A commonly used measure of outcome for such analyses is QALY (i.e. quