabolized by PGK and DPGM is determined mostly by the concentration of ADP (Rapoport, 1968). ATP and 2,3DPG influence the relative amount of flow through each route by product inhibition of their own synthesis.

The absolute flow is also determined by the overall glycolytic rate. 2,3DPG inhibits HK, PFK, and GAPD in human RBCs (Srivastava and Beutler, 1972). The formation of 2,3DPG is stimulated by increased P_i concentration and increased pH, which stimulate glycolysis by activating PFK greater than PK (Jacobasch *et al.*, 1974). Hypoxic conditions stimulate 2,3DPG synthesis primarily by inducing hyperventilation, which results in alkalosis; however, intracellular pH also increases in hypoxia because DeoxyHb binds more H^+ than OxyHb (Duhm and Gerlach, 1971). Conversely, acidosis and hypophosphatemia result in decreased 2,3-DPG concentrations (Haglin *et al.*, 1994; Ibrahim *et al.*, 2005).

The concentration of 2,3DPG can be affected by a decrease in PK activity. When PK activity is reduced relative to PFK activity, as occurs in PK deficiency, phosphorylated intermediates between the PK and GAPD reactions increase in concentration (Harvey, 2006; Mueggler and Black, 1982). The synthesis of 2,3DPG is increased as a result of the increased concentration of the 1,3DPG substrate. Thyroid hormones can increase 2,3DPG in human (Snyder *et al.*, 1970) and sheep (Studzinski *et al.*, 1982) RBCs, possibly by a direct effect on the DPGM enzyme.

RBCs of dogs, horses, pigs, and humans normally contain high concentrations of 2,3DPG, whereas those of cats and domestic ruminants have low concentrations (Tables 7-4 and 7-5). Based on results from a large number of mammalian species, only cats, hyenas, and civets among carnivores, and deer, giraffe, antelope, and the cattle family among artiodactyls have low RBC 2,3DPG concentrations (Bunn, 1981; Bunn *et al.*, 1974). Low concentrations of 2,3DPG in cat, goat, and sheep RBCs result primarily from low RBC DPGM activities, whereas RBCs of cattle have relatively high DPGP activity in association with moderately low DPGM activity (Chemtob *et al.*, 1980; Harkness *et al.*, 1969; Pons *et al.*, 1985).

The concentration of 2,3DPG increases more than twofold during reticulocyte maturation in rats and rabbits, which are species that naturally have high 2,3DPG concentrations in their RBCs (Gallego *et al.*, 1991). In contrast to these species, sheep reticulocytes have low 2,3DPG concentration, which decreases even further during reticulocyte maturation to mature RBCs (Gallego and Carreras, 1990).

I. Hb Oxygen Affinity

1. *Oxygen Dissociation Curve*

DeoxyHb exists in a low affinity "tense" structure. With oxygenation it undergoes a transition to OxyHb with a "relaxed" structure that has a lower binding capacity for CO_2, H^+, Cl^-, and organophosphates (Barvitenko *et al.*, 2005). The initial binding of a molecule of O_2 to a monomer of tetrameric, deoxygenated Hb facilitates further binding of additional O_2 molecules to the Hb molecule. Because the O_2 binding of one heme group influences the affinity of other heme groups for O_2, this characteristic has been called the heme-heme interaction. The changing oxygen affinity of Hb with oxygenation results in a sigmoid oxygen dissociation curve (Fig. 7-6) when the percentage saturation of Hb with oxygen is plotted against the partial pressure of oxygen (pO_2). The pO_2 at which Hb is 50% saturated is the P_{50}. The steepness of the middle portion of the curve is of great physiological significance, because it covers the range of oxygen tensions present in tissues. Consequently, relatively small decreases in oxygen tension can result in substantial oxygen release from Hb (Benesch *et al.*, 1975).

When blood from many mammalian species is studied, an inverse linear correlation is recognized between the log P_{50} of whole blood and the log of body weight (Scott *et al.*,

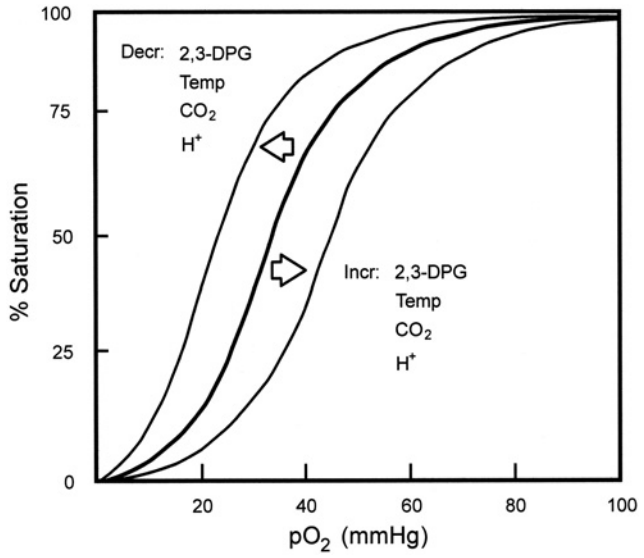

FIGURE 7-6 The hemoglobin-oxygen dissociation curve and factors influencing the position of the curve.

1977). There is an inverse relationship between metabolic rate (oxygen consumption per gram of tissue) and body weight (Kleiber, 1961). Consequently, the higher P_{50} in smaller animals should be beneficial in meeting tissue oxygen requirements associated with their higher metabolic rates. The RBCs of most mammal species adapted to living at high altitude exhibit greater Hb oxygen affinity than those living at low altitudes, and RBCs from animals of the same species adapted to living at high altitude may have greater Hb oxygen affinity than their counterparts living at low altitude (León-Velarde *et al.*, 1996).

A number of factors, including innate Hb oxygen-binding characteristics, H^+ concentration, pCO_2, organic phosphate concentrations, Cl^- concentrations, and temperature, influence the oxygen affinity of Hb within RBCs. In addition to their innate Hb oxygen-binding characteristics, different Hb types respond to differing degrees to these various effectors (Bårdgard *et al.*, 1997; Haskins and Rezende, 2006). Fetal Hbs in ruminants have higher oxygen affinities than their respective adult Hbs (Battaglia *et al.*, 1970; Blunt *et al.*, 1971). HbC-containing RBCs from neonatal or anemic adult goats exhibit lower oxygen affinity, with a greater Bohr effect, than RBCs containing only adult Hb (Huisman *et al.*, 1969). Both factors should potentiate the delivery of oxygen to the tissue in goats with HbC. The presence of MetHb (iron in the ferric state) in one or more of the Hb monomers not only results in decreased oxygen carrying capacity but also in increased oxygen affinity of the remaining monomers (Hrinczenko *et al.*, 2000). The binding of Hb to the cytoplasmic domain of band 3 decreases the oxygen affinity of bound Hb, but a human RBC membrane has about 1 million copies of band 3 compared to 471 million Hb tetramers (Jensen, 2004).

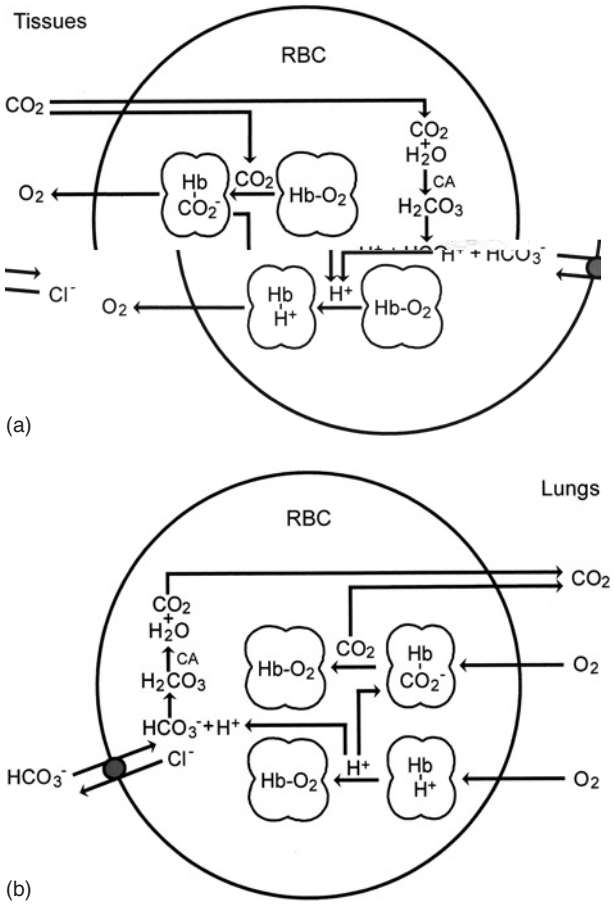

FIGURE 7-7 Coupled O_2, and CO_2 transport and H^+ buffering in RBCs. Reactions taking place in the tissues (a) and lungs (b) are shown. Hb-CO_2^- denotes carbamino Hb, and Hb-H^+ denotes Hb binding H^+. Abbreviation: CA, carbonic anhydrase.

2. *Effects of* H^+, CO_2, *and Temperature*

The addition of H^+ to a suspension of RBCs results in a decrease in oxygen affinity of Hb (Bohr effect), an increase in P_{50}, and a shift of the oxygen dissociation curve to the right (Fig. 7-6). The magnitude of the Bohr effect is defined numerically as Δ log P_{50}/-Δ pH. There is an inverse relationship between the magnitude of the Bohr effect and average body size of various animal species (Riggs, 1960).

In capillaries of metabolizing tissues, CO_2 enters RBCs and about 80% is rapidly converted to H_2CO_3 by carbonic anhydrase (Hsia, 1998). This carbonic acid spontaneously ionizes to H^+ and HCO_3^-. The increased H^+ concentration decreases the oxygen affinity of Hb and facilitates oxygen delivery to the tissues. DeoxyHb is a weaker acid than OxyHb; therefore, DeoxyHb binds the excess H^+ and limits the decrease in pH. The increased HCO_3^- diffuses out of the cell down a concentration gradient and $C1^-$ moves in (chloride shift) to maintain electrical neutrality (Fig. 7-7a).

The direct binding of CO_2 to Hb in carbamino groups lowers oxygen affinity, but this effect is generally considered to be of minor importance. An exception appears to be in

goats and some sheep with HbC, a Hb type prominent in the neonate and induced in anemic and hypoxemic adults (see Section III.C.4). HbC binds twice as much CO_2 as does HbA in goats (Winslow *et al.*, 1989), and CO_2 decreases the oxygen affinity of HbC in goats and sheep more than it does the oxygen affinity of normal adult Hbs (Huisman and Kitchens, 1968). The carbamino formation also produces H^+, which further lowers Hb oxygen affinity (see Section I.B).

The processes discussed previously are reversed at the lungs (Fig. 7-7b). O_2 enters RBCs and the resultant binding of O_2 to Hb promotes the release of Hb-bound CO_2 and H^+ that were buffered by DeoxyHb. The H^+ binds to HCO_3^- to form H_2CO_3, which dissociates to form CO_2 and water. The lungs expel the CO_2, and the resultant decreases in CO_2 and H^+ concentrations increase the Hb oxygen affinity of RBCs passing through pulmonary capillaries. Because CO_2 and H^+ effects are interrelated and additive, the combined change in Hb oxygen affinity has been called the "classical Bohr effect," whereas the change in Hb oxygen affinity produced only by H^+ is called the "Bohr effect" (Zhang *et al.*, 2003).

Increased temperature decreases the oxygen affinity of Hb, a response that appears physiologically appropriate considering that increased heat production accompanies increased oxygen consumption in tissues (Benesch *et al.*, 1975). Body temperature increases during prolonged strenuous exercise (Hsia, 1998), with muscle temperature increasing more than pulmonary arterial temperature (Fenger *et al.*, 2000). Increased muscle temperature, increased CO_2 production, and increased H^+ production (from lactic acidosis and transport of CO_2) decrease the Hb oxygen affinity and promote the release of O_2 to muscles during prolonged heavy exercise. Oxygen extraction from the blood of horses increases from 20% at rest to 80% at maximal exercise (Fenger *et al.*, 2000). Increased cardiac output and higher blood Hb concentrations (from splenic contraction) are equally important for maximal oxygen delivery to muscles in exercising horses (Fenger *et al.*, 2000).

Breed differences in P_{50} have been described in dogs (Clerbaux *et al.*, 1993), horses, and goats (Haskins and Rezende, 2006). The P_{50} for greyhound RBCs in whole blood is lower than that for mongrel dogs, yet the groups have similar 2,3DPG concentrations (Sullivan *et al.*, 1994). The cause of this difference remains to be determined, but it is suggested that the higher hematocrit found in greyhound dogs may represent a compensatory response to a higher oxygen affinity of Hb in this species.

3. Effects of 2,3DPG

In RBCs from most mammalian species, 2,3DPG decreases the oxygen affinity of Hb, resulting in an increase in P_{50} (Bunn *et al.*, 1974). In contrast, poikilothermic animals generally use ATP or GTP (primarily fish), and birds typically use inositol pentaphosphate, to decrease the oxygen affinity of Hb (Barvitenko *et al.*, 2005; Val, 2000). 2,3DPG reacts with Hb in a ratio of one molecule per Hb tetramer. Negatively charged groups of 2,3DPG bind to specific positively charged groups in the N-terminal region of Hb beta chains. There is a marked preference for binding to DeoxyHb as compared to OxyHb because of differences in the conformation of the molecules. The interaction of 2,3DPG with Hb is represented as follows:

$$\text{HbDPG} + \text{O}_2 \leftrightarrow \text{HbO}_2 + \text{DPG}$$

When 2,3DPG is increased the reaction is displaced to the left, and when pO_2 is increased the reaction is displaced to the right. ATP has a similar effect on Hb oxygen affinity but is generally much less important than 2,3DPG in mammals, because it usually occurs in lower concentration and is complexed with Mg^{+2} (Bunn, 1971).

When the oxygen affinity of Hb is studied in hemolysates dialyzed to remove 2,3DPG and ATP, the "stripped" Hb from species with low 2,3DPG RBCs has considerably lower oxygen affinities than stripped Hb from species with high 2,3DPG RBCs (Bunn, 1971; Bunn *et al.*, 1974). The Hb oxygen affinity of most mammalian Hbs is decreased in the presence of chloride ions and, to a lesser extent, phosphate ions (Bårdgard *et al.*, 1997; Fronticelli, 1990; Gustin *et al.*, 1994; Haskins and Rezende, 2006). Consequently, the oxygen affinities of stripped Hbs can vary depending on the buffer system used for these assays. The oxygen affinity of stripped cattle Hb is lower in buffers containing NaCl than in buffers without NaCl. Although the addition of 2,3DPG to stripped cattle Hb causes a prominent increase in P_{50} in the absence of Cl^-, it causes only a tiny additional increase in P_{50} in the presence of physiological concentrations of Cl^- (Marta *et al.*, 1998). In contrast, the addition of 2,3DPG to stripped dog Hb results in a prominent increase in P_{50}, even in the presence of physiological concentrations of Cl^- (Bårdgard *et al.*, 1997). Because stripped Hbs from species such as dogs with high 2,3DPG RBCs naturally have high oxygen affinities, 2,3DPG is needed within RBCs of these species to maintain Hb oxygen affinity within a physiologically useful range (Benesch *et al.*, 1975).

When blood from many mammalian species is studied, an inverse linear correlation is recognized between the log P_{50} of whole blood and the log of body weight (Scott *et al.*, 1977); however, oxygen affinity of stripped Hb from various mammals does not correlate with body weight (Nakashima *et al.*, 1985). The maintenance of 2,3DPG in mammals is energetically expensive because the ATP-generating PGK reaction is bypassed. 2,3DPG apparently allows for an evolutionary adaption of blood Hb oxygen affinity to metabolic rate.

Mammals with naturally high 2,3DPG in RBCs may alter their Hb oxygen affinity to meet metabolic needs. The significance of (and in some cases the appropriateness of) alterations in 2,3DPG in disease states is not always clear.

RBC 2,3DPG increases in some anemic animals (Agar *et al.*, 1977; King *et al.*, 1992; Paltrinieri *et al.*, 2000; Studzinski *et al.*, 1978). The resultant increase in P_{50} would seem to be beneficial in response to anemia. Increased 2,3DPG has also been reported in RBCs from horses with hypoxic conditions (Giordano *et al.*, 2004). When humans and animals enter higher altitude, their ventilation frequency increases. This hyperventilation decreases the pCO_2 and increases arterial pH, which increases the oxygen affinity for Hb. However, the increased pH stimulates RBC glycolysis and 2,3DPG synthesis, which tends to counteract the effect of increased pH. This response is appropriate as long as the increased ventilation can maintain alveolar O_2 tension sufficient for O_2 loading in the lungs (Nikinmaa, 2001). In the case of severe hypoxic hypoxemia the response might be detrimental, because Hb cannot be fully saturated (Jensen, 2004). Various studies in dogs indicate that cardiac output and microcirculation adjustments are much more important than changes in Hb oxygen affinity in adapting to hypoxia (Liard and Kunert, 1993; Schumacker *et al.*, 1985; Zachara *et al.*, 1981). However, a reduction in Hb oxygen affinity secondary to increased 2,3DPG can be beneficial, because it is far less energy demanding than is an increase in cardiac output (Liard and Kunert, 1993; Mairbäurl, 1994; Teisseire *et al.*, 1985). RBC 2,3DPG increases in hibernating mammals, but the effect of the decrease in body temperature associated with hibernation on Hb oxygen affinity *in vivo* would more than offset the effect of increased 2,3DPG (Bunn, 1981). Because pH has a substantial effect on Hb oxygen affinity, changes in RBC 2,3DPG concentration, in response to acidosis and alkalosis, produce effects on Hb oxygen affinity that counteract alterations induced by the respective changes in pH (Bellingham *et al.*, 1971).

Aged human RBCs lose K^+, organic phosphates (especially 2,3DPG), and water. The loss of organic phosphates results in increased Hb oxygen affinity in these older RBCs (Schmidt *et al.*, 1987).

4. Maternal-Fetal Oxygen Transport

Except for in the domestic cat, the oxygen affinity of Hb in fetal blood is higher than that of maternal blood when measured under standard conditions (Bunn and Kitchen, 1973; Novy and Parer, 1969). This difference in oxygen affinity probably enhances the transport of oxygen across the placenta to the fetus (Comline and Silver, 1974; Hebbel *et al.*, 1980). Oxygen is adequately transported to cat fetuses, without the advantage of increased oxygen affinity, because of the nature of the placentation and a countercurrent arrangement of blood flows (Novy and Parer, 1969).

During late gestation, mean umbilical venous pO_2 values of 48, 38, 35, and 30 mmHg have been reported for horses, cattle, sheep, and pigs, respectively (Comline and Silver, 1974). Fetal systemic arterial pO_2 values may be even lower, especially in species such as the pig and horse, which lack a ductus venosus, requiring that all returning umbilical venous blood pass through the liver. These pO_2 values are considerably lower than normal adult arterial pO_2 values of about 100mmHg. Because Hb in adult RBCs of these species is only partially saturated at these low arterial pO_2 values (Schmidt-Neilsen and Larimer, 1958), the increased oxygen affinity of fetal blood would result in a greater saturation of Hb and, therefore, a greater oxygen-carrying capacity of blood than would otherwise be present.

Fetal RBCs maintain Hb oxygen affinities higher than those of the mother by one of three mechanisms (Bunn and Kitchen, 1973). (1) Ruminants have structurally distinct fetal Hbs that have higher oxygen affinities than adult Hbs in the absence of organic phosphates (Battaglia *et al.*, 1970; Blunt *et al.*, 1971). Interactions between 2,3DPG and both fetal and adult Hbs in ruminants are weak when Cl^- is present (Bunn and Kitchen, 1973). (2) A structurally distinct fetal Hb (HbF) also occurs in humans, but the oxygen affinity of stripped HbF and adult human Hb is about the same. Differences in whole blood oxygen affinity occur primarily because HbF interacts weakly with 2,3DPG, in contrast to the strong interaction with adult Hbs (Oski and Gottlieb, 1971). (3) Animals without structurally distinct fetal Hbs, such as dog, horse, and pig, have much lower 2,3DPG concentrations in fetal RBCs than in adult RBCs, thereby creating higher oxygen affinities in fetal RBCs (Bunn and Kitchen, 1973; Comline and Silver, 1974; Dhindsa *et al.*, 1972; Tweeddale, 1973). The actual *in vivo* difference in oxygen affinity between fetal and maternal RBCs is presumably less than suggested by differences in P_{50} values measured *in vitro* at pH 7.4, because fetal blood pH is lower than that of maternal blood (Comline and Silver, 1974). However, the diffusion of CO_2 from fetal blood to maternal blood helps increase the pH and oxygen affinity in fetal blood, and it simultaneously decreases the pH and oxygen affinity in maternal blood. This "double Bohr effect" enhances the mother-to-fetus O_2 transfer (Zhang *et al.*, 2003).

5. Postnatal Changes in 2,3DPG and Oxygen Affinity

Although the higher oxygen affinity of Hb in fetal RBCs may be beneficial in the uterus, it would seem to be disadvantageous to the newborn animal breathing air. Whole blood P_{50} values and RBC 2,3DPG concentrations (Fig. 7-8) increase after birth in most domestic animals.

RBC 2,3DPG concentrations are higher in fetuses than in adult ruminants, and they increase markedly within a few days after birth (Aufderheide *et al.*, 1980; King and Mifsud, 1981; Zinkl and Kaneko, 1973a). Because neither fetal nor adult Hbs from ruminants bind 2,3DPG to any extent (at least in the presence of physiological concentrations of Cl^-), 2,3DPG decreases oxygen affinity primarily by lowering intracellular pH (Aufderheide *et al.*, 1980; Battaglia *et al.*, 1970; Blunt, 1972). Several mechanisms are involved

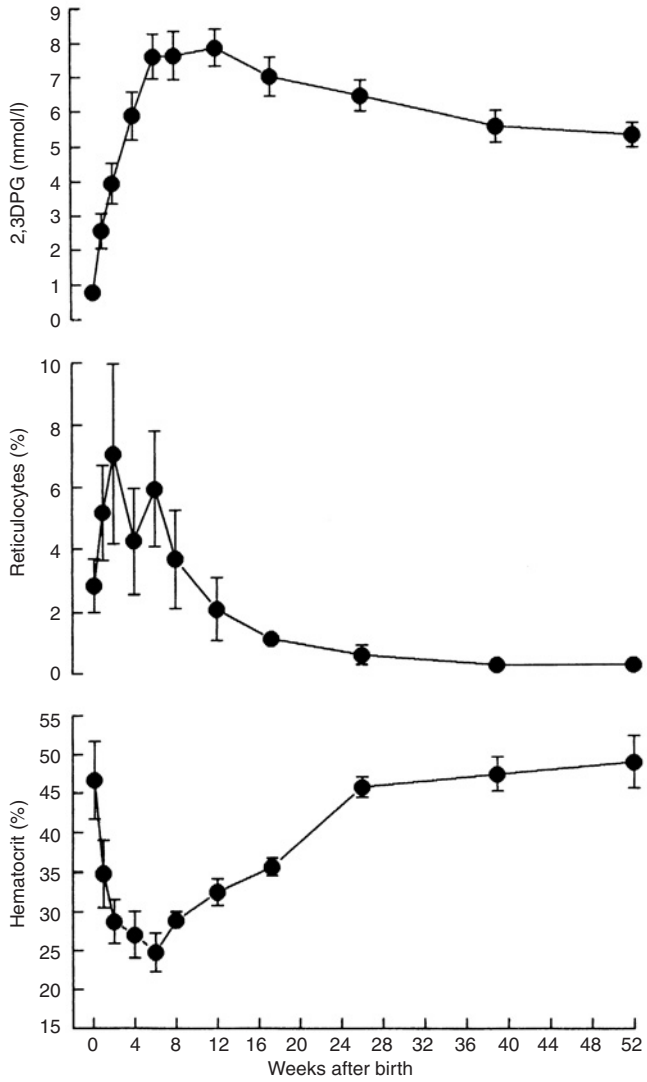

FIGURE 7-8 Changes in hematocrit, uncorrected reticulocyte count, and RBC 2,3DPG content in dogs following birth. Values are mean ± standard deviation (Harvey, unpublished, 1994).

in the 10-fold increase in RBC 2,3DPG during the first 5 days of life in lambs (Noble *et al.*, 1983). (1) Plasma glucose increases from 40 to 100 mg/dl during the first 2 days of life and allows for an increased consumption of glucose by the glucose-permeable neonatal RBC. (2) The blood pH increases during the first day of life and activates the PFK enzyme, as evidenced by changes in RBC intermediates. (3) Plasma P_i concentration increases to a level sufficient to increase GAPD activity at 3 days of age. (4) DPGM activity in neonatal RBCs is 12-fold higher than that of adults. (5) RBC PFK activity is still above adult values, but PK activity has decreased to adult values by birth.

The decline in 2,3DPG in postnatal ruminant RBCs is more gradual, requiring 1 to 2 months to reach adult values. The whole blood P_{50} is maintained, however, because of concomitant decreases in fetal Hb and increases in adult Hb types (Aufderheide *et al.*, 1980; Blunt *et al.*, 1971; Lee *et al.*, 1971; Zinkl and Kaneko, 1973b). In goat RBCs, HbC replaces most of the fetal Hb initially, but after 2 months, other adult Hbs begin to replace HbC (Huisman *et al.*, 1969). Goat RBCs containing predominantly HbC have lower Hb oxygen affinity with a moderately increased Bohr effect compared to RBCs containing other adult Hbs (e.g., HbA, HbB, HbD) (Huisman *et al.*, 1969). Only a small percentage of HbC is present in lambs up to 2 months of age. The percentage of fetal Hb at birth varies from 70% to 100%. The signal to switch production of fetal Hb to HbA in lambs appears to result from an inherent programming of hematopoietic stem cells (Wood *et al.*, 1985).

Rapid, but modest, increases in 2,3DPG and P_{50} occur after birth in horse RBCs (Bunn and Kitchen, 1973). As in ruminants, blood pH increases significantly within 1 h after birth (Rose *et al.*, 1982). Plasma P_i concentration also increases during the first 2 weeks of life (Bauer *et al.*, 1984). Gradual, but large, increases in 2,3DPG and P_{50} occur postnatally in blood of dogs (Dhindsa *et al.*, 1972; Harvey and Reddy, 1989; Mueggler *et al.*, 1980) and pigs (Baumann *et al.*, 1973; Kim and Duhm, 1974; Watts and Kim, 1984). A decreasing activity of PK has been reported to account for the increasing 2,3DPG concentration during the first 60 days of life in dogs (Mueggler and Black, 1982), but activation of PFK may also play a role in this increase.

In human RBCs, 2,3DPG increases slightly after birth, but most of the increase in P_{50} that occurs during the first 6 months of life results from the replacing of HbF with adult Hbs (Oski and Gottlieb, 1971). Whereas P_{50} values changed slightly in kittens after birth, RBC 2,3DPG values remained in the normal adult range (Dhindsa and Metcalfe, 1974). Data concerning changes in these and other species have been compiled by Isaacks and Harkness (1983).

6. RBCs as Sensors and Effectors of Local O_2 Delivery

RBCs may also have a role in the regulation of local O_2 delivery to tissues that is mediated by Hb O_2 saturation (SO_2). In addition to releasing O_2 from Hb in the tissues, one or more signals are released from RBCs that trigger vasodilation and increased blood flow to the feeding arterioles (Jagger *et al.*, 2001; Singel and Stamler, 2005). Nitric oxide ($^{\cdot}NO$), generated from L-arginine by $^{\cdot}NO$ synthases in the endothelium and in other cells, is a potent vasodilator. Some evidence suggests that $^{\cdot}NO$ can be transported by RBCs to microvascular sites of action in a protected form as an S-nitrosothiol on the highly conserved Hb β-93 cysteine residue. On the release of oxygen, this S-nitrosoHb purportedly delivers $^{\cdot}NO$ to arterioles (Singel and Stamler, 2005). An alternate mechanism of $^{\cdot}NO$ delivery has been proposed that reutilizes nitrite formed when $^{\cdot}NO$ reacts with OxyHb (Crawford *et al.*, 2006). Nitrite is stored within RBCs and reduced back to $^{\cdot}NO$ by DeoxyHb, which serves as a nitrite reductase (Rifkind *et al.*, 2006). Both

mechanisms would result in $^{\cdot}NO$ production, vasodilation, and increased blood flow at sites where SO_2 in RBCs is low (Crawford *et al.*, 2006).

RBCs also promote vasodilation by the release of micromolar amounts of ATP, an endothelium-dependent vasodilator, when SO_2 is low. As oxygen is released from OxyHb, the increased concentration of DeoxyHb binds to the cytoplasmic domain of band 3, displacing PFK and other glycolytic enzymes. It is hypothesized that this results in a stimulation of glycolysis (see Section IV.G), which results in increased production and release of ATP (Jagger *et al.*, 2001). The precise mechanism of ATP release is unknown, but band 3 and nucleoside transporter band 4.5 have been implicated in transport (Jagger *et al.*, 2001). In addition, a member of the ATP-binding cassette, the cystic fibrosis transmembrane conductance regulator (CFTR), appears to mediate a deformation-induced release of ATP from RBCs (Gov and Safran, 2005; Sprague *et al.*, 2005), and this transport mechanism may also play a role in SO_2-mediated ATP release (Jagger *et al.*, 2001). Blood levels of ATP rise and fall within minutes, compared to seconds for $^{\cdot}NO$ effects. Consequently, $^{\cdot}NO$ and ATP may have complementary roles in acute local and prolonged systemic hypoxia, respectively (Singel and Stamler, 2005).

J. Pentose Phosphate Pathway

The pentose phosphate pathway (PPP) generates NADPH, the major source of reducing equivalents in the protection of RBCs against oxidative injury. This pathway also produces ribose 5-phosphate (R5P), which is required for adenine nucleotide synthesis (Eaton and Brewer, 1974). The PPP competes with the EMP for the G6P substrate (Fig. 7-5). Normally only about 5% to 13% of glucose metabolized by RBCs flows through the PPP (Harvey and Kaneko, 1976a), but this flow can be accelerated markedly by oxidants (Harvey and Kaneko, 1977).

The first step in the metabolism of glucose through the PPP generates NADPH from the oxidation of G6P in the glucose-6-phosphate dehydrogenase (G6PD) reaction. An additional NADPH is generated from the oxidative decarboxylation of 6-phosphogluconate (6PG) to ribulose 5-phosphate in the 6-phosphogluconate dehydrogenase (6PGD) reaction. This is the only known reaction producing CO_2 in mature RBCs. The remaining reactions in the PPP are nonoxidative and freely reversible. R5P is produced from ribulose 5-phosphate by the R5P isomerase reaction. The net effect of the metabolism of 3 molecules of G6P through the PPP is as follows (Eaton and Brewer, 1974):

$$3G6P + 6NADP^+ \rightarrow 3CO_2 + 2F6P + G3P + 6NADPH + 6H^+$$

G6PD is the rate-limiting reaction in the PPP under physiological conditions. Normally, the G6PD reaction in intact human RBCs operates at only 0.1% to 0.2% of the maximal enzyme activity, as determined in hemolysates under optimal conditions. The low rate of this reaction in RBCs occurs because of limited substrate availability (especially $NADP^+$) and because G6PD is strongly inhibited by NADPH and ATP at physiological concentrations (Yoshida, 1973). The maximal G6PD activities measured in hemolysates from goat and sheep RBCs are much lower than those of humans or of other domestic animals (Tables 7-2 and 7-3). However, this comparatively low enzyme activity does not render sheep RBCs unduly susceptible to the hemolytic effects of oxidant drugs (Maronpot, 1972; Smith, 1968), in part because ATP does not inhibit G6PD in this species (Smith and Anwer, 1971).

About 91% of total NADP is in the reduced form in horse RBCs (Stockham *et al.*, 1994) and 92% to 99% of total NADP is NADPH in human RBCs (Kirkman *et al.*, 1986; Zerez *et al.*, 1987). NADPH is utilized to reduce oxidized glutathione to GSH, the substrate for the glutathione peroxidase reaction, and it is bound to catalase, preventing and reversing the accumulation of an inactive form of catalase that is generated when catalase is exposed to H_2O_2 (Kirkman *et al.*, 1987). In the presence of oxidants, NADPH is oxidized and the PPP is stimulated because the activities of G6PD and 6PGD are directly related to the concentration of NADP and inversely related to that of NADPH (Yoshida, 1973). Glutathione metabolism affects PPP activity via the glutathione reductase (GR) enzyme, which generates NADP as a result of the reduction of GSSG with NADPH (Fig. 7-5).

K. Nature of Oxidants in Biology

Reactive oxygen species (ROS) and reactive nitrogen species (RNS) are produced as products of normal cellular metabolism. They play dual roles as beneficial and deleterious species. At low to moderate concentrations, $^{\cdot}NO$ and superoxide ($^{\cdot}O_2^-$) free radicals are involved in signal transductions between cells (Valko *et al.*, 2007). A free radical is defined as any species with one or more unpaired electrons. When generated at higher concentrations in diseased states, these free radicals (and even more potent oxidative metabolites they produce) can overwhelm protective systems within the body, producing cellular injury or destruction (Valko *et al.*, 2007). The oxidants generated vary in their overall reactivities, and some are fairly selective for certain biomolecules (e.g., tyrosine, glutathione, linoleic acid, and ascorbate) (Pryor *et al.*, 2006).

Increased amounts of endogenous oxidants are generated in association with various disorders including inflammation (Lykkesfeldt, 2002; Spickett *et al.*, 1998; Weiss *et al.*, 1992a; Weitzman and Gordon, 1990), RBC parasites (Otsuka *et al.*, 2001; Shiono *et al.*, 2003), neoplasia (Christopher, 1989; Della Rovere *et al.*, 2000), diabetes (Christopher, 1995), intense exercise (Hargreaves *et al.*,

2002; Lykkesfeldt, 2002), and ischemia/reperfusion (Valko *et al.*, 2007).

1. Reactive Oxygen Species

From a thermodynamic standpoint, oxygen is a strong oxidant, but its reactivity is limited by virtue of its unusual electronic configuration (Green and Hill, 1984). Although it is relatively unreactive, oxygen can be metabolized *in vivo* to form highly reactive derivatives. A single-electron reduction of O_2 yields the superoxide ($^{\cdot}O_2^-$) free radical. The major source within RBCs appears to be the autoxidation of OxyHb (Johnson *et al.*, 2005). There are a wide variety of other sources of $^{\cdot}O_2^-$ production in various tissues; examples include the ubiquinone-cytochrome *b* region in mitochondria; uncoupled cytochrome *P*-450 reactions; autoxidation of adrenaline, certain flavins, and SH groups; enzyme reactions such as xanthine oxidase and tryptophan deoxygenase; and the oxidant burst of activated neutrophils and mononuclear phagocytes (Freeman and Crapo, 1982). In the absence of inflammation, the major source of $^{\cdot}O_2^-$ production in nonerythroid cells is the mitochondrion (Johnson *et al.*, 2005). Superoxide undergoes spontaneous and enzyme catalyzed dismutation to H_2O_2. In the presence of a metal ion such as iron or copper, $^{\cdot}O_2^-$ and H_2O_2 interact to form the highly reactive hydroxyl radical ($^{\cdot}OH$). Additional ROS include singlet O_2 (an excited state of O_2), ozone (O_3) and hypochlorous acid (HOCl), generated by myeloperoxidase in neutrophils from H_2O_2, and Cl^- (Pryor *et al.*, 2006).

2. Reactive Nitrogen Species

Nitric oxide is a stable free radical generated from arginine by the nitric oxide synthase (NOS) reaction. Three isoforms of NOS exist. The endothelial enzyme (eNOS) and the neuronal enzyme (nNOS) are constitutively expressed. The third form (iNOS) is induced in a variety of cells, often as a result of immunologic/inflammatory stimulation (Pryor *et al.*, 2006). Nitric oxide is a second messenger involved in a variety of biological functions. Within the vasculature, it promotes vasodilation and inhibits platelet aggregation and leukocyte adhesion to the endothelium. It also functions as a neurotransmitter and has antimicrobial functions in phagocytes. The half-life of $^{\cdot}NO$ in the circulation is believed to be $<$0.1sec (Rifkind *et al.*, 2006). It combines with oxygen to produce additional oxidants, nitrogen dioxide ($^{\cdot}NO_2$) and dinitrogen trioxide (N_2O_3), which are eventually converted to nitrite (NO_2^-). Nitric oxide reacts with $^{\cdot}O_2^-$, to form the strong oxidant peroxynitrite ($ONOO^-$). Peroxynitrite combines with CO_2 to form $ONOOCO_2^-$, which decomposes to form $^{\cdot}NO_2$ and the carbonate radical ($^{\cdot}CO_3$).

Nitric oxide exhibits complex interactions with Hb to form several products, including nitrosylhemoglobin [Hb(II)NO], S-nitrosylated Hb, MetHb, and nitrate, depending on whether it reacts with OxyHb or DeoxyHb (Rifkind *et al.*, 2006). The RBC was considered to be an important $^{\cdot}NO$ scavenger in earlier literature, but much of the $^{\cdot}NO$ apparently does not enter the cytoplasm of RBCs, primarily because their membranes and associated cytoskeleton layers limit its uptake (Han *et al.*, 2005). However, free Hb in plasma scavenges $^{\cdot}NO$ up to 600 times more readily than Hb within RBCs. Consequently, intravascular hemolysis disrupts $^{\cdot}NO$ homeostasis, which may lead to vasoconstriction, decreased blood flow, platelet activation, increased endothelin-1 expression, and organ injury (Gladwin *et al.*, 2004).

3. Drugs, Environmental Agents, and Metabolic Intermediates

A wide variety of drugs, environmental agents, and metabolic intermediates either exist as free radicals or can be converted to free radicals by cellular metabolic processes (Freeman and Crapo, 1982; Mason, 1982). These free radicals can be more damaging than the ROS and RNS species listed previously.

L. Metabolic Protection against Oxidants

1. Superoxide Dismutase

Superoxide dismutase (SOD) is a copper- and zinc-containing enzyme that was first isolated from cattle blood (McCord and Fridovich, 1969). It promotes the dismutation of two $^{\cdot}O_2^-$ molecules to H_2O_2 and O_2 (Fig. 7-5). SOD helps prevent the buildup of superoxide, which can act as an oxidant by itself, or combine with H_2O_2 to form the $^{\cdot}OH$ radical, or combine with $^{\cdot}NO$ to form peroxynitrite (Pryor *et al.*, 2006). The activity of SOD in RBCs of domestic animals is about the same as or higher than that in humans (Harvey and Kaneko, 1977; Suzuki *et al.*, 1984). RBC SOD activity is reduced in animals fed diets deficient in copper (Andrewartha and Caple, 1980; Williams *et al.*, 1975). Zinc is also needed for optimal activity, and consequently, SOD activity may also be low in zinc-deficient animals (Hirose *et al.*, 1992).

2. Glutathione

Reduced glutathione (GSH) is of central importance in the protection against oxidant injury. It is a tripeptide of glutamic acid, cysteine, and glycine that occurs in approximately 2 m*M* concentrations in RBCs. It is synthesized *de novo* in RBCs of humans and animals from constituent amino acids via two ATP-requiring reactions, utilizing gamma-glutamylcysteine synthetase and glutathione synthetase (Beutler, 1989). GSH has a highly reactive (easily oxidizable) sulfhydryl (SH) group that, like other thiols, may act nonenzymatically as a free radical acceptor to counteract oxidant damage (Prins and Loos, 1969). GSH can also bind free hemin (containing iron as Fe^{+3}) that may be

released during Hb oxidative denaturation, thereby reducing the potential of hemin for membrane injury (Shviro and Shaklai, 1987). GSH functions as an electron donor in various reductive enzyme reactions including glutathione peroxidase (GPX), phospholipid hydroperoxide glutathione peroxidase, glutathione S-transferase, and glutaredoxin (discussed subsequently).

Although GSH is constantly being oxidized to a disulfide (GSSG) within RBCs, most glutathione is maintained in its reduced form by the glutathione reductase reaction. RBCs increase PPP metabolism to provide the NADPH necessary for the regeneration of GSH by the GR reaction (Eaton and Brewer, 1974). The selective oxidation of a renewable SH group helps limit irreversible damage to RBCs that would otherwise occur. GSSG accounts for only about 0.2% of the total glutathione in normal human RBCs (Beutler, 1984). GSH is easily oxidized during the process of sample preparation and handling for GSSG assays; therefore, care must be taken not to produce artifactual increases in GSSG concentration (Rossi *et al.*, 2002). RBC membranes are not permeable to GSH, but GSSG is exported from RBCs using an ATP-dependent multidrug resistance protein (MRP) transporter (Keppler *et al.*, 1998). The half-life of glutathione in dog and rabbit RBCs (2 to 5 days) is similar to that in human RBCs (4 days), whereas longer times (10 to 12 days) are reported in sheep RBCs. The GSSG transport rate may be the main determinant of glutathione turnover in RBCs (Smith, 1974). Intracellular GSSG that is not exported from RBCs or reduced to GSH reacts with protein SH (PSH) groups to form glutathione-protein mixed disulfides (GS-SP) according to the reaction GSSG + PSH → GS-SP + GSH (Di *et al.*, 1998).

3. *Glutathione Reductase*

GSSG produced by the various oxidative reactions is reduced to GSH by NADPH and the flavin adenine dinucleotide (FAD)-dependent glutathione reductase (GR) reaction. Riboflavin metabolism affects the availability of FAD and the fraction of the protein that exhibits activity (Beutler, 1989; Harvey and Kaneko, 1975b). GR activity is unmeasurable in RBCs from horses that are deficient in FAD secondary to a defect in RBC riboflavin metabolism (Harvey *et al.*, 2003). NADPH is produced by the initial enzyme reactions of the pentose phosphate pathway, and RBCs increase pentose phosphate pathway metabolism in response to oxidants to provide the NADPH necessary for the regeneration of GSH. Excepting the cat, RBCs of domestic animals have lower GR activity than those of humans (Agar *et al.*, 1974b; Harvey and Kaneko, 1975b). RBCs from horses are slower than RBCs from other species studied in their ability to regenerate GSH after it has been oxidized *in vitro*. Horses also appear less able to protect their RBCs against oxidative injury induced by incubation with high levels of ascorbate, which stimulates the GR reaction by the oxidation of GSH. These reduced abilities may be related to the finding that horses have lower RBC GR activities than RBCs from humans and most domestic animal species. In addition, the K_m of GSSG for GR is higher in horses than in three other species measured (Harvey and Kaneko, 1975b).

4. *Glutathione S-Transferase*

Glutathione S-transferase (GST) catalyzes the formation of glutathione S-conjugates between GSH and certain electrophilic substrates. The same ATP-dependent MRP transport system appears to transport GSSG and glutathione S-conjugates out of RBCs (Keppler *et al.*, 1998). GST is susceptible to inactivation by electrophilic compounds; consequently, RBC GST activity may provide a marker for certain types of chemical exposure (Ansari *et al.*, 1987). GST activity is present in RBCs of all mammalian species studied thus far, but natural electrophilic substrates and the potential involvement of these glutathione S-conjugates in glutathione turnover in normal animals are unknown (Board and Agar, 1983; Vodela and Dalvi, 1997). A direct correlation between GST activity and GSH concentration has been reported in sheep and dog RBCs (Goto *et al.*, 1992). This is probably related to the fact that GST is stabilized by GSH.

The GST-mediated conjugation of various carcinogens and other electrophilic drugs in the liver is important in the protection of the body against these agents (Chasseaud, 1979), but the importance of this activity in protecting RBCs against xenobiotics remains to be documented. The distribution of GST isozymes varies in tissues, including RBCs. As a result, RBCs from different individuals (even within the same species) may vary in their conjugating abilities with various xenobiotics (Ploemen *et al.*, 1995). GST can also bind free hemin that is released during Hb oxidation, presumably reducing damage to RBC membranes (Harvey and Beutler, 1982).

5. *Glutathione Peroxidase*

Low levels of H_2O_2 are produced in the course of normal cellular events and higher levels may be generated by exogenously administered redox active compounds (Saltman, 1989). GPx catalyzes the conversion of H_2O_2 to H_2O (Fig. 7-5). It also catalyzes the reduction of fatty acid hydroperoxides, and 1-monoacylglycerol hydroperoxides (Thomas *et al.*, 1990). Another GPx in RBCs termed *phospholipid hydroperoxide glutathione peroxidase* participates in the reduction of more complex phospholipid hydroperoxides using GSH (Fujii *et al.*, 1984).

Selenium is incorporated as selenocysteine at the active site of a wide range of selenoproteins, including GPx, phospholipid hydroperoxide glutathione peroxidase, and thioredoxin reductase in RBCs (Brown and Arthur, 2001). GPx activity in RBCs correlates directly with blood selenium concentration in ruminants, horses, and rats but not in pigs or higher primates (Anderson *et al.*, 1978; Beilstein

and Whanger, 1983; Caple *et al.*, 1978; Thompson *et al.*, 1976). Selenium deficiency can be diagnosed by measuring decreased RBC GPx activity in some species (Anderson *et al.*, 1978; Caple *et al.*, 1978); however, caution is indicated in using this activity as a direct indicator of selenium status because polymorphism in GPx activity may be present, as occurs in Finn sheep (Sankari and Atroshi, 1983). A wide variety of abnormalities or lesions (most notably in skeletal and cardiac muscle) have been described in association with selenium deficiency in animals (Shamberger, 1986), but hemolytic anemia rarely, if ever, occurs in the absence of external oxidant stress. Heinz body (HzB) hemolytic anemia has been reported during the summer months in selenium-deficient cattle grazing on St. Augustine grass growing on peaty muck soils in South Florida (Morris *et al.*, 1984). Although HzB formation was greatly reduced by selenium supplementation, it is likely that these animals were also exposed to a seasonal oxidant, possibly incorporated in the grass.

6. *Thioredoxin, Glutaredoxin, and Peroxyredoxin*

Thioredoxin (Trx) and glutaredoxin (Grx) are small proteins with two closely associated cysteines in their active sites (Lillig and Holmgren, 2007). They may be present in either oxidized disulfide forms or reduced dithiol forms. The reduced forms of these proteins interact with and reduce intramolecular protein disulfides that form in oxidatively damaged proteins. Resultant oxidized Trx is reduced to the dithiol form by NADPH and thioredoxin reductase (together called the thioredoxin system) (Cha and Kim, 1995; Mendiratta *et al.*, 1998). In contrast, oxidized Grx is reduced by GSH, and the GSSG formed is reduced by NADPH and GR (together called the glutaredoxin system) (Papov *et al.*, 1994). Reduced Grx can also reduce mixed disulfides that form between glutathione and oxidized protein SH groups (S-glutathionylation) (Klatt and Lamas, 2000). These various reactions regenerate SH groups, presumably protecting proteins such as Hb and enzymes with reactive SH groups from irreversible denaturation. Trx is also important in the scavenging of free radicals (both directly and indirectly) and as an electron donor for peroxyredoxins. Grx is also utilized in the reduction of dehydroascorbate. Both Trx and Grx have additional functions in other cell types (Lillig and Holmgren, 2007).

Peroxyredoxins are an emerging family of multifunctional SH-dependent enzymes that reduce H_2O_2 and alkyl hydroperoxides to water and alcohol, respectively. Oxidized peroxyredoxins are regenerated using the Trx system (Lee *et al.*, 2003). Peroxiredoxin 2 (Prx2) is the third most abundant protein in human RBCs, in which it has been shown to be an efficient scavenger of H_2O_2 generated endogenously at low concentrations (Low *et al.*, 2007). Knockout mice lacking Prx2 have severe hemolytic anemia characterized by an increase in RBC reactive oxygen species, leading to protein oxidation, HzB formation, and decreased RBC life span (Lee *et al.*, 2003).

7. *Catalase*

Catalase is a heme-containing homotetrameric enzyme that also destroys H_2O_2 by conversion to H_2O and O_2 (Kirkman and Gaetani, 2007). Except in dogs, mammalian RBCs generally have high catalase activities (Allison *et al.*, 1957; Nakamura *et al.*, 1998; Paniker and Iyer, 1965; Suzuki *et al.*, 1984). Catalase is linked metabolically to the PPP because NADPH is tightly bound to catalase in mammals (Kirkman and Gaetani, 2007). The oxidation of bound NADPH to bound $NADP^+$ results in the accumulation of an inactive form of catalase (compound II). This inactive catalase can be returned to normal function by reduction of bound $NADP^+$ with unbound NADPH and (to a lesser degree) unbound NADH using reductase and transhydrogenase activities, respectively, inherent in catalase (Gaetani *et al.*, 2005). This may explain the finding of normal catalase activity in RBCs from a horse with extremely low NADPH concentration secondary to G6PD deficiency (Stockham *et al.*, 1994). In addition to its benefit to RBCs, the presence of catalase in RBCs may help protect somatic cells exposed to high levels of H_2O_2, such as in sites of active inflammation (Agar *et al.*, 1986).

The relative importance of catalase versus GPx in the detoxification of low levels of endogenous H_2O_2 produced *in vivo* has been controversial (Gaetani *et al.*, 1994; Nagababu *et al.*, 2003; Scott *et al.*, 1993). Dogs have been identified that lack catalase within their RBCs but have catalase in other tissues (Nakamura *et al.*, 1999). RBCs from acatalasemic humans, mice, and dogs have not been reported to exhibit increased oxidative damage *in vivo* (Goth, 2001; Kirkman and Gaetani, 2007). RBCs from mice with GPx deficiency exhibit nearly normal defenses against H_2O_2 *in vitro*, although some loss of membrane sulfhydryls occurs *in vivo* (Ho *et al.*, 2004; Johnson *et al.*, 2000). Based on information available at this time, it appears that Prx2 is the most important enzyme in protecting RBCs against the low levels of H_2O_2 normally produced *in vivo* (Lee *et al.*, 2003). Catalase appears to be important in protecting RBCs against higher levels of exogenous H_2O_2 (Johnson *et al.*, 2005; Stagsted and Young, 2002). The primary physiological role of GPx in RBCs appears to be the detoxification of organic peroxides (Johnson *et al.*, 2000).

8. *Vitamin E (α-Tocopherol)*

Vitamin E is lipid soluble and the most important antioxidant in the cell membrane. It donates reducing equivalents to lipid peroxyl radicals, converting them to less toxic lipid hydroperoxides (May, 1998; Valko *et al.*, 2007). GSH-dependent phospholipid hydroperoxidase can reduce the lipid hydroperoxides that form. Oxidized vitamin E can be

reduced by ascorbate, presumably at the aqueous-lipid interface of the lipid bilayer (May, 1998). Vitamin E deficiency increases the susceptibility of RBCs to peroxidative hemolysis (Duthie *et al.*, 1989; Pillai *et al.*, 1992). Its location in the membrane provides little protection against cytosolic oxidative injury (Rotruck *et al.*, 1972). Vitamin E also inhibits hemolysis induced by hemin, purportedly by functioning as a membrane-stabilizing agent (Wang *et al.*, 2006).

9. Vitamin C (Ascorbate)

Vitamin C is an antioxidant with high reducing potential. It donates one or two electrons to a variety of oxidants, including oxygen free radicals and peroxides. It also appears to have an important function in the reduction of oxidized vitamin E within RBC membranes (May, 1998). The single electron-oxidized form is a stable free radical that can either donate or accept electrons. Dehydroascorbate, the two electron-oxidized form, can be reduced back to ascorbate nonenzymatically by GSH and enzymatically via the glutaredoxin reaction and by a separate GSH-dependent dehydroascorbate reductase enzyme (Xu *et al.*, 1996). Dehydroascorbate can also be reduced by the NADPH-dependent thioredoxin reductase reaction (May, 1998). Ascorbate enters and leaves cells slowly, but dehydroascorbate is rapidly taken up by RBCs by facilitated diffusion on the glucose transport protein (GLUT-1) and reduced to ascorbate within RBCs. Ascorbate is a major antioxidant in plasma. Ascorbate within human RBCs readily donates electrons to extracellular ascorbate free radicals via a plasma membrane redox system (possibly involving a membrane cytochrome b561), which helps prevent depletion of extracellular ascorbate. However, this membrane redox system appears to be less active in mouse RBCs (Su *et al.*, 2006).

10. Lipoic Acid

Lipoic acid is a sulfur-containing compound that is absorbed from the diet and synthesized in mitochondria (Smith *et al.*, 2004). Upon entering cells, it can be reduced to the dithiol form dihydrolipoic acid by the thioredoxin system (Smith *et al.*, 2004). Reduction of lipoic acid in human RBCs is reported to occur via GSH and glutathione reductase (Constantinescu *et al.*, 1995). Dihydrolipoic acid scavenges various ROS and RNS and chelates heavy metals; however, it is present in much lower concentrations in tissues compared to GSH and ascorbate. Consequently, the importance of its function as an antioxidant *in vivo* is questionable (Smith *et al.*, 2004).

11. MetHb Reduction

MetHb differs from Hb only in that the iron moiety of the heme groups is in the ferric rather than the ferrous state. MetHb forms *in vivo* at low levels normally and at much higher levels in the presence of oxidative compounds (Bodansky, 1951).

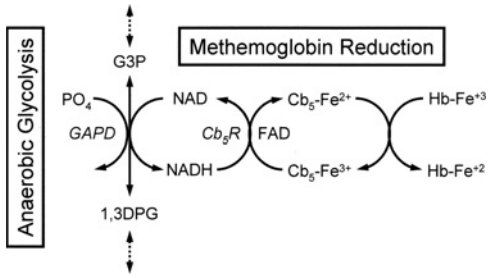

FIGURE 7-9 Methemoglobin reduction pathway. Abbreviations: G3P, glyceraldehyde-3-phosphate; GAPD, glyceraldehyde-3-phosphate dehydrogenase; PO_4, inorganic phosphate; 1,3DPG, 1,3-diphosphoglycerate; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; Cb_5R, cytochrome b_5 reductase; FAD, flavin adenine dinucleotide; Cb_5-Fe^{+3}, ferricytochrome b_5; Cb_5-Fe^{+2}, ferrocytochrome b_5; Hb-Fe^{+3}, methemoglobin; and Hb-Fe^{+2}, deoxyhemoglobin. From Harvey, 2006, with permission.

MetHb is unable to bind oxygen and must be reduced to Hb to be functional. MetHb is primarily reduced by cytochrome-b_5 reductase (Cb_5R), also called MetHb reductase. In this reaction, electrons are transferred from NADH to ferricytochrome-b_5 using FAD as the enzyme-bound prosthetic group; then the resulting ferrocytochrome-b_5 reduces MetHb nonenzymatically to Hb (Higasa *et al.*, 1998) (Fig. 7-9). MetHb reduction is more corrective than protective.

RBCs contain another enzyme, NADPH diaphorase (NADPH MetHb reductase, NADPH dehydrogenase) that is capable of MetHb reduction when appropriate electron carriers are present. In addition to redox dyes, such as methylene blue, various flavins may function as substrates for reduction by NADPH, prompting investigators to classify the enzyme as an NADPH flavin reductase (Yubisui *et al.*, 1980). The contribution of this enzyme to MetHb reduction in human RBCs is believed to be insignificant because flavin concentrations are normally low (Hultquist *et al.*, 1993). The finding that this protein also binds heme, porphyrins, and fatty acids raises additional questions about its possibly physiological role in RBCs (Xu *et al.*, 1992).

Following the oxidation of Hb to MetHb with nitrite *in vitro*, horse RBCs reduce MetHb at a slower rate than those of other domestic animals (except pigs) when glucose is added as the substrate for energy (Robin and Harley, 1966). RBCs from adult pigs cannot reduce MetHb with glucose as the substrate because they lack a membrane glucose transporter (Kwong *et al.*, 1986). In contrast to NADP, only about half of the total NAD is normally present in the reduced (NADH) form (Zerez *et al.*, 1987). Horse (Medeiros *et al.*, 1984; Robin and Harley, 1967) and pig (Rivkin and Simon, 1965) RBCs utilize lactate better than glucose to generate NADH (by the LDH reaction) for the reduction of MetHb. Because lactate occurs in blood and easily diffuses into RBCs, it may be an important substrate of MetHb reduction *in vivo*.

Methylene blue (MB) is used to treat toxic methemoglobinemia because it causes MetHb to be reduced faster than occurs by the relatively slow Cb_5R reaction. MB is reduced to leukomethylene blue (LMB) by the NADPH-dependent diaphorase discussed previously (Fig. 7-5), and LMB reacts spontaneously with MetHb, reducing it to Hb and regenerating MB (Sass *et al.*, 1969). MB was suggested to be of limited value in the treatment of methemoglobinemia in horses, as it had a limited ability to stimulate MetHb reduction in horse RBCs *in vitro* using glucose as the substrate (Robin and Harley, 1966). However, MB was subsequently found to be effective in reducing methemoglobinemia in horses *in vivo* (Dixon and McPherson, 1977; Harvey *et al.*, 2003).

Being a redox dye, MB can participate in various oxidative reactions on entering RBCs. It is important that it be used judiciously lest it potentiate HzB body formation and hemolysis that might result from the original oxidative insult (Harvey and Keitt, 1983).

V. DETERMINANTS OF RBC SURVIVAL

A wide variety of conditions, including immune-mediated hemolytic anemias and infectious diseases, result in shortened RBC survival. Readers are referred to *Schalm's Veterinary Hematology* (Feldman *et al.*, 2000) for information concerning conditions beyond the scope of this chapter.

A. Oxidative Injury

Oxidants produce different patterns of intracellular and membrane damage. For example, nitrite produces MetHb with minimal damage to Hb or membranes (May *et al.*, 2000); onion toxicity produces Heinz bodies and membrane damage with minimal methemoglobinemia in dogs (Harvey and Rackear, 1985); and acetaminophen toxicity results in significant methemoglobinemia, Heinz body formation, and membrane damage in cats (Finco *et al.*, 1975). Different patterns may be related to differences in lipid solubility, redox potentials, reactivity with SH groups, binding to heme, and the source or site of oxidant generation. Extracellularly produced oxidants can damage the membrane before reaching the cytosolic protective mechanisms. Oxidants that are generated intracellularly in coupled reactions with OxyHb tend to produce more Hb injury than membrane injury. Hb has been described as a "frustrated" oxidase, because it potentiates the generation of oxidants by a variety of drugs (Carrell *et al.*, 1977).

1. MetHb Formation

Although MetHb formation is reversible and does not enhance RBC destruction per se, it is a component of oxidative injury to RBCs and is generally involved as a step in HzB formation. Clinical signs associated with methemoglobinemia are the result of hypoxia because MetHb cannot bind O_2. Lethargy, ataxia, and semistupor do not become apparent until MetHb content exceeds 50%, with a coma-like state and death ensuing when it exceeds 80% (Bodansky, 1951). The cyanotic appearance of mucous membranes associated with this condition may not be easily recognized in heavily pigmented animals. MetHb content is quantified spectrophotometrically, but a spot test can determine whether clinically significant levels of MetHb are present. One drop of blood from the patient is placed on a piece of absorbent white paper and a drop of normal control blood is placed next to it. If the MetHb content is 10% or greater the patient's blood should have a noticeably brown coloration.

Approximately 3% of Hb is spontaneously oxidized to MetHb each day in normal people (Mansouri and Lurie, 1993) and dogs (Harvey *et al.*, 1991). A similar rate of MetHb formation (4%) has been calculated for mice (Johnson *et al.*, 2005). This MetHb formation results primarily from spontaneous autoxidation of OxyHb (Johnson *et al.*, 2005).

Although the iron moiety of DeoxyHb is in the ferrous state, in OxyHb it exists in (or near) the ferric state, with an electron being transferred to the O_2 molecule to give a bound superoxide ($\cdot O_2^-$) ion (Mansouri and Lurie, 1993). During deoxygenation, the electron returns to the iron moiety and O_2 is released. Autoxidation to MetHb with the release of $\cdot O_2^-$ occurs when the bound $\cdot O_2^-$ is replaced by a nucleophile such as $C1^-$ (Wallace *et al.*, 1974).

Oxidants such as hexavalent chromates, chlorates, cobalt, and copper oxidize Hb iron by extracting electrons (Umbreit, 2007). Cupric ions oxidize the reactive SH group on the beta chains of human and animal Hbs (Taketa and Antholine, 1982), and then an electron is transferred from heme iron to regenerate the SH group. Cupric ion is regenerated by interaction with oxygen. The series of reactions by which copper catalyzes Hb oxidation to MetHb (Carrell *et al.*, 1978) are as follows:

$$Cu^{+2} + Fe^{+2}S^- \rightarrow Cu^{+1} + Fe^{+2}S^{\cdot}$$
$$Fe^{+2}S^{\cdot} \rightarrow Fe^{+3}S^-$$
$$Cu^{+1} + O_2 \rightarrow Cu^{+2} + \cdot O_2^-$$

These reactions occur rapidly but continue only until about 50% of total hemes are oxidized because alpha chains are resistant to oxidation (Taketa and Antholine, 1982). Additional oxidative reactions involving copper can denature Hb and damage membranes (Hochstein *et al.*, 1978).

Rather than extracting electrons, many oxidant drugs produce MetHb by donating electrons to OxyHb (Carrell *et al.*, 1977), as is shown below for phenylhydroxylamine (PHA):

$$Hb^{+3.}\cdot O_2^- + PHA \rightarrow Hb^{+3.}\cdot O_2^{-2} + PHA^{\cdot}$$
$$Hb^{+3.}\cdot O_2^{-2} + 2H^+ \rightarrow Hb^{+3} + H_2O_2$$

Drug free radicals, such as PHA, that are generated can donate the unpaired electron to molecular oxygen to form

superoxide or to another OxyHb molecule to form more MetHb and H_2O_2. To achieve greater stability, free radicals may also extract electrons by oxidizing SH groups of Hb, enzymes, membrane proteins, or GSH; by oxidizing membrane unsaturated fatty acids; by oxidizing NADPH or NADH; and possibly by extracting an electron from DeoxyHb to form MetHb.

Nitrite quickly enters RBCs and equilibrates across their membranes and then continues to enter RBCs as a consequence of its intracellular removal. This involves the formation of nitrate and MetHb in the presence of OxyHb and the formation of ˙NO and MetHb in the presence of DeoxyHb (Jensen, 2005). The reactions involved in MetHb formation in the presence of nitrite are complex (Titov and Petrenko, 2005; Umbreit, 2007). MetHb formation by nitrite is significantly higher in oxygenated than deoxygenated pig RBCs (Jensen, 2005). Nitrite produces MetHb within RBCs, but otherwise does not exert strong oxidant stress on these cells (May *et al.*, 2000). Methemoglobinemia occurs in ruminants eating nitrate-accumulating plants, especially when the plants have been fertilized with nitrogenous compounds. Nitrate is relatively nontoxic, but it is reduced to nitrite by ruminal microorganisms (Burrows, 1980).

Methemoglobinemia can occur in animals following the topical application of benzocaine-containing products to skin (Harvey *et al.*, 1979; Wilkie and Kirby, 1988), or in laryngeal (Krake *et al.*, 1985) or nasopharyngeal sprays (Davis *et al.*, 1993; Lagutchik *et al.*, 1992). Benzocaine appears to have only a limited ability to produce other forms of RBC injury, although HzB formation can occur (Harvey *et al.*, 1979).

Many compounds can produce MetHb (Ash-Bernal *et al.*, 2004; Bodansky, 1951; Umbreit, 2007), and most of them also produce variable degrees of Hb denaturation and membrane injury. Acetaminophen and phenazopyridine toxicity in cats (Harvey, 1995), red maple toxicity in horses (Alward *et al.*, 2006), copper toxicity in sheep (Soli and Froslie, 1977), and skunk musk absorption in dogs (Zaks *et al.*, 2005) are examples of drugs or chemicals that produce prominent methemoglobinemia and Heinz body hemolytic anemia. Following exposure to oxidants, MetHb forms within minutes, but HzB take hours to form. If the oxidant is rapidly metabolized, MetHb content will generally be reduced to values approaching normal within 24 h (Harvey and Keitt, 1983).

Low levels of MetHb may form in response to endogenous oxidant generation during inflammation (Morita *et al.*, 1996; Ohashi *et al.*, 1998; Weiss and Klausner, 1988). Remarkable methemoglobinemia, with evidence of RBC membrane oxidant damage, has been described in cattle infected with *Theileria sergenti* (Shiono *et al.*, 2003).

2. HzB Formation

HzB are composed of oxidized denatured Hb. They are often not recognized on routinely stained blood films, because they either are not stained or stain similarly to the remaining intact Hb. If they are of sufficient size (1 to 2 μm), they may appear as pale inclusions within RBCs or as nipple-like projections from the surface of RBCs. HzB can be visualized as dark, refractile inclusions in new methylene blue "wet" preparations and as light blue inclusions with reticulocyte stains (Harvey, 2001).

The following sequence of oxidant-triggered biochemical events leading to HzB formation is proposed (Allen and Jandl, 1961; Chiu and Lubin, 1989; Hebbel and Eaton, 1989; Low, 1989; Mawatari and Murakami, 2004): (1) ferrohemes are oxidized to ferrihemes (MetHb). (2) Reactive SH groups of MetHb are oxidized (cysteine 93 of the human Hb β chain) and mixed disulfide bonds form following interaction with GSSG (also generated in response to oxidative stress). This glutathionylation of MetHb may be protective, because these globin SH groups can be regenerated via the glutaredoxin, and possibly thioredoxin, systems (Klatt and Lamas, 2000). (3) As further oxidation continues, normally "buried" SH groups of MetHb are oxidized causing additional glutathionylation reactions and presumably disulfide bond formation between globin chains. These reactions are probably not reversible (Mawatari and Murakami, 2004). (4) Conformational changes in globin chains result in dissociation of the tetramer to dimers and monomers and hemichrome formation (hemichromes have both the ferric iron's fifth and sixth coordinate positions occupied by a ligand provided by the globin chain). (5) Hemichromes bind to band 3 and to a lesser degree other membrane components, forming clusters of copolymers. (6) The precipitation and accumulation of denatured globin molecules result in HzB formation. Precipitation is potentiated by the dissociation of the ferriheme (hemin) moieties from the hemichromes because the resultant free globin chains are unstable.

Hemolytic anemias associated with HzB formation in domestic animals have resulted from a variety of compounds. Dietary causes include consumption of onions by cattle (Lincoln *et al.*, 1992), sheep (Kirk and Bulgin, 1979; Knight *et al.*, 2000; Verhoeff *et al.*, 1985), horses (Pierce *et al.*, 1972), cats (Kobayashi, 1981), and dogs (Harvey and Rackear, 1985; Ogawa *et al.*, 1986), consumption of garlic by dogs and horses (Lee *et al.*, 2000; Pearson *et al.*, 2005; Yamato *et al.*, 2005), and consumption of kale and other *Brassica* species by ruminants (Greenhalgh *et al.*, 1969; Smith, 1980; Suttle *et al.*, 1987). Dipropyl and diallyl di-, tri-, and tetrasulfides and possibly other organosulfur compounds derived from plants in the *Allium* genus (onions, garlic, and chives) cause oxidative damage to RBCs. ROS are formed during redox recycling of these compounds or their metabolites in the presence of GSH and OxyHb (Munday *et al.*, 2003). The role of GSH as a source of electrons in this redox cycle may explain why dogs with high RBC GSH concentrations are more susceptible to onion-induced RBC damage than dogs with normal RBC GSH concentrations (Yamoto and Maede, 1992). In the

case of *Brassica* species, the hemolytic factor is reported to be dimethyl disulfide, produced by the action of rumen microbes on S-methylcysteine sulfoxide contained within the plants (Smith, 1980).

HzB hemolytic anemia occurs in Florida in cattle grazing on lush rye (*Secale cereale*) pastures in the winter (Simpson and Anderson, 1980) and in selenium-deficient cattle grazing on St. Augustine grass pastures in the summer (Morris *et al.*, 1984). The nature of oxidants involved is unknown. Methemoglobinemia, HzB formation, severe intravascular hemolysis, and death have followed the consumption of red maple leaves by horses (Alward *et al.*, 2006; George *et al.*, 1982; Tennant *et al.*, 1981) and alpacas (Dewitt *et al.*, 2004). Wilted or dried leaves are toxic, but freshly harvested leaves are not. Gallic acid and other compounds have been identified in the leaves that are capable of inducing oxidative damage (Boyer *et al.*, 2002).

Postparturient hemoglobinuria with HzB formation occurs in cattle in New Zealand grazing primarily on perennial ryegrass (*Lolium perenne*) (Martinovich and Woodhouse, 1971). Postparturient cattle may be more susceptible to the development of anemia because increased food consumption associated with lactation could increase exposure to an unidentified dietary oxidant. Both hypocuprosis (Gardner *et al.*, 1976) and hypophosphatemia (Jubb *et al.*, 1990) have been considered to contribute to the severity of the anemia in these cattle. An apparently different syndrome of postparturient hemoglobinuria has also been reported in hypophosphatemic cattle of North America (MacWilliams *et al.*, 1982). HzB have not been reported in affected animals, and the anemia appears to develop because affected animals have decreased RBC ATP concentrations (Ogawa *et al.*, 1987, 1989).

Methemoglobinemia and HzB hemolytic anemia occur acutely when large amounts of copper are released from the liver of ruminants that have accumulated excessive amounts of liver copper secondary to increased dietary intake (Brewer, 1987; Kerr and McGavin, 1991; Soli and Froslie, 1977). Zinc toxicity has primarily resulted from the consumption and retention of zinc-containing objects within the stomach of dogs. Sources of zinc include U.S. pennies minted after 1982, metallic hardware, toys, and ointment containing zinc oxide (Bexfield *et al.*, 2007; Breitschwerdt *et al.*, 1986). The mechanism(s) by which zinc produces hemolytic anemia is unclear, but HzB have been recognized in some clinical cases (Bexfield *et al.*, 2007; Hammond *et al.*, 2004; Harvey, 2001; Houston and Myers, 1993; Luttgen *et al.*, 1990). HzB anemia was also reported in a dog following possible naphthalene ingestion (Desnoyers and Hebert, 1995).

Clinical cases of HzB hemolytic anemias have occurred following the administration of a variety of drugs including methylene blue in cats (Schechter *et al.*, 1973) and dogs (Fingeroth and Smeak, 1988; Osuna *et al.*, 1990), phenazopyridine in a cat (Harvey and Kornick, 1976), acetaminophen in cats (Finco *et al.*, 1975; Gaunt *et al.*, 1981; Hjelle and Grauer, 1986) and dogs (Harvey *et al.*, 1986; Houston and Myers, 1993), methionine in cats (Maede *et al.*, 1987), menadione (vitamin K_3) in dogs (Fernandez *et al.*, 1984), and phenothiazine in horses (McSherry *et al.*, 1966). The application of benzocaine to inflamed dog skin can result in methemoglobinemia and Heinz body formation (Harvey *et al.*, 1979). Heinz body hemolytic anemia has been reported in a dog that had been sprayed with skunk musk (Zaks *et al.*, 2005). A variety of additional oxidants produce HzB hemolytic anemias experimentally in animals (Fertman and Fertman, 1955).

Cats are generally recognized as the species most susceptible to HzB formation. Although species differences in metabolism and excretion of various drugs may partially account for this increased susceptibility, cat Hb generally appears more susceptible to oxidative denaturation than do Hbs of other species (Harvey and Kaneko, 1976b). The presence of 8 to 10 reactive SH groups per Hb tetramer in cat Hb may render it more susceptible to oxidation (Mauk and Taketa, 1972); apparently no other species has more than 4 reactive SH groups per tetramer (Snow, 1962).

HzB are rarely recognized in RBCs from most species, but are frequently present in cat RBCs because of the susceptibility of cat Hb to form HzB, combined with a poor ability of the cat spleen to remove HzB from RBCs (Jain, 1986). Even normal cats may have low numbers of HzB ($<5\%$), and increased HzB numbers have been seen in kittens fed fish-based diets (Hickman *et al.*, 1990), in cats fed commercial soft-moist diets containing propylene glycol (Christopher *et al.*, 1989; Hickman *et al.*, 1990), and in cats fed baby food containing onion powder (Robertson *et al.*, 1998). Increased HzB formation can occur in cats with repeated propofol anesthesia (Andress *et al.*, 1995; Matthews *et al.*, 2004). Increased HzB numbers have also been documented in cats with diabetes mellitus, hyperthyroidism, and lymphoma (Christopher, 1989). Diabetic cats with ketoacidosis have more HzB and lower hematocrits than do nonketotic diabetic cats (Christopher *et al.*, 1995). Although RBC survival tends to be shortened, anemia is either absent or mild in the preceding conditions. The oxidative reactions involved in these conditions are not clearly defined.

3. Membrane Injury

Various types of oxidant-induced membrane injury have been recognized. These include oxidation of membrane SH groups, lipid peroxidation, cross-linking of spectrin, inhibition of enzymes and membrane transport systems, and band 3 clustering. Glutathionylation of oxidized SH groups in actin-, spectrin-, and membrane-associated GAPD is present. It is unclear whether this is a protective reaction or simply a biochemical reaction that occurs with excessive oxidative stress (Mawatari and Murakami, 2004). Damaged cells exhibit increased membrane rigidity, decreased deformability, and impaired ability to maintain ion gradients (Baskurt

and Meiselman, 1999; Chiu and Lubin, 1989). The relative importance of HzB formation, hemin release, and the generation of various free radicals remains to be clarified.

The binding of HzB to the inner surface of the RBC membrane and clustering of band 3 and other components alter the normal membrane organization. Potential negative effects include weakening or disruption of the cytoskeleton, altered distribution of membrane phospholipids, altered cell surface charges, and formation of abnormal external cell surface antigens that can be recognized by autologous antibodies (Low, 1989). HzB cause focal membrane rigidity but do not affect global cellular deformability until they nearly cover the entire internal surface of RBCs (Reinhart *et al.*, 1986).

Hemin released during HzB formation binds to and causes damage to RBC membranes. Evidence has been presented that hemin can mediate the dissociation of RBC cytoskeletal proteins, impair the ability of the RBC membrane to maintain ionic gradients, oxidize membrane sulfhydryl proteins, and potentiate peroxide-induced membrane lipid peroxidation (Chiu and Lubin, 1989; Hebbel and Eaton, 1989; Jarolim *et al.*, 1990). The molecular mechanism(s) has not been clearly defined, but hemin may exert its toxic effects via catalysis of the formation of reactive oxygen species (Vincent, 1989). Iron may also be released from hemin when oxidative damage results in porphyrin degradation, and free iron may be a catalyst for the generation of more oxidants (Umbreit, 2007).

Oxidative injury to RBC membranes is sometimes recognized by the appearance of eccentrocytes in stained blood films. Eccentrocytes are formed by the adhesion of opposing areas of the cytoplasmic face of the RBC membrane (Fischer, 1986). Denatured spectrin is believed to be of primary importance in the cross bonding of membranes (Arese and De Flora, 1990; Fischer, 1988). These cells have been reported to occur in horses with red maple toxicity (Reagan *et al.*, 1994) and in dogs exposed to acetaminophen and other nonsteroidal anti-inflammatory drugs, onions, garlic, naphthalene, propofol, vitamin K, and vitamin K anticoagulant drugs (Caldin *et al.*, 2005; Ham *et al.*, 1973; Harvey *et al.*, 1986; Harvey and Rackear, 1985; Lee *et al.*, 2000). Eccentrocytes have also been reported in the blood of dogs with ketoacidotic diabetes, inflammation, and neoplasia (especially lymphoma), secondary to increased endogenous oxidants (Caldin *et al.*, 2005). Eccentrocytes occur in RBC G6PD-deficient and FAD-deficient horses with inadequate metabolic protection against endogenous oxidants (Harvey *et al.*, 2003; Stockham *et al.*, 1994).

4. RBC D*estruction*

Following extreme oxidative injury, RBCs may lyse within the circulation. Hb released to plasma dissociates into dimers, and is bound to haptoglobin for removal by macrophages. Free Hb in plasma also scavenges $\dot{N}O$ (Rifkind *et al.*, 2006), which may lead to vasoconstriction, decreased blood flow, platelet activation, increased endothelin-1 expression, and organ injury (Gladwin *et al.*, 2004; Minneci *et al.*, 2005). Free Hb in plasma spontaneously oxidizes to MetHb, which activates endothelial cells by stimulating the production of IL-6 and IL-8 cytokines and the expression of E-selectin (Liu and Spolarics, 2003). Hemin released from MetHb is bound by hemopexin for removal by the liver. Free hemin, like MetHb, promotes inflammation. It increases vascular permeability, adhesion molecule expression, and the infiltration of leukocytes (Wagener *et al.*, 2001). Hemoglobinuria occurs if intravascular hemolysis is of sufficient magnitude to saturate the haptoglobin-binding capacity of plasma and exceed the ability of renal tubules to reabsorb filtered Hb.

In most cases, however, enhanced RBC destruction results primarily from increased phagocytosis of injured RBCs by macrophages of the spleen, liver, and bone marrow. Of the organs of the mononuclear phagocyte system, the spleen is most adept at recognizing and removing damaged RBCs. In most species, RBCs must pass through narrow slits between endothelial cells lining venous sinus walls of the spleen to reenter the general circulation. As a consequence, oxidant-induced decreased RBC deformability tends to result in increased transit time of RBCs in the splenic reticular meshwork, thereby enhancing the likelihood of phagocytosis by resident macrophages (Baerlocher *et al.*, 1994; Weiss, 1984).

When HzB are larger than openings in walls of splenic venous sinuses, they are retained within the trabecular meshwork of the spleen. The whole cell may be phagocytized, or the HzB and closely associated membrane may be removed. The remainder of the RBC reseals and passes through the sinus wall. This removal of HzB is the so-called pitting function of the spleen (Weiss, 1984). Cat spleens have poor pitting capabilities (Jain, 1986) owing to the presence of large openings in venous sinus walls (Blue and Weiss, 1981).

Macrophages can recognize damaged RBCs by antibody-dependent and by antibody-independent mechanisms; however, the relative importance of the different mechanisms remains to be defined. Macrophages do not recognize less-deformable cells per se, but phagocytize them at a higher rate because of their slower transit time or entrapment in the spleen as discussed earlier (Baerlocher *et al.*, 1994).

Oxidative damage to RBCs can induce suicidal death of RBCs (eryptosis), with reactions similar to some of those that occur during apoptosis of nucleated cells. Eryptosis is characterized by Ca^{+2} entry, RBC shrinkage, membrane blebbing, activation of proteases, and exposure of phosphatidylserine in the outer membrane leaflet. The exposed phosphatidylserine is recognized by receptors on macrophages that phagocytize and degrade the affected cells (Lang *et al.*, 2006). Phosphatidylserine exposure has been reported in RBCs from humans with hemolytic anemia secondary to PK deficiency and unstable Hbs, but it does not

appear to be a death signal for most causes of hemolytic anemia (Boas *et al.*, 1998). Macrophages contain a number of antibody-independent receptors that can bind to oxidized lipoproteins, anionic phospholipids, polysaccharides, and polyribonucleotides (Sambrano *et al.*, 1994). Evidence has been presented to indicate that several scavenger receptors may be involved in the recognition and phagocytosis of oxidatively damaged RBCs (Terpstra and van Berkel, 2000).

The cross-linking of band 3 molecules by hemichromes during oxidative denaturation of Hb results in clustering of band 3 molecules and greatly enhanced binding of autologous IgG (Cappellini *et al.*, 1999; Low, 1991). Because macrophages contain Fc receptors on their surfaces, the damaged RBCs would presumably become bound to the surface of macrophages once a sufficient number of clusters of band 3 had formed. Sheep with chronic copper toxicity may become direct Coombs' test positive, indicating a possible *in vivo* role of antibody-mediated removal of oxidatively injured RBCs (Wilhelmsen, 1979).

B. RBC Aging and Normal Life Spans

Most RBCs circulate in blood for a finite period (survival time or life span) that varies from 2 to 5 months in domestic animals, depending on the species (Table 7-1). Methods for measurement of RBC life spans and results of life span determinations from many species have been compiled (Vacha, 1983). RBC life spans are related to body weight (and consequently metabolic rate) with the smallest animals (highest metabolic rate) having the shortest RBC life spans (Vacha, 1983). The RBC life span can be prolonged by reducing the metabolic rate within an individual animal. Examples include thyroidectomy in rats, hibernation in hibernating mammals, and reduced ambient temperatures in poikilotherms (Landaw, 1988). A variety of changes occur in RBCs as they get older (Kosower, 1993; Low, 1991; Siems *et al.*, 2000), but the nature of the factor(s) that initiates age-related changes and the mechanism(s) of removal of senescent RBCs from the circulation require further clarification. Exposure of phosphatidylserine on the external surface, modified external membrane carbohydrate residues (e.g., desialation of sialoglycoproteins), or modified membrane proteins (e.g., partially degraded band 3) are possible signals for removal (Boas *et al.*, 1998; Kay, 2005; Kosower, 1993).

1. *Metabolic Impairment*

Because RBCs cannot synthesize new enzymes, one theory is that one or more critical enzymes, involved in generating ATP or in the protection against oxidants, may decrease to a point that metabolic impairment results in irreversible RBC membrane changes (Piomelli and Seaman, 1993). Although the inability to maintain normal ATP and NADPH concentrations appears to account for premature destruction of RBCs in patients with hereditary enzyme deficiencies of the EMP and PPP, respectively, the theory that metabolic impairment occurs as a result of age-related decreases in critical enzymes has been questioned (Beutler, 1985; Zimran *et al.*, 1990). Much of the decline in activities of enzymes, considered in the past to be correlated with RBC age, occurs as reticulocytes mature into RBCs. Even if metabolic impairment is not the primary factor responsible for RBC senescence, it may render the aged RBC vulnerable to events in the circulation that require a burst of metabolic activity (Piomelli and Seaman, 1993).

2. *Cumulative Oxidant Damage*

Oxidative injury, especially near the end of their life span, appears to be responsible for normal RBC aging and removal (Kay, 2005; Kiefer and Snyder, 2000; Rettig *et al.*, 1999; Seppi *et al.*, 1991). Senescent dog RBCs exhibit increased membrane-bound, denatured globin and only 30% of normal GSH (Rettig *et al.*, 1999). Even reported decreases in RBC enzymes may be the result of oxidative damage (Stadtman, 1992). The presence of HzB in RBCs from splenectomized humans, horses, and dogs, and in RBCs from nonsplenectomized cats (Jain, 1986; Low, 1989), provides evidence for ongoing oxidant injury *in vivo*. The inverse correlation between RBC life span and metabolic rate discussed previously may result from differences in endogenous oxidant generation, but other factors such as differing amounts of mechanical stress should also be considered as a possible cause of this relationship (Landaw, 1988).

Oxidative stress promotes eryptosis that leads to externalization of phosphatidylserine. The damaged RBCs can be phagocytized by macrophages following binding to phosphatidylserine receptors such as CD36 (Kiefer and Snyder, 2000; Terpstra and van Berkel, 2000). An increased exposure of phosphatidylserine on the surface of aged rabbit RBCs correlates with their removal from the circulation (Boas *et al.*, 1998).

3. *Senescent Cell Antigen*

The appearance of a senescent cell antigen may be an important signal in the removal of senescent RBCs (Kay, 2005). This senescent cell antigen is derived from the band 3 anion transporter. The specific alteration required for band 3 to become antigenic remains to be clarified, but oxidative mechanisms are probably involved. Low (1991) has demonstrated copolymerization between hemichromes and band 3 and has suggested that the senescent antigen represents clusters of band 3. In contrast, studies by Kay (2005) suggest that the senescent cell antigen results from band 3 degradation rather than clustering.

A natural antibody against the senescent cell antigen is present in human plasma. This antibody binds to senescent cell antigens on the surface of aged cells and, together with bound complement, promotes the phagocytosis of aged RBCs by macrophages that exhibit Fc and C3b surface

receptors (Lutz *et al.*, 1991). Senescent dog RBCs accumulate surface-associated immunoglobulin, which is believed to promote their removal by macrophages (Rettig *et al.*, 1999). The relative importance of the immune- and nonimmune-mediated phagocytosis of senescent RBCs remains to be clarified.

C. Anemia of the Newborn

Animals are generally born with hematocrits near values for adults. Following birth, there is a rapid decrease in hematocrit that is followed by a gradual increase to adult values (Jain, 1986). Factors involved to variable degrees in the development of the anemia of the newborn include the following: (1) absorption of colostral proteins during the first day of life, which increases plasma volume through an osmotic effect (Harvey *et al.*, 1987; Mollerberg *et al.*, 1975); (2) decreased RBC production during the early neonatal period; (3) shortened life span of RBCs formed *in utero* (Kim and Luthra, 1977; Landaw, 1988; Lee *et al.*, 1976; Mueggler *et al.*, 1979); and (4) rapid growth with hemodilution resulting from expansion of total plasma volumes more rapidly than total RBC mass (Mueggler *et al.*, 1979).

In some species, production of RBCs is decreased because of low Epo concentrations at birth (Halvorsen and Halvorsen, 1974; Huisman *et al.*, 1969; Meberg, 1980; Meberg *et al.*, 1980; Schwartz and Gill, 1983). The decreased stimulus for Epo production may occur as a result of a placental blood transfusion that increases RBC mass immediately after birth (Rossdale and Ricketts, 1980), a rapid increase in pO_2 associated with breathing air, and an increase in P_{50} as discussed previously.

Much of the postnatal anemia of dogs occurs as a physiological response to increased RBC 2,3DPG and subsequent improved oxygen transport (Mueggler *et al.*, 1981). The "anemia" of childhood in humans is also associated with RBC 2,3DPG above adult values. In children this increase appears to occur secondarily to increased plasma P_i concentrations (Card and Brain, 1973). Serum P_i values are also above adult values in young dogs (Pickrell *et al.*, 1974).

Although not involved in the early, rapid decrease in hematocrit, iron availability may limit the response to anemia in some rapidly growing animals (Chausow and Czarnecki-Maulden, 1987; Dhindsa *et al.*, 1971; Harvey *et al.*, 1987; Holman and Drew, 1966; Mollerberg *et al.*, 1975; Siimes *et al.*, 1980; Weiser and Kociba, 1983b).

VI. INHERITED DISORDERS OF RBCS

Many hereditary disorders of RBCs have been described in humans, but a limited number of inherited RBC disorders have been identified in laboratory and domestic animals. RBC enzyme deficiencies in dogs, cats, and horses have recently been reviewed (Harvey, 2006). Congenital porphyrias are discussed elsewhere in this volume (Chapter 8).

A. Cytosolic Enzyme Deficiencies

1. *Phosphofructokinase Deficiency in Dogs*

Autosomal recessive inherited PFK deficiency occurs in English springer spaniel (Giger *et al.*, 1985; Giger and Harvey, 1987; Harvey and Giger, 1991), American cocker spaniel (Giger *et al.*, 1992), mixed-breed (Giger, 2000), whippet (Hayes *et al.*, 2007), and wachtelhund (Tvedten and Rowe, 2007) dogs. Canine PFK is genetically controlled by three separate loci. They code for muscle (M)-, liver (L)-, and platelet (P)-type subunits (Vora *et al.*, 1985). Random tetramerization of the subunits produces various isozymes. PFK in normal dog RBCs consists of 86% M-type, 2% L-type, and 12% P-type subunits, and normal dog muscle is composed exclusively of M-type subunits (Mhaskar *et al.*, 1992).

Studies of brain and RBCs from homozygous-deficient dogs indicated that native M-type subunits were not present, but small amounts of a structurally unstable truncated M-type subunit were found (Mhaskar *et al.*, 1991, 1992). A single mutation in the M-type gene of deficient dogs converted a tryptophan codon to a stop codon, resulting in a loss of 40 amino acid residues (Smith *et al.*, 1996). As would be expected from the subunit composition of normal tissues, total RBC and muscle PFK activities are markedly reduced in affected dogs (Giger and Harvey, 1987; Vora *et al.*, 1985). Changes in concentrations of glycolytic intermediates in muscle and RBCs reflect the block at the PFK step (Harvey *et al.*, 1992a, 1992b). RBCs from affected dogs also exhibit altered enzyme kinetic properties because of the loss of the M-type subunit (Harvey *et al.*, 1992b).

Homozygously affected dogs have persistent compensated hemolytic anemias and sporadic episodes of intravascular hemolysis with hemoglobinuria (Giger *et al.*, 1985; Giger and Harvey, 1987; Harvey and Giger, 1991; Skibild *et al.*, 2001). RBC mean cell volumes are usually between 80 and 90fl. Reticulocyte counts are generally between 10% and 30%, with hematocrit values between 30% and 40% (Harvey and Smith, 1994), except during hemolytic crises when the hematocrit may decrease to 15% or less. Lethargy, weakness, pale or icteric mucous membranes, mild hepatosplenomegaly, muscle wasting, and fever as high as 41°C may occur during hemolytic crises (Giger and Harvey, 1987).

Hemolytic crises occur secondary to hyperventilation-induced alkalemia *in vivo*, and PFK-deficient dog RBCs are extremely alkaline fragile *in vitro* (Giger and Harvey, 1987). For unknown reasons, normal dog RBCs are more alkaline fragile than those of humans and other mammals studied (Iampietro *et al.*, 1967; Waddell, 1956). The even greater alkaline fragility of PFK-deficient dog RBCs results from decreased 2,3DPG, which is formed below the PFK reaction (Harvey *et al.*, 1988). Because 2,3DPG is the major impermeant anion in dog RBCs, a substantial decrease in its concentration results in a higher intracellular pH (Hladky and Rink, 1977) and thereby greater alkaline fragility than

normal dog RBCs. As expected, the low 2,3DPG concentration also results in an increased oxygen affinity of Hb in affected dog RBCs (Giger and Harvey, 1987).

Hematological parameters of affected dogs are similar to normal dogs at birth, because all newborn dogs have RBC PFK activities about three times that of normal adult dogs (Harvey and Reddy, 1989). This high PFK activity results from the presence of the L-type subunit of PFK, which is negligible in normal adult canine RBCs (Harvey and Reddy, 1989; Mhaskar *et al.*, 1992). Both total PFK activities and the amounts of L-type subunit present decrease dramatically during the first 6 to 8 weeks of life. The M-type subunit is low at birth, but increases as the L-type decreases in normal dogs. These changes result from the replacement of RBCs formed in the fetus with those formed after birth.

Deficient dogs generally exhibit less evidence of myopathy than is observed in PFK-deficient people, probably because canine skeletal muscle is less dependent on anaerobic glycolysis than human skeletal muscle, owing to a lack of the classical fast-twitch glycolytic (type IIB) fibers in dogs (Snow *et al.*, 1982). Affected dogs appear to tire more easily than normal, and *in vivo* muscle studies of PFK-deficient dogs indicate altered muscle function in these animals (Brechue *et al.*, 1994; Giger *et al.*, 1988b; McCully *et al.*, 1999). A severe progressive myopathy with associated abnormal polysaccharide deposits in skeletal muscle has been recognized in an aged PFK-deficient dog (Harvey *et al.*, 1990a). In contrast to PK deficiency, myelofibrosis and liver failure have not been recognized in dogs with PFK deficiency.

Homozygous affected animals over 3 months of age can easily be identified by measuring RBC PFK activity. Heterozygous carrier dogs have approximately one-half normal enzyme activities in RBCs (Harvey and Reddy, 1989). A DNA test using polymerase chain reaction technology has been developed that can clearly differentiate normal, carrier, and affected English springer spaniel dogs regardless of age (Giger *et al.*, 1995). This test is also positive in American cocker spaniel and whippet dogs with PFK deficiency (Giger *et al.*, 1992; Hayes *et al.*, 2007).

2. Pyruvate Kinase Deficiency in Dogs and Cats

PK deficiency occurs in basenji (Giger and Noble, 1991; Searcy *et al.*, 1971, 1979), beagle (Giger *et al.*, 1991; Harvey *et al.*, 1977; Prasse *et al.*, 1975), West Highland white terrier (Chapman and Giger, 1990), Cairn terrier (Schaer *et al.*, 1992), miniature poodle, Chihuahua, pug, dachshund, and toy American Eskimo dogs (Giger, 2000; Harvey, 1996). PK deficiency is transmitted as an autosomal recessive trait. Homozygously affected animals have decreased exercise tolerance, pale mucous membranes, tachycardia, and splenomegaly.

Affected animals have mild to moderate anemia with marked reticulocytosis when young (Harvey, 2006). Myelofibrosis and osteosclerosis develop in the bone marrow, and hemachromatosis and cirrhosis develop in the liver as the dogs age (Searcy *et al.*, 1979; Weiden *et al.*, 1981). Hematocrit and reticulocyte counts decrease as myelofibrosis and osteosclerosis become severe (Whitney and Lothrop, 1995). Affected dogs generally die between 1 and 5 years of age because of bone marrow failure or liver failure (Giger, 2000; Zaucha *et al.*, 2001). It is proposed that the marrow fibrosis, like the cirrhosis, occurs in response to damage caused by iron overload (Zaucha *et al.*, 2001). However, factors associated with marked erythropoiesis may also contribute to the development of myelofibrosis (Bader *et al.*, 1992).

RBCs of affected dogs lack the normal adult R isozyme of PK but have a persistence of an M_2 isozyme that is normally present in many fetal and adult tissues, including erythroid precursor cells, but not in mature RBCs (Becker *et al.*, 1986; Black *et al.*, 1978; Whitney *et al.*, 1994). Consequently, many affected dogs have normal or increased PK activity, making it difficult to diagnose this defect based solely on total RBC PK activity. Heterozygous animals have approximately 50% of normal RBC PK activity.

The enzyme activity in hemolysates of affected dogs is unstable and decreases rapidly when samples are kept at room temperature (Standerfer *et al.*, 1974). If the M_2-isozyme is unstable *in vivo*, as it is *in vitro*, its rapid loss of activity would explain the dramatically shortened life span of RBCs in this disorder (Dhindsa *et al.*, 1976).

Because the defect in glycolysis occurs below the diphosphoglycerate shunt, RBCs from PK-deficient dogs have increased concentrations of 2,3DPG (Harvey, 2006). As a consequence, the whole blood P_{50} is higher than that of normal dogs (Dhindsa *et al.*, 1976).

Additional assays (an enzyme heat stability test, measurement of RBC glycolytic intermediates, electrophoresis of isozymes, and enzyme immunoprecipitation) may be used to reach a diagnosis of PK deficiency in dogs in which the total enzyme activity is not decreased (Giger and Noble, 1991; Harvey *et al.*, 1990b; Schaer *et al.*, 1992). The defect in basenji dogs is the result of a single nucleotide deletion in the R-type PK gene (Whitney *et al.*, 1994; Whitney and Lothrop, 1995). Unfortunately, different mutations in the R-type PK gene have been identified in other dog breeds (Giger, 2000; Skelly *et al.*, 1999). Consequently, different DNA-based diagnostic assays must be developed or validated for each affected dog breed. Fortunately, DNA-based tests for PK deficiency have been developed for several breeds of dogs (Giger, 2005).

RBC PK deficiency has been characterized in Abyssinian, Somali, and domestic shorthair cats (Ford *et al.*, 1992; Giger *et al.*, 1997; Mansfield and Clark, 2005). Affected cats have intermittent mild to moderate anemia that may be slightly macrocytic and hypochromic. Reticulocyte counts are slightly to markedly increased. Splenectomy may reduce the severity of the anemia in cats. In contrast to dogs in which the anemia is typically first recognized in young animals, some cats have not been diagnosed until they were old aged

(Giger, 2000). Total RBC PK activity is markedly reduced in deficient cats, with no evidence of the persistent M_2 isozyme reported in dogs (Ford *et al.*, 1992), and all PK-deficient cats identified thus far have had the same mutation (Giger, 2000; Giger *et al.*, 1997; Mansfield and Clark, 2005). Also in contrast to dogs, osteosclerosis has not been recognized in cats (Giger, 2000).

3. *Cytochrome-β_5 Reductase Deficiency in Dogs and Cats*

Persistent methemoglobinemia associated with RBC Cb_5R deficiency has been recognized in chihuahua, borzoi, English setter, terrier-mix, cockapoo, coonhound, poodle, corgi, Pomeranian, toy American Eskimo, cocker-toy American Eskimo, and pit bull-mix dogs and in domestic shorthair cats (Atkins *et al.*, 1981; Fine *et al.*, 1999; Giger *et al.*, 1999; Harvey, 2000; Harvey *et al.*, 1974, 1991, 1994, Letchworth *et al.*, 1977). The deficiency appears to be an inherited autosomal recessive disorder, as it is in humans (Harvey, 2000). The nature of the enzyme deficiency is unknown; however, it does not appear to be the result of an FAD cofactor deficiency in dogs, because RBC glutathione reductase (another enzyme that requires FAD as a cofactor) activities were normal in three affected dogs assayed (Harvey, 2006).

Affected animals have cyanotic appearing mucous membranes and may exhibit lethargy or exercise intolerance at times, but they usually have no clinical signs of disease. Blood samples appear dark, suggesting hypoxemia, but arterial pO_2 values are normal. MetHb content in dogs with Cb_5R deficiency varies from 13% to 41%. The MetHb content in five deficient domestic shorthair cats varied from 44% to 52% (Harvey, 2006). There is an inverse correlation between RBC enzyme activity and MetHb content in deficient dogs (Harvey, 2000). The hematocrit is usually normal in deficient dogs, but usually slightly to moderately increased in deficient cats, secondary to the chronic methemoglobinemia and resultant decreased blood oxygen content. Animals with Cb_5R deficiency do not require treatment and have normal life expectancy (Harvey, 2006).

4. *Glucose-6-Phosphate Dehydrogenase Deficiency in a Dog and Horse*

G6PD deficiency is a very common X-linked inherited defect of human RBCs, affecting millions of people worldwide (Beutler, 1994). Smith *et al.* (1976) screened more than 3000 dogs for G6PD activity and found one male dog to have approximately 44% of normal activity. The enzyme was partially purified and characterized, and it was found to be similar to that of normal dogs. The deficient dog was not anemic and exhibited no clinical signs; studies were not done to determine whether his RBCs were more sensitive to oxidant damage than normal.

In contrast, a persistent hemolytic anemia and hyperbilirubinemia have been described in an American standardbred colt with $<1\%$ of normal G6PD activity (Stockham *et al.*, 1994). Morphological abnormalities of RBCs included eccentrocytosis, pyknocytosis, increased anisocytosis, increased Howell-Jolly bodies, and rare Hb crystals. The presence of eccentrocytes in the absence of exposure to external oxidants indicated that the deficient RBCs did not have adequate metabolic capabilities to defend themselves against endogenous oxidants. Biochemical abnormalities in RBCs included low GSH, markedly reduced NADPH, and increased $NADP^+$. RBC catalase activity was normal even though NADPH concentration was $<1\%$ of normal. It was suggested that catalase activity may have been maintained by the action of NADH. Polymerase chain reaction amplification of segments of the G6PD gene of the affected colt revealed a G to A mutation, converting an arginine codon to a histidine codon (Nonneman *et al.*, 1993).

5. RBC FAD *Deficiency and Resultant Enzyme Deficiencies in Horses*

RBC FAD deficiency has been recognized in an adult Spanish mustang mare (Harvey *et al.*, 2003) and in a 7-year-old Kentucky mountain saddle horse gelding (Harvey, 2006). FAD-deficient horses have persistent methemoglobinemia (25% to 46%), eccentrocytosis, pyknocytosis, and variable numbers of Hb crystals. No Heinz bodies were observed in RBCs stained with new methylene blue. Hematocrits were normal or slightly decreased. The presence of eccentrocytes and pyknocytes in the absence of administered or consumed oxidants indicates deficient metabolic protection against endogenously generated oxidants. RBC biochemical abnormalities measured include decreased Cb_5R activity (about 40% of normal), decreased GSH concentration (about 60% of normal), and undetectable GR activity. The GR activity increased to near-normal values after addition of FAD to the enzyme assay, indicating a severe deficiency of FAD in RBCs. FAD is a cofactor for GR and Cb_5R enzymes; consequently, both RBC enzyme deficiencies in these horses can be attributed to decreased RBC FAD concentrations.

The presence of eccentrocytes and pyknocytes were attributed to inadequate metabolic protection against endogenously generated oxidants, resulting from a marked deficiency in GR and resultant decreased GSH concentration within RBCs. The methemoglobinemia was attributable to Cb_5R deficiency.

Following transport into RBCs, riboflavin is first converted to flavin mononucleotide (FMN) by riboflavin kinase and then to FAD by FMN adenylyltransferase. Measurements of RBC flavin concentrations suggest a defect in the riboflavin kinase reaction. Systemic signs attributable to a generalized defect in riboflavin metabolism are absent, suggesting that the defect may be limited to RBCs.

Laboratory findings in these horses were similar to those from two related trotter mares that were reported to have persistent hemolytic anemia, methemoglobinemia, GR deficiency, and decreased GSH concentrations within RBCs (Dixon and McPherson, 1977). However, the GR deficiency did not appear to result from FAD deficiency, and the Cb_5R activity was reportedly normal.

6. Gamma-Glutamylcysteine Synthetase Deficiency in Sheep

An autosomal dominant inherited deficiency in RBC GSH in Corriedale and Merino sheep results from low levels of gamma-glutamylcysteine synthetase (GCS), the first enzyme involved in GSH synthesis (Fisher *et al.*, 1986; Smith *et al.*, 1973). Although the specific activity of the enzyme is low, the molecular weight, K_m values for glutamate and cysteine, K_i for GSH, and other characteristics of purified GCS from deficient sheep are remarkably similar to those from normal sheep (Board *et al.*, 1980). Deficient sheep have only about 20% to 30% of normal RBC GSH but exhibit no clinical signs, are not anemic, and have normal RBC life spans (Smith *et al.*, 1973). A similar RBC GSH-deficient syndrome has been reported in Spanish Churra sheep (Bayon *et al.*, 1994). Although RBCs from these low-GSH sheep do not appear to have greater susceptibility to injury by superoxide or hydrogen peroxide than do RBCs from high-GSH sheep (Eaton *et al.*, 1989), they do exhibit greater HzB formation when exposed to acetylphenylhydrazine *in vitro* (Goto *et al.*, 1993) and kale feeding *in vivo* (Tucker *et al.*, 1981).

B. Membrane Abnormalities

1. Hereditary Stomatocytosis in Dogs

Stomatocytes are uniconcave or cup-shaped RBCs that have slitlike areas of central pallor on stained blood films. Stomatocytosis is recognized in association with three different inherited syndromes in dogs. All disorders appear to be transmitted as autosomal recessive traits. Hereditary stomatocytosis also consists of a heterogeneous group of disorders in humans (Delaunay, 2004).

No clinical signs occur in miniature schnauzers (Brown *et al.*, 1994b; Giger *et al.*, 1988a), standard schnauzers (Bonfanti *et al.*, 2004), or a Pomeranian (Harvey, 2001) with stomatocytosis. Chondrodysplasia (short-limbed dwarfism) occurs along with stomatocytosis in Alaskan malamutes (Fletch *et al.*, 1975; Pinkerton *et al.*, 1974). This disorder is deforming but not life threatening. The syndrome in Drentse patrijshond dogs has been termed *familial stomatocytosis-hypertrophic gastritis* (Slappendel *et al.*, 1991). Affected animals have polysystemic disease with growth retardation, diarrhea, polyuria/polydipsia, hind limb weakness, pale or icteric mucous membranes, and a somnolent mental state. Pathological findings include hypertrophic gastritis, progressive liver disease, polyneuropathy, and renal cysts. Affected Drentse patrijshond dogs are usually euthanized by the time they reach young adulthood because of a progressive deterioration in clinical condition.

Hb values and RBC counts are low-normal or slightly reduced, but hematocrits are normal in malamutes, schnauzers, and Pomeranians. The MCV is increased and MCHC decreased even though reticulocyte counts are normal or only slightly increased. Affected Drentse patrijshond dogs have lower hematocrits and higher reticulocyte counts than those found in the other breeds (Slappendel *et al.*, 1991; Slappendel *et al.*, 1994). The MCHC is moderately decreased, but the MCV is normal or only slightly increased. RBCs from all breeds have increased osmotic fragility and shortened RBC survival.

Although the specific defects are not known, the pathogenesis of stomatocyte formation in malamutes, schnauzers, and Pomeranians is attributed to an increase in monovalent cations, and consequently increased water content of RBCs caused by abnormal membrane permeability (Giger *et al.*, 1988a; Paltrinieri *et al.*, 2007; Pinkerton *et al.*, 1974). The swelling associated with water accumulation accounts for the increased MCV and decreased MCHC values in affected dogs. Stomatocytosis in these breeds resembles overhydrated hereditary stomatocytosis in humans, a disease characterized by a reduced or absent stomatin expression (Fricke *et al.*, 2003). However, standard schnauzers with hereditary stomatocytosis exhibit normal stomatin expression (Paltrinieri *et al.*, 2007). The GSH content in affected RBCs is about 50% to 60% of normal (Giger *et al.*, 1988a; Harvey, 2001; Pinkerton *et al.*, 1974). This GSH deficiency appears to occur from increased catabolism, but the mechanism responsible is unknown (Smith *et al.*, 1983b).

In contrast to malamutes and schnauzers with stomatocytosis, RBCs from affected Drentse patrijshond dogs do not have increased total monovalent cations, and cell water is only slightly increased; consequently, stomatocyte formation appears to be caused by a different mechanism (Slappendel *et al.*, 1994). The composition of phospholipids and cholesterol in plasma and RBC membranes is abnormal in these dogs (Slappendel *et al.*, 1994). The authors suggest that a defect in lipid metabolism results in altered membrane lipid composition and a loss or contracture of membrane components.

2. Hereditary Elliptocytosis in Dogs

Hereditary elliptocytosis is a common disorder of RBC shape in humans of African and Mediterranean ancestry. There is a mechanical weakness or fragility of the RBC membrane skeleton resulting from defects in α-spectrin, β-spectrin, or protein 4.1 (Gallagher, 2004).

Persistent elliptocytosis and microcytosis have been described in a crossbred dog that lacked RBC membrane

protein 4.1 (Smith *et al.*, 1983a). Although the animal was not anemic, the reticulocyte count was about twice normal in compensation for a shortened RBC life span. This dog was an offspring of a father-daughter mating. Both parents had decreased band 4.1 and some elliptocytes.

Persistent marked elliptocytosis was recognized as an incidental finding in a Labrador-chow crossbred dog (Di Terlizzi *et al.*, 2007). Occasional microspherocytes and rare RBCs containing Hb crystals were also present. RBC membrane mechanical stability and deformability were reduced. Further analysis revealed a decreased ability of spectrin to form tetramers because of a defect in β-spectrin.

3. Hereditary Spherocytosis in Cattle

Severe hemolytic anemia with icterus and splenomegaly is present shortly after birth in Japanese black cattle that lack band 3 in their RBC membranes (Inaba, 2000). The mortality rate is high in affected animals, especially during the first week of life. Those that survive exhibit persistent mild hemolytic anemia (hematocrit 25% to 35%) with marked spherocytosis and anisocytosis, but not reticulocytosis (Inaba, 2000; Inaba *et al.*, 1996). Slight acidosis and growth retardation are present. Affected RBCs also have reduced amounts of other membrane proteins, including spectrin, ankyrin, actin, and protein 4.2. RBCs exhibit defective anion transport and a disrupted membrane skeletal network that makes them extremely unstable. Spherocyte formation results from a loss of surface area by invagination, vesiculation, and extrusion of microvesicles, and fragmentation. This defect is inherited as an autosomal dominant trait. RBCs from carrier cattle that are heterozygous for this defect have decreased band 3 (about 30% of normal), impaired anion transport, and mild spherocytosis, but hematocrits are generally normal. Osmotic fragility was increased in both heterozygous and homozygous cattle. This defect demonstrates the functional importance of the association of band 3 with skeletal proteins in maintaining membrane stability.

4. Hereditary Spectrin Deficiency in Dogs with Increased Osmotic Fragility

Increased RBC osmotic fragility secondary to spectrin deficiency (50% to 70% of normal) has been reported as a common autosomal dominant trait in golden retriever dogs in the Netherlands (Slappendel *et al.*, 2005). Hematocrits and reticulocyte counts are within reference intervals. Although originally reported as hereditary spherocytosis (Slappendel, 1998), spherocytes are not recognizable on stained-blood films. Rather, RBCs from affected dogs exhibited abundant echinospherocytes after 24 h of incubation at room temperature. In contrast, control dog RBCs exhibited only slight echinocyte formation after incubation. The nature of the spectrin defect has not been reported, but it is presumably different from the β-spectrin defect described in a dog that caused elliptocyte formation (Di Terlizzi *et al.*, 2007).

5. Hemolytic Anemia with Increased RBC Osmotic Fragility in Cats

A hemolytic anemia with markedly increased osmotic fragility has been reported in Abyssinian and Somali cats (Kohn *et al.*, 2000). Splenomegaly and polyclonal hyperglobulinemia were common. The hematocrit was generally between 15% and 25%, but values as low as 5% were recognized. A macrocytosis with mild to moderate reticulocytosis was present in most cats. Most samples exhibited extreme hemolysis after 1 day of refrigeration; however, *in vivo* hemolysis also occurred, as evidenced by hemoglobinuria in some cats. An RBC membrane defect was suspected, but none was identified using conventional membrane protein electrophoresis.

6. Amino Acid Transport Deficiency in Sheep and Horses

A second type of GSH deficiency, inherited as an autosomal recessive trait, occurs in Finnish Landrace sheep (Tucker and Kilgour, 1970). Although affected animals are not anemic, the life span of deficient RBCs is shortened (Tucker, 1974), possibly from increased oxidant injury as evidenced by the presence of HzB. These sheep are more likely to become anemic following the administration of oxidants *in vivo* (Tucker *et al.*, 1981).

The amino acid transporter normally responsible for cysteine transport (system C) into RBCs is defective (Young *et al.*, 1975), thereby limiting cysteine uptake and restricting GSH synthesis. As a consequence, GSH concentrations in RBCs are about 30% of normal (Young *et al.*, 1975). Intracellular Na^+ and K^+ are decreased, because dibasic and other amino acids accumulate in this disorder (Ellory *et al.*, 1972). The transport deficiency appears to develop during reticulocyte maturation, and intracellular amino acids accumulating in these cells are believed to come from protein degradation during reticulocyte maturation (Tucker and Young, 1980). When RBCs are separated by age, using density gradients, intracellular GSH decreases and HzB numbers increase in older RBCs from system C-deficient sheep, but not from normal or GCS-deficient sheep (Tucker and Young, 1980). This decreasing GSH with RBC age may explain why system C-deficient sheep are more susceptible to oxidants than are GCS-deficient ones, even though they have similar whole blood GSH levels.

About 30% of Thoroughbred horses and 3% of ponies are deficient in a similar amino acid transporter. The lesion results in increased amino acid levels and GSH deficiency in some cases (Fincham *et al.*, 1985).

7. High Membrane Na^+,K^+-ATPase Activity in Dogs

Although dog reticulocytes have considerable membrane Na^+,K^+-ATPase (Na^+,K^+-pump) activity, it is rapidly lost

during maturation into mature RBCs in most dogs (Maede and Inaba, 1985). Consequently, RBCs from most dogs have low potassium concentrations owing to the absence of Na^+,K^+-pump activity (Parker, 1977). However, some Japanese mongrel dogs, some Japanese Akita dogs, some Japanese Shiba dogs, and some Korean dogs (especially Jindo dogs) have HK^+ RBCs, because the Na^+,K^+-pump is retained in mature RBCs (Degen, 1987; Fujise *et al.*, 1997a; Maede *et al.*, 1983, 1991; Yamato *et al.*, 1999). Clinically, these dogs appear normal. This trait is inherited in an autosomal recessive manner. HK^+ dog RBCs have higher MCV, lower MCHC, and similar MCH values compared to LK^+ dogs of the same breed, suggesting an increase in cell water (Maede *et al.*, 1983). Although dogs with HK^+ RBCs are not anemic, their RBCs have shortened life spans (Maede and Inaba, 1987), and some dogs have slightly increased reticulocyte counts (Maede *et al.*, 1983). The osmotic fragility was increased in mongrel dogs (Maede *et al.*, 1983), but not in Jindo dogs (Yamato *et al.*, 1999).

RBCs from most of these dogs also have high GSH, glutamate, glutamine, and aspartate concentrations secondary to increased glutamate and aspartate uptake. GSH concentration is increased five to seven times normal because the feedback inhibition of GCS by GSH is released by the markedly increased glutamate concentration (Maede *et al.*, 1982). These HK^+, high GSH RBCs promote *Babesia gibsoni* replication compared to LK^+, normal GSH RBCs (Yamasaki *et al.*, 2005).

Dog RBCs have a high affinity Na^+-dependent transport system for glutamate and aspartate (Young, 1983). The increased transport of these amino acids into RBCs of affected dogs apparently occurs as a consequence of the Na^+ and K^+ concentration gradients produced by the presence of a Na^+,K^+-ATPase activity three times higher than that of human RBCs (Inaba and Maede, 1984). The glycolytic rate of HK^+ dog RBCs is about twice that of LK^+ cells, because greater ATP production is required to provide energy for active cation transport by the Na^+,K^+-pump and for increased GSH synthesis (Maede and Inaba, 1987).

The high GSH concentration in the HK^+ dog RBCs provides increased protection against oxidative damage induced by acetylphenylhydrazine (Ogawa *et al.*, 1992) but increased susceptibility to oxidative damage induced by 4-aminophenyl disulfide (Maede *et al.*, 1989), n-propylthiosulfate (Inaba, 2000), and onions (Yamoto and Maede, 1992). Evidence suggests that the increased GSH concentration potentiates the generation of superoxide through its redox reaction with organosulfur compounds present in onions (Munday *et al.*, 2003).

A variant of this HK^+ RBC disorder has been reported in dogs that lack GSH accumulation (Fujise *et al.*, 1993, 1997b). It was suggested that these dogs had a defect in amino acid metabolism in addition to the persistence of the Na^+,K^+-pump. Potassium concentration was estimated to be increased in RBCs from a Chinese shar-pei dog that was evaluated to determine the cause of pseudohyperkalemia (Battison, 2007). Increased osmotic fragility was present along with some macrocytic hypochromic RBCs. RBC Na^+,K^+-ATPase activity and GSH concentration were not assayed.

C. Miscellaneous Abnormalities

1. *Familial Nonspherocytic Hemolytic Anemia in Poodles*

A nonspherocytic hemolytic anemia occurs in poodles (Randolph *et al.*, 1986). An autosomal dominant trait with incomplete penetrance mode of transmission was suggested. Affected animals had severe persistent macrocytic hypochromic anemia (hematocrits 13% to 31%) with marked reticulocytosis. As in dogs with PK deficiency, myelofibrosis, osteosclerosis, and excess iron deposition in hepatocytes and mononuclear phagocytes were observed at necropsy. One dog died when 2.5 years old with liver failure. Despite extensive studies, the defect in this disorder could not be determined, but PK deficiency cannot be ruled out.

2. *Hereditary Nonspherocytic Hemolytic Anemia in Beagles*

A mild hemolytic anemia with reticulocytosis, slightly increased RBC osmotic fragility, shortened RBC life span, and normal RBC morphology have been reported in beagle dogs (Maggio-Price *et al.*, 1988). Studies of RBC enzymes, membrane protein electrophoresis, and Hb failed to identify a defect. Decreased calcium pump ATPase activity (Hinds *et al.*, 1989) and accelerated RBC swelling under osmotic stress (Pekow *et al.*, 1992) have been reported in RBCs from anemic dogs, but these abnormalities may be the consequence of an unknown membrane defect rather than representing primary abnormalities. Although the etiology remains elusive, this abnormality appears to be transmitted as an autosomal recessive trait.

3. *Familial Erythrocytosis in Cattle*

Marked erythrocytosis (hematocrits 60% to 80%) has been described in calves from a highly inbred Jersey herd (Tennant *et al.*, 1967, 1969). Affected calves had normal Hb types and arterial blood gas values. As with normal calves, hematocrits were within the adult range at birth, fell during the first month of life, and then increased during the next 2 months. In contrast to normal calves, however, the hematocrit continued to increase in affected calves until 6 to 7 months of age. The majority of affected calves died during this time. Hematocrits of surviving animals returned slowly to normal by maturity. Serum of affected calves lacked measurable Epo but contained a growth factor that appeared to enhance Epo activity *in vitro* (Van Dyke *et al.*, 1968). The pathogenesis of this disorder may involve an abnormally controlled increased RBC production in response to the anemia of the neonate (Tennant *et al.*, 1969). A variety of familial and congenital erythrocytosis syndromes have been

described in people. They include altered hypoxia sensing, Epo receptor gene mutations, high affinity Hbs, and 2,3DPG deficiency (Gordeuk *et al.*, 2005; Rives *et al.*, 2007).

Chapter 8

Porphyrins and the Porphyrias

J. Jerry Kaneko

I. INTRODUCTION

The metal-porphyrin complexes are found widespread in nature as constituents of compounds of fundamental importance in the metabolic processes of life. The photosynthetic pigment of plants, chlorophyll, is a magnesium porphyrin. The iron-porphyrin complexes of animals are found as prosthetic groups of proteins, including the hemoglobins, myoglobins, and the heme enzymes peroxidase, catalase, and the cytochromes. The porphyrins also exist in nature in their free state or as zinc complexes, and it is this group that is associated with the porphyrias and the porphyrinurias.

Present knowledge of the porphyrins has its basis in the classic studies of the German physician and chemist Hans Fischer, whose work on the porphyrins dates back to 1915. The development of elegant methods of detection and identification of porphyrins and sophisticated enzymological techniques have resulted in the present clear understanding of the mechanisms of porphyrin biosynthesis and the biochemical and molecular bases for the disorders of porphyrin metabolism.

II. PORPHYRINS

A. Structure of the Porphyrins

The parent nucleus of the porphyrins is a cyclic tetrapyrrole, which consists of four pyrrole nuclei with their α(adjacent to the β) carbon atoms linked together by methene (-C=) bridges. This compound is called porphin and is shown in Figure 8-1. The various synthetic and naturally occurring porphyrins are derivatives of porphin, distinguished from each other by the type and position of the radicals substituted for the hydrogen atoms at positions 1 through 8. For convenience in discussing the substitutions, the simplified representation of the porphin nucleus as shown in Figure 8-1 is used.

The classification of the porphyrins is based on the synthetic porphyrin, etioporphyrin (ETIO), in which two different radicals are substituted at positions 1 through 8. The substituted radicals are four methyl (M) and four ethyl (E) groups. The number of structural isomers possible with these eight substituted radicals is four, as shown at the top of Figure 8-2. The naturally occurring porphyrins are only those in which the positioning of their substituted radicals correspond to isomer I or III of etioporphyrin, ETIO I and ETIO III. This observation led Fischer to speak of a "dualism" of porphyrins in nature, which is in essential agreement with present knowledge of the biosynthesis of the

porphyrin isomers as proceeding along parallel and independent paths.

The uroporphyrins also contain two different radicals, acetic (A) and propionic (P) acids, and four each of these are arranged to correspond to either isomer ETIO I or ETIO III (Figure 8-2). In this case, A corresponds to M and P corresponds to E. Therefore, these are designated uroporphyrin I (URO I) or uroporphyrin III (URO III). Similarly, the coproporphyrins contain four M and four P groups and are designated coproporphyrin I (COPRO I) and coproporphyrin III (COPRO III). The protoporphyrin of heme (iron-protoporphyrin, the prosthetic group of hemoglobin) corresponds to the series III isomer. In this case, however, three different radicals instead of two are substituted. These consist of four M, two P, and two vinyl (V) radicals. With three different radicals, 15 isomers are possible, but the protoporphyrin of heme is the only naturally occurring isomer known. This isomer was designated protoporphyrin IX because it was the ninth in the series of protoporphyrin isomers synthesized by Fischer. The arrangement of the methyl groups of this isomer as shown in Figure 8-2 corresponds to that of a type III etioporphyrin isomer and more properly should be called protoporphyrin III. However, by convention, the name protoporphyrin IX (PROTO IX) is the designation for this porphyrin.

An interesting isomer with only one vinyl group located on the A ring occurs and is known as harderoporphyrinogen, which is thought to be an intermediate in the synthesis of protoporphyrinogen III. Other naturally occurring or chemically synthesized porphyrins are derivatives of PROTO IX. If the two vinyl groups are hydrogenated to ethyl groups, the product is mesoporphyrin IX. If the

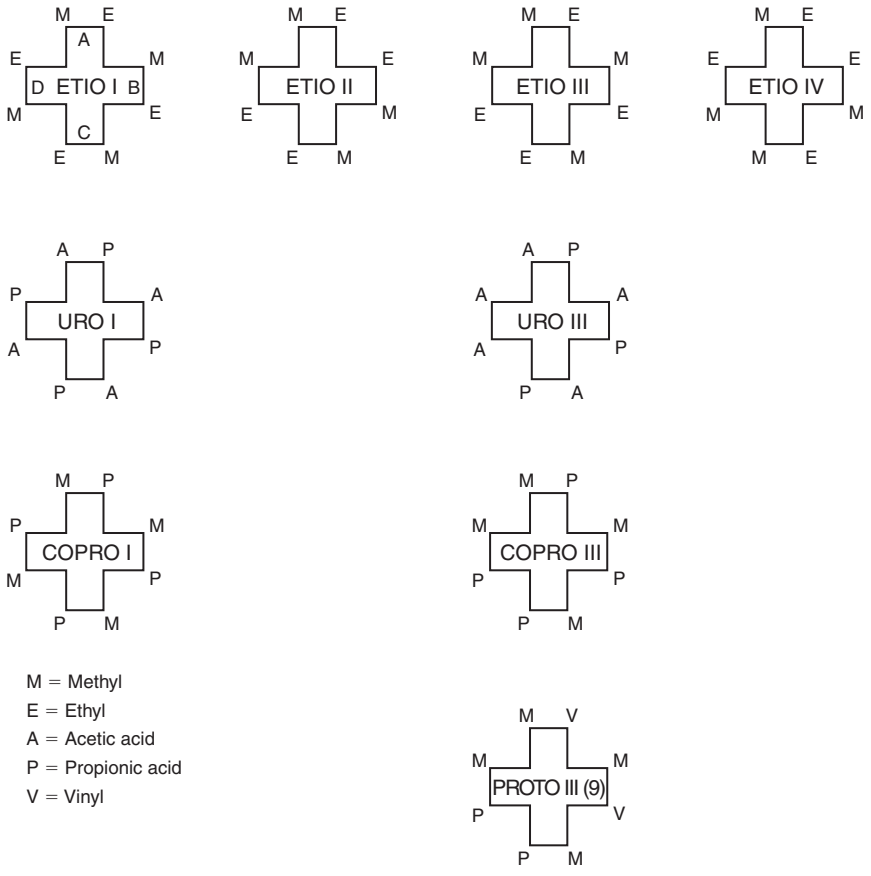

FIGURE 8-2 The isomeric porphyrins. The nomenclature of the porphyrins URO, COPRO, and PROTO is based on the isomeric structure of the etioporphyrins. Note that there are only the type I and type III isomers.

two vinyl groups are converted to hydroxy-ethyl groups, the product is hematoporphyrin IX. If the two vinyl groups are replaced by hydrogen atoms, the product is deuteroporphyrin IX. Protoporphyrin and deuteroporphyrin normally occur in feces but are primarily products of intestinal bacterial degradation.

B. Synthesis of Porphyrins and Heme

The initial steps in the pathway for porphyrin and heme biosynthesis begins with the incorporation of the methyl carbon (C-2) and nitrogen atom of glycine into the porphyrin ring and ultimately into the heme of hemoglobin. Porphyrin metabolism and the porphyrias have been periodically reviewed (Elder and Sheppard, 1982; Hindmarsh, 1986; Sassa, 2006; Sassa and Kappas, 2000).

The methyl carbons (C-2) of glycine supply 8 of the 34 carbons of protoporphyrin: one for each of the four methene bridges and one for each of the pyrrole rings (Fig. 8-3). The carboxyl carbon atom of glycine is given off as CO_2 and is not incorporated into the protoporphyrin molecule (Fig. 8-3). The direct incorporation of the nitrogen or the methyl carbon glycine into the heme of hemoglobin has been the basis for a useful technique to label the erythrocyte and to measure its survival time. After administering ^{15}N-glycine, the concentration of ^{15}N in heme rises rapidly, remains constant for a time, and then falls. Mathematical analysis of the curve indicates a survival time of 120 days for the human erythrocyte. On a similar basis, methyl carbon labeled glycine has been used to determine the life span of the erythrocytes of a number of domestic animals (Table 8-1).

The remaining carbons of protoporphyrin are supplied by the tricarboxylic acid (TCA) cycle intermediate, succinyl-CoA. An outline of the pathway of heme and porphyrin synthesis is given in Figure 8-4, which depicts the compartmentalization of their pathways between the mitochondria and cytosol. The nomenclature of the enzymes of porphyrin synthesis varies among authors, so a guide to the nomenclature of the enzymes is provided in Table 8-2.

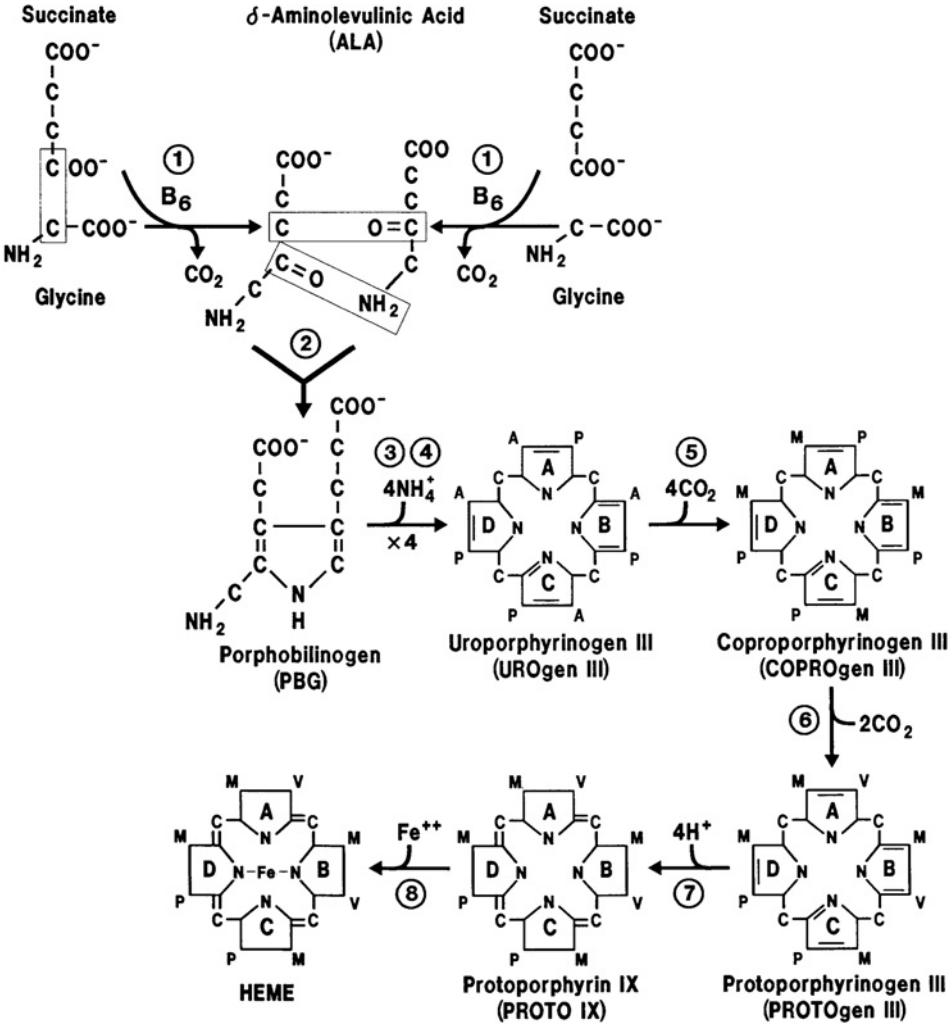

FIGURE 8-3 The synthetic pathway for protoporphyrin and heme. Note that two enzymes are required to catalyze the formation of UROgenIII. The circled numbers correspond to the enzymes listed in Table 8-2.

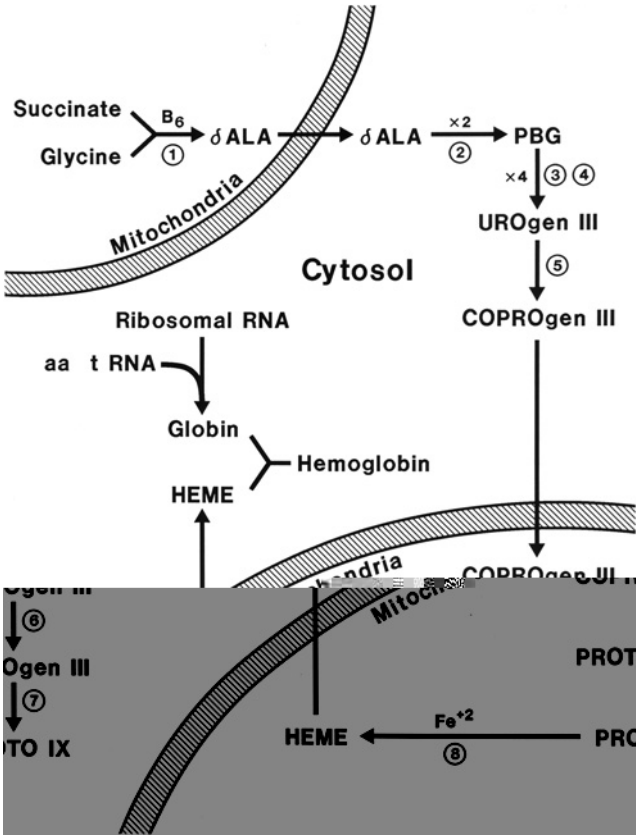

FIGURE 8-4 The synthetic pathway for protoporphyrin and heme. Note the partitioning of the heme synthetic pathway between the mitochondria and the cytosol. The circled numbers correspond to the enzymes listed in Table 8-2.

1. δ-Amino Levulinic Acid

The initial step in the pathway of δ-aminolevulinic acid (ALA) synthesis occurs in the mitochondria and involves the enzymatic condensation of glycine with succinyl-CoA to form ALA. This reaction requires vitamin B_6 as pyridoxal phosphate, and it is the pyridoxal-phosphate-glycine complex that condenses with succinyl-CoA (Gibson *et al.*, 1958, Kikuchi *et al.*, 1958). The requirement for pyridoxine explains the pyridoxine responsive anemia of pyridoxine deficiency because in the absence of pyridoxine, the condensation cannot occur. The condensing reaction is catalyzed by the enzyme ALA synthase (ALA-Syn). ALA-Syn is the rate-controlling enzyme for heme synthesis (Granick, 1966). ALA-Syn is induced by heme and is also suppressed by negative feedback inhibition by heme. Thus, the end product, heme, controls its own synthesis (Granick and Levere, 1964). The ALA is next transferred into the cytosol (Sano and Granick, 1961).

2. Porphobilinogen

Two moles of ALA are next condensed to form the precursor pyrrole, porphobilinogen (PBG) in the cytosol (Cookson and Rimington, 1953). The enzyme ALA-dehydrase (ALA-D), an enzyme that is strongly inhibited by lead, catalyzes this reaction. The activity of this enzyme has been assayed in lead poisoning, and a reduced activity is generally regarded as presumptive evidence of exposure to lead.

TABLE 8-2 Nomenclature for Enzymes of Porphyrin and Heme Synthesis and Their Synonyms

Abbreviations	Nomenclature
1. ALA-Syn	delta-aminolevulinate synthase (synthetase)
2. ALA-D	delta-aminolevulinate dehydrase (dehydratase); porphobilinogen synthase
3. PBG-D	porphobilinogen deaminase, uroporphyrinogen I synthase (synthetase), hydroxymethylbilane synthase
4. UROgenIII-Cosyn	uroporphyrinogen III cosynthase (cosynthetase)
5. UROgen-D	uroporphyrinogen decarboxylase
6. COPROgenIII-Ox	coproporphyrinogen III oxidase
7. PROTOgen-Ox	protoporphyrinogen oxidase
8. FER-Ch	ferrochelatase; heme synthase (synthetase)

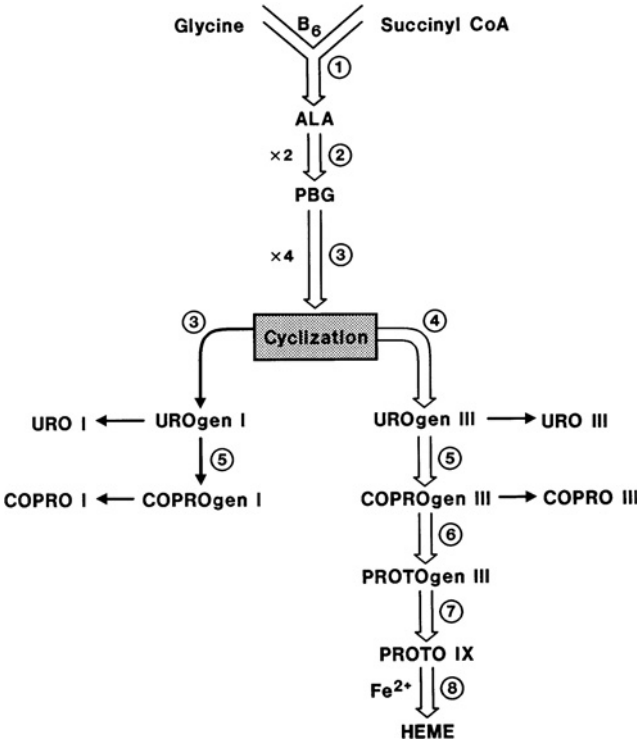

FIGURE 8-5 Alternate pathways for porphyrin synthesis. Normally, enzymes 3 and 4 function together in a coordinated manner to form heme. In the absence of enzyme 4, the alternate and terminal pathway to form the I isomers is taken. The circled numbers correspond to the enzymes listed in Table 8-2.

3. U*roporphyrinogen*

Next, two enzymes, porphobilinogen deaminase (PBG-D) (formerly called uroporphyrinogen I synthase [UROgenI-Syn]) and uroporphyrinogen III cosynthase (UROgenIII-Cosyn) act together to condense four moles of PBG into the cyclic tetrapyrrole, uroporphyrinogen III (UROgenIII). PBG-D initially catalyzes the formation of a symmetrical linear tetrapyrrole. UROgenIII-Cosyn then flips the D ring and closes the pyrroles into an asymmetrical porphyrin ring of the type III configuration. In the absence of the UROgenIII-Cosyn, the symmetrical linear tetrapyrrole spontaneously closes into a symmetrical porphyrin ring of the type I configuration. Normally, there is a great excess of UROgenIII-Cosyn, so UROgenIII is synthesized. Both enzymes have been isolated from the spleens of anemic mice and *in vitro*, in the presence of both enzymes, UROgenIII was produced (Levin and Coleman, 1967).

4. C*oproporphyrinogen*

The eight carboxyl UROgens I or III are next progressively decarboxylated into the four carboxyl coproporphyrinogens (COPROgen) I or III with the decarboxylations catalyzed by the enzyme uroporphyrinogen decarboxylase (UROgen-D). UROgen-D is nonspecific so it catalyzes the decarboxylation of either UROgenI or UROgenIII. The COPROgens now move back into the mitochondria (Fig. 8-4).

5. P*rotoporphyrinogen*

Within the mitochondria, coproporphyrinogen III oxidase (COPROgenIII-Ox) catalyzes the decarboxylation of the two propionic acid groups on the A and B pyrrole rings of COPROgenIII to vinyl groups and the resulting product is protoporphyrinogen III (PROTOgenIII). COPROgenIII-Ox is highly specific for COPROgenIII, and this explains the presence of only type III porphyrin isomers in nature. This also means that COPROgenI is a terminal intermediate that is oxidized to coproporphyrin I, the end product of this path (Fig. 8-5). COPROgenIII, when in excess, is also oxidized to coproporphyrin III. Similarly, the UROgens I and III can be oxidized to their end products, the uroporphyrins I and III. Figure 8-5 illustrates that each of the -gen forms can be oxidized into their free forms, which are the forms usually found in the circulatory system. These free porphyrins and protoporphyrins are photoreactive and are the causative agents of the photosensitivity in the porphyrias.

6. P*rotoporphyrin*

PROTOgenIII, the 2-carboxyl porphyrinogen, is next oxidized at the carbon bridges to form the methene bridges connecting the pyrroles and is catalyzed by protoporphyrinogen III oxidase (PROTOgenIII-Ox). The resulting product is protoporphyrin IX (PROTO IX).

7. *Heme*

Within the mitochondria, ferrous iron (Fe^{+2}) is chelated with PROTO IX to form heme and is catalyzed by the enzyme ferrochelatase (FER-Ch). Iron can also be incorporated with relative ease by a nonenzymic method, but the enzymic iron incorporation is more than 10 times that of the nonenzymic route (Labbe and Hubbard, 1961). Conditions that help to maintain iron in its ferrous form including the presence of reducing agents (ascorbic acid, cysteine, glutathione) enhance both enzymic and nonenzymic iron incorporation. Because iron is incorporated into heme as an integral part of the molecule, labeled iron can also be used as a cohort label to determine the life span of the erythrocyte (Table 8-1).

8. *Hemoglobin*

Heme next moves into the cytosol where it is linked to the heme pocket of globin in a precise and stable position that permits binding of oxygen to the heme. Hemoglobin consists of four moles of this heme-globin moiety linked together as a globular tetramer. It is this globular tetrameric form of the hemoglobin molecule that permits the cooperative interaction of oxygen binding, which gives the familiar sigmoid oxygen-hemoglobin saturation curve.

9. *Summary*

In summary, the synthesis of porphyrins, heme, and globin can only occur in those respiring cells with full complements of mitochondrial and cytosolic enzymes. The TCA cycle is an aerobic cycle, and therefore a lack of oxygen would preclude synthesis of succinyl-CoA and hence of heme. PROTO IX formation and the chelation of iron to form heme are also oxygen-requiring systems. Therefore, the reticulocyte with its residual complement of enzymes can synthesize hemoglobin, but the mature erythrocyte, which is devoid of mitochondrial enzymes, cannot.

III. METHODOLOGY

The principal method now employed for the detection of porphyrins in biological materials in the clinical laboratory is based on the characteristic red fluorescence observed when acidic solutions of the porphyrins are exposed to ultraviolet light. The color of the fluorescence cannot be used to distinguish between the uroporphyrins and the coproporphyrins, and, therefore, these must be separated before examination for fluorescence. The separation procedures are based on the solubility differences of the porphyrins in various organic solvents. In general, the following solubility properties are used in the separation of the uroporphyrins from the coproporphyrins:

1. The coproporphyrins are soluble in diethyl ether, whereas the uroporphyrins are not, and therefore uroporphyrins remain in the aqueous phase.

2. Both uroporphyrin and coproporphyrin are soluble in strong acid, 1.5 N HCl. Coproporphyrins are therefore extracted from the organic phase with 1.5 N HCl. The uroporphyrins in the aqueous phase are absorbed with aluminum trioxide and subsequently eluted with 1.5 N HCl.

The acidic solutions of the porphyrins are then observed visually for fluorescence or examined in a sensitive fluorometer. The most suitable condition for the excitation of fluorescence is the use of ultraviolet light in the near visible range using aqueous solutions of the porphyrins at pH 1–2. Further means of identification include spectrophotometric examination, melting points of their methyl esters, and high-performance liquid chromatography (HPLC). The quantitative methods employing HPLC with fluorometric detection have been described in detail by Hindmarsh *et al.* (1999). The HPLC method now appears to be the most accurate method for urine and fecal porphyrins (Zuijderhoudt *et al.*, 2000, 2002). The following screening procedures are guides for further laboratory examinations.

A. Urinary Porphyrins

The urine for porphyrin examination must be alkalinized because porphyrins readily precipitate in acid urine. Addition of 0.5 g of sodium bicarbonate to the collecting bottle for each 100 ml of urine will keep the urine alkaline. The alkalinized urine can be stored at 4°C for 2 to 3 days before analysis. All contact of the urine with metal must be avoided and unfiltered urine is used. The following is a simplified screening procedure:

1. Place 5ml urine in a 250-ml separatory funnel and add 5ml acetate buffer (four parts glacial acetic acid: 1 part saturated sodium acetate) and adjust pH to 4.6 to 5.0.

2. Add 15ml cold water.

3. Extract the mixture with two 50ml aliquots of diethyl ether (or until the ether phases show no fluorescence under ultraviolet [UV] light) and pool the aliquots. The coproporphyrins will enter the ether phase.

4. Most of the porphyrins in urine are in the form of their nonfluorescent precursors. Storage of the urine for 24 h in a refrigerator will enhance their conversion to the fluorescent pigments. If fresh urine is used, the ether phase is gently shaken with 5ml of fresh 0.005% iodine solution (dilute 0.5ml of a stock 1% iodine in ethanol solution to 100 ml with water) to convert the precursors to the porphyrins.

5. Extract the pooled ether phases with 20 ml 5% HCl (1.5 N) and examine for fluorescence under UV light. Fluorescence indicates the presence of coproporphyrins.

6. Uroporphyrins are insoluble in ether. Therefore, fluorescence in the aqueous urinary phase indicates the presence of uroporphyrins.

B. Fecal Porphyrins

The screening test as described for urine can also be used with fecal samples after prior extraction with strong acid. First, 5g of a fecal sample is emulsified with 10ml 95% ethanol. Then 25ml of concentrated HCl and 25ml water are added to the emulsion, and the mixture is kept overnight at room temperature. The mixture is next diluted to 200ml with water, filtered, and the filtrate examined for porphyrins as described for urine.

C. Blood Porphyrins

Almost all porphyrins in blood are present in the erythrocytes, and only trace amounts are in plasma. Therefore, it is important to use whole blood in the test and to understand that the test is a measure of the porphyrin content of the erythrocytes. Mix 2ml heparinized whole blood and 6ml ethyl acetate:glacial acetic acid (4:1) in a glass centrifuge tube. Stir thoroughly, centrifuge, and pour off the supernate into a second centrifuge tube. Add 1ml 3N HCl, vortex, and allow the phases to separate. Fluorescence under UV light in the aqueous layer indicates the presence of porphyrins in the erythrocytes. Normally, there will only be a trace of fluorescence so that more than a trace indicates an abnormal concentration.

D. Porphobilinogen

The Watson and Schwartz test for porphobilinogen is reliable for screening (Watson and Schwartz, 1941). For this test, 3ml fresh urine is mixed with 3ml Ehrlich's aldehyde reagent (0.7g p-dimethylaminobenzaldehyde, 150ml concentrated HCl, and 100ml water), the reagent that is used for the urine urobilinogen test. Next, 5ml chloroform are added, shaken vigorously in a separatory flask, and allowed to separate. The porphobilinogen aldehyde formed in the test is insoluble in chloroform and will remain in the lower aqueous phase. If the pink color is due to urobilinogen, it will be extracted into the chloroform phase. Porphobilinogen is found characteristically in the urine of patients with hepatic forms of porphyria, forms that have not been reported in animals.

IV. PORPHYRIAS

A. Classification

By convention, the term *porphyria* is used to define those disease states that have a hereditary basis and increased urinary or fecal excretion of uroporphyrins and coproporphyrins. Depending on the fundamental biochemical defect, the porphyrias can be broadly classified on the basis of their tissue of origin, the erythropoietic system, or the liver. The term *porphyrinuria* is used to define those acquired conditions in which the principal, if not the sole, porphyrins being excreted are the coproporphyrins. Excess coproporphyrin excretion is observed in a wide variety of conditions including infections, hemolytic anemias, liver disease, and lead poisoning. The screening test for coproporphyrinuria has been especially useful for detecting exposure to lead.

Many systems for classifying porphyrias have been devised, and most are based on the defect in the tissue of origin, the erythropoietic system, or the liver. There is general agreement on the classification of the erythropoietic forms, but there is still some uncertainty as to the classification of the hepatic forms. These have been classified on the basis of their clinical manifestations, heredity, porphyrins excreted, and their enzymatic defects (Elder and Sheppard, 1982; Hindmarsh, 1986; Sassa, 2006; Sassa and Kappas, 2000). Each of the enzymatic defects has now been described on a molecular level in humans, and they have been summarized by Sassa and Kappas (2000). The genes have been cloned, and it is now known that there is a great deal of genetic heterogeneity, which presumably accounts for the wide variety of disease manifestations in each of the porphyrias. A useful system of classification is given in Table 8-3.

Methods are also available for the experimental production of the two major types of porphyria. In lead or

TABLE 8-3 Classification of the Porphyrias[a]

Porphyria Type	Inheritance	Enzyme Deficiency
I. Erythropoietic porphyries		
A. Congenital erythropoietic porphyria	AR	UROgenIII-Cosyn
B. Erythropoietic protoporphyria	AD	FER-Ch
II. Hepatic porphyrias		
A. ALA-D deficiency porphyria	AR	ALA-D

phenylhydrazine poisoning, a type of porphyrinuria has been observed that has some of the characteristics of erythropoietic porphyria of humans and cattle (Schwartz *et al.*, 1952). A hepatic form can be produced with sedormid (allylisopropylacetylcarbamide) (Schmid and Schwartz, 1952), dihydrocollidine (Granick and Urata, 1963), or hexachlorobenzene.

B. Erythropoietic Porphyrias

1. *Bovine Congenital Erythropoietic Porphyria*

a. Introduction

One of the characteristic findings in bovine congenital erythropoietic porphyria (CEP) is a reddish brown discoloration of the teeth and bones. Discolorations of this type have been observed in cattle at slaughter since the turn of the century, and these cattle are presumed to have had the disease. The first living cases were encountered in South Africa in a herd of grade Shorthorn cattle. Since then, CEP has been reported in cattle in Denmark (Jorgensen and With, 1955), the United Kingdom (Amoroso *et al.*, 1957), the United States (Rhode and Cornelius, 1958), and Jamaica (Nestal, 1958). The disease has been seen primarily in Holsteins with a few cases in Shorthorns and Jamaican cattle.

The simple Mendelian autosomal recessive heredity of the disease was established by the study of the genealogy of the affected cattle and by breeding experiments. The affected homozygotes are characterized by discoloration of the teeth and urine, photosensitivity of the light areas of the skin, and generalized lack of condition and weakness. The condition is present at birth, and severely affected calves must be protected from sunlight if a state of health is to be maintained.

The predominant symptoms of teeth and urine discoloration and the photosensitization of the severely affected animal are readily apparent, and a tentative diagnosis can be confirmed by the orange-red fluorescence of the teeth and urine when examined with near ultraviolet light or a Woods lamp. The symptomatology of affected animals, however, may vary from minimal to severe and with age and season. The discoloration of the teeth may vary in the same breed, being more pronounced in the young and less apparent in the older animals. Porphyrin deposits are heavily concentrated in the dentine so the occlusal surfaces should also be examined. If porphyrins are present, the discoloration and the fluorescence of the dentine will be readily detected.

The degree of photosensitization will vary with the amount of porphyrin deposition in the dermis, coat color, density of the coat, and extent of exposure to sunlight. The photosensitization may be so slight as to escape detection. At times, loss of condition may be the only outward symptom for which the veterinarian is called. Marked variations in the urinary excretion of the porphyrins also occur. These may range from minimal to thousands of micrograms in the same animal so that the urine color may vary widely. The variations observed in this disease indicate the dynamic state of flux of porphyrin metabolism in the living animal, and the porphyrin deposits constitute a part of this dynamic state.

b. Distribution of Porphyrins

Some normal values for the porphyrins in animals are given in Table 8-4. These values are to be considered as best approximations obtained from a relatively few animals. The figures, however, indicate the very low concentrations of the free porphyrins normally found in the body. Thus, the finding of porphyrins in greater than trace amounts is always significant. Porphyrin concentrations in porphyric cows and calves are given in Table 8-5 (Kaneko and Mills, 1970).

TABLE 8-4 Reference Values for Porphyrin Concentrations[a]

i. Urine It is known that porphyrin excretion varies over wide limits. Jorgensen (1961) in 52 cases found values for urinary uroporphyrins between 6.3 to 3900μg/dl (0.076 to 46.96μmol/l) and coproporphyrins between 2.1 and 8300μg/dl (0.032 to 126.74μmol/l). At concentrations of 100μg/dl (1.53μmol/l) or more, a reddish discoloration is discernible in the urine. At 1000μg/dl (15.27μmol/l) or more, an intense red fluorescence of the urine is readily observed when examined in the dark with Woods light. The principal porphyrins excreted are URO I and COPRO I and only a small fraction is of the type III isomers. The percentage of each appearing in the urine is also variable. There is usually a greater excretion of URO I than COPRO I, but Jorgensen (1961) observed a greater excretion of COPRO I than URO I.

Porphobilinogen is not usually found in bovine CEP urine, and earlier reports of its presence (Jorgensen and With, 1955) have not been confirmed (Jorgensen, 1961). Normally colored, nonfluorescent urine of a CEP cow has consistently given a definite pink Ehrlich reaction, but unlike porphobilinogen aldehyde, the pigment is soluble in chloroform. The nature of the pigment is unknown. Upon heating on a steam bath for an hour or standing at room temperature for several days, a red fluorescence is apparent on exposure to UV light. Quantitative porphyrin determinations of this urine yielded values of 135μg/dl (1.63μmol/l) and 87μg/dl (1.33μmol/l) for uroporphyrin and coproporphyrin, respectively. Watson *et al.* (1959) also described a similar experience with bovine CEP urine.

ii. Bile and Feces Bovine fecal porphyrins may be derived from two sources: the bile and from chlorophyll of the food. The porphyrins derived from chlorophyll are excluded by the usual analytical method. Essentially, the only porphyrin found in the bile and feces of CEP cattle is COPRO I, and its concentration varies over wide limits (Tables 8-4 and 8-5). Fecal coproporphyrin varied between 1.9 and 11,800μg/g (0.003 to 18.0μmol/g) and biliary coproporphyrin between 320 and 13,600μg/dl (4.88–207.67μmol/l) (Jorgensen, 1961). Only small amounts of COPRO III have been observed in feces. Watson *et al.* (1959) also observed this preponderance of COPRO I in feces and also reported the presence of small amounts of URO I.

iii. Plasma and Erythrocytes Only traces of free porphyrins are normally present in the plasma and in the erythrocytes. In bovine CEP plasma, Watson *et al.* (1959) observed variable amounts of porphyrins that were in general equally URO I (1 to 27μg/dl; 0.012-0.33μmol/l) and COPRO I (4.2 to 25μg/dl; 0.064 to 0.38μmol/l). A striking difference as compared to the human disease was the high level of free protoporphyrin in the erythrocytes of the CEP cow. The significance of this high level of protoporphyrin was unclear but was most likely related to the severe hemolytic

anemia in the CEP cow. Excess PROTO IX is commonly found in iron deficiency, hemolytic anemia, and in lead poisoning. In iron deficiency, PROTO IX accumulates because of failure to form hemoglobin, but in CEP, serum iron is normal or elevated (Kaneko, 1963; Kaneko and Mattheeuws, 1966; Watson *et al.*, 1959). Similarly, PROTO IX accumulates in lead poisoning because of inhibition of ferrochelatase and a subsequent inability to insert iron into hemoglobin.

iv. Tissue The range of concentrations of porphyrins in the tissues of CEP cattle is given in Table 8-6. The deposition of porphyrins throughout the bones and soft tissues is readily apparent at postmortem of severe cases by the generalized discoloration. A reddish brown discoloration is most apparent in the teeth, bones, and bone marrow. Greatest discoloration of soft tissues occurs in the lungs and spleen in which characteristic fluorescence may be observed with UV light. The high concentration of porphyrins in the spleen is consistent with the hemolytic type of anemias in CEP. Discoloration of skin, muscle, heart, liver, and kidney is also observed but only a part is due to porphyrins. The discoloration is likely due to other porphyrin derivatives and to hemoglobin staining.

c. Hematology

The hematological picture of the majority of reported cases is one of a responsive hemolytic anemia. In general, the degree of response is correlated with the severity of the hemolytic anemia. The anemia in mild cases of bovine CEP is normocytic and in the more severe cases is macrocytic, a reflection of the severity of the hemolysis and the acuteness of the response. In the severe cases of bovine CEP, there is reticulocytosis, polychromasia, anisocytosis, basophilic stippling, and an increase in nucleated erythrocytes. A consistent monocytosis has been observed (Kaneko, 1963; Rhode and Cornelius, 1958), but this remains unexplained. There is a markedly decreased M:E ratio in the presence of the anemia, indicating a marked bone marrow hyperplasia. Bone marrow is also a principal site of porphyrin deposition, and Watson *et al.* (1959) found high concentrations of uroporphyrins in the bone marrow of a CEP cow.

The presence of porphyrins in the nucleated erythrocytes is clearly evident by examination of unfixed and unstained bone marrow smears with a fluorescent microscope. These fluorescent cells have been called fluorocytes. This phenomenon was originally observed by Schmid *et al.* (1955) in the bone marrow of a human patient and helped

to localize the metabolic lesion in the erythropoietic tissue. They also reported that the fluorescence was seen only in morphologically abnormal nucleated erythrocytes that contained abnormal nuclear inclusions. Similar nuclear abnormalities were observed in bovine CEP bone marrow (Watson *et al.*, 1959). Schmid *et al.* (1955) concluded that there were two populations of erythrocytes, one normal and one containing free porphyrins.

The presence of two populations of erythrocytes was reported in humans, but this was attributed to the intermittent hemolytic crises that occurred (Gray *et al.*, 1950). Runge and Watson (1969), who were studying fluorescing bovine CEP bone marrow cells after bleeding, also concluded that there was only a single population of erythrocytes in bovine CEP.

The hematology of newborn CEP calves also has striking differences from that of older CEP calves and cows (Kaneko and Mills, 1970). There is an intense erythrogenic response in the neonatal CEP calf, which persists for the first 3 weeks of life. Nucleated erythrocyte counts during the first 24 h of life ranged from 5000 to 63,500 μl. Reticulocyte counts were lower than expected (6.4%) and increased to a peak of only 12.5% at 4 days of age. The persistent reticulocytosis is thought to be due to a delay in maturation of the reticulocytes (Rudolph and Kaneko, 1971; Smith and Kaneko, 1966). This delay in maturation of the reticulocyte, which is proportional to the degree of anemia, is now a well-established phenomenon during the reticulocyte response to a blood loss or hemolytic anemia. In essence, this delay represents the increase in survival time of the reticulocyte beyond its normal 1-day survival time. This increased survival time is the now commonly used maturation correction factor (MCF) for estimating the reticulocyte production index (RPI) when evaluating the response to an anemia.

d. Mechanism of the Anemia

A responsive hemolytic anemia is a well-established occurrence in CEP. Erythrocyte porphyrins are high in CEP, and if these erythrocytes with high porphyrin concentrations were more susceptible to destruction, a shortening of their life span would be expected. Erythrocyte life span is shortened in bovine (Kaneko, 1963) and in human CEP (Gray *et al.*, 1950). There is general agreement that this shortening of life span is associated with the hemolytic process, but the mechanism of the hemolysis remains obscure. It has been shown that erythrocyte survival in bovine CEP is inversely correlated with erythrocyte coproporphyrin concentration (Kaneko *et al.*, 1971). The shortest erythrocyte survival time of 27 days (normal = 150 days) was associated with the highest erythrocyte coproporphyrin concentration. The porphyrins through their lipid solubility are presumed to damage the erythrocyte membrane leading to the hemolysis. *In vivo* ^{59}Fe metabolic studies were completely compatible with a hemolytic type of anemia, and ineffective erythropoiesis (i.e., bone marrow hemolysis) was also demonstrated (Kaneko, 1963; Kaneko and Mattheeuws, 1966). Plasma iron turnover and transfer rates, erythrocyte iron uptake, and organ uptakes were increased as expected in a hemolytic process.

The mechanism of cell damage has also been studied in reticulocytes and in nucleated erythrocytes. A biochemical defect in the bovine CEP reticulocyte *in vitro* was expressed as an increase in porphyrin synthesis, a marked decrease in heme synthesis and a delay in the maturation time of the reticulocyte (Smith and Kaneko, 1966). The $T_{1/2}$ for the maturation of the reticulocyte was 50 h compared to a normal of 3 to 10 h. This delay in reticulocyte maturation is thought to be the direct result of the defect in heme synthesis, because the rate of heme synthesis controls the rate of maturation of the reticulocyte (Schulman, 1968). This means that there is an increase in the reticulocyte survival time inversely proportional to the degree of anemia.

A similar delay in the maturation of the metarubricyte to the reticulocyte was observed in the bone marrow cells of CEP cows (Rudolph and Kaneko, 1971), but there was no effect on the earlier stages of nucleated erythrocytes. Therefore, the more mature erythrocytic cells are the cells most affected by the high porphyrin content. This is not surprising because heme and hemoglobin synthesis are most active in the later stages of erythrocytic cell development. Ultimately, the accumulation of porphyrins in these cells, whether in bone marrow or in blood, induces hemolysis. Upon exposure of surface capillaries to sunlight, photohemolysis of the type observed in erythropoietic protoporphyria (Harber *et al.*, 1964) would further aggravate the hemolysis.

This hemolytic mechanism might also explain the striking erythrogenic response seen in the neonatal porphyric calf. Because most of the porphyrins are within the fetal erythrocytes and these would not normally cross the placenta, the porphyrin containing erythrocytes would accumulate in the fetus and a profound hemolysis would occur *in utero.* This hemolysis in turn would induce a marked erythrogenic response in the fetus, and this is observed at birth. At birth, porphyrins are high, but they fall to their steady state level in about 3 weeks in CEP calves. This is comparable to the rate of clearance of ^{14}C-porphyrin into urine, which fell to 0.1% of the initial concentration in 3 weeks. Furthermore, 3 weeks is also the time at which the erythrogenic response is stabilized at a steady state level in the neonatal calf (Kaneko and Mills, 1970).

In summary, as a result of the heme synthetic defect in erythropoietic porphyria, there is excess porphyrin accumulation in the mature and developing erythrocytes, which induces their hemolysis in the circulation or in the bone marrow. There is a corresponding shortening of erythrocyte

life span. In addition, the decrease in heme synthesis induces an increase in the survival time of the reticulocyte by inhibiting the maturation of the developing erythrocytes, which further aggravates the anemia. This biochemical defect in heme synthesis is morphologically expressed in the fluorocytes and in the evidence of erythrogenic response in the blood and bone marrow, the degree of which is directly related to the severity of the enzymatic defect of the porphyria.

e. Detection of the Carrier State

Bovine CEP is inherited as an autosomal recessive trait. Previously, carrier animals were detectable only by the occurrence of the disease in their progeny. Levin (1968a) developed an assay for UROgenIII-Cosyn and found that its activity was considerably less in CEP cattle than in normals (Levin, 1968b). Heterozygous cattle, which are the clinically unaffected carriers of the porphyria gene, had UROgenIII-Cosyn activities intermediate between porphyrics and normals (Romeo *et al.*, 1970). Similarly low UROgenIII-Cosyn activity is found in human CEP, but carriers are less readily detectable in humans than in cattle (Romeo and Levin, 1969). These findings are also in keeping with the concept that the genetic defect in CEP is a deficiency of UROgenIII-Cosyn. Romeo (1977) has reviewed the genetic aspects of all forms of hereditary porphyrias and determined that the evidence is conclusive for a UROgenIII-Cosyn deficiency in CEP.

f. Metabolic Basis of Bovine Congenital Erythropoietic Porphyria

The mechanisms for heme biosynthesis and the biochemical nature of the porphyrins in the tissues and excreta provide an explanation for the metabolic defect in CEP. Certain features of the biosynthetic mechanism are particularly important in an explanation of the clinical and metabolic manifestations of CEP, which has its ultimate pathogenesis in a hereditary deficiency of UROgenIII-Cosyn. These may be summarized as follows:

1. There is a compartmentation of the enzymes of heme biosynthesis between the mitochondria and the cytosol.
2. Mitochondrial systems are involved in the synthesis of ALA, PROTO IX, and heme.
3. Cytosolic systems catalyze the formation of PBG, UROgenIII or I, and COPROgenIII or I.
4. Mitochondria are present only in the immature nucleated erythropoietic cells and in the reticulocytes. Mitochondria are not present in the mature erythrocyte. The most active heme and hemoglobin synthesis occurs in the metarubricyte and secondly in the reticulocyte.
5. There is no heme or hemoglobin synthesis in the mature erythrocyte.

The enzymatic deficiency in CEP is localized in the erythropoietic tissue within the developing erythropoietic cells, which are the mitochondria-containing cells. Normally, the combined action of UROgenI-Syn and UROgenIII-Cosyn catalyzes the formation of the normal type III porphyrin isomer, UROgenIII leading to the formation of heme. In the absence of UROgenIII-Cosyn, the type I isomer, UROgenI, and then COPROgenI are formed. Thus, the relative activities of these enzymes govern the extent as to which of these pathways is traversed. The type I isomers that are formed in the deficiency state cannot be converted into PROTOgenI and thus into a type I heme. This is because there is no coproporphyrinogen I oxidase and the COPROgenIII-Ox is highly specific only for the type III isomer. The type UROgenI and COPROgenI isomers are oxidized to their corresponding uroporphyrins and coproporphyrins. These oxidized free porphyrins accumulate in the erythropoietic tissues, developing erythrocytic cells, and in the mature erythrocytes where they induce the hemolysis characteristic of CEP. In addition, the porphyrins are released into the circulation and are widely distributed throughout the body in all body fluids and are readily excreted in the feces and urine. They are deposited in all tissues, most notably in the teeth, bones, and skin. When exposed to ultraviolet light, the porphyrins in the skin are excited by absorption of the ultraviolet light energy into an unstable higher-level energy state. The excitation energy is then emitted when the excited molecule returns to its ground state. The energy can be emitted as fluorescence or transferred to molecular oxygen to form singlet oxygen. Singlet oxygen is a powerful oxidant for many forms of biologically important compounds including the peroxidation of membrane lipids, membrane and cellular proteins, cell enzymes, and cell organelles. Peroxidation appears to be the primary event in the photosensitivity and photodermatitis seen in the porphyrias (Poh-Fitzpatrick, 1982).

Total deficiency of UROgenIII-Cosyn is obviously incompatible with life so that surviving cases of CEP have only a partial deficiency of UROgenIII-Cosyn. Also, there is a wide variation in the severity of the disease commensurate with the degree of the enzyme deficiency as well as with the conditions of husbandry. The severity of the disease, however, is constant in each bovine if it is kept under standard controlled conditions. The metabolic basis for bovine CEP is summarized in Figure 8-4, in which the central theme is the genetically controlled UROgenIII-Cosyn deficiency with the resultant type I porphyrin accumulation and a failure of heme synthesis.

2. *Bovine Erythropoietic Protoporphyria*

This disorder of porphyrin metabolism occurs in humans and in cattle. Erythropoietic protoporphyria (EPP) was first reported by Magnus *et al.* (1961), and is now well

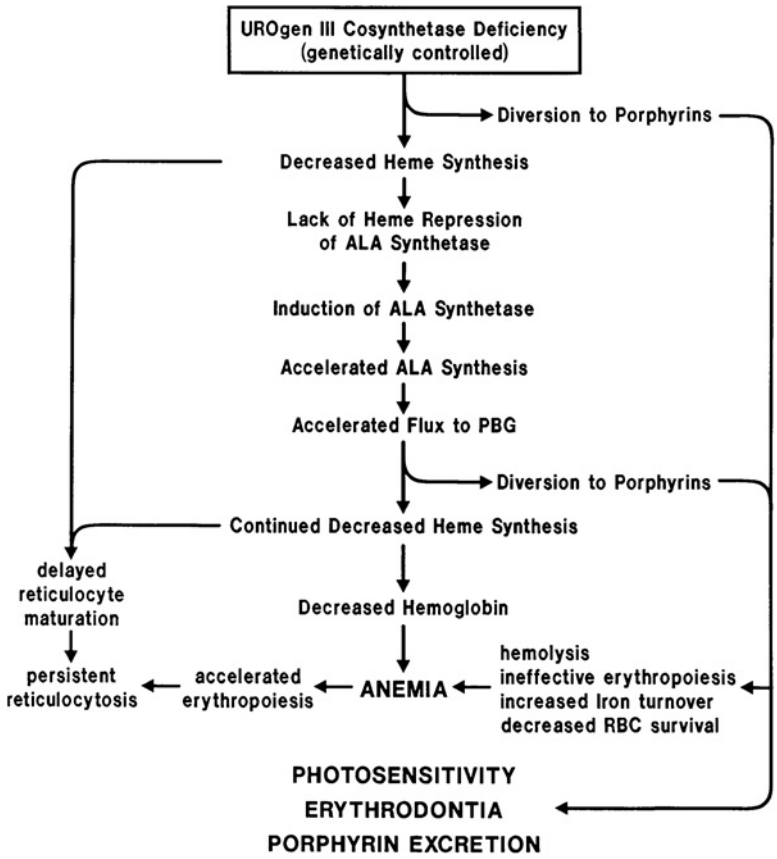

FIGURE 8-6 Metabolic basis of bovine congenital erythropoietic porphyria. The fundamental defect is a deficiency of UROgenIII-Cosyn leading to the accumulation of type I uroporphyrins and coproporphyrins. These type I porphyrins account for the clinical, hematological, and biochemical features of this disease.

recognized in humans (Harber *et al.*, 1964; Redeker *et al.*, 1963). It is inherited as a dominant autosomal trait (Romeo, 1977). Patients do not have the major signs of CEP such as anemia, porphyrinuria, or discolored teeth. Photosensitivity of the skin is the only significant clinical manifestation of the disease, and this is associated with a high plasma protoporphyrin concentration. In the laboratory, the most striking findings are the high concentrations of PROTO IX in the erythrocytes and feces.

In cattle, EPP is inherited as an autosomal recessive trait in contrast to humans and may be sex linked because to date it has only been seen in females. The photosensitivity also seems to diminish in adult life. Affected cattle also do not have anemia, porphyrinuria, or discoloration of the teeth. Erythrocyte and fecal protoporphyrins are very high in comparison to normal cows (Ruth *et al.*, 1977).

The fundamental enzymatic defect in bovine EPP is a deficiency of ferrochelatase (FER-Ch) (Ruth *et al.*, 1977), which results in the accumulation of PROTO IX. Low FER-Ch was found in all tissues of EPP calves so that the defect is a total body defect.

3. *Porphyria of Swine*

Porphyria in swine was first recognized in New Zealand by Clare and Stephens (1944) and later in Denmark (Jorgensen and With, 1955). Porphyria in swine is inherited as a simple autosomal dominant trait. Except for the very severe cases, there appears to be little or no effect on the general health of the pig. Photosensitivity is not seen even in the white pigs. The predominant feature in the affected pig is a characteristic reddish discoloration of the teeth, which fluoresces on exposure to ultraviolet light. Porphyrin deposition in the teeth of the newborn pig is virtually pathognomonic of porphyria in swine. Occasionally, darkly discolored teeth may not fluoresce, but porphyrins may be extracted from these teeth with 0.5N HCl (With, 1955). Similar, though less apparent, deposition occurs in the bones. The porphyrins are principally URO I and have been found in concentrations of up to 200μg/g of teeth or bones. The liver, spleen, lungs, kidneys, bones, and teeth are also discolored by another dark pigment, the nature of which is unknown.

The urine of the affected pig is discolored only in the more severely affected pig. The 24-h urinary excretion of uroporphyrins ranged between 100 and 10,000μg and for coproporphyrin, only 50μg. These were both the type I isomers. PBG is absent in the urine. Close similarities in this pattern of porphyrin excretion to that found in bovine CEP are apparent, but the localization of the defect in the erythropoietic tissue has not been established. This disease has not been observed in pigs since the original occurrences.

4. *Porphyria of Cats*

Porphyria in cats was first reported in a male kitten (Tobias, 1964). One of its three littermates and kittens from a previous litter were also reported to have had the same unusually discolored teeth. The kitten's teeth were brown and fluoresced red under ultraviolet light. Its urine was amber colored and was qualitatively positive for uroporphyrin, coproporphyrin, and porphobilinogen. There was no evidence of anemia or photosensitization. These cats had been kept indoors all their lives. One of these cats was the propositus for a porphyric cat colony (Glenn *et al.*, 1968). The inheritance of the porphyria in these cats is a simple autosomal dominant trait analogous to that seen in swine.

Detailed studies of the porphyria in a family of Siamese cats has been reported (Giddens *et al.*, 1975) in which excessive accumulation of URO I, COPRO I, and PROTO IX were observed in erythrocytes, urine, feces, and tissues. These cats had photosensitivity, severe anemia, and severe renal disease. The researchers concluded that the principal defect in these cats was a deficiency of UROgenIII-Cosyn similar to CEP of humans and cows.

5. *Normal Porphyrias*

All fox squirrels (Sciurus niger) have red bones caused by the accumulation of URO I and COPRO I (Flyger and Levin, 1977). The fox squirrel porphyria resembles the CEP of humans, cows, and cats by having a deficiency of UROgenIII-Cosyn, type I porphyrins in their urine and feces, and discolored bones, teeth, and tissues, which fluoresce on exposure to ultraviolet light. There is increased erythropoiesis but no apparent hemolytic anemia, no photosensitivity, or any other clinically deleterious effects. These relatively benign effects are most likely due to their thick hair coats and nocturnal living habits. It is interesting that an enzyme deficiency with serious health effects in other animals should have evolved as a "normal" characteristic in the fox squirrel. This is understandable when one appreciates that CEP cattle always kept indoors and protected from sunlight tend to thrive and reproduce normally.

The UROgenIII-Cosyn deficiency is found only in the fox squirrel and not in the closely related gray squirrel (*Sciurus carolinensis*). Urine porphyrin excretion in the fox squirrel is 10-fold greater than in the gray squirrel and is markedly increased when erythropoiesis is stimulated by bleeding. The UROgenIII-Cosyn of fox squirrel erythrocytes is very heat sensitive, and this may indicate that its CEP is due to an increased lability of the enzyme.

In the feathers of certain brightly colored birds (e.g., Touracos and in certain lower animals and microorganisms), porphyrins accumulate but these appear to be normal phenomena.

C. Hepatic Porphyrias

This group of diseases is seen only in humans as naturally occurring diseases. They constitute the most common group of porphyrias seen in humans. The salient features of this group of porphyrias are also summarized in Table 8.2. As the name of this group implies, the predominant site of the metabolic defect is localized in the liver, and the group is further subdivided on the bases of their principal clinical manifestations. Specific enzyme deficiencies have been identified for all forms of hereditary porphyria (Table 8.2). As mentioned earlier, their genetic heterogeneity accounts for the wide variety of symptoms.

1. *δ-Amino-Levulinic Acid Dehydratase Porphyria*

This rare hepatic form of porphyria has a marked deficiency of the enzyme δ-amino-levulinic acid dehydratase (ALA-D) in the homozygous state (Brandt and Doss, 1981; Doss *et al.*, 1979) and is referred to as ALA-D porphyria (ADP). It is characterized by neurological symptoms without skin photosensitivity. It is inherited as an autosomal recessive trait. A similar though less marked ALA-D deficiency that was without symptoms was reported (Bird *et al.*, 1979), and this is thought to be the heterozygous state of the deficiency.

2. *Acute Intermittent Porphyria*

Acute intermittent porphyria (AIP) is a common form in humans characterized by acute abdominal pain and neurological symptoms. Photosensitivity is not a feature of this form. Most patients are not clinically affected unless some form of aggravating factor is present. The attacks are precipitated by a large number of causative factors, the principal ones being barbiturates, sulfonamides, estrogens, and alcohol. The disease occurs more commonly in the adult female than in the male. The principal urinary finding is the excretion of large amounts of ALA and PBG. This is in keeping with the hereditary deficiency of UROgenI-Syn (PBG-D) in this disease (Strand *et al.*, 1970). AIP is the major autosomal dominant form of hepatic porphyria.

3. *Porphyria Cutanea Tarda*

Porphyria cutanea tarda (PCT) is caused by a deficiency of UROgen-D and presents as both a sporadic form and a familial form. The sporadic form is the acquired form of PCT and is the most common of all forms of human porphyria. The familial form is inherited as an autosomal dominant. As the name implies, the characteristic clinical signs of PCT are the photosensitive lesions of the skin. The disease occurs in mid to late adult life and common precipitating causes of this disease are alcohol and

estrogens. The disease can be successfully treated by the avoidance of alcohol and estrogens. There is a decrease in hepatic UROgen-D in both forms, but the enzyme deficiency is found in extrahepatic tissues only in the familial form (Pimstone, 1982). In the sporadic form, erythrocyte UROgen-D activity is normal, whereas in the familial form, erythrocyte UROgen-D is less than 50% of normal (McManus *et al.*, 1988). The erythrocyte UROgen-D assay is difficult and not readily available, therefore indirect means of distinguishing the sporadic form from the familial are used. One of the most simple, indirect methods has been to assay the plasma γ-glutamyltransferase activity (GGT). Sporadic PCT has a significant increase in GGT, whereas the familial form has normal GGT activity (Badcock *et al.*, 1993). Furthermore, the ratio of fecal COPRO III:COPRO I when combined with the plasma GGT was found to give an even more accurate differentiation of the sporadic form from the familial form (Badcock *et al.*, 1995).

4. *Hepatoerythropoietic Porphyria*

Hepatoerythropoietic porphyria (HEP) is a form that clinically resembles congenital erythropoietic porphyria (CEP), but there is a severe deficiency of UROgen-D as in PCT. It is thought to be the homozygous form of familial PCT. HEP is characterized by a severe photosensitivity, but there is no liver involvement.

5. *Harderoporphyria*

This is a rare form of porphyria in which the propionate group on the A ring only is converted to a vinyl group. The normal next step of B ring conversion is somehow disrupted. There is a deficiency of COPROgenIII-Ox, but the mechanism explaining why the groups on both rings are not oxidized is unknown.

6. *Hereditary Coproporphyria*

Hereditary coproporphyria (HCP) is clinically similar to PCT with a mild cutaneous photosensitivity, and it may also have neurological symptoms as in AIP. Like AIP, HCP is commonly precipitated by drugs and alcohol. As in harderoporphyria, COPROgenIII-Ox is the deficient enzyme.

7. *Variegate Porphyria*

The symptoms of variegate porphyria (VP) are generally more variable than the other forms but in most cases, acute abdominal pain and photosensitivity are seen. VP is most common among the South African white population. VP is inherited as an autosomal dominant. There is a deficiency of PROTOgenIII-Ox, which can be observed in cultured fibroblasts and in leukocytes of VP patients. Hift *et al.* (2004) found plasma fluorescence scanning to be a more sensitive and specific test for VP than fecal porphyrin analysis.

D. Porphyrinurias (Acquired Toxic Porphyrias)

1. *Chemical Porphyrinurias*

The two major forms of the porphyrinurias are those due to organic chemical intoxication and to heavy metal poisonings, mainly lead. Experimentally, hexachlorobenzene (HCB) (Elder *et al.*, 1976), 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) (Elder and Sheppard, 1982), allylisopropylacetylcarbamide (Sedormid) (Schmid and Schwartz, 1952), or dihydrocollidine (DHC) (Granick and Urata, 1963) has been used to produce the hepatic forms of porphyria.

2. *Lead Poisoning*

Lead poisoning occurs in all domestic animals and is a significant clinical problem, particularly in the dog. In the dog as in other animals, the principal clinical features are related to the gastrointestinal and the nervous systems. Anemia is usually seen only in the long-standing chronic lead toxicities. The anemia has certain features that suggest lead poisoning but are not diagnostic. The anemia is a mild to moderate normocytic normochromic anemia with basophilic stippling and nucleated erythrocytes (NRBC) out of proportion to the degree of anemia. Zook *et al*. (1970) considered that $>$15 stippled cells per 10,000 erythrocytes is suggestive of and that $>$40 stippled cells per 10,000 erythrocytes is diagnostic of lead poisoning in the dog. Stippling is thought to be accumulated ribosomal RNA aggregates that have not been normally degraded to their nucleotides and subsequently dephosphorylated by pyrimidine-5′ nucleotidase (P5NT). Lead has been shown to decrease the activity of the dephosphorylating enzyme, P5NT in humans (Valentine *et al.*, 1976) and in calves (George and Duncan, 1982).

Lead is known to have widespread toxic effects on sulfhydryl-, carboxyl-, and imidazole-containing proteins that would include enzymes, cell proteins, globins, and membrane proteins (Fell, 1984). However, only a few are altered specifically and significantly to be of diagnostic value. Globin synthesis and therefore hemoglobin synthesis is disrupted, and this is the major mechanism of the anemia of lead poisoning. The anemia, however, occurs late in chronic lead poisoning, and its nonspecific nature makes it of less diagnostic importance than is usually attributed to it.

A major focus is on the enzyme systems of heme synthesis because several of the enzymes are very sensitive in early exposure to small quantities of lead. The most sensitive are ALA-D and FER-Ch, and these enzymes and their accumulated substrates are widely used as screening tests

for lead exposure. Erythrocyte ALA-D is strongly inhibited by lead, and as a result, ALA rises in plasma and is excreted in the urine. Measurement of ALA is difficult, and the results lack sensitivity for low-level lead exposure; therefore, instead of its substrate ALA, erythrocyte ALA-D is more commonly assayed. Farant and Wigfield (1982), using the ratio of ALA-D activities assayed at two different pH's, demonstrated ALA-D inhibition at blood lead concentrations of 10 to 15μg/dl (0.50 to 0.70μmol/l). They found this to be a highly sensitive and reliable index of the blood lead concentration.

Coproporphyrin also rises in plasma and is excreted in urine, and like ALA, it is also difficult to measure and lacks sensitivity. Hence, this method is not used as an index of lead poisoning.

FER-Ch is the second major enzyme that is strongly inhibited by lead, and as a result, PROTO IX accumulates in the erythrocytes. This PROTO IX is a zinc complexed PROTO IX instead of the "free" PROTO IX. Piomelli *et al*. (1982) found that erythrocyte zinc PROTO IX increased when blood lead concentrations were at 15 to 18μg/dl (0.75 to 0.85μmol/l).

It is not quite as sensitive an index of blood lead concentration as ALA-D but is well below the diagnostic criteria for lead poisoning. George and Duncan (1981) found marked elevations in erythrocyte PROTO IX in experimental lead poisoning in calves. Modern fluorometers specifically designed to measure porphyrins have greatly simplified the assay. For these reasons, the current test of choice to monitor lead exposure is the blood zinc PROTO IX concentration.

The final diagnosis of lead poisoning ultimately rests on the measurement of blood lead concentration, and this is best done using flame atomic absorption spectrophotometry. In children, a blood lead concentration of $<30\mu$g/dl (1.45μmol/l) is currently regarded as normal, but it has been shown that zinc PROTO IX rises at blood lead levels of half that amount (Piomelli *et al.*, 1982). It is clear that the heme synthetic pathway is affected at blood lead concentrations well below that considered normal. Zook *et al*. (1970) reported a normal range for blood lead in the dog of 10 to 50μg/dl (0.48 to 2.41μmol/l) and considered a blood lead concentration of $>60\mu$g/dl (2.90μmol/l) diagnostic of lead poisoning. In the domestic rabbit, the blood lead concentration is reported to be 2 to 27μg/dl (0.10 to 1.30μmol/l) (Gerken and Swartout, 1986). Therefore, lead concentrations of $>30\mu$g/dl (1.45μmol/l) are considered diagnostic of lead poisoning in the dog and in all animals.

Chapter 9

Iron Metabolism and Its Disorders

John W. Harvey
Department of Physiological Sciences
College of Veterinary Medicine
University of Florida
Gainesville, Florida

I. INTRODUCTION

Iron is an essential nutrient required in a wide variety of metabolic processes. In solution, iron exists in two oxidation states, ferrous (Fe^{+2}) and ferric (Fe^{+3}), which can donate or accept electrons, respectively. Iron is typically in the Fe^{+2} state for transport across membranes and in the Fe^{+3} state when bound to transport and storage proteins. Iron may be in either oxidation state when present in heme and iron-sulfur (Fe-S) cluster-containing proteins. The ability of iron to vary in oxidation state and redox potential, depending on the ligands it forms, enables iron to serve multiple functions. Iron-containing proteins are critical for oxygen transport and storage, respiration, DNA synthesis, citric acid cycle function, and various enzymatic reactions. Unfortunately, the same physical characteristics that allow iron to function as a cofactor in controlled redox biochemistry also makes iron potentially toxic to cells, because of its ability to catalyze the formation of reactive oxygen species. The binding of iron to coordinating ligands, such as O, N, and S, in proteins and the tight regulation of iron uptake, transport, and storage tends to shield iron from reactions with molecular oxygen that generate free radicals and injure tissues (Ryan and Aust, 1992).

Iron is absorbed from the diet in the small intestine and transferred to plasma, where it is bound to transferrin for transport to cells within the body. Once inside the body, iron cycles in a nearly closed system (Fig. 9-1) because little iron is lost in domestic animals unless hemorrhage occurs (Finch *et al*., 1978). About 75% of the iron present in plasma will be transported to the bone marrow for incorporation into hemoglobin in developing erythroid cells (Smith, 1997). The remaining plasma iron is taken up by nonerythroid tissues, primarily the liver (Koury and Ponka, 2004). Erythrocytes containing hemoglobin normally circulate for several months before being phagocytized by macrophages when senescent. After phagocytosis, erythrocytes are lysed, hemoglobin is degraded, and iron is released. Most iron from degraded hemoglobin is quickly released back into plasma, but a small amount may be stored as ferritin or hemosiderin within macrophages, which is released more slowly into plasma. The vast majority of iron entering plasma each day comes from macrophage release.

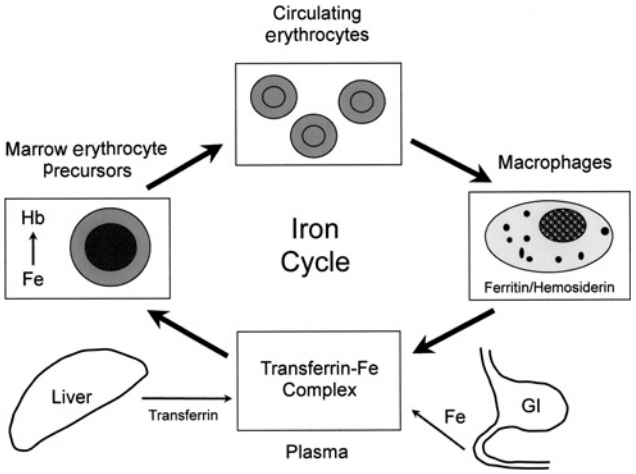

FIGURE 9-1 Iron cycle. Iron (Fe) is highly conserved in the body. Iron in plasma is bound to transferrin, a transport protein that is synthesized in the liver. Iron is transported to all tissues, but most iron is utilized to synthesize hemoglobin in developing erythroid cells. Aged blood erythrocytes are phagocytized by macrophages, and hemoglobin is degraded. Released iron is either returned to plasma or stored in macrophages as ferritin and hemosiderin. Nearly all of the iron in plasma under normal conditions comes from the release of iron by macrophages that have phagocytized and degraded erythrocytes (large arrow). Only about 3% of the iron in plasma results from gastrointestinal (GI) enterocyte absorption in normal individuals (small arrow).

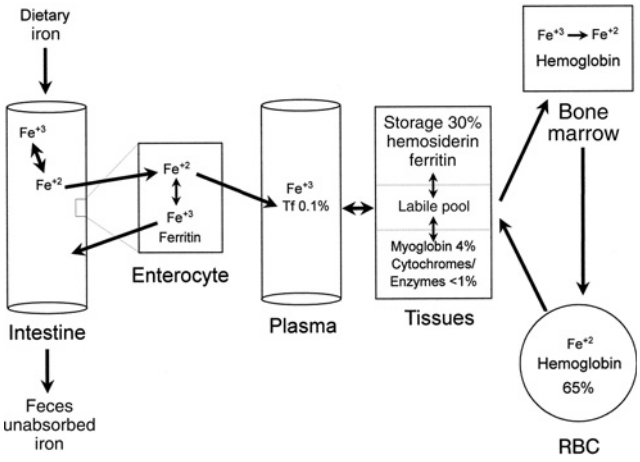

FIGURE 9-2 Overview of iron metabolism. Ferric iron (Fe^{+3}) ions present in the diet are reduced to ferrous iron (Fe^{+2}) ions and absorbed by duodenal enterocytes. Once inside enterocytes, Fe^{+2} may be oxidized and stored as ferritin or exported to plasma where it is oxidized and bound to transferrin (Tf) for transport to the tissues. Iron stored as ferritin is returned to the small intestine lumen when enterocytes are sloughed at the tip of the villus. Iron is incorporated into many proteins in all tissues, but most iron is utilized to synthesize hemoglobin in developing erythroid cells, where Fe^{+3} must be reduced to Fe^{+2} during heme synthesis. Aged blood erythrocytes are phagocytized by macrophages. Hemoglobin is degraded and iron is either returned to plasma or stored in macrophages as ferritin and hemosiderin. Modification of Kaneko, 1964, with permission.

Iron absorption from the small intestine compensates for the small amount of iron lost each day, largely from skin exfoliation and cell desquamation in urine, bile, sweat, and feces (Beutler, 2006b; Underwood, 1977).

II. IRON DISTRIBUTION

The relative distribution in the body is shown in Figure 9-2. Normally about 60% to 70% of total body iron is present in hemoglobin. About 20% to 30% is stored as ferritin and hemosiderin (primarily within macrophages and hepatocytes), 3% to 7% is present in myoglobin (with the higher values occurring in myoglobin-rich species such as dogs, horses, and cattle), 1% is present in enzymes, and less than 0.1% is bound to transferrin in plasma (Ponka *et al*., 1998).

A. Hemoglobin

Hemoglobin accounts for more than 90% of the protein within erythrocytes (Quigley *et al*., 2004). It contains 0.34% iron by weight; consequently, each milliliter of packed erythrocytes contains 1.1mg of iron. Hemoglobin plays vital roles in oxygen transport, carbon dioxide transport, and buffering of hydrogen ions (see Chapter 7 for details). It is a tetrameric protein consisting of four polypeptide globin chains, each of which contains a heme prosthetic group. Heme is a planar molecule composed of the tetrapyrrole protoporphyrin IX, containing a central iron ion. A hemoglobin tetramer is capable of binding four molecules of oxygen when fully saturated. To bind oxygen, iron ions within heme molecules must be in the Fe^{+2} state. Methemoglobin is formed when iron is oxidized to the Fe^{+3} state. Fortunately, the oxidation of Fe^{+2} ions to Fe^{+3} ions is minimized by the location of heme groups within hydrophobic pockets of globin chains, and methemoglobin that forms can be reduced enzymatically within erythrocytes.

B. Storage Iron

Ferritin is a ubiquitous iron storage protein that is detected in almost all animal and plant tissues, as well as in bacteria and fungi. The binding of iron in ferritin minimizes its potential to catalyze the formation of damaging free radicals (Arosio and Levi, 2002). Each mammalian ferritin molecule is composed of a protein shell of 24 apoferritin H or L monomeric subunits surrounding a central cavity that can accommodate as many as 4000 iron atoms in a ferric hydroxide core. The inner surface of the protein shell has catalytic sites (associated with H subunits) that promote the oxidation of Fe^{+2} ions to Fe^{+3} ions (Arosio and Levi, 2002). The L subunit lacks ferroxidase activity, but it is more efficient than the H subunit in the enucleation and mineralization of iron in the ferritin core (Levi *et al*., 1994). Subunit composition varies between cell types, with the H subunit predominating in erythrocytes and muscle, and the L subunit predominating in liver, spleen, and

plasma of humans (Beutler, 2006b). Dog and horse ferritin H and L subunit cDNA clones have been prepared and sequenced from various tissues. The amino acid residues involved in the ferroxidase center and in iron nucleation were conserved in H and L subunits of canine and equine ferritins, respectively (Orino *et al*., 2005).

Although iron is generally stored in cells as ferritin, iron overloaded cells (macrophages in normal animals) contain another storage form of iron called hemosiderin, which represents partially degraded ferritin that forms after uptake by lysosomes (Anderson and Frazer, 2005; Ponka *et al*., 1998). Surprisingly little is known about how ferritin releases its iron in cells. It is possible that intracellular iron release requires catabolism in lysosomes (Ponka *et al*., 1998).

Free cytoplasmic ferritin molecules are water soluble and visible by electron microscopy, but they are not visible by light microscopy unless present in large aggregates. Hemosiderin is insoluble and visible by light microscopy. Hemosiderin appears gray to black in aspirate smears stained with routine bloodstains, golden-brown in H & E-stained tissue sections, and blue when stained with Prussian blue stain. There is a fairly good correlation between Prussian blue staining of tissues and the measurement of storage iron chemically, but staining is less sensitive in detecting storage iron (Blum and Zuber, 1975; Franken *et al*., 1981). Storage iron can be present as ferritin that is not identified by Prussian blue staining (Blum and Zuber, 1975).

Major sites of iron storage include the liver, spleen, and bone marrow. The amount stored in a given tissue may vary by species. The liver appears to be the major site of iron storage in humans, but the spleen is reported to be more important in horses and cattle (Blum and Zuber, 1975; Franken *et al*., 1981; Kolb, 1963). The relative contributions of ferritin and hemosiderin to the storage iron pool vary with species, organ, and amount of iron stored. In normal adults, ferritin concentration generally equals or exceeds hemosiderin concentration in the liver, but hemosiderin concentration typically exceeds ferritin concentration in the spleen. When iron stores are high, hemosiderin tends to accumulate more than ferritin, and when iron stores are low, ferritin tends to be higher than hemosiderin (Kolb, 1963; Underwood, 1977). Total body iron stores vary at birth between species, with considerable iron stores in humans, dogs, cattle, goats, horses, and rabbits; intermediate iron stores in cats and rodents; and minimal iron stores in pigs (Keen *et al*., 1981; Kolb, 1963; Underwood, 1977). Iron stores decrease in nursing animals when demands for growth exceed iron absorption from milk (Blum and Zuber, 1975; Harvey *et al*., 1987a; Keen *et al*., 1981; Kolb, 1963).

C. Myoglobin

Myoglobin is an oxygen-binding protein located primarily in muscles. It contains one heme group per molecule and has a structure similar to that of hemoglobin monomers. Myoglobin serves as a local oxygen reservoir that can temporarily provide oxygen when blood oxygen delivery is insufficient during periods of intense muscular activity. Iron within the heme group must be in the Fe^{+2} state to bind oxygen. If iron is oxidized to the Fe^{+3} state, metmyoglobin is formed. The total amount of myoglobin in an animal depends on body weight, degree of muscle development, and the myoglobin concentration in muscle, which varies between muscle types (red muscle is rich in myoglobin and white muscle is myoglobin poor). The myoglobin concentration in muscle varies with species. For example, the myoglobin concentration in muscles of racehorses is about 6 times that of human muscles (Kolb, 1963). Because much of the iron in muscle is in myoglobin, the percentage of total body iron present in muscle is higher in horses than in humans.

D. Tissue Iron

In addition to the need for iron in hemoglobin and myoglobin, iron is vital in various metabolic processes. Nearly half of the enzymes in the citric acid cycle either contain iron or need it as a cofactor. Heme-containing proteins include catalase, peroxidase, and cytochromes. Cytochromes a, b, and c are required for oxidative phosphorylation in mitochondria. Other cytochromes, such as cytochrome P450 located in the endoplasmic reticulum, function in oxidative degradation of endogenous compounds and drugs. Nonheme iron, in Fe-S compounds and metalloflavoproteins, is required for enzymes including succinate dehydrogenase, cytochrome c reductase, nicotinamide adenine dinucleotide dehydrogenase, xanthine oxidase, and aconitase (Smith, 1997).

E. Plasma Iron

Nearly all of the iron present in plasma in healthy animals is bound to apotransferrin, a 72 to 83 kDa glycoprotein (containing 2 to 4 sialic acid residues/molecule) to form transferrin (Welch, 1990). Apotransferrin is a bilobar protein with two binding sites for Fe^{+3} that is synthesized by the liver. It is believed to have evolved from duplication of a primordial gene coding for a protein with one iron-binding site. The concomitant binding of a bicarbonate anion is required for each Fe^{+3} molecule bound to apotransferrin (Ponka *et al*., 1998). Normally 25% to 50% of the plasma apotransferrin binding sites are saturated with iron. When one or two Fe^{+3} ions are bound, the protein is referred to as monoferric or diferric transferrin, respectively. There is a random distribution of iron on binding sites (Fig. 9-3), with apotransferrin predominant at low plasma iron concentrations and diferric transferrin predominant at high plasma iron concentrations (Huebers *et al*., 1984). Monoferric transferrin is predominant at 50% saturation of transferrin

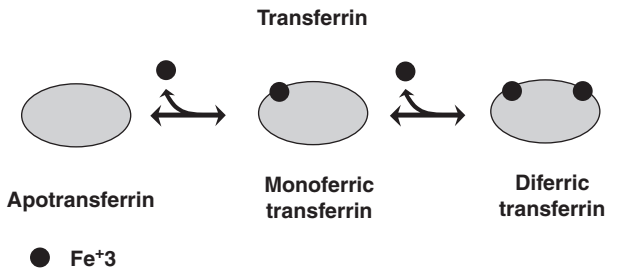

FIGURE 9-3 Apotransferrin is a bilobar protein with two binding sites for Fe^{+3} ions. When one or two Fe^{+3} ions are bound, the protein is referred to as monoferric or diferric transferrin, respectively. There is a random distribution of iron on binding sites, with apotransferrin predominant at low plasma iron concentrations and diferric transferrin predominant at high plasma iron concentrations. Monoferric transferrin is predominant at 50% saturation of transferrin with iron, with lesser amounts of apotransferrin and diferric transferrin present.

with iron, with lesser amounts of monoferric and diferric iron present. Transferrin is primarily responsible for iron transport throughout the body.

Ferritin is another iron-binding protein that can be measured in plasma. Although ferritin is released in small amounts from the liver and macrophages and can be taken up by cells (especially hepatocytes), it is of little or no importance in iron transport under normal conditions. Ferritin is normally present in very low concentrations in plasma and has low iron content; consequently, it contributes little to the plasma iron pool (Ponka *et al*., 1998).

Nontransferrin bound iron (NTBI) has been measured in people with severe iron overload, when transferrin is fully saturated, and in mice with hereditary hypotransferrinemia. The nature of NTBI is unclear, but it may be complexed with low-molecular-weight molecules such as citrate, sugars, and amino acids or nonspecifically bound to albumin and other plasma proteins. NTBI has the potential to promote the formation of oxygen-free radicals and cause tissue injury (Ponka *et al*., 1998).

III. IRON ABSORPTION

Iron is not actively excreted from the body and minimal iron loss normally occurs, except in menstruating primates and egg-laying birds (Finch *et al*., 1978; Kolb, 1963); consequently, the amount within the body must be controlled at the point of absorption. Iron absorption from the diet depends on age, species of the animal, iron stores, changes in rate of erythropoiesis, hypoxia, inflammation, and pregnancy, as well as the amount and chemical form of iron ingested (Frazer and Anderson, 2005; Mackenzie and Garrick, 2005; Stewart *et al*., 1953). A low percentage (0.2% to 4.5%) of dietary iron is generally absorbed in normal adult animals (Finch *et al*., 1978; Nathanson *et al*., 1985). Iron absorption occurs through mature villus enterocytes of the duodenum and proximal jejunum. Absorption

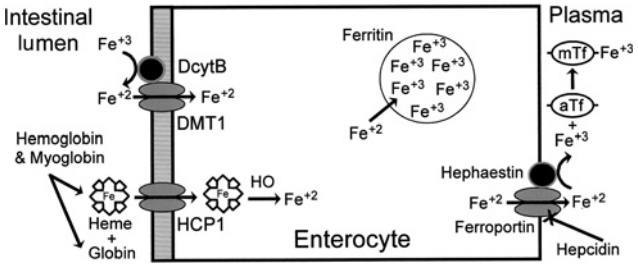

FIGURE 9-4 Mechanisms of iron absorption. Ferrous iron (Fe^{+2}) ions are transported into enterocytes in the duodenum by the divalent metal transporter-1 (DMT1) after reduction of ferric iron (Fe^{+3}) ions using a duodenal cytochrome b (DctyB). Heme is transported into enterocytes using heme carrier protein-1 (HCP1). Once inside, inorganic iron is released from heme by the action of the heme oxygenase (HO) reaction. Fe^{+2} ions are exported from enterocytes using ferroportin, oxidized to Fe^{+3} using hephaestin, and bound by apotransferrin (aTf) to form monoferric transferrin (mTf) and diferric transferrin (not shown). Hepcidin in plasma inhibits iron export to plasma by interacting directly with ferroportin, leading to ferroportin's internalization and lysosomal degradation. Fe^{+2} not transported to plasma is stored as ferritin following oxidation to Fe^{+3}. Iron stored as ferritin is returned to the small intestine lumen when enterocytes are sloughed at the tip of the villus.

includes iron uptake at the apical membrane of the enterocyte, translocation within the cytoplasm, and transfer to plasma at the basolateral membrane of the enterocyte. Iron can be taken in by enterocytes as free ions or as heme by different pathways (Fig. 9-4). The relative importance of these pathways varies depending on animal species and diet (Steele *et al*., 2005).

Compounds in the diet such as phytates, tannins, and phosphates bind iron in insoluble complexes that cannot be absorbed. Most nonheme iron in the diet is in the Fe^{+3} state. Dietary Fe^{+3} is solubilized from food by hydrochloric acid in the stomach and binds to mucins and various small molecules, which keep the iron soluble and available for absorption in the more alkaline environment of the small intestine (Mackenzie and Garrick, 2005). Unbound Fe^{+3} is prone to hydrolysis, forming essentially insoluble ferric hydroxide and oxohyroxide polymers (Ponka *et al*., 1998). The most important pathway for nonheme iron uptake utilizes the divalent metal transporter-1 (DMT1). A proton-coupled process facilitates this uptake. Although DMT1 has the highest affinity for iron, it can also transport manganese and potentially other divalent metal ions. Fe^{+3} ions must be reduced to Fe^{+2} ions before they can be transported into the enterocyte via the DMT1. Ascorbic acid in the diet or from gastric or biliary secretions promotes the reduction of Fe^{+3} ions. Although some Fe^{+3} ion reduction may occur by direct interaction with ascorbic acid, most reduction appears to rely on the presence of one or more brush border ferrireductase enzymes. A duodenal cytochrome b (DcytB) is believed to be important in this regard, but other intestinal ferrireductases may also exist (Mackenzie and Garrick, 2005).

Although the dominant role of DMT1 is acknowledged, debate continues as to whether important alternative

pathways of nonheme iron uptake exist. The role of the protein mobilferrin needs further evaluation. It might be part of a separate uptake pathway for Fe^{+3} ions, or it might interact with DMT1 in Fe^{+2} ion uptake (Conrad *et al*., 2000; Mackenzie and Garrick, 2005). Although humans absorb Fe^{+2} salts more readily from the intestine than the Fe^{+3} salts, dogs are reported to absorb both valence forms equally well (Moore *et al*., 1944). The reason for this difference is not known, but it could be related to a greater ability to reduce Fe^{+3} in the dog intestine, the presence of an important pathway for Fe^{+3} absorption in the dog intestine, or a greater ability to prevent the formation of insoluble Fe^{+3} complexes in the gastrointestinal tract of dogs.

Heme is released from dietary myoglobin and hemoglobin by the action of digestive enzymes. Dietary heme iron is generally more bioavailable than is nonheme iron and is an important nutritional source of iron in carnivores and omnivores. Heme enters duodenal enterocytes as an intact metalloporphyrin using a membrane protein named heme carrier protein 1 (HCP1) that has homology to bacterial metal-tetracycline transporters (Shayeghi *et al*., 2005). The expression of HCP1 is regulated pre- and posttranslationally in hypoxic and iron-deficient mice, respectively (Latunde-Dada *et al*., 2006b). Once inside the enterocyte, inorganic iron is apparently released from heme by the action of the heme oxygenase reaction, and this heme-splitting reaction appears to be the rate-limiting step in the absorption of iron contained within hemoglobin and myoglobin (Wheby and Spyker, 1981).

The intracellular transport of iron within the enterocyte is poorly understood. Iron ions in this labile iron pool (LIP) are presumably bound to chaperone molecules to keep them soluble. The nature of these chaperone molecules is yet to be defined. Iron ions can catalyze oxidative reactions that would injure the cell. The enterocyte protects itself against the toxic effects of excess iron by increasing apoferritin synthesis and incorporating the excess iron into ferritin. Consequently, iron uptake into enterocytes in excess of that needed for metabolic purposes or transferred to plasma is stored as ferritin. Iron stored as ferritin is returned to the small intestine when enterocytes are sloughed at the tip of the villus after 1 to 2 days (Steele *et al*., 2005).

The transfer of iron atoms from enterocytes to transferrin in plasma is mediated by ferroportin (also known as Ireg1), an iron transport protein located on the basolateral surface of mature enterocytes. In addition to ferroportin, the efflux of iron from enterocytes requires a copper-containing protein called hephaestin that is also located on the basolateral membranes of mature enterocytes. Hephaestin is a membrane-bound ferroxidase that has significant homology to the plasma protein ceruloplasmin. Hephaestin's function may relate to its ability to oxidize Fe^{+2} ions to Fe^{+3} ions for binding to transferrin in plasma (Steele *et al*., 2005). Sex-linked anemia (sla) mice have a block in mucosal iron transfer to plasma, with resultant microcytic hypochromic anemia because these animals have an inherited hephaestin defect (Wessling-Resnick, 2006).

Components of brush border iron uptake, including DMT1 and DcytB, are strongly influenced by the iron concentration within enterocytes, with increased components expressed when intracellular iron content is low and decreased components expressed when iron content is high (Frazer and Anderson, 2005). These locally responsive changes in brush border transport components help buffer the body against the absorption of excessive iron, but it is the control of the basolateral transport of iron from enterocytes to plasma that represents the primary site at which iron absorption is controlled (Steele *et al*., 2005). Hepcidin, a peptide produced by hepatocytes and secreted into plasma, inhibits iron transfer from enterocytes to plasma by interacting directly with ferroportin, leading to the internalization and lysosomal degradation of this iron export protein. Hepcidin production is increased in disorders such as iron overload and inflammation that result in decreased intestinal iron absorption. Hepcidin production is decreased in iron deficiency and disorders with increased erythropoiesis that result in increased iron absorption by enterocytes. Hephaestin expression is minimally affected by iron status (Vokurka *et al*., 2006).

IV. PLASMA IRON TRANSPORT

At physiological pH and oxygen tension, Fe^{+2} in solution is readily oxidized to Fe^{+3}, which is prone to hydrolysis and precipitation. In addition, unless appropriately chelated, iron in plasma can promote harmful oxygen radical formation and peroxidative tissue damage because of its catalytic action in one-electron redox reactions (Ponka *et al*., 1998). Fortunately, most iron in plasma is bound to the protein apotransferrin to form transferrin. The binding of iron to apotransferrin keeps iron molecules soluble and prevents iron catalyzed oxidative reactions. In addition, the vast majority of iron is transported to cells within the body following binding to apotransferrin in plasma (Ponka *et al*., 1998). At normal iron saturation levels, apotransferrin is most abundant in plasma, followed by monoferric transferrin and diferric transferrin (Ponka *et al*., 1998). Although diferric transferrin is normally much lower in concentration (about 10% of total transferrin) than monoferric transferrin, it accounts for most of the iron delivery to cells because diferric transferrin binds with 8- to 10-fold higher affinity to transferrin receptor-1 (TfR1) receptors on cells than does monoferric transferrin (Anderson and Frazer, 2005; Huebers *et al*., 1985). Apotransferrin has very low affinity for TfR1 receptors on cells (Ponka *et al*., 1998).

Iron turns over in 3 h or less in plasma (Smith, 1997). Nearly all of the iron in plasma under normal conditions comes from the release of iron by macrophages that have phagocytized and degraded erythrocytes (Fig. 9-1).

In contrast, only about 3% of the iron in plasma results from enterocyte absorption in normal individuals (Ponka *et al*., 1998).

V. REGULATION OF IRON METABOLISM

A. Intracellular Regulation of Iron Metabolism

1. Cx , R

The synthesis of a number of proteins important in iron metabolism, including apotransferrin, TfR1, apoferritin, DMT1, DcytB, ferroportin, iron responsive protein-1 (IRP1), and erythroid-specific 5-aminolevulinic acid synthase (eALAS or ALAS2), is regulated posttranscriptionally depending on intracellular iron content (Beutler, 2006b; Koury and Ponka, 2004; Latunde-Dada *et al*., 2006a). The mRNA for each protein contains one or more iron responsive elements (IREs), each consisting of a stem-loop structure. The IREs located at the 5′ end of mRNAs regulate translation, and IREs located at the 3′ end regulate mRNA stability. IRP1 contains an Fe-S (4Fe-4S) cluster and exhibits aconitase activity when cells are iron replete, but it lacks the Fe-S cluster and aconitase activity when cytoplasmic iron is scarce. IRP1 binds tightly to IREs when cytoplasmic iron content is low. IRP2 is closely related to IRP1, but it lacks aconitase activity. The regulation of IRP2 is mediated by proteosomal degradation when cellular iron is adequate, through binding to iron and possibly heme (Wingert *et al*., 2005). The binding of IRPs to IREs at the 5′ end of mRNAs (including apoferritin and eALAS) inhibits translation and protein synthesis from these mRNAs, but the binding of IRPs to IREs at the 3′ end of mRNAs (including TfR1 and intestinal DMT1) promotes mRNA stability, thereby enhancing protein synthesis from these mRNAs. When cytoplasmic iron content is high, IRPs are displaced from IREs, resulting in opposite effects on protein synthesis (Starzynski *et al*., 2004). Because of these controlling factors, TfR1 synthesis is higher and apoferritin synthesis is lower when cytoplasmic iron content is low, and TfR1 synthesis is lower and apoferritin synthesis is higher when cytoplasmic iron content is high (Napier *et al*., 2005).

2. M M R

Mitochondria are clearly central in the intracellular metabolism of iron; however, much remains to be discovered about their iron metabolism. The first enzyme reaction in heme synthesis (ALAS) and the final three enzyme reactions (including the insertion of Fe^{+2} into protoporphyrin IX by ferrochelatase to form heme) occur within mitochondria (see Chapter 8 for details), and proteins involved in Fe-S cluster synthesis are located within mitochondria. Fe-S cluster synthesis has been studied in microbes, but this pathway has not been well characterized in mammals. An inherited defect in a small protein called frataxin causes Friedreich ataxia in humans (Napier *et al*., 2005). This disorder results in spino/cerebellar ataxia, cardiomyopathy, and diabetes associated with mitochondrial iron overload in nerve and cardiac tissue, but not in erythroid cells. Frataxin participates in the synthesis of Fe-S clusters, possibly as a mitochondrial iron chaperone that shields this metal from reactive oxygen species and renders it bioavailable as Fe^{+2} (Napier *et al*., 2005). Heme and Fe-S clusters synthesized within mitochondria are used locally and exported from mitochondria for insertion into cytoplasmic and nuclear enzymes. With the exception of a limited number of enzymes, such a ribonucleotide reductase, that have mono- or di-iron-binding sites, iron in heme and Fe-S clusters accounts for most of the enzyme iron. Consequently, almost all of the iron within cells must transit through mitochondria to be functionally active (Arosio and Levi, 2002).

Mitoferrin, a member of the vertebrate mitochondrial solute carrier family (SLC25), appears to be essential for the uptake of iron into mitochondria (Shaw *et al*., 2006). The transporter needed to export heme from mitochondria to the cytoplasm is unknown; however, an inner mitochondrial membrane ATP-binding cassette protein B7 (ABCB7) appears to be required as an exporter for Fe-S clusters (Napier *et al*., 2005). Studies in a zebra fish shiraz model indicate that heme synthesis in erythroid cells is dependent on the production of Fe-S clusters (Wingert *et al*., 2005). Deficient Fe-S cluster formation (resulting from glutaredoxin 5 deficiency) and the resultant deficiency of Fe-S clusters in the cytoplasm of developing erythroid cells result in IRP1 binding to IREs of eALAS and the inhibition eALAS translation. A deficiency in eALAS activity in zebra fish erythroid cells results in deficient heme synthesis and the formation of hypochromic erythrocytes (Wingert *et al*., 2005). A human with mitochondrial glutaredoxin 5 deficiency has recently been described with sideroblast-like microcytic anemia and iron overload (Camaschella *et al*., 2007).

Mitochondria can store excess iron using mitochondrial ferritin (m-ferritin). Unlike cytoplasmic apoferritin, mitochondrial apoferritin lacks an IRE and may be transcriptionally regulated by iron. M-ferritin forms homopolymeric shells that have more homology with cytoplasmic H-ferritin chains than L-ferritin chains (Napier *et al*., 2005). M-ferritin concentration is very low in most cells, including erythroid cells, but it is markedly increased in disorders with mitochondrial iron overload, presumably limiting the oxidative damage generated by the excess iron. M-ferritin appears to be degraded to hemosiderin-like material within mitochondria, but the mechanism is unknown (Napier *et al*., 2005).

B. Systemic Regulation of Iron Metabolism

Hepcidin, a small antimicrobial peptide secreted by hepatocytes into the circulation, is an important regulator

of iron absorption in the small intestine, as well as iron transport across the placenta, and iron release from macrophages and hepatocytes. Hepcidin inhibits iron export from cells by interacting directly with ferroportin, leading to the internalization and lysosomal degradation of this iron export protein (Nemeth *et al*., 2004b). Hepcidin production is decreased in iron deficiency and disorders resulting in increased erythropoiesis, which has increased demand for iron (Pak *et al*., 2006). Decreased plasma hepcidin results in abundant ferroportin transporters on the basolateral surface of enterocytes and increased iron absorption and release to plasma. Ferroportin transporters are also abundant on the surface of macrophages and hepatocytes, promoting the export of iron from the storage pool to plasma (Ganz and Nemeth, 2006; Vokurka *et al*., 2006). Conversely, hepcidin production is increased and ferroportin transporter expression on cell surfaces is decreased in disorders such as iron overload and inflammation. As a consequence, increased plasma hepcidin results in decreased iron absorption from the intestine and decreased iron release to plasma from macrophages and hepatocytes (Steele *et al*., 2005). Hepcidin production is modulated by body iron requirements, which are largely influenced by the magnitude of erythropoiesis present (Pak *et al*., 2006; Wilkins *et al*., 2006). However, hepcidin production is also increased during inflammation by a pathway not dependent on body iron requirements (Steele *et al*., 2005). Possible mechanisms involved in the control of hepcidin production are discussed in the section on liver iron metabolism.

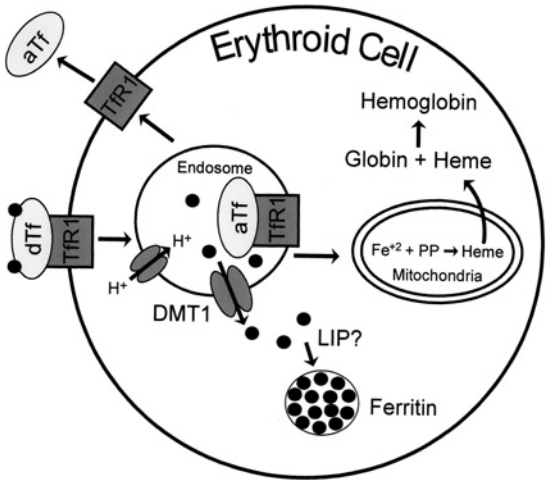

FIGURE 9-5 Iron metabolism in erythroid cells. Diferric transferrin (dTf) binds to transferrin receptor-1 (TfR1) on the surface of developing erythroid cells. The dTf-TfR1 complexes are internalized within an endosome and a proton pump decreases the pH in the endosome, resulting in release of iron ions (dark spheres). Iron is exported from the endosome using the divalent metal transporter-1 (DMT1). The resultant apotransferrin (aTf)-TfR1 complex is recycled to the cell membrane, where aTf is released from the cell, and the TfR1 is available for binding additional dTf. A direct interorganelle transfer of iron occurs between endosomes and mitochondria for insertion into protoporphyrin IX (PP) to form heme and for synthesis of iron-sulfur clusters (not shown). Some iron presumably exists in a cytoplasmic labile iron pool (LIP), with excess iron stored as ferritin.

VI. IRON METABOLISM IN CELLS

A. Iron Metabolism in Erythroid Cells

Although all cells require iron, erythroid precursors have iron requirements that far exceed the iron requirements of any other cell type because of the need for hemoglobin synthesis. Erythrocytes contain approximately 45,0000-fold more heme iron (largely in hemoglobin) than nonheme iron, and the delivery of iron to erythrocytes is stringently dependent on transferrin as the source of iron (Koury and Ponka, 2004). Diferric transferrin molecules bind to TfR1 on the surface of cells, and these transferrin-TfR1 complexes localize to clathrin-coated pits, which invaginate to initiate endocytosis (Beutler, 2006b). Clathrin is a structural protein that enables endocytosis through the formation of concave lattices with the plasma membrane. After the transferrin-TfR1 complexes are internalized as endosomes, a proton pump decreases the pH in the endosome, resulting in conformational changes in the proteins and subsequent release of Fe^{+3} ions from transferrin (Fig. 9-5). Iron is exported from the endosome using DMT1, following reduction with Steap3, an NADPH-dependent ferrireductase (Ohgami *et al*., 2005). The resultant apotransferrin-TfR1 complex is recycled to the cell membrane, where apotransferrin is released from the cell, and the TfR1 is again available for binding additional iron-containing transferrin molecules. Erythroid precursor cells in the bone marrow and reticulocytes that synthesize hemoglobin have TfR1 on their surfaces for iron uptake, but reticulocytes lose their TfR1 as they develop into mature erythrocytes (Ponka *et al*., 1998).

A direct interorganelle transfer of iron occurs between endosomes and mitochondria where iron is used for heme and iron-sulfur cluster synthesis (Sheftel *et al*., 2007). Some iron is presumably released from endosomes into a cytoplasmic labile iron pool (LIP), with excess cytoplasmic iron stored as ferritin. Various chaperone molecules have been proposed, but the nature of the iron in the LIP remains enigmatic (Beutler, 2006b). Iron stored as ferritin in the cytoplasm is not available for hemoglobin synthesis in erythroid cells (Ponka *et al*., 1998).

TfR1, apoferritin, and eALAS synthesis are regulated by the amount of intracellular iron present. An increase in the LIP stimulates apoferritin synthesis and inhibits TfR1 expression to minimize the potential of iron toxicity to the cell. A decrease in the LIP results in decreased apoferritin synthesis and increased TfR1 expression on cell surfaces to maximize iron uptake and use for heme synthesis (Beutler, 2006b). Erythrocytes coordinate protoporphyrin IX formation with the availability of iron by increasing the synthesis

of eALAS (rate limiting enzyme in porphyrin synthesis) when the LIP is high, and decreasing eALAS synthesis when the LIP is low.

Even though three different pathways are required for hemoglobin synthesis in erythrocyte precursors and reticulocytes, virtually no intermediates (iron, globin chains, or heme) accumulate in the cytoplasm of these cells. Several positive and negative feedback mechanisms account for the balanced production of these hemoglobin components. As already discussed, an increase in the LIP limits the uptake of additional iron by decreasing TfR1 synthesis. The availability of iron also limits, and thereby controls, heme synthesis. Free "uncommitted" heme inhibits iron uptake by erythroid cells and consequently heme synthesis. In addition, free heme is essential for the synthesis of globin chains at both the transcriptional and translational levels (Koury and Ponka, 2004). Consequently, globin synthesis does not occur in the absence of heme.

A heme exporter termed FLVCR is up-regulated on colony-forming units-erythroid (CFU-E) progenitor cells. It may provide a safety mechanism to prevent the accumulation of toxic amounts of cytoplasmic heme before globin synthesis is initiated. FLVCR is the cell surface receptor for feline leukemia virus, subgroup C (FeLV-C). Cats with FeLV-C infections develop erythroid aplasia because of a block at the CFU-E stage of erythroid development. It appears that the binding of FeLV-C to receptors on CFU-E progenitor cells inhibits heme export and results in apoptosis of these cells (Quigley *et al*., 2004).

In addition to the entry of iron into mitochondria for incorporation into protoporphyrin IX to form heme, iron is critical for Fe-S cluster biogenesis within mitochondria. Fe-S clusters are important prosthetic groups for numerous proteins involved in electron transfer, metabolic, and regulatory processes. Although Fe-S clusters are formed within mitochondria, Fe-S proteins are located in the nucleus and cytoplasm of cells, as well as in mitochondria (Lill *et al*., 2006). Recent studies in zebra fish provide evidence for a regulatory link between Fe-S cluster formation and heme synthesis. In the absence of Fe-S clusters, IRP1 binds to eALAS mRNA, which inhibits eALAS synthesis and heme production (Wingert *et al*., 2005).

B. Iron Metabolism in Macrophages

In contrast to erythroid cells, virtually no iron enters macrophages via plasma transferrin. Rather, nearly all iron enters macrophages by the phagocytosis of aged or prematurely damaged erythrocytes (Fig. 9-6) (Ponka and Richardson, 1997). Following phagocytosis, erythrocytes are lysed, and hemoglobin is degraded to heme and globin. The microsomal heme oxygenase reaction within macrophages degrades heme and releases iron. Most of the iron from degraded heme is quickly exported (half-life 34 min in dogs) from the macrophage and bound to plasma transferrin for transport

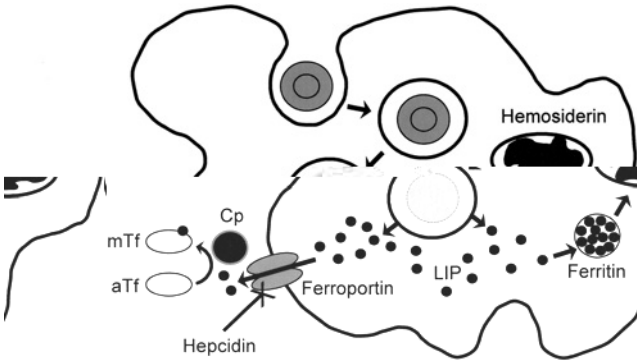

FIGURE 9-6 Iron metabolism in macrophages. Nearly all iron enters macrophages by the phagocytosis of aged or prematurely damaged erythrocytes. Following phagocytosis, erythrocytes are lysed, and hemoglobin is degraded to heme and globin. The microsomal heme oxygenase reaction within macrophages degrades heme and releases iron to the labile iron pool (LIP). Most of the released iron is exported from the macrophage by ferroportin as ferrous iron, oxidized to ferric iron by ceruloplasmin (Cp) in plasma, and bound to apotransferrin (aTf) to form monoferric transferrin (mTf) or diferric transferrin (not shown). Hepcidin in plasma inhibits iron export by interacting directly with ferroportin, leading to ferroportin's internalization and lysosomal degradation. Iron not rapidly released to plasma is stored within macrophages as ferritin, which may be degraded to hemosiderin within lysosomes.

to other cells (especially erythrocyte precursors in the bone marrow). The export of iron from macrophages is mediated by ferroportin and controlled by hepcidin as has been discussed for enterocytes (Verga Falzacappa and Muckenthaler, 2005). In contrast to enterocytes that utilize membrane-bound hephaestin, macrophages utilize the copper-containing plasma protein ceruloplasmin to oxidize Fe^{+2} ions to Fe^{+3} ions for binding to transferrin in plasma (Nemeth *et al*., 2004b). Iron not rapidly released to plasma is stored within macrophages as ferritin and hemosiderin. Iron that is stored within macrophages is released to plasma more slowly, with a half-life of 7 days in dogs (Fillet *et al*., 1974). The mononuclear phagocyte system accounts for much of the total body iron stores. Iron in the storage pool turns over slowly unless there is an increased need for iron for hemoglobin synthesis (Beutler, 2006b). In addition to iron export by ferroportin, a small amount of iron is apparently released as ferritin. It is not clear whether this is secreted or simply represents a "leak" from damaged cells (Ponka *et al*., 1998).

Macrophages can take up iron present in hemoglobin-haptoglobin complexes and heme-hemopexin complexes in plasma. Haptoglobin-hemoglobin complexes form following intravascular hemolysis when released hemoglobin binds with high affinity to the plasma glycoprotein haptoglobin. Heme-hemopexin complexes can also form secondary to intravascular hemolysis when hemoglobin heme is released, but additional heme-containing proteins (such as myoglobin) release heme that binds to the plasma protein hemopexin. The hemoglobin-haptoglobin complex undergoes endocytosis after binding to the hemoglobin scavenger receptor CD163. Expression of this receptor is

induced by interleukin-6 (IL-6), IL-10, and glucocorticoids (Graversen *et al*., 2002). The heme-hemopexin complexes undergo endocytosis after binding to CD91, also called the low-density lipoprotein receptor-related protein (LRP) or α_2-macroglobulin receptor. Once inside the cell, the complexes are transported to lysosomes for degradation, and receptors are recycled to the cell surface (Hvidberg *et al*., 2005).

C. Iron Metabolism in Hepatocytes

The liver is essential for normal iron homeostasis in the body. It regulates iron movement into and around the body through hepcidin synthesis, accounts for about 40% of the body iron stores, and is the site of synthesis of apotransferrin, ceruloplasmin, haptoglobin, and hemopexin plasma proteins (Anderson and Frazer, 2005).

Hepatocytes synthesize hepcidin in an endocrine manner to regulate iron metabolism in the body. Hepcidin is a small cationic peptide (25 amino acids in humans) that forms from a larger prohepcidin peptide (84 amino acids) (Park *et al*., 2001). Hepcidin has been cloned, expressed, and sequenced in several species, including dogs (Fry *et al*., 2004; Verga Falzacappa and Muckenthaler, 2005). Because of its small size, hepcidin is rapidly cleared by the kidney and is measurable in urine. Using immunohistochemistry techniques, prohepcidin is localized to organelles of the secretory pathway, particularly the Golgi apparatus, of hepatocytes suggesting that molecules may accumulate before receiving a signal for secretion (Wallace *et al*., 2005). Prohepcidin circulates in plasma, but its plasma concentration does not correlate well with urinary hepcidin concentrations or other iron parameters (Kemna *et al*., 2005). The site, nature, and potential regulation of the conversion of prohepcidin to hepcidin remain to be identified.

A number of systemic stimuli, including body iron stores, anemia, hypoxia, degree of erythropoiesis, and inflammation have been reported to modulate hepcidin levels; however, the pathways involved in hepcidin production remain to be elucidated (Anderson and Frazer, 2005; Steele *et al*., 2005). Anemia, hypoxia, and erythropoietin themselves do not seem to be of primary importance (Pak *et al*., 2006; Vokurka *et al*., 2006). Hepcidin production is modulated by body iron requirements, which are largely influenced by the magnitude of erythropoiesis present (Wilkins *et al*., 2006). A signal arising from erythropoietic activity in bone marrow is proposed to regulate hepcidin production, but its nature is unknown at the time of this manuscript preparation (Pak *et al*., 2006). The content of diferric transferrin in plasma may be a key indicator of body iron requirement (Wilkins *et al*., 2006). Many questions remain concerning how hepcidin expression is modulated in response to body iron requirements; however, three molecules (hemochromatosis [HFE] protein, TfR2, and hemojuvelin) have been identified that are involved in the regulation of this pathway(s). Defects in each of these molecules in humans or mice have resulted in inappropriately low hepcidin levels and increased iron absorption leading to hemochromatosis. It is hypothesized that hepcidin is regulated by HFE and TfR2 on hepatocyte surfaces in response to plasma transferrin saturation. TfR2 has a 25-fold lower affinity for diferric transferrin than does TfR1 and would presumably become active when diferric transferrin concentrations are high (Anderson and Frazer, 2005). The pathway involving plasma diferric transferrin concentration may not be the only way hepcidin production is regulated. Hemojuvelin may modulate this pathway or affect hepcidin synthesis independently (Steele *et al*., 2005). Studies indicate that hepcidin synthesis is stimulated by certain bone morphogenetic proteins (BMPs) that bind to hemojuvelin, regulating hepcidin expression through a BMP signal transduction pathway (Truksa *et al*., 2006). In addition, hepcidin expression increases in response to inflammation, and this increase precedes any alteration in transferrin saturation (Steele *et al*., 2005).

Most of the iron stored within the liver is found in hepatocytes stored as ferritin. Hepatocytes secrete a glycosylated form of ferritin into plasma (Ghosh *et al*., 2004). Ferritin in human plasma is primarily composed of L subunits, but H subunits predominate in ferritin in dog plasma (Watanabe *et al*., 2000). Plasma ferritin concentrations generally correlate with body iron stores; however, ferritin is an acute phase protein that increases in plasma during inflammation (Torti and Torti, 2002).

Hepatocyte membranes contain ferritin receptors. However, serum ferritin is present in low concentrations and contains little iron, so it is unlikely that hepatocytes take up significant amounts of iron from plasma by this mechanism under normal conditions (Anderson and Frazer, 2005; Ponka *et al*., 1998). Like other cells, hepatocytes utilize TfR1 to transport iron into the cells. NTBI is thought to be chelated by small organic acids, such as citrate, but some may be bound loosely to proteins such as albumin (Anderson and Frazer, 2005). The liver rapidly clears NTBI. In experimental studies using mice, the half-time of clearance of NTBI in plasma was 30 sec, compared to a half-time clearance for transferrin-bound iron of 50 min (Craven *et al*., 1987). Like macrophages and enterocytes, hepatocytes utilize ferroportin to export iron to plasma. Ferroportin expression is lower in hepatocytes than in enterocytes and macrophages, which may help explain why these cells preferentially accumulate iron in most iron-overload conditions (Rivera *et al*., 2005).

As discussed earlier, transferrin (apotransferrin with bound Fe^{+3} ions) is critical for normal iron transport to cells. Liver synthesis and release of apotransferrin to plasma is increased in most species in response to iron deficiency (but not generally in dogs) and decreased in response to inflammation (negative acute phase protein). Transferrin deficient

mice have iron deficiency anemia, but iron accumulates in the liver, presumably because of the ability of hepatocytes to take up NTBI (Verga Falzacappa and Muckenthaler, 2005).

Ceruloplasmin is a glycoprotein with a molecular weight of 100 to 155 kDa depending on species. It migrates in the α_2-region in humans but in the α_1-region in horses on protein electrophoresis (Okumura *et al*., 1991). During biosynthesis, six atoms of copper are incorporated into ceruloplasmin late in the secretory pathway (Hellman and Gitlin, 2002). It contains most of the copper in the circulation in all species studied, except for the dog in which ceruloplasmin accounts for only about 40% of the plasma copper content (Montaser *et al*., 1992). It plays no role in copper transport or delivery to tissues (Hellman and Gitlin, 2002). Ceruloplasmin has ferroxidase enzyme activity that facilitates the oxidation of Fe^{+2} to Fe^{+3}, a process involved in iron mobilization from liver and other tissue, but not from enterocytes (Osaki *et al*., 1971; Wessling-Resnick, 2006). It also appears to function as an antioxidant in plasma. Ceruloplasmin is a mild to moderate acute phase protein that increases in concentration in association with inflammation (Ceron *et al*., 2005; Smith and Cipriano, 1987). Its synthesis may also be enhanced by iron deficiency, estrogen, and progesterone. In contrast to iron, hepatocytes can excrete copper in the bile by a process that is dependent on the intracellular concentration of copper (Hellman and Gitlin, 2002).

Haptoglobin is a glycoprotein of approximately 80 kDa molecular weight that contains approximately 20% carbohydrate. As an acute phase protein, the liver secretes increased amounts of haptoglobin into the circulation in response to inflammation (see Chapter 5). Plasma haptoglobin concentration may also increase following glucocorticoid administration in dogs and cattle (Harvey and West, 1987; Higuchi *et al*., 1994; Yoshino *et al*., 1993). Haptoglobin exists in dimer and polymer forms and is a major component of the α_2-protein band identified by electrophoresis in most species. Lysis of erythrocytes in the circulation (intravascular hemolysis) releases free hemoglobin into plasma, and hemoglobin tetramers spontaneously dissociate into α-β dimers that are bound by haptoglobin. Each haptoglobin monomer can irreversibly bind a hemoglobin α-β dimer, preventing some hemoglobin loss (and therefore iron loss) in the urine following intravascular hemolysis. Macrophages remove hemoglobin-haptoglobin complexes from plasma, degrade the protein complex, and subsequently recycle the released iron. Haptoglobin also assists in the protection against bacterial infections by binding to free hemoglobin in infected tissues, limiting iron availability for bacterial growth. In addition, haptoglobin functions as an antioxidant because free hemoglobin promotes oxidative injury, which is inhibited by binding to haptoglobin (Melamed-Frank *et al*., 2001).

Hepatocytes synthesize hemopexin, a 60-kDa acute phase plasma protein with a remarkably high binding affinity for heme. Free heme may be released in toxic amounts when intravascular hemolysis, rhabdomyolysis, or internal hemorrhage occur. Heme binds to cell membranes and other lipophilic structures, such as low-density lipoproteins, and promotes oxidative injury and inflammatory reactions. Binding of heme to hemopexin dampens these toxic effects. Like macrophages, hepatocytes can endocytose heme-hemopexin complexes following binding to CD91 on their surfaces. Once inside the cell, the complexes are transported to lysosomes for degradation and release of iron, and receptors are recycled to the cell surface (Hvidberg *et al*., 2005).

VII. TESTS FOR EVALUATING IRON METABOLISM

A. Hematology

When the hemoglobin concentration reaches a certain level in developing erythroid cells, it appears to signal the cessation of cell division. Abnormalities in heme or globin synthesis result in deficient hemoglobin synthesis and a delay in the signal for cell division to cease. When this happens, one or more extra cell divisions occur during erythroid cell development, resulting in the formation of microcytic erythrocytes (Stohlman *et al*., 1963). A deficiency in hemoglobin synthesis can also result in the formation of hypochromic erythrocytes with decreased hemoglobin concentration. Iron is essential for heme synthesis; consequently, iron deficiency results in deficient heme synthesis and the formation of microcytic, hypochromic erythrocytes. In addition to true iron deficiency, disorders that result in functional iron deficiency or defective iron incorporation into heme in mitochondria may result in the formation of microcytic, and possibly hypochromic, erythrocytes. These disorders include the anemia of inflammatory disease, copper deficiency, myelodysplastic disorders, drug or chemical toxicities, and possibly portosystemic shunts (Harvey, 2000).

The mean cell volume (MCV) represents the average volume of a single erythrocyte in femtoliters (fl = 10^{-15}l). The MCV is determined most accurately with appropriately calibrated electronic cell counters that determine the size of individual cells and compute the MCV. The MCV varies greatly depending on species and, in some cases, depending on a breed within a species. Some dogs from Japanese breeds (Akita and Shiba) normally have MCV values below the reference intervals established for other breeds of dogs (Gookin *et al*., 1998), but these dogs are not anemic. The MCV is a fairly insensitive indicator of the formation of microcytes because a relatively high percentage of microcytes must generally be present in blood for the MCV to decrease below the reference interval.

The mean cell hemoglobin concentration (MCHC) represents the average hemoglobin concentration within erythrocytes. It is calculated by dividing the

hemoglobin value (in g/dl) by the hematocrit (as a percentage) and multiplying by 100. The MCHC is expressed as g/dl of erythrocytes. It may be normal in iron deficiency anemia when MCV values are only slightly decreased, but the MCHC is typically low when the MCV is moderately to markedly decreased.

The mean cell hemoglobin (MCH) represents the average amount of hemoglobin in a single erythrocyte. It is calculated by dividing the Hb value (in g/dl) by the RBC count (in millions per μl) and multiplying by 10. The MCH generally provides little added information beyond that obtained from the MCV and MCHC because the MCH depends on both the size and hemoglobin concentration of erythrocytes. It usually correlates directly with the MCV, except in animals with macrocytic hypochromic erythrocytes. Exceptionally low MCH values strongly suggest true iron deficiency is present.

Although quite useful when abnormal, MCV and MCHC values are relatively insensitive in identifying the presence of erythrocytes with abnormal volumes or hemoglobin concentrations. Many microcytic or macrocytic erythrocytes are required to move the MCV below or above the reference interval, respectively, and many hypochromic erythrocytes are needed to move the MCHC below the reference interval. In addition to counting cells, electronic cell counters can determine and plot the volume of individual erythrocytes, and examination of these erythrocyte volume histograms can reveal the presence of increased numbers of microcytes or macrocytes even when the MCV is within the reference interval (Weiser and Kociba, 1983). Some electronic cell counters such as the Advia 120 (Siemens Medical Solutions Diagnostics, Tarrytown, NY) can also determine the hemoglobin concentration of individual erythrocytes from the deflection of light that occurs when a laser beam strikes individual cells. Inspection of hemoglobin concentration histograms can reveal the presence of increased numbers of hypochromic erythrocytes, even when MCHC has not decreased below the reference interval. Individual erythrocytes can be further characterized by creating a cytogram in which the erythrocyte volumes of individual cells are plotted against their respective hemoglobin concentrations. In addition, the percentages of microcytes, macrocytes, hypochromic erythrocytes, hyperchromic erythrocytes, erythrocytes with low hemoglobin content, and erythrocytes with high hemoglobin content can be determined, and these same parameters can also be determined for reticulocytes in a blood sample. Because reticulocytes are recently formed immature erythrocytes, reticulocyte parameters may best reflect the current state of iron sufficiency in an animal. Alterations in several reticulocyte indices—including reticulocyte MCV (MCV_{retic}), reticulocyte hemoglobin content (CH_{retic}), percentage of hypochromic reticulocytes (% $Hypo_{retic}$), percentage of reticulocytes with low hemoglobin content (% Low CH_{retic}), percentage of reticulocytes with high hemoglobin content (% High CH_{retic}), and percentage of macrocytic reticulocytes (% $Macro_{retic}$)—appear to be of value in the diagnosis of iron deficiency in dogs (Fry and Kirk, 2006; Steinberg and Olver, 2005).

B. Serum Iron

Serum iron can be measured to assess the transport compartment of iron (Table 9-1). Serum iron concentration is increased in animals with hemolytic anemia and dyserythropoiesis, in which iron transfer from macrophages to plasma is increased (Harvey and Smith, 1994; Smith, 1992; Steffen *et al*., 1992; Stewart *et al*., 1953; Watanabe *et al*., 1998; Weiss and Lulich, 1999); in hypoplastic or aplastic anemia, in which iron transfer from plasma is decreased (Lange *et al*., 1976; Smith, 1992; Stokol and Blue, 1999; Stokol *et al*., 2000); in iron overload (Arnbjerg, 1981; House *et al*., 1994; Lavoie and Teuscher, 1993; Paglia *et al*., 2001; Sprague *et al*., 2003); in pigs with experimental pyridoxine deficiency (Deiss *et al*., 1966); in dogs and horses following the administration of glucocorticoid steroids (Fig. 9-7) (Adamama-Moraitou *et al*., 2005; Harvey *et al*., 1987b; Smith *et al*., 1986b); and in dogs with chronic hepatopathy (Soubasis *et al*., 2006). Serum iron concentrations are high at birth in foals, with most of the transferrin saturated with iron (Fig. 9-8), but serum iron

TABLE 9-1 Serum Iron Analyte Reference Intervals in Domestic Animals[a]

Species	Iron (μmol/l)	TIBC (μmol/l)	Ferritin (μg/l)	Reference(s)
Dog	5.9–26.3	50.5–69.1	80–800	Weeks *et al*. (1988)
Cat	5.9–24.2	30.3–58.2	32–123	Andrews *et al*. (1994)
Horse	9.0–35.4	41.3–81.4	43–261	Smith *et al*. (1986a)
Cattle	7.0–27.7	33.3–48.3	33–55	Kolb (1963), Smith (1997)
Pig	9.8–33.5	43.1–70.3	20–125	Kolb (1963), Smith *et al*. (1984a)

[a]*Iron and total iron-binding capacity* (TIBC) *values can be converted from* SI *units to conventional units* (μg /dl) *by multiplying by* 5.59.

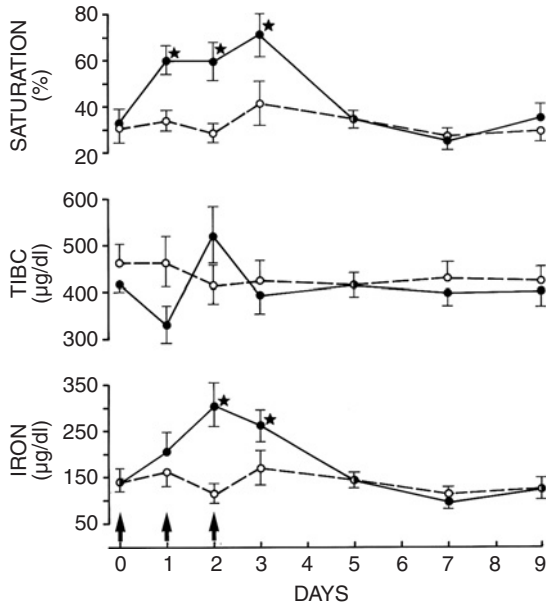

FIGURE 9-7 Effect of oral prednisone (2 mg/kg bid) administration for 3 consecutive days (arrows) on serum iron parameters in dogs (closed circles with solid lines) compared to control dogs without prednisone (open circles with dashed lines). Values are mean ± standard error with stars indicating significant differences between groups ($p < 0.05$). TIBC = total iron-binding capacity. Saturation refers to the percentage saturation of transferrin with iron. From Harvey *et al*. (1987b), with permission.

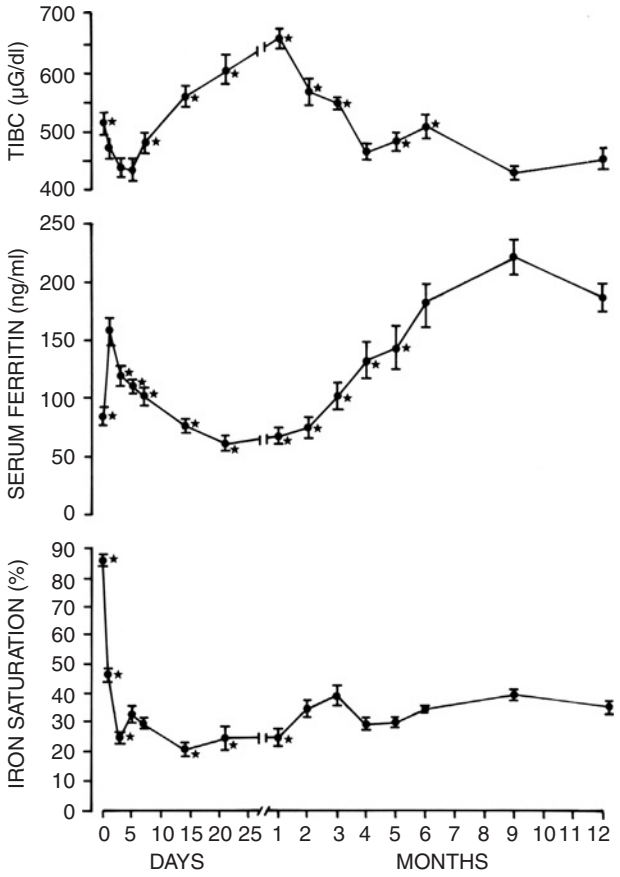

FIGURE 9-8 Serum total iron-binding capacity (TIBC), ferritin concentration, and percentage saturation of transferrin with iron (mean ± standard error) from 21 healthy foals during the first year of life. The day 0 sample was taken before foals were allowed to nurse. The sharp increase in serum ferritin when 1 day old resulted from the consumption of colostrum with high ferritin concentration compared to that in blood. Values marked with a star were significantly different from 77 healthy adult horses. From Harvey *et al*. (1987a), with permission.

decreases to adult values by 3 days of age (Harvey *et al*., 1987a). Although serum iron values in calves and piglets are not as high as values in foals at birth, a rapid decrease in serum iron also occurs in these species within a few days after birth (Kolb, 1963). Serum iron increases markedly in chickens associated with increased estrogen secretion and the onset of egg laying (Kolb, 1963). Serum iron values may be spuriously increased if laboratory tubes or pipettes used to handle serum are contaminated with iron. The use of disposable plastic pipettes and tubes minimizes this possibility. Iron concentrations may be spuriously increased in plasma samples if kits designed for serum iron determinations are used to measure iron in plasma.

Serum iron concentration is generally low in both iron deficiency (Furugouri, 1972; Halvorsen and Halvorsen, 1973; Harvey *et al*., 1982; Harvey *et al*., 1987a; Kolb, 1963; Mollerberg *et al*., 1975; Weiser and Kociba, 1983) and with inflammation (Borges *et al*., 2007; Feldman *et al*., 1981b; Kolb, 1963; Neumann, 2003; Smith and Cipriano, 1987; van Miert *et al*., 1986; van Miert *et al*., 1990). It may also be decreased when demands for erythropoiesis exceed the iron flow from the diet and storage pools, such as might occur with erythropoietin administration (Brugnara *et al*., 1993; Cowgill *et al*., 1998; Pak *et al*., 2006). Serum iron concentration is decreased following glucocorticoid administration to cattle and goats (Maddux *et al*., 1988; van Miert *et al*., 1986; Weeks *et al*., 1989a).

C. Serum Total Iron-Binding Capacity

The total iron-binding capacity (TIBC) of serum is a measure of total serum transferrin (apotransferrin, monotransferrin, diferric transferrin) concentration because insignificant amounts of plasma iron are bound to other proteins. TIBC is calculated by measuring serum iron and serum unsaturated iron-binding capacity and summing these values. The percentage saturation of transferrin with iron is calculated by dividing the serum iron concentration by the TIBC and multiplying by 100. Serum TIBC is low-normal or decreased in association with inflammatory disorders (Feldman *et al*., 1981b; Ottenjann *et al*., 2006; Smith and Cipriano, 1987) and increased in iron-deficient humans, rabbits, pigs, horses, and cattle (Furugouri, 1972; Halvorsen and Halvorsen, 1973; Harvey *et al*., 1987a; Miltenburg *et al*., 1992b; Mollerberg *et al*., 1975). A slight increase in serum TIBC was reported in an experimental study of diet-induced iron deficiency anemia in young

growing dogs (Fry and Kirk, 2006), but serum TIBC is generally normal in dogs with naturally occurring iron deficiency anemia (Harvey *et al*., 1982; Weiser and O'Grady, 1983). TIBC may be increased in some animals with iron overload (House *et al*., 1994; Sprague *et al*., 2003) and in dogs with chronic hepatopathy (Soubasis *et al*., 2006).

D. Serum Ferritin

Serum ferritin concentration correlates with tissue iron stores in humans and domestic animals (Andrews *et al*., 1994; Smith *et al*., 1984a; Smith *et al*., 1984b; Weeks *et al*., 1989b). Increased serum ferritin occurs in animals with increased storage iron as reported in dogs with chronic hemolytic anemia (e.g., pyruvate kinase and phosphofructokinase deficiency) (Harvey and Smith, 1994), malignant histiocytosis (Newlands *et al*., 1994), and hemochromatosis secondary to repeated blood transfusion (Sprague *et al*., 2003). Serum ferritin is also increased in cattle with increased iron stores secondary to Theileria sergenti—induced hemolytic anemia (Watanabe *et al*., 1998). Serum ferritin is transiently increased in horses after moderate to severe exercise (Hyyppa *et al*., 2002) and in foals following consumption of colostrum, which contains high ferritin concentrations compared to milk (Harvey *et al*., 1987a). Serum ferritin is decreased in animals with iron deficiency (Harvey *et al*., 1987a; Smith *et al*., 1986a; Weeks *et al*., 1990).

Serum ferritin is an acute phase protein; consequently, increased values are expected in inflammatory conditions, in addition to conditions with increased iron stores (Ottenjann *et al*., 2006; Smith *et al*., 1986a; Smith and Cipriano, 1987). The proinflammatory cytokine tumor necrosis factor-α (TNFα) stimulated sustained ferritin secretion in cultured human hepatocytes (Torti and Torti, 2002). Serum iron concentration may be decreased in both iron deficiency and in inflammatory conditions (Andrews and Smith, 2000). Consequently, serum ferritin concentration can help differentiate true iron deficiency (serum ferritin is low) from the anemia of inflammatory disease (serum ferritin is normal or high). It should be remembered that true iron deficiency could be missed if concomitant inflammation was present and resulted in increased ferritin secretion into blood. Commercial assay kits are not available for serum ferritin assays in animals, but ferritin assays may be performed for several species at Kansas State University.

E. Bone Marrow Iron

Prussian blue stain is used to evaluate bone marrow hemosiderin stores. Smears may be sent to a commercial laboratory for this stain, or a stain kit can be purchased and applied in-house (Harleco Ferric Iron Histochemical Reaction Set, #6498693, EM Diagnostic Systems, Gibbstown, New Jersey). When this stain is applied, iron-positive material stains blue, in contrast to the dark pink color of the cells and background. A good-quality marrow aspirate smear with at least nine particles has been recommended to adequately access marrow hemosiderin stores in macrophages using the Prussian blue stain (Hughes *et al*., 2004). Determination of stainable iron in bone marrow is used as a measure of total body iron stores (Blum and Zuber, 1975; Franken *et al*., 1981). A lack of stainable iron is consistent with iron deficiency; however, negative iron staining is not necessarily predictive of iron deficiency (Ganti *et al*., 2003). Cats normally lack stainable iron in the marrow (Harvey, 1981). In addition, some cattle (especially younger animals) lack stainable iron in the marrow even though marrow iron can be demonstrated by chemical assay (Blum and Zuber, 1975). Cattle that lack stainable iron generally have lower marrow iron concentrations when measured chemically than cattle with a positive iron stain. Similarly, recently weaned dogs have little or no stainable iron in marrow, presumably reflecting low iron stores at the end of the nursing period (Fry and Kirk, 2006). Stainable iron in the marrow tends to increase with advancing age in humans, horses, and cattle (Blum and Zuber, 1975; Franken *et al*., 1981). Stainable iron in bone marrow is generally increased in animals with hemolytic anemia and dyserythropoiesis, in which phagocytosis of erythroid cells is increased (Canfield *et al*., 1987; Holland *et al*., 1991; Steffen *et al*., 1992; Weiss and Lulich, 1999), and in animals with anemia resulting from decreased erythrocyte production, including the anemia of inflammatory disease (Feldman *et al*., 1981b).

Some nucleated erythrocytes in Prussian blue-stained smears from normal animals may contain one to three small, blue granules in their cytoplasm (Deiss *et al*., 1966; Feldman *et al*., 1981a). When heme synthesis is impaired (other than by iron deficiency), mitochondria accumulate excess amorphous iron aggregates, and increased siderotic granules are present that may form a ring around the nucleus (generally called a ringed sideroblast in human hematology) (Bottomley, 2004). Read Section VIII.F in this chapter for more information.

F. Erythrocyte Zinc Protoporphyrin

Heme is formed inside mitochondria when an Fe^{+2} ion is inserted into protoporphyrin IX in a reaction catalyzed by ferrochelatase. The ferrochelatase enzyme also catalyzes zinc chelation with protoporphyrin IX to form zinc protoporphyrin (ZnPP) in trace amounts in normal animals. When iron is deficient or iron utilization is impaired, zinc becomes a prominent substrate for ferrochelatase, leading to increased ZnPP formation and accumulation in erythroid cells (Labbe *et al*., 1999). ZnPP is a stable chelate that remains in erythrocytes throughout their life spans. It can be extracted from erythrocytes and measured using fluorometry or spectrophotometry. Unfortunately, ZnPP was unknowingly converted to free protoporphyrin during analysis for many years; consequently,

investigators using these methods reported ZnPP as free protoporphyrin (Labbe *et al*., 1999). Fortunately, ZnPP can now be measured without extraction in washed erythrocytes using a hematofluorometer. This dedicated instrument measures the ratio of ZnPP fluorescence to heme (hemoglobin) absorption (Labbe *et al*., 1999). In addition, a new fluorescent method for the direct and simultaneous measurement of ZnPP, free protoporphyrin IX, and fluorescent heme degradation product has been described using human and mouse hemolysates (Chen and Hirsch, 2006).

Increased ZnPP concentrations in circulating erythrocytes indicates that Fe^{+2} availability was insufficient in the mitochondria of their precursors (nucleated erythroid cells and reticulocytes) and limited heme synthesis in these precursor cells. Because high ZnPP concentration is only present in erythrocytes formed during periods of limited iron availability and erythrocytes have long life spans in the circulation, conditions of limited iron availability need to persist for weeks before whole blood erythrocyte ZnPP concentrations are clearly above reference intervals (Martin *et al*., 2004). Erythrocyte ZnPP concentration is high in true iron deficiency and in inflammatory disorders in which iron delivery to erythroid cells is limited (Feldman *et al*., 1981a; Labbe *et al*., 1999; Weeks *et al*., 1990).

ZnPP concentration is also increased in association with lead toxicity (Hawke *et al*., 1992; Kowalczyk *et al*., 1981; Martin *et al*., 2004). Lead inhibits the ferrochelatase enzyme to some degree. This inhibition should result in increased free protoporphyrin, rather than the increase in ZnPP that predominates in lead toxicity in humans (Lamola and Yamane, 1974) and the 2:1 increase in ZnPP versus free protoporphyrin that occurs in cattle with lead toxicity (George and Duncan, 1981). Consequently, it appears that lead impairs iron utilization in an additional way (Labbe *et al*., 1999). Erythrocyte ZnPP may also increase when iron is being delivered to developing erythroid cells in the marrow at a rate insufficient to meet the demands of conditions with accelerated erythropoiesis.

G. Tissue Nonheme Iron

Iron stores (ferritin and hemosiderin) can be determined directly by measuring nonheme iron concentrations in various organs. Although it may be desirable to measure total body nonheme iron stores, this is impossible in clinical patients and impractical in most research animals. Consequently, nonheme iron concentration is generally only determined in the liver and spleen because these organs contain large quantities of stored iron and are easily biopsied.

Total tissue iron includes heme-containing proteins, including hemoglobin, myoglobin, and certain enzymes, in addition to iron stored as ferritin and hemosiderin. Heme resists acid hydrolysis; consequently, nonheme iron can be separated from heme iron by extraction in acid and determined colorimetrically or coulometrically (Smith, 1997). Nonheme iron stores are decreased in iron deficiency and increased in iron overload disorders (see Section VII.D). Nonheme stores are also increased in animals with hemolytic anemia and in animals with anemia resulting from decreased erythrocyte production. These conditions are not necessarily associated with an increase in total body iron, but rather with a shift of heme iron normally present in hemoglobin in circulating erythrocytes to nonheme iron stored as ferritin and hemosiderin within macrophages.

H. Ferrokinetics

Ferrokinetics refers to measurements that are made following the intravenous injection of transferrin labeled with radioactive iron or the absorption of radioactive iron from the diet. Ferrokinetics studies of intravenously administered radioactive iron provide information concerning plasma iron turnover and iron incorporation in hemoglobin in circulating erythrocytes. Radioactive iron is cleared from plasma with half-time of about 60 to 90min (Nathanson *et al*., 1985; Smith, 1997), and from 60% to 95% of the iron present in plasma is transported to the bone marrow for incorporation into hemoglobin in developing erythroid cells in animals (Fillet *et al*., 1974; Gillis and Mitchell, 1974; Kaneko, 1964; Kaneko and Mattheeuws, 1966; Smith, 1997). Plasma iron transfer rates, plasma iron turnover rates, and marrow transit times may also be calculated (Smith, 1997). Ferrokinetic studies of experimental iron deficiency in dogs revealed that iron absorption was increased, plasma iron clearance was shortened, and iron retention in the body was increased compared to normal dogs (Nathanson *et al*., 1985). Ferrokinetic studies provide useful pathophysiological information, but they are not practical for use in diagnostic veterinary medicine. The reader is referred to the fifth edition of this text for more detailed ferrokinetic information (Smith, 1997).

VIII. DISORDERS OF IRON METABOLISM

A. Iron Deficiency

Iron deficiency may be classified in three stages: storage iron deficiency, iron-deficient erythropoiesis, and iron deficiency anemia (Table 9-2). Iron deficiency in domestic animals is generally not recognized until microcytic anemia is present. Iron deficiency results from insufficient iron absorption in the intestine (rare except in nursing animals) or from hemorrhage and associated iron loss from the body.

1. C‰ ‰S, ,

Clinical signs associated with iron deficiency anemia include pale mucous membranes, lethargy, weakness, and weight loss or retarded growth. These signs result not only from decreased hemoglobin synthesis, but from deficiencies

Table 9-2 Iron Analytes in Various Stages of Iron Deficiency

Analyte	Iron Deficiency	Iron-Deficient Erythropoiesis	Iron Deficiency Anemia
Bone marrow iron	Low	Low	Low
Serum ferritin	Low	Low	Low
Serum iron	Normal	Low	Low
Zinc protoporphyrin	Normal	High	High
Transferrin saturation	Normal	Low	Low
Blood hemoglobin	Normal	Normal	Low
Erythrocyte size	Normal	Normal	Low

From Hastka et al. (1994).

in other iron-containing proteins including myoglobin, cytochromes, citric acid cycle enzymes, and other heme and nonheme iron-containing enzymes (Kolb, 1963; Smith, 1997). Additional signs that may be present include diarrhea, dermatitis, hematuria, hematochezia, and melena, depending on the cause of the iron deficiency anemia and the presence of other concomitant disorders. Iron-deficient animals are more susceptible to infections because of lowered immunity (Kolb, 1963). Asymptomatic dogs are commonly recognized serendipitously when complete blood counts are done as a routine screen before surgery and microcytic anemia is found.

2. C[illegible] D[illegible]

With the exception of young growing animals, iron deficiency in domestic animals usually results from blood loss. Chronic iron deficiency anemia is common in adult dogs and ruminants in areas where bloodsucking parasite infestations are severe (Harvey *et al*., 1982; Weiser and O'Grady, 1983). Chronic hemorrhage resulting in iron deficiency may also occur with intestinal neoplasms, transitional cell carcinomas, gastrointestinal ulcers, thrombocytopenia, inherited hemostatic disorders, hemorrhagic colitis, and menorrhea (primates only). Excessive removal of blood from a blood donor animal can result in an iron-deficient state. Iron deficiency anemia appears to be rare in adult cats and horses (French *et al*., 1987; Fulton *et al*., 1988; Smith *et al*., 1986a).

Milk contains relatively low concentrations of iron (Anderson, 1992; Kolb, 1963); consequently, nursing animals can easily deplete body iron stores as they grow (Kolb, 1963; Smith, 1997). Piglets reared in modern facilities without access to soil are especially susceptible to the development of dietary iron deficiency anemia because they have lower iron stores at birth than other domestic animals studied, and they exhibit remarkably rapid growth while nursing (Kolb, 1963; Underwood, 1977). Iron deficiency can be prevented in piglets by allowing them to eat earth while rooting in open fields or by adding pieces of sod to their pens; however, iron deficiency is generally prevented by intramuscular iron dextran injections when pigs are raised in confinement (Kolb, 1963; Underwood, 1977). The concomitant occurrence of bloodsucking parasite infestations can result in especially severe iron deficiency anemia in nursing animals. Once the consumption of solid food begins, dietary iron deficiency in growing animals usually resolves (Kolb, 1963). At least 80mg available iron per kilogram diet is required to avoid iron-limited erythropoiesis in puppies, kittens, and piglets (Chausow and Czarnecki-Maulden, 1987; Kolb, 1963). Iron deficiency anemia is an unavoidable consequence of feeding practices designed to produce pale meat in veal calves (Miltenburg *et al*., 1992a).

3. L[illegible] F[illegible]

Anemia in iron-deficient animals generally results from a combination of hemorrhage and impaired (iron-limited) erythrocyte production. However, iron-deficient erythrocytes also exhibit decreased life spans, with evidence of enhanced eryptosis characterized by cell shrinkage, membrane blebbing, and surface exposure of phosphatidylserine (Kempe *et al*., 2006). The hematocrit decreases before the MCV and MCHC decrease, especially when iron deficiency is caused by bleeding. The MCV is generally normal in acute iron deficiency. If the iron-deficient state persists for weeks to months, the number of microcytic cells produced can constitute a sufficient enough portion of the erythrocyte population to reduce the MCV below the normal reference intervals. Iron deficiency anemia is defined as iron deficiency that results in microcytic anemia. Because erythrocyte indices are generally normal during early iron deficiency, most cases of iron deficiency go undiagnosed at this stage. Microcytic erythrocytes are produced in response to iron deficiency in nursing kittens and pups, but low MCV values may not develop postnatally because the MCV is above adult values at birth in these species and some fetal macrocytes may persist during the iron-deficient nursing period. The review of erythrocyte volume histograms can reveal the presence of microcytes in iron-deficient pups and kittens that have normal MCV values (Weiser and Kociba, 1983). New hematology instruments have the ability to calculate the percentage of microcytes present.

The mean cell hemoglobin concentration (MCHC) within iron-deficient erythrocytes may be low because iron

is needed for normal hemoglobin synthesis. A decrease in MCV generally precedes a decrease in MCHC in iron-deficient animals (Harvey, 2000). A low MCHC is often present in severely affected dogs and ruminants, but it is rarely present in iron-deficient horses or adult cats. The red cell distribution width (RDW) is often increased because of the presence of increased numbers of microcytes together with normocytic cells.

Because reticulocytes are recently formed immature erythrocytes, reticulocyte parameters may better reflect the current state of iron sufficiency in an animal. A retrospective study of dogs with natural disease found that low MCV_{retic} and low, CH_{retic} were indicators of iron deficiency (Steinberg and Olver, 2005). In addition to these parameters, a prospective study of diet-induced iron deficiency in post-weaning dogs found that increased % $Hypo_{retic}$, increased % Low CH_{retic}, decreased % High CH_{retic}, and decreased % $Macro_{retic}$ were indicators of iron deficiency (Fry and Kirk, 2006). Of these various reticulocyte parameters, the CH_{retic} appears to be the most widely used in the diagnosis of iron deficiency in humans (Brugnara *et al*., 2006).

Erythrocytes from dogs and ruminants with iron deficiency anemia often appear hypochromic on stained blood smears (Harvey, 2001). In these species in which erythrocytes appear as discocytes, hypochromic erythrocytes have a narrow rim of lightly stained hemoglobin and greater than normal area of central pallor. This hypochromasia results from both decreased hemoglobin concentration within cells and from the fact that the cells are thin (leptocytes). Because these microcytic leptocytes have increased diameter-to-volume ratios, they may not appear as small cells when viewed in stained blood films. Erythrocytes from members of the family Camelidae are elliptical and not biconcave. Microcytic erythrocytes from iron-deficient llamas exhibit irregular or eccentric areas of hypochromasia within the cells (Morin *et al*., 1993).

Poikilocytosis (keratocytes and schistocytes) is often present, being most pronounced in association with severe microcytosis (Harvey, 2001). Poikilocytosis is common in young calves. In some cases it may result from iron deficiency, but abnormalities in protein 4.2 in the membrane and hemoglobin composition have also been suggested as causative factors (Okabe *et al*., 1996). Folded cells and dacryocytes are common erythrocyte shape abnormalities in iron-deficient llamas (Morin *et al*., 1993).

Not only is there apparently a low incidence of this disorder in horses and adult cats, but some cases may not be recognized because hypochromasia is usually not apparent when stained blood films from iron-deficient horses and adult cats are examined. Additionally, some electronic cell counters may not count the microcytic cells present, resulting in a spuriously increased MCV. Electronic cell counters with erythrocyte histogram displays provide visual evidence that a threshold failure has occurred (Weiser and Kociba, 1983).

Increased production and release of reticulocytes from bone marrow typically occur in response to hemorrhage in species other than the horse. Consequently, absolute reticulocytosis is often present in the early stage of iron deficiency secondary to hemorrhage, at least in the dog (Harvey *et al*., 1982). As iron depletion becomes more severe, there is insufficient iron for reticulocyte production, and the absolute reticulocyte count no longer increases. Thrombocytosis is often present in animals with iron deficiency anemia. This platelet increase may in part be related to a stimulation of megakaryopoiesis by high erythropoietin concentration in plasma (Loo and Beguin, 1999), but the mechanism has not been clearly defined (Kadikoylu *et al*., 2006). Plasma protein concentrations may decrease if substantial recent or ongoing hemorrhage is present.

Serum iron concentration is usually low in animals with iron deficiency anemia (Furugouri, 1972; Halvorsen and Halvorsen, 1973; Harvey *et al*., 1982; Harvey *et al*., 1987a; Mollerberg *et al*., 1975; Weiser and Kociba, 1983), but it can also be low in association with inflammatory disorders (Feldman *et al*., 1981b; Kolb, 1963; Neumann, 2003; Smith and Cipriano, 1987; van Miert *et al*., 1990). Serum iron is also affected by other factors such as endogenous cortisol concentration, administration of glucocorticoids (Harvey *et al*., 1987b), and consumption of meat (Brugnara, 2003).

TIBC is usually normal in dogs and cats, but it is increased in humans, rabbits, pigs, horses, and cattle (Furugouri, 1972; Halvorsen and Halvorsen, 1973; Harvey *et al*., 1982; Harvey *et al*., 1987a; Mollerberg *et al*., 1975; Weiser and Kociba, 1983). However, transferrin is a negative acute phase protein (Ceron *et al*., 2005), and the concomitant presence of inflammation with iron deficiency might lower serum TIBC concentration in animals that could otherwise have high values.

Serum ferritin concentration correlates directly with body iron stores in dogs, cats, horses, and pigs (Andrews *et al*., 1994; Smith *et al*., 1984a; Smith *et al*., 1984b; Weeks *et al*., 1989b). Consequently, serum ferritin is low in iron deficiency (Fry and Kirk, 2006). A problem with serum ferritin is that it is an acute phase protein and it can increase secondarily to inflammation or liver disease (Ottenjann *et al*., 2006; Smith and Cipriano, 1987), resulting in an overestimation of total body iron content that might mask the presence of concomitant iron deficiency (Coenen *et al*., 1991). Suspected iron deficiency can be confirmed by finding minimal or absent stainable iron in the bone marrow of most species. However, stainable iron is not present in the bone marrow of normal cats (Harvey, 1981); consequently, a lack of stainable iron does not indicate iron deficiency in this species. Although cat bone marrow normally lacks stainable iron (hemosiderin), it presumably still has ferritin stores not identified using Prussian blue staining (Blum and Zuber, 1975; Navone *et al*., 1988).

Serum soluble TfR levels and erythrocyte ZnPP concentrations have been used in the diagnosis of iron deficiency

in humans (Metzgeroth *et al*., 2005). Soluble TfR levels are increased in iron deficiency and other disorders with increased erythropoiesis, but not in the anemia of inflammatory disease (Ferguson *et al*., 1992). This assay is not available for domestic animals at this time. Erythrocyte ZnPP is increased when iron delivery to mitochondria is limited (iron deficiency and anemia of inflammatory disease), but not influenced by the erythropoietic activity (Metzgeroth *et al*., 2005).

B. Anemia of Inflammatory Disease

A mild to moderate nonregenerative anemia often accompanies chronic inflammatory disease. It has been called the anemia of inflammatory disease or the anemia of chronic disease. The anemia of inflammatory disease has also been associated with neoplastic conditions, but this could not be confirmed in dogs with lymphoma (Lucroy *et al*., 1998). Clinical signs and physical findings vary depending on the nature of the disorder, but weight loss and fever are often present. The anemia is generally normocytic, but it may be slightly microcytic in long-standing cases (Harvey, 2000; Ottenjann *et al*., 2006). The cause of the anemia is multifactorial. Abnormalities that contribute to the anemia include the production of inflammatory mediators that directly or indirectly inhibit erythropoiesis, blunt the erythropoietin response to the anemia, decrease serum iron, and shorten erythrocyte life spans (Theurl *et al*., 2006; Weiss and Goodnough, 2005).

The proliferation of erythroid progenitor cells (burst-forming unit-erythroid [BFU-E] and CFU-E) is inhibited in the presence of TNFα, IL-1, and the interferon-α, -β, and -γ. Of these molecules, interferon-γ appears to be the most potent inhibitor. The underlying mechanism responsible for this inhibition may involve cytokine-mediated apoptosis, which may be related to down-regulation of erythropoietin receptors on progenitor cells and reduced expression of hematopoietic growth factors. Cytokines may also stimulate macrophages in the marrow to form nitrogen and oxygen-free radicals that could be toxic to neighboring progenitor cells (Weiss and Goodnough, 2005). Erythrocyte proliferation is further reduced because cytokines such as IL-1 and TNFα inhibit erythropoietin expression by the kidney. As a result, the erythropoietin response to the anemia of inflammatory disease is inadequate for the degree of anemia present (Ottenjann *et al*., 2006; Weiss *et al*., 1983; Weiss and Goodnough, 2005).

Erythropoiesis is also limited in the anemia of inflammatory disease because serum iron concentration is generally low (Feldman *et al*., 1981a; Neumann, 2003; Smith and Cipriano, 1987; Verheijden *et al*., 1982; Weiss *et al*., 1983), although hypoferremia was reported in a minority of cats with naturally occurring inflammation (Ottenjann *et al*., 2006). Altered iron metabolism associated with inflammatory and neoplastic disorders is attributable to increased hepcidin production. Hepcidin expression is induced by IL-6 and possibly IL-1 (Lee *et al*., 2005; Nemeth *et al*., 2004a). Increased hepcidin expression occurs within hours following an inflammatory insult. Hepcidin interacts directly with ferroportin, leading to the internalization and lysosomal degradation of this iron export protein. Decreased ferroportin expression results in decreased iron absorption and decreased iron release from macrophages and hepatocytes (Verga Falzacappa and Muckenthaler, 2005). Continued utilization of transferrin-bound iron, with decreased entry of iron into plasma, results in hypoferremia (Steele *et al*., 2005). Injection of recombinant human hepcidin resulted in hypoferremia within 1 h in mice. This decrease occurs rapidly because the plasma iron pool is small compared to the iron flux needed for erythropoiesis (Rivera *et al*., 2005). This hypoferremia is part of an iron-withholding defense system, which deprives microbial invaders and neoplastic cells of iron essential for their growth (Kontoghiorghes and Weinberg, 1995). Hepcidin itself has antimicrobial properties, but the clinical importance of this function is unclear (Park *et al*., 2001; Verga Falzacappa and Muckenthaler, 2005).

Although reduced erythropoiesis primarily accounts for the anemia associated with inflammatory diseases, shortened erythrocyte life spans also contribute to the development of anemia in these disorders (Weiss and Krehbiel, 1983). Inflammatory reactions generate free radicals that can damage erythrocyte membranes, resulting in premature erythrophagocytosis (Weiss *et al*., 1992; Weiss and Klausner, 1988; Weiss and Goodnough, 2005).

The hematocrit is generally only slightly decreased in association with inflammation in most animals but is more likely to be moderately decreased (or rarely markedly decreased) in cats, in which anemia develops more rapidly than in dogs (Mahaffey and Smith, 1978; Ottenjann *et al*., 2006; Weiss *et al*., 1983). The MCV is usually at the low end of the reference interval but may occasionally be slightly below the reference interval (Harvey, 2000; Ottenjann *et al*., 2006). The MCHC and RDW are generally normal. The erythrocyte morphology is usually normal, except for increased rouleaux formation at times in dogs. Reticulocyte counts in blood are not increased in response to the anemia because of the impaired erythropoiesis present (Feldman *et al*., 1981a; Ottenjann *et al*., 2006; Weiss *et al*., 1983).

Serum iron is generally decreased (Feldman *et al*., 1981b; Weiss *et al*., 1983) because inflammation results in increased hepcidin secretion into plasma by hepatocytes. TIBC in serum is a measure of total transferrin (apotransferrin, monoferric transferrin, and diferric transferrin) concentration. Transferrin is a negative acute phase protein and tends to decrease during inflammation. Consequently, TIBC may be decreased in association with the anemia of inflammatory disease (Feldman *et al*., 1981a; Ottenjann *et al*., 2006; Smith and Cipriano, 1987). An exception to

TABLE 9-3 Laboratory Findings in Chronic Iron Deficiency Anemia versus the Anemia of Inflammatory Disease

Parameter	Iron Deficiency Anemia	Anemia of Inflammatory Disease
Hematocrit	Slight to marked decrease	Slight to moderate decrease
Mean cell volume	Slight to marked decrease	Normal to slight decrease
Serum iron	Slight to marked decrease	Slight to moderate decrease
Serum TIBC	Normal to increased	Normal to decreased
Serum ferritin	Decreased	Normal to increased
Marrow hemosiderin	Decreased or absent	Normal to increased

Abbreviation: TIBC, *total iron-binding capacity.*

this pattern appears to be chronic hepatitis, in which serum iron and TIBC may be increased rather than decreased (Soubasis *et al*., 2006). Serum ferritin, bone marrow stainable iron, and liver nonheme iron are increased with inflammation (Feldman *et al*., 1981a, 1981c). Serum ferritin may be increased both as a result of increased iron stores and because it is an acute phase protein (Ottenjann *et al*., 2006; Smith and Cipriano, 1987). Hematological aspects of the anemia of inflammatory disease are compared to iron deficiency in Table 9-3.

C. Portosystemic Shunts

Vascular connections between the portal and systemic circulation that preferentially divert portal blood around the liver are called portosystemic shunts (PSS). They may be congenital or develop secondary to portal hypertension associated with chronic primary hepatobiliary disease (Center and Magne, 1990).

Microcytosis occurs in approximately two-thirds of the dogs with PSS. The cause of the microcytosis is not completely understood, but it is associated with abnormal iron metabolism. The MCV is seldom more than 7fl below the reference interval and the hematocrit is within or slightly below the reference interval. The MCHC is slightly decreased and the RDW is slightly increased in a majority of cases. Codocytes are commonly observed in dogs. The MCV is slightly decreased in about one-third of the cats with PSS. Poikilocytosis (keratocytes and elliptocytes) is common, but anemia is not usually present (Center and Magne, 1990; Levy *et al*., 1995).

About half of the dogs with PSS exhibit hypoferremia with normal or slightly decreased serum TIBC. Serum ferritin and stainable iron (hemosiderin) in the liver and bone marrow are normal or high (Bunch *et al*., 1995; Doberneck *et al*., 1963; Laflamme *et al*., 1994; Meyer and Harvey, 1994; Simpson *et al*., 1997). Erythrocyte protoporphyrin and serum ceruloplasmin concentrations are normal (Bunch *et al*., 1995). Although the animals are not truly iron deficient, the low serum iron appears to be related to the development of microcytosis (Simpson *et al*., 1997).

D. Copper Deficiency

Copper deficiency generally results in anemia in mammals (Auclair *et al*., 2006; Brewer, 1987; Lahey *et al*., 1952), although anemia was not a feature of experimental copper deficiency in the cat (Doong *et al*., 1983). The anemia is generally microcytic hypochromic; however, normocytic anemia has been reported in experimental studies in dogs, and normocytic or macrocytic anemias have been reported in cattle and adult sheep (Brewer, 1987).

Copper deficiency results in impaired iron metabolism (Lee *et al*., 1968b). In experimental studies in pigs, serum iron concentration is low in early copper deficiency when iron stores are normal (Lahey *et al*., 1952; Lee *et al*., 1968b). Functional iron deficiency occurs because copper-containing proteins hephaestin and ceruloplasmin are required for normal iron transport (Lee *et al*., 1968a; Wessling-Resnick, 2006). Decreased hephaestin levels in intestinal enterocytes of copper-deficient animals result in decreased iron release from enterocytes into plasma because hephaestin facilitates iron export by ferroportin (Reeves *et al*., 2005; Wessling-Resnick, 2006). Copper deficiency in pigs results in a marked decrease in circulating ceruloplasmin and decreased release of iron from tissue stores. Administration of ceruloplasmin to these copper-deficient pigs results in a prompt release of iron into the circulation bound to transferrin (Lee *et al*., 1968b; Roeser *et al*., 1970). Iron is diminished in the liver of copper-deficient pigs but accumulates in the liver of copper-deficient rats and mice, suggesting that intestinal iron absorption may not be as compromised in copper-deficient rodents (Auclair *et al*., 2006; Wessling-Resnick, 2006). Humans with hereditary aceruloplasminemia have iron accumulation in liver and other tissues. Clinical signs include diabetes, dementia, and retinal degeneration, but not liver disease (Hellman and Gitlin, 2002).

If experimental copper deficiency is prolonged in pigs, hyperferremia occurs and nucleated erythroid cells with cytoplasmic siderotic (iron-positive) inclusions increase in bone marrow (Lee *et al*., 1968a). Reticulocyte mitochondria from copper-deficient pigs are unable to synthesize heme at the normal rate using Fe^{+3} (Williams *et al*., 1976). A deficiency in copper-containing cytochrome oxidase within mitochondria may slow the reduction of Fe^{+3} to Fe^{+2} within mitochondria. That would limit heme synthesis, which

requires iron in the Fe^{+2} state (Porra and Jones, 1963). Siderotic inclusions have also been reported in erythroid cells in copper deficiency in humans (Gregg *et al*., 2002).

Zinc toxicity results in copper deficiency (presumably secondary to impaired copper absorption), hypoferremia, and microcytic anemia in humans (Beutler, 2006a; Fosmire, 1990; Gyorffy and Chan, 1992), and zinc toxicity, from the use of galvanized feeding bins, resulted in copper deficiency and anemia in pigs (Pritchard *et al*., 1985).

E. Iron Overload

Iron accumulates in hepatocytes when transferrin saturation is high. In addition to transferrin-bound iron, the liver can readily take up NTBI from plasma and iron contained within heme that is bound to the plasma protein hemopexin. Ferroportin expression is lower in hepatocytes than in enterocytes and macrophages, which may help explain why hepatocytes preferentially accumulate iron in most iron overload conditions; however, considerable amounts of iron are stored in macrophages with transfusional iron overload (Anderson and Frazer, 2005; Rivera *et al*., 2005). The increased uptake of iron by hepatocytes results in increased synthesis of apoferritin and formation of ferritin in cytoplasm and formation of hemosiderin in lysosomes. Although binding of iron molecules in these storage proteins minimizes the amount of "free" iron available to catalyze the formation of reactive oxygen species, oxidation of polyunsaturated phospholipids within organelles and cellular membranes and oxidative damage to proteins and DNA may still occur in conditions resulting in excess intracellular iron accumulation (Ramm and Ruddell, 2005; Rothman *et al*., 1992; Ryan and Aust, 1992). Hepatic stellate cells become activated into highly proliferative myofibroblast-like cells during conditions with excessive iron accumulation. This activation results in increased fibrogenesis and subsequently cirrhosis within the liver in conditions with chronic iron accumulation (Ramm and Ruddell, 2005). Other sites that may accumulate iron, depending on the cause of iron overload, include pancreas, heart, kidneys, and endocrine organs (House *et al*., 1994; Lowenstine and Munson, 1999).

Serum iron and serum ferritin concentrations are increased in animals with iron overload, but both can be increased in other conditions (see serum iron section). Consequently, a liver biopsy is needed to definitively diagnose iron overload (Lowenstine and Munson, 1999). Excessive accumulation of iron within hepatocytes can be identified by the staining of hepatocytes using an iron stain (Perl's Prussian blue) and quantified using flame atomic absorption (Sprague *et al*., 2003).

1. A[illegible]

NTBI in plasma may play a significant role in the pathogenesis of tissue injury in severely iron-overloaded individuals, especially in individuals with acute iron toxicity (Koury and Ponka, 2004). The amount of iron taken up by hepatocytes and other cells in acute iron toxicity far exceeds the ability of these cells to increase apoferritin synthesis as a protective response. Most fatal cases of acute iron toxicity in animals have resulted from the parenteral administration of large doses of iron, and animals with hypovitaminosis E appear to be especially susceptible (Arnbjerg, 1981). Acute iron toxicity from parenteral iron administration in calves and goats resulted in clinical findings including central nervous system signs, vocalization, respiratory distress, icterus, and death. Pulmonary edema, hemorrhages on serosal surfaces, and hepatic necrosis were documented at necropsy (Ruhr *et al*., 1983). The oral consumption of large amounts of iron can also result in central nervous system signs, hemorrhage, icterus, and pulmonary edema, but clinical findings can also include vomiting, bloody diarrhea, and subsequently, dehydration, metabolic acidosis, and hypovolemic shock. Histological findings associated with oral iron toxicity include small intestine ulceration, hemorrhage, and necrosis; pulmonary edema and hemorrhage; and degenerative changes in kidneys and liver (Arnbjerg, 1981). Newborn foals exhibited hepatotoxicity following the oral administration of a digestive paste containing ferrous fumarate iron at a concentration much lower than is required for acute iron toxicity in adult animals of various species (Mullaney and Brown, 1988). This liver injury may have resulted from increased NTBI uptake by the liver because serum transferrin is highly saturated at birth in foals (Harvey *et al*., 1987a). In addition, iron absorption may be higher in neonatal foals as reported in neonatal piglets and rats (Mullaney and Brown, 1988). Cirrhosis is not a feature of acute iron toxicity except in animals that survive long enough for fibrosis to develop (Mullaney and Brown, 1988).

2. H[illegible]

The term *hemochromatosis* refers to the accumulation of iron in parenchymal cells, resulting in organ injury and dysfunction. Accumulation of iron within cells (typically macrophages), without evidence of organ dysfunction, is termed *hemosiderosis*. Localized iron overload occurs in macrophages in areas where hemorrhage has occurred. Systemic iron deposition may occur in a variety of organs, but it is especially prominent in hepatocytes (Lowenstine and Munson, 1999). The accumulation of large amounts of iron in hepatocytes results in hepatocellular injury, increased fibrogenesis, and liver failure in severe cases. Hemochromatosis is classified as primary, secondary, or idiopathic. Primary hemochromatosis refers to inherited disorders of iron metabolism resulting in hemochromatosis. Secondary hemochromatosis refers to disorders in which iron accumulation occurs secondary to other disorders, including excessive dietary iron, unnecessary parenteral

iron supplementation, chronic hemolytic anemia, repeated blood transfusions, ineffective erythropoiesis, and possibly primary liver disease (Lowenstine and Munson, 1999). The etiology of idiopathic hemochromatosis by definition cannot be determined.

3. H[illegible] A[illegible]

Intestinal iron absorption is increased in animals and humans with hemolytic anemia and compensatory increased erythropoiesis (Latunde-Dada *et al*., 2006a). Hepcidin synthesis is down-regulated and DMT1, DcytB, and ferroportin are up-regulated during hemolysis in rats induced by phenylhydrazine (Latunde-Dada *et al*., 2006a).

This increased iron absorption, even with high hepatic iron stores, documents the importance of erythroid drive over iron storage in the regulation of iron absorption (Latunde-Dada *et al*., 2006a). Hemosiderin is typically increased in macrophages in animals with hemolytic anemia because of increased phagocytosis of erythrocytes. However, increased iron absorption associated with persistent regenerative anemia can also result in iron accumulation within hepatocytes.

Hemosiderosis, hemochromatosis, and fibrosis develop in the liver of erythrocyte pyruvate kinase-deficient dogs secondary to progressive iron overload (Searcy *et al*., 1979; Weiden *et al*., 1981; Zaucha *et al*., 2001). Dogs with inherited pyruvate kinase deficiency also exhibit the progressive development of myelofibrosis and osteosclerosis, and it is proposed that the marrow fibrosis, like the cirrhosis, occurs in response to damage caused by iron overload (Zaucha *et al*., 2001). Pyruvate kinase-deficient dogs generally die between 1 and 5 years of age because of bone marrow failure or liver failure (Harvey, 2006).

4. R[illegible] B[illegible] T[illegible]
P[illegible] A[illegible]

Long-term repeated blood transfusions commonly result in iron overload in human patients, but animals are rarely given sufficient transfusions for this to be a risk in veterinary medicine. Hemochromatosis, with subsequent liver failure, occurred in a dog given whole blood transfusions every 6 to 8 weeks for 3 years as treatment for pure red cell aplasia (Sprague *et al*., 2003). Histological evaluation of the liver revealed hepatocellular degeneration, bridging portal fibrosis, lobular atrophy, biliary hyperplasia, and large amounts of hemosiderin in hepatocytes and mononuclear phagocytes. The repeated administration of large doses of parenteral iron to dogs in experimental studies over several years resulted in hepatic iron overload and cirrhosis (Lisboa, 1971).

5. D[illegible] O[illegible]

Some species of wild animals develop iron overload, and sometimes hemochromatosis, when housed in captivity. These animals include black rhinoceroses, lemurs, and birds (most notably mynahs and toucans) (Lowenstine and Munson, 1999; Paglia *et al*., 2001). Dietary iron overload may occur from increased amounts of iron in the diet or from an alteration in the diet that results in increased absorption of iron. Compounds including tannins and phytates in natural diets may chelate much of the dietary iron into insoluble complexes. When diets fed in captivity contain less of these inhibitory compounds, iron may be absorbed in excess of what is needed for hemoglobin synthesis and other metabolic functions. For example, black rhinoceroses are browsers in the wild with a diet rich in woody plants, but they are fed manufactured pellets and domestic forages in captivity that contain more bioavailable iron (Paglia *et al*., 2001). Kinetic studies comparing Fe^{+2} absorption by enterocytes from mynahs and chickens revealed a three-fold higher V_{max} for mynahs, even though liver iron content was at least 10-fold higher in mynahs than chickens (Mete *et al*., 2003). This results from an overexpression of intestinal iron transporters DMT1 and ferroportin (Mete *et al*., 2005). Although mynahs can down-regulate iron uptake to some extent (Mete *et al*., 2001), this evolutionary adaption to their natural diet results in excessive iron absorption when they are fed a different diet in captivity.

6. H[illegible] H[illegible]

Most types of hereditary hemochromatosis in humans are characterized by primary or secondary hepcidin deficiency. Primary hepcidin deficiency results from a mutation in the hepcidin gene. Secondary hepcidin deficiency occurs when there are mutations in the HFE gene, TfR2 gene, or hemojuvelin gene (Verga Falzacappa and Muckenthaler, 2005). Murine models of each of these defects have been created and each results in iron overload (Vaulont *et al*., 2005). The mechanisms by which the protein products of these genes control hepcidin synthesis remain to be defined. Iron also accumulates in humans with various mutations in ferroportin that result in resistance to down-regulation by hepcidin. Most patients have iron accumulation predominantly in hepatocytes, but some have iron accumulation predominantly in macrophages (Fleming *et al*., 2005; Wessling-Resnick, 2006).

Hemochromatosis has been described in related Salers cattle, and it is presumed to be inherited (House *et al*., 1994; O'Toole *et al*., 2001). Affected animals were young (about 2 years old or less) with a history of poor growth, weight loss, and poor hair coat. They had iron accumulations in liver, spleen, lymph nodes, kidney, brain, thyroid, and other glandular organs. Histopathology of the liver revealed marked accumulations of stainable-iron in hepatocytes, Kupffer cells, and arteriolar walls, with bridging periportal fibrosis. Affected cattle also have markedly increased iron content in bone, periosteal dysplasia, and osteopenia resulting in pathological fractures and tooth loss

(Norrdin *et al*., 2004). The cause of this disorder in cattle is unknown, but the findings that BMPs can stimulate hepcidin expression (Truksa *et al*., 2006), and that deficient BMP activity can result in osteopenia (Rosen, 2006), suggest that a BMP defect or a BMP signal transduction pathway defect should be investigated.

7. [illegible]

Idiopathic hemochromatosis with hepatic cirrhosis and biliary hyperplasia has been described in three full-sized horses (14 years to 16 years old) and an 11-year-old racing pony (Lavoie and Teuscher, 1993; Pearson *et al*., 1994). Hepatocytes and Kupffer cells contained markedly increased stainable iron in all horses, and iron accumulations were noted outside the liver in tissues including the epithelium of large bile ducts, follicular epithelium of the thyroid gland, cortical tubules of the kidneys, and in the neurohypophysis in the pony (Lavoie and Teuscher, 1993). Iron can accumulate in the liver of animals with chronic liver disease; consequently, one might speculate that the full-sized horses had primary liver disease with secondary iron accumulation (Pearson *et al*., 1994; Schultheiss *et al*., 2002). However, iron accumulation secondary to chronic liver disease is reported to occur in Kupffer cells and macrophages, but not hepatocytes (Schultheiss *et al*., 2002). The widespread iron deposition in the pony is similar to that seen in people with hereditary hemochromatosis.

F. Siderotic Inclusions in Erythroid Cells

Anucleated erythrocytes containing siderotic inclusions are called siderocytes. Nucleated siderocytes have been called sideroblasts in human hematology, in which terminology used for erythrocyte precursors is generally different from that conventionally used in veterinary hematology (Bottomley, 2004). Siderotic inclusions in erythroid cells may consist of cytoplasmic ferritin aggregates or iron-loaded mitochondria. Ferritin aggregates can occur normally in nucleated erythroid cells, but the presence of iron-loaded mitochondria is a pathological finding (Cartwright and Deiss, 1975). Electron microscopy is used to definitively identify the nature of siderotic inclusions (Fresco, 1981; Hammond *et al*., 1969); however, the location of iron-positive inclusions in a ring around the nucleus of a nucleated siderocyte (termed ringed sideroblast in human hematology) strongly suggests the presence of iron-loaded mitochondria (Bottomley, 2004).

Except for iron deficiency, disorders in heme synthesis have the potential to cause excess iron accumulation in mitochondria (Beutler, 1995; Fairbanks and Beutler, 1995). Chronic copper deficiency, as a cause for the formation of siderotic inclusions, was discussed previously. Pyridoxine, vitamin B_6, is required for the first step in heme synthesis, and erythroid cells with iron-loaded mitochondria have been documented in pigs fed a pyridoxine-deficient diet (Hammond *et al*., 1969). Drugs or chemicals reported to cause siderocytes or nucleated siderocytes in dogs include chloramphenicol (Harvey *et al*., 1985), lead, hydroxyzine, zinc (Harvey, 2001), and an oxazolidinone antibiotic (Lund and Brown, 1997).

Siderotic inclusions in erythroid cells have been recognized in some dogs and cats with myeloproliferative disorders (Blue *et al*., 1988; Weiss and Lulich, 1999). Acquired dyserythropoiesis with siderocytes have been reported in dogs in which specific etiologies could not be determined, although some of these animals had inflammatory disorders (Canfield *et al*., 1987; Weiss, 2005). Persistent siderotic inclusions have been recognized in microcytic hypochromic erythrocytes from an English bulldog. Erythrocytes also contained Heinz bodies and rare hemoglobin crystals (Harvey *et al*., 2007). A congenital defect resulting in mitochondrial iron overload and secondary oxidant injury was suspected but not identified.

Congenital anemias with ringed nucleated siderocytes have been reported in humans but not in domestic animals (Bottomley, 2004, 2006). Inherited causes recognized in humans include defective eALAS, adenosine triphosphate-binding cassette 7 (ABC7) transporter, glutaredoxin 5, thiamine transporter, pseudouridine synthase I, and respiratory chain components (Bottomley, 2006; Camaschella *et al*., 2007). Siderotic inclusions occur in erythroid cells of mice genetically altered to produce eALAS deficiency (Nakajima *et al*., 2006) and mitochondrial superoxide dismutase 2 deficiency (Friedman *et al*., 2004).

I. INTRODUCTION

The maintenance of blood fluidity occurs through the process of finely balancing hemorrhage and clotting. Hemostasis, which is the process of arresting the escape of blood from the vascular system, is integral to survival in animals, is regulated by a series of orchestrated events, and is dependent on the vessels through which blood flows, as well as numerous proteins (coagulation factors, inhibitors, and fibrinolytic proteins) and cells (platelets, endothelial cells, and monocytes predominantly). Other systems in the body are also closely related to blood clotting and influenced by the activation of hemostasis such as the innate immune system (complement and phagocytes) and the inflammatory response (the kinin system and the cells important for hemostasis). The stepwise process that takes place to minimize blood loss and repair the injury includes (1) initial vasospasm, (2) platelet activation and plug formation, (3) assembly and activation of the coagulation cascade factors, (4) fibrin clot formation at the site of injury, and (5) dissolution of the clot and vascular repair. Each of these processes is described in more detail in the discussion that follows.

Numerous reviews are available that describe the hemostatic process in detail (Crawley *et al*., 2007; Hoffman and Monroe, 2007; Hopper and Bateman, 2005; Sere and Hackeng, 2003). The goals of this chapter are to review the comparative biochemistry of hemostasis and to describe how the dramatic variations in blood clotting in different species impact laboratory testing, response to therapeutic agents, downstream effects on other body systems, and the array of diseases that can occur.

II. MECHANISMS OF HEMOSTASIS

A. Role of Vascular Endothelium

Endothelial cells that line the lumen of blood vessels are the principal components of the vessel wall that contribute to maintenance of the fluid state of blood during health and the formation of clots during vascular compromise. Besides serving as a direct barrier between blood and tissue, these cells are actively involved in the regulation of hemostasis, inflammation, host defense, and numerous metabolic reactions. The phenotype of endothelial cells varies throughout the body, so the importance of these functions in different parts of the vascular system also varies. The endothelium exhibits plasticity with respect to hemostasis in that it is the balance of pro- and antithrombotic mediators that determine whether normal blood flow, hemorrhage, or clot formation occurs (Table 10-1). Unregulated or widespread activation of endothelial cells can have drastic consequences, as observed with disseminated intravascular coagulation (DIC).

TABLE 10-1 Antithrombotic and Prothrombotic Properties of Endothelium

Antithrombotic Properties	Prothrombotic Properties
Prostacyclin (PGI_2)	Tissue factor release/expression
Nitric oxide	von Willebrand factor
Thrombomodulin	Plasminogen activator inhibitor-1 (PAI-1)
Tissue factor pathway inhibitor (TFPI)	Factor V
Heparan sulfate	Platelet activating factor
Tissue plasminogen activator	P-selectin expression

During homeostasis, endothelial cells promote an anticoagulant and anti-inflammatory state. This is facilitated by several factors including the production of prostacyclin (PGI_2), adenosine, and nitric oxide, which act together to inhibit the association of platelets with the endothelium and with other platelets (Becker *et al*., 2000). The expression of thrombomodulin on the lumenal surface binds any thrombin that may be formed and activates protein C to down-regulate the effects of any factor V (FV) and factor VIII (FVIII) that may be activated (see Section II.C.5.c). Tissue factor pathway inhibitor (TFPI) is synthesized by endothelial cells and is important for preventing co-localization of tissue factor with activated FVII (FVIIa), which would stimulate downstream production of thrombin and subsequently fibrin (see Section II.C.5.a). Tissue plasminogen activator (tPA) from endothelial cells activates plasmin, which results in lysis of any fibrin that is formed (see Section II.D.3). Proteoglycans such as heparin, heparan sulfate, and dermatan sulfate inhibit clotting factors and platelet aggregation. Finally, there is a relative lack of expression of adhesion molecules (e.g., P selectin) that would facilitate tethering of platelets to the endothelial surface (Becker *et al*., 2000).

The initial reaction to vessel injury is vasoconstriction. This is a transient effect that minimizes blood flow to the affected area and is mediated by an autonomic neurogenic reflex and vasoactive mediators including endothelin. Within minutes of vascular injury or activation, the anticoagulant effect can change to a procoagulant milieu with resultant clot formation. Several factors contribute to this alteration. The expression of TF on the endothelial cell luminal surface is usually limited, but if expression is enhanced, activation of the clotting mechanism can occur. At the same time, expression of thrombomodulin and heparan sulfate can be lost, removing an important inhibitor to fibrin clot formation. Release of von Willebrand factor (vWF) from endothelial Wiebel-Palade bodies facilitates the binding of platelets to subendothelial collagen. This contributes to platelet activation and release of granule contents, facilitating platelet aggregation and plug formation (see Section II.B.3.a). Plasminogen activator inhibitor-1 is released, negating the activation of plasmin and thereby minimizing fibrinolysis (see Section II.D.4.a). Thromboxane A2 and platelet activating factor (PAF) are released, which encourage further platelet aggregation and activation. Endothelial cells also contain FV, which, when available, greatly amplifies thrombin formation. Additionally, there is locally enhanced expression of adhesion molecules such as P-selectin, which promote tethering of platelets to the endothelial surface. If the endothelial cell becomes apoptotic, the exposure of phosphatidylserine (PS) on the outer cell membrane leaflet can support the direct formation of thrombin because it can act as the phospholipid source for the prothrombinase complex (Becker *et al*., 2000).

Besides traumatic injury, endothelial dysfunction can occur in various disease states, which may have clinical consequences on a proper functioning hemostatic system. Examples include systemic inflammatory mediators such as tumor necrosis factor (TNF) and interleukin-1 (IL-1), various systemic viral infections, Gram-negative bacteria, rickettsial agents, and in people, cholesterol and oxidative lipoproteins as observed in atherogenesis (see Cullen *et al*., 2005 for a thorough review on atherosclerosis). The outcome of endothelial dysfunction observed in these disease states includes local or disseminated formation of thrombi, vascular permeability causing accumulation of extravascular fluid, and petechiae or hemorrhage.

B. Platelets

Platelet plug formation involves a complex, interrelated sequence of events that overcome local resistance to platelet activation long enough to permit the cessation of bleeding. It is not possible to describe the biochemical events involved in platelet function, activation, and aggregation in a strictly temporal sequence because of the numerous positive feedback reactions, multiple agonists, and complementary intracellular pathways that function in a cooperative, coordinated fashion (Fig. 10-1). For simplicity, the process that results from activation, and leads to platelet plug formation, can be divided into three major events. The initiating response is the tethering of platelets to ligands exposed in the perturbed extracellular matrix (ECM) and subsequent formation of a platelet monolayer around the site of damage. The platelet plug grows when additional activated platelets accumulate on top of this monolayer in a complex series of reactions involving "outside-in" and "inside out" signaling (see Section II.B.2). These events involve platelet shape change, the release of granule contents, and the formation of platelet-platelet aggregates that initiate contact-dependent signaling

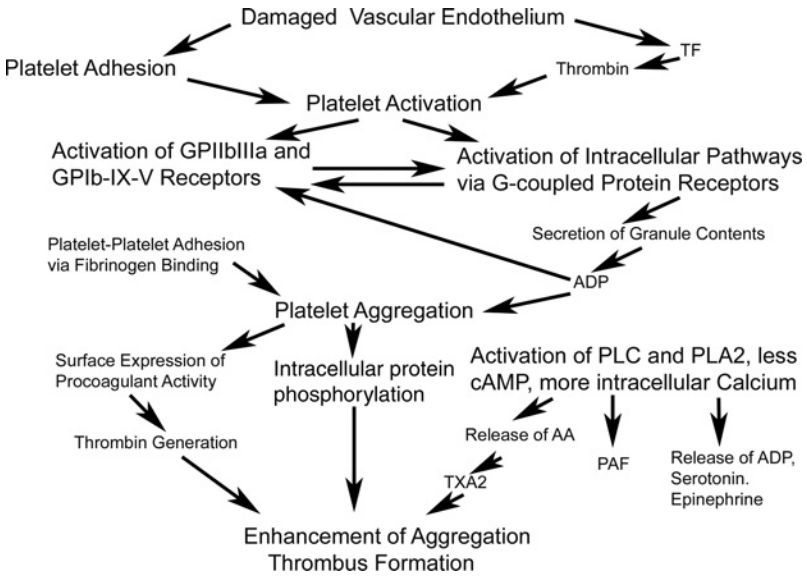

FIGURE 10-1 Simplified sequence of platelet activation and aggregation. Abbreviations: AA, arachidonic acid; ADP, adenosine diphosphate; PAF, platelet activating factor; TF, tissue factor; TXA_2, thromboxane A_2.

and the recruitment of additional intracellular signals. The various reactions are controlled by an integrated network of biochemical pathways (Levy-Toledano, 1999). Results of *in vitro* studies, involving the exposure of platelets from various mammalian species to a single agonist, indicate that there are species differences in the relative importance of various membrane receptors and signaling pathways (Gentry, 1992, 2000b). However, it is difficult to extrapolate the results of *in vitro* studies to the physiological setting. Under *in vivo* conditions, circulating platelets are exposed to multiple agonists and, once platelets are activated, the phenomenon of "crosstalk" between the various extracellular and intracellular signaling pathways occurs (Fig. 10-1). Although most of the current knowledge regarding platelet biochemistry has come from human and murine studies, it is likely that there are more similarities than differences in biochemical mechanisms among species. In addition to a full complement of biochemical pathways, an adequate number of circulating platelets with structural integrity are required for platelets to fulfill their central role in hemostasis.

1. Platelet Production

Platelet formation is the culminating event of megakaryopoiesis. In bone marrow, long, cylindrical processes of megakaryocyte cytoplasm are pinched off, to form proplatelets, and released into the circulation (Nagata *et al*., 2003). These fusiform, or elongated, platelets undergo morphogenesis into mature platelets through additional fragmentation processes involving the fusion of cytoplasmic vesicles with the plasma membrane (Benke, 1993). Fusiform platelets constitute about 15% of the platelet population in the rat and guinea pig, and elongated platelets, up to 20μ long, can occur in horses (Tablin, 2000). The mature mammalian platelet is small, 5 to 7μ long and frequently less that 3μ wide (Tablin, 2000). Early clinical studies indicated that among the physiological roles of interleukins, including IL-1, IL-3, IL-6, and IL-11, was their ability to stimulate platelet production. More recent studies have confirmed that thrombopoietin (TPO) is the primary biochemical regulator of steady state megakaryopoiesis and platelet production (Kuter and Begley, 2002). TPO, also known as c-Mp1 ligand, is a lineage-specific cytokine that is constitutively synthesized in the liver. It is removed from the circulation by binding to the c-Mp1 receptor on platelets and bone marrow megakaryocytes (Kaushansky, 2002). The TPO molecule consists of 331 amino acids organized in two domains, a receptor-binding domain that shows some homology to erythropoietin and a highly glycosylated carboxy-terminal portion that stabilizes the TPO protein. Although TPO increases the size, ploidy, and number of megakaryocytes, and also stimulates the expression of platelet-specific markers, it does not appear to increase the rate of platelet shedding from late-stage megakaryocytes (Choi *et al*., 1996). Circulating TPO levels appear to be directly influenced by platelet mass because TPO levels rise and remain elevated during persistent thrombocytopenia. It is likely that TPO-independent mechanisms are also involved in platelet production because TPO$-/-$ mice are healthy and show no signs of spontaneous hemorrhage, despite being thrombocytopenic (Alexander *et al*., 1996).

The normal circulating life span of mammalian platelets is in the range of 3 to 10 days. The mechanisms involved in the clearance of senescent platelets from the circulation are not yet known, but evidence is emerging that platelet aging is associated with the universal cellular phenomenon of loss of membrane asymmetry. For example, the proportion of canine platelets with PS exposed on the plasma membrane increases with age and is accompanied by

TABLE 10-2 Major Platelet Ligands, Integrin/Receptors, and Their Physiological Effects

Integrin/Receptor	Major Ligand	Effect
$\alpha_2\beta_1$	Collagen	Platelet adhesion to ECM ↑ effectiveness GPVI receptor
GPVI	Collagen	Platelet adhesion to ECM Activation of PLC_r2
GP1b-IX-V	vWF	Up-regulation of $\alpha_2\beta_1$ receptor ↑ intracellular calcium Up-regulation of GPIIb-IIIa receptors
GPIIb-IIIa	Fibrinogen	Calcium mobilization Protein kinase activation Cytoskeleton rearrangement Platelet aggregation
PAR-1 PAR-4	Thrombin	Activation of G_q receptor → $PLC_{\beta 2}$ activation Activation of G_i receptor → ↓ adenylyl cyclase activity

mitochondrial changes consistent with apoptosis (Pereira *et al*., 2002).

2. *Platelet Structure*

Mammalian platelets circulate as discoid, anucleate subcellular particles that contain several types of organelles including α-granules, dense granules, mitochondria, and lysosomes (Triplett, 2000). The majority of mammalian platelets exhibit an extensive canalicular system that is continuous with the plasma membrane, also known as the open-canalicular system (OCS). The OCS not only plays an essential role in platelet adhesion and aggregation but it also facilitates the two-way exchange of biological compounds between the platelet interior and the surrounding plasma (Escolar and White, 1991). In platelets of domestic cattle, horses, and Asian elephants, there is no evidence for the presence of an OCS. Despite this major ultrastructural difference, the biochemical mechanisms involved in platelet aggregation in these species are generally similar to those of other mammalian species (Bondy and Gentry, 1988; Cheryk *et al*., 1997; Gentry *et al*., 1989; Segura *et al*., 2006). The biochemical mechanisms required for normal platelet function are tightly regulated. Multiple positive feedback reactions facilitate rapid adhesion and aggregation at sites of vascular injury, whereas negative feedback responses modulate the continuation of platelet activation and thus regulate the extent of thrombus formation once wound healing has been initiated.

Several types of membrane proteins and phospholipids are essential for platelet adhesion and aggregation (Tables 10-2 and 10-3). Integrins are heterodimeric ($\alpha\beta$) type 1 transmembrane receptors in which each subunit typically contains a large extracellular domain and a short cytoplasmic tail composed of 20 to 60 amino acids. Integrins, like the membrane G-protein coupled receptors (GPCR), can be viewed as "two-faced" receptors. In the case of integrins, the face oriented to the platelet exterior interacts with ligands on the ECM, and the face internally oriented interacts with platelet cytoplasmic proteins. Ligand binding to either face can trigger information transfer across the plasma membrane to initiate biochemical responses at the other face. This type of cross-membrane signaling is referred to as "outside-in" and "inside-out" signaling depending on the direction of information transfer (Barkalow *et al*., 2003; Shattil and Newman, 2004). Current knowledge of integrin biochemistry has come primarily from the investigation of human and murine platelets and the impaired aggregation responses in "knockout" mice. The major integrins involved in platelet adhesion and the stabilization of the primary hemostatic plug are the glycoproteins GPIIb-IIIa (also termed $\alpha_{IIb}\beta_3$), $\alpha_2\beta_1$, the glycoprotein complex GP1b-V-IX, and GPVI, which is a member of the Ig receptor superfamily (Boudreaux, 1996; Gibbins,

TABLE 10-3 Intracellular Activation Signaling Pathways

Effector	Major Actions
Tyrosine and serine/threonine kinases (e.g., Src, Syk, Erk, PKC)	Enzyme activation including PLC, PLA_2, MLCK
↑ intracellular calcium	Calmodulin mediated activation of MLCK Activation of PLC, PLA_2, PKC Activation of phosphodiesterase → ↓ cAMP
PLC_α, PLC_β	Hydrolysis of PI to IP_3 and DAG
IP_3	Activation of calcium-dependent ATPase → release of calcium from dense granules
DAG	Activation of PKC → integrin conformation changes → ↑ affinity of GPIIb-IIIa for fibrinogen
PLA_2	Hydrolysis of PC → release of AA and lyso-PAF

Abbreviations: AA, *arachidonic acid*; DAG, *diacyl glycerol*; IP_3, *inositol 3-phosphate*; MLCK, *myosin light chain kinase*; PAF, *platelet activating factor*; PI, *phosphoinositol*; PKC, *protein kinase* C; PLA_2, *phospholipase* A_2; PLC, *phospholipase* C.

2004; Shattil and Newman, 2004). Other examples of integrins involved in cross-membrane signaling are the ephrins that activate specific Eph kinases to ephrins, enhancing platelet adhesion through phosphatidylinositol 3 (PI3) kinase and protein kinase C (PKC) mediated mechanisms (see Table 10-3) (Prevost *et al*., 2004). CD40, a phosphorylated transmembrane glycoprotein, a member of the TNF receptor superfamily, is constitutively expressed in platelets, but it is only functional following platelet activation by other agonists. It has been shown that CD40 participates in the release of P selectin (CD62P) and other α-granule constituents, following agonist stimulation of human platelets (Inwald *et al*., 2003).

Several members of the GPCR superfamily have been identified as integral components of platelet membranes (Coughlin, 2005b). Platelet agonists bind to the surface-accessible N-terminal domain of these proteins causing information to be transmitted through a seven-transmembrane domain. This induces a conformational change in the intracellular C-terminal domain which, in turn, activates GPCR proteins associated with the intracellular surface of the receptor (Hamm, 2001). GPCR proteins are heterotrimeric, being composed of single α, β, and γ subunits, and are classified into families according to the structure of their α subunit. Members of four families have been identified in human platelets. Activation of G_s and G_i proteins induces an increase and decrease in intracellular cAMP levels, respectively, activation of G_q stimulates the β isoforms of phospholipase C (PLC, see Section II.B.3.c), and activation of the G_{12} contributes to the regulation of the platelet actin cytoskeleton through protein phosphorylation (Brass, 2003). Whether a similar array of G protein receptors is expressed on other types of mammalian platelets has yet to be determined. However, based on studies with murine platelets, it is evident that the abundance of G protein types is necessary to support the similarity of platelet responses to multiple dissimilar agonists (Yang *et al*., 2002).

The most important group of platelet membrane lipids involved in hemostasis are the *phospholipids* (phosphoglycerides), which constitute 63% and 57% of the total lipid content of pig and human platelets, respectively (Gentry and Nyarko, 2000). The major phospholipids involved in platelet function are phosphatidylserine (PS), phosphatidyl ethanolamine (PE), phosphatidylcholine (PC), sphingosine (SP), and phosphatidyl inositol (PI). PI is the parent molecule for the downstream, or secondary messenger, signal transducers inositol triphosphate (IP3) and 1,2 diacylglycerol (DAG) (Table 10-3), whereas PC is hydrolyzed to arachidonic acid (AA) in activated platelets (Nozawa *et al*., 1991). In all species, AA serves as the precursor of thromboxane A_2 (TXA_2) and prostaglandins, such as prostacyclin (PGI_2), and serves as an autocrine agonist in some species (Gentry and Nyarko, 2000). In unstimulated platelets the negatively charged PS and PE are found predominantly on the intracellular side of the plasma membrane, whereas the neutral phospholipids, PC and SP, are localized to the outer leaflet. In response to the elevated intracellular calcium levels that occur following platelet activation, PS and PE are translocated to the outer leaflet of the membrane. Here they congregate to form the lipid platform that is essential for the localized platelet membrane binding and proteolytic activity of two key enzyme complexes in thrombin formation, namely the factor VIIIa-IXa-Ca-PS (tenase) complex and the factor Va-IXa-Ca-PS (prothrombinase) complex (see Section II.C.3).

Platelets contain three types of organelles, also known as granules, in which they transport various specific hemostatic and wound healing compounds around the body (Tablin, 2000). Dense granules contain small nonprotein molecules such as ADP, ATP, serotonin, Ca^{2+}, and Mg^{2+}. The release of ADP and serotonin, from the first layer of activated platelets that adhere to a site of vascular damage, is important in the recruitment of additional platelets and the development of the platelet plug (Fig. 10-1) α-granules, the largest granule population, contain a variety of proteins such as albumin, fibronectin, thrombospondin, and the hemostatic proteins, fibrinogen, and FV (Polasek, 2004). They also contain platelet-specific proteins, including β-thromboglobulin and platelet factor 4, platelet derived growth factor (PDGF), epidermal growth factor (EGF), transforming growth factor β (TGFβ), and endothelial cell growth factor (ECGF) (Rendu and Brohard-Bohn, 2001).

The proteins stored in the α-granules are either synthesized by megakaryocytes or are endocytosed by platelets as they circulate around the body (Reed, 2004). Like other endocytotic cell types, platelets contain lysosomes that release hydrolases. It has been suggested that these hydrolases assist in the elimination of circulating platelet aggregates to prevent inappropriate thrombus formation (Rendu and Brohard-Bohn, 2001). Mitochondria and cytoplasmic glycogen stores provide the energy to support the granule exocytotic secretory process in activated platelets (Flaumenhaft, 2003). This exocytosis process involves contraction of the actin-myosin cytoskeleton and the apposition and fusion of each granule membrane with the platelet plasma membrane (Escolar and White, 1991; Reed, 2004; Rendu and Brohard-Bohn, 2001). In addition to the extrusion of granule contents, the alteration in platelet morphology results in the exposure of both GPIIb-IIIa integrin complexes and membrane markers, such as CD62 and CD63, on the surface of the activated platelets (Polasek, 2004). CD62, also referred to as P-selectin, has been used as a marker of activated canine platelets (Moritz *et al*., 2003a, 2003b).

3. *Platelet Activation*

a. Immobilized Agonists

When the ECM is damaged, various macromolecules interact with platelets as they roll along the exposed subendothelial surface collagen. Of these, collagen-bound vWF is considered to be the most important for the initial tethering and adhesion of platelets to areas of vascular damage (Nieswandt and Watson, 2003). This occurs through the interaction of collagen-bound vWF with the GPIb-IX-V integrin complex. However, at the medium and high shear rates found in arteries and arterioles, this reaction is reversible and must be followed by the more stable binding of collagen to its specific platelet receptors $\alpha_2\beta_1$ and GPVI (Table 10-2). The initial interaction between platelets and the ECM through vWF-GPIb-IX-V binding is important because it induces activation of intracellular tyrosine kinases, causing increased affinity of $\alpha_2\beta_1$ for collagen binding as well as an increase in the affinity of GPIIb-IIIa for a variety of ligands including fibrinogen, vWF, fibronectin, vitronectin, and thrombospondin (Calvete, 2004). The two collagen receptors, $\alpha_2\beta_1$ and GPVI, are thought to have complementary functions in platelet adhesion (Andrews and Berndt, 2004). In human platelets, $\alpha_2\beta_1$ binds collagen in an Mg^{2+}-dependent manner, tethering platelets to the ECM before platelet activation. At the same time, collagen-$\alpha_2\beta_1$ binding facilitates the interaction between collagen and GPVI in a nontyrosine kinase-dependent reaction. GPVI is currently considered to be the major collagen receptor because it initiates shape change, activation, and secretion reactions following platelet adhesion (Nieswandt and Watson, 2003). In mouse platelets, it appears that GPVI provides the primary collagen signal that activates and recruits $\alpha_2\beta_1$ integrins to the surface of the platelet so that collagen signaling is amplified (Chen and Kahn, 2003). One of the important intracellular pathways activated as a result of collagen binding to GPVI is the PLC pathway, specifically the activation of the $PLC_{\gamma 2}$ isomer (Savage *et al*., 2001).

As platelets adhere to collagen and receptor activation occurs, they lose their resting discoid shape and extend pseudopods as they spread over the endothelial surface (Escolar and White, 1991; Gentry, 2000b). This increases the surface area of the platelets, which, coupled with the clustering of integrin molecules on platelet membranes and the increase in integrin affinity, results in the formation of irreversible platelet-endothelial binding via vWF and the GPIb-IX-V receptors and platelet-platelet interactions via vWF and fibrinogen binding to GPIIb-IIIa receptors (Boudreaux, 1996; Savage *et al*., 2001). The GPIb-IX-V receptor is a sialoglycoprotein-rich complex that contributes to the net negative charge on the platelet surface. GPIb consists of two disulfide-linked subunits, $GPIb_\alpha$ and $GPIb_\beta$, that are associated with GPIX in a 1:1 complex (Lopez and Dong, 1997). In mouse platelets, the activation function of vWF binding to GPIb-IX-V is, like collagen binding to the GPVI receptor, dependent on tyrosine phosphorylation (Shattil and Newman, 2004). This phosphorylation activity is dependent on the FcR, a molecule that associates noncovalently with GPVI and GPIb-IX-V. FcRγ is a component of the multisubunit high-affinity receptor for immunoglobulin (IgE), and its tyrosine-phosphorylated active motif helps to recruit tyrosine kinases to the glycoprotein receptors. The binding site for vWF on the receptor complex is localized to a site on the $GPIb_\beta$ chain, which can also serve as a thrombin receptor. The outside-in signaling events that ensue from vWF-$GPIb_\beta$ binding include activation of protein kinase C (PKC), protein kinase G (PKG) and phosphoinositol 3 kinase (PI3K), elevation of intracellular Ca^{2+}, and rearrangement of the cytoskeleton (Gibbins, 2004). These reactions complete the irreversible adhesion of the activated platelet monolayer to the damaged endothelium. As part of the defense mechanism against inappropriate platelet adhesion and aggregation, GPIb-IX-V receptors only bind vWF immobilized on collagen and not soluble vWF, except under conditions of high shear flow rates (Lopez and Dong, 1997).

The continued growth of the platelet plug requires platelet-platelet adhesion that is accomplished through a process described as "contact-dependent" signaling and involves the expression and activation of GPIIb-IIIa receptors (Shattil and Newman, 2004). GPIIb-IIIa is the most abundant integrin on the platelet surface and is not only necessary for platelet-platelet aggregation but also for platelet secretion, the development of procoagulant activity, and clot retraction. This integrin is typical of type 1 membrane receptors in that it contains a relatively large

globular external domain, formed by the association of the N-terminal ends of both the α and β subunits, a single pass transmembrane domain and short C-terminal cytoplasmic tails composed of 20 to 60 amino acids (Hynes, 2002). The ligand binding sites contained in the external domain are converted to a high-affinity state through several inside-out signaling mechanisms. Among these signals are the interaction of the α and β subunit cytoplasmic tails with cytoskeleton proteins, actin and talin, inducing the formation of larger actin-based signaling complexes that are essential for granule migration and the fusion of granule and plasma membranes that precede the secretion of granule contents (Williams *et al*., 1995). Fibrinogen is the primary hemostatic ligand for GPIIb-IIIa, and fibrinogen bridges between platelets are the backbone of stable platelet aggregates. Other plasma proteins, including vWF, fibronectin, vitronectin, and thrombospondin, that have an RGD sequence similar to that present in fibrinogen can also bind to the α subunit of the GPIIb-IIIa. Fibrinogen has two RGD sequences per monomer, but it can also bind to GPIIb-IIIa through a recognition site involving residues 400 to 411 on its γ chain (Calvete, 2004; Williams *et al*., 1995). Occupancy of GPIIb-IIIa binding sites with fibrinogen up-regulates this integrin by inducing microclustering, as well as initiating downstream signaling through activation of Src and Syk protein kinases (Tables 10-2 and 10-3) (Shattil and Newman, 2004).

It is now recognized that GPIIb-IIIa plays a continuing role in platelet function after a thrombus has formed through its role in clot retraction (Osdoit and Rosa, 2001). It has been postulated that one of the reasons platelet-rich clots are more resistant to thrombolysis than platelet-poor clots is related to the lower affinity of tissue plasminogen activator (tPA) for the retracted fibrin fibers of a platelet-rich clot compared to the less retracted fibrin fibers of a platelet-poor clot (Collet *et al*., 2002) (see Section II.D.2.b). Although the biochemical mechanisms involved in clot retraction are poorly understood, studies with mouse platelets have shown that after the initial wave of tyrosine phosphorylation initiated by activation of the β_3 cytoplasmic tail of the GPIIb-IIIa receptor, a sustained GPIIb-IIIa-dependent tyrosine dephosphorylation of several polypeptides occurs (Osdoit and Rosa, 2001). This dephosphorylation response causes actin-dependent changes in the cytoskeleton that result in shrinkage in the size of the platelet-fibrin mass.

b. Soluble Agonists

In addition to immobilized collagen and vWF on the surface of damaged ECM, there are several soluble mediators that act as potent platelet agonists in the aggregation of mammalian platelets (Gentry, 2000b). The local accumulation of thrombin, generated from TF expression on the surface of damaged endothelial cells (see Section II.C.2), and ADP, released from α-granule stores in activated platelets, is essential for the growth of the primary hemostatic plug on top of the initial monolayer of collagen-bound platelets. Thrombin and ADP, and in some species TXA_2, induce similar platelet-platelet aggregation formation through activation of the $\alpha_{IIb}\beta_3$ receptors (Brass, 2003).

The major pathways of thrombin-induced activation result from hydrolysis of specific thrombin substrates, protease-activated receptors-1 and -4 (PAR-1, PAR-4), that are members of the G-protein coupled seven transmembrane domain receptor family (Major *et al*., 2003). To activate these receptors, thrombin cleaves the N-terminus, exposing a new N-terminus that serves as a "tethered-ligand" and binds to the extracellular-2 domain of the cleaved receptor (Dugina *et al*., 2002). A highly effective local concentration of this ligand is present, as it is not free to diffuse away from the platelet surface (Brass, 2003). Activation of PAR-1 and PAR-4 causes a downstream activation of G_q, G_{12}, and G_i that, in turn, leads to the activation of the β isomer of PLC, PI3-kinase, and the inhibition of adenylyl cyclase, respectively (Table 10-2) (Grand *et al*., 1996). Studies on PAR receptors to date have focused on human and murine platelets, and results have revealed distinct differences in PAR receptor expression. In human platelets, activation of PAR-4 requires 10- to 100-fold higher concentrations of thrombin than PAR-1. Hence, PAR-1 is considered to be the more important thrombin receptor (Kahn *et al*., 1998). This difference in receptor sensitivity may be related to the hirudin-like sequences in PAR-1, but not PAR-4, that facilitate receptor cleavage by thrombin. In contrast, PAR-4 is the primary thrombin receptor in mouse platelets (Ishihara *et al*., 1997). In this species the cleavage of PAR-4 is facilitated by PAR-3 receptors. PAR-3 is the only member of the PAR family that does not possess an activating peptide, and, hence, it cannot directly activate platelets. PAR-2, the fourth member of the PAR family to be identified, is not activated by thrombin but by other serine proteases such as trypsin, TF, and FXa (Camerer *et al*., 2000). The PAR-2 receptor has not been found on platelets but is present in a number of other cell types, including endothelial cells. The potency of thrombin as an agonist may also be related to its ability to interact not only with PARs but also non-PARs, particularly the GPIbα component of the GPIb-IX-V complex (Soslau *et al*., 2001). It has been suggested that, in human platelets, binding of thrombin to GPIbα may facilitate PAR-1 cleavage in a manner analogous to the role of PAR-3 in mouse platelets (DeCandia *et al*., 2001).

ADP was the first low-molecular-weight platelet-aggregating agent to be discovered and, like thrombin, is recognized as a universal agonist. It is stored in dense granules, in near molar amounts, and can be released not only from this source but also from damaged endothelial cells and red blood cells at sites of vascular damage (Gachet, 2001). ADP induces a broad range of biochemical changes in platelets. By itself, it is a relatively weak agonist, but it

exhibits synergy with the stronger agonists, such as collagen and thrombin, which induce its secretion from dense granules (Mills, 1996). Further, low concentrations of ADP potentiate and amplify the effects of other weak agonists such as serotonin, epinephrine, and TXA2 (Dangelmaier *et al*., 2001). So far, three platelet ADP receptors have been identified: $P2Y_1$, $P2Y_{12}$, and $P2X_1$ (Table 10-2) (Gachet, 2001). The central role of ADP in platelet function may be due, at least in part, to its ability to directly cause an elevation in intracellular calcium levels while simultaneously stimulating two biochemical pathways, one of which is mediated through G_q/PLC-mediated reactions (Table 10-3) and the other through G_{i2}-mediated inhibition of adenylyl cyclase. Co-activation of both G_q and G_{i2} pathways, through $P2Y_1$ and $P2Y_{12}$, respectively, are essential for normal ADP-induced aggregation (Gachet, 2001). $P2Y_1$ and $P2Y_{12}$ are GPCRs that exhibit the usual seven hydrophobic domains and are sometimes referred to as "metabotropic." In addition to activating the PLC_β isomer of PLC, the $P2Y_1$ receptor induces phosphorylation of myosin light chain kinase (MLCK), which permits reversible incorporation of proteins, such as actin and talin, into the cytoskeleton to promote shape change (Savage *et al*., 2001). This cytoskeletal reorganization is accompanied by an increase in the levels of the regulatory subunit of P13 kinase analogous to that observed following activation of platelets by thrombin (Rittenhouse, 1996). When ADP interacts with the $P2Y_{12}$ receptor it causes the heterodimeric G_i protein to disassociate into its α_{i2} and β_γ subunits, which in turn causes the inhibition of adenylyl cyclase and a reduction in intracellular cAMP levels. These biochemical reactions slow the rate of calcium removal from the cytosol, which helps sustain the aggregation response. ADP also facilitates the development of stable platelet-platelet aggregates because activation of both the $P2Y_1$ and $P2Y_{12}$ receptors enhances the number and clustering of binding sites for fibrinogen on $\alpha_{IIb}\beta_3$ receptors (Gachet, 2001). The $P2X_1$ receptor resembles a ligand-gated ion channel protein, exhibits two hydrophobic domains, and is referred to as "ionotropic" (Gachet, 2001; Mills, 1996). ADP interacts with its receptors as the anion ADP^{3-}, indicating that positively charged groups on the receptors are involved in ligand binding. The major advances in knowledge of ADP receptors have come from studies with human and mouse platelets. It appears that at least the $P2Y_1$ and $P2Y_{12}$ receptors may be ubiquitous, although the relative number and sensitivity of receptors may differ (Coomber *et al*., 2006). For example, compared to human platelets, the $P2Y_{12}$ receptor may have a more important role in equine platelets than the $P2Y_1$ receptor (Mateos-Trigos *et al*., 2002).

Platelet-activating factor (PAF) is also a potent soluble inducer of platelet aggregation but, unlike the universal agonists thrombin and ADP, not all mammalian platelets exhibit specific PAF receptors. Like human platelets, cow, sheep, horse, pig, dog, cat, elephant, guinea pig, and rabbit platelets respond to PAF at concentrations between 10^{-10} and 10^{-7}M (Kulikov and Muzya, 1998). Platelets from mice, rabbits, and hamsters are unresponsive to PAF. PAF is a proinflammatory lipid mediator with a unique 1-O-alkyl-glycerophospholipid backbone that exhibits multiple biological properties, including activation of platelets, neutrophils, monocytes, and macrophages (Chao and Olson, 1993; Prescott *et al*., 2000). In PAF activated endothelial cells and platelets, cytoplasmic PLA_2 simultaneously releases AA and lyso-PAF that is converted to additional PAF molecules by acetyl CoA lyso-PAF transferase (Chao and Olson, 1993; Honda *et al*., 2002). In endothelial cells, PAF is translocated from its site of synthesis in the endoplasmic reticulum to the plasma membrane where the polar head of the molecule is inserted into the outer leaflet and serves as a juxtacrine ligand (Honda *et al*., 2002). In contrast, PAF formed in platelets, from lyso-PAF, is released into the circulation. PAF is degraded in the plasma by removal of an acetyl group at the sn-2 position, regenerating lyso-PAF and acetate. This reaction is catalyzed by a PAF acetylhydrolase that circulates in association with low-density and high-density lipoproteins (Prescott *et al*., 2000). The PAF receptor (PAFR) possesses the typical structure of the GPCRs. Therefore, PAF can induce intracellular protein phosphorylation in activated platelets indirectly through DAG stimulated protein kinase C activation, as well as through activation of tyrosine kinases (Table 10-2).

It is well established that platelets from various species exhibit different sensitivities when exposed *in vitro* to a single dose of a weak agonist such as serotonin, epinephrine, or arachidonic acid (Dodds, 1978; Meyers and Wardrop, 1991, Pelagalli *et al*., 2002). Serotonin causes only a weak aggregation response in human, rabbit, cat, cow, sheep, and horse platelets, whereas canine platelets are unresponsive (Bailey *et al*., 2000; Mischke and Schulze, 2004; Ogawa *et al*., 1998). As in mammalian platelets, serotonin is present in thrombocytes of birds and reptiles (Maurer-Spurej, 2005). In these species serotonin acts as a vasoconstrictor and plays a role in endothermic body temperature regulation through its ability to regulate skin blood flow. It has been postulated that serotonin released from activated platelets may also have a role in mammalian thermoregulation (Maurer-Spurej, 2005). Canine and equine platelets are relatively unresponsive to epinephrine alone (Mischke and Shulze, 2004; Segura *et al*., 2005). The ability of epinephrine to act synergistically with collagen is used to advantage for the assessment of platelet function in whole blood with the PFA analyzer (see Section III.B.2.c). However, the response of both canine and equine platelets is lower when collagen-epinephrine is used as the agonist compared to collagen-ADP (Mischke and Shulze, 2004; Segura *et al*., 2005).

c. Intracellular Signaling Mechanisms

The ligand binding of integrins and agonist binding to G-protein coupled receptors initiate intracellular signaling

through multiple, interrelated pathways. The major signal transduction systems are summarized in Table 10-3. These biochemical pathways appear to be universal in platelets from all species, although they have been primarily investigated in human platelets. The limited information available for nonhuman platelets indicates that variations occur in the relative predominance of the individual enzymatic pathways (Gentry, 1992, 2000b). Protein phosphorylation by tyrosine and serine/threonine kinases is known to be critical for the modulation of the biological functions of platelets. Enzyme systems that have been identified include the nonreceptor tyrosine kinases, Src and Syk, that activate the cytoplasmic tail of the GPIIb-IIIa integrin β_3 chain inducing an increase in the affinity of the α_{IIb} chain for fibrinogen (Marshall *et al*., 2004). The fibrinogen binding reaction is also enhanced by protein kinase C (PKC), following its activation through a diacylglycerol (DAG)-dependent mechanism (Buensuceso *et al*., 2005). $\alpha_2\beta_1$ activation of collagen-adherent platelets also stimulates phosphorylation of proteins such as Src, Syk, and the $PLC_{\gamma 2}$ isomer of PLC, all of which are components in the GPVI-FcRγ-chain cascade (Inoue *et al*., 2003). Activation of platelets by collagen-GPVI interaction induces PKC-Ca^{2+}-mediated activation of the MLCK that, in turn, induces the cytoskeletal changes necessary for granule secretion. The phosphorylation of the myosin light chain can also occur through a Ca^{2+}/calmodulin mechanism that is mediated by an extracellular signal regulated kinase (Erk2) (Toth-Zsamboki *et al*., 2003).

The elevation of free cytosolic calcium, following receptor-mediated influx of extracellular calcium and secondary release of calcium from the dense tubular system, is one of the critical biochemical events in platelet activation in all species (Gentry, 2000b; Heemskerk and Sage, 1994). In addition to mediating the activation of PKC, calcium is directly involved in the regulation of phospholipid metabolism through activation of the calcium-dependent enzymes phospholipase C (PLC) and phospholipase A2 (PLA2). A further response to increased intracellular calcium is the lowering of intracellular cyclic adenosine monophosphate (cAMP) levels through activation of cAMP phosphodiesterase. The reduced cAMP levels exert a positive feedback response to further increase intracellular calcium levels, which, in turn, further enhance platelet reactivity and aggregation (Table 10-3).

PLC is one of the secondary messenger systems that is universally activated by platelet agonists. It catalyses the cleavage of membrane bound phosphatidyl 4,5 bisphosphate (PIP2), one of the phosphorylated derivatives of PI, to lipophilic membrane bound DAG and hydrophilic IP3 that is released into the cytoplasm (Kroll and Schafer, 1989; Nozawa *et al*., 1991). DAG and IP3 act synergistically as signal transducers to promote all aspects of the basic platelet response, including shape change, increase in integrin and receptor affinity, and secretion of granule contents (Table 10-3). As noted previously, DAG-activated kinases, such as PKC, cause protein phosphorylation to mediate cellular changes such as increased affinity of GPIIb-IIIa integrins and a rise in intracellular calcium. IP_3 is also instrumental in elevating calcium levels through the activation of a calcium transporting adenosine triphosphate (ATPase) system that mobilizes calcium from the dense tubular system. The continued functioning of the IP_3-DAG system depends on the continued agonist-receptor-mediated activation of PLC, as both IP_3 and DAG are rapidly converted to inositol and phosphatidic acid (PA), respectively. Both inositol and PA can be utilized for the resynthesis of PI and therefore are recycled within the platelet (Nozawa *et al*., 1991).

In platelets from most species of domestic animals, collagen and thrombin are more potent activators of the phospholipase A_2 (PLA_2)-mediated secondary messenger system than are ADP or PAF (Gentry and Nyarko, 2000). PLA_2 is an acyl hydrolase that cleaves the sn-2 acyl bond of the platelet membrane phospholipids, PC and PE, to release AA and lysophospholipids (Puri, 1998). AA is the major free fatty acid present in both platelet membranes and granules. Following its release into the cytoplasm, it is rapidly metabolized by the cyclooxygenase and lipoxygenase enzyme systems into labile products that function as both intracellular and extracellular messengers (Gentry and Nyarko, 2000). Unlike many nucleated cells, including endothelial cells that contain two forms of cyclooxygenase (COX), only the constitutively expressed form, COX-1, is found in platelets. In platelets, COX-1 first oxidizes and cyclizes AA to form prostaglandin PGG_2, which it subsequently hydrolyzes to prostaglandin PGH_2. These cyclic endoperoxides are rapidly metabolized to TXA_2 by thromboxane synthetase; prostacyclin (PGI_2) by PGI synthetase; or are converted to the eicosanoids, PGD_2, PGE_2, or PGF_2 by isomerase enzymes that have yet to be fully characterized in platelets. In most mammalian platelets, TXA_2 is the major metabolite, and in human platelets, it exerts a positive feedback effect on platelet aggregation through its receptor. Variable responses to TXA_2 have been found in canine platelets, and bovine platelets do not respond to this agonist (Gentry, 1992, 2000b). It is possible that the variable response of mammalian platelets to the agonist effect of TXA_2 is related to different receptor populations in different species. Because of the labile nature of TXA_2, its stable metabolite, TXB_2, is used to evaluate the extent of AA metabolism in activated platelets. Comparable to the difference in aggregation response to TXA_2, the level of TXB_2 released from thrombin-stimulated human, horse, and cat platelets is 10-fold greater than the amount released after similar activation of cow, pig, sheep, and mink platelets (Gentry and Nyarko, 2000).

d. Negative Regulation of Aggregation

To balance the ability of platelets to be rapidly activated when needed, a number of regulatory mechanisms exist

TABLE 10-4 Inhibitory Intracellular Signaling Mechanisms

Effector	Major Actions
PGI_2	↑ adenylyl cyclase activity → ↑ cAMP Inhibition of PI hydrolysis → ↓ IP_3 and ↓ DAG
cAMP	↓ free cytosolic calcium Inhibition of PI hydrolysis Suppression of adhesion and aggregation responses
NO/cGMP/cGKI	Inhibition of $ADP2Y_{12}$ receptor activation Inhibition of GPIIb-IIIa receptor activity
PECAM-1	Inhibition of collagen stimulated calcium Mobilization, granule secretion, and aggregation

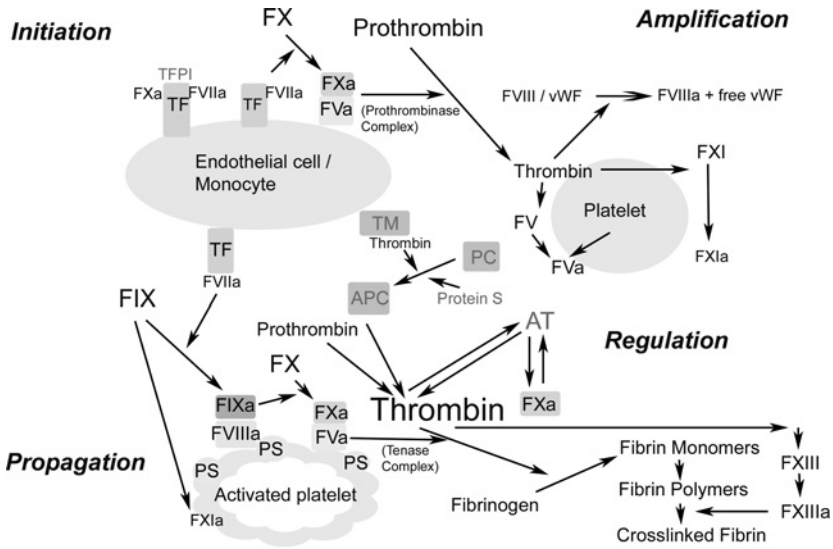
Abbreviations: DAG, *diacyl glycerol*; GKI, GMP-*dependent protein kinase*; IP_3, *inositol 3-phosphate*; NO, *nitric oxide*; PECAM, *platelet endothelial cell adhesion molecule*; PGI_2, *prostacyclin*; PI, *phosphoinositol*.

that prevent unwarranted platelet activation and limit the extent of aggregation. Most of the important physiological platelet inhibitors are endothelial-derived factors and their mediators (Table 10-4). The PGI_2/cAMP and nitric oxide (NO)/cGMP inhibitory pathways have multiple synergistic interactions with respect to cyclic nucleotide generation/degeneration and protein phosphorylation in platelets (Schwarz *et al*., 2001).

Eicosanoids, such as PGI_2 and TXA_2, are autocoids that only influence the activity of cells in the proximity of the producing cell. Both compounds are metabolites of AA, and whereas TXA_2 is the major product in platelets, PGI_2 is the major end product in endothelial cells after stimulation by agonists such as thrombin, ADP, and inflammatory mediators. PGI_2 acts as a potent platelet inhibitor, whereas enhancement of aggregation occurs in response to TXA_2 (deGroot and Sixma, 1996). To a great extent, platelet function is regulated by the intracellular concentration of cAMP. In platelets, as in other cells, cAMP formation is regulated bimodally by GPCRs that stimulate or inhibit adenylyl cyclase (Tables 10-2 and 10-3). PGI_2 suppresses intracellular signaling in activated platelets by stimulating adenylyl cyclase formation via G_s-coupled IP receptors (Moncada and Vane, 1976). This results in the activation of a cAMP-dependent protein kinase (PKA) that stimulates the phosphorylation of a low-molecular-weight GTP-binding protein, rap 1B, which subsequently dissociates from the platelet membrane and inhibits PLC membrane binding. The net effect of this response is to suppress PI hydrolysis and reduce intracellular levels of IP_3 and DAG (Table 10-4). In addition to these effects on phospholipid metabolism, elevated cAMP levels reduce platelet reactivity through a number of mechanisms. These include a reduction in GPIIb-IIIa expression and a reduction in the magnitude and duration of elevated cytosolic-free calcium after platelet activation (Gentry, 2000b).

Human platelets generate cGMP through the soluble NO-activated guanylyl cyclase enzyme and degrade it through the phosphodiesterase (PDE 2 and 5) (Feil *et al*., 2003). The inhibitor effects of cGMP on platelet adhesion/activation are mediated through a cGMP-dependent protein kinase, cGKI (Table 10-4). The isomer present in platelets is $cGKI_\beta$, a homodimer consisting of two 75-kDa subunits. Each subunit is composed of an N-terminal domain that suppresses kinase activity in the absence of cGMP, a regulatory domain that contains two nonidentical cGMP-binding sites, and a kinase domain that catalyzes the transfer of the γ phosphate of ATP to the hyroxyl group of a serine/threonine side chain of the target protein (Feil *et al*., 2003). One of the ways in which cGKI contributes to a negative feedback response is through the inhibition of the G_q/G_i-coupled receptor responses, particularly in response to activation of the ADP-$P2Y_{12}$ receptor (Atkas *et al*., 2002). Another negative feedback response is initiated by cGKI-mediated phosphorylation of platelet proteins, such as vasodilator-stimulated phosphoprotein (VASP), and is correlated with inhibition of the GPIIb-IIIa-fibrinogen receptor (Feil *et al*., 2003). Studies with cGKI-deficient mice have shown that platelet cGKI, but not endothelial or smooth muscle cGKI, plays an important role in the prevention of platelet adhesion and aggregation in the microcirculation after ischemia (Massberg *et al*., 1999).

Platelet endothelial cell adhesion molecule (PECAM-1), also known as CD31, is a 130-kDa type 1 transmembrane glycoprotein whose function is regulated by phosphorylation of serine residues in the cytoplasmic domain (Newman and Newman, 2003). Based on cDNA sequencing, there appears to be considerable homology in PECAM-1 across species. Phosphorylated PECAM-1 serine residues have been detected in resting platelets, and their level of phosphorylation increases two- to three-fold in collagen and thrombin-activated platelets. PKC is thought to play a primary role in this phosphorylation process, although Src kinases may also be involved (Edmead *et al*., 1999). The presence of two distinct immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in the cytoplasmic domain characterize PECAM-1 as belonging to the Ig-ITIM family of inhibitory receptors (Newman, 1999). ITIM-containing inhibitory receptors are thought to function primarily by counteracting signal transduction pathways initiated by receptors via their immunoreceptor tyrosine-based activation motifs, such as the FcR_γ chain that is associated with the GPVI collagen receptor (Ravetch and Lanier, 2000). PECAM-1 is capable of inhibiting calcium mobilization, granule secretion, and aggregation following collagen activation of the GPVI/FcR_γ chain complexes (Table 10-4) (Newman and Newman, 2003). It is important to note, however, that PECAM-1 inhibitory signaling can be overcome



*Adapted from Roberts, Monroe & Hoffman, William's Hematology, 6th Ed. Ch. 112

FIGURE 10-2 Major components of pro- and anticoagulant systems. Black lines represent activation reactions, and red lines represent inhibitory reactions. Abbreviations: APC, activated protein C; AT, antithrombin; PC, protein C; PS, phosphatidylserine; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; vWF, von Willebrand factor.

by strong stimulation of GPIV/FcR$_\gamma$ chain receptors, and that PECAM-1 does not inhibit GCPR signaling (Patil *et al*., 2001). Consequently, when endothelial damage is severe enough to expose high concentrations of collagen and to locally generate thrombin, PECAM-1 will not be an effective inhibitor of thrombus formation.

C. Coagulation Proteins, Complexes, and Thrombin Activation

1. *Overview*

Bleeding from a vessel may be transiently arrested by vasospasm and platelet plug formation, but the formation of a thrombus eventually occurs and provides a permanent clot while repair occurs. The soluble plasma coagulation proteins are required for formation of the thrombus. Most of these proteins are made in the liver, but other cells, including endothelial cells and platelets, are important sources of additional coagulation factors. Most coagulation proteins circulate in plasma as inactive zymogens, but when provided with the appropriate catalyst, they become activated in a cascade-like manner to ultimately produce thrombin and then fibrin (Fig. 10-2). Along with a phospholipid surface provided by activated platelets and calcium as a cofactor, this series of enzymatic reactions result in cross-linked fibrin deposition within the platelet plug. Most coagulation proteins have a Roman numeral designation, which is followed with an "a" when referring to the activated form (e.g., FVII is the inactive zymogen, whereas FVIIa is the activated protein). All coagulation proteins additionally may be referred to by a common or alternate name (Table 10-5). Specific details of the characteristics of individual factors can be found elsewhere (Dodds, 1997), but details on groups of proteins and how they contribute to blood clot formation are provided in Section II.C.2.

TABLE 10-5 Coagulation Factors

Traditional Designation	Alternate Name(s)
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue factor
Factor V	Proaccelerin, accelerator globulin
Factor VII	Proconvertin
Factor VIII	Antihemophiliac factor
Factor IX	Christmas factor
Factor X	Stuart factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman factor
Factor XIII	Fibrin stabilizing factor
Prekallikrein	Fletcher factor

2. *Complexes of the Procoagulant System*

a. Tissue Factor-FVIIa Complex

Currently, a single pathway, the tissue factor (TF) pathway, formerly known as the extrinsic pathway, is considered to be predominant in the initiation of thrombin formation (see Fig. 10-2). TF is a lipid-dependent transmembrane glycoprotein

that is present in unactivated endothelial cells and monocytes, as well as free in plasma (Monroe and Key, 2007). TF is recognized to contribute to many biological processes in addition to coagulation, which include thrombus propagation, migration and proliferation of vascular smooth muscle cells, development of embryonic blood vessels, tumor neovascularization and metastasis, and induction of the proinflammatory response (Monroe and Key, 2007). Following cellular activation by vascular trauma or an inflammatory stimulus, TF becomes exposed on the plasma membrane where it interacts with circulating FVII, or its activated form, FVIIa, to form the enzymatically reactive TF-FVIIa complex (Gentry, 2004). About 99% of FVII circulates in the inactive zymogen form (Monroe and Key, 2007). Cell-associated TF binds to either FVII or FVIIa in order to either promote FVII activation or enhance catalysis, respectively. TF and FVII/FVIIa bind together over a large area at multiple sites in a Ca^{+}-dependent manner to form the binary complex. The stabilization of the structure of FVIIa is crucial for its procoagulant activity. Unique from tenase and prothrombinase complex formation, TF-FVIIa complex formation is less dependent on a phospholipid surface for expression of its procoagulant activity (Monroe and Key, 2007). This complex functions primarily to convert FX to its activated form, FXa, but it also activates circulating FIX to FIXa. It is this FXa formation that results in initial production of thrombin (see Section II.C.3).

b. Tenase Complex

Factor IX in plasma is proteolytically activated to the serine protease factor IXa by the TF-VIIa complex (see Section II.C.2.a) (see Fig. 10-2). FVIII normally circulates in a complex with von Willebrand factor (vWF), which effectively extends the plasma half-life of FVIII because it is protected from proteolytic degradation in the complex form (Gentry, 2004). Initial thrombin formation not only results in dissociation of FVIII from vWF, but it also converts it to a more potent cofactor, FVIIIa. Factor IXa and factor VIIIa then assemble on phosphatidyl-L-serine-containing phospholipid membranes in the presence of Ca^{2+} to form an enzymatic complex known as the tenase complex (Blostein *et al*., 2003). The tenase complex converts factor X to factor Xa, the enzyme that converts prothrombin to thrombin leading to the conversion of fibrinogen to fibrin and the formation of a fibrin clot. This tenase complex cleaves FX at the same reactive site as that cleaved by the TF-FVIIa complex and hence produces the same FXa product. Factor X activation by the tenase complex is the rate-limiting step for thrombin generation during tissue factor-dependent coagulation (Blostein *et al*., 2003).

c. Prothrombinase Complex

The generation of thrombin requires the formation of the prothrombinase complex, which consists of FXa, phospholipid, calcium, and a protein cofactor, FV (Gentry, 2004) (see Fig. 10-2). The complex catalyzes two cleavages in prothrombin, at Arg320 (to produce meizothrombin) and at Arg271, leading to the formation of thrombin (Autin *et al*., 2006). The first few molecules of thrombin generated by this prothrombinase complex initiate several positive-feedback reactions that sustain its own formation and facilitate the rapid growth of the blood clot or thrombus around the area of vascular damage. For example, thrombin can convert FXI to its proteolytically active form, FXIa, which, in turn, converts FIX to FIXa. The thrombin-induced conversion of FV to FVa, along with the increased availability of FXa, greatly enhances the rate and extent of thrombin formation by the prothrombinase complex. This is a crucial reaction for normal blood coagulation. FXa alone can slowly activate PT, but the rate of thrombin formation is enhanced several orders of magnitude by the presence of FVa in the PTase complex (Autin *et al*., 2006). Another positive feedback response is the increased availability of phospholipids on the surface on thrombin-activated platelets that accumulate at sites of vascular damage (Gentry, 2004).

3. *Mechanisms of Thrombin Formation*

Minimal activation of coagulation proteins is needed to initiate further propagation and amplification of the cascade of reactions that ultimately leads to the formation of thrombin, which then converts fibrinogen to fibrin and forms the stable clot at a site of vascular injury (see Fig. 10-2). Each complex that participates in thrombin generation is simply composed of a serine protease interacting with a cofactor or receptor on an activated cell membrane surface (Mann, 2003). Coagulation is dependent on vitamin K because adequate concentration of this vitamin is required for activation of procoagulants, FVII, FIX, FX, prothrombin, and for anticoagulants, protein C, and protein S. The clinical consequences of antagonism or deficiency of vitamin K demonstrate how important it is to proper hemostasis (see Sections IV.B.5).

The release of tissue thromboplastin or TF from damaged cells or its enhanced expression on cell membranes initiates *in vivo* coagulation. This occurs when TF binds with and activates FVII to FVIIa (see Section II.C.2.a). The TF-FVIIa complex then has the ability to activate subsequent zymogens FIX and FX in the presence of calcium ions and a negatively charged phospholipid surface provided by activated platelets (see Section II.B.2), resulting in the formation of their respective activated forms, FIXa and FXa. The latter is the more efficient substrate in the early phase of thrombin generation. Once some Xa has been formed, it actually facilitates further activation of FIX (Lawson and Mann, 1991). The TF-FVIIa activation process has historically been referred to as the extrinsic coagulation pathway and is currently often referred to

as the tissue factor pathway. There appears to be a small proportion (1% to 2%) of constitutively activated FVII in plasma (Mann *et al*., 2003). However, it does not exhibit proteolytic activity unless bound to TF. Once the TF-FVIIa complex forms, the rate of FXa formation increased fourfold (Mann *et al*., 2003). During the initiation stage, any membrane-bound Xa produced is able to begin converting a small amount of prothrombin to thrombin. This small amount of thrombin is crucial for further propagation of the coagulation cascade, as it activates platelets and converts FV to FVa and FVIII to FVIIIa (Brummel *et al*., 2002).

The ability of the TF-FVIIa complex to continue the generation of FIXa is compromised by the presence in the circulation of tissue factor pathway inhibitor (TFPI) (see Section II.C.5.a). Alternative activation pathways exist for the activation of FIX so that the tenase complex can be formed at a sufficient rate and adequate level to sustain thrombin formation until a clot has formed and wound healing is initiated. In a direct positive feedback reaction, thrombin can convert FIX to the same enzymatically active form of FIXa as produced by the TF-FVIIa complex (Minnema *et al*., 1999). In an indirect feedback pathway, thrombin can activate FXI to a proteolytically active enzyme (FXIa), which can, in turn, convert FIX to FIXa (Gailani, 2000; Gailani and Broze, 1991). FXI is one of the proteins involved in the coagulation pathway historically known as the intrinsic pathway that is now referred to as the contact activation system. The other components of this system are FXII, prekallikrein (PK), and high-molecular-weight kininogen (HK) (Table 10-5). This pathway is initiated when the zymogen FXII comes into contact with a negatively charged surface (e.g., damaged endothelium or an endotoxin contact) and undergoes a conformational change to become an active serine protease (FXIIa). FXIIa then propagates coagulation by activating the next protein in this system, FXI, in a reaction that is accelerated by the presence of PK and HK (Wachtfogel *et al*., 1993). In plasma, HK circulates as biomolecular complexes with FXI and PK, respectively. The initial molecules of FXIIa generated on damaged endothelium convert HK to HKa. HKa has a high surface binding affinity and thus brings large amounts of FXI and PK to the charged surface in close proximity to the already adherent FXIIa. The spatial configuration of these complexes permits FXIIa to rapidly convert FXI to FXIa and convert PK to kallikrein. It is now generally accepted that activation of the contact activation system is not the predominant *in vivo* mechanism of thrombin generation (Gentry, 2004; Rojkjaer and Schmaier, 1999). However, it may serve as a link between fibrin formation, fibrinolysis, and inflammation because kallikrein can function as a weak activator of the fibrinolytic system (see Section II.E) and as stimulator of both chemotaxis and degranulation in neutrophils attracted to a site of endothelial damage (Jiminez and Fernandez, 2000).

After the coagulation cascade is initiated, further amplification ensures that sufficient thrombin is produced to cleave fibrinogen and form insoluble fibrin. Once FIXa is formed, it complexes with calcium ions (Ca) and platelet PSs and FVIIIa to form the FIXa-FVIIIa-Ca-PS (tenase or Xase) complex, a potent stimulator of further FX activation. Large amounts of FXa are created by the tenase complex, which is approximately 50-fold more efficient than the TF-FVIIa complex at performing the same process (Ahmed *et al*., 1992). Once formed, FXa converts prothrombin (factor II) to thrombin (FIIa). This reaction is additionally dependent on the formation of the prothrombinase complex, composed of FVa, FXa, platelet phospholipid surface, and calcium ions (FXa-FVa-Ca-PS) and is 300,000-fold more potent than Xa at catalyzing prothrombin conversion (Mann *et al*., 2003).

Thrombin (FIIa) converts fibrinogen to fibrin and additionally activates factor XIII, which is important for cross-linking and stabilizing the fibrin clot (see Section II.C.4).

4. *Fibrin Clot Formation*

Ultimately, repair of a vascular lesion requires development of a more permanent clot than a platelet plug can provide. A stable fibrin clot is the end point of the conversion of fibrinogen to fibrin and involves three phases: proteolysis, polymerization, and stabilization. Proteolysis occurs when thrombin cleaves fibrinogen to form fibrin monomers and the secondary by-product fragments fibrinopeptides A and B (FPA and FPB). These fibrinopeptide molecules are cleaved from the N-terminal regions of the Aα and Bβ chains (Sidelmann *et al*., 2000). It is proposed that removal of FPA permits end-to-end polymerization, whereas removal of FPB promotes side-to-side polymerization (Mosesson, 1992). The cleaved fibrinogen molecules can then form complexes with other fibrinogen and fibrin molecules to form what is referred to as soluble fibrin or fibrin monomers (Sidelmann *et al*., 2000). Fibrin monomers then polymerize at their ends via hydrogen bonding, and the polymers are then stabilized covalently via peptide bond formation under the influence of the transglutaminase FXIIIa (which is activated by thrombin) to form cross-linked fibrin strands.

Thrombin cleaves a peptide from each of two alpha chains on FXIII, which results in the formation of an inactive intermediate. In the presence of Ca, this intermediate dissociates and produces the activated protein. FXIIIa then induces adjacent γ-chains to quickly cross-link to form γ-dimers, whereas α-chain cross-linking occurs more slowly. Even native fibrinogen can be cross-linked by FXIIIa, following the same pattern of initial γ-chain dimerization followed by Aα-chains to form high-molecular-weight polymers.

The cross-linking that occurs between fibrin polymers makes the fibrin "gel" more resistant to lysis by fibrinolytic

TABLE 10-6 Major Inhibitors of Coagulation and Fibrinolysis

Inhibitor	Target Enzymes	Cofactor(s)
TFPI	Factor Xa Tissue factor/factor VIIa	Calcium
Antithrombin	Thrombin, factor Xa Factors IXa, XIa, XIIa	Heparin/heparan sulfate
Heparin cofactor II	Thrombin	Heparin/heparan sulfate
α_1-Antitrypsin/α_1-protease inhibitor	Thrombin, factors Xa, XIa Activated protein C, plasmin	—
α_2-Macroglobulin	Factor Xa, thrombin Activated protein C, plasmin	—
C1 inhibitor	Factors XIa, XIIa, kallikrein	—
Protein C inhibitor	Thrombin, factors Xa, XIa Activated protein C tPA, uPA	Thrombomodulin Heparin/heparan sulfate
Activated protein C	Factor VIIIa, factor Va TAFI, PAI-1	Protein S, thrombomodulin, EPCR
TAFI	tPA	Fibrin
PAI-1	tPA, uPA	—
α_2-Antiplasmin	Plasmin	Fibrin

Abbreviations: EPCR, *endothelial cell protein C receptor*; PAI-1, *plasminogen activator inhibitor -1*; TAFI, *thrombin activatable fibrinolysis inhibitor*; tPA, *tissue-type plasminogen activator*; u-PA, *urokinase-type plasminogen activator.*

proteins such as plasmin. One way this occurs is by FXIIIa-mediated incorporation of plasmin inhibitor into the developing fibrin meshwork (see Section II.D.3). Plasmin inhibitor becomes bound to α-chains of both fibrinogen and fibrin and prevents the absorption of plasminogen to fibrin. FXIIIa can also cross-link other plasma proteins to fibrin strands (see Section II.C.4) (Sidelmann *et al*., 2000). Once the lesion has been repaired, which may also be partly mediated by FXIIIa (Barry and Mosher, 1988), a process called fibrinolysis dissolves the fibrin clot (see Section II.D).

5. *Inhibitors of Coagulation*

Several biochemical mechanisms exist that function to keep the formation of a blood clot localized to a site of vascular injury, to prevent the excessive growth of the clot, and to prevent thrombin generation and fibrin formation from becoming generalized to nondamaged areas of the vascular system. The target enzymes and cofactors for these and other circulating inhibitors are summarized in Table 10-6.

a. Tissue Factor Pathway Inhibitor (TFPI)

TFPI is the principal endogenous inhibitor of the tissue factor pathway. TFPI is a Kunitz-type serine protease inhibitor that has a double inhibitory effect: it inhibits both FXa and the TF/FVIIa complex (Golino *et al*., 2002; Lindhahl, 1997). Between 75% and 90% of the total body TFPI is located in endothelial cells; the remaining 10% to 25% circulates bound to plasma lipoproteins with only trace amounts being detectable free in plasma or in platelet cytosol. Because of its association with lipoproteins, TFPI was formerly known as lipoprotein-associated coagulation inhibitor (LACI). TFPI is a single-chain 32-kDa glycoprotein that has a highly negatively charged N-terminus connected to three tandem domains that show homology to Kunitz-type protease inhibitors and a highly positively charge C-terminal region (Broze, 1992). Multiple forms of TFPI have been identified in human plasma with 36- and 43-kDa forms predominating. This size variation appears to be due to the formation of disulfide bonds and glycosolation of the TFPI molecule (Broze, 1992; Lindahl, 1997). A 34-kDa form of TFPI circulates in association with plasma LDL, and a 40-kDa form associates with HDL. TFPI is not uniformly dispersed in the vasculature. It is constitutively expressed by endothelial cells of the microvasculature but not by endothelial cells of larger vessels (Doshi and Mamur, 2002). A localized increase of TFPI can occur at the site of a clot because thrombin is able to induce the release of TFPI from activated platelets (Novotny *et al*., 1988). TFPI is stored on

the extracellular matrix of endothelial cells bound to GAGs such as heparan sulfate (Abildgaard, 1992). Consequently, infusion of heparin can displace this surface-bound TFPI to induce a two- to four-fold increase in circulating TFPI levels (Golino *et al*., 2002; Novotny *et al*., 1991). The liver effectively clears circulating TFPI by receptor-mediated endocytosis resulting in a half-life for TFPI of less than 70 min (Lindhal, 1997). The inhibitory activity of TFPI depends on the activation of the TF pathway and the formation of FXa. TFPI binds to FXa at, or near, its serine active site in a reversible calcium-independent reaction to form a 1:1 complex (Broze, 1992). This complex is formed most efficiently when FXa is incorporated into the prothrombinase complex (see Section II.C.3). The ability of TFPI to inhibit the activity of the TF/FVIIa complex depends on the TFPI/FXa complex forming an irreversible, calcium-dependent quaternary complex consisting of TFPI-FXa-TF-FVIIa (Lindahl, 1997). Hence, TFPI is not only able to inhibit FXa activity, but it is also able to suppress the generation of additional FXa by blocking the TF/FVIIa-catalyzed conversion of FX to FXa. TFPI is able to exert this bimodal inhibitory effect because the inhibition of FXa depends on the first Kunitz-type domain and an intact C-terminal region, whereas the second Kunitz-type domain of TFPI molecule is responsible for the binding of the TFPI/FXa complex to the TF/FVIIa complex (Lindahl, 1997). Because TFPI does not interfere with FXa activation by the tenase complex (FIXa-FVIIIa-Ca-PL, see Section II.C.3), it does not completely block thrombin formation. The importance of TFPI in regulating thrombin generation and fibrin formation has been demonstrated in animal models depleted of TFPI. These animals are sensitized to TF and readily develop DIC (see Section IV.B.4) in response to endotoxin, which causes the release of TF from endothelial cells (Huang *et al*., 1997; Sandset *et al*., 1991). Hence, one of the factors involved in DIC is an imbalance between the levels of TF and TFPI.

b. Serine Protease Inhibitors (Serpins)

Antithrombin (AT, also known as antithrombin III, ATIII) is the principal member of the superfamily of serine protease inhibitors, or serpins, that inhibit the action of several serine proteases of the hemostatic system (Pike *et al*., 2005). Serpins have a common mechanism of action that involves trapping and irreversibly inactivating the proteases through the formation of a covalent bond followed by the removal of the serpin-enzyme complex from the circulation by the action of receptors, which specifically recognize the inhibited conformation of the serpin (Gettins, 2002). One of the functions of serpins is to neutralize any of the procoagulant enzymes that escape from the vicinity of a blood clot and thus prevent inappropriate thrombus formation.

AT is a 58-kDa single-chain glycoprotein synthesized in the liver and endothelial cells. Structural similarities exist in the AT molecule across many species (Frost *et al*., 2002; Johnstone, 2000). Although AT can inhibit several serine protease of the coagulation system including thrombin, FIXa, FXa, FXIa, and FXIIa, the principal targets are considered to be thrombin and FXa (Pike *et al*., 2005). The AT molecule has two functional sites: the reactive site for serpins and a binding a site for glycosaminoglycans (GAGs), such as heparin and heparan sulfate. GAGs serve as potent cofactors that enhance the rate of thrombin inhibition from one that is nonphysiological to a physiologically relevant level. In its unactivated, or native state, the AT molecule contains a reactive center loop that is partially inserted into its Aβ-sheet. When thrombin comes in contact with AT, it cleaves a specific bond in the reactive center loop causing it to become fully inserted into the Aβ-sheet and at the same time translocating thrombin from the top of the AT molecule to the bottom (Munoz and Linhardt, 2004). In this way, a 1:1 stoichiometric complex is formed through covalent bonding between the active site serine of thrombin and the reactive site arginine of AT. The interaction between GAGs, like heparin, and AT involves several steps. First, a low-affinity interaction occurs forming ion pairs between a cluster of positively charged amino acids, such as arginine and lysine, in the D-helix of the AT molecule and specific spatially defined negatively charged sulfo- and carboxyl groups in the heparin pentasaccharide sequence (Huntington *et al*., 1996). This binding induces a conformation change in AT that results in both stronger heparin binding and the expulsion of the reactive center loop of AT from the Aβ-sheet (Munoz and Linhardt, 2004). In effect, heparin facilitates the diffusion of thrombin and AT toward each other through the formation of a tertiary complex between heparin and AT. For example, in the presence of heparin the inhibition of thrombin by AT is accelerated 1000-fold from 4.4 min to 0.27sec and the rate of inhibition of FXa by AT is accelerated 10,000-fold (Olson and Shore, 1982; Pike *et al*., 2005). The formation of the FXa-AT-heparin complex requires the presence of calcium ions to overcome the negative effects of the Gla-domains in FXa (Rezaie, 1998). Because clot-bound thrombin and FXa are protected from inactivation by AT, the physiological role of AT is not to cause the cessation of clotting but rather to localize the clot and prevent it from spreading too far beyond the site of damage (Weitz *et al*., 1990). It also functions to prevent thrombin formation from occurring on undamaged endothelium. Heparan sulfate is an extracellular component of the extracellular matrix of all animal cells, whereas heparin is localized to the granules of mast cells and is only released locally in an allergic reaction. In the vasculature, only heparan sulfate in the outer monolayer of endothelial cells possesses the AT binding sites that can accelerate the inhibitory action of AT, whereas the heparan sulfate contained in the underlying layer of smooth muscle cells lacks AT binding sites (Munoz and Linhardt, 2004). Thus, when thrombin comes in contact with AT-heparan sulfate complex on the "healthy" intact vascular wall, the T-AT complex irreversibly inactivates it.

However, when the vessel wall is damaged, thrombin is so inefficiently inhibited by AT, the conversion of fibrinogen to fibrin and hence clot formation can proceed (Pike *et al*., 2005).

Heparin cofactor II (HCII) is a specific thrombin inhibitor that has a similar mechanism of action as AT, but it is dissimilar both antigenically and in its cofactor requirements (Johnstone, 2000). HCII appears to be synthesized exclusively by the liver as a 65.6-kDa glycoprotein with a unique amino-terminal extension that contains two tandem repeats rich in acidic amino acids with two sulfated tyrosines (Inhorn and Tollefsen, 1986). These repeats are homologous to the carboxyl-terminal sequence of hirudin, the specific thrombin inhibitor from the medicinal leech. Although heparin, heparan sulfate, and dermatan sulfate are all physiological activators of HCII, many different polyanions, including polyphosphates, polysulfates, and polycarboxylates, are also able to accelerate HCII inhibition of thrombin up to 1000-fold (Tollefsen, 2004). Although the physiological function of HCII has not been fully elucidated, it has been suggested that it may function as a thrombin-inhibitor reserve when AT levels become subnormal such as occurs in DIC (see Section IV.B.4; Tran and Duckert, 1984). Experimental animal studies and human clinical studies indicate that HCII may have a protective antithrombotic effect following arterial oxidative damage (Tollefsen, 2004).

As summarized in Table 10-6, a number of other serpins participate in modulating hemostasis (Silverman *et al*., 2001). The broad spectrum protease inhibitor known both as α_1-antitrypsin and α_1-protease inhibitor (α_1-PI) can inhibit thrombin, FXa and FXIa, APC, and plasmin, although its main physiological function is as a circulating antitryspin inhibitor. However, α_1-PI appears to be a more effective inhibitor of FXIa than AT (Scott *et al*., 1982). It circulates as a 50-kDa glycoprotein and contains the characteristic reactive site loop of a serpin (Long *et al*., 1984).

α_2-Macroglobulin circulates as a large 650-kDa glycoprotein composed of four identical subunits. This protein can bind one or two molecules of a protease depending on its size. Small proteases such as trypsin maximally form 2:1 complexes with α_2-M, whereas larger proteases such as plasmin form 1:1 complexes. It has been suggested that α_2-M is one of the major physiological inhibitors of FXa *in vivo* (Fuchs and Pizzo, 1983). α_2-M-protease complexes are rapidly removed from the circulation by the liver through interaction with the lipoprotein receptor-related protein that serves as a large multifunctional endocytosis receptor (Narita *et al.*, 1998). This receptor protein is also responsible for the removal of other proteases such as tissue-type plasminogen activator and thrombin activatable fibrinolysis inhibitor (TAFI) (Orth *et al.*, 1992; Warshawsky *et al.*, 1994).

C1 inhibitor is a 104-kDa single-chain glycoprotein that exhibits structural homology with other members of the serpin superfamily. It appears to be the main circulating inhibitor of FXIa, although it can also suppress the activity of FXIIa and kallikrein but not FXa or plasmin (Harpel *et al*., 1985; Pixley *et al*., 1985). As its name suggests, the main physiological role of C1 inhibitor is to modulate the complement system.

Protein C inhibitor (PCI), also known as plasminogen activator inhibitor-3, inactivates the proteolytic activity of numerous serine proteases including thrombin, FXa, FXIa, APC, tissue-type plasminogen (tPA) activator, and urokinase-type plasminogen activator (uPA) (Meijers *et al*., 2002). The mature PCI protein is 57 kDa and is found in several body fluids as well as plasma (Pike *et al*., 2005). Like HCII, several GAGs and polyanions can enhance the activity of PCI. In the presence of heparin, a ternary complex is formed between PCI and the active protease through a GAG binding region localized on the H-helix region of PCI (Pratt and Church, 1992). However, even in the presence of heparin, the inhibitory effects of PCI for thrombin and FXa are still modest compared to those of AT and HCII (Pike *et al*., 2005). Although PCI can inhibit APC in the presence of heparin and calcium ions, the more physiologically relevant role of PCI in modulating the protein C anticoagulant system is the result of its ability to inhibit the activity of the thrombin-thrombomodulin (T-TM) complex (Yang *et al*., 2003). As described later, this complex is key to the conversion of the inactive zymogen protein C to its active form.

c. Protein C Anticoagulant System

The protein C anticoagulant system regulates thrombin formation by modulating the activity of the cofactors FVIIIa and FVa (Dahlback, 1995). This inhibitory system is composed of several components: protein C (PC), thrombomodulin (TM), endothelial cell protein C receptor (EPCR), and protein S (Table 10-6). Protein C, the key component, is a vitamin K-dependent, 62-kDa glycoprotein that is synthesized by the liver and circulates as a biologically inactive molecule consisting of a 40-kDa heavy chain and a 20-kDa light chain joined by a disulfide bond (Stenflo and Fernlund, 1982). As occurs with other vitamin K-dependent proteins, PC lacks biological activity unless it has undergone vitamin K-dependent posttranslational carboxylation of glutamine residues in the N-terminal region of the molecule. Thrombin cleavage of this N-terminal region converts PC to its proteolytic active form, APC (Esmon, 2003). For thrombin to activate PC at a physiologically relevant rate, it requires the presence of the cofactor thrombomodulin (TM) so that T-TM complexes can form. TM is a 58.7-kDa transmembrane glycoprotein that is present on vascular endothelial cells with the highest concentrations being present in microvascular beds (Esmon, 2003). In the presence of TM, the rate of PC activation is increased by more than 1000-fold (Van de Wouwer *et al*., 2004). The TM molecule is organized into five distinct domains.

A short cytoplasmic tail at the C-terminus is followed by a membrane-spanning region that contains serine/threonine-rich domains that serve as glycosylation sites, which support its attachment to chondroitin sulfate (CS) in the extracellular matrix. The membrane-spanning domain is followed by a domain that consists of six epidermal growth factor (EGF)-like repeats, which determine the biological activity of TM. The N-terminal region of TM includes two amino acid sequences that play no role in its hemostatic function. Rather, the anticoagulant activity of TM is conferred by EGF domains 4, 5, and 6, which are also the areas that are involved in the ability of TM to enhance thrombin inhibition by PCI (Tsiang *et al*., 1992). The EGF5 and EGF6 domains have been identified as thrombin binding sites (Van de Wouwer *et al*., 2004). For APC to act efficiently as an anticoagulant, the presence of the cofactor, protein S, at the endothelial cell surface is also required. Protein S is a single-chain polypeptide that is synthesized by hepatocytes, endothelial cells, and megakaryocytes in forms that vary in size from 69 to 84 kDa (Johnstone, 2000). In plasma, the majority of protein S circulates bound to the complement regulatory protein C4b-binding protein and only about 30% is in the free, more biologically active form (Dahlback, 1995). Unlike the other vitamin K-dependent hemostatic proteins, protein S is not a zymogen and functions solely as a cofactor to promote the formation of the inhibitory complex that consists of APC-protein S-calcium on the negatively charged phospholipids (PL) that are exposed on damaged endothelium and activated platelets (Walker, 1984). These PLs are also those that are involved in the formation of the tenase complex and the prothrombinase complex (see Section II.C.3). Hence, protein S effectively acts as a mediator to increase the number of APC molecules bound to the PL, to bring them in closer contact with FVIIIa and FVa, and thus to accelerate the rate at which APC can cleave these proteins to produce their inactive forms, FVIIIai and FVai (Dahlback, 2000). The reduction in FVIIIa and FVa cofactor activity effectively reduces the rate of thrombin formation. APC can only inhibit FVIII when it is a component of the tenase complex because it is protected from proteolysis as FVIII circulates in plasma bound to vWF (see Section II.C.2). In contrast, circulating FV, like FVa, can bind to membrane PLs where it can be cleaved to generate an anticoagulant form of FV that functions in synergy with protein S as an APC cofactor in the inactivation of FVIIIa (Dahlback, 2000). In this way, FV can, like thrombin, function as both a procoagulant and an anticoagulant cofactor in hemostasis. It is now recognized that TM is not the only cofactor expressed on endothelial cells that can function as a cofactor for thrombin-induced PC activation. EPCR is constitutively expressed in endothelial cells, particularly in large blood vessels, and is structurally similar to the major histocompatibility class 1/CDI family of molecules that are involved in immunity and inflammation (Di Cera, 2003; Esmon, 2003; Van de Wouwer *et al*., 2004). Not only does EPCR accelerate thrombin-mediated activation of PC, but it also concentrates APC near the surface of the vessel wall (Stearns-Kurosawa *et al*., 1996). When APC is generated, it remains bound to EPCR for only a short time before it becomes associated with protein S on the surface of activated platelets or damaged endothelium (Van de Wouwer *et al*., 2004). After APC has caused the inhibition of FVIIIa and FVa, it is itself inactivated by several serpins including, α_1-protease inhibitor, α_2-M, and protein C inhibitor (Table 10-6). The APC pathway can also be down-regulated by inflammatory cytokines such as IL-1β and TNF$\alpha\in$, which reduce the expression of both TM and EPCR (Esmon, 2003). It would appear that TM can exert multifunctions in the regulation of hemostasis. For example, when TM is bound to CS on the extracellular matrix, not only is the PC cofactor activity of TM enhanced but the rate of neutralization of thrombin by both heparin-AT and by PCI is accelerated (Koyama *et al*., 1991). TM also exhibits antifibrinolytic activity through the ability of both EGF domains 3 through 6 of the thrombin-TM complex to activate TAFI (see Section II.D.3) (Nesheim, 2003).

D. Fibrinolysis

1. *Overview*

It is essential that the coagulation pathways are counterbalanced by a functional fibrinolytic cascade so that blood fluidity can be maintained in the vascular system (Welles, 1996). Like the coagulation pathway, the fibrinolytic system is normally latent but can be fully activated within a minute or two after stimulation (Nesheim, 2003). The major enzymatic component of this fibrin degradation system is plasmin, which, like thrombin, is a serine protease but with broader substrate specificity (Lijnen, 2002). In addition to cleaving specific sites on polymerized fibrin, under some pathophysiological conditions plasmin can also degrade fibrinogen, FV, and FVIII and activate metalloproteinases (Darien, 2000b). The fibrinolytic system shares several biochemical characteristics with the coagulation system. These include an initiation phase that involves the liberation of tissue-type plasminogen activator (tPA) from damaged endothelium; the conversion of the circulating zymogen, plasminogen, to the active protease, plasmin; and positive feedback reactions that increase the concentration of plasmin in the area of a clot (Fig. 10-3). The system is down-regulated by both protease inhibitors, such as plasminogen activator inhibitor type 1 (PAI-1) and antiplasmin (AP), and by a reaction mediated by the thrombin-TM complex (Table 10.6) (Coughlin, 2005a; Nesheim, 2003). The ability of fibrin to act as an effective cofactor for enhanced plasmin activity is an important factor in localizing the physiological activity of this protease to the site of a fibrin clot (Medved and Nieuwenhuzen, 2003). Nonphysiological activators of fibrinolysis, such as streptokinase, have only proved to be effective in dissolving fibrin clots in human plasma.

2. Components of the Fibrinolytic System

a. Plasminogen

Plasminogen is secreted by the liver as a single-chain 92-kDa glycoprotein with glutamine as the N-terminal amino acid (Glu-plasminogen). It is composed of five kringle-like domains containing "lysine-binding sites" and a C-terminal domain homologous to other trypsin-like proteases (Ponting *et al*., 1992). The kringle domains mediate the interaction of plasminogen, and its active form plasmin, with substrates, inhibitors, and cell membranes. Consequently the kringle domains are important in both regulation of plasminogen activation and the localization of the proteolytic activity of plasmin to the appropriate physiological site (Wu *et al*., 1990). Plasminogen can be cleaved by plasmin at several sites resulting in lysine as the N-terminal amino acid (Lys-plasminogen) and the release of an 8-kDa N-terminal polypeptide. Lys-plasminogen, in the absence of fibrin, is converted to plasmin at a faster rate than Glu-plasminogen. The cleavage of an Arg-Val peptide bond in single-chain plasminogen converts it to plasmin, which now consists of two polypeptide chains linked by a disulfide bond (Dobrovolsky and Titaeva, 2002). The N-terminal heavy A chain contains the kringle domains that convey substrate specificity to plasmin, whereas the C-terminal light B chain contains the catalytic site.

b. Plasminogen Activators

tPA is synthesized and secreted by endothelial cells as a 70-kDa single-chain active enzyme. It is the only protease of the hemostatic system secreted in an active form (Dobrovolsky and Titaeva, 2002). The molecule is composed of five domains: the N-terminal domain, which is homologous to the finger-like domains of fibronectin, is followed by a region homologous to the epidermal growth factor (EGF) domain, two kringle-like domains similar to those of plasminogen, and a C-terminal domain homologous to other trypsin-like proteases (van Zonneveld *et al*., 1986). The finger-like kringle domains possess two distinct fibrin-binding sites. Plasmin, kallikrein, and FXa can all cleave tPA to form a two-chain form of the molecule that, in the presence of fibrin, activates plasminogen at the same rate as single-chain tPA (Dobrovolsky and Titaeva, 2002). Stimuli such as exercise, venous occlusion, and intravenous injection of vasoactive drugs can increase the release of tPA from endothelial cells, whereas inflammatory mediators such as tissue necrosis factor α (TNFα) and interleukin-1 (IL-1) cause a decrease in free plasma tPA levels. Recombinant tPA is currently being used to induce thrombolysis in human patients with myocardial infarctions and other thromboembolic problems (Dobrovolsky and Titaeva, 2002).

A trypsin-like protease capable of activating plasminogen was originally isolated from human urine and named urokinase. It is now known that many cell types can synthesize and secrete a single-chain 54-kDa glycoprotein, which was initially referred to as prourokinase. Current nomenclature designate these proteins as two forms: single-chain urokinase-type plasminogen activator (scuPA) and two-chain urokinase-type plasminogen activator (tcuPA). The scuPA molecule is composed of three domains. The N-terminal domain is homologous to the EGF domain, the middle protein is homologous to the kringle domain of plasminogen, and the C-terminal domain is homologous to trypsin-like proteases (Dobrovolsky and Titaeva, 2002). Both plasmin and kallikrein can cleave a Lys-Lys peptide bond in uPA to form fully functional tcuPA. Thrombin cleaves an Arg-Phe bond to produce a variant tcuPA molecule that appears incapable of directly activating plasminogen until after it has been further hydrolyzed by plasmin cleavage of a Lys-Ile bond (Dobrovolsky and Titaeva, 2002). Although initially considered to be a major component of the plasma fibrinolytic system, it is now recognized that a more important physiological function of uPA may be its ability to activate metalloproteinases that degrade cellular matrix components inducing pericellular proteolysis (Lijnen, 2002). uPA mediates this effect through its ability to bind to specific cellular receptors (uPARs), which bring uPA into close contact with cell-bound plasminogen and thus promote plasmin generation on the cell surface. Thus, uPAR plays an important role in cell migration and the tissue remodeling processes that are required following vascular damage and thrombus formation.

3. Mechanism of Fibrinolysis

Fibrinolysis, like coagulation, is organized on a surface that facilitates the assembly and

components of the system in close proximity to each other. The formation of a fibrin clot is not only the physiological trigger for the activation of the fibrinolytic system, but it also accelerates the rate of tPA induced conversion of plasminogen to plasmin up to three orders of magnitude (Collen, 1999). Fibrin essentially acts as a cofactor in plasmin activation through a two-step process (Medved and Nieuwenhuizen, 2003). As fibrinogen undergoes polymerization to fibrin, cryptic tPA and Glu-plasminogen binding sites are exposed on its D-domains that facilitate the formation of tertiary complexes between the three molecules. The Glu-plasmin generated on the fibrin surface begins to cleave specific arginine and lysine residues in the α, $\beta\in$, and γ chains to form a modified fibrin polymer that has additional exposed C-terminal lysine residues that promote increased binding of tPA and plasminogen. Thus, this modified form of the fibrin gel is three-fold more potent as a cofactor for fibrinolysis than the unmodified form. Not only does the modified fibrin increase the concentration of tPA and plasminogen on the fibrin surface, but it also enhances the plasmin-induced conversion of Glu-plasminogen to Lys-plasminogen (Nesheim, 2003). This serves as a positive feedback response, because Lys-plasminogen is approximately 20-fold better than Glu-plasminogen as a substrate for tPA catalysis. Plasmin sequentially digests fibrin with the formation of degradation products designated as X-, Y-, D-, and E-fragments (Dobrovolsky and Titaeva, 2002). The sites most sensitive to proteolysis are specific Lys/Arg residues on the α- and β-chains. The cleavages result in a set of X-fragments with molecular masses ranging from 330 to 240 kDa. Degradation of insoluble fibrin clots to the soluble Y-, D-, and E-fragments occurs after at least one D-fragment has been cleaved. The presence of fibrin fragments in the circulation is used diagnostically as evidence of inappropriate fibrinolysis (see Sections III.B.4.a and b).

4. *Inhibitors of Fibrinolysis*

The major inhibitor components of fibrinolysis are shown in Table 10-6.

a. Plasminogen Activator Inhibitor Type-1 (PAI-1)

PAI-1 is the major endogenous inhibitor of fibrinolysis, or thrombolysis, as it is effective in blocking the conversion of plasminogen to plasmin by either tPA or uPA (Kruithof, 1998). PAI-1 is a 52-kDa-glycoprotein synthesized and secreted by endothelial cells in its active form. In plasma, PAI-1 is present in two forms: an active form in which the reactive site is exposed on the surface of the molecule and a latent form in which the reactive site is concealed within the protein globule (Dobrovolsky and Titaeva, 2002). The change of active PAI-1 to its latent form occurs spontaneously in plasma. Although the physiological mechanisms that induce the reverse transformation are not fully understood, it appears that latent PAI-1 can be reactivated by phospholipid vesicles containing PS or phosphatidylinositol (PI). This indicates that at sites of vascular injury, activated platelets may be able to activate latent PAI-1 (see Section II.B.2.a). Hence, the local concentration of active PAI-1 can be significantly increased at sites of thrombus formation as approximately 90% of PAI-1 circulates as one of the constituents of platelet α-granules. Thus, PAI-1, along with the action of thrombin activatable fibrinolysis inhibitor (TAFI, see Section II.D.4.c), is a contributing factor in the stabilization of the fibrin matrix. It has been shown in people that circulating PAI-1 levels vary more than any other component of the fibrinolytic system. This is likely due to the ability of a wide variety of substances to stimulate PAI-1 production. These include insulin, TNFα, IL-1, transforming growth factor β (TGFβ), and thrombin (Tsikouris *et al.*, 2002). Endotoxin and TNFα have been shown to stimulate PAI-1 production in the liver, kidney, lung, and adrenals of mice. At least in human and murine plasma, PAI-1 exhibits the characteristics of an acute phase protein. In various disease states, a companion serine proteinase inhibitor of tPA known as plasminogen activator inhibitor type-2 (PAI-2) can appear in the circulation (Dobrovolsky and Titaeva, 2002). PAI-2 is synthesized by placenta, monocytes, and macrophages and is an effective inhibitor of t-PA.

b. Antiplasmin (AP)

Antiplasmin (AP, also referred to α_2-antiplasmin, α_2AP) is the principal inhibitor of plasmin in the circulation. The liver secretes it as a single-chain 70-kDa protein. AP possesses the conserved core structure of the serpin family of proteins, and its amino acid sequence is highly conserved across species (Coughlin, 2005a). Human AP is 80% identical with the bovine protein and 74% identical with murine AP. In people, 30% of AP circulates in the form of Met-AP and 30% as Asn-AP. The latter is a truncated form that has lost a 12-amino acid sequence from the N-terminal end of the protein. Both Met-AP and Asn-AP inhibit plasmin at similar rates, but Asn-AP has a higher affinity for fibrin than Met-AP (Dobrovolsky and Titaeva, 2002). The N-terminal portion of AP is cross-linked to fibrin by a transglutaminase reaction catalyzed by FXIIIa. The amount of AP cross-linked to fibrin is a more important determinant of the rate of clot lysis than is the amount of free plasmin in the circulation (Coughlin, 2005a).

c. Thrombin Activatable Fibrinolytic Inhibitor (TAFI)

The function of TAFI is to down-regulate the onset of fibrinolysis once the fibrin clot has successfully stopped blood loss. TAFI is a single-chain, 46-kDa plasma protein that is classified as a zinc-containing metalloproteinase (Bajzar, 2000). It can be cleaved by thrombin, plasmin, and trypsin to yield an activation peptide and an enzyme, TAFIa, that exhibits carboxypeptidase activity. Thrombin, by itself,

is a relatively poor activator of TAFI, but in the presence of TM its catalytic efficiency is increased over 1000-fold (Nesheim, 2003). This enhancement of TAFI activation is dependent on the formation of a ternary complex between thrombin-TAFI and the EGF 3 through EGF 6 domains of the TM molecule. Like the thrombin-TM-mediated activation of PC, the activation of TAFI is calcium dependent (Bajzar *et al*., 1995). Plasmin is also a physiological activator of TAFI with a catalytic efficiency eight times that of thrombin. However, the ability of plasmin to activate TAFI is reduced to only one-tenth that of thrombin-TM in the presence of glycosaminoglycans, such as those found in the extracellular matrix (Mao *et al*., 1999).

5. *Regulation of Plasminogen Activation and Plasmin Activity*

Although it is important that fibrinolysis occurs after wound healing has been initiated, it is equally important that the degradation of the clot not occur prematurely. This is achieved because, in the initial stages of thrombus formation, the thrombin-induced release of tPA from endothelial cells is effectively opposed by the localized activation of TAFI. Through its affinity for and its ability to modify partially degraded fibrin, TAFIa functions to block the ability of tPA to activate plasminogen (Fig. 10-3). Following partial degradation by plasmin, the newly exposed lysine residues of fibrin bind both tPA and plasmin with high affinity promoting fibrinolysis (see Section II.D.3). TAFIa catalyzes the release of both arginine and lysine residues from the partially degraded fibrin thus reducing both tPA and Glu-plasminogen binding, which has the effect of reducing plasmin formation. The reduced binding of Glu-plasminogen to TAFIa modified fibrin has been correlated with an increase in clot lysis time (Sakharov *et al*., 1997). Both TAFI and TAFIa are cross-linked to fibrin by FXIIIa, which localizes these molecules to the fibrin clot. TAFIa is an unstable molecule, which decays rapidly at 37°C such that its half-life is approximately 8 min (Nesheim, 2003). To date no physiological inhibitor of TAFI has been identified (Bajzar, 2000).

PAI-1 is the major inhibitor of both tPA and uPA (Tsikouris *et al*., 2002). It inhibits plasminogen activation by first forming a reversible complex with tPA that then cleaves PAI-1 at its reactive site to release the C-terminal peptide of the inhibitor. Further proteolytic activity of tPA is blocked because the carboxyl group of one of the cleaved PAI-1 arginine residues remains covalently bound to a serine residue at the reactive center of tPA (Dobrovolsky and Titaeva, 2002). Because of the relatively high levels of PAI-1 in the circulation, most of the tPA released by endothelial cells is inactivated before it can interact with plasminogen. Hence, in the absence of fibrin plasminogen is only slowly converted to plasmin. Once tPA becomes bound to fibrin, it is protected from the inhibitory effects of PAI-1 and plasmin formation can proceed rapidly.

Antiplasmin is the major physiological inhibitor of plasmin irrespective of whether the plasmin is bound to fibrin or is free in the circulation. In plasma, the reaction between AP and plasmin is rapid and the formation of a stable 1:1 bimolecular complex between the two molecules results in the irreversible inactivation of plasmin (Darien, 2000b). Because AP is partially degraded by plasmin, other circulating protease inhibitors (Table 10-6) can act as plasmin inhibitors, particularly when the capacity of AP is exceeded by high concentrations of free plasmin. These reactions are important in preventing systemic lytic states from developing such as occurs in certain disease states (see Section IV.B.4). When fibrin is formed, it binds plasminogen and AP in equimolar amounts. AP is bound via its N-terminal portion, which leaves the C-terminal portion free to bind to one of the kringle domains of the plasmin molecules that form in response to tPA activity (Coughlin, 2005a). This modulates plasmin such that the proteolytic cleavages do not initially destroy the fibrin network but rather open new affinity binding sites for additional tPA and plasminogen. As this first phase of fibrinolysis proceeds, more plasmin is generated on the partially degraded fibrin, which can induce the second phase that produces final degradation of the fibrin meshwork. The existence of the two sequential phases of fibrin degradation may be one of the mechanisms that provide temporary stability of fibrin clots at sites of vascular damage (Dobrovolsky and Titaeva, 2002).

III. LABORATORY ASSESSMENT OF HEMOSTASIS

A. Quality Control and Reagent Variation

The common laboratory assays available to assess the integrity of the hemostatic system can be divided into those assessing primary hemostasis (platelet quantity and function) and those assessing secondary hemostasis (clotting factor activity and fibrin formation and dissolution).

Proper collection of plasma that is free from clots and activated platelets is very important for all hemostasis testing. To obtain the best sample, minimal pressure should be placed on the vein and a single clean venipuncture performed, to avoid release of excessive TF, which would activate the clotting mechanism, consume coagulation factors, and therefore artifactually prolong the clotting times. The stopper should be removed from the Vacutainer and blood slowly expelled from the syringe into the tube because excessive vacuum turbulence may activate platelets. Ideally, the first few drops of blood collected should be discarded because they most likely would contain some TF. The blood should be gently mixed with the citrate, to ensure anticoagulation, but not too aggressively mixed so as to activate hemostasis.

There is controversy whether a citrated plasma sample obtained directly from a peripheral catheter is suitable for hemostatic testing. Advocates of this technique argue that the ability to get the sample from a previously placed access port minimizes patient discomfort, allows for more accurate volume extraction, and ensures no contamination with tissue factor. If this approach is used, the catheter should be flushed with saline, and then blood volume equal to six times the catheter dead space should be removed and discarded before collecting the sample for analysis (Arkin *et al*., 1998). A study by Mills *et al*. (1995) documented that this procedure did not result in significant differences compared with direct venipuncture in healthy dogs.

Several reports have compared the effect on various hemostatic parameters with respect to the concentration of citrate used and the volume of blood to citrate obtained. Historically, 3.8% sodium citrate tubes only were available, but recently 3.2% sodium citrate tubes have become the standard in Europe and are now available in the United States and elsewhere (Morales *et al*., 2007). One study determined that for some coagulation assays there can be significant differences between the two types of tubes (Stokol *et al*., 2000a), whereas another more recent study (Morales *et al*., 2007) suggests that there is no difference in any common coagulation assay between the two concentrations. It is recommended that each laboratory specify the citrate concentration preferred and develop reference intervals based on results from samples collected in the defined manner.

The time a sample is stored before assessment may also have an impact on the test result. Most often samples are analyzed relatively quickly (i.e., within a few hours or at least the same day), but there may be an occasion when a sample cannot be assessed until the following day or two, or, depending on the assay, samples may be stored until sufficient numbers are collected and then run as a batch. Although longer than generally considered acceptable, a recent paper (Furlanello *et al*., 2006) found that samples could be kept at room temperature for up to 48 h without any significant change from immediate analysis, whereas storage at either room temperature or refrigeration was not recommended beyond 48 to 72 h. The typical recommendation is to perform assays within 4 h of sampling, after centrifuging and removal of plasma or to freeze the sample until analysis can be performed. Plasma samples can be safely stored at −70°C for up to 6 months with minimal change in results except for the aPTT (Bateman *et al*., 1999a; Iazbik *et al*., 2001).

B. Testing of Hemostasis

1. *Assessment of Platelet Quantity*

a. Platelet Concentration and Volume

Platelets can be enumerated from either an EDTA or sodium citrate-anticoagulated blood sample. Heparinized blood is not suitable as marked platelet clumping often occurs. Assessment is best performed within 4 to 5 h, but the count may remain relatively stable for up to 24 to 48 h if the sample is refrigerated (Stockham and Scott, 2002).

Manual or automated methods can be used for platelet quantity assessment. Manual methods include estimation of platelet quantity from a stained blood smear and hemacytometer chamber counting. Most automated hematology analyzers using impedance or light scattering technology can also enumerate platelets.

Platelet clumping must be avoided for any platelet quantification method, or underestimation of the platelet count will occur. This can happen in any species with traumatic sampling and tends to occur most frequently in cats and cattle. Therefore, it is critical that a peripheral blood smear be examined for the presence of clumps; this also provides an opportunity to ensure appropriate cell morphology and to perform an estimate of platelet numbers as a cross-check of an automated determination.

The mean platelet volume (MPV) is frequently determined by automated analyzers and reflects the average volume of all cells that are enumerated as platelets. For an accurate determination, platelet clumping needs to be avoided, and the cells should be unactivated and circular in shape without pseudopod formation. Variables such as time to analysis, storage temperature, and anticoagulant used can all impact MPV assessment. Generally, there tends to be an inverse relationship between platelet concentration and MPV; the value is higher when platelet concentration is low, and it is lower when numerous platelets are present. This has been documented in healthy cats (Weiser and Kociba, 1984.) An increase in MPV is a favorable finding in an animal with thrombocytopenia, as it is usually a reflection of active thrombopoiesis. Excessively large platelets are often observed in Cavalier King Charles spaniels, but the corresponding platelet concentration also tends to be lower, making overall platelet mass similar to other breeds (Smedile *et al*., 1997).

b. Clot Retraction

Retraction of a blood clot depends on platelets, so defects in platelet quantity or quality will prolong the time required for whole blood to clot in a tube. Measurements of clot retraction are available, but this test is limited by subjectivity and is not often performed.

c. Buccal Mucosal Bleeding Time

Although typically assessed as an indicator of platelet function, a sufficient quantity of platelets also needs to be present to form a platelet plug in a standardized mucosal incision. Once thrombocytopenia is present, the BMBT may be prolonged simply from lack of platelets. See Section III.B.2.a for further details.

2. *Assessment of Platelet Quality*

a. Buccal Mucosal Bleeding Time

The BMBT is an *in vivo* test of platelet function, which also depends on adequate platelet concentration and properly functioning endothelium. The incision is small enough that secondary hemostasis is not required to stop blood flow; formation of a platelet plug alone will stop the bleeding. A standardized incision using a commercially available device is made on the buccal mucosa of the lip and the time to clotting recorded in seconds or minutes. Time to clotting can vary substantially within and between observers, making this a less than ideal test, but most healthy dogs clot in less than 4 min (Sato *et al*., 2000). It is, however, useful as a quick and inexpensive screening test for congenital or acquired thrombopathia, which can be followed up by more specific testing if the result is prolonged. Skin and toenail bleeding time tests have also been described but are even less standardized than the BMBT and are not recommended.

b. Platelet Aggregometry

The propensity of platelets to bind to each other in the presence of certain agonistic substances can be exploited as a method to determine appropriate platelet function. Platelet aggregometers trace the optical density of a standardized platelet preparation after the addition of an aggregating substance such as ADP, epinephrine, or collagen. There are marked species differences with respect to concentration and type of agonist required to promote aggregation. Platelet aggregation is technically demanding, time consuming, and therefore generally limited to specialized or research laboratories.

c. PFA-100

The Platelet Function Analyzer-100 (Bayer) has revolutionized assessment of platelet function in human medicine. The ability to quickly assess aperture closure time in a whole blood sample in a clinical setting has eliminated all the limitations of time-consuming and technically demanding platelet aggregometry. The PFA-100 simulates high shear flow blood vessel conditions and, with the addition of either epinephrine or ADP as an agonist on a collagen membrane, determines how quickly a platelet plug can close an aperture and arrest blood flow.

The method has been evaluated for use in the dog (Couto *et al*., 2007), and the collagen/ADP cartridge has been found to be useful to screen for platelet dysfunction in von Willebrand disease (Mischke and Keidel, 2003), NSAID administration (Gaal *et al*., 2007; Neilsen *et al*., 2007), and during endotoxemia (Yilmaz *et al*., 2005).

There are single reports evaluating the instrument for horses where it was determined it was sensitive enough to detect decreased platelet function related to ASA administration (Segura *et al*., 2005) and in a pig model of severe hemorrhagic shock (Arnaud *et al*., 2006).

3. *Screening Tests of Hemostasis*

a. OSPT

The one-stage prothrombin time (OSPT) assesses the plasma activity of prothrombin, FV, FVII, and FX after addition of calcium and activator known as tissue thromboplastin. The test therefore gives information about the tissue factor (extrinsic) pathway and the common pathway. Different sources of thromboplastin will result in different clotting times, and although the use of homologous tissue is ideal, human source reagents can be used effectively (Hall, 1970; Mischke and Nolte, 1997; Mischke *et al*., 2003). Clotting times tend to be rapid in domestic animals, often less than 10sec, which reduces the sensitivity of the assay for detecting minor abnormalities. Dilution of reagents has been advocated as a way to extend clotting times to 10 to 15sec.

As a screening test, the OSPT is not sensitive to minor coagulation abnormalities, and it generally takes loss of $>70\%$ activity of one or more factors to prolong the clotting time. Modification of the test to assess individual factor activity can be achieved using specific factor deficient plasma, and several assays have been shown to have similar ability to detect factor deficiencies (Mischke, 2002). The effects of common interferences (lipid, hemoglobin, bilirubin) on the PT assay have been studied (Moreno and Ginel, 1999). These authors found that bilirubin caused a statistically significant prolongation of the OSPT but that clinical significance associated with this prolongation was unlikely. Point-of-care analyzers are now available that can quickly perform the OSPT at the animal's cage side and have been evaluated in dogs (Tseng *et al*., 2001).

The International Normalized Ratio (INR) is frequently used in place of the OSPT in human medicine for monitoring people on warfarin anticoagulant therapy because different thromboplastins have variable sensitivities to warfarin-induced changes in factor activity (Stockham and Scott, 2002). The International Sensitivity Index (ISI), which is specific for an individual reagent, is incorporated into the INR calculation and is meant to correct for reagent variation. ISI values are not widely available for domestic animal species, so the INR is not frequently used in veterinary medicine.

b. aPTT

The activated partial thromboplastin time (aPTT) assay detects fibrin clot formation after addition of an activating agent, partial thromboplastin (phospholipids that lack TF), and recalcification of plasma. It assesses the activity of prothrombin, FV, FVIII, FIX, FX, FXI, and FXII, therefore providing information about the integrity of the contact activation (intrinsic) and common pathways (see Section II.C.3). Activating agents include substances such as kaolin and ellagic acid, and clotting times can vary between species

and depending on the specific activators used. Pooled plasma from a similar species is required as a control to avoid interpretive errors. There can be significant variations in the assay method and reagents used, so it is crucial that each laboratory define its own species-specific reference interval (Evans and Flynn, 1992; Johnstone, 1984). Similar to the OSPT, the test is relatively insensitive, requiring loss of activity of 70% of at least one factor before prolongation of the clotting time. Common interferences (lipid, hemoglobin, bilirubin) may interfere with an optical method and provide an erroneous result. Hemoconcentration was demonstrated to prolong aPTT in one study, emphasizing the importance of the blood-anticoagulant ratio for accurate testing (O'Brien *et al*., 1995).

The aPTT can additionally be used to monitor cats and dogs receiving heparin therapy (Greene and Meriwether, 1982; Mischke, 2003). The assay can be modified to detect specific factor deficiencies (Deniz *et al*., 1995; Mischke, 2000).

c. ACT

The activated clotting time (ACT) is similar to the aPTT in that it provides information about the same portions of the clotting mechanism (intrinsic or common pathways), but it is a less sensitive test. It is a point-of-care test performed on whole blood, where a compound in the tube, typically siliceous earth, activates the contact (intrinsic) pathway (Stockham and Scott, 2002). It depends on endogenous platelets in the sample as the phospholipid source for clotting. Because of this, although not well documented, severe thrombocytopenia may result in a prolonged ACT. It is used primarily as a screening test for coagulopathies, but it requires loss of greater than 95% loss of activity of one or more factors before it is prolonged, so disease is often advanced by the time the ACT is abnormal. The ACT is the time in seconds to first visible clot formation while gently inverting the tube after initial incubation for 60sec at 37°C either in a heating block or in a human axilla. The ACT is used in humans and sometimes in animal patients to monitor therapeutic heparinization.

Reference values have been published for cats (Bay *et al*., 2000), but each facility should follow a standard protocol and ideally define its own reference interval. Automated ACT methods are available on some point-of-care instruments that offer OSPT and aPTT, but they are not exactly the same as the tube ACT (phospholipid is added) and provide no advantage over an automated aPTT (Tseng *et al*., 2001).

d. TCT

The thrombin clotting time (or simply thrombin time) assesses the ability of thrombin to convert fibrinogen to fibrin, so it is abnormal when there are quantitative or qualitative abnormalities in fibrinogen. Variations of the test are available, so a reference interval specific for the laboratory and species should be developed (Mischke and Jacobs, 2001). The Clauss method is specifically used to derive a concentration of fibrinogen in a plasma sample (see Section III.B.5.b).

4. *Assessment of Fibrinolysis*

a. FDPs

Fibrin-fibrinogen degradation product (FDP) assays measure the breakdown split products of either fibrinogen or fibrin, and increased values indicate enhanced fibrinogenolysis or fibrinolysis. Elevated FDPs are used to help confirm the presence of DIC (see Section IV.B.4). Several human assays are available, including both serum and plasma-based assays, but the plasma latex agglutination test appears more sensitive for detecting DIC in dogs (Boisvert *et al*., 2001; Stokol *et al*., 1999). FDP assays have also been used in cats and horses.

b. D-Dimer

D-dimers and x-oligomers are small fragments created when fibrinolysis occurs. They are products of fibrin degradation, not fibrinogen degradation, so are more specific for enhanced fibrinolysis. There are currently no available animal-specific assays, but there appears to be sufficient cross-reactivity between human and canine proteins as some human-based semiquantitative immunological latex agglutination methods have been used in canine patients (Griffin *et al*., 2003; Nelson and Andreasen, 2003; Stokol, 2003; Stokol *et al*., 2000b). D-dimers have been assessed in horses, predominantly in an attempt to document DIC related to colic (Dallap *et al*., 2003; Heidmann *et al*., 2005; Monreal, 2003; Sandholm *et al*., 1995).

5. *Assessment of Specific Hemostasis Proteins*

a. Prothrombin, FV, FVII, FVIII, FIX, FX, FXI, FXII

Specific factor activity is traditionally assessed using coagulometric methods. Depending on the factor, modifications of the OPST (for extrinsic or common pathway factors) or the APTT (for intrinsic factors) are used where the activity of the factor in patient plasma is measured in a sample mixed with plasma known to be deficient in the factor. If the patient sample is deficient in the factor in question, the OSPT or APTT, as appropriate, does not correct (Stockham and Scott, 2002). The activity of the factor in the patient's plasma is derived from a standard curve created from serial dilutions of pooled homologous plasma from clinically healthy animals that has been added to the factor-deficient plasma. Factor-deficient plasmas for domestic animal species are not generally available, so methods must be validated using human reagents.

Chromogenic methods are now available and used quite extensively in human medicine. However, the expense, the

necessity to use a 96-well plate, and the limited shelf life of reagents once the kit is opened limit extensive use of this methodology for veterinary medicine unless samples can be batched.

b. Fibrinogen

For the heat precipitation method, EDTA-anticoagulated blood is centrifuged in a microhematocrit tube and heated for 3 to 9 min at 56°C, and then the amount of precipitate formed is quantified as a measure of fibrinogen. This method is useful only as a crude estimate of an increased concentration of fibrinogen and is no longer routinely used.

Derivation of fibrinogen concentration from the Clauss thrombin clotting time (Stockham and Scott, 2002) is more often performed at veterinary labs, because routine fibrin-based clotting assays are usually offered. Fibrinogen concentration is inversely proportional to the time it takes for thrombin to form fibrin from fibrinogen, so it depends on the amount of fibrinogen present when excessive thrombin is used to negate the effects of any inhibitors such as heparin or fibrin degradation products (Stockham and Scott, 2002). The time to clot formation is recorded in seconds and then converted to mg/dl or g/l based on a standard curve. A fibrinogen antigen assay is available but is not a functional test. Therefore, if the antigen assay is not decreased but the TCT is abnormal, dysfibrinogenemia is likely.

c. von Willebrand Factor

Assessment of von Willebrand factor (vWF) protein is most commonly determined by detecting antigen concentration in plasma, but additional tests are available if more detailed information is needed to manage the animal. See Section IV.A.1.b for more details.

d. Antithrombin

As an indicator of anticoagulant status, there are both functional and antigenic assays for the detection of antithrombin (AT) in plasma. Functional assays can be either thrombin or FXa based, where the more AT there is, the less activity of either of these enzymes there will be. A standard curve from homologous pooled plasma must be prepared to determine the test plasma activity. Both manual and automated methods are available. The activity of AT is stable, and in one study values remained relatively unchanged after 6 months of storage of plasma at −70°C and after 6 weeks of storage of whole blood at 4°C (Green, 1988). The same study suggested that FXa-based assays may be more appropriate because heparin cofactor II activity may be measured in some thrombin-based assays and falsely elevate the AT measurement. Hemoglobin in the sample may interfere with the ability to accurately determine plasma AT activity in some chromogenic assays (van der Merwe and Reyers, 2007).

C. Additional Assays

Several additional assays of activation of coagulation and fibrinolysis have been examined on a limited basis in veterinary medicine (Roncales and Sancho, 2000). Most of these tests are used widely in human medicine but need more thorough evaluation and standardization before being offered as routine tests for domestic animals. Some of the proteins or complexes tested include activated clotting factors such as FVIIa and FVIIa, activation peptides such as fibrinopeptides A and B, and indicators of fibrinolysis such as plasmin-antiplasmin complexes and PAI-1. Thrombin-antithrombin complexes (TAT) have been measured as an indicator of coagulation activation in dogs with malignant neoplasia (Maruyama *et al*., 2005) and horses with colic (Topper and Prasse, 1996).

The Russell viper venom time (RVVT) test is an additional assay used occasionally to provide information about common pathway abnormalities (Stockham and Scott, 2002). The time to clot formation depends on activation of FX by the venom of a Russell's viper. This test is not routinely used.

Proteins induced by vitamin K antagonism or absence (PIVKA) are inactive vitamin K-dependent clotting factors produced by hepatocytes when this important cofactor is unavailable (see Section IV.B.5). The Thrombotest PT is a modification of the prothrombin time that is sensitive, but not entirely specific, to the presence of these abnormal proteins (Center *et al*., 2000).

Thromboelastography (TEG) provides a global assessment of hemostasis and specifically provides general information about the rate of fibrin polymerization and overall clot strength. Analysis of the TEG tracing can give a summary of platelet function, coagulation proteins, and fibrinolysis (Luddington, 2005). TEG has traditionally been used in human medicine to facilitate blood product use decisions in patients undergoing liver transplant or cardiac surgery. Its use has been minimally evaluated in veterinary medicine (Donahue and Otto, 2005). One study used TEG to document hypercoagulability in dogs with parvoviral enteritis (Otto *et al*., 2000). Routine use of TEG suffers from lack of standardization, although a group recently developed TEG values for clinically healthy dogs (Wiinberg *et al*., 2005).

IV. DISORDERS OF HEMOSTASIS

A. Hereditary Disorders

1. *von Willebrand Disease*

Although von Willebrand disease (vWD) is the most common inherited bleeding disorder in both humans and dogs, it has also been reported in swine and cats (Denis and Wagner, 1999; Thomas, 1996). Human vWD was described initially

TABLE 10-7 Recognized Types of Canine von Willebrand Disease and Their Features

	Type I	Type II	Type III
vWF Concentration[a]	Decreased	Decreased	Undetectable
vWF Structure[a]	Normal	Decrease in large multimers	Undetectable
Breed Predilection[a]	Doberman pinschers Airedales Dachshunds German shepherds Shetland sheepdogs Several other breeds	German shorthaired and wirehaired pointers only	Chesapeake Bay retriever Dutch kooiker Scottish terrier Shetland sheepdog
Inheritance Pattern	Autosomal dominant	Appears autosomal recessive	Autosomal recessive
Hemorrhage	Variable	Severe	Severe

[a] *See Brooks,* 1992.

in the 1920s by Erik von Willebrand, and since then it has been classified into three distinct variants (Ewenstein, 1997). Two are quantitative deficiencies (types I and III), with a decrease in circulating vWF, and one is a qualitative defect (type II) (Ewenstein, 1997). Human type II vWD is further divided into four subtypes (A, B, M, and N) (Ewenstein, 1997). The first incidence of vWD in dogs was reported in 1970 in a family of German shepherd dogs (Denis and Wagner, 1999). Since then, as in humans, three types of vWD have been identified and are summarized in Table 10-7. Whereas types I and III vWD share phenotypic characteristics with the respective human types, the qualitative defect (type II) is characterized by a decrease in high-molecular-weight vWF multimers without further subclassification. Although modes of inheritance have been identified, the actual genetic defect is unknown for many of the affected breeds (Denis and Wagner, 1999).

Inheritance of type I vWD is autosomal dominant with incomplete penetrance. A dominant trait requires only one copy of the gene to produce abnormalities. Therefore, clinical signs can be identical for homozygotes and heterozygotes (Brooks, 2000). Hemorrhage in type I vWD can vary from mild to severe, and even dogs with comparable concentrations of vWF can show a range of clinical signs (Brooks, 2000). Manifestations of type I vWD are due to a proportional decrease in all multimer sizes (Brooks, 1999). It has been reported that in Doberman pinschers there is a decrease in vWF mRNA as well as a reduced release of vWF from endothelial cells, suggesting that the disease is a result of defective expression of the gene (Denis and Wagner, 1999). However, immunofluorescent studies have shown that there is no detectable difference in the localization of vWF:Ag or the fluorescence intensity in endothelial cells from control dogs and type I vWD-positive Doberman pinschers (Meyers *et al*., 1990b). As of 1981, the reported prevalence of vWD in Dobermans in North America was 63% (Dodds *et al*., 1981). Although the Doberman pinscher is the most well-known breed associated with type I vWD, the condition is also commonly found in a variety of other breeds including Airedale terriers, dachshunds, Pembroke Welsh Corgis, and German shepherd dogs.

Type II disease is rare in dogs and has been reported only in German shorthaired and wirehaired pointers (Brooks, 2000). Disease manifestation is due to lack of high-molecular-weight multimers of vWF and tends to produce recurrent severe hemorrhage. Generally, one or more episodes of bleeding occur by the time the animal is 1 year old (Brooks, 2000). In one study, a particular family line of German shorthaired pointers, in which some members were positive for type II vWD, was examined and it was found that none of the affected dogs had a vWF:Ag concentration higher than 68% (Kramer *et al*., 2004). Persistent spontaneous bleeding episodes in this family of dogs was confined to homozygotes, dogs with vWF:Ag concentrations of less than 10%, or both (Kramer *et al*., 2004). The pattern of inheritance in this family line appeared consistent with an autosomal recessive trait. This study was successful in identifying a consistent single nucleotide defect within the sequence for the vWF A2 domain of the affected dogs and an identical defect in German wirehaired pointers (Kramer *et al*., 2004).

Similar to type I disease, the type III phenotype is dependant on the level of vWF:Ag present. This manifestation of vWD is autosomal recessive. Homozygotes have no measurable circulating factor and are clinically affected, whereas heterozygotes exhibit low levels of vWF and clinically appear normal (Brooks, 2000). FVIII activity tends to vary between 15% to 50% in type III patients (Denis and Wagner, 1999).

a. Hemorrhagic Tendencies

In type I vWD, it is not uncommon for animals to present without a bleeding history, in contrast to type II and III

disease where bleeding generally occurs during the first year of life. The ability of vWF to mediate platelet adherence and aggregation is a key component in primary hemostasis (see Section II.B.3.a). In the absence, or dysfunction, of vWF in high-flow conditions, the inability of platelets to successfully bind collagen and form aggregates can resemble a primary platelet disorder. As such, thrombocytopenias, thrombocytopathias, and vWD can present in a similar fashion; however, petechiae can be a distinguishing feature. In contrast to platelet disorders, petechiae are not a feature of vWD, and to the authors' knowledge, the reason for this has not been explained in the literature. When the interaction between vWF and platelets is examined, the importance of hemorrheology quickly becomes evident. The role of vWF is most important in platelet adherence in high blood flow environments. As mentioned previously (see Section II.B.3.a), the platelets are able to bind collagen through the GP VI and GP Ia-IIa receptors independent of vWF in areas of low blood flow. Capillaries are sites of low blood flow, and therefore, during normal wear and tear, platelets are able to occlude small vessel defects without assistance from vWF. Therefore, a decreased concentration or function of vWF would not be reflected as a defect in this process. However, a decrease in platelet number or function would prevent occlusion of these vessel defects and result in petechiae.

Bleeding in vWD-positive dogs generally involves hemorrhage from mucosal surfaces and excessive hemorrhage after surgery or trauma (Thomas, 1996). Epistaxis, hematuria, gastrointestinal hemorrhage, prolonged estral bleeding, and gingival bleeding at tooth eruption are some of the more commonly reported occurrences (Brooks, 2000). In some dogs, rebleeding from incised tissues has been observed as long as 24 h after a surgical procedure (Brooks, 1992). In general, animals that tend to be more likely to hemorrhage have vWF concentrations below 20%; however, the concentration of vWF:Ag does not accurately predict the risk of hemorrhage (Brooks, 2000; Thomas, 1996). Multiple factors, beyond the concentration of vWF, can influence an animal's likelihood to bleed. The type of tissue affected can contribute to the level of hemorrhage. For example, the oronasal cavity and urinary tract are areas that are high in fibrinolysins and therefore tend to produce a more severe bleed (Brooks, 2000). Concurrent platelet dysfunction can also increase the likelihood that a vWD patient will experience hemorrhage. Therefore, in conditions that can influence platelet function (e.g., uremia, hypoproteinemia, anemia, and liver disease), an increased possibility of hemorrhage should be considered (Brooks, 2000).

b. Diagnosis

Determination of both vWF concentration and function is important in the diagnosis of vWD, as no single test is comprehensive enough to detect all of the variants (Favaloro *et al*., 1999; Paczuski, 2002). The current gold standard is the vWF antigen concentration (vWF:Ag) test. Reported ranges include normal (>70%), abnormal (<50%), and indeterminate values that comprise the difference (Thomas, 1996). This test can identify some of the dogs with types I and III vWD, but it can leave some diagnoses indeterminate. In addition, this test is not effective for identifying type II disease as this is a qualitative rather than a quantitative deficiency. Type I disease can also be problematic to diagnose because of extragenic influences that can temporarily increase vWF into the normal range, as discussed later in the chapter (Ewenstein, 1997).

In 1986 the use of a collagen binding assay (CBA) as an alternate to ristocetin-induced platelet aggregation assays (vWF:RCof) was proposed (Paczuski, 2002). This assay measures the quantity of vWF bound to immobilized collagen in a procedure similar to that of an ELISA (Paczuski, 2002). The coefficient of variation for this test has been reported as low as 4.4% (Callan *et al*., 2005). When compared to the vWF:RCof, the CBA was superior in its detection of type II vWD and had decreased assay variability (interassay and interlaboratory) (Favaloro, 2000). Collagen has been shown to bind vWF with a preference for the high-molecular-weight forms, and therefore the CBA can be used to assess the relative proportion of large vWF multimers (Brown and Bosak, 1986; Duggan *et al*., 1987). In vWD patients the collagen binding activity is significantly decreased compared to control patients (Paczuski, 2002). In types I and III vWD, the decrease in function of vWF parallels the level of vWF:Ag present; in type II vWD, there is a disproportionate decrease in activity (Denis and Wagner, 1999). Collagen binding assays, in conjunction with the antigen assay, can therefore be used to assess the quantity of vWF as well as its function (Paczuski, 2002). This makes these assays valuable not only as screening tests for vWD but also to distinguish between types I and II (Paczuski, 2002). The ratio of vWF:Ag to vWF:CBA in normal patients and type I vWD is generally less than or equal to 1 (Favaloro *et al*., 1991). In type II vWD, this ratio has been reported to range from 2 to 8 (Brown and Bosak, 1986; Favaloro *et al*., 1991). Although the CBA is currently utilized extensively in human diagnostics, it is only recently becoming available for the diagnosis of canine vWD.

c. Extragenic Influences on vWF Concentration

The value of a single sample in an animal with an indeterminate vWF:Ag ELISA result is limited by daily and weekly variation in vWF:Ag concentration (Kramer *et al*., 2004). In humans there is question as to whether other traits may influence the phenotypic expression in type I disease. For instance, individuals with blood type O have levels of vWF 20% to 30% lower than individuals with other blood types (Ewenstein, 1997). Several other factors have also been found to increase the plasma concentration of vWF, including azotemia, liver disease, strenuous exercise, endotoxemia, parturition, and increased plasma vasopressin (Thomas, 1996). In dogs, significant increases in the vWF concentration occur during the last one-third

of gestation; however, values return to normal by 7 to 14 days postpartum (Moser *et al*., 1998). This change is more notable in normal dogs but does also occur in type I vWD patients (Moser *et al*., 1998). It has been suggested that this may be a result of rapidly dividing endothelial cells in a highly vascular placenta (Moser *et al*., 1998). In contrast, there is no significant change in vWF concentration during the estrus cycle (Moser *et al*., 1998). Age can also have an effect on the vWF concentration, with younger puppies generally having lower concentrations that gradually approach mean adult values by 11 weeks of age (Mansell and Parry, 1992).

In humans, patient response to desmopressin has a positive correlation with the level of platelet vWF (Ewenstein, 1997). Vasopressin stimulates V2 vasopressin receptors, resulting in the release of intracellular stores of vWF (Brooks, 2000). A study involving normal dogs and Doberman pinschers with vWD was conducted in order to assess the effect of exercise, DDAVP, and epinephrine on vWF concentration and FVIII activity (Meyers *et al*., 1990a). The vWF-deficient dogs were unable to sustain intense exercise for longer than 30 min, whereas the normal dogs were able to complete a 10 km run in 40 min. An increase in FVIII activity was noted in the normal dogs that was related to the intensity of exercise and increased blood lactate concentrations, although the basis for the increase was not clear. vWF increased in these dogs to a greater extent than FVIII. There was no significant change in FVIII or vWF concentration in the vWD-positive dogs. Although their level of exercise was less than that of the normal dogs, the equivalent exercise was sufficient to cause an increase in vWF:Ag concentration of 30% in the normal dogs. The increase in vWF:Ag and FVIII concentrations after infusion of DDAVP in normal dogs is less than observed in humans, and some dogs react poorly to this therapy (Meyers *et al*., 1990a). In the Meyers *et al*. study, the vWF:Ag concentration increased in normal dogs after treatment with DDAVP. Although the increase noted in the vWF-deficient dogs was less than 0.1 U/ml, bleeding time decreased in three of six of these dogs. This finding suggested that DDAVP may induce the release of the high-molecular-weight (and therefore more active) forms of vWF; however, Callan *et al*. (2005) confirmed through multimer analysis that DDAVP produces an increase in all multimer sizes. Finally, whereas the vWF:Ag concentration increased 30 min after administration of epinephrine in the normal dogs, there was no change in FVIII activity, nor were there changes in either factor in the vWF-deficient dogs. Breed variations have also been noted, for example Airedale terriers tend to have decreased concentrations of vWF compared to control dogs, yet a history of bleeding is rare (Thomas, 1996).

2. *Platelet* N*umber*

Typical clinical signs of thrombocytopenia include petechiae and ecchymoses, bleeding from mucosal surfaces, and cutaneous bruising. As mentioned (see Section IV.A.1.a), with the exception of petechiae, these signs are similar to those noted in patients with vWD.

Greyhounds and Cavalier King Charles spaniels (CKCS) have been shown to have lower platelet numbers when compared to other breeds, without apparent consequence (Cowan *et al*., 2004; Sullivan *et al*., 1994). In addition to decreased platelet numbers, in 51% of the CKCS studied, 33% exhibited macrothrombocytes (Cowan *et al*., 2004). In fact, the platelet counts in those dogs with macrothrombocytes were significantly lower than in CKCS dogs with normal-sized platelets (Cowan *et al*., 2004). The apparent connection between platelet size and number in these dogs is not surprising based on the association between platelet mass and TPO concentration (see Section II.B.1). Although, as mentioned, this platelet anomaly is benign, there is a decreased platelet aggregation response to ADP in CKCS (Cowan *et al*., 2004).

3. P*latelet* F*unction*

As noted previously (see Section II.B.2), the GPIIb-IIIa integrin is essential for platelet aggregation. A deficiency of this integrin results in thrombasthenic thrombopathia, also known as Glanzmann's thrombasthenia. This deficiency has been identified in humans, dogs (otterhounds and Great Pyrenees), and horses. Clinical signs of bleeding in affected canine patients are generally recognized before 1 year of age and include mucosal hemorrhage, melena, hematuria, cutaneous ecchymoses, and excessive surgical bleeding (Boudreaux and Catalfamo, 2001). In platelet aggregation studies, affected platelets will undergo shape change but fail to aggregate normally. Abnormal *in vitro* clot retraction is also typical of this disease and has been used as a screening tool; however, this test is not reliable for identification of carrier animals (Boudreaux and Catalfamo, 2001). Documentation of decreased or absent membrane GPIIb-IIIa through flow cytometry or electrophoretic studies provides a definitive diagnosis. Thus far, two genetic defects have been identified in Great Pyrenees dogs, and a single defect in otterhounds (Boudreaux and Catalfamo, 2001; Lipscomb *et al*., 2000). Similar to the dog, equine cases also present with mucosal bleeding, and they have markedly impaired platelet aggregation and markedly decreased clot retraction (Livesey *et al*., 2005). A single genetic defect has been identified in the horse and was consistent between two affected horses of different breeds (Christopherson *et al*., 2006).

Platelet storage pool defects, specifically a deficiency of dense granules and their contents, result in thrombopathia in Chediak-Higashi syndrome (CHS). In both cattle and humans affected with this disease, compared to unaffected individuals, platelet aggregation was decreased in response to collagen; concentrations of serotonin, ATP, and ADP were decreased; and the ratio of ATP:ADP was abnormally increased (Bell *et al*., 1976). Similarly, in CHS cats, platelet aggregation required considerably higher

concentrations of serotonin, ADP, or collagen; platelet ATP, ADP, and serotonin content was decreased; and secretion of Ca^{2+} and Mg^{2+} by activated platelets was markedly decreased (Meyers *et al*., 1981). More recent studies have demonstrated that, in addition to the dense granule deficiency, the collagen-induced increase in cytosolic Ca^{2+}, through the PLCγ pathway (see Sections II.B.3.a and c), is depressed in the platelets of Japanese black cattle affected with CHS (Shiraishi *et al*., 2002a, 2002b). These results suggest an additional mechanism for the decreased platelet function in CHS. A dense granule storage defect, similar to that in CHS, has been described in three families of American cocker spaniel dogs with moderate to severe bleeding (Callan *et al*., 1995). Although these dogs had a decrease in ADP content and an increased ATP:ADP ratio, in contrast to CHS, the number and morphology of dense granules on ultrastructural studies and concentrations of serotonin appeared normal (Callan *et al*., 1995). The defect identified in these dogs appears to be an isolated abnormality in the δ-granule adenine nucleotide storage (Callan *et al*., 1995).

Platelet dysfunction in basset hounds has been attributed to defective intracellular signaling. Ultrastructural appearance, surface molecules, and granule constituents appear normal in these dogs; however, secretion of dense granules, expression of fibrinogen binding sites on GPIIb-IIIa, and platelet aggregation are impaired in response to several platelet agonists (Catalfamo *et al*., 1986). An elevation of basal cAMP levels has been detected in these platelets and is thought to result from a defect in cAMP metabolism (Boudreaux *et al*., 1986; Catalfamo and Dodds, 2000). As previously mentioned, elevated cAMP levels reduce platelet reactivity through a number of mechanisms (see Section II.B.3.d, and Table 10-3) and thus would be detrimental during hemostatic challenge. The thrombopathia of Simmental cattle has also been attributed to defective intracellular signal pathways. Whole blood from these cattle exhibit normal clot retraction, but aggregation in response to ADP and collagen is markedly impaired (Searcy *et al*., 1990). Similar to basset hounds, these cattle express normal levels of GPIIb-IIIa on the platelet surface; however, in contrast, dense granule secretion is unimpaired (Searcy *et al*., 1990). The cytoskeletal assembly in response to ADP was shown to be incomplete, and this is thought to result in delayed activation of GPIIb-IIIa and therefore delayed fibrinogen binding (Frojmovic *et al*., 1996; Searcy *et al*., 1994).

4. *Coagulation Factor Disorders*

a. Fibrinogen Deficiency

As previously discussed, fibrinogen not only takes part in primary hemostasis but is imperative for final clot formation in secondary hemostasis (see Section II.C.4). Fibrinogen is primarily synthesized in hepatocytes through production and assembly of three polypeptide chains (Aα, Bβ, and γ), which subsequently dimerize to form hexameric fibrinogen (Asselta *et al*., 2006). Each of the fibrinogen chains is encoded by separate genes, and all are required for successful assembly and secretion (Roy *et al*., 1991). Numerous genetic defects have been identified in humans, with variable influence on production, secretion, and function of the molecule. Hereditary fibrinogen deficiencies are generally categorized into quantitative (afibrinogenemia and hypofibrinogenemia) and qualitative disorders (dysfibrinogenemia) (Asselta *et al*., 2006). In humans, the quantitative deficiencies are generally inherited as autosomal recessive disorders, whereas the qualitative deficiencies are generally autosomal dominant (Asselta *et al*., 2006). Bleeding tendencies are variable; however, umbilical cord bleeding, hemorrhages from mucosal surfaces, hemarthroses, and hematomas are some of the more frequently encountered symptoms (Lak *et al*., 1999). Hemarthrosis and hematomas tend to be less frequent and severe than in the hemophilias (Lak *et al*., 1999). In afibrinogenemic and hypofibrinogenemic patients, the majority of bleeding episodes occurs as a result of trauma or surgery (71% and 80%, respectively), with the remainder comprising spontaneous episodes (Acharya *et al*., 2004). Thrombin time is prolonged in fibrinogen defects; however, partial thromboplastin time and prothrombin time are also prolonged because of their dependency on a fibrin clot end point (see Section III.B.3.d). Further investigation should include quantification of fibrinogen, an absence indicating afibrinogenemia, and decreased levels in hypofibrinogenemia. Although fibrinogen concentration is generally within reference intervals for dysfibrinogenemias, some present with low fibrinogen concentrations (Hayes, 2002). It is important to measure activity in conjunction with concentration in order to reveal functional deficiencies. Typically a 1:1 ratio of functional to quantitative levels are present; however, in dysfibrinogenemia the ratio is more typically 1:2, with disproportionately low function compared to concentration (Hayes, 2002).

Although significant progress has been made in the characterization of human fibrinogen deficiencies, this disorder is still exceedingly rare and poorly characterized in animals. Fibrinogen defects have historically been identified in goats and various breeds of dog (Dodds, 2000). More recent reports include a Border Leicester lamb with disproportionately low fibrinogen function when compared to concentration (Fecteau *et al*., 1997). However, in this report, diagnostic limitations prevented definitive distinction between dysfibrinogenemia and afibrinogenemia. Clinical signs were consistent with those reported in humans, including umbilical bleeding and a hematoma. A case of congenital afibrinogenemia was confirmed, through extensive testing, in a Bichon Frise. This patient experienced excessive bleeding at sites of venipuncture, a hematoma, and uncontrolled hemorrhage following ovariohysterectomy (Wilkerson *et al*., 2005).

Acquired deficiencies of fibrinogen are generally associated with consumptive coagulopathies, but they can also result from decreased production in liver failure.

b. Vitamin K-Dependent Factor Deficiencies (Prothrombin, FVII, FIX, FX, Protein C, Protein S)

The presence of vitamin K is essential to the function of several procoagulant and anticoagulant proteins, including prothrombin, FVII, FIX, FX, protein C, and protein S. These vitamin K-dependent factors rely on posttranslational carboxylation to allow binding of calcium and subsequent binding to negatively charged phospholipid membranes (Dowd *et al*., 1995a). Before participation in the carboxylation of the vitamin K-dependent proteins, conversion of vitamin K_1 to its biologically active form, vitamin K hydroquinone (vitamin K_1H_2), through an NADH-dependent reductase is necessary (Dowd *et al*., 1995b). The oxidation of vitamin K_1H_2 to vitamin K_1 2,3 epoxide occurs simultaneously with, and provides energy for, carboxylation of the glutamic acid residue through γ-glutamyl carboxylase (Dowd *et al*., 1995b). The resultant vitamin K_1 2,3 epoxide is then reduced to vitamin K_1 through vitamin K epoxide reductase, completing the cycle.

Inherited defects in the vitamin K cycle have been identified in Devon Rex cats and Rambouillet sheep. Initial reports in related Devon Rex cats observed multiple factor deficiencies that resembled anticoagulant toxicity and were responsive to vitamin K therapy (Maddison *et al*., 1990). These cats presented with hematomas, intrathoracic hemorrhage, and hemorrhage in the bladder, sublumbar area, and perineum (Maddison *et al*., 1990). The specific mechanism for the disorder was not identified in that report. A later case report on two littermates was able to identify a decreased affinity of the γ-glutamyl carboxylase for vitamin K (Soute *et al*., 1992). Investigation into a flock of Rambouillet sheep experiencing increased lamb mortality because of ineffective hematopoiesis also identified a defect in γ-glutamyl carboxylase, specifically a single nucleotide polymorphism resulting in truncation of the enzyme (Johnson *et al*., 2006a, 2006b). The affected lambs continually bled from the umbilicus and experienced subcutaneous and body cavity hemorrhage, resulting in death (Johnson *et al*., 2006b). Breeding data from the flock indicated an autosomal recessive trait (Johnson *et al*., 2006b). Unlike the defect in the Devon Rex cats, vitamin K therapy was not effective in these lambs (Johnson *et al*., 2006b). To the authors' knowledge, there has been a single case report of naturally occurring protein C deficiency in animals. A 2-year-old Thoroughbred colt was diagnosed with a functional deficiency in protein C resulting in recurrent venous thrombosis (Edens *et al*., 1993). Although a specific genetic defect was not identified, it was suggested that this deficiency was a result of either a primary inherited abnormality in protein C or an abnormal posttranslational γ-carboxylation (Edens *et al*., 1993).

c. Factor VII Deficiency

FVII deficiency is well described in beagles but has also been documented in Alaskan malamutes and a mixed-breed dog (Macpherson *et al*., 1999; Mills *et al*., 1997). Presenting hemorrhagic signs in nonbeagle dogs have included mucosal hemorrhage, subcutaneous bruising, and excessive surgical hemorrhage. Although clinical manifestations are occasionally reported in beagles, the coagulation deficiency is often an incidental finding in beagle colonies when routine coagulation screens are performed before experimental studies (Spurling *et al*., 1972, 1974). Routine OSPT is prolonged and FVII coagulant activity decreased in affected dogs; however these are not reliable methods to detect carrier status (Callan *et al*., 2006). In contrast, both homozygous and heterozygous beagles appear to have impaired clotting profiles in rotational thromboelastography when compared to normal canine plasma (Callan *et al*., 2006). A missense mutation has been identified in beagles and is consistent within the breed (Callan *et al*., 2006).

d. Factor VIII Deficiency (Hemophilia A)

Hemophilia A is one of the most common inherited coagulopathies in dogs, having been identified in many breeds, and it has also been reported in cats, cattle, horses, and an alpaca (Cotter *et al*., 1978; Healy *et al*., 1984; Henninger, 1988; Miesner and Anderson, 2006). Reported hemorrhagic signs have included umbilical hemorrhage, gingival bleeding at teething, hematomas, hemarthrosis, intraspinal hemorrhage, excessive surgical bleeding, and delayed rebleeding postsurgery (Fogh, 1988; Miesner and Anderson, 2006; Thompson and Kreeger, 1999). Mildly affected animals (FVIII activity of 5% or higher) do not tend to bleed spontaneously and are generally able to maintain adequate hemostasis, whereas moderately affected animals (FVIII activity of 2% to 5%) are more likely to experience severe sequelae to minor trauma, and severely affected animals (FVIII activity less than 2%) may bleed spontaneously (Mansell, 2000). The buccal mucosal bleeding time (see Sections III.B.1.a and b) is within reference intervals for FVIII-deficient dogs; however, cuticle bleeding time is prolonged (Brooks and Catalfamo, 1993; VanderVelden and Giles, 1988). Evaluation of biopsies from experimentally injured cuticles, using light and electron microscopy, have shown significant differences in the platelet component of the platelet plug as well as gross abnormalities in fibrinous transformation in FVIII-deficient dogs compared to normal dogs (Fogh and Fogh, 1988; VanderVelden and Giles, 1988). The platelet plugs were larger, often fragmented, and frequently did not appear to be associated with the vessel. Platelets within the plug appeared quiescent (remained granular and lack of OCS dilatation), and minimal fibrinous transformation of the plug occurred (VanderVelden and Giles, 1988). The changes noted in FVIII-deficient animals cannot be extrapolated to other secondary hemostatic deficiencies. Under the same conditions, the sequential events that occurred during clot formation in normal dogs were also observed in FVIII-deficient dogs; however, a time delay was apparent (VanderVelden and Giles, 1988). The rebleeding phenomenon described in hemophiliacs can be explained by

the role of TAFI (see Section II.C.4.c) in fibrinolysis inhibition. Although a small amount of thrombin formation is sufficient to stabilize the initial platelet plug, the secondary burst of thrombin that occurs in the propagation phase of coagulation is required for the activation of TAFI (Mosnier *et al*., 2001). In hemophilia A, this secondary burst of thrombin formation is inadequate, resulting in deficient TAFI and fibrinolysis of the initial clot (Monroe and Hoffman, 2006; Mosnier *et al*., 2001). Hemophilia A is an X-linked recessive trait, and therefore males are most commonly affected. Laboratory findings in homozygotes generally include prolonged aPTT, OSPT within reference intervals, and decreased FVIII activity. There is a poor correlation between the degree of prolongation of the aPTT and the activity of FVIII in plasma (Mansell, 2000). Heterozygotes are asymptomatic, and typical laboratory testing does not reliably discriminate between normal and carrier animals. Recently, a marker allele associated with the hemophilia A phenotype has been identified in a golden retriever family and was able to define carrier status (Brooks *et al*., 2005).

e. Factor IX Deficiency (Hemophilia B)

Based on clinical signs, hemophilia B is indistinguishable from hemophilia A. Generally, it is considered that clinical signs are more severe in young and large-breed dogs (Nakata *et al*., 2006). As with FVIII deficiency, this disorder is an X-linked recessive trait and has been reported in both dogs and cats. Laboratory testing reveals a prolonged aPTT, a normal OSPT, and a decrease in plasma FIX activity. In contrast to the variability seen in hemophilia A, FIX activity is generally low (<5%) in homozygotes (Mansell, 2000). In addition, mild decreases in FIX activity appear more consistent in heterozygotes of hemophilia B, and therefore factor activity screening is more reliable in their identification (Mansell, 2000). A variety of genetic mutations have been identified in dogs, and recently two distinct nucleotide changes were identified in two cats (Evans *et al*., 1989; Goree *et al*., 2005; Gu *et al*., 1999).

f. Factor X Deficiency

Canine FX deficiency was first reported in a breeding colony of cocker spaniels in 1973 (Dodds, 1973). This colony was experiencing increased morbidity and mortality in newborn puppies, within 7 to 10 days of birth, from obvious hemorrhagic complications (Dodds, 1973). Dogs with factor activities between 18% and 68% experienced moderate to severe hemorrhagic signs, and the trait appeared to be lethal in many of these dogs (Dodds, 1973). FX deficiency has also been identified in a Jack Russell terrier and domestic shorthair cat (Cook *et al*., 1993; Gookin *et al*., 1997). In humans, this deficiency is inherited as an autosomal recessive trait; however, in the initial canine report an autosomal dominant inheritance, with incomplete penetrance, was suspected (Dodds, 1973). aPTT, OSPT, and Russell viper venom time (RVVT) are all prolonged in affected animals, factor X activity is decreased, and thrombin time is within reference intervals.

Acquired FX deficiency resulting from *Hymenoxys odorata* (bitterweed) has been demonstrated experimentally in sheep (Steel *et al*., 1976). This annual weed produces illness and death, as early as 24h postingestion, in sheep and occasionally cattle. Experimentally exposed sheep had prolongation of both the OSPT and aPTT within 3 days (Steel *et al*., 1976). Plasma FX activity was decreased; however, all other specific factors remained within reference intervals (Steel *et al*., 1976).

g. Factor XI Deficiency

Congenital FXI deficiency is uncommon in animals; however, it has been identified in dogs, cattle, and more recently in a cat (Dodds and Kull, 1971; Gentry *et al*., 1975; Troxel *et al*., 2002). Hemorrhagic signs associated with this deficiency tend to be mild; however, they can be substantial after challenge with surgery or severe trauma (Gentry, 2000a). FXI deficiency is transmitted as an autosomal recessive trait, and although the degree of reduced factor activity varies between species, in general homozygotes have less than 11% FXI activity and heterozygotes vary from 23% to 48% (Gentry, 2000a; Gentry and Ross, 1994; Knowler *et al*., 1994). Prolongation of the aPTT, an OSPT within reference intervals, and a decreased plasma FXI activity are typical of homozygous animals. The aPTT has been proven inadequate to identify heterozygotes, and identification based on FXI activity has proven difficult because of an overlap in the range of activities between carrier and normal animals (Gentry and Ross, 1986; Kunieda *et al*., 2005). Two distinct genetic mutations, both insertions, have been identified in the Holstein and Japanese black cattle, thus providing a more accurate diagnostic approach to the heterozygote in this species (Kunieda *et al*., 2005; Marron *et al*., 2004).

To the authors' knowledge, there has been a single report of acquired FXI deficiency. A 5-year-old neutered male cat without a previous history of hemorrhage was presented with epistaxis. FXI activity was markedly decreased (<5%), and mixing studies indicated the presence of an inhibitor (Feldman *et al*., 1983). A systemic lupus erythematosus (SLE) inhibitor was suspected on subsequent detection of erythrocyte autoagglutination (Feldman *et al*., 1983). Marked intraperitoneal hemorrhage resulted in the death of this patient.

h. Contact Factor Deficiencies

Of the contact factors, FXII (Hageman factor) deficiency is the most common. This deficiency is generally associated with cats, and an autosomal recessive mode of transmission has been identified in this species (Kier *et al*., 1980). Homozygotes for FXII deficiency have a factor activity of

less than 2%, whereas heterozygotes average approximately 50% (Kier *et al*., 1980). Laboratory evidence for this deficiency includes a prolonged aPTT and decreased plasma FXII activity. Cats are often identified incidentally during routine coagulation screening and do not exhibit hemorrhagic signs. An absence of FXII has been demonstrated as a normal phenomenon in several species, including some marine mammals, birds, and reptiles (Robinson *et al*., 1969). This finding suggests that FXII is not integral to the coagulation system, and similarly may explain the absence of hemorrhage in deficient cats. FXII deficiency in combination with other factor deficiencies has been reported in both dogs and cats (Dillon and Boudreaux, 1988; Littlewood and Evans, 1990; Otto *et al*., 1991; Randolph *et al*., 1986).

Prekallikrein deficiency is rare; however, it has been reported in the dog and in miniature and Belgian horses (Chinn *et al*., 1986; Geor *et al*., 1990; Otto *et al*., 1991; Turrentine *et al*., 1986). Excessive hemorrhage after castration occurred in the proband Belgian horse, but in other animals hemorrhagic signs were not present without concurrent underlying disease or combination factor deficiencies. Laboratory tests reveal a prolonged aPTT, and decreased prekallikrein activity in this deficiency. In the equine families examined, an autosomal recessive mode of inheritance was suggested (Geor *et al*., 1990; Turrentine *et al*., 1986). In general, homozygotes exhibited markedly decreased prekallikrein activities, and heterozygotes exhibited mild to moderate decreases (Geor *et al*., 1990; Turrentine *et al*., 1986). Additional reports of contact factor pathway deficiencies have included a horse and German shorthaired pointer; however, definitive identification of the specific factor deficiency was not possible (Ainsworth *et al*., 1985; Lisciandro *et al*., 2000). Bleeding diathesis was not present in either case, despite challenge with ovariohysterectomy in the German shorthaired pointer.

B. Acquired Disorders

1. Thrombocytopenia

Clinically relevant thrombocytopenias are generally acquired; however, there are numerous etiologies, and detailed discussion of each extends beyond the scope of this chapter. Refer to Russell and Grindem (2000), Scott (2000), Zimmerman (2000) and for more details. In general, the pathogenesis of acquired thrombocytopenias can be grouped into three categories: (1) decreased production, (2) increased consumption or destruction, and (3) sequestration. Decreased production can result from infectious agents (e.g., *Ehrlichia* spp., bovine viral diarrhea virus, feline leukemia virus, equine infectious anemia virus), toxins, or drugs that suppress bone marrow (such as chemotherapeutic agents, estrogen, and NSAIDs); myelophthisis; or immune-mediated mechanisms that target megakaryocytes. Increased destruction of platelets is frequently associated with consumptive coagulopathies (see Section IV.B.4) and immune-mediated mechanisms. Immune-mediated thrombocytopenias can be idiopathic (primary) or associated with systemic immune disease, drug therapy, neoplasia, or infectious agents (secondary). Finally, abnormal distribution or sequestration (e.g., enlarged spleen) can result in decreased platelet numbers; however, this tends not to be responsible for the more dramatic cases of thrombocytopenia.

2. Platelet Dysfunction

As with acquired thrombocytopenias, acquired platelet function disorders are numerous, and detailed discussion is beyond the scope of this chapter (see Boudreaux [2000], for more details). Briefly, uremia, increased FDPs (DIC or liver failure), neoplasia, and hyperproteinemia or paraproteinemia can impair adhesion of platelets. Several therapeutic agents can also impede platelet function through various mechanisms, including inhibition of the cyclooxygenase enzyme (nonsteroidal anti-inflammatories), inhibition of calcium influx across the platelet membrane (calcium channel blockers), and inhibition of agonist receptors (β-lactam antibiotics) (Boudreaux, 2000).

3. Liver Disease

The majority of coagulation proteins is synthesized in the liver, and therefore, as seen with other products of the liver, decreased synthesis occurs with severe decreases in functional hepatic mass. Refer to recent reviews on hemostatic abnormalities of liver disease in humans for a detailed discussion (Lisman *et al*., 2002; Senzolo *et al*., 2006). Briefly, the effect of liver disease is complex, as it is involved in both procoagulant and anticoagulant systems. Therefore, dysfunction can result in either hemorrhagic or thrombotic complications (Senzolo *et al*., 2006). Dysfunction can include decreased production of coagulation proteins or production of abnormal proteins with altered function (Lisman *et al*., 2002). Studies comparing acute (toxicity induced) liver failure and chronic cirrhosis have suggested different mechanisms for coagulation factor deficiencies. In acute failure, prothrombin, FV, FVII, and FX were significantly reduced and proposed to result from a concurrent increase in IL-6 and TNF-α that resulted in increased TF expression (Kerr *et al*., 2003). Although TF activates the thrombin-generating pathways (see Section II.C.3), because of a simultaneous increase in thrombin-antithrombin (TAT) complexes the activity of thrombin is suppressed, effectively reducing the subsequent consumption of FVIII, FIX, and FXI (Kerr *et al*., 2003). In fact, FVIII levels were markedly elevated in acute liver failure, which can assist in the differentiation of acute hepatic failure from DIC, where FVIII levels would be decreased (Kerr *et al*., 2003; Senzolo *et al*., 2006). In contrast, prothrombin, FV, FVII, FIX, and FX were found to decrease in similar

proportions as a result of chronic liver failure (i.e. cirrhosis), suggesting decreased production (Kerr *et al*., 2003). FXI was more notably decreased than the other factors in chronic liver failure, and FVIII was increased in relation to the other factors but not in relation to normal patients (Kerr *et al*., 2003). The concurrent decreased production of anticoagulant factors may allow the liver to maintain its balance between procoagulant and anticoagulant systems, under stable conditions (Senzolo *et al*., 2006).

In some studies of coagulation testing in canine liver disease, up to 93% of subjects exhibit at least one coagulation test abnormality (Badylak *et al*., 1983). Reports of the relative frequency of these abnormalities vary, with some suggesting a higher frequency of prolonged aPTT (Badylak *et al*., 1983) and others reporting a higher frequency of prolonged OSPT (Badylak and Van Vleet, 1981; Toulza *et al*., 2006). In general, these routine coagulation tests lack specificity for any given hepatic disease (Badylak and Van Vleet, 1981). Evaluation of specific factor changes in hepatic disease has demonstrated trends that may provide more specificity (Badylak *et al*., 1983). For instance, similar to humans, decreased FIX, FX, and FXI activities have been demonstrated in canine cirrhosis (Badylak *et al*., 1983). Coagulation factor trends have also been identified in canine congenital portosystemic shunts (CPS). Presurgically there is a decrease in prothrombin, FV, FVII, and FX, with a concurrent increase in FVIII, and in the immediate postsurgical period, fibrinogen and FVIII, FIX, and FXI also decrease (Kummeling *et al*., 2006). In the canine studies, hemorrhagic complications were not observed; however, more intensive monitoring of potential bleeding sites in postoperative CPS patients has been recommended (Kummeling *et al*., 2006). In feline studies of naturally occurring hepatic disease, the frequency of abnormal coagulation tests varied from 60% to 82% (Center *et al*., 2000; Lisciandro *et al*., 1998). Abnormal PIVKA and OSPT results were the most frequent coagulation test abnormalities reported in each study, respectively, and vitamin K deficiency appeared to be the most common underlying pathogenesis of the abnormal coagulation tests (Center *et al*., 2000; Lisciandro *et al*., 1998). In the Center *et al*. study (2000), only 14% of the cats with liver disease (representing 23% of those with coagulation test abnormalities) demonstrated bleeding tendencies. All of the hemorrhagic signs were associated with clinical procedures (such as catheterization or venipuncture) rather than spontaneous episodes (Center *et al*., 2000). In the Lisciandro *et al*. study (1998), only 1 of 22 cats was reported to exhibit clinically relevant (and fatal) hemorrhage after a liver biopsy. This particular patient had coagulation abnormalities consistent with vitamin K deficiency (Lisciandro *et al*., 1998).

Various guidelines exist for prediction of bleeding based on diagnostic test results in human medicine and are discussed in Senzolo *et al*. (2006). At this time, formal guidelines have not been developed for domestic animals, and routine coagulation tests do not appear to consistently predict the risk of hemorrhage.

TABLE 10-8 Diseases and Disorders That Predispose to the Development of Disseminated Intravascular Coagulation

Condition	Etiology
Infectious disease/sepsis	Bacteria, protozoa, fungi, viruses
Neoplasia	Solid tumors, lympho- and myeloproliferative disease
Trauma	Tissue damage, burns, fat embolism
Organ damage/failure	Severe pancreatitis, liver failure
Toxic/Immunologic	Envenomation, transfusion reactions, immune-mediated disease

4. *Disseminated Intravascular Coagulation*

Disseminated intravascular coagulation (DIC) is a potentially life-threatening hemostatic complication of many serious clinical diseases and disorders (Levi, 2004). (See Table 10-8 for common precipitating causes in animals.) It is characterized by systemic activation of the clotting mechanism that leads to widespread deposition of fibrin in the vascular tree, to the point of potentially compromising blood flow to tissues and causing ischemic damage and even organ failure. Concurrently, platelet and clotting factor supply becomes depleted as a result of widespread thrombus formation, and subsequent hemorrhage may occur. Although it may seem paradoxical and complicates management, a patient with DIC can be presented with clinical signs of both thrombosis and bleeding simultaneously.

The pathogenesis of DIC varies with the underlying primary disease process, and much of the understanding of how the process develops comes from human and animal sepsis models. It appears that either a systemic inflammatory response or release of procoagulant materials into the vascular space can activate coagulation on a widespread basis (Levi, 2004). The simultaneous development of increased thrombin generation, suppressed anticoagulant mechanisms, impaired fibrinolysis, and activation of the inflammatory response provide all the factors necessary for the syndrome to occur (Franchini *et al*., 2006).

Cell membrane components of organisms (such as endotoxin and lipopolysaccharide) or bacterial exotoxins cause a generalized inflammatory response resulting in elaboration of proinflammatory cytokines that can activate endothelial cells directly (Slofstra, 2003). Excessive generation of

thrombin during endotoxemia appears to occur from activation of the TF pathway via FVIIa. Inhibition of this pathway resulted in complete absence of thrombin generation in experimental primate studies (Biemond *et al*., 1995; Pixley *et al*., 1993), and administration of TFPI completely abrogates this response (DeJonge *et al*., 2000). The source of TF may be from activated monocytes, other leukocytes, or altered endothelium (Levi, 2004). The role of neutrophils in the pathogenesis of DIC has been examined, and it appears they may interact with platelets and stimulate TF production and fibrin formation (Goel and Diamond, 2001). Neutrophil elastase also has the potential to degrade fibrinolytic proteases (Moir *et al*., 2002), thereby minimizing clot dissolution.

Additionally, the natural anticoagulant pathways may become inhibited, which would further amplify thrombin generation. AT activity can be markedly reduced because of consumption from enhanced thrombin generation, degradation by elastase released by neutrophils, and possibly decreased synthesis if liver synthetic function is impaired (Levi, 2005). The protein C system can similarly become exhausted by enhanced consumption, impaired hepatic synthesis, and down-regulation of TM expression on endothelial cells as part of the change from an antithrombotic to a prothrombotic milieu (Faust *et al*., 2001) (see Section II.A).

Fibrinolysis is impaired due to rapidly increased levels of PAI-1, which suppresses plasminogen activation, and therefore subsequently any clots that develop are not as efficiently degraded. Many of the hemostatic abnormalities that occur during DIC can be attributed to up-regulation of proinflammatory cytokines such as tumor necrosis factor alpha (TNF-alpha) and interleukin-1 (IL-1), which then promote a procoagulatory endothelial phenotype. It is also known that parts of the coagulation cascade, once activated, can also stimulate further activation of inflammation as well. For example, thrombin, via PARs on cell membranes, activates additional inflammatory mediators. So it is indeed a bidirectional process once either inflammation or coagulation is stimulated. Additionally, suppression of the protein C pathway may result in a proinflammatory state because it has anti-inflammatory properties (Yuksel *et al*., 2002). It must be emphasized that different disease states can result in DIC by a different mechanism. For example, some neoplastic cells may directly express TF or other procoagulant molecules (Rickles and Falanga, 2001), whereas DIC secondary to trauma or burns is related to systemic release of fat and phospholipids (Gando, 2001).

The diagnosis of DIC is based on clinical signs of the primary disease, as well as those associated with both hemorrhage and thrombosis, in conjunction with abnormal laboratory tests. Overt hemorrhage is often more prominent in animals with DIC, which may reflect the stage the syndrome is detected, or it may be that thrombosis is not detected readily antemortem. Because there is no single test that confirms the present of DIC, most often the diagnosis is made on a series of tests in an animal with an appropriate clinical context in which DIC can develop. Molecular markers of activation of coagulation or fibrin formation such as prothrombin fragment F1 + 2 and soluble fibrin concentration may be the most sensitive indicators of the presence of DIC, but they are poorly specific and not widely available (Levi, 2004).

The common laboratory test abnormalities include thrombocytopenia; presence of schistocytes on a blood smear; prolonged OSPT and aPTT; increased levels of indicators of fibrinolysis (FDPs, d-dimers); and decreased fibrinogen, AT, protein C, and coagulation factors. Some of these tests are more commonly altered than others, and serial measurements may sometimes be more helpful than a single sample. Fibrinogen concentration can sometimes actually be within the reference interval or even elevated as it is also an acute phase reactant in some species. Furthermore, although elevated products of fibrinolysis do occur during DIC, they can be increased in other disease states as well, which limits their specificity. The International Society on Thrombosis and Haemostasis (ISTH) has developed a scoring system to facilitate establishing the presence of DIC in human patients using a combination of results of different tests in a patient with a disease that can predispose to the condition and has a reported sensitivity and specificity of >90% (Bakhtiari *et al*., 2004).

DIC has been documented in many species of domestic animals (Bateman *et al*., 1999b; Dolente *et al*., 2002; Irmak and Turgut, 2005) but is most commonly reported in dogs. The most common precipitating diseases are listed in Table 10-8.

5. *Vitamin K Antagonism or Deficiency*

Anticoagulant rodenticides are the most common cause of acquired vitamin K-dependent factor deficiencies. Their action is through inhibition of the vitamin K epoxide reductase enzyme, preventing recycling of vitamin K and resulting in depletion of vitamin K_1H_2 (Murphy, 2002). The development of resistance, by rodents, to the first generation anticoagulant rodenticides (e.g., warfarin) necessitated the development of second-generation compounds (e.g., brodifacoum, bromadiolone) with more potent and persistent action (Boermans *et al*., 1991; Park and Leck, 1982). In experimental exposure to anticoagulant rodenticides, initial clinical signs generally include anorexia and somnolence, whereas clinical reports generally identify dyspnea, lethargy, and coughing/hemoptysis as the most frequent initial presenting complaints (Boermans *et al*., 1991; Forbes *et al*., 1973; Sheafor and Couto, 1999). Additional clinical signs can often include epistaxis, melena, lameness, spontaneous subcutaneous hematoma formation, hematuria, collapse, abdominal distension, and sudden death (DuVall *et al*., 1989; Sheafor and Couto, 1999). Case reports of rodenticide toxicity in neonates provide circumstantial evidence that rodenticides can cross the placenta and therefore should be

a consideration in neonatal hemorrhagic disorders (Munday and Thompson, 2003).

Although anticoagulant toxicity is most common in canine patients, accidental exposure can also occur in cats, horses, and ruminants. Ruminants have historically been thought more resistant to these rodenticides because of rumenal degradation of the compounds (Berny *et al*., 2006). It has recently been shown that there is no significant breakdown of the rodenticides in the rumen, and oral bioavailability of these compounds is excellent (79% for warfarin, 88% for bromadiolone) (Berny *et al*., 2006). Further, prolongation of the OSPT was observed for both compounds; however, no clinical signs of toxicosis were evident (Berny *et al*., 2006). A prolonged OSPT is generally the initial laboratory change in rodenticide toxicity because of the relatively short half-life of FVII (4 to 6 h). With subsequent decreases in FIX, FX, and prothrombin, a prolonged aPTT develops. Interestingly, experimental brodifacoum toxicity in the horse resulted in prolongation of the aPTT before the OSPT was affected (Boermans *et al*., 1991). As a result of this observation, it was proposed that clearance of vitamin K-dependent factors in the horse may differ from that in the dog and human (Boermans *et al*., 1991). The onset of laboratory changes and clinical signs varies with the amount and type of anticoagulant rodenticide consumed. In addition to changes in routine coagulation tests (OSPT and aPTT), the accumulation of the nonfunctional forms of the vitamin K-dependent coagulation proteins (PIVKA) can be detected by a commercial Thrombotest assay (see Section III.C).

In addition to anticoagulant rodenticides, ingestion of moldy sweet clover (dicumarol) can result in vitamin K-dependent coagulation factor deficiencies, acting through the same mechanism. However, clinical signs generally only develop after weeks of exposure (Berny *et al*., 2006). Ingestion of sulfaquinoxaline, a poultry coccidiostat, has also been reported to result in vitamin K-dependent factor deficiencies in dogs through inhibition of vitamin K epoxide reductase (Neer and Savant, 1992; Preusch *et al*., 1989).

6. *Thrombosis*

Pathological thrombus formation can occur in any vascular structure and, depending on the extent of obstruction and the tissue affected, can elicit a wide range and severity of clinical signs. Acute dyspnea and hemoptysis is observed with pulmonary thromboemboli, hematuria, and abdominal pain with renal thrombosis and pain and paresis or paralysis in with distal aortic thromboembolism in cats with cardiac disease.

Although not frequently easily detected clinically, predisposition to thrombosis can occur with many diseases in various domestic species. Most often, thrombosis is associated with an underlying disease process that causes a disturbance of hemostatic processes, particularly those that promote a hypercoagulable state. However, additional abnormalities including inappropriate platelet and endothelium activation may exist concurrently to exacerbate the situation (Darien, 2000a).

An example of a disease associated with a high risk for thromboembolic complications in dogs is immune-mediated hemolytic anemia (IMHA). Up to 50% of patients with this disease develop thrombi, often in the pulmonary system (Balch and Mackin, 2007). These dogs are frequently in a hypercoagulable state as a result of inflammatory cytokine activation of endothelial cells from red blood cell necrosis and hypoxia, vascular stasis from catheterization and immobility, and enhanced platelet activation (Weiss and Brazzell, 2006).

Other diseases associated with pathological thrombus development include endotoxemia, heartworm disease, hemangiosarcoma, hyperadrenocorticism, and various cardiac diseases (Darien, 2000a).

V. BEYOND HEMOSTASIS: INTERACTIONS WITH INFLAMMATION

It has become quite well documented that there is a continuum between the inflammatory response and the hemostatic system and that activation of one system up-regulates the other. Numerous recent reviews summarize this active research area (Esmon, 2005; Franchini *et al*., 2007; Gear and Camerini, 2003; Levi and van der Poll, 2005; Vincent, 2003; Zarbock *et al*., 2007).

Inflammatory mediators can increase platelet production, activate platelets, diminish endogenous anticoagulant activity, initiate and contribute to propagation of the coagulation cascade, increase fibrinogen concentration, and inhibit fibrinolysis (Esmon, 2005). Inversely, activation of the hemostatic mechanism can cause the release of inflammatory mediators from activated platelets and endothelial cells (Table 10-9). Traditional figurative depictions of either system rarely include elements of the other. More recently, however, appreciation for interactions between the two systems has become apparent. There are even some structural similarities between proteins in the two systems, which supports the theory of a parallel evolution (Esmon, 2005). Examples include protein S with C4 binding protein, endothelial cell protein C receptor with MHC class 1, and TM's similarity with lectins.

The release or enhanced expression of TF during inflammation is central to the widespread activation of coagulation observed during a systemic inflammatory response. It has been proposed that phospholipid-rich microparticles derived from leukocytes (especially monocytes) or endothelial cells express TF, and this facilitates further development of the thrombus via P-selectin-glycoprotein ligand-1 and P-selectin binding, which brings platelets and leukocytes into close approximation (Day *et al*., 2005). The role of TF in inflammation is further corroborated by

TABLE 10-9 Effects of Inflammation on Coagulation and Vice Versa

Inflammation—Coagulation	Coagulation—Inflammation
Increased fibrinogen—substrate for fibrin formation	Platelet granule release—CD40 ligand, which increases IL-6 and IL-8
Tissue factor expression on monocytes—procoagulant surface	Tissue factor—activates PARs, which facilitates leukocyte adhesion and activation
Increased C reactive protein—promotes PAI-1 and TF formation	Fibrin formation—increased TNF-α, IL-β, binding of neutrophils
Complement activation—increased procoagulant surface	Antithrombin—decreased expression of CD11b/CD18 on leukocytes
Interleukin-6—increased platelet production with increased reactivity	Antithrombin—inhibits chemokine-induced neutrophil migration
Histamine, TNF-α, IL-8, IL-6—release of high-molecular-weight vWF multimers	TAFI—inhibits bradykinin and C5a
Various inflammatory mediators—consume/inactivate antithrombin and heparin-like molecules	Thrombomodulin—inhibits leukocyte migration
Endotoxin, IL-1β, TNF-α, elastase—down-regulation of thrombomodulin and EPCR	Activated protein C—inhibits NF-κB in monocytes, decreased TF expression

Abbreviations: EPCR, *endothelial cell protein C receptor*; PAR, *protease activated receptor*; TAFI, *thrombin activatable fibrinolytic inhibitor*; TF, *tissue factor.*

the fact that inhibition of TF–FVIIa reduces inflammation in animal models of endotoxemia and in patients with sepsis (Monroe and Key, 2007)

As can be observed by looking at the mechanisms listed in Table 10-9, if the natural anticoagulant mechanisms do not occur, promotion of inflammation takes place. Therefore, in addition to traditional anti-inflammatory therapy, treatment with anticoagulants may also reduce inflammation. Of antithrombin, TFPI, and APC, only the latter actually reduced 28-day mortality in septic patients (Bernard *et al*., 2001).

I. INTRODUCTION

Pluripotential hematopoietic stem cells in the bone marrow differentiating in response to specific growth factors give rise to committed progenitors and then neutrophils. These cells are characterized by their multilobed nuclei and abundant granules in the cytoplasm (polymorphonuclear neutrophilic granulocytes). Except in disease states, only functionally mature neutrophils are released into the blood from the bone marrow, and these cells contain much of their effector molecules prepackaged in cytoplasmic granules or in the plasma membrane. Mature neutrophils do not multiply but instead are continuously replaced. Neutrophils circulate in the blood for only a few hours and survive in the tissue for only a few days; however, this can be extended by a day or two upon their exposure to various activating agents at sites of inflammation. In any case, neutrophils eventually succumb to programmed cell death by an intrinsic or extrinsic apoptotic pathway. Once neutrophils are recruited into the underlying tissue from the blood and encounter a microorganism, they phagocytize and kill the pathogen to eliminate the infection. This chapter provides an overview of the mechanisms of neutrophil adherence, chemotaxis, phagocytosis, and organism killing. It also discusses congenital and acquired defects in neutrophil function that predispose animals to infection. Finally, this chapter discusses neutrophil-mediated tissue injury.

II. NEUTROPHIL FUNCTIONS

A. Adherence and Chemoattractants

1. *Overview*

The recruitment of neutrophils to sites of tissue injury and infection is a hallmark of the acute inflammatory response. Efficient neutrophil extravasation at sites of inflammation requires a coordinated cascade of adhesive and signaling events. Neutrophils leave the flowing blood stream by first tethering and then rolling on the inflamed endothelium lining the blood vessel lumen. In the systemic circulation, this occurs primarily as neutrophils enter the venule from the capillaries (postcapillary venules) and in the collecting venules (Atherton, 1972; Schmid-Schonbein *et al.*, 1980). With the appropriate chemoattractants, rolling neutrophils will arrest (stop rolling) becoming firmly adherent to the endothelial surface and then migrate across the endothelium.

Estimates from *in vitro* studies of leukocyte extravasation show the process to be rapid, with transmigration being completed in <2 minutes (Beesley *et al.*, 1978; Burns *et al.*, 1997). Neutrophil transendothelial migration can occur through distinct routes, either paracellular (between endothelial cells) or transcellular (through endothelial cells) (Feng *et al.*, 1998; Yang *et al.*, 2005). Some of the first observations of leukocyte interactions with the vascular wall come from Albrecht von Haller (1756), Rudolf Virchow (1871), and Rudolf Wagner (1839). Early mechanistic insights into leukocyte transmigration came from Julius Conheim (1877, 1889) and Elle Metchnikoff (1893), who attributed leukocyte emigration to activities primarily by endothelial cells or leukocytes, respectively. Research since the 1980s has greatly enhanced our understanding of the molecular basis for the regulation of leukocyte interactions with the vascular endothelium at sites of inflammation. The following is a general overview of the various physiological parameters, adhesion molecules, and chemoattractants that play a critical role in neutrophil capture/rolling, activation, and arrest/locomotion.

2. Physiological Factors Contributing to Neutrophil Adherence

Neutrophil accumulation predominantly occurs along the vascular endothelium of venules as a result of several physiological factors. Neutrophil capture by the endothelium is enhanced by red blood cells, those lined up behind neutrophils as they leave the capillaries as well as by red blood cells occupying the center of the bloodstream, which force neutrophils toward the venular endothelium (Nobis *et al.*, 1985; Schmid-Schonbein *et al.*, 1980). Endothelial cells lining postcapillary venules in secondary lymphoid organs of humans and mice (high endothelial cell venules) bulge into the luminal space, thus increasing their collision with lymphocytes (Von Andrian, 1996). Though endothelial cells lining venules in nonlymphoid tissues tend to be flat, attached neutrophils at sites of inflammation appear to provide temporary extensions into the blood vessel lumen, causing collisions and capture of free-flowing neutrophils. This process is referred to as indirect or secondary capture (tethering) and was observed as early as 1955 when Allison and colleagues reported that "leukocytes were frequently seen to stick to one another, indicating that the increased adhesiveness characteristic of the inflammatory response is not limited to the endothelium" (Allison *et al.*, 1955). Indeed, neutrophils individually and as a monolayer facilitate indirect capture, and this appears to accelerate and sustain their accumulation (Bargatze *et al.*, 1994; Eriksson *et al.*, 2001; Sperandio *et al.*, 2003; St. Hill *et al.*, 2003; Walcheck *et al.*, 1996). In addition, because leukocyte accumulation on activated endothelium at sites of inflammation shows spatial variability (Kunkel *et al.*, 1998), indirect capture may be a mechanism for compacting (pavementing) leukocytes within discrete sites of activated endothelium, as illustrated in Figure 11-1.

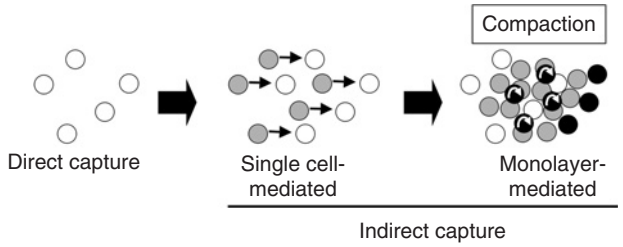

FIGURE 11-1 Indirect (2°) neutrophil capture increases their accumulation rate and density on the vascular endothelium. Direct neutrophil binding to the endothelium (e.g., via P-selectin) occurs randomly (open circles). Next, neutrophil-neutrophil interactions mediate two means of indirect capture. Individual attached neutrophils capture free-flowing neutrophils (gray circles) during initial neutrophil accumulation. In addition, a monolayer of attached neutrophils will capture free-flowing neutrophils, which roll across the neutrophil monolayer (black circles containing arrows) resulting in pavementing by the neutrophils and their compaction in discrete locations.

Neutrophils from the flowing blood that adhere to the vascular endothelium incur forces (wall shear stresses) that are affected by several factors, including blood flow velocity, vessel diameter, red blood cell concentration, and plasma viscosity. Shear stresses on adhered neutrophils in venules *in vivo* range between ~1 and 35 dynes/cm^2, assuming a cell-free, plasma viscosity of 1.1 centipoise (Damiano *et al.*, 1996). In general, leukocyte adhesion and rolling are reduced with increasing wall shear stress (Damiano *et al.*, 1996). The wall shear stress is generally lower in venules than in arterioles of equal size. These forces are balanced by the interaction of adhesion molecules on the leukocyte with those on the endothelium, which is discussed in more detail later.

3. Selectins

Selectins mediate the initial interactions between neutrophils and the endothelium resulting in their attachment and rolling at velocities considerably below that of cells in the flowing blood. The nature of cell adhesion mediated by selectins differs from that mediated by most other classes of adhesion molecules. Rapid on and off bonding events between selectins and their ligands cause leukocytes attached to the endothelium to roll under blood flow conditions (Fig. 11-2). There are three known selectins, each with a highly specific pattern of cellular expression. Forgoing the listing of all of their earlier more descriptive names, they are known today by single letters designating the cell type by which they were first identified. L-selectin (CD62L) is expressed by leukocytes, E-selectin (CD62E) expression is limited to endothelial cells, and P-selectin (CD62P) is expressed by platelets as well as endothelial cells.

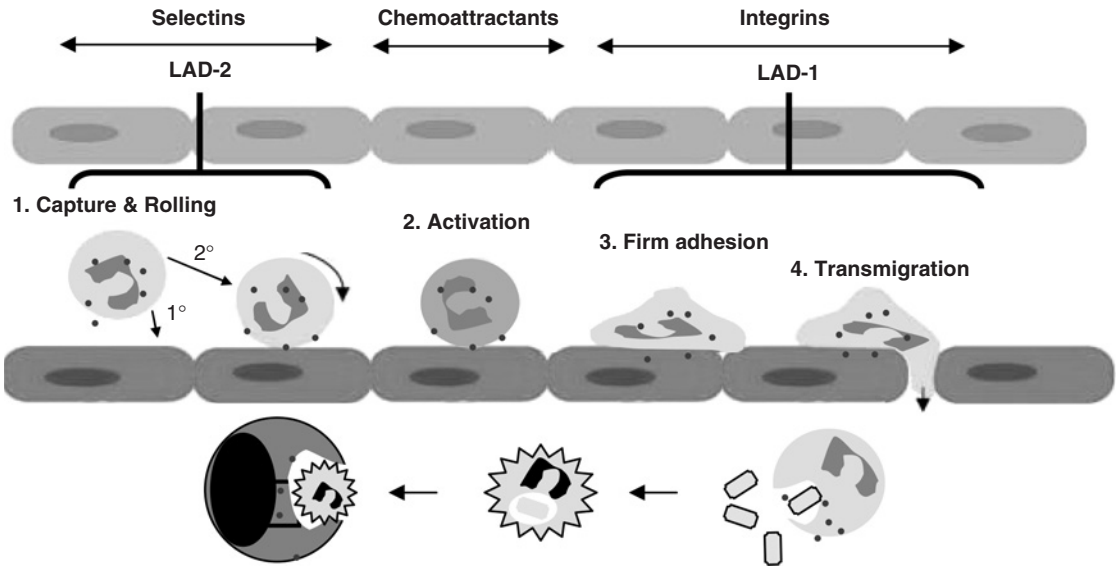

FIGURE 11-2 Multistep process of neutrophil effector functions. Neutrophils in flowing blood initially accumulate along the vascular endothelium by direct (1°) or indirect (2°) capture. The tethered neutrophils then roll and upon chemoattractant recognition become activated. This leads to firm adhesion and transendothelial cell migration. Upon entering the underlying tissues, neutrophils phagocytize bacterial pathogens, which induces their programmed cell death (apoptosis). Eventually, the apoptotic neutrophils are recognized and engulfed by macrophages to down-regulate the inflammatory response. Additionally, this figure depicts the site of classical leukocyte adhesion deficiency (LAD-1), a deficiency of CD18, and LAD-2, a defect in the selectin-mediated adhesion.

The selectins are type I integral membrane proteins composed of distinct tandem protein domains. At the amino-terminus is a C-type (Ca^{+2}-dependent) lectin domain. Following this is a single epidermal growth factor (EGF)-like domain, followed by a series of short-consensus-repeat (SCR) domains. Next are a transmembrane domain and a short cytoplasmic region. The genes for the selectins are arranged in tandem on chromosome 1 for both mouse and human, indicating that they arose by gene-duplication (Watson *et al.*, 1990). Selectin ligands are carbohydrate in nature, and the lectin domain of the selectins is responsible for ligand specificity and recognition (Weis *et al.*, 1998).

E-selectin expression is induced on most cultured endothelium as well as most postcapillary endothelium *in vivo* by a number of inflammatory mediators (Bevilacqua *et al.*, 1989). Induction of E-selectin by cytokines occurs exclusively at the transcriptional level. E-selectin mRNA is first detectable approximately 2 h after initial exposure of endothelial cells to cytokine. In cultured endothelium, E-selectin expression peaks in 4 to 8h, and subsequently declines even in the continued presence of the cytokine. *In vivo*, however, E-selectin can be chronically expressed at sites of inflammation, especially in the skin (Ley and Kansas, 2004).

P-selectin is expressed on both activated platelets and activated endothelium. Unlike E-selectin, P-selectin is expressed in the Weibel-Palade bodies of endothelial cells as well as the α-granules of platelets (Bonfanti *et al.*, 1989; McEver *et al.*, 1989). Exposure of either of these two cell types to various stimuli induces rapid (seconds to minutes) fusion of the P-selectin-containing granules with the outer membrane of the cell, exposing P-selectin at the cell surface. In the case of endothelial cells, histamine released from tissue mast cells in response to an inflammatory insult is one of the physiological inducers of rapid P-selectin expression. Interestingly, P-selectin-deficient mice have a defect in leukocyte rolling immediately following tissue exteriorization, as determined by intravital microscopy, and neutrophil recruitment into inflammatory lesions is delayed by about 2h (Mayadas *et al.*, 1993). In addition to its rapid surface expression, P-selectin is also transcriptionally induced (Weller *et al.*, 1992). Moreover, P-selectin can be chronically expressed at sites of long-standing inflammation, such as atherosclerotic vessels, rheumatoid arthritis, and psoriasis (Grober *et al.*, 1993; Johnson-Tidey *et al.*, 1994; Terajima *et al.*, 1998).

Neutrophils uniformly and constitutively express L-selectin. This selectin arguably plays the broadest and most significant role of the family members in neutrophil accumulation on the endothelium as it mediates both direct and indirect capture. In an assortment of inflammatory models, leukocyte accumulation along the microvasculature and recruitment into the tissue were greatly reduced ($\sim$60% to 85%) upon blocking L-selectin function with antibodies or in L-selectin-deficient mice (Davenpeck *et al.*, 1997;

Jung *et al.*, 1998; Kanwar *et al.*, 1999; Ley *et al.*, 1993; Tedder *et al.*, 1995; Von Andrian *et al.*, 1991, 1992, 1993).

Consistent with L-selectin's broad role in neutrophil recruitment, it is tightly regulated. For instance, neutrophils down-regulate L-selectin expression by ectodomain proteolysis (shedding) in a very efficient and rapid manner upon their stimulation by cytokines and chemoattractants (Alexander *et al.*, 2000; Kishimoto *et al.*, 1989; Rizoli *et al.*, 1999; Walcheck *et al.*, 1996). Studies performed *in vitro* and *in vivo* indicate that L-selectin shedding affects leukocyte adhesiveness and recruitment (Hafezi-Moghadam and Ley, 1999; Venturi *et al.*, 2003, Walcheck *et al.*, 1996). In addition, homeostatic L-selectin shedding maintains high levels of soluble L-selectin in the serum (~1 to 3 μg/ml) (Kishimoto *et al.*, 1995; Palecanda *et al.*, 1992), which is functional and can diminish leukocyte-endothelium interactions. Soluble L-selectin may thus serve as an adhesion buffer to suppress neutrophil accumulation below a certain inflammatory threshold. Interestingly, a reduced level of serum L-selectin correlates with susceptibility to inflammatory disease (Donnelly *et al.*, 1994; Seidelin *et al.*, 2002). TNF-α converting enzyme (TACE or ADAM17) appears to be a key sheddase of L-selectin upon overt cell activation.

The selectin family of adhesion proteins is highly selective lectins that recognize specific glycan structures displayed in most cases on an appropriate protein backbone. The main glycoprotein ligand for P-selectin on neutrophils is a homodimeric sialomucin designated PSGL-1 (P-selectin glycoprotein ligand-1) (Moore *et al.*, 1995; Sako *et al.*, 1993). PSGL-1 also serves as the primary ligand for L-selectin during leukocyte-leukocyte facilitated indirect neutrophil accumulation along the endothelium (Walcheck *et al.*, 1996). Importantly, specific posttranslational modifications of PSGL-1 are required for L- and P-selectin recognition. PSGL-l has a tyrosine sulfate motif at its amino-terminus, and mutational analyses have revealed that at least one of the three tyrosines in the motif must be sulfated for recognition (Pouyani and Seed, 1995; Sako *et al.*, 1995). In addition, a threonine residue just downstream from the tyrosine sulfate motif must be modified by sialylated, fucosylated oligosaccharides, such as a core 2 O-glycan terminated by sialyl Lewis X (sLe^X) (Leppanen *et al.*, 1999, 2003). PSGL-1 has also been reported to function as a ligand for E-selectin (Asa *et al.*, 1995; Sako *et al.*, 1993). However, leukocytes derived from PSGL-l knockout mice demonstrated no obvious defect in rolling on E-selectin (Yang *et al.*, 1999). Altogether, various studies suggest that PSGL-1 expression by neutrophils is not as critical for E-selectin binding as it is for L- and P-selectin. Indeed, other E-selectin ligands on neutrophils have been described, including E-selectin ligand-1 (ESL-1), glycolipids, and L-selectin (Alon *et al.*, 1995; Steegmaier *et al.*, 1995). In addition to recognizing its leukocyte ligand PSGL-1, L-selectin on neutrophils also mediates their direct accumulation on the endothelium, yet these endothelial ligands remain poorly characterized.

4. *Chemoattractants*

Chemoattractants are small soluble molecules that bind to receptors on leukocytes causing their stimulation, polarization, and locomotion, in part through the activation of the integrin adhesion molecules. Leukocyte locomotion toward higher concentrations of a chemoattractant is referred to as chemotaxis, and this can occur in a hierarchal manner. For instance, neutrophils become less sensitive to an initially encountered chemoattractant gradient, allowing them to then respond to a newly encountered chemoattractant (Foxman *et al.*, 1997, 1999). This process allows neutrophils to find their ultimate target through a complex stimulant environment. Different classes of chemoattractants include chemokines, lipid mediators, complement factors, and other peptides. The largest class of chemoattractants constitutes the chemokines, a superfamily of small, secreted proteins (8 to 10 kDa). The chemokines are structurally homologous and are subdivided into four subfamilies based on the position of conserved cysteine residues near the amino-terminus of the molecules (Rot and von Andrian, 2004). CXC chemokines (α-chemokines) are characterized by the presence of two cysteine residues that are separated by one amino acid, CC chemokines (β-chemokines) have two cysteine residues that are adjacent, C chemokines have one cysteine residue near the amino-terminus, and the CXXXC subfamily is characterized by cysteines being separated by three amino acids. The CC and CXC chemokines represent the largest of the chemokine families and contain many members. The C and CXXXC subfamilies together consist of three members at this time. The CXC chemokines can be further subdivided based on the presence or absence of a glutamatic acid-lysine-arginine (ELR) sequence preceding the CXC motif. This structural difference determines separate functional activities of chemokines in this subfamily. CXC chemokines that contain an ELR sequence (e.g., IL-8) are chemotactic for neutrophils, whereas non-ELR-containing CXC chemokines and CC chemokines appear not to be active on neutrophils (DeVries *et al.*, 1999). Chemokines induce leukocyte activation and locomotion by binding to specific G-protein-coupled cell surface receptors. Most chemokine receptors recognize more than one chemokine, and several chemokines can bind to more than one receptor. However, there is receptor-ligand specificity within chemokine subfamilies, with CXC chemokines binding exclusively to CXC receptors and CC chemokines binding to CC receptors (Rot and von Andrian, 2004).

5. *Integrins*

Integrins mediate neutrophil firm adhesion and locomotion by interacting with ligands on cells and in the extracellular

matrix with a dependence on divalent cations (Fig. 11-2). Integrins are noncovalent heterodimers (α and β subunits) of type I transmembrane glycoproteins, and are made up of various subfamilies that are organized around a particular subunit (Harris *et al.*, 2000). For instance, the β_2 (CD18) subfamily is expressed on all cells of hematopoietic origin and plays a critical role in neutrophil transendothelial cell migration (Simon and Green, 2005) and other key effector activities, such as phagocytosis and apoptosis (Mayadas and Cullere, 2005). CD18 integrins are present in an inactive state on circulating leukocytes; however, upon cell stimulation with various stimuli (e.g., chemoattractants) and ligand interactions, they undergo rapid affinity and valency changes required for optimal integrin function (Carman and Springer, 2003). There are four known α (CD11) subunits that can combine with the CD18 subunit to form unique receptors. The α subunits are defined, in part, as CD11a, b, c, and d. The α and β subunits are expressed from different genes and can be independently expressed on different cell types.

CD11a/CD18 ($\alpha_L\beta_2$ or lymphocyte function-associated antigen [LFA-1]) is the most broadly expressed leukocyte integrin. It is expressed on early hematopoietic progenitor cells and on all mature leukocytes. LFA-1 interacts with cell surface ligands known as intercellular adhesion molecules (ICAMs). ICAMs are type I transmembrane glycoproteins and belong to the immunoglobulin superfamily (Kishimoto and Rothlein, 1994). ICAM-l is expressed on resting endothelium and is induced on many cell types by inflammatory cytokines. LFA-1 also binds to ICAM-2 or ICAM-3, which are mainly expressed on endothelial cells and leukocytes, respectively. ICAM-l is a more active LFA-l ligand than ICAM-2 or ICAM-3.

CD11b/CD18 ($\alpha_M\beta_2$ or Mac-1) is constitutively expressed by neutrophils, monocytes, and macrophages. Mac-l is stored in endosome-like vesicles in neutrophils that are translocated to the surface following certain types of activation, allowing increased Mac-l surface expression (Borregaard *et al.*, 1987). Mac-1, like LFA-l, is less active on resting cells than activated cells. Mac-l also interacts with ICAM-l, but at a site distinct from LFA-l (Diamond *et al.*, 1991). Both of these CD18 subfamily members function as the primary integrins that mediate arrest and transmigration at sites of inflammation. Mac-1 interacts with a wider variety of ligands compared to LFA-l, including fibronectin, fibrinogen, vitronectin, laminin, collagen, ICAM-2, albumin, myeloperoxidase, kininogen, elastase, heparin, and zymosan (Kishimoto and Rothlein, 1994; Simon and Green, 2005). Mac-l also participates in a number of adhesion reactions where the nature of the ligand is not known, such as adhesion of neutrophils to plastic or glass surfaces and binding to a variety of denatured proteins, suggesting a scavenger receptor-like function. Of particular importance is that Mac-1, also referred to as complement receptor 3, binds to C3bi. This complement fragment bonds to surfaces when triggered by immunoglobulin or microbial surfaces, and particles coated with C3bi (opsonization) are readily phagocytized by neutrophils (Mayadas and Cullere, 2005).

CD11c/CD18 ($\alpha_X\beta_2$ or P150,95) is highly homologous to Mac-1, but it is expressed at lower levels on neutrophils and not nearly as well studied. Like Mac-1, CD11c/CD18 binds to some of the same ligands, including C3bi as well as binding to many pathogens directly to promote their phagocytosis, fibrinogen, and a variety of denatured proteins (Kishimoto and Rothlein, 1994; Mayadas and Cullere, 2005).

CD11d/CD18 ($\alpha_D\beta_2$) is the most recently defined member of the leukocyte integrin family and is expressed on tissue macrophages, dendritic cells, and eosinophils and binds to ICAM-3 and vascular cell adhesion molecule-l (VCAM-l) (Danilenko *et al.*, 1995; Grayson *et al.*, 1998; Van der Vieren *et al.*, 1995). The later binding interaction may contribute to recruitment of eosinophils to inflamed airways.

6. *Leukocyte Adhesion Deficiency*

Leukocyte adhesion deficiency (LAD) syndromes (LAD-1, LAD-1 variants, and LAD-2) result in immunodeficiency disorders caused by an impaired extravasation of neutrophils into sites of inflammation because of dysfunctional selectin- or integrin-mediated adhesion events (Fig. 11-2). The LAD syndromes are relatively uncommon; however, the clinical consequences are often severe and lethal and include recurrent or unresolved localized infections, systemic sepsis, and impaired wound surveillance and repair.

Classical leukocyte adhesion deficiency type I (LAD-1) is an autosomal recessive disorder arising from germline mutations in the gene encoding CD18 and thus affects all CD18 subfamilies. LAD-1 has been described in humans, Holstein cattle, and dogs (Anderson and Springer, 1987; Gu *et al.*, 2004; Nagahata, 2004). In humans, the CD18-integrin subunit is either not synthesized or unable to associate with the respective CD11 subunits, and the resulting LAD can be characterized as severe to moderate. Children with severe deficiency typically display less than 1% of normal levels of CD11/CD18, and children with moderate deficiency typically express 5% to 10% of normal levels of the integrin.

Bovine leukocyte adhesion deficiency (BLAD) has been extensively investigated (Nagahata, 2004; Shuster *et al.*, 1992). The molecular basis of BLAD is a single point mutation that results in an aspartic acid to glycine substitution at amino acid 128 of the CD18 polypeptide. Interestingly, expression of L-selectin on neutrophils from BLAD calves appears to be reduced as well. Neutrophil adhesion is markedly impaired and chemotactic responses are diminished. The hallmark clinical findings in BLAD include recurrent or chronic diarrhea, chronic pneumonia, ulcerative stomatitis, gingivitis, chronic dermatitis, stunted growth, and impaired wound healing. Persistent and severe neutrophilia is the most prominent hematological finding; however, neutrophil morphology is normal. Pathological lesions are primarily located in the lungs and intestinal tract. Neutrophils

are present within the lung lesions but not within intestinal ulcers or lesions in other tissues. Therefore, neutrophils can enter the lung by integrin-independent processes (Ackermann *et al.*, 1996).

Canine leukocyte adhesion deficiency (CLAD) occurs in Irish setter and Irish setter-cross-bred dogs (Giger *et al.*, 1987; Gu *et al.*, 2004; Kijas *et al.*, 1999; Renshaw *et al.*, 1975). As with BLAD, the molecular basis of CLAD is due to a single point mutation; however, in the dog, a cysteine at amino acid 36 is substituted for a serine. This cysteine is a highly conserved residue in the extracellular domain of CD18, and the structural defect from the mutation results in the failure to express the CD11/CD18 complex on the leukocyte surface. Affected dogs develop severe bacterial infections shortly after birth and usually die or are euthanized.

More recently, variant forms of LAD-1 have been reported in humans in which CD18 integrins are expressed on the surface of leukocytes at normal levels but fail to support their adhesion (Wehrle-Haller and Imhof, 2003). In one case, LAD-1 was caused by a point mutation in the β_2-integrin, rendering it nonresponsive to inside-out activation of leukocytes (Hogg *et al.*, 1999). In other cases, the leukocyte adhesion deficiency was extended to various integrin families as well, including β_1-, β_2-, and β_3-integrin function. Interestingly, these latter cases result from a failure by intracellular factor(s) or signaling pathway(s) essential for integrin activation/clustering. Under physiological shear stress, these LAD-affected leukocytes are unable to generate firm adhesion and arrest.

Another human adhesion deficiency (LAD-2) was first described in 1992 in two children of Arab origin (Etzioni *et al.*, 1992). LAD-2 is a rare congenital disease resulting in mutations in a GDP-fucose transporter and a generalized fucosylation defect that affects α1,2-, α1,3-, α1,4-, and α1,6-linkages of fucose in glycoproteins and glycolipids (Wild *et al.*, 2002). Among other effects, LAD-2 neutrophils demonstrate strongly reduced sLe^X expression, which diminishes their adhesivity with the selectin family members and their accumulation on endothelium (Fig. 11-2). Thus, this disorder disrupts leukocyte extravasation at an earlier stage than LAD-1.

B. Phagocytosis

The process of phagocytosis has been extensively studied in macrophages but less well studied in neutrophils. Therefore, we will present a general overview of phagocytosis based on knowledge gained primarily from macrophages. Phagocytic cells ingest bacteria and other particulate material by receptor-mediated phagocytosis (Peyron *et al.*, 2001; Stossel, 1974). This process forms a vesicle around the organism and internalizes it (Fig. 11-3). After internalization, the vesicle containing the organism undergoes a stepwise process of maturation in which the vesicle fuses with early

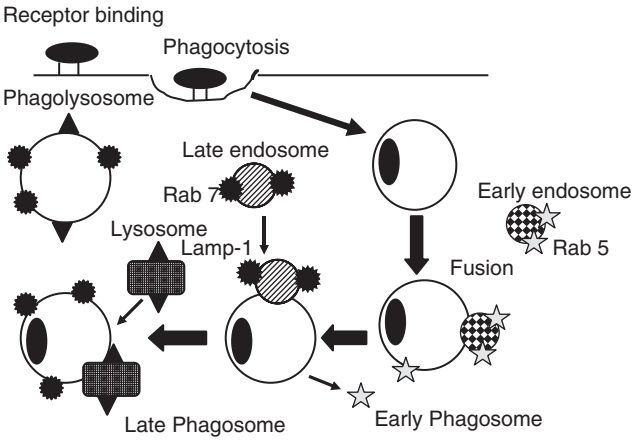

FIGURE 11-3 Receptor-mediated phagocytosis of organisms by leukocytes. After binding of organisms to cell membrane receptors, organisms are endocytosed into a phagosome. After fusion with early endosomes, the early phagosome is characterized by the presence of Rab5. Acidification of the phagosome occurs at this stage. Thereafter, fusion with late endosomes results in acquisition of Rab7 and shedding of Rab5. The late phagosome then fuses with lysosomes, forming the phagolysosome that is characterized by the presence of Rab7 and Lamp-1.

and late endosomes and lysosomes to create a phagolysosome. Within the phagolysosome, lysosomal enzymes and reactive oxygen radicals digest organisms. The process of phagolysosome fusion and organism killing is complex, and the details are still being investigated. Fusion of early endosomes coincides with initiation of vesicle acidification. This phase is marked by the presence of high levels of the GTP-binding protein Rab5 on the phagosome membrane. It is not clear whether Rab5 is brought to phagosome by the early endosome or is acquired from the cytoplasm (Via *et al.*, 1997). Fusion of the phagosome with late endosomes is marked by acquisition of Rab7 and loss of Rab5. Subsequent fusion of lysosomes to the late phagosome is characterized by acquisition of lysosome-associated membrane protein (LAMP)-1 and LAMP-2.

Neutrophils contain primary, secondary, and, in some species, tertiary granules in addition to lysosomes (Stossel, 1974). Primary granules contain oxygen-dependent killing mechanisms and a variety of cationic proteins and bactericidal/permeability-increasing (BPI) protein (Klebanoff and Clark, 1978). Secondary granules contain most of the lysozyme and lactoferrin. Secondary granules appear to fuse first followed by primary granules (Klebanoff and Clark, 1978).

Phagosome-to-endosome fusion is a highly controlled process. The fusion system is typically composed of specific receptor-mediated processes. An ATPase N-ethyl-maleimide-sensitive factor (NSF) and α soluble NSF attachment protein (αSNAP) interact with vesicle and target integral membrane SNAP receptors (v- and t-SNAREs) that serve as docking and fusion devices (Vieira *et al.*, 2002). v- and t-SNAREs form complexes spontaneously, and NSF and SNAP provide the energy necessary to separate

the v- and t-SNAREs. When separated, SNAREs from apposed membranes are paired resulting in fusion of the lipid bilayers. However, fusion occurs in a highly controlled manner being regulated primarily by an Src family of RAB GTPases (Peyron *et al.*, 2001).

Phagolysosome fusion is a critical event in killing of pathogenic organisms. Defective phagolysosome fusion occurs in Chediak-Higashi syndrome. Chediak-Higashi syndrome has been described in several breeds of cattle, Persian cats, foxes, mink, and a killer whale (Ayers *et al.*, 1988; Colgan *et al.*, 1992). Humans and animals have partial oculocutaneous albinism, frequent infections, and mild bleeding diatheses. Neutrophils, monocytes, and melanocytes contain giant granules that result of abnormal fusion events that appear to be due to defects in lysosomal docking proteins. Granule membrane fusion is defective and discharge of granule contents into the phagosome is delayed (Mills and Noya, 1993).

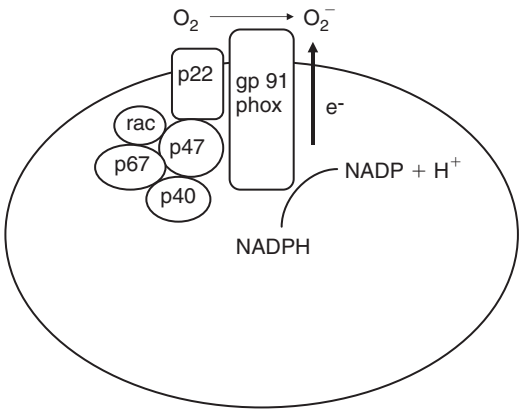

FIGURE 11-4 The NADPH oxidase complex consists of a membrane-bound flavocytochrome b_{558} consisting of two subunits (22 and 91kDa) and three cytosolic molecules (p40, p47, and p67). The assembly of NADPH and electron flow are dependent on three GTP-binding proteins (Rac).

C. Bactericidal Mechanisms

The mature phagolysosome has multiple mechanisms to kill microorganisms. These have generally been divided into oxygen-dependent and oxygen-independent mechanisms (Klebanoff, 1975).

1. *Oxygen-Dependent Mechanisms*

Oxygen-dependent mechanisms are located within primary granules (Babior, 1984; Babior *et al.*, 2002). These mechanisms are initiated by the process of phagocytosis or by perturbation of the cell membrane. A membrane-bound nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase consists of five essential protein components; two of these are in the membrane and three are in the cytosol (Fig. 11-4). The membrane-associated component is a flavocytochrome b_{558} that consists of a heterodimer composed of 91 ($gp91^{phox}$) and 22 ($gp22^{phox}$) kDa proteins. Flavocytochrome b_{558} is distributed in the cell membrane and in the membrane of the granules and is incorporated into the wall of phagocytic vacuoles. The cytosolic components consist of a 40-kDa protein (p40-*phox*), a 47-kDa protein (p47-*phox*) and a 67-kDa component (p67-*phox*). When stimulated, the cytosolic components are translocated to the membrane. Both the assembly of the NADPH oxidase complex and the electron flow are dependent on the influence of three GTP-binding proteins; Rac1, Rac2, and Rap1A. The NADPH oxidase complex catalyzes the reduction of molecular oxygen to superoxide anion ($NADPH + O_2 \rightarrow NADP^+ + H^+ + O_2^-$). The associated rapid consumption of oxygen has been termed the "respiratory burst." Superoxide anions are rapidly dismutated to hydrogen peroxide (H_2O_2). Superoxide anions also can be converted to hydroxyl radicals ($OH^\cdot$) in the presence of catalytic metals such as iron according to the Haber-Weiss reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH^\cdot + O_2$). Myeloperoxidase catalyzes the conversion of H_2O_2 and halide ions to hypohalous acids with hypochlorous acid being the primary acid produced. Finally H_2O_2 interacts with hypohalous acids to produce singlet oxygen ($^1O_2$). Singlet oxygen is a high-energy form of oxygen that can attack double bonds. These reactive oxygen intermediates interact with unsaturated lipids, carbon bonds, sulfhydryl and amino groups, nucleic acids, pyrimidine nucleotides, and enzymes within organisms. The extent to which these events contribute directly to disruption of organism function and organism killing is controversial (Segal, 2005; this subject is discussed in more detail in the next section). Myeloperoxidase is not essential for antimicrobial activity because humans with myeloperoxidase deficiency do not have severe bacterial infections. Additionally chicken heterophils lack myeloperoxidase.

Products of the respiratory burst are toxic to cells as well as to invading organisms. A variety of antioxidant systems exist to protect cells from the harmful effect of these oxidants (VanSteenhouse, 1987). These systems include cytosolic superoxide dismutase, glutathione peroxidase, glutathione reductase, and catalase, all of which convert oxygen radicals to water. Other compounds with oxygen radical scavenging potential including vitamin E, vitamin C, selenium, transferrin, and cysteine (VanSteenhouse, 1987). The glutathione needed for the reaction is maintained in the reduced state by reduced NADPH that is supplied by the hexose monophosphate pathway.

Several defects in the capacity of neutrophils to generate oxygen radicals have been described. These include chronic granulomatous disease, glutathione peroxidase deficiency, glucose-6-phosphatase deficiency, and myeloperoxidase deficiency (Malech and Nauseef, 1997).

Chronic granulomatous disease is caused by mutations in genes encoding components of NADPH oxidase. In excess of 40 specific mutations have been reported in human

patients (Cross *et al.*, 2000). Chronic granulomatous disease is characterized by recurrent severe, but usually not fatal, bacterial and fungal infections beginning in early childhood (Malech and Nauseef, 1997). Neutrophils have an inability to mount a respiratory burst because of an inability to activate the NADPH oxidase system. A neutrophil bactericidal dysfunction with decreased capacity to mount a respiratory burst has been described in eight closely related Doberman pinschers (Breitschwerdt *et al.*, 1987). However, the defect in oxygen radical generation was not as severe as in humans, and it is not clear if the defect is in NADPH or in another pathway such as myeloperoxidase deficiency.

Glutathione peroxidase deficiency is clinically similar to chronic granulomatous disease (Malech and Nauseef, 1997). The defects appear to result from a failure of the hexose monophosphate pump to generate NADPH. Impaired neutrophil bactericidal activity is also found in selenium-deficient cats and cattle and in copper-deficient cattle. Because selenium is required for glutathione metabolism, selenium deficiency probably causes a defect in the oxygen-dependent pathway of bacterial killing (Serfass and Ganther, 1975).

Myeloperoxidase deficiency has also been documented as the most common of the inherited neutrophil defects in humans (Malech and Nauseef, 1997). However, the condition produces few clinical signs. The number of individuals that develop severe infections is small. Although killing of bacterial organisms is delayed, killing is eventually complete. Myeloperoxidase deficiency has been described in cyclic hematopoiesis of gray collie dogs. Affected dogs have defective bactericidal activity. These dogs have an insertion of an adenine nucleotide in AP3B1 leading to a frame shift with premature termination (Horwitz *et al.*, 2004). This is equivalent to the mutation in Hermansky-Pudlak syndrome type II in humans but is unlike the ELA2 mutation seen in cyclic neutropenia in humans.

Abnormal neutrophil chemiluminescence responses have been described in a group of Weimaraner pups with recurrent fevers, diarrhea, pneumonia, pyoderma, lymphadenopathy, stomatitis, and osteomyelitis (Couto *et al.*, 1989). Decreased chemiluminescence in response to phorbol esters was the major neutrophil function alteration noted in these dogs. Defects in humoral or cellular immune responses were not detected.

2. *Oxygen-Independent Mechanisms*

Nonoxidative mechanisms may be more important in killing of microorganisms than previously suspected. Some investigators hypothesize that the major role of the NADPH oxidase system is to adjust phagosomal pH and to pump electrons into the phagocytic vacuole (Roos *et al.*, 2003; Segal, 2005). This movement of ions across the phagosome membrane produces conditions that are conducive to oxygen-independent organism killing. For example, the initiation of superoxide production is accompanied by phagosomal alkalinization because of the proton-acceptor function of the superoxide anion. This pH change may be essential for activation of enzymes within the phagolysosome. Additionally, $gp91^{phox}$ of NADPH oxidase functions as a proton channel. This proton pump appears to play a critical role in shuttling hydrogen ion and several other ions across the cell and phagosomal membranes (Geiszt *et al.*, 2001). An influx of potassium appears to be important in liberating proteases such as elastase and cathepsins from their acidic proteoglycan matrix within granules. NADPH oxidase also is thought to induce depolarization that inhibits calcium influx into neutrophils.

Neutrophil-independent bacterial killing mechanisms are present within primary, secondary, and tertiary granules and lysosomes (Klebanoff and Clark, 1978). The primary granules contain a variety of cationic proteins including defensins, cathepsin G, azurocidin, and BPI protein. Primary granules also contain hydrolases including collagenase, elastase, β-glucuronidase, and lysozyme. The secondary granules contain much of the lysozyme, lactoferrin, adhesin, and chemotactic receptors, and gelatinase. A third type of granule has been identified in humans, cows, sheep, goats, horses, dogs, and rabbits (Bertram, 1985). In some species these granules contain gelatinase and some acid hydrolases. However, tertiary granules of bovine neutrophils appear to be distinct in that they contain a potent antimicrobial system (Gennaro *et al.*, 1983).

Defensins are a family of low-molecular-weight, antimicrobial peptides that have been isolated from neutrophils and heterophils of humans, rats, guinea pigs, and rabbits (Evans and Harmon, 1995). They contain six invariant cysteine residues and are arginine rich. The cysteine residues form disulfide bonds, and pairing of the first and sixth residues creates a cyclic structure. Similar peptides have been isolated from bovine and equine neutrophils and from chicken heterophils. These defensin-like peptides have a broad spectrum of antimicrobial activity being active against both Gram-positive and Gram-negative bacteria, as well as some fungi, enveloped viruses, protozoa, and cells.

Cathepsin G is rich in cysteine and has microbicidal activity against Gram-positive and Gram-negative bacteria as well as some fungal organisms. Cathepsin G inhibits bacterial respiration and energy-dependent transport systems, as well as protein, DNA, and RNA biosynthesis.

BPI is a large, lysine-rich protein that is highly active against *E. coli* and *Salmonella typhimurium* (Weiss *et al.*, 1978). However, it lacks antimicrobial activity against Gram-positive bacteria and fungi. BPI appears to bind to the outer membrane of susceptible Gram-negative bacteria and increases membrane permeability to hydrophobic molecules. BPI also activates enzymes that degrade envelope phospholipids and peptidoglycans. Neutrophils from neonatal children were reported to have three- to four-fold less BPI per neutrophil compared to adults. This correlated with a decreased antibacterial activity against *E. coli*

(Levy *et al.*, 1999). This selective deficiency of BPI may explain the increased incidence of Gram-negative sepsis among newborns.

Granulocytes also contain a variety of proteases and acid hydrolases, the most notable of which are cathepsin G, elastase, collagenase, lysozyme, acid phosphatase, aryl sulfatase, neuramidase, and nuclease. Elastase degrades bacterial cell wall proteins and potentiates the lytic activity of lysozyme and the microbicidal activity of cathepsin G. Lysozyme is a cationic protein that hydrolyzes bacterial cell walls by attacking the β1-4 glycosidic linkage that joins N-acetyl muramic acid and N-acetyl glucosamine of peptidoglycan. Although a wide variety of bacteria are sensitive to the action of lysozyme, group A *Streptococcus*, *Staphylococcus*, and most Gram-negative organisms resist the action of lysozyme.

Lactoferrin has bacteriostatic activity that is associated with its capacity to sequester iron. However, lactoferrin also exerts a bactericidal effect independent of its bacteriostatic effects (Lehrer and Ganz, 1990).

Few deficiencies of oxygen-independent mechanisms have been described. A specific granule deficiency has been described in humans in which specific granules lack lactoferrin, vitamin B_{12} binding protein, and defensins (Gallin, 1985). Affected individuals have recurrent severe bacterial infections. Neutrophils have small, elongated granules that appear late in maturation.

D. Neutrophil-Mediated Amplification of Inflammation

Neutrophils secrete a variety of proinflammatory mediators that amplify the inflammatory process. These include leukotrienes, prostaglandins, cytokines, and chemokines.

1. *Prostaglandins and Leukotrienes*

Arachidonic acid and other C20 polyunsaturated fatty acids containing four and five carbon-carbon double bonds are the immediate precursors of prostaglandins and leukotrienes. They are released from phospholipids by the action of phospholipase A, phospholipase C, and diacylglycerol lipase. Among the leukocytes, macrophages appear to be the major producers of prostaglandins, whereas neutrophils, monocytes, macrophages, eosinophils, and mast cells are major producers of leukotrienes (Lewis and Austen, 1984). Leukotriene (LTB) synthesis begins when 5-lipoxygenase catalyzes the production of 5-monohydroperoxy-eicosatetraenoic acid (5-HPETE) from arachidonic acid. 5-HPETE is converted to 5-hydroxyeicosatetraenoic acid (5-HETE). In addition, 5-lipoxygenase converts 5-HPETE to LTA_4. Separate pathways synthesize LTB_4 and sulfidopeptide leukotrienes (LTC_4, LTD_4, LTE_4). Neutrophils synthesize mostly LTB_4 (Lewis and Austen, 1984). LTB_4 has both priming and direct activating effects on neutrophils. It is a potent chemotactic and chemokinetic agent for neutrophils, monocytes, and eosinophils. It also stimulates neutrophil aggregation, superoxide production, and integrin expression.

2. *Cytokines and Chemokines*

Neutrophils secrete a broad spectrum of cytokines. Most of these are involved in the innate immune response, however, neutrophils also secrete cytokines that affect adaptive immunity (Petrofsky and Bermudez, 1999; Tacchini-Cottier *et al.*, 2000). Activated neutrophils release a variety of proinflammatory cytokines including tumor necrosis factor-α (TNF-α), IL-1β, and IL-6. At sites of inflammation, release of these cytokines amplifies the inflammatory process. Neutrophils also produce interferon-γ (IFN-γ), IL-12, and transforming growth factor-β (TGF-β), known to affect adaptive immunity. Several studies indicate that neutrophils may modulate the adaptive immune response to infectious agents. For example, in a mouse model of leishmaniasis, depletion of neutrophils 6 h before infection prevented the early Th2-type immune response suggesting a role of neutrophils in initiating this response (Tacchini-Cottier *et al.*, 2000).

Neutrophils also have cell surface receptors for many cytokines. These include TNF-α, IL-1, IL-4, IL-6, IL-8, IL-10, G-CSF, and GM-CSF (Lapinet *et al.*, 2000; Lavkan *et al.*, 1998; Skoutelis *et al.*, 2000). Although most of these cytokines activate neutrophils, IL-4 and IL-10 are potent inhibitors of neutrophil function (Lapinet *et al.*, 2000).

Neutrophils secrete both CC and CXC chemokines (Lapinet *et al.*, 2000). CC chemokines include macrophage inflammatory protein-1α (MIP-1α) and MIP-1β. CXC chemokines include IL-8 and IFN-γ-inducible protein-10. Therefore, neutrophils at a site of inflammation amplify the inflammatory response by attracting more inflammatory cells to the site.

III. VIRULENCE FACTORS PREVENTING NEUTROPHIL-MEDIATED KILLING

Many pathogenic organisms have developed the capacity to evade killing by neutrophils and macrophages. Each pathogen has developed its own group of evasion tactics that provide a competitive advantage for survival and growth (Allen, 2003; Mayer-Scholl *et al.*, 2004).

Staphylococcus aureus is resistant to neutrophil phagocytosis. This is largely due to the capsule. A slime layer is composed of capsular polysaccharide. Like other Gram-positive bacteria, *S. aureus* is resistant to defensins, probably as a result of the composition of the cell wall.

Anaplasma phagocytophilum survives and replicates within neutrophils. The organism has the capacity to block

oxygen radical generation. Although the mechanism of this suppression is unknown, both the membrane-bound and cytoplasmic components of NADPH oxidase appear to be down-regulated in infected neutrophils.

Yersinia enterocolitica blocks phagocytosis by neutrophils and macrophages. Tight binding of the organism to cell membrane receptors of these cells causes a local decrease in extracellular calcium that results in uptake of TTSS and Yop proteins from the organism into the cytosol. Yop H is a tyrosine phosphatase that targets SH2 domains and prevents increases in intracellular calcium necessary for phagocytosis and degranulation. Mutant bacteria lacking Yop H are rapidly phagocytized and cleared by phagocytes.

Salmonella spp. have several virulence factors (Roos *et al.*, 2003). Spi-1 encodes proteins that are secreted into cells and modulate the actin cytoskeleton. This leads to uptake of the organism into a membrane-bound vacuole within the cell. Once in the target cell, the Spi-2 gene cluster promotes bacterial survival. These proteins interfere with formation of the NADPH oxidase complex thus reducing the generation of oxygen radicals.

Shigella invade the colonic mucosa and are engulfed by macrophages and epithelial cells. *Shigella* contain virulence factors IpaB and IpaC that enable them to escape from phagosomes of both macrophages and epithelial cells. However, elastase within neutrophils selectively degrades IpaB and IpaC, which prevents escape of the organism from the phagosome and facilitates organism killing.

Mycobacteria enhance their survival within phagocytes primarily by inhibiting fusion of late endosomes and lysosomes with the phagosome (Peyron *et al.*, 2001). As a result, phagosomes fail to obtain markers of maturation including Rab7, LAMP-1, and LAMP-2 (Fig. 11-3). This process has been most studied in macrophages. Mechanisms responsible for the arrest of phagosome maturation are complex and involve both host and organism factors. Coronin 1, also termed tryptophan-aspartate-containing coat protein (TACO), has been identified as being involved. Coronin 1 is a member of a family of proteins involved in actin-cytoskeletal remodeling and phagocytosis as well as other cell functions. In murine macrophages, coronin 1 is retained on the phagosomes of macrophages infected with live mycobacteria, whereas it rapidly dissociates from phagosomal membranes of dead mycobacteria (Tailleux *et al.*, 2003). Mycobacteria appear to be able to arrest phagosome maturation by depleting the phosphatidylinositol 3-phosphate (PI3P) content within the phagosomal membrane (Hmama *et al.*, 2004). PI3P is synthesized in early endosome and phagosome membranes and functions as a membrane-trafficking regulatory lipid essential for phagolysosome biosynthesis. This effect may be mediated by glycosylated phosphatidylinositol lipoarabinomannan derived from the cell wall of pathogenic mycobacterial organisms (Hmama *et al.*, 2004).

IV. ACQUIRED NEUTROPHIL FUNCTION DEFECTS

A. Neutrophil Dysfunction in Periparturient Dairy Cattle

Numerous studies have documented neutrophil dysfunction in periparturient dairy cattle. Significantly decreased random migration, iodination, and chemiluminescence of neutrophils were observed 1 week after parturition (Kehrli *et al.*, 1989). In another study, a decrease in neutrophils oxidative burst activity was observed 1 to 3 weeks after calving (Dosogne *et al.*, 1999). This was related to a pregnancy-associated glycoprotein in the blood.

The cause of periparturient neutrophil dysfunction is incompletely understood. Selenium concentrations in periparturient cattle may be a significant factor in predicting neutrophil function. Neutrophils from postparturient dairy cows with relatively high blood selenium concentrations had greater superoxide production and greater potential to kill bacteria when compared to cows with relatively low selenium concentrations (Cebra *et al.*, 2003). Excessive glucocorticoid production may also be involved in the neutrophil dysfunction. In a study in which microarrays and real-time RT-PCR techniques were used to study neutrophils from periparturient and glucocorticoid-treated cattle, similar functional alterations were observed (Burton *et al.*, 2005).

Altered neutrophil function and recruitment to the mammary gland have been incriminated as a factor in the increased incidence of mastitis during the periparturient period (Kehrli *et al.*, 1989; Paape *et al.*, 2003). In general, milk neutrophils are less effective than blood neutrophils in phagocytizing and killing bacteria (Paape *et al.*, 2003). This has been attributed to the lower energy reserve of milk neutrophils and phagocytosis of milk fat globules and casein. Lysosomes fuse with phagosomes containing milk-fat globules and casein thus reducing the number available to fuse with phagosomes containing bacteria. Milk has been reported to reduce the capacity of neutrophils to phagocytize bacteria three-fold. (Paape *et al.*, 1981). A negative correlation has been reported between the capacity of milk to support neutrophil phagocytosis and clinical mastitis (Paape *et al.*, 2003). In another field study of 70 lactating dairy cows, decreased milk neutrophil chemiluminescence activity was associated with susceptibility to mastitis caused by *S. aureus* (Piccinini *et al.*, 1999). This relationship indicates that neutrophil oxidative burst activity may play a major role in preventing mastitis. Additionally, postparturient cows have a reduced capacity to recruit neutrophils into the mammary gland during coliform mastitis (Shuster *et al.*, 1996).

Neutrophil recruitment appears to be a critical determinant of resistance to mastitis. Several studies have documented that increasing the milk somatic cell count is highly effective in preventing mastitis. In one field trial,

insertion of a polyethylene intramammary device into the gland cisterns increased the somatic cell count and resulted in a 75% reduction in clinical mastitis (Goodger *et al.*, 1993). Additionally, intramammary administration of soluble CD14 in coliform mastitis causes binding of endotoxin and results in recruitment of neutrophils.

Genetic markers have also been associated with susceptibility to bovine mastitis. Cows with allelic variation in CXCR2 (i.e., the IL-8 receptor) had increased susceptibility to mastitis (Rameaud and Pighetti, 2005). Cows with a CC or GC at CXCR2 + 777 had decreased neutrophil migration in response to IL-8 when compared to cows expressing the GG genotype. Additionally, decreased up-regulation of cell surface CD18 was observed on neutrophils after stimulation with IL-8. The results of these studies support a genetic predisposition to mastitis and further emphasize the importance of rapid mobilization of neutrophils into the mammary gland in prevention of infection.

B. Neutrophil Dysfunction in Neonatal Animals

Neutrophil dysfunction appears to contribute to the susceptibility of newborn calves and foals to pneumonia, septicemia, enteritis, and endotoxemia. Reports on neutrophil function in calves tend to be inconsistent. This is in part due to variation in the age of the calves, the colostrum status, and the techniques used to evaluate neutrophil function. For example, both increased and decreased respiratory burst activity have been reported in neonatal calves when compared to adult cows (Dore *et al.*, 1991; Higuchi and Nigahata, 1998). Respiratory burst activity in neonates is dependent on the agonist used. Respiratory burst activity appears to be reduced when neonatal neutrophils are activated by heat-aggregated albumin or protein kinase C and enhanced when activated by opsonized zymosan. This suggests age-related alterations in cell membrane receptors or differences in intracellular signal transduction probably involving protein kinase C activity and tyrosine phosphorylation of cellular proteins (Higuchi and Nigahata, 1998). Other functional alterations in neonatal neutrophils when compared to adult neutrophils include decreased myeloperoxidase and increased alkaline phosphatase activities, decreased concanavalin A capping, decreased Fc receptor number, increased chemotaxis, increased aggregation, and increased shape change (Zwahlen *et al.*, 1992).

Reports of neutrophil dysfunction in foals are also somewhat inconsistent. When compared to adult horses, some reports indicate that foals have no difference in phagocytic activity, others report decreased phagocytosis when organisms are opsonized with autologous serum but not when opsonized with adult serum, whereas yet others state that phagocytosis of *Staphylococcus aureus* is decreased when opsonized with either autologous or adult serum (McTaggart *et al.*, 2001). Bacterial killing has been reported to be similar to that of adult horses in several studies but was found to be reduced in other studies (Wichtel *et al.*, 1991). Other neutrophil function alterations reported in foals include increased random migration, decreased chemotaxis, decreased iodination, increased CD18 expression, and the presence of an unidentified serum factor that suppresses oxidative burst activity.

C. Neutrophil Dysfunction Associated with Viral Infection

Viral infections have frequently been incriminated as predisposing food animals to bacterial infections. This effect may, in part, be mediated by virus-induced neutrophil dysfunction. The bovine viral diarrhea (BVD) virus is a classic example of a virus that induces neutrophil dysfunction (Brown *et al.*, 1991; Roth *et al.*, 1981). Neutrophils from cows experimentally infected with cytopathogenic or noncytopathogenic strains of BVD developed marked impairment of iodination capacity. Alternatively, other measures of oxygen radical generation were not altered. Cattle that were persistently infected with BVD had multiple alterations in neutrophil function including decreased random migration, decreased *Staphylococcus aureus* ingestion, decreased cytochrome C reduction, decreased iodination, decreased antibody-independent cell-mediated cytotoxicity, decreased cytoplasmic calcium flux, and decreased oxygen radical production.

Another virus incriminated as predisposing cattle to bacterial pneumonia is infectious bovine rhinotracheitis (IBR) virus (McGuire and Babiuk, 1983/1984). In an *in vivo* study, calves were exposed to an aerosol of IBR virus and then to an aerosol of *Mannheimia haemolytica* 5 days later. When compared to calves not exposed to IBR virus, IBR-exposed calves had delayed neutrophil migration into the lungs. Neutrophils from IBR-exposed calves also had decreased random migration and chemotactic responses. Further, alveolar macrophages had decreased capacity to produce chemotactic factors. The results of this study indicate that IBR infection may predispose cattle to secondary bacterial infections.

Neutrophil function has also been investigated in cats infected with feline leukemia virus (Kiehl *et al.*, 1987). Neutrophil chemotaxis was evaluated *in vitro* by use of a modified Boyden chamber apparatus. Cats that were viremic and clinically ill had lower chemotactic responses compared to subclinically infected cats. This did not appear to be a nonspecific effect in that cats that were sick from other causes did not have reduced chemotactic responses.

D. Effects of Nutrition on Neutrophil Function

Selenium and vitamin E appear to be important nutrients in maintaining neutrophil function. As stated previously,

neutrophils from postparturient dairy cows with relatively high blood selenium concentrations had greater superoxide production and greater capacity to kill bacteria compared to cows with relatively low selenium concentrations (Cebra *et al.*, 2003). In another study, injection of selenium-vitamin E into cows was reported to increase the capacity of neutrophils to kill bacteria (Gyang *et al.*, 1984).

Copper deficiency may also adversely affect neutrophil function. Neutrophils from cattle made copper deficient by feeding diets low in copper and high in molybdenum or iron were reported to have decreased capacity to kill *Candida albicans* organisms (Boyne and Arthur, 1986).

E. Effects of Stress on Neutrophil Function

The effects of environmental, transportation, and exercise stress on neutrophil function have been evaluated. The effect of 4 h of transportation was evaluated on four 4- to 6-month-old Holstein calves (Murata *et al.*, 1987). Total and differential leukocyte counts, lymphocyte blastogenesis, nitroblue tetrazolium (i.e., measures neutrophil superoxide production), and plasma cortisol concentration were measured before and after transportation. After transportation calves had a neutrophilia, enhanced NBT activity, suppressed lymphocyte blastogenesis, and increased plasma cortisol concentration. These data suggest that neutrophils became activated during transportation despite the potentially suppressive effects of cortisol on neutrophil function.

The effect of cold stress on neutrophil function has been evaluated in bovine neonates (Woodard *et al.*, 1980). Exposure of neonatal calves to temperatures of 1°C for 3 days had no effect on bactericidal activity of neutrophils.

The effects of exercise on equine neutrophil function have been evaluated (Raidal *et al.*, 2000). When previously untrained horses were subjected to moderately intense exercise, an increase in neutrophil oxidative burst activity and neutrophil phagocytosis was observed. However, high-intensity exercise was associated with transient impairment of these responses. After 17 weeks of exercise training, neutrophil oxidative burst activity and neutrophil phagocytosis were decreased when compared to neutrophil function test results at 0 and 10 weeks. These data suggest that high-intensity exercise training and long duration training have a general suppressive effect on equine neutrophil function.

V. NEUTROPHIL-MEDIATED TISSUE INJURY

Under certain circumstances neutrophils cause injury to host tissues by the same mechanisms used to kill invading organisms (Lee and Downey, 2001; Lehr *et al.*, 2000; Lush and Kveitys, 2000). This injury can vary from local tissue injury at a site of inflammation to systemic activation of neutrophils resulting in a systemic inflammatory response syndrome. Several experimental models of neutrophil-mediated tissue injury have been developed. These include neutrophil-mediated rat lung injury associated with thermal injury to skin, ischemia-reperfusion-induced injury to several organs, endotoxin-induced lung injury, and injury of isolated perfused organs. Localized tissue injury in which neutrophils have been incriminated include sites of inflammation and ischemia/reperfusion injury. Systemic disease states have variously been termed systemic inflammatory response syndrome, adult respiratory distress syndrome (ARDS), endotoxic shock, septic shock, and multiple organ dysfunction syndrome (MODS; Lee and Downey, 2001; Lehr *et al.*, 2000; Maier, 2000). The lungs are particularly sensitive to neutrophil-mediated injury both because of their extensive capillary network and a unique sensitivity of their capillary endothelium to neutrophil-mediated injury. However, other organs, including heart, liver, and kidneys, also can be damaged and undergo functional compromise.

A. Neutrophil-Mediated Injury at Sites of Inflammation

The most studied localized neutrophil-mediated organ injury in veterinary medicine is lung injury associated with shipping fever in cattle. Invasion of the causative organism, *Mannheimia haemolytica*, results in rapid recruitment of neutrophils into the lungs within the first 2h. These changes are characterized histopathologically by a fibrinopurulent pneumonia and ultrastructurally by endothelial disruption and alveolar epithelial swelling (Whiteley *et al.*, 1992). Lesions are characterized by severe endothelial and alveolar epithelial damage that occurs immediately beneath sites of neutrophil attachment. Alveolar and pulmonary intravascular macrophages appear to play a central role in attracting neutrophils into the lungs (Whiteley *et al.*, 1992). Activated macrophages secrete proinflammatory cytokines, including TNF-α and IL-1, that activate alveolar capillary endothelium, converting it from an antiadhesive and anticoagulant surface to a proadhesive (for leukocytes and platelets) and procoagulant surface (Fig. 11-5). Production of IL-8 and platelet-activating factor by alveolar capillary endothelial cells may be involved in activating neutrophils while they are attached to endothelium (McClenahan *et al.*, 2002). The resultant vascular injury and increased permeability cause flooding of alveoli with plasma and promote thrombotic events.

The role of neutrophils in the lung injury has been investigated by neutrophil depletion studies. Neutrophil depletion before experimental inoculation of *Mannheimia haemolytica* organisms into the lungs of calves markedly attenuates alveolar capillary endothelial injury in the first 6 to 8h after inoculation of the organism.

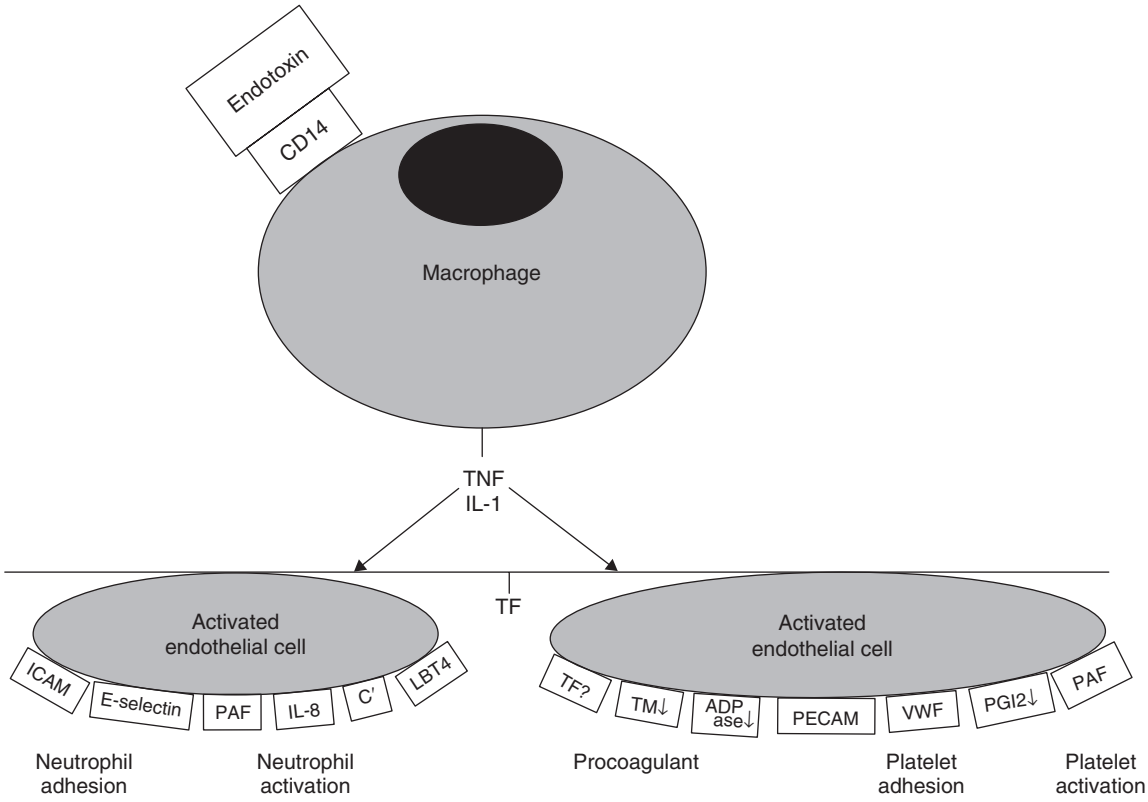

FIGURE 11-5 The activation of endothelial cells at a site of inflammation. At sites of inflammation, activated macrophages release proinflammatory mediators including tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1). These cytokines activate endothelial cells, converting their surface from antiadhesive and anticoagulant to proadhesive and procoagulant. Activated endothelium express intercellular adhesion molecules (ICAM) and selectin molecules that promote neutrophil adhesion. Activated endothelium also express platelet-activating factor (PAF), interleukin-8 (IL-8), and leukotriene-B4 (LTB4) and may bind complement, all of which will activate neutrophils while attached to endothelium. Decreased expression of adenosine diphosphatase and thrombomodulin as well as increased expression of platelet-endothelial cell adhesion molecules (PECAM) and von Willebrand's factor promote platelet adhesion. Decreased production of prostaglandin I_2 (PGI2) and expression of PAF promotes platelet activation. Finally, tissue factor (TF), a potent activator of the extrinsic clotting pathway, may be expressed on activated endothelium.

B. Ischemia/Reperfusion Injury

Prolonged ischemia results in numerous metabolic and ultrastructural changes within cells. Ischemia decreases cellular oxidative phosphorylation resulting in failure to resynthesize high-energy phosphate compounds such as adenosine 5′-triphosphate. Adenosine 5′-triphosphate catabolism during ischemia results in accumulation of hypoxanthine. Hypoxanthine is subsequently converted to oxygen radicals upon reperfusion of the tissue. Ischemia also promotes expression of leukocyte and platelet adhesion receptors on the cell surface; promotes expression of proinflammatory cytokines (e.g., IL-8) and bioactive agents (e.g., platelet-activating agents, endothelin, thromboxane A2); and suppresses certain gene products including nitric oxide, nitric oxide synthase, thrombomodulin, and prostacyclin.

Restoration of blood flow after a period of ischemia places tissues at risk of further cellular necrosis (Carden and Granger, 2000; Eltzschig and Collard, 2004). Reperfusion injury is primarily directed at the endothelial cells lining the microvasculature and is manifest as accelerated production of a variety of bioactive agents and expression of adhesion molecules for neutrophils. Neutrophils appear to become activated while attached to endothelium-releasing oxygen radicals and granule contents directly onto the endothelial surface. In addition to production of superoxide by neutrophils, superoxide is generated from hypoxanthine within endothelial cells and is produced by mast cells and macrophages.

Neutrophils may also contribute to tissue hypoperfusion after blood flow is reestablished. Activated neutrophils are rigid and tend to lodge in capillaries, obstructing blood flow. Neutrophil-neutrophil aggregates and platelet-neutrophil aggregates also may contribute to capillary malperfusion by plugging capillaries resulting in prolonged maldistribution of blood flow. Platelet-neutrophil aggregates may also contribute to microthrombus formation.

The observation that blood flow to an ischemic organ is not fully restored after release of a vascular occlusion has been termed the no-reflow phenomenon. Experimental studies, using leukocyte depletion models, have demonstrated a central role of neutrophils in the no-reflow phenomenon.

C. Neutrophil-Mediated Injury at Distant Sites

Neutrophils become activated within the circulation during a variety of physiological and pathological conditions in domestic animals. Circulating activated neutrophils have been documented during strenuous exercise, inflammatory disease, equine colic, and equine laminitis. At least in some circumstances, there is evidence to suggest that these activated neutrophils may contribute to the pathogenesis of the disease process.

1. *Exercise*

Strenuous exercise has been associated with up-regulation of neutrophil surface-associated integrin receptors in dogs undergoing short duration sled-pulling activity (Moritz *et al.*, 2003). Additionally, decreased neutrophil granularity was observed postexercise. Because CD11b/CD18 integrin is stored in neutrophil granules and transported to the cell surface when neutrophils degranulate, the combination of increased cell surface integrin concentration and decreased granularity postrace is consistent with exercise-associated neutrophil degranulation.

2. *Inflammatory Disease*

Neutrophils circulate in an activated state in a variety of inflammatory conditions. Dogs with naturally occurring septic and nonseptic inflammatory diseases had increased cell surface expression of CD11b (Weiss *et al.*, 2004). Neutrophils from dogs with septic inflammatory diseases and those with evidence of multiple organ dysfunction also had decreased neutrophil granularity and increased neutrophil size. However, neutrophil activation markers may not predict neutrophil function. In a study by Gosset *et al.* (1983/1984), neutrophils from dogs with severe inflammatory disease were reported to have a defect in bactericidal activity. Monocytes and lymphocytes from dogs with septic and nonseptic inflammation and multiple organ dysfunction had decreased expression of major histocompatibility factor class-II suggesting impaired immune responsiveness (Weiss *et al.*, 2004).

Leukocyte deformability, neutrophil CD11b expression, and neutrophil size were evaluated in calves experimentally inoculated intrabronchially with *Mannheimia haemolytica* organisms (McClenahan *et al.*, 1999). Infected calves had decreased leukocyte deformability and increased neutrophil size by 1h and increased CD11b expression by 6h after organism inoculation. Decreased neutrophil deformability and increased size may contribute to sequestration of neutrophils in alveolar capillary beds during sepsis.

3. *Colic*

The activation status of circulating neutrophils was evaluated in horses with naturally occurring colic (Weiss and Evanson, 2003). Activated neutrophils were not detected in healthy horses or horses with impaction or gas colic. Conversely, horses with inflammatory bowel disease consistently had increased neutrophil cell membrane CD11/CD18 expression, increased neutrophil size, and decreased neutrophil granularity consistent with circulating activated and degranulated neutrophils. These horses also had decreased leukocyte deformability indicating that neutrophils were rigid. Horses with strangulating colic had variable results. Among horses with strangulating colic, changes in leukocyte deformability, neutrophil size, and neutrophil granularity correlated directly with adverse outcome.

4. *Equine Laminitis*

Neutrophils may become activated in the prodromal stages of equine laminitis. At various times during the first 12h after induction of black walnut-induced laminitis, horse neutrophils had increased oxygen radical production, and some horses had increased phagocytosis of bacteria (Black *et al.*, 2006). These changes were associated with neutropenia and were presumed to be due to a systemic inflammatory response resulting from absorption of inflammatory mediators from the intestine. These activated neutrophils have been incriminated in the pathogenesis of the laminar injury (Black *et al.*, 2006).

5. *Adult Respiratory Distress Syndrome and Multiple Organ Failure*

Activated neutrophils are central to the pathogenesis of ARDS and MODS associated with sepsis and endotoxemia (Lehr *et al.*, 2000). As in ischemia/reperfusion injury, microvascular injury is a major site of injury in these conditions. The lungs are particularly sensitive to neutrophil-induced vascular injury. The process of lung involvement has been divided into four sequential stages: (1) sequestration of neutrophils in pulmonary capillaries, (2) adhesion, (3) activation, and (4) release of oxygen radicals and proteases (Lee and Downey, 2001). The process of neutrophil sequestration in the lungs differs from that of other tissues. In other tissues, neutrophil sequestration occurs predominately in postcapillary venules and is dependent on selectin and integrin adhesion molecules. Alternatively, neutrophil sequestration in the lungs occurs primarily in pulmonary capillaries and is largely independent of adhesion molecules. Sequestration

is thought to be due to the fact that activated neutrophils are rigid and tend to lodge in capillary beds.

Limited neutrophil activation while in contact with the endothelium is probably a normal process. This results from binding of neutrophil adhesion molecules to endothelial cells. Although not completely elucidated, these signaling pathways appear to involve the Src-family of tyrosine kinases, mitogen-activated protein kinases, and phosphatidylinositol 3-kinase (Lee and Downey, 2001). However, excessive activation of neutrophils while attached to endothelium can result in direct release of oxygen radicals and granule contents onto the endothelial surface. A variety of factors, including platelet-activating factor, IL-8, LTB_4, and complement, have been incriminated as neutrophil activating agents. Platelet activating factor and IL-8 are produced by activated endothelial cells and expressed on the cell surface. Neutralization of platelet activating factor both *in vitro* and *in vivo* has been reported to attenuate bovine neutrophil-induced endothelial injury (McClenahan *et al.*, 2000, 2002). Multiple mediators are involved in neutrophil-mediated endothelial injury. Mediators implicated in various experimental models of ARDS include oxygen radicals, activated complement factors, nitric oxide, proteolytic enzymes, and metalloproteinases (Lee and Downey, 2001). Consequences of this endothelial injury include (1) massive leakage of plasma into alveoli, (2) vasodysregulation leading to maldistribution of blood flow, and (3) disturbances of oxygen transport and utilization. All of these lead to dyspnea and hypoxemia.

As in ischemia/reperfusion injury, capillary plugging by activated neutrophils appears to play a central role in ARDS and MODS. Activated neutrophils are stiff because of the assembly of F-actin filaments and tend to lodge in capillaries. Additionally activated neutrophils form neutrophil-neutrophil and neutrophil-platelet aggregates, which form microvascular plugs in larger vessels. This leads to microvascular thrombosis, tissue necrosis, and release of additional toxic substances.

D. Role of Neutrophils in Microvascular Thrombosis

Local and disseminated activation of coagulation frequently accompanies sepsis and endotoxemia (Weiss and Rashid, 1998). The mechanism responsible for this sepsis-induced procoagulant effect is complex. The role of neutrophils in microvascular thrombosis appears to be in their capacity to induce endothelial injury and to bind and activate platelets. Endothelial injury results in conversion of the endothelial cell surface from an anticoagulant surface to a procoagulant surface (Fig. 11-5). Destruction of endothelial cells activates the intrinsic clotting system through exposure of subendothelial collagen and activates the extrinsic coagulation system through contact with tissue factor.

Platelets also frequently become activated during sepsis and endotoxemia. Both activated neutrophils and activated endothelial cells express platelet activating factor that is a potent platelet agonist. When activated platelets degranulate, P-selectin is transported from alpha granules to the cell membrane. P-selectin interacts with PSGL-1 on the neutrophil surface forming platelet-neutrophil aggregates. Platelet-neutrophil aggregates are rigid and therefore lodge in capillary beds and initiate microvascular inflammatory and thrombotic events. Platelet-neutrophil aggregates have been detected in horses undergoing near-maximal treadmill exercise and in horses and ponies with carbohydrate overload-induced laminitis (Weiss *et al.*, 1998a, 1998b). The potential causative role of activated platelets/platelet-neutrophil aggregates in laminitis was inferred from *in vivo* studies in which ponies were treated with a competitive inhibitor of platelet aggregation before administration of carbohydrate overload. The platelet aggregation inhibitor prevented the formation of platelet-neutrophil aggregates and the prevented onset of lameness in all eight ponies tested (Weiss *et al.*, 1998a).

I. INTRODUCTION

The detection of proteins in serum by their catalytic activity as a reporter of tissue damage is a cornerstone of medical laboratory analyses (Rej, 1998).

Clinical enzymology is the discipline that studies and tests enzyme activity in serum, plasma, urine, or other body fluids for the purpose of helping to establish the diagnosis and prognosis of disease and to screen for abnormal organ function. Although not the subject of this chapter, it should be noted that some enzymes are also of major importance as analytical reagents. This chapter first explores the universal factors affecting changes in enzyme content of bodily fluids and then delves into specific details relevant to particular enzymes. Discussion of basic concepts in enzymology, such as enzyme structure, kinetics, or analysis, is limited to those that are of clinical relevance or that add insight into interpreting changes in body fluid enzyme activity. Additional information regarding enzyme structure and enzyme kinetics can be found in numerous biochemistry texts as well as clinical texts such as *Tietz Fundamentals of Clinical Chemistry* (Burtis and Ashwood, 2001) and the previous edition of this book. In addition, the methodology of the various enzyme assays can be found in the literature provided by the vendors of enzyme assay reagents.

II. HISTORY OF CLINICAL ENZYMOLOGY

Although the presence of enzymes in cells and plasma was first recognized in the 1800s, the development of clinical enzymology began after the introduction of an assay for serum amylase by Wohlgemuth in 1908 and the report in 1916 that serum amylase activity in blood and urine was a reliable test for pancreatic disorders (Rosenfeld, 1999). This finding was followed in 1927 by the discovery of alkaline phosphatase (ALP) in bone and the description of serum alkaline phosphatase as a diagnostic test (Rosenfeld, 1999). The development and marketing by Sigma Chemical Company in St. Louis in the 1950s of simplified enzyme assays in kit form, such as aspartate and alanine aminotransferases, and an ALP assay that used p-nitrophenylphosphate as substrate (Technical Bulletin 104), were major factors in their routine clinical use and encouraged additional studies in diagnostic enzymology (Berger, 1993; Bessey *et al.*, 1946; Reitman and Frankel, 1957). In addition to assay reagent development, an equally significant contribution to the development of clinical enzymology was the invention by Leonard Skeggs of a multichannel autoanalyzer that was

marketed by Technicon in 1964 (Skeggs, 2000). The autoanalyzer increased the availability of reduced cost serum enzyme analyses, which ultimately led to their routine use in both human and veterinary diagnostic medicine.

The advancement of clinical enzymology included the development and evaluation of enzyme assays for use in nonhuman animal species, some of which have been found useful, whereas others have been dropped for various reasons. In some cases, the decision to investigate an enzyme for diagnostic use may have related not only to its potential clinical relevance but also to the efficiency of offering the test. In spite of recognition of species differences, veterinary medicine has often followed human medicine in its choice of diagnostic tests. The bias toward enzyme assays used in human medicine is due in part to their availability on automated analyzers, making all tests low-cost, on-demand assays with a high degree of precision and accuracy.

The automation of enzyme assays, and the popularity of the serum chemistry profile in veterinary medicine, has allowed retrospective studies to be conducted and has given the veterinarian an opportunity to critically evaluate the diagnostic function of the common assays in a large number of animals on a regular basis, as well as gain a "feel" for the results, thereby allowing for more subtle clinical interpretations. It is likely that diagnostic tests that are not automated are less understood and interpreted in a more rigid manner with less appreciation for nuances and significance of the test result. Interestingly, during the first approximately 30 years of serum enzyme testing in veterinary medicine, these tests were often viewed as "diagnostic" tests, whereas in the past approximately 20 years their variable and often somewhat limited degree of diagnostic specificity has been appreciated and they are now most often recognized as "screening" tests.

Although serum enzyme activity is reported as part of numerous studies published in the literature, the number of studies directed primarily at answering specific questions regarding the enzymes appears to have decreased since the late 1990s from what might be considered the heyday of clinical enzymology in the 1960s to mid-1990s.

III. FACTORS AFFECTING SERUM ENZYME ACTIVITY

As the field of clinical enzymology has developed, so has our understanding of the physiological factors responsible for the alterations in serum enzyme activity that occur with disease, although several unanswered questions remain. Organ specificity, subcellular location of the enzyme, the mechanism of enzyme release from cells, the clearance from blood, and the rate of induction of enzyme synthesis all affect to a lesser or greater extent the diagnostic accuracy of the various enzyme assays (Hoffmann and Solter, 1989; Solter, 2005). This section discusses the physiological, biochemical, and anatomical factors that affect changes to serum enzyme activity.

A. Organ Mass and Enzyme Tissue Concentration

The roles that enzyme tissue concentration and organ mass play on the magnitude of blood enzyme activity are relatively straightforward. Organs with a high concentration of an enzyme have the potential to cause a greater increase in serum enzyme activity with disease. For example, the intracellular to extracellular concentration gradient of hepatocellular alanine aminotransferase (ALT) is 100,000:1. Injury to hepatocytes, therefore, has the potential of causing markedly increased serum ALT activity. The higher the concentration gradient of the enzyme or protein marker between the cell and the interstitial space, the faster is the translocation of significant quantities of the enzyme to the interstitial space and ultimately the blood (Mair, 1999). Likewise, the liver has a large mass, thereby adding to the potential increase in serum ALT activity.

B. Cell Location

The location of cellular enzymes relative to the blood, urine, or other fluids is an especially significant determinant of whether an increase in enzyme activity will occur with enzyme release and in which fluid it will be found. A well-known example is renal tubular gamma glutamyltransferase (GGT) located on the luminal surface of renal tubular epithelial cells. Injury to these cells results in release of the gamma GT into urine but not into blood. Similarly, alkaline phosphatase (ALP) located on the luminal surface of enterocytes is lost into the gut lumen rather than blood with enterocyte injury. Hepatocellular ALP, however, with activity over both bile canalicular and sinusoidal surfaces, can be increased in both bile and blood.

C. Mechanisms of Release of Cytoplasmic Enzymes or Other Protein Biomarkers from Cells to Blood

Cytoplasmic enzymes are contained within cell membranes. Healthy plasma membranes are thought to be impermeable to macromolecules such as enzymes. Therefore, alteration in the cell membrane is necessary to allow cytoplasmic enzymes to gain access to the blood. In the event of cell necrosis, perforations and tears of the cell membrane allow the release of cytosolic contents in a relatively straightforward process. However, increases of serum enzymes do not always correlate to the degree of histological evidence of cell necrosis. Hence, it is has been long postulated that under certain circumstances, cytoplasmic enzymes may "leak" from

diseased cells that remain viable, perhaps through membrane pores or tears. However, it is difficult to envision that a cell could develop a pore or tear large enough to allow "leakage" of macromolecules such as enzymes while maintaining the intracellular-to-extracellular electrolyte ratios necessary to remain viable. An alternative mechanism by which a cell could sustain damage from which it survives and yet allows the release of cytoplasmic enzymes is the formation of membrane blebs (Coltran *et al.*, 1999; Gores *et al.*, 1990; Lemasters *et al.*, 1983; Mair, 1999). These blebs then are ruptured or are released as vesicles into the blood where they are eventually broken down, releasing their contents, including cytoplasmic enzymes. The body of knowledge supporting this concept has been growing since the 1980s (Gore *et al.*, 1990; Kristensen, 1994; Mair, 1999; Solter, 2005).

Cell membrane bleb formation has been recognized following hypoxic insults and likely reflects two sequential developments. Depletion in energy stores in the form of ATP is followed by several events including the influx of calcium into the cell (Coltran *et al.*, 1999). This calcium influx results in activation of intracellular phospholipases, endonucleases, and proteases and ultimately in disruption in the phosphorylation state of cytoskeletal proteins and an alteration in lipid membrane content. A combination of the altered cytoskeletal proteins, lipid membrane content, and osmotic swelling of the cell leads to bleb formation, release of these blebs, and resealing of the cell membrane (Fig. 12-1). Hepatocyte bleb formation, projection of these blebs through the fenestrations of endothelial cells, and release of these blebs during hypoxia are clearly shown in scanning electron micrographs (Lemasters *et al.*, 1983). Bleb formation has been described with many conditions including ischemia, shock, viral infections, toxemia, and cholestasis. The magnitude of serum enzyme increase with reversible cell injury and bleb formation is not clearly understood, but it is likely that the magnitude of release and resultant increase activity in serum are considerably less than what might be observed with cell necrosis. Hence, it is reasonable to assume that the greater the magnitude of serum enzyme increase, the greater likelihood of some irreversible cell death, whereas mild serum enzyme activity increases may be associated with reversible cell injury.

Although cytoplasmic enzymes may be released from cells into blood because of bleb formation, enzymes associated with the mitochondria are not released by this mechanism (Kamiike *et al.*, 1989). Appreciable loss of membrane integrity and presumably cell death are necessary for release of mitochondrial aspartic aminotransferase (mAST) from hepatocytes. Ischemic liver does not lose mAST until almost all cytoplasmic aspartic aminotransferase (cAST) is lost.

Regardless of the mechanism of release of the enzymes, there is evidence that the enzymes are released into the interstitial space where the greater portion is carried by lymphatics to the thoracic duct and emptied into the blood

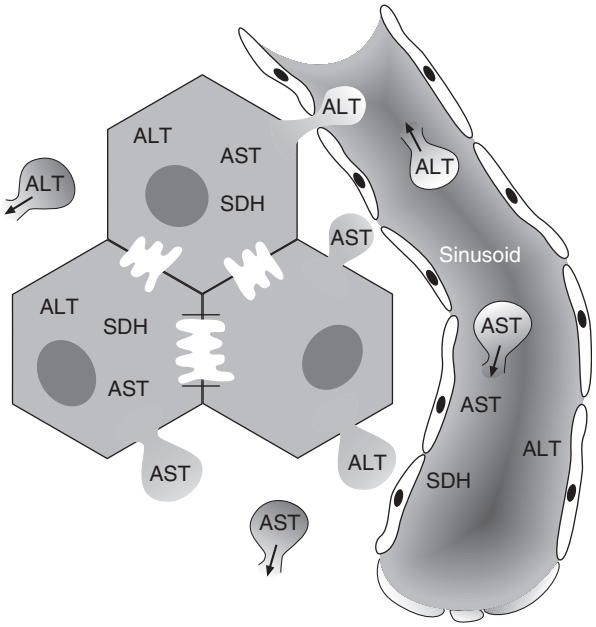

FIGURE 12-1 Membrane bleb formation in reversible injury, allowing the release of cytoplasmic enzymes either directly into blood or into the interstitial space where they can be carried by lymphatics to blood.

(Bolter and Critz, 1976; Lindena *et al.*, 1986). Lymph-to-serum ratios of most enzymes are greater than 1:1, providing support for the delivery of enzymes to blood via the lymphatics. However, the direct delivery of the enzyme from the injured cell to blood cannot be discounted and is supported by the electron micrographs of cell blebs extending through the fenestrations of the endothelium as discussed earlier. This delivery of the enzyme from the injured cell to blood, whether directly or indirectly via lymphatics, likely affects the time of maximum serum increase of the enzyme after injury and duration of the presence of the increase of the enzyme in blood as suggested by the longer half-life of CK when injected intramuscularly as opposed to intravenous injection (Aktas *et al.*, 1995).

D. Mechanisms of Release of Membrane-Bound Enzymes

Those enzymes attached to the external surface of cell membranes such as alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), and 5′nucleotidase (5′N) are released from cells to blood by distinctly different mechanisms than enzymes derived from the cytoplasm.

Of historical interest, increases of serum ALP activity were perhaps first thought to result from a failure of excretion of bone ALP by the liver. This concept was put to rest many years ago and followed by the concept that cholephilic enzymes were shed from the bile canalicular surface of hepatocytes or biliary epithelial cells into bile and then regurgitated into blood through tight junctions. Support for

this pathway was provided by evidence of disruptive changes to tight junctions in cholestasis and by experimental observations of infused horseradish peroxidase moving through tight junctions (Boyer, 1993; Lowe *et al.*, 1988). However, increases of serum ALP and GGT activity have been shown to occur in the absence of increased biliary pressure and any evidence of alterations in tight junctions, and it is unlikely that this paracellular pathway is a significant contributor to the appearance of cholephilic enzymes in serum in most cases (Debroe *et al.*, 1985; Putzki, 1989; Toyota *et al.*, 1983). An alternative pathway of movement of cholephilic enzymes to blood has been suggested as a retrograde vesicular transport system following the observation that retrograde infusion of ferritin and polymeric and secretory forms of IgA undergo reversed transcytosis from the biliary or apical surface of the hepatocytes to the basolateral or sinusoidal surface during cholestasis (Carpino *et al.*, 1981; Jones *et al.*, 1984). However, neither of these pathways allows explanation of the appearance of ALP and GGT activity in blood in the absence of cholestasis. Studies using a choledochocaval shunt model show that within 12h of shunting of bile or taurocholic acid into blood, there is a marked induction of ALP synthesis, appearance of ALP on the basolateral membranes, and a parallel increase in serum ALP activity (Ogawa *et al.*, 1990). This occurs in the absence of increased biliary pressure and any evidence of alterations in tight junctions (Toyota *et al.*, 1983). These observations along with others led to a third and more likely mechanism of the appearance of cholephilic enzymes, especially ALP, in blood. The basolateral appearance of enzymes typically considered to be on the apical membrane or bile canalicular surface is not unexpected as following synthesis all apical membrane proteins are believed to first be transported to the basolateral surfaces before vesicular transport to their final site on the bile canalicular membrane (Bartles *et al.*, 1987; Maurice *et al.*, 1994; Schell *et al.*, 1992). Therefore, these so-called biliary enzymes or proteins have a brief period of residence on the sinusoidal surface of the hepatocytes with the enzyme on the external surface in the space of Disse so that they can potentially be released into blood if and when a suitable release mechanism exists. In addition, the quantity of enzyme available on the basolateral membrane and accessible for release into blood is increased at any time there is increased synthesis of the enzyme as described previously with the choledochocaval shunt model, as occurs with cholestasis and as may occur during hormonal or drug-driven induction of enzyme synthesis (Ogawa *et al.*, 1990; Putzki *et al.*, 1989; Solter and Hoffmann, 1999; Solter *et al.*, 1997). Although positioned on the basolateral membrane facing the space of Disse for a brief period allows the possibility of release into blood, this does not occur without appropriate conditions to cleave the hydrophobic anchor. Alkaline phosphatase and 5′nucleotidase are anchored to the membrane via a hydrophobic phosphatidylinositol glycan anchor, whereas GGT is anchored via a transmembrane peptide therefore requiring different mechanisms of release. These release mechanisms will be discussed specifically in the sections dealing with each of these enzymes.

E. Blood Clearance Rates of Enzymes

The amount of enzyme activity in blood is very dependent on the rate of clearance of the enzyme from the blood following its release from cells. The half-lives of various enzymes range from minutes to hours to days, and the mechanisms or factors that determine the half-life of the various enzymes vary.

The actual mechanisms of removal of enzymes from blood are not well established but likely are varied. Some small-molecular-weight enzymes such as amylase and lipase are, in part, filtered through the glomerulus. Enzymes that are glycoproteins are likely endocytosed by the galactose receptors on hepatocytes either directly via exposed galactose molecules or after loss of terminal sialic acid molecules resulting in exposed galactose residues, or are endocytosed by mannose receptors on Kupffer cells. Other enzymes may be degraded by proteases or are labile and activity is lost while the protein continues to circulate. The rate of clearance of enzymes from blood can be affected by disease and may complicate the correct interpretation of diagnostic test results. For example, pancreatic amylase activity, which is normally cleared by the kidneys, will increase in patients with renal failure because of the decreased glomerular filtration rate. A false-positive test result for pancreatitis could result.

F. Enzyme Induction

Changes to serum enzyme activity may in some cases reflect changes in enzyme production by the cells, rather than cell injury. Although there is certainly evidence of varying concentrations of cytoplasmic enzymes in cells, these generally do not result in dramatic changes in the serum activity of these enzymes. Marked increases in serum enzymes as a result of induction are most often associated with enzymes that are membrane bound where they can readily be released from the membrane into the lymphatics or blood or secreted by the cell. This induction can be as a result of hormonal changes, pathophysiological events such as cholestasis, or can be drug induced.

IV. SPECIFIC ENZYMES

A. Alanine Aminotransferase

Alanine aminotransferase (EC 2.6.1.2) (ALT), formerly known as glutamic pyruvate transaminase, catalyzes the reversible transamination of L-alanine and 2-oxoglutarate to pyruvate and L-glutamate. ALT, along with other transaminases,

plays a role in amino acid catabolism and interorgan nitrogen transport. Pyridoxal 5′-phosphate (PP) is the cofactor of ALT, thus forming the active holoenzyme. PP is generally present in serum in sufficient quantities to provide near maximum activity of the ALT with only a reported 11% and 7% inactive apoenzyme in dog and cat serum, respectively (Stokol and Erb, 1998). There was no difference found between the percentage of inactive apoenzyme in the serum of normal animals and those with hepatic disease. However, two dogs were identified with 14,225% and 336% greater serum ALT activity when PP was added (Mesher *et al.*, 1998). Approximately half the ALT in serum from a group of exercising Thoroughbred horses was in the inactive apoenzyme form (Rej *et al.*, 1990). Hence, because there are cases in which PP seems to be limiting the measured ALT activity, some, but not all, commercial assays for ALT now contain added PP reagent.

ALT activity is found in several body organs, but the magnitude of activity varies dramatically with species. In dogs, the ALT activity per gram of liver is at least four times greater than in other organs, although considerable activity is found in both heart and skeletal muscle (Clampitt and Hart, 1978; Keller, 1981; Zinkl *et al.*, 1971). Similar findings are true for cats, but in horses, cattle, and swine, the ALT activity per gram of tissue differs little in liver when compared to muscle. Hence, based on tissue concentrations of ALT, increased serum ALT activity is somewhat specific for hepatic injury in dogs and cats but offers no specificity for detection of liver injury in horses and cattle.

ALT, found in the cytoplasm of hepatocytes, is also found in mitochondria but generally at considerably lower concentrations, depending on species and tissue. Although it has been suggested that the mitochondrial enzyme may be released into blood more slowly following hepatocellular injury, this activity is still poorly understood and has not been utilized as a diagnostic tool.

The half-life of ALT in blood is not clearly defined, although the circulation time is obviously adequately long to evaluate organ injury and release of ALT into blood for hours to days after the event. In dogs, reports have suggested half-lives of 3, 20, 45, and 60h (Fleisher and Wakim, 1963; Reichard, 1959; Zinkl *et al.*, 1971). Semilogarithmic plots of the decline in serum ALT activity following peak activity induced by acute CCl_4 exposure suggest a half-life of between 45 and 60h in dogs, although this may be a slight overestimation, as injured tissue is still likely present and contributing to the blood pool (unpublished data). The half-life of ALT from feline liver extracts, administered intravenously to cats, was estimated as 3 to 4h (Nilkumuhaug and Thornton, 1979). This is consistent with the half-life of 6h for ALP activity in the blood of cats (Hoffman *et al.*, 1977).

Serum ALT has been recognized as a marker of hepatocellular injury since the 1950s (Chimsky *et al.*, 1956; Cornelius, 1958). The use of ALT as a diagnostic tool was expedited by the development in the mid-1950s of a simple coupled assay for ALT activity in serum that eliminated the problem of product inhibition (Reitman and Frankel, 1957). Numerous studies using carbon tetrachloride have clearly shown the value of serum ALT as an indicator of hepatocellular necrosis, especially in dogs and cats, but to a much lesser extent in horses, cattle, swine, sheep, and goats (Cornelius *et al.*, 1958; Everett *et al.*, 1977; Noonan, 1981; Noonan and Meyer, 1979; Spano *et al.*, 1983; Turgut *et al.*, 1997; Zinkl *et al.*, 1971). The length of time that serum ALT activity is increased ranges from 9 to 23 days in dogs, which suggests prolonged injury to the liver but also supports the longer half-life suggested earlier (Guelfi *et al.*, 1982; Noonan, 1981; Turgut *et al.*, 1997). Relatively mild increases in serum ALT activity occur in dogs and cats with biliary obstructive diseases that cause serum ALP activity to increase markedly (Everett *et al.*, 1977; Spano *et al.*, 1983). Hence, the ratio of serum ALT-to-ALP activity is far greater in cases of hepatic necrosis than with cholestasis, suggesting that very general interpretive conclusions can be made by comparing the magnitude of increase of serum activity of these two enzymes. Increased serum ALT activity occurs with a wide range of other disorders including hypoxia secondary to anemia, metabolic diseases such as lipidosis, nutritional disorders such as copper toxicosis, inflammatory or infectious diseases, neoplastic diseases, and traumatic liver injury. Increased serum ALT activity has also been associated with numerous drugs; in many cases, these are likely idiosyncratic reactions causing hepatocellular toxicity. Exposure to carbon tetrachloride, mushroom alkaloids, or acetaminophen is clearly a hepatotoxic event.

Mild to moderate increases in serum ALT activity are also observed in dogs and cats with endocrine diseases such as diabetes mellitus, hyperthyroidism, hyperadrenocorticism, and hypothyroidism. For example, 163 (78%) dogs with diabetes mellitus have increased serum ALT activity (Hess *et al.*, 2000). Cats with diabetic ketoacidosis commonly have increased serum ALT activity (Bruskiewicz *et al.*, 1997). Increased serum ALT activity is common in dogs with hyperadrenocorticism or dogs treated with glucocorticoids (DeNova and Prasse, 1983; Dillon *et al.*, 1980; Solter *et al.*, 1994). It has been shown in rats that ALT synthesis may be induced by glucocorticoids in order to increase function of the gluconeogenic pathways. However, experimental treatment of healthy dogs with glucocorticoids did not result in an increase in the concentration of hepatic tissue ALT activity, suggesting that increased hepatic mass plays a larger role than increased hepatocellular enzyme induction for an observed increased serum ALT activity (Solter *et al.*, 1994).

Although early studies of increased serum ALT activity following experimentally induced hepatocellular injury and the studies demonstrating much higher ALT activity

in liver than other organs led to the early conclusion that increases of ALT activity in serum are specific for hepatocellular injury, there is clear evidence that serum ALT activity can also be increased as a result of injury to myocytes as well. Dogs in a colony with canine X-linked muscular dystrophy and ongoing muscle necrosis had increased serum CK, AST, and up to a 25-fold increase in ALT activity but a normal SDH activity, suggesting that myonecrosis contributed to the increased serum ALT activity (Valentine *et al.*, 1988). This is consistent with the presence of some ALT activity in cardiac and skeletal muscle of dogs. In a case report of a cat with myokymia and neuromyotonia, the CK activity was 28,380, whereas the ALT activity was only 195 U/l; in a study of rhabdomyolysis in three dystrophin-deficient cats, the CK activity ranged up to 2040 times the upper limit of the reference range, whereas the ALT activity only increased to 19 times the upper limit of the reference range, suggesting only a minimal increase of serum ALT activity should be expected with muscle injury in this species (Galano *et al.*, 2005; Gaschen *et al.*, 1998).

Although at least one early study in dogs showed a correlation between the magnitude of serum ALT activity and histological evidence of necrosis, other studies have reported little correlation (VanVleet and Albert, 1968). Similarly, bile duct ligation of dogs led to a 25-fold increase in serum ALT activity with minimal evidence of hepatocellular necrosis. As discussed in the introduction, the recognition of the formation of membrane blebs on hepatocytes and the rupture of these blebs during various conditions such as endotoxic shock, carbon tetrachloride-induced injury, cholestasis, and experimentally induced hypoxia have led to the understanding that there can be an increase of serum enzymes derived from the cytoplasm of the cell in cases of reversible cellular injury. In summary, the observation of increased serum ALT activity indicates hepatocellular (or myocyte) injury, but it does not necessarily imply irreversible injury and does not suggest a specific cause.

B. Aspartate Aminotransferase

Aspartate aminotransferase (AST: EC 2.6.1.1) (formerly glutamic oxaloacetic transaminase; GOT) catalyzes the transamination of L-aspartate and 2-oxoglutatarate to oxaloacetate and glutamate. As with ALT, pyridoxal-5′-phosphate (PP) is required as a cofactor. Although serum ALT was poorly saturated with PP in a study following exercise in horses, 94% of the AST was saturated and present as the holoenzyme (Rej *et al.*, 1990). Providing PP in the assay reagent may be less of a concern when determining serum AST activity than when determining serum ALT activity.

AST activity is relatively high and in similar amounts in liver and in skeletal and cardiac muscle, but it varies between species (Boyd, 1983; Keller, 1981). It is routinely used in equine and food animal medicine as a screening test for injury to both organs. Serum AST activity is readily available on the biochemical profile, has a longer blood half-life than sorbitol dehydrogenase and creatine kinase, and is stable for days in serum at room temperature, refrigerated, or frozen. AST is found in erythrocytes, and the addition of erythrocyte lysate to serum increases the apparent AST activity (unpublished data).

AST is located in the cytosol but is in higher concentrations in mitochondria. There is only 48.1% amino acid sequence homology between cytosolic AST (cAST) and mitochondrial AST (mAST) from horse heart (Doonan *et al.*, 1986). Likewise, the nucleotide sequences of cDNA of bovine mAST and cAST are also distinctly different (Aurila *et al.*, 1993; Palmisano *et al.*, 1995). Although there have been some efforts to show enhanced ability to identify organ-specific injury by assays for mAST and cAST, this has been shown to be of no diagnostic value (Jones and Blackmore, 1982). It may be theoretically possible to estimate the magnitude of reversible versus irreversible cell injury by determining mAST and cAST separately; however, this has not been studied empirically.

Although the half-life of AST has been reported to be as long as 7 to 8 days in horses and as short as 163min in dogs, neither of these seems reasonable based on data obtained following carbon tetrachloride toxicity (Fleisher and Wakim, 1963; Zinkl *et al.*, 1971). Decreasing serum AST activity in horses recovering from CCl_4-induced hepatotoxicity, as well as studies of equine myoglobinuria, suggests a half-life of 3 to 4 days (Bernard and Divers, 1989; Cardinet *et al.*, 1967; Noonan, 1981). In cattle with mild CCl_4-induced hepatotoxicity, serum AST activity during recovery suggests a half-life of approximately 1 day (Yonezawa *et al.*, 2005). Serum AST has a longer half-life than creatine kinase, and therefore it would be expected to have increased diagnostic sensitivity during recovery from myocyte or hepatocyte injury.

Increased serum AST activity is observed with both reversible and irreversible injury to hepatocytes and can be seen following hepatocellular injury and cholestasis, similar to serum ALT activity in dogs and cats. Likewise, serum AST is increased following myocyte injury. In either case, the definitive disease process cannot be identified, only that cellular injury in muscle or liver has occurred. Because serum AST activity cannot differentiate between hepatocellular or myocyte injury, further testing is often required using organ-specific enzymes such as sorbitol dehydrogenase or creatine kinase. Markedly increased serum AST and sorbitol dehydrogenase activity suggest acute or active hepatocellular injury, and markedly increased serum AST with modest to moderate sorbitol dehydrogenase activity suggests chronic hepatic injury or recovery from acute liver injury. Similar conclusions can be drawn using serum AST and creatine kinase activity. As with other cytosolic enzymes, serum AST activity cannot distinguish between

reversible and irreversible cell injury as the cAST can be released by mechanisms involving nonlethal cell membrane blebbing. However, because a major portion of AST is of mitochondrial origin, the magnitude of increase during reversible cell injury is expected to be less than in irreversible injury, but this has yet to be clearly shown.

The diagnostic sensitivity of serum AST activity in horses has been reported as 72% for hepatic necrosis and 100% for hepatic lipidosis (West, 1989). The specificity of serum AST activity was variable, and it decreased with primary gastrointestinal and orthopedic conditions secondary to affects on liver and skeletal muscle, respectively. In cattle, the sensitivity is reported to be 94% for hepatic lipidosis, 100% for leptospirosis, but only 53% for hepatic abcessation, and 46% for fascioliasis (West, 1991). Specificity was again variable depending on the primary condition.

In summary, serum AST determinations are still part of many biochemical profiles because of their relatively high sensitivity for detection of hepatocyte injury and myocyte injury and stability in serum. However, serum AST activity clearly lacks specificity when compared to tissue-specific enzymes, such as sorbitol dehydrogenase and glutamate dehydrogenase for the detection of hepatocyte injury and creatine kinase for the detection of myocyte injury.

C. Sorbitol Dehydrogenase

Sorbitol dehydrogenase (SDH; EC 1.1.1.14), also known as iditol dehydrogenase, catalyzes the following reaction:

$$\text{sorbitol} + \text{NAD}^+ \leftrightarrow \text{fructose} + \text{NADH}$$

The active sites of SDH contain Zn^{2+}. Hence, when EDTA blood collection tubes are used, SDH activity is inhibited. Serum or heparinized plasma can be used for analysis. Sample stability has also been of concern for the use of SDH in diagnostic medicine with bovine serum SDH activity stable for at least 5h at room temperature, 24h refrigerated, and 72h frozen, whereas in equine serum SDH remains stable for 5h at room temperature, 5h refrigerated, and 48h frozen (Horney *et al.*, 1993). In another study, bovine SDH activity was stable for 1 month at −20°C (West, 1991).

SDH is not membrane bound and is located in the cytoplasm of cells. The highest concentration of SDH activity is in liver followed by kidney, but it is also found in most other tissues at much lower amounts (Boyd, 1983; Keller, 1981; Nilkumang and Thornton, 1979). SDH activity is considered liver specific in all species, and there have been no reports of nephrotoxicity causing increased serum SDH activity.

The $T_{1/2}$ of SDH in blood is likely relatively short in all species. Its reported $T_{1/2}$, based on intravenous administration of cat or dog liver extracts, is 3 to 4h for cats and 5h for dogs (Nilkumhang and Thornton, 1979; Zinkl *et al.*, 1971). The $T_{1/2}$ of SDH in swine is reported as 1.6h. In dogs and horses treated with CCl_4, a rapid decrease in SDH activity following peak activity, supports a $T_{1/2}$ of less than 12h. The short circulatory half-life may be due in part to the labile nature of the enzyme, similar to that observed in serum samples *in vitro*. This short $T_{1/2}$ limits to some extent the usefulness of the test, as it is easy to miss peak activity following a hepatic insult, and serum SDH activity may be within reference intervals in chronic hepatic disease.

Because of its short half-life and the labile nature of SDH activity in serum, SDH activity is less favored for detection of hepatic disease in dogs than serum ALT activity. However, there are two occasions when SDH analysis may be useful in dogs. First, in dogs with traumatic muscle injury, where there is increased serum ALT and CK activity, a determination of SDH activity will quickly rule out whether there is concurrent hepatic injury. A second use of SDH activity determination in dogs might be in conjunction with ALT activity to determine if there is persistent hepatocellular injury. If the ALT activity is markedly increased and SDH activity is not, recovery is likely, but if both are markedly elevated, an ongoing insult to the liver is likely present. This sort of interpretation, however, is highly subjective and would require repeated monitoring to be of value.

Serum SDH activity is of greater value than serum AST activity in large animals because of its increased specificity for hepatocellular injury. Marked increases of serum SDH activity occur within hours of experimentally induced hepatic necrosis in horses and cattle (Noonan, 1981). Serum SDH activity has been reported as a value for the detection of hepatic lipidosis, hepatic necrosis, leptospirosis, fascioliasis, and hepatic abscessation in cattle, and detection of hepatic necrosis, lipidosis, and cirrhosis in horses (Cebra *et al.*, 1997; Lechtenberg and Nagaraja, 1991; West, 1989, 1991). Whereas the specificity of serum SDH activity in both cattle and horses with nonhepatic disease is 100%, the sensitivity for detecting hepatic lipidosis, hepatic abscessation, and leptospirosis in cattle was less than 50%; for detecting hepatic cirrhosis and lipidosis in horses it was less than 50%; and for detecting hepatic necrosis in horses it was 76% (West, 1989, 1991). In essentially all conditions evaluated in these two species, serum AST and glutamate dehydrogenase (GDH) activity were more sensitive than SDH activity. However, the specificity of serum AST and GDH was generally less than the specificity of SDH activity. The lower sensitivity may be in part due to the short half-life of the enzyme in circulation; especially in chronic low-grade conditions where large numbers of cells are not injured at any one time, the SDH activity may not exceed the reference range.

D. Glutamate Dehydrogenase

Glutamate dehydrogenase (GDH) (EC 1.4.1.3) is a mitochondrial enzyme that catalyzes the removal of hydrogen from L-glutamate to form the corresponding ketimine acid that then undergoes spontaneous hydrolysis to

2-osoglutarate. The liver has by far the highest concentration of GDH activity (Boyd, 1983; Keller, 1981). Lesser amounts are found in the kidney and small intestine, where the GDH activity is located in the proximal and distal tubular epithelial cells and in the mucosal epithelial cells, respectively. The GDH activity of nonhepatic tissues is relatively small compared to that found in liver, where GDH is concentrated in the central areas of the lobule. In all species, increases in serum GDH activity are considered liver specific. As a result, there has been little or no interest in investigating isoenzymes of GDH in serum for diagnostic purposes. GDH is a zinc-containing enzyme whose activity can be inhibited by EDTA.

Bovine serum GDH activity reported as stable for greater than 1 month at −20°C and was considered more stable than SDH (West, 1991). The *in vivo* half-life in six cows was reported as 14h (Collis *et al.*, 1979). This value is consistent with data from cattle recovering from hepatic injury and suggests that the half-life of serum GDH is greater than SDH but slightly less than the half-life of AST (Braun *et al.*, 1995). The half-life of circulating GDH in dogs is reported as 8h, based on intravenous injection of liver extract (Zinkl *et al.*, 1971).

Serum GDH activity is used most commonly in food animals and horses. Because of its location within mitochondria, GDH should be released only with irreversible cell injury. Following carbon tetrachloride–induced hepatic necrosis in calves and sheep, GDH activity increases but peaks approximately 1 day later than serum AST activity (Boyd, 1962). This may be due to the intramitochondrial location of GDH. Nevertheless, serum GDH activity was shown to significantly increase in acute, subacute, and chronic grass sickness in horses (Marrs *et al.*, 2001). However, serum GDH activity was found to be highly variable in ponies exposed to pyrrolizidine alkaloids, suggesting that GDH activity may only be diagnostically useful in the acute stages of liver injury (Craig *et al.*, 1991). This study found that serum GDH activity was increased with zone 1 hepatocyte necrosis, but it returned to normal reference intervals once all cells in this region were destroyed. These findings are consistent with the reported hepatic location of GDH in humans (Burtis and Ashwood, 1994). Increases in GDH activity of approximately 12-fold and AST activity two-fold were observed 24h following halothane anesthesia in horses, which also may reflect the centrolobular location of GDH activity (Durongphongtom *et al.*, 2006).

As suggested earlier, the sensitivity of GDH activity varies depending on the nature of the disease. For example, in a study of calves with hepatic disease, GDH activity increased in only 60% of the animals (Pearson *et al.*, 1995). Similarly, in cattle, the sensitivity of GDH activity for the detection of hepatic lipidosis, hepatic abscessation, leptospirosis, and fascioliasis was only 28%, 53%, 71%, and 72%, respectively (West, 1991). However, with all categories of hepatic disease described, the sensitivity of GDH activity was higher than SDH activity. The specificity for GDH was slightly less than that of SDH. In a similarly designed study in horses, the sensitivity of GDH activity for detection of hepatic necrosis, hepatic lipidosis, and hepatic cirrhosis was 78%, 86%, and 44%, respectively (West, 1989). The sensitivity was higher than that of SDH and comparable to that observed with serum AST activity. The specificity of GDH in this study was nearly 100%, which was comparable to the specificity of SDH and superior to that of AST activity. In a more recent study of the sensitivity of increased liver enzymes for diagnosis of hepatic disease, GDH showed a sensitivity of 63% (Durham *et al.*, 2003). The determination of GDH activity is best done in conjunction with the determination of other hepatic enzymes and other indicators of hepatic injury or disease.

Serum GDH determinations for diagnosis of hepatic disease in domestic animals have received less attention in the United States than in some other countries. However, the increased stability of the enzyme, longer half-life, and apparent greater sensitivity discussed earlier suggest it may be a more useful test for horses and food-producing animals than the determination of SDH activity.

E. Gamma Glutamyltransferase

Gamma glutamyltransferase (GGT) (EC 2.3.2.2) functions in the gamma glutamyl cycle where it catalyzes the transfer of gamma glutamyl groups from gamma glutamyl peptides such as the tripeptide glutathione to other peptides, amino acids, and water. In conjunction with a peptidase, GGT plays a major role in regulation of intracellular glutathione by hydrolysis of the tripeptide glutathione outside the cell into its three components, which can readily be taken up by the cells and be available for glutathione synthesis as needed within the cell. GGT also functions in the GSH transferase/GGT pathway that cleaves gamma glutamyl moieties from GSH conjugates, which aids in the detoxification of xenobiotics and carcinogens by rendering them more water soluble and readily excreted (Lieberman *et al.*, 1995). This pathway also plays a role in metabolism of mediators such as leukotrienes, hepoxillins, and prostaglandins.

The tissue distribution of GGT has been studied in numerous domestic species with the highest concentration found in kidney, pancreas, intestines, and the mammary glands of dogs, cattle, goats, and sheep but at much lower concentration in mammary gland of horses. Less GGT activity is found in liver, spleen, intestine, lung, and seminal vesicles. The GGT activity per gram of liver tissue is consistently lower than in kidney but varies between species, with the highest liver GGT activity in cattle, horses, sheep, and goats. Serum GGT reference values are consequently higher in those species than in dogs and cats (Braun *et al.*, 1983, 1987; Milne and Doxey, 1985; Rico *et al.*, 1977a, 1977b; Shull and Hornbuckle, 1979).

GGT is a membrane-bound enzyme on the external surface of cells and is bound to the cell membrane via a hydrophobic transmembrane peptide. The cellular location of GGT is of interest as it affects the organ specificity when used as a diagnostic test in serum. GGT is located on the luminal surface of the proximal tubular cells of the kidney where it is shed into urine during tubular injury. In the pancreas, GGT is located on the luminal surface of cells lining the acini and pancreatic ducts. Increases of serum GGT activity are not generally associated with injury to the pancreas or kidney. The location of GGT in liver is of considerable interest because the liver likely contributes most if not all of the serum GGT activity. In liver, GGT activity is primarily associated with the biliary epithelial cells. Early reports suggested GGT was not present on hepatocyte membranes; however, when GSH was used in the fixative solution to prevent fixation-induced inhibition of GGT activity, GGT activity was identified on both the canalicular and sinusoidal surfaces of hepatocytes of rats, although to a considerably lesser extent than on biliary epithelial cells (Lanca and Israel, 1991). GGT mRNA has been detected in hepatocytes of normal rats and rats depleted of glutathione, supporting the presence of GGT on hepatocytes (Moriya *et al.*, 1994). Whether GGT activity is present on the hepatocyte membranes of domestic animals is not documented to our knowledge.

Efforts have been made to determine the presence of isoenzymes of GGT in laboratory animals and humans, but it is likely that only one form of GGT exists. Variations in sialic acid content have been reported and likely explain the ability to separate different fractions of GGT by various means, such as isoelectric focusing (Mortensen and Huseby, 1997). Only one band of GGT activity was found with cellulose acetate electrophoresis of serum from dogs (Milne and Doxey, 1985).

Removal of GGT activity from blood likely involves endocytosis by the asialoglycoprotein or galactose receptor, as purified human liver GGT that has been fractionated by ion exchange chromatography and infused into rats has shown that the slowest rate of clearance is associated with the most sialated forms (Morensen and Huseby, 1997). Clearance can be blocked with asialofetuin, also suggesting that clearance of GGT is via the asialoglycoprotein or galactose receptor on hepatocytes. GGT is apparently eliminated from blood without prior desialylation via exposed galactose units binding with low affinity to the receptor. The rate of removal of each molecule may be related to the number of available galactose molecules not blocked by sialic acid.

The half-life of GGT activity in blood is not known, as there have been no definitive studies done in domestic animals to our knowledge. However, in dogs, serum GGT and ALP activity increase and decrease in parallel during cholestasis, suggesting that in dogs the half-life of GGT may be similar to the approximate 3-day half-life of liver ALP. A half-life of 3 days is also suggested for GGT activity in horses (Barton and Morris, 1998). In any event, the half-life of liver GGT activity is of sufficient length that increases are maintained throughout the disease process and diagnostic sensitivity is not lost because of a rapid return of the GGT activity to reference ranges.

Conditions such as hepatic necrosis and reversible hepatocellular injury induced by CCl_4, dibromobenzene, chloroform toxicity, and trauma result in minimal or no changes in serum GGT activity in dogs (Barakat and Ford, 1988; Guelfi *et al.*, 1982; Noonan and Meyer, 1979). However, some increase in serum GGT activity is observed with chloroform toxicity in horses, although no increase is observed in calves and sheep (Barakat and Ford, 1988). Following administration of CCl_4 to ponies, a four-fold increase in serum GGT activity was observed, which persisted up to 10 days with no increase in serum ALP activity (Hoffmann *et al.*, 1987). The minimal increase in GGT activity in serum following hepatocellular injury is likely due to the fact that GGT in liver is primarily associated with biliary epithelial cells and the absence of significant increase of bile acids to release the hydrophobic transmembrane attachment to the cell membrane. Increases in serum GGT are most often observed with cholestasis and conditions resulting in biliary hyperplasia in all species, as observed in experimentally induced cholestasis (DeNovo and Prasse, 1983; Hoffmann *et al.*, 1987; Shull and Hornbuckle, 1979; Spano *et al.*, 1983).

Serum GGT activity is an especially useful clinical indicator of cholestasis in horses and cattle because of relatively high liver GGT activity compared to dogs and cats. Serum GGT activity in horses and cattle has relatively higher sensitivity for the identification of cholestatic disorders than serum ALP activity. Only a two-fold increase of serum ALP activity was observed with cholestasis, whereas serum GGT activity rose nine-fold in horses (Hoffmann *et al.*, 1987). Although the magnitude of increase is greatest in cholestasis, serum GGT activity can be used in large animals as a screening test for generalized hepatic disease as well. In a retrospective study of 50 cases of hepatic disease in horses, of the serum chemistry parameters evaluated only serum GGT activity increased in all cases (McGorum *et al.*, 1999). Similarly, serum GGT activity showed 75% sensitivity and 90% specificity for detecting subclinical liver disease in horses exposed to pyrrolizidine alkaloids, whereas serum ALP activity showed only 58% sensitivity (Curran *et al.*, 1996). Serum GGT activity was shown to be the most sensitive serum enzyme for detection of hepatic injury secondary to proximal enteritis in horses (Davis *et al.*, 2003). Increases in serum GGT activity in numerous cases of plant-related hepatotoxicity in both cattle and horses have also been reported (Craig *et al.*, 1991; Curran *et al.*, 1996; Mendel *et al.*, 1988).

Serum GGT activity in cats and dogs is often interpreted in conjunction with serum ALP activity. The suggested advantage of serum GGT activity determination over serum ALP activity in dogs is increased specificity, as GGT activity is derived solely from liver whereas serum ALP activity is derived from bone and liver as well as the

canine corticosteroid induced isoenzyme of ALP. A study of 270 dogs with suspected hepatic disease had the results of hepatic biopsies compared to serum hepatic enzyme results (Center *et al.*, 1992). Hepatic disease was confirmed by histology in 207 of the 270 cases. The sensitivity of serum ALP and GGT activity to detect histologically confirmed hepatic disease was 85% and 46%, respectively. However, the specificity of serum ALP was only 51%, whereas the specificity of serum GGT was 87%. In a study of 69 cats with suspected hepatic disease, of which 54 had histological evidence of hepatic disease, the overall sensitivity of serum ALP and GGT activity was 48% and 83%, respectively (Center *et al.*, 1886). Serum GGT activity was more sensitive than serum ALP activity for detection of extrahepatic cholestasis, cholangiohepatitis, and cirrhosis. In contrast, the percentage increase of serum ALP activity was greater than serum GGT activity in 11 of 15 cats with hepatic lipidosis. This is likely because hepatic lipidosis is a form of intracellular cholestasis, ALP is primarily associated with hepatocytes, and GGT is primarily associated with the biliary epithelial cells.

Several laboratory animal models have been used to study the mechanism of increase of serum GGT activity. These include bile duct ligation, treatment of the animals with alpha naphthyl isothiocyanate (ANIT) to cause necrosis of biliary epithelial cells, and a choledochocaval shunt (CCS) model that shunts bile from the common bile duct directly into the anterior vena cava (Bulle *et al.*, 1990; Hardison *et al.*, 1983; Kryszewski *et al.*, 1973; Leonard *et al.*, 1984; Putzki *et al.*, 1989). In the bile duct ligation model, there is an initial increase of serum GGT activity and a decrease in liver tissue GGT activity. The rise in serum GGT activity is associated with a parallel increase in serum bile acids, and it is almost certain that the bile acids alone or in conjunction with a hydrolytic enzyme facilitate solubilization or release of GGT from the membrane. With persistence of cholestasis, there is a proliferation of biliary epithelial cells and an increase in bile duct volume in the liver, which is paralleled by an increase in GGT activity in the liver and a second phase of increase in serum GGT activity. In the ANIT model, chronic treatment with ANIT results in repeated necrosis of the biliary epithelial cells and bile duct proliferation. As the bile duct mass increases, there is a persistent increase in serum GGT activity. These two models both support the concept that there is an initial release of GGT activity from injury to biliary epithelial cells and retention of bile, the magnitude of which is determined in part by whether the species has low or high tissue GGT activity. Persistently increased serum GGT activity may indicate biliary hyperplasia that provides an increased source of GGT for release. Although not confirmed experimentally, clinical observations suggest that domestic animals with markedly increased serum GGT activity often have biliary hyperplasia.

The CCS model in rats is unique in that it provides persistently increased liver and blood bile acids and increased bile flow, but without increased biliary pressure (Hardison *et al.*, 1983). In this model, within 24h, serum GGT activity nearly equals that seen with experimental bile duct ligation, suggesting that bile acids or other bile constituents mediate the release of GGT into serum. Moreover, increased biliary pressure and regurgitation of GGT through tight junctions are not necessary for the observation of increased serum GGT activity (Putzki *et al.*, 1989). The actual pathway traveled by GGT from the biliary epithelial cells to blood is unclear. It is also unclear if the amount of GGT on the sinusoidal surfaces of hepatocytes is adequate to account for the magnitude of increase of serum GGT activity observed in any of the three models described previously. A mechanism of release from hepatocytes analogous to that described for ALP, but with a different hydrolytic enzyme, might be considered.

Increased serum GGT activity in calves led to the recognition that species that produce large amounts of GGT activity in mammary glands may excrete or release GGT into colostrum. Colostral GGT is taken up by passive transfer in the newborn and serves as an easy, inexpensive, and automated test for successful passive transfer (Braun *et al.*, 1982; Perino *et al.*, 1993; Wilson *et al.*, 1999; Zanker *et al.*, 2001). The difference between presuckling and postsuckling serum GGT activity can be more than a 100 fold in calves (Braun *et al.*, 1982). This increase correlates well enough with increased serum immunoglobulin to allow serum GGT activity to substitute as a test of adequate immunoglobulin transfer (Perino *et al.*, 1993). However, GGT activity decreases steadily for the first 18 to 20 days, so the ability of serum GGT activity to accurately conclude failure of passive transfer is reduced after approximately 8 days (Wilson *et al.*, 1999). In a review of failure of passive transfer in calves, the authors concluded that the loss of correlation between serum GGT activity and immunoglobulin concentrations after the first few days of suckling negates the value of the test, and its use should be discouraged in cattle (Weaver *et al.*, 2000). Serum GGT activity also indicates passive transfer of immunoglobulins in goats, but in foals there is no difference in pre- and postsuckling serum GGT activity (Braun *et al.*, 1984; Patterson and Brown, 1986). In canine pups postsuckling serum GGT activity can reach up to 100 times the upper interval because of high colostral GGT activity (Center *et al.*, 1991).

Although renal tissue has the highest concentration of GGT activity per gram of tissue in all species studied, there is no evidence supporting the presence of renal tubular GGT in blood. This is likely the result of the location of GGT on the luminal surface of the tubular epithelial cells and possibly rapid clearance from blood by the galactose receptor on hepatocytes. However, the location of GGT on the tubular epithelial cells means that the enzyme is readily shed into urine and can indicate renal tubular cell injury. Because of the variability of urine volume, urine GGT activity must be normalized to urine creatinine concentration using a GGT activity:creatinine ratio. Numerous reports show that the urine GGT activity:creatinine ratio in dogs is a sensitive

and early indicator of chemical-induced nephrotoxicity with several compounds including maleic acid, aminoglycosides, and cyclosporine (Clemo, 1998; Graur *et al.*, 1995; Nahas *et al.*, 1997; Rivers *et al.*, 1996). Furthermore, both 24h excretion of GGT and the GGT activity:creatinine ratio of single urine samples have proven useful in detecting tubular injury in dogs (Gosset *et al.*, 1987; Rivers *et al.*, 1996). Although there is no apparent circadian variation (Uechi *et al.*, 1994), it has been suggested that the within-day variation of the GGT activity:creatinine ratio limits its usefulness (Gosset *et al.*, 1987). As in dogs, the urine GGT activity: creatinine ratio in horses and cattle has proven of value in detecting nephrotoxicity (Meyer *et al.*, 2005; Rossier *et al.*, 1995; Ulutas and Sahal, 2005). The magnitude in all species is greatest in the acute phase of injury after which the GGT activity in urine drops rapidly during the chronic stage. These studies support the use of urine GGT activity as a screening test of potentially nephrotoxic drug exposure. Evaluation of more than one enzyme and at multiple time points is required to properly evaluate for nephrotoxicity. It should also be noted that the urinary GGT activity:creatinine ratio is extremely sensitive and increases can be observed with no clinical signs of nephrotoxicity or azotemia (van der Harst *et al.*, 2005). For example, normal horses and horses with pneumonia who are both treated with gentamycin show significant increases in the urinary GGT activity:creatinine ratio but retain normal serum creatinine concentrations (Rossier *et al.*, 1995).

Dogs treated with glucocorticoids or dogs with hyperadrenocorticism generally have increased serum GGT activity (Abraham *et al.*, 2005; DeNovo and Prasse, 1983; Solter *et al.*, 1994). However, the ratio of serum GGT-to-liver tissue GGT activity in glucocorticoid-treated dogs is similar to that of untreated controls, suggesting that increased serum GGT activity is a result of increased liver tissue GGT and increased synthesis of the enzyme (Solter *et al.*, 1994).

F. Alkaline Phosphatase

The alkaline phosphatases (ALP) (EC 3.1.3.1) have been relatively well studied. They have been shown to hydrolyze a range of monophosphates or pyrophosphates at alkaline pH, as well as at physiological pH although at a lesser rate. There are likely several *in vivo* functions of ALP. A role for ALP in bone mineralization had been speculated since the 1920s and was first substantiated in human beings who suffer from hypophosphatasemia, which results from several different mutations that lead to a nonactive ALP and markedly defective bone mineralization in children (Mumm *et al.*, 2002; Whyte *et al.*, 1996). The role of ALP in bone mineralization has been subsequently confirmed in numerous studies using bone ALP gene knockout mice to create hypophosphatasemia, resulting in the impaired mineralization of bone (Anderson *et al.*, 2004). One specific function of ALP in bone is the hydrolysis of pyrophosphate, which is a potent inhibitor of mineralization, thus allowing mineralization to proceed. Other suggested functions of ALP are the *in vivo* dephosphorylation of bacterial endotoxin, which diminishes its toxic effects (Poelstra *et al.*, 1997; van Veen *et al.*, 2005; Xu *et al.*, 2002), and as a rate-limiting step in intestinal fat absorption (Narisawa *et al.*, 2003).

Although many tissues or cell types have some ALP activity, cells from liver, bone, kidney, intestinal mucosa, and placenta have the greatest ALP activity on a per gram of tissue basis with intestinal mucosa having the most (Clampitt and Hart, 1978; Nagode *et al.*, 1969). Serum ALP activity, however, is not generally a reflection of tissue concentration. In most domestic species, intestinal ALP (IALP) is not found in serum, and liver, which has relatively low ALP activity, contributes over half the serum activity.

The alkaline phosphatases are ectoenzymes attached to the cell membrane via a hydrophobic phosphatidylinositol-glycan (PIG) anchor. Extraction of ALP from tissue requires butanol, bile salts, or detergent in the presence of an acidic buffer to allow the hydrolytic activity of endogenous phosphatidylinositol-specific phospholipase D (PIPLD) to cleave the ALP PIG anchor (Low, 1987; Solter and Hoffmann, 1995; Solter *et al.*, 1997). In intestine, especially the small intestines, ALP is located on the tips of villi of the enterocytes (Watanabe and Fishman, 1964), whereas in kidney the ALP is located on the luminal surface of the proximal tubular epithelial cells (Wachstein and Bradshaw, 1965). Although the ALP in bone is well recognized to be located on the osteoblasts and the matrix vesicles derived from osteoblasts, staining liver for ALP activity reveals that most of the ALP is found on the bile canalicular surface of hepatocytes in normal animals although this may vary with species. During conditions in which hepatic ALP is increased, sinusoidal and lateral surfaces of the hepatocytes also show substantial ALP activity (Ogawa *et al.*, 1990; Sanecki *et al.*, 1987; Solter *et al.*, 1997). Because many newly synthesized bile canalicular (apical) membrane proteins traffic from the Golgi to the sinusoidal (basolateral) membrane before their transcytosis to the bile canalicular surface of hepatocytes, the presence of ALP on sinusoidal membrane during disease conditions likely represents increased synthesis of ALP rather than a difference in enzyme trafficking (Kipp and Arias, 2000; Maurice *et al.*, 1994; Zegers and Hoekstra, 1998). ALP activity is presumably present on the sinusoidal membrane at all times, but because of the short time in residence before transcytosis to the canalicular membrane and relatively small amount of ALP, the insensitivity of enzymatic staining and light microscopy make it difficult to visualize the small fraction of ALP present.

In the human, chimpanzee, and orangutan, at least three genes express ALP and are named for the primary organ of their expression. These are the intestinal ALP, placental ALP, and the tissue-nonspecific or bone/liver/kidney ALP (Goldstein *et al.*, 1982). In humans, a fourth gene is

expressed in the germ cell that is similar to the placental isoenzyme (Millan and Manes, 1988). In domestic species, there are two genes, namely the intestinal gene and the tissue-nonspecific ALP gene that is expressed in bone, liver, kidney, and placenta and to a lesser extent in some other tissues. Although true ALP isoenzymes result from specific genes, posttranslational modification (primarily varied glycosylation) is generally organ specific and results in additional isoforms. For example, liver ALP and bone ALP are the products of the same gene but are glycosylated differently, resulting in isoforms or isoenzymes that can be differentiated by a number of techniques. True ALP isoenzymes expressed by different genes differ enzymatically, biochemically, and antigenically, and they respond to inhibitors such as L-phenylalanine and levamisole in a different manner; isoforms of ALP tend to behave enzymatically and antigenically in a similar manner and are equally inhibited by L-phenylalanine and levamisole, although there are some exceptions. Although these isoforms are not true isoenzymes, historical and clinical precedence has resulted in these isoforms also being referred to as isoenzymes.

Liver ALP is highly glycosylated with terminal sialic acid residues, which results in a marked anodal migration on electrophoresis. It is generally inhibited by greater than 95% with levamisole but is relatively insensitive to L-phenylalanine inhibition. LALP is only moderately sensitive to heat inhibition at 56°C.

Bone ALP is a product of the TNS ALP gene, as is the liver ALP, but has a slightly slower anodal electrophoretic migration and is more sensitive to heat inhibition (Hoffmann and Dorner, 1975). The bone ALP isoform is more susceptible to precipitation by wheat germ lectin (WGL) than is the LALP as a result of differing glycosylation (Hank *et al.*, 1993; Kidney and Jackson, 1988; Sanecki *et al.*, 1993). Antibodies produced against liver ALP or bone ALP generally cross-react with the other isoforms from the same gene. However, there are commercially available immunoassays for human BALP that have been validated for use in canine, feline, and equine BALP analysis (Allen *et al.*, 2000; Delaurier *et al.*, 2002; Jackson *et al.*, 1996).

Intestinal ALP (IALP) is a product of the intestinal ALP gene, and it is distinctly different from BALP and LALP. IALP is more heat stable and more readily inhibited by L-phenylalanine, but it shows less than 10% inhibition with levamisole at concentrations adequate to inhibit greater than 95% of BALP and LALP (Eckersal *et al.*, 1986; Hoffmann *et al.*, 1987; Nagode *et al.*, 1969). IALP is generally thought of as an asialoglycoprotein; however, some identifiable sialic acid is present on canine IALP (Sanecki *et al.*, 1990). The reduced number of sialic acid residues is responsible for the fact that IALP has minimal anodal migration on agarose or cellulose acetate electrophoresis. Typically, IALP produces a broad band rather than a sharp narrow band when compared to LALP and BALP.

Alkaline phosphatases in other organs, such as kidney and placenta, are usually a product of the TNS gene. These alkaline phosphatases are not fully sialated and have less anodal migration on electrophoresis than BALP and LALP. However, the ALP extracted from horse kidney is likely a product of the intestinal gene as it is similar to IALP in levamisole inhibition and antigenic recognition by anti-equine IALP antibodies (Hoffmann *et al.*, 1983a).

The so-called corticosteroid-induced isoenzyme of ALP (CALP) has been identified in dogs treated with corticosteroids, dogs with hyperadrenocorticism, or in some older dogs with chronic disease or possibly chronic stress (Sanecki *et al.*, 1990; Solter *et al.*, 1993; Wellman *et al.*, 1982). This enzyme has not been identified in any other species; however, it is similar to one of the two forms of ALP expressed in the liver of rabbits (Noguchi *et al.*, 1987). CALP is a highly glycosylated isoform of IALP, produced in the liver from the intestinal gene. It has markedly greater anodal migration than IALP on cellulose acetate electrophoresis, but it is antigenically similar to IALP with both monoclonal and polyclonal antibodies and responds to levamisole and L-phenylalanine inhibition in a similar manner. It also has the identical N-terminal amino acid sequence to IALP but has markedly higher concentrations of N-acetylglucosamine, mannose, galactose, and sialic acid. Hence, CALP differs from IALP only in glycosylation. Northern blot analysis with a 1338bp cloned segment of the CALP gene, which is identical to the IALP sequence, has confirmed the liver as the origin of CALP production (Wiedmeyer *et al.*, 2002a, 2002b).

The epididymal and seminiferous tubular epithelium of the dog is rich in ALP activity. This ALP is a product of the TNS gene, but it is glycosylated differently than either BALP or LALP based on electrophoretic migration (Kutzler *et al.*, 2003). ALP activity is also present in epididymal fluid from horses (Gobella *et al.*, 2002).

Serum alkaline phosphatase isoenzyme analyses have been conducted in many species with numerous publications describing techniques and diagnostic value of the analyses. The techniques described include electrophoresis on a number of mediums, isoelectric focusing, heat inhibition, chemical inhibition, immunochemistry, and selective lectin binding. Although electrophoresis is still in use, a combination of inhibition with levamisole and selective precipitation of BALP with wheat germ lectin is an effective means to quantitatively evaluate BALP, LALP, and CALP in dog serum; BALP, LALP, and IALP in rat serum; and BALP and LALP in horse, cat, and cow serum (Hank *et al.*, 1993; Hoffman *et al.*, 1988; Hoffmann *et al.*, 1994; Sanecki *et al.*, 1993). Very likely, the combination of levamisole inhibition and wheat germ lectin precipitation will be compatible with many other species that have not yet been tried. Immunoassays for BALP in canine, feline, and equine serum have also been used (Allen *et al.*, 2000; Delaurier *et al.*, 2002; Delaurier *et al.*, 2004; Jackson *et al.*, 1996; Price *et al.*, 1995).

Studies of the blood half-lives of the various alkaline phosphatase isoenzymes are of interest in that they help to explain the magnitude and time of increase of serum ALP activity following insult to an organ. Unlike in most species, IALP is always identified in rat serum and is often identified in human serum. It has not been observed in serum from dogs, cats, horses, and cattle (Hoffmann and Dorner, 1975; Hoffmann *et al.*, 1983b). The clearance of intravenously injected IALP in dogs has a half-life of shorter than 5.4min, whereas the half-life of phase 2 of rat IALP is 54.1 to 68.3min (Hoffmann and Dorner, 1977; Young *et al.*, 1984). The rate of clearance of IALP from dog blood can be inhibited by simultaneous injection of galactose-terminated bovine serum albumin, supporting the theory that IALP is cleared by hepatocyte asialoglycoprotein or galactose receptors (Kuhlenschmidt *et al.*, 1991). However, the clearance of IALP from rat blood is not blocked by asialofetuin but is blocked by glucosamine-terminated bovine serum albumin, suggesting that IALP in rats is cleared by mannose/N-acetylglucosamine-specific receptors on hepatic reticuloendothelial cells (Young *et al.*, 1984). The presence of IALP in rat serum and not dog serum may be explained in part by the differences in IALP serum half-lives between the two species. However, the description in rats of a surfactant-like secretory particle containing ALP may offer a second mechanism for increased IALP in the blood of rats (Eliakim *et al.*, 1991).

The half-life of IALP in cats following intravenous injection is approximately 4min, and in horses it is approximately 8min, which likely explains in part the absence of IALP in the serum of these two species (Hoffmann *et al.*, 1977, 1983b).

The half-life of intravenously injected LALP and CALP into dogs is approximately 3 days (Hoffmann and Dorner, 1977). The removal of the ALP under normal conditions is not known but may involve the slow hydrolysis of sialic acid from the carbohydrate portion of the molecule allowing recognition and uptake by the galactose receptor on hepatocytes. The half-life of intravenously injected cat LALP is approximately 5.8h (Hoffmann *et al.*, 1977). Likewise canine LALP intravenously injected into cats has a half-life of approximately 5h. Therefore, the difference in half-life of dog LALP and cat LALP (3 days versus 5h) is likely a species difference in removal of the enzyme and not a difference in the enzyme. The mechanism of removal of ALP from the blood of cats is not known.

The blood half-life of BALP is not known, but has an electrophoretic migration near that of LALP from dogs, cats, and horses, suggesting that a full compliment of sialic acid is present resulting in a half-life similar to LALP.

The half-life of renal and placental ALP from dogs is less than 6min (Hoffmann and Dorner, 1977). They have minimal anodal migration on electrophoresis, suggesting that they have little or no sialic acid and are likely removed by the asialoglycoprotein or galactose receptor on hepatocytes.

Approximate percentages of BALP and LALP in adult dogs are 30% and 70%, respectively, with an increasing percentage of LALP in older age, whereas in adult horses, there is approximately 20% BALP and 80% LALP (Allen *et al.*, 2000; Hank *et al.*, 1993).

Cholestasis is the most common cause of significant increases in serum LALP in most species. Experimentally induced cholestasis in dogs, generally by bile duct ligation, results in marked increases in serum LALP activity beginning after approximately 24h and reaching a maximum of 30 to 40 times normal serum ALP activity at 4 to 7 days (Guelfi *et al.*, 1982; Shull and Hornbuckle, 1979). A similar response time of ALP increase was seen in two cats following bile duct ligation, but the magnitude of the increase was approximately 10% of that seen in the dog (Hoffmann *et al.*, 1978). This marked difference in the magnitude of increase between the two species is in part due to the 12-fold shorter serum half-life of LALP in cats as compared to dogs. The marked increase of serum LALP in cholestasis is paralleled by a marked increase in LALP activity in the liver as well. Numerous studies in rats have shown that this increase results from increased synthesis, regulated at the level of transcription or translation (Kaplan *et al.*, 1983; Schlaeger, 1975).

For many years, the mechanism of increased LALP in blood was thought to involve regurgitation from bile through tight junctions into blood. Although there is evidence of disruptive changes within tight junctions during cholestasis (Boyer, 1983), it is doubtful if these alterations permit passage of macromolecules the size of ALP (Debroe *et al.*, 1985). Studies using a chloledochocaval shunt model show that within 12h of shunting of bile or taurocholic acid into blood, there is a marked induction of ALP synthesis and appearance of ALP on the basolateral membranes and a parallel increase in serum ALP (Ogawa *et al.*, 1990). This occurs in the absence of increased biliary pressure and any evidence of alterations in tight junctions (Toyota *et al.*, 1983). Bile acids appear to participate in both induction and release of ALP into serum.

A second model to study the mechanism of release of ALP from liver into serum utilizes the observation that dogs acutely treated with high doses of prednisone first induce LALP synthesis in the absence of cholestasis, as evidenced by a lack of increase of serum or hepatic tissue bile acids (Solter *et al.*, 1994, 1997). This model results in the appearance of easily identified LALP activity on the basolateral surface and marked increases of serum LALP activity. The appearance of LALP activity on the basolateral membrane is likely a transient appearance of the protein before it is sorted to the apical or bile canalicular membrane as part of the normal trafficking of bile canalicular membrane proteins (Bartles *et al.*, 1987; Maurice *et al.*, 1994). The ALP on the sinusoidal or basolateral membrane is susceptible to release into blood or hepatic lymph. However, in contrast to the choledochocaval shunt model, where bile acid concentrations

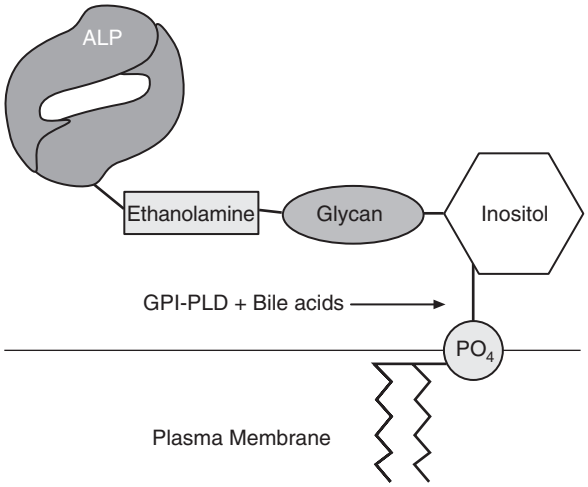

FIGURE 12-2 The glycosylphosphatidylinositol membrane anchor of alkaline phosphatase and the site of release of ALP from the membrane anchor by phosphatidyl inositol-specific phospholipase D, which is facilitated by bile acids.

are increased in both blood and hepatic tissue and facilitate the release of ALP from its membrane attachment, serum and tissue bile acids are not increased in the prednisone-treated model. However, within 2 to 4h following cholecystokinin (CCK) administration to initiate the enterohepatic circulation and a flux of bile acids through the portal vein and liver, there is a significant increase in the serum LALP activity (Solter *et al.*, 1997). This provides support for a bile acid-facilitated release of ALP from hepatocyte sinusoidal membranes, most likely by activation of PIPLD and cleavage of the phosphatidylinositol anchor (Fig. 12-2). Whether the bile acids actually activate the PIPLD or simply allow accessibility to the PI anchor of ALP is unclear.

The marked increase of serum CALP and presence of CALP on the sinusoidal membrane of dogs with spontaneous hyperadrenocorticism or chronically treated with glucocorticoids and an absence of cholestasis provides additional support to the conclusion that the mechanism of serum ALP increase from liver does not require regurgitation. Because CALP is attached to the membrane by the same PI anchor as LALP, it is released by PIPLD during flux of bile acids through the liver (Solter and Hoffmann, 1995).

Although cholestasis is the most recognized cause of increased LALP activity, increases in serum LALP activity are also observed in steroid hepatopathy in dogs, especially early in the condition (Solter *et al.*, 1994, 1997; Syakalima *et al.*, 1997). Mild to moderate increases in serum LALP are also observed in dogs with other hepatic diseases and secondary to primary conditions ranging from enteritis to pancreatitis. In cats, increased serum LALP activity is most commonly associated with cholestasis, cholangiohepatitis, hepatic lipidosis, and hyperthyroidism. Increase in serum LALP activity is the first observed laboratory abnormality observed in cats with experimentally induced hepatic lipidosis, occurring before the onset of hyperbilirubinemia (Biourge *et al.*, 1994). Although the increased serum ALP activity in hyperthyroid cats is attributed to both LALP and BALP activity, LALP activity is the most consistently increased isoenzyme and makes up the major portion of the ALP activity (Archer and Taylor, 1996; Foster and Thoday, 2000).

An increase in serum BALP activity is generally associated with increased osteoblastic activity and has been increasingly evaluated as a marker of bone formation in several domestic species (Allen *et al.*, 1998; DeLaurier *et al.*, 2002; Price *et al.*, 2001). Increased serum BALP activity is observed in all young animals and is up to 10-fold greater in puppies than adult dogs (Allen *et al.*, 2000; Sanecki *et al.*, 1993). In newborn foals, serum BALP activity is nearly 100-fold greater than in adult serum, but it drops precipitously during the first 3 weeks after birth and then more gradually over the next 2 to 4 years (Hank *et al.*, 1993; Price *et al.*, 1995). Increased serum BALP activity can be observed in dogs with hyperparathyroidism, renal disease, and during fracture healing. Peak serum total ALP activity (presumably BALP) is reported to occur in dogs at approximately 10 days after surgical fixation of long bone fractures and returns to normal within 2 months with normal healing but can remain increased 3 to 5 months with delayed union (Komneuou *et al.*, 2005). This study reported no increase in serum ALP activity in dogs that had nonunions and suggested that monitoring serum ALP activity may be a useful tool for identifying dogs at risk for progressing to nonunion. Familial hyperphosphatasemia with increased BALP activity has been reported in a family of Siberian huskies (Lawler *et al.*, 1996).

By far the highest values of serum BALP have been observed in selected cases of canine osteosarcoma, but this is not consistently observed. Hence, serum BALP activity has poor diagnostic sensitivity for osteosarcoma. However, serum BALP is of prognostic value as increased preoperative serum BALP activity is associated with shorter survival time and disease-free (metastasis) intervals following surgery and chemotherapy (Ehrhart *et al.*, 1998; Garzotto *et al.*, 2000; Kirpensteijn *et al.*, 2002). Furthermore, whereas a drop in serum BALP activity is often noted following surgical removal of the primary tumor, persistence of increased serum BALP activity following surgery is associated with a shorter survival time. Dogs with increased serum total ALP activity did not benefit from additional chemotherapy; however, dogs with serum ALP activity in the normal range did benefit (Kirpensteijn *et al.*, 2002). The absence of increased serum BALP activity in a majority of dogs with osteosarcoma presents an intriguing question. Cells obtained via fine needle aspirates of all canine osteosarcomas stain positive for ALP activity (Barger *et al.*, 2005). The mechanism that allows some of these patients to have increased serum BALP activity but not others is unclear but does not appear to relate to tumor mass (Ehrhart *et al.*, 1998).

Serum CALP activity is a good screening test for hyperadrenocorticism because of its high sensitivity for detecting increased cortisol secretion over time. It is not a diagnostic test because of its low specificity for the diagnosis of hyperadrenocorticism (Solter *et al.*, 1993; Teske *et al.*, 1989). Increased serum CALP activity observed in animals with disease processes other than hyperadrenocorticism is consistent with a presumed increase in cortisol secretion as indicated by reportedly abnormal low-dose dexamethasone suppression tests or ACTH stimulation tests in dogs with nonadrenal disease (Kaplan *et al.*, 1995).

Hypophosphatasemia is uncommon in domestic species, although it is observed in humans with the genetic mutations to the TNS ALP gene. Similar genetic mutations have not been reported in domestic species to our knowledge, but reduced alkaline phosphatase activity has been associated with zinc deficiency in cattle (Machen *et al.*, 1996; Sharma and Joshi, 2005).

Significant amounts of ALP activity have been found in seminal plasma from numerous species. Low seminal ALP activity has been proposed as a means of differentiating partial or complete blockage of the epididymal and deferent ducts from testicular azoospermia and oligospermia (Stornelli *et al.*, 2003; Turner and McDonnell, 2003).

The serum activity of several diagnostic enzymes appears to be induced by various pharmaceutical agents. Anecdotally, serum ALP is the enzyme most often increased in drug safety trials. There are likely many drugs that stimulate some increase in liver ALP activity; however, an incomplete understanding of the factors regulating ALP synthesis in many cases makes it difficult to determine if increased ALP activity is due to primary induction of synthesis, a secondary response of the liver to drug-mediated cytokines, or drug-induced hepatic injury.

Glucocorticoids are well-recognized inducers of ALP activity in dogs. The initial response to treatment of dogs with high doses of glucocorticoids is an increase of LALP activity in the liver and serum (Solter *et al.*, 1994). This is followed after approximately 5 to 7 days with the appearance of the CALP isoenzyme. Interestingly, the magnitude of the increase in CALP activity in the experimental treatment of normal dogs has never been shown to reach the magnitude of CALP activity in many clinical patients. This suggests that the induction of CALP synthesis may result from glucocorticoids acting in a synergistic manner with other cytokines that are increased in various pathological conditions. Glucocorticoids do not have the same ability to induce ALP activity in cats and horses (Ellison and Jacobs, 1990; Hoffmann *et al.*, 1978).

Markedly increased serum CALP activity has also been observed in vacuolar hepatopathy of Scottish terriers (Twedt, 2004). Although the hepatopathy is similar to steroid hepatopathy, and all of the dogs have the increased CALP activity, they have normal serum GGT activity, ALT activity, and bilirubin concentration, along with normal ACTH stimulation and low-dose dexamethasone suppression tests. Preliminary evidence indicates that these dogs have increased serum 17-hydroxyprogesterone or progesterone concentrations, suggesting that other adrenal hormones may result in increased CALP activity and vacuolar hepatopathy.

Phenobarbital is another drug routinely associated with increased serum ALP activity. It is not known whether this occurs as a result of enzyme induction or hepatotoxicity. However, increased serum ALP activity is considered a frequent observation in epileptic dogs treated with phenobarbital, whereas hepatotoxicity is an infrequent observation (Foster *et al.*, 2000; Muller *et al.*, 2000). In a retrospective study of 78 dogs treated with phenobarbital for epilepsy, 19 had serum ALP activity greater than two-fold the upper limit of the reference interval, with 11 having predominantly CALP activity and 7 having predominantly LALP activity (Gaskill *et al.*, 2004). However, pretreatment serum ALP activity was not reported. In a prospective study of 23 otherwise healthy epileptic dogs treated with phenobarbital, 8 had ALP activity greater than the reference range and 3 had ALP activity two-fold greater than the upper limit of the reference range (Gaskill *et al.*, 2004). Two of these 3 dogs had predominantly the CALP isoenzyme, and 1 the LALP isoenzyme. In a subsequent study of 11 phenobarbital-treated dogs with increased serum ALP activity, the predominant isoenzyme in 6 of the dogs was CALP and in 5 was LALP (Gaskill *et al.*, 2005). Histopathological evaluation of liver biopsies from these 11 dogs revealed more severe and frequent abnormalities than in controls but no increase of ALP activity in liver tissue. Focal areas of injury may have enhanced the release of ALP from the membranes and an increase of serum ALP. These studies, however, do not explain why CALP is present in a few phenobarbital-treated dogs but not others, with or without evidence of hepatic disease.

G. Lipase

The lipase (EC 3.1.1.3) that is of interest in the diagnosis of pancreatic disease is a low-molecular-weight protein of approximately 42kDa that hydrolyzes triglycerides at the 1 and 3 positions, leaving a monoglyceride. Pancreatic lipase binds at the lipid-water interface emulsified in the presence of bile salts, colipase, and calcium. The original pancreatic lipase assay described used an incubation medium consisting of an emulsion of long chain triglycerides in a buffer containing glycocholic acid and colipase. Such assays minimize nonpancreatic lipase and esterase activity but do not completely inhibit it, which tends to broaden the diagnostic reference intervals. This decreases the sensitivity of total serum lipase activity to detect pancreatic disease and decreases specificity because of an increased false-positive rate. To further illustrate the phenomenon of nonpancreatic lipase in serum, serum lipase activity has been determined in two conditions in which serum lipase activity would be

anticipated to be low or nonexistent. First, the serum lipase activity of pancreatectomized dogs remains near 50% of the presurgery activity, pointing to the presence of nonpancreatic lipase and strongly suggesting that the reference interval of serum lipase activity is broadened by nonpancreatic sources (Simpson *et al.*, 1991). Second, in a study of dogs with exocrine pancreatic insufficiency (EPI), there was no difference in the mean serum lipase activity between the dogs with EPI and the control dogs, suggesting again that a significant portion of normal serum lipase is of nonpancreatic origin (Steiner *et al.*, 2006). Lipase assays that are likely specific for pancreatic lipase include a canine immunoreactive pancreatic lipase assay (cPLI) (Steiner *et al.*, 2003). Using immunohistochemistry, it was demonstrated that test antibody recognizes lipase in pancreatic acinar cells and no other tissues (Steiner *et al.*, 2002).

Although there are nonpancreatic lipases and esterases in serum, there is apparently only one gene for canine pancreatic lipase (Mickel *et al.*, 1989). Likewise, only one protein with a molecular weight of approximately 50.7kDa was recovered from dog pancreas by affinity purification of tissue lipase (Steiner and Williams, 2002), suggesting that isoenzymes of pancreatic lipase do not exist.

The blood half-life of lipase activity from pancreatic juice or extracts in dogs is 1 to 3 hours (Hayakawa *et al.*, 1992; Hudson and Strombeck, 1978). The half-life was found to increase from 2 to 11 hours following nephrectomy, suggesting that there is renal clearance or inactivation of lipase (Hudson and Strombeck, 1978). Only a small amount of lipase activity is identified in urine, and it is assumed the renal tubular cells metabolize the filtered lipase.

Activity assays for serum lipase have been used classically for the diagnosis of acute pancreatitis in dogs. Typically, an approximately 25-fold increase in serum lipase activity is observed within 2 to 5 days following experimentally induced pancreatitis (Brobst *et al.*, 1970; Mia *et al.*, 1978; Simpson *et al.*, 1989). This increase tends to parallel increased serum amylase activity, but it may persist a few days longer. The sensitivity of serum lipase for the diagnosis of pancreatitis ranges from approximately 60% to 75% (Cook *et al.*, 1993; Graca *et al.*, 2005; Mansfield and Jones, 2000). The low sensitivity of some assays is likely associated with the broad reference range usually seen for serum lipase (influenced by nonpancreatic lipase activity) and possibly influenced by the relatively short half-life of the enzyme in blood. However, in a study using 1,2-o-dilaryl-rac-glycero-3-glutaric acid-(6′-methylresorufin) ester as substrate, a sensitivity of 93% was achieved suggesting this substrate may be more appropriate for identifying pancreatic lipase (Graca *et al.*, 2005). The specificity of serum lipase is generally low, ranging from approximately 50% to 75%. These reports point to the variable results associated with assay methodology. The low specificity may be due to the wide range of conditions that can lead to increased serum lipase activity, as well as the release of nonpancreatic lipase into serum (Cook *et al.*, 1993; Polzin *et al.*, 1983; Rallis *et al.*, 1996; Strombeck *et al.*, 1981). Renal failure, enteritis and gastroenteritis, some hepatic disorders, bile duct carcinoma, and lymphosarcoma of the gastrointestinal tract among others are examples of nonpancreatic disease conditions that have been associated with increased serum lipase activity. In addition, treatment with glucocorticoids is routinely associated with increased serum lipase activity. Dexamethasone-treated dogs had serum lipase increase fourfold from the baseline activity without histological evidence of pancreatitis (Fittscen and Bellamy, 1984; Parent, 1982). Whether this increase in serum lipase activity is truly pancreatic lipase has not been determined.

Serum lipase activity may also be useful in differentiating severe from mild pancreatitis, with values of greater than 4010 U/l having a sensitivity of 64% but a specificity of 100% (Mansfield *et al.*, 2003). Some of the most dramatic increases of serum lipase in dogs have been associated with pancreatic or hepatic neoplasia. In three pancreatic carcinomas, two endocrine carcinomas involving liver, and one hepatic carcinoma of unknown origin, serum lipase activity increased from 11 to 93 times the upper limit of the reference interval, whereas serum amylase remained normal (Quigley *et al.*, 2001).

Six cats with experimentally induced acute pancreatitis had increases in serum lipase activity of two- to six-fold within 4 days (Kitchel *et al.*, 1986). However, there were no differences in serum lipase activity found between 12 cats with severe, naturally occurring pancreatitis, and 43 healthy cats or 31 cats with other diseases (Parent *et al.*, 1995). Hence, serum lipase activity assays have little use in the diagnosis of pancreatitis in cats. However, in a study using a radioimmunoassay for determining feline pancreatic lipase immunoreactivity (fPLI), a sensitivity of 100% was demonstrated for cats with moderate to severe pancreatitis and a sensitivity of 54% for cats with mild pancreatitis, resulting in an overall sensitivity of 67% (Forman *et al.*, 2004). In this study, a specificity of 100% was observed for healthy cats.

Serum lipase activity has been of little use in the diagnosis of exocrine pancreatic insufficiency, likely because of the presence of nonpancreatic lipase masking the loss of pancreatic lipase activity in serum. In a study of dogs with EPI and healthy dogs, the range of serum lipase activity was essentially the same in the two groups (Steiner *et al.*, 2006). However, using a cPLI assay, all of the 25 dogs with EPI in the study had cPLI values below the reference range, allowing for 100% diagnostic sensitivity. There was some overlap of the lowest cPLI values in healthy dogs and the highest values in EPI dogs, resulting in the possibility of false-positive test results.

H. Amylase

Alpha-amylase (EC 3.2.1.1) is a low-molecular-weight enzyme (approximately 45kDa) that cleaves the alpha-D-(1–4)

glycan linkage of starch and glycogen. It has been in use as a diagnostic enzyme longer than any of the other enzymes. It is found in very high concentration in the pancreas in dogs and cats. Human beings and rats have substantial amounts of salivary amylase activity, but in most species there is very little. Amylase is also produced in the small intestines and liver, both of which may contribute to normal serum amylase activity (Murtaugh and Jacobs, 1985; Nothan and Callow, 1971). The liver secretes its amylase in a similar fashion to albumin. Amylase mRNA has been identified by RT-PCR in dog liver, intestine, fallopian tubes, and the pancreas (Mocharla *et al.*, 1990). Pancreatectomy results in up to a 50% decrease in serum amylase, consistent with the assumption of nonpancreatic sources of some serum amylase (Simpson *et al.*, 1991). There have been several attempts to identify isoenzymes of amylase in serum and tissue, with the results dependent on the technique used. There have been four isoenzymes or isoforms of amylase identified using cellulose acetate and agarose gel electrophoresis (Jacobs *et al.*, 1988; Murtaugh and Jacobs, 1985; Simpson *et al.*, 1989). Although fraction three was increased to the greatest extent with experimentally induced pancreatitis suggesting this is the true pancreatic amylase, pancreatectomy did not result in a drop in this fraction (Murtaugh and Jacobs, 1985). Analysis of amylase isoenzymes has not found a place in diagnostic veterinary medicine.

Estimates of the half-life of serum amylase in normal dogs ranges from 1 to 5h (Hayakawa *et al.*, 1992; Hudson and Strombeck, 1978; Yacoub *et al.*, 1969). Following nephrectomy, the half-life increases to 14h (Hudson and Strombeck, 1978; Nakashima *et al.*, 1980). Although nephrectomy increases its serum half-life, less than 1% of pancreatic amylase infused in normal dogs is found in urine, suggesting amylase is catabolized by the kidney. The fact that pancreatic amylase infused into nephrectomized dogs still clears suggests that there are additional means of clearing amylase from blood besides the kidneys. This is supported by an increase in amylase in liver, which could be prevented by blocking the reticuloendothelial system following infusion of pancreatic amylase (Hiatt and Bonorris, 1966).

Serum amylase is routinely used as a screening test for acute pancreatitis. In experimentally induced pancreatitis in dogs, increases of eight- to twelve-fold and as much as 29-fold were seen at 1 to 3 days, and returned to normal in 3 to 5 in one study, and 8 days in another study (Brobst *et al.*, 1970; Mia *et al.*, 1978; Simpson *et al.*, 1989). An increase of serum amylase activity of two-fold or greater above the reference interval, in the absence of renal disease, is generally considered suggestive of pancreatitis. However, the sensitivity of serum amylase activity in the diagnosis of pancreatitis in dogs is low, with reports of 63% and 78% (Cook *et al.*, 1993; Jacobs *et al.*, 1988). The specificity of serum amylase activity has been reported as 77%. Increased serum amylase activity in dogs has been observed with renal disease, diabetes mellitus, lymphosarcoma, and hemangiosarcoma (Strombeck *et al.*, 1981). Increased serum amylase activity is commonly observed with renal disease in dogs. Ligation of the renal vessel results in a 60% increase in serum amylase activity in 48h (Hudson and Strombeck, 1978). A 2.5-fold increase above the reference interval was observed in dogs with both induced and spontaneously occurring renal disease (Polzin *et al.*, 1983). Dogs with renal insufficiency may have both increased serum amylase and urinary amylase (Corazza *et al.*, 1994). The increased serum amylase may be due in part to a decreased glomerular filtration rate, but the authors also detected a macroamylase in 77% of the dogs with proteinuria. The increase in urinary amylase is likely due to reduced renal tubular absorption.

Serum amylase activity for the diagnosis of acute pancreatitis in cats is considered of little value and has been shown to actually decrease in experimentally induced pancreatitis (Kitchell *et al.*, 1986).

Treatment of normal dogs with either low or high doses of dexamethasone results in a statistically significant decrease in serum amylase activity (Parent, 1982). Similar observations have been made in dogs treated with prednisone (Fittscen and Bellamy, 1984). However, the stress associated with surgery does not affect the normal serum amylase activity (Bellah and Bell, 1989; Finco and Stevens, 1969), although there was a transient increase in serum amylase activity following endoscopic retrograde pancreatography (Spillmann *et al.*, 2004).

I. Trypsin and Trypsinogen

Trypsin (EC 3.4.21.4) is a serine proteinase enzyme produced by the pancreas in the form of the proenzyme trypsinogen. The pancreas secretes trypsinogen into the intestine where it is converted by enterokinase to trypsin, the active proteolytic enzyme. Early attempts to evaluate pancreatic function by utilizing assays for the tryptic activity in serum were unsuccessful. This is likely because the enzyme released into the vascular space is trypsinogen and not trypsin and therefore has no tryptic activity (Steiner and Williams, 1999). Hence, the development of species-specific immunoassays for trypsin referred to as trypsin-like immunoreactivity (TLI) (Steiner *et al.*, 1996; Williams and Batt, 1983). These immunoassays detect both trypsin and trypsinogen.

Trypsinogen in serum is thought to be derived primarily from the pancreas. This is supported by the observation that pancreatectomy of healthy dogs reduced serum canine TLI (cTLI) from a mean of 6.2μg/l to 1.2μg/l (Simpson *et al.*, 1991). The blood half-life of TLI is not reported, but it is likely relatively short, as these enzymes are rapidly scavenged by endopeptidases whose role it is to inactivate enzymes released from the pancreas (Zoran, 2006). cTLI

has been most useful for the detection of canine exocrine pancreatic insufficiency (EPI). In a group of 25 dogs with EPI, serum cTLI concentrations were all less than 1.9μg/l (reference interval = 5.2–34μg/l), resulting in a test sensitivity of 100% (Williams and Batt, 1988). In 50 dogs with small intestinal disease, there was no difference in the cTLI values from normal dogs, suggesting a specificity of 100%. The high degree of sensitivity and specificity of cTLI for the diagnosis of EPI is supported by a more recent study (Steiner *et al.*, 2006). Hence, cTLI has become the gold standard for the diagnosis of EPI in dogs. Serum cTLI may also increase in acute pancreatitis, as evidenced by the observation in one study that, following pancreatic duct ligation of eight dogs, cTLI increased within 24h and remained increased above control values in six of the eight for 5 days (Simpson *et al.*, 1989). Serum cTLI also decreased more rapidly than amylase and lipase activity. In spontaneous pancreatitis, only 6 of 10 dogs with severe pancreatitis and 2 of 5 dogs with mild pancreatitis had serum cTLI greater than the reference range (Mansfield *et al.*, 2003). Because trypsinogen is cleared by the kidneys, decreased glomerular filtration rate may result in increased cTLI (Geokas *et al.*, 1982). The relative lack of sensitivity and the historically longer turnaround time for cTLI determination compared to serum lipase and amylase has made cTLI of little value for determination of pancreatitis in dogs.

When serum fTLI has been evaluated for the diagnosis of pancreatitis in cats, the results have been variable depending on the study. Reported reference ranges have been variable resulting in reported sensitivities ranging from 33% when the cutoff is 100μg/l to 86% when the cutoff is 49μg/l (Gerhardt *et al.*, 2001). Although specificity was not reported in this study, an overlap in TLI values in cats with confirmed pancreatitis and cats without pancreatitis are reported (Forman *et al.*, 2004; Swift *et al.*, 2000). Increased serum fTLI concentration may be associated with azotemia, inflammatory bowel disease, and gastrointestinal lymphoma (Simpson, 2001; Swift *et al.*, 2000). To improve specificity, higher cutoff values must be used, which reduces sensitivity. Even at lower sensitivity, the fTLI concentration was considered a useful diagnostic test in cats because clinical signs in cats are less specific and other minimally invasive tests such as serum amylase and lipase, ultrasonography, and contrast-enhanced computed tomography were insensitive or of no value (Gerhardt *et al.*, 2001; Simpson, 2001; Steiner, 2003). However, a more recent study has demonstrated a higher sensitivity of fPLI (67%) in the diagnosis of feline pancreatitis along with a higher specificity, suggesting that fPLI may supplant determination of fTLI in the diagnosis of pancreatitis in cats (Forman *et al.*, 2004).

Although fewer data are available compared to that for dogs, there is evidence that determination of fTLI concentration is useful for the diagnosis of EPI in cats as well. Of 20 cats with fTLI of $<8\mu$g/l (controls = 17–49μg/l), 17 had compelling evidence of EPI (Steiner and Williams, 2000).

J. Creatine Kinase

Creatine kinase (CK) (EC 2.7.3.2) catalyzes the exchange of a phosphate moiety between creatine phosphate and ATP. In myocardial and skeletal muscle, CK allows energy storage as creatine phosphate when demand is low, but when energy is needed for muscle contraction, CK catalyzes the transfer of the high-energy phosphate from creatine phosphate to ADP to form ATP. A small amount of CK activity is associated with the mitochondria, where it is responsible for transfer of high-energy phosphate to creatine, the cytosolic carrier.

The greatest amount of data for CK in domestic species is available for dogs, as this species has often been used as an experimental model for myocardial disease in humans. Canine CK is reviewed in depth elsewhere (Aktas *et al.*, 1993).

CK activity is in greatest concentration in skeletal muscle followed by heart muscle, diaphragm and smooth muscle, and then brain (Keller, 1981). In most species, the amount of activity is two- to four-fold greater in skeletal muscle than heart muscle, although in cats it is nearly equal (Boyd, 1983). The CK activity in brain tissue is approximately 10% of that in skeletal muscle. CK is primarily found in the cytoplasm; however, there is a mitochondrial form that makes up a small percentage of the total CK activity of the cell. There is evidence of breed differences, with higher skeletal muscle CK activity in greyhounds than mongrels and more CK activity in fast-acting than in slow-twitch muscles (Guy and Snow, 1981; Lindena *et al.*, 1982).

There are two distinct subunits of CK, referred to as the M (muscle) and B (brain) subunits. These combine randomly to form three isoenzymes of CK: CK-MM, CK-BB, and CK-MB. Skeletal muscle of most species has nearly 100% CK-MM (Aktas *et al.*, 1993; Boyd, 1983). Heart muscle has primarily CK-MM, and a variable amount of CK-MB, with dogs and horses having approximately 3% and 10% CK-MB, respectively. The brain has primarily CK-BB with a small percentage of CK-MB and CK-MM. In dogs, intestine and spleen have predominantly CK-BB, followed by CK-MB and then CK-MM. The normal distribution of serum CK isoenzymes in dogs is approximately 50% CK-MM and 40% CK-BB with the remaining being CK-MB (Aktas *et al.*, 1993). Although CK isoenzyme analysis is of great importance in human medicine as an indicator of myocardial infarction, the need for CK isoenzyme analysis in veterinary species has not been demonstrated. However, experimentally induced left ventricular hypertrophy in dogs resulted in a 50% reduction in CK-MM and a 10-fold increase in CK-MB (Ye *et al.*, 2001).

Serum CK-MB, presumably from myocardial injury, has also been shown to increase in foals with sepsis, but there is no difference between survivors and nonsurvivors, thereby suggesting no prognostic value to CK isoenzyme analysis (Slack *et al.*, 2005). The mitochondrial form of CK (MtCK) exists in two isoenzymes encoded by separate genes (Payne and Strauss, 1994). These have no apparent diagnostic value at this time.

The half-life of CK activity in blood is relatively short in all species. The half-life of CK from myocardial extracts is 2 to 3h in dogs (Cairns and Klassen, 1977; Sobel *et al.*, 1977). The mean half-lives for administered CK solution made from skeletal muscle from dogs, sheep, horses, and cattle are 2.61, 2.07, 2.05, and 8.67h, respectively (Aktas *et al.*, 1995; Houpert *et al.*, 1995; Lefebvre *et al.*, 1994; Volfinger *et al.*, 1994; see also Lefebvre *et al.* [1996] for review). The half-life following intramuscular injection of muscle homogenate in dogs was approximately 6.5h with the rate-limiting step being the absorption from the site of injection into blood via lymphatics (Aktas *et al.*, 1995). This half-life may be more clinically relevant as it better reflects the source of CK in blood following muscle injury. The mechanism by which CK is cleared from blood is not known, but it may involve inactivation of enzyme thiol groups. CK activity is not lost via the kidneys, and creation of a portocaval shunt with arrest of hepatic blood flow had no effect on the clearance rate of CK activity in dogs (Oostenbroek *et al.*, 1985).

Reference values for serum CK activity are highest in dogs under 1 month of age and decline until 1 year of age (Aktas *et al.*, 1994). The reference value is nearly two-fold higher in small dogs compared to large dogs. However, these differences are not likely to have significant impact on the diagnostic value of CK activity.

In domestic species, CK activity is mainly used as a marker of skeletal muscle injury associated with trauma, nutritional myopathies, exercise-induced muscle injury, or congenital myopathies. Increased CK activity in dog serum is seen secondary to myocardial diseases such as dirofilariasis and parvovirus infection, but it is unchanged in myocardial hypertrophy (Jacobs *et al.*, 1980; Kitagawa *et al.*, 1991). Markedly increased serum CK activity has been reported in congenital myopathies such as myotonia and X-linked myopathy of golden retrievers (Cooper *et al.*, 1988; Jones *et al.*, 1977; Valentine *et al.*, 1988). Only modest to moderate increases in serum CK activity were observed in acquired myopathies of dogs such as malignant hyperthermia, hyperadrenocorticism, hypothyroidism, and vitamin E-selenium deficiency (Green *et al.*, 1979; Kaelin *et al.*, 1986; O'Brien *et al.*, 1990; Van Vleet, 1975). Serum CK can be expected to increase following surgery. Serum CK activity is often increased with neurological disorders but is usually due to increased CK-MM rather than CK-BB (Hoffmann, 1994). Therefore, the increased serum CK activity is most likely a result of involuntary skeletal muscle contractions. However, an increase in CK-BB was observed in a Yorkshire terrier with necrotizing encephalitis (Sawashima *et al.*, 1996). The sensitivity and specificity of serum CK activity for diagnosis of skeletal muscle, myocardial, and neurological disease has been assessed in dogs (Aktas *et al.*, 1994). False-positive results, causing a decrease in test specificity, were attributed to the high concentration of CK in muscle, the large muscle mass, and the release of enzyme for nonspecific reasons. There were also several false negatives, thereby lowering the sensitivity, which were attributed to the short half-life of the CK activity in blood.

In cats, increased serum CK activity can be associated with trauma, surgery, and intramuscular injections. There has also been a reported increase (median CK activity of 2529 U/l) observed in anorectic cats (Fascetti *et al.*, 1997), suggesting that serum CK activity could serve as a marker of nutritional status in cats. The increased CK activity with anorexia in cats is thought to result from muscle catabolism secondary to decreased caloric intake. Serum CK activity decreases significantly within 48h of nutritional supplementation.

Serum CK activity is increased in horses in a variety of conditions causing muscle injury. As early as 1967, and in numerous reports since, increased serum CK activity has been associated with paralytic myoglobinuria (Cardinet *et al.*, 1967). A markedly increased serum CK activity has been observed in four horses with severe rhabdomyolysis associated with *Streptococcus equi* infection (Sponseller *et al.*, 2005). Increased serum CK activity has also been described in horses with exertional rhabdomyolysis associated with heritable polysaccharide storage myopathy (Ribeiro *et al.*, 2004). Cattle also have increases in serum CK activity with a variety of muscle injuries and diseases. Increased serum CK activity is common with selenium and vitamin E deficiency (Arthur, 1988; Zust *et al.*, 1996). Large animal species also frequently have increased serum CK activity because of prolonged recumbency or pressure necrosis of muscle.

There are numerous reports of increases in serum CK activity associated with intramuscular injection of drugs. A noninvasive technique using area under the curve and total plasma clearance of CK activity has been proposed for determining postinjection muscle damage in dogs, horses, sheep, and cattle (Aktas *et al.*, 1995; Houpert *et al.*, 1995; Lefebvre *et al.*, 1994; Toutain *et al.*, 1995; see Lefebvre *et al.* [1996] for review). For example, the amount of muscle tissue damaged following an IM injection of imidocarb in a 10-kg beagle is 2.5g (Aktas *et al.*, 1995). This quantitative technique has potential use in evaluating local tolerance of intramuscular administration of new drugs to satisfy regulatory requirements.

There has been some interest in exercise-induced increases of CK activity in horses and dogs. Increases have been observed in sled dogs following long-distance races and in horses in various training programs (Harris *et al.*, 1998; Hinchcliff *et al.*, 1993, 1998; Vnolfinger *et al.*, 1994).

In long-distance sled dog races, there are marked interindividual variations with activity ranging from unchanged to more than 13-fold increase. However, there is minimal increase in serum CK activity following exercise in untrained beagle dogs (Chanoit *et al.*, 2002). In horses, it has been concluded through kinetic studies that the amount, in grams, of striated muscle damaged is negligible following exercise (Volfinger *et al.*, 1994). It has been reported that increases tend to occur more frequently in fillies, younger animals, and untrained horses (Harris *et al.*, 1998).

In all species, CK has the advantage over serum aspartate aminotransferase in being specific for muscle injury and not affected by hepatocellular injury. The short half-life of the enzyme may tend to reduce the diagnostic sensitivity of the test, but it also offers an effective means of monitoring response to therapy.

K. Other Enzymes

As mentioned in the introduction, numerous other enzymes have been investigated for use in diagnosis and prognosis of disease and organ dysfunction in nonhuman animals. Some of these have been dropped altogether or receive limited use, such as lactic acid dehydrogenase, 5′nucleotidase, glutathione S-transferase, leucine aminopeptidase, arginase, aldolase, and acid phosphatase, among others. The reasons for their limited use vary but include relatively poor diagnostic accuracy, diagnostic redundancy with already established tests, and a lack of readily available test kits. For example, serum lactic acid dehydrogenase (LDH) activity originates from several tissues including liver, skeletal muscle, heart muscle, and erythrocytes. This resulting decreased test sensitivity and specificity limits the diagnostic accuracy of serum LDH activity. Although LDH isoenzyme analysis may improve tissue specificity, the tests are relatively time consuming, expensive, and still only provide a subjective assessment of the contribution of each organ to the total serum activity. In addition, the test does not offer a substantial improvement over assays to other enzymes such as alanine aminotransferase or creatine kinase. A few laboratories still offer 5′nucleotidase, but it provides much of the same information as ALP and perhaps has lost favor as a result. Arginase is highly specific for injury to hepatocytes but suffers from a short half-life and is not readily available for autoanalyzers.

V. FUTURE OF SERUM ENZYMOLOGY

Although the number of studies investigating enzyme activity assays for diagnostic purposes has decreased since the 1990s, they are still of immense importance to diagnostic medicine. The currently increasing interest in identifying protein and peptide markers of organ injury or dysfunction will require immunoassays to determine their concentrations in serum. This is often problematic to veterinarians, as appropriate antibodies to these markers in domestic animals are frequently unavailable. The divergence of human biomarker research away from classical serum enzymology has the unintended consequence of limiting the universality of new biomarker application across species. Although this continues to be a deterrent, there is increased interest in the development and utilization of immunoassays in veterinary medicine as evidenced by the assays for trypsin-like immunoreactivity and pancreatic lipase immunoreactivity in dogs and cats, as well as immunoassays for nonenzymatic proteins, such as the natruretic peptides and troponins. Problems regarding the availability of immunoassays and long turnaround time from submission to obtaining laboratory results are increasingly being addressed. For example, the development of automated analyzers for immunoassays has allowed test results to be available on the same day as sample submission. Canine TLI is available on the Immulite system from Diagnostic Products Corporation, and more are expected in the future. The fields of serum enzymology and serum protein markers have merged in human medicine as evidenced by the topic section "Proteomics and Protein Markers" in the table of contents of the journal *Clinical Chemistry.* The development of this merger in nonhuman animal medicine is almost certain to happen.

I. INTRODUCTION

The liver has an essential role in nutrient metabolism including the control and maintenance of the blood glucose level; in detoxification and excretion of hydrophobic metabolites and xenobiotics; in the synthesis of most plasma proteins; and in digestion through synthesis, biliary secretion, and conservation of bile acids that are essential both for digestion and intestinal absorption of fats and other lipids including fat soluble vitamins. The clinical manifestations of hepatic disease are directly attributable to alterations in the metabolic, excretory, synthetic, and digestive functions of the liver. The liver has great reserve, and signs of hepatic failure often do not develop until 70% or more of functional capacity is lost. Importantly, even when a major fraction of the hepatocellular mass has been lost following acute injury, recovery is possible because of the unique regenerative capacity of the liver.

Since Dr. Charles E. Cornelius wrote this chapter for earlier editions of this textbook (Cornelius, 1970), remarkable advances have been made in our understanding of the pathophysiological, biochemical, and molecular mechanisms responsible for hepatic disease. Our current knowledge of veterinary hepatology is the result of the collective work of individuals from a variety of disciplines, including practicing veterinarians, biomedical scientists, and, more recently, molecular and cell biologists and molecular geneticists. No one individual had a more important or sustained impact than Dr. Cornelius, and no one was more active in maintaining a comparative perspective on the subject (Cornelius, 1993). In this chapter, we describe the biochemical mechanisms responsible for the cardinal clinical manifestations of hepatic insufficiency and the biochemical tests used in the clinical diagnosis of liver disease and to assess hepatic function. As in previous editions, the goal is to provide students of veterinary medicine at all stages of career development with information useful for managing the diseases of animal patients.

II. FUNCTIONAL ANATOMY

During embryological development, the liver arises as an outgrowth of the primitive gut and is located cranial to the abdominal viscera and other abdominal organs between the splanchnic and the peripheral (systemic) circulatory systems. Unlike other mammalian organs, afferent blood to the liver is derived from two sources, the hepatic artery and the hepatic portal vein. Efferent blood leaves the liver by the hepatic vein and enters the systemic circulation via the caudal vena cava. Twenty to 30% of afferent blood comes from the hepatic artery, and the remainder from the hepatic portal vein, which drains the pancreas, spleen, stomach, small intestine, and all but the most terminal portion of the large intestine.

The peripheral border of the classical liver lobule is formed by the most peripheral row of hepatocytes (the terminal plate) and by two, three, or more portal tracks (portal triads) that contain preterminal branches of the hepatic artery, the hepatic portal vein, and bile ductules.

Lymphatic vessels also are present in the portal tracts, but because of their small size and thin walls they are difficult to recognize morphologically. Although the classical lobular architecture of the liver remains in use for the morphological description of pathological lesions of the liver, most analyses indicate that the functional unit of the liver is the hepatic acinus in which blood flows from terminal hepatic artery and terminal portal vein of the portal tracts toward two, three, or more terminal collecting veins (central veins). Significant structural and functional heterogeneity has been demonstrated between hepatocytes of the periphery of the hepatic acinus (zone 1), the midzonal hepatocytes (zone 2), and perivenous hepatocytes (zone 3) (Jungermann and Katz, 1989). The functional significance of some of these differences will be discussed in this chapter.

Hepatocytes are the principal cell type of the liver and make up approximately 70% of the total volume. Kupffer cells are the macrophages of the liver located in the sinusoids with pseudopodia that are attached to endothelial cells and hepatocytes. The Kupffer cells and other perisinusoidal cells are responsible for local inflammatory and other immune responses. The stellate cells or Ito cells are found in the space of Disse where they are identified are the vitamin A-containing vacuoles in the cytoplasm. When activated by Kupffer cells, the stellate cells transform into myofibroblasts and are responsible for the production of collagen in liver diseases that are associated with fibrosis or cirrhosis.

The hepatocytes are arranged in single-cell plates separated by sinusoids lined by vascular endothelial cells. Blood from the terminal branches of the hepatic artery and the hepatic portal vein enters and mixes in the periphery of the liver acinus and percolates through the sinusoids to the terminal hepatic vein. The vascular endothelium lining the hepatic sinusoids differs from that of other capillaries in two ways. Under normal conditions, hepatocytes do not rest on a basement membrane but are separated from endothelial cells by the perisinusoidal space of Disse. Second, dynamic fenestrations of the sinusoidal endothelium are responsible for formation of hepatic lymph that has a protein content much higher than that of the lymph formed in other tissues, which is an ultrafiltrate of plasma with a characteristically low protein content.

Blood exits the liver through branches of the hepatic vein and obstruction of hepatic vein outflow increases the formation of hepatic lymph that is rich in protein. This may occur in congestive heart failure, in mechanical obstruction of hepatic vein outflow (Budd-Chisari syndrome), and in the early stages of hepatic fibrosis. In advanced hepatic cirrhosis, dense intracellular matrix forms in the space of Disse. "Capillarization" of the sinusoids develops reducing the fenestrations of the sinusoidal endothelium, and in formation of hepatic lymph that is typically low in protein, closely resembling the lymph produced by other normal tissues (see Section III.D).

Bile is secreted via the microvillous membrane of bile canaliculus located in the apical cell membrane of the hepatocyte and flows in the direction of the portal tracts in channels formed by the canaliculi of 2, 3, or more adjacent hepatocytes. These channels converge near the portal tracts forming the canals of Herring through which bile drains into the bile ductules of the portal tracts and finally into the ducts of the biliary tree. Hepatic lymph formed in the space of Disse flows in a similar direction and exits the liver via lymphatics vessels located in the portal tracts. Hepatic lymph leaves the liver primarily via the hilar lymphatic, hilar lymph nodes, and the thoracic duct. Hepatic lymph also leaves the liver by lymph vessels associated with the hepatic vein.

Cells of the periportal Zone 1 of the acinus are more likely to divide than other hepatocytes (Grisham, 1959). Mitochondria are larger and more numerous in Zone 1 hepatocytes than are those of Zone 3 (Loud, 1968; Uchiyama and Asari, 1984). Fenestrae of Zone 1 sinusoidal endothelial cells are larger than those of the Zone 3 region, and this may account for selective uptake of large, more complex molecules such as remnants of chylomicrons by Zone 1 hepatocytes (Wisse *et al.*, 1985).

A significant oxygen gradient has been demonstrated between sinusoids of Zones 1 and 3. The concentrations of glucose and amino acids that arrive primarily from the hepatic portal vein are higher in zone 1 sinusoids during digestion. Such metabolic differences are associated with important functional differences between Zones 1 and 3. The enzymes of glycolysis, gluconeogenesis, and glycogen metabolism have different activities within zones. Glucose-6-phosphatase, phosphoenolpyruvate carboxykinase, and fructose-1,6-diphosphatase activities are higher in periportal hepatocytes, whereas glucokinase and pyruvate kinase activities are higher in pericentral hepatocytes (Zakim, 1996). Glycogen appears to be uniformly distributed within the cells of the acinus during steady-state conditions, but during fasting, glycogen of periportal hepatocytes is utilized more rapidly and, during feeding, is replaced more rapidly.

Two plasma membrane transporters for glucose are expressed in the liver. Glut-2 is the primary glucose transporter of the liver and is expressed in plasma membranes of all hepatocytes. The Km of Glut-2 for glucose is 15 to 20 mM, a concentration of glucose that can be reached or exceeded in the hepatic portal vein during and immediately after feeding. Under these conditions, glucose is transported into hepatocytes for the synthesis of glycogen, amino acids, and triglycerides. Between meals, the glucose concentration in the portal vein is approximately 5mM and is similar to that in the peripheral circulation. During the interdigestive period, the concentration of glucose in hepatocytes is high relative to that of sinusoidal blood. Glut-2 also facilitates transport of glucose from the cytoplasm of hepatocytes into the sinusoid. Glucose reaching the systemic circulation, maintains the peripheral blood glucose

concentration, and contribute to meeting systemic energy requirements. The Glut-1 transporter is present only in the plasma membranes of Zone 3 (Tal *et al.*, 1990). The affinity of Glut-1 for glucose is much higher (Km 1–2 mM) than that of Glut-2. The Glut-1 gene is transcribed and translated by all hepatocytes of the acinus; however, by means of a post-translational control mechanism, Glut-1 is inserted into the plasma membrane of only pericentral hepatocytes (Bilir *et al.*, 1993).

The liver plays a critical role in the removal of ammonia from the blood. Two separate reactions within the liver acinus are involved. The concentration of ammonia in the Zone 1 sinusoids is high compared to that of the Zone 3 sinusoids. Most of the ammonia that enters the liver diffuses into the hepatocytes of Zones 1 and 2, and a relatively small amount of ammonia reaches the hepatocytes of Zone 3. Hepatocytes of Zones 1 and 2 contain carbamoyl phosphate synthase and other enzymes of the urea cycle that are responsible for conversion of ammonia to urea. The activity of glutamine synthase is confined to the hepatocytes located adjacent to the terminal hepatic vein, and in these perivenous hepatocytes, glutamate synthase is responsible for the use of ammonia in the catalytic amination of glutamate forming glutamine. The Km of carbamoyl phosphate synthase for ammonia is approximately 1.2 mM, whereas that of glutamine synthase for ammonia is 0.3 mM (Gumucio and Berkowitz, 1992; Gumucio *et al.*, 1994). Synthesis of urea from ammonia in periportal hepatocytes and of glutamine from ammonia in pericentral hepatocytes represents complementary enzymatic processes. Ammonia is first seen by hepatocytes that synthesize urea utilizing a low-affinity, high-capacity system. At the end of passage through the hepatic sinusoid, the small amount of ammonia remaining is removed for glutamine synthesis using a relatively high-affinity, low-capacity mechanism.

Zone 1 and 2 hepatocytes are responsible primarily for the bile salt-dependent fraction of bile formation and appear to be the primary site of bile salt synthesis. The enzymes necessary for fatty acid synthesis, CoA carboxylase and fatty acid synthase, are located primarily in Zone 3 hepatocytes. Drug-metabolizing enzymes of the cytochrome P-450 family are located predominantly in Zone 2 and 3 hepatocytes, explaining hepatocellular damage and fatty metamorphosis preferentially in Zone 3 hepatocytes (Jungermann and Katz, 1989) after exposure to toxins such as carbon tetrachloride.

III. CLINICAL MANIFESTATIONS OF HEPATIC INSUFFICIENCY

A. Icterus

1. Formation of Bile Pigments

Bilirubin is a yellow pigment produced by the enzymatic degradation of heme. Approximately 80% of the bilirubin produced normally by mammals is derived from the removal of senescent erythrocytes from the circulation by the reticuloendothelial systems (Landau and Winchell, 1970; Robinson *et al.*, 1966). Degradation of heme from other sources (myoglobin, cytochromes, peroxidase, catalase, guanylate cyclase) accounts for production of the remaining bilirubin. Significant amounts of microsomal cytochromes (P-450, b_5) are present in the liver and are the most important non-erythroid source of bilirubin.

The initial step in bilirubin formation is the opening of the heme (ferriprotoporphyrin) ring at the α-methene bridge (Fig. 13-1). This reaction is catalyzed by microsomal heme oxygenase (Tenhunen *et al.*, 1968, 1969, 1970a, 1970b). Cytochrome P450 serves as the terminal oxidase and requires reduced nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen. The products of heme degradation are equimolar amounts of iron, biliverdin, and carbon monoxide (Sassa, 2004; Tenhunen *et al.*, 1968, 1969). It has been estimated that more than 86% of

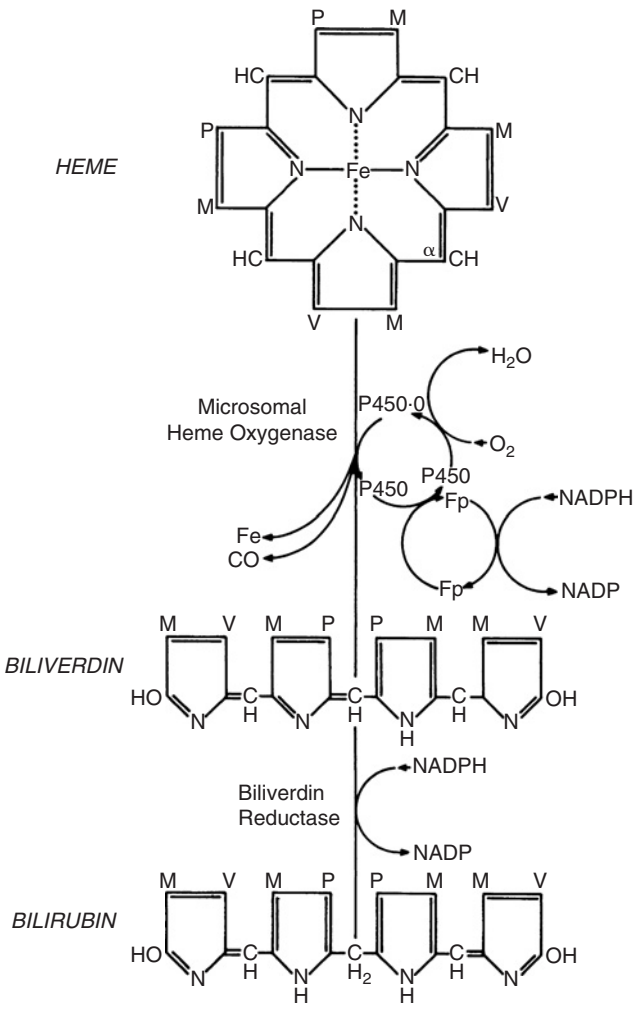

FIGURE 13-1 Enzymatic degradation of heme (ferriprotoporphyrin) and formation of bilirubin.

endogenously produced carbon monoxide is derived from the enzymatic breakdown of heme (Ryter *et al.*, 2006), and quantitation of respiratory carbon monoxide has been used as an indirect measurement of bilirubin production (Landaw and Winchell, 1970). A minor amount of carbon monoxide arises from other metabolic processes including peroxidation of lipids (Archakov *et al.*, 2002; Vreman *et al.*, 1998). In primary hepatocyte cultures, degradation of hepatic heme also has been shown to use pathways that do not yield carbon monoxide (Bissell and Guzelian, 1980).

Bilirubin is formed by the catalytic reduction of biliverdin by the cytosolic enzyme biliverdin reductase, which, like heme oxygenase, requires NADPH (Tenhunen *et al.*, 1970b). In most mammals, hepatic biliverdin reductase activity is sufficient and normally is not rate limiting in the synthesis of bilirubin. Biliverdin reductase activity, however, is almost completely lacking in birds; consequently, in avian species, biliverdin is the major pigment of bile. Biliverdin also is the predominant bile pigment of the rabbit, in which 70% of bile pigment is biliverdin and biliverdin reductase activity is low (George *et al.*, 1989; Munoz *et al.*, 1986).

Heme oxygenase is most active in the tissues that remove erythrocytes and degrade heme. The spleen is the most important in this regard, followed by the liver and the bone marrow (Tenhunen *et al.*, 1968, 1969, 1970a). The kidney normally plays a minor role in heme degradation but in hemolytic disorders associated with hemoglobinuria, the kidney has a quantitatively more important role in heme degradation. When intravascular hemolysis begins, glomerular filtration of hemoglobin is initially prevented by the binding of hemoglobin to the plasma protein haptoglobin. When the haptoglobin binding capacity is exceeded, however, glomerular filtration of hemoglobin occurs. Depending on the amount filtered, some hemoglobin is reabsorbed by renal tubular epithelium. This induces formation of heme oxygenase and production of bilirubin by the kidney (de Schepper and Van Der Stock, 1972a, 1972b; Pimstone *et al.*, 1971). Degradation of hemoglobin in this manner may have a homeostatic function that conserves iron and diminishes renal injury associated with hemoglobinuria.

2. Hepatic Excretion of Bilirubin
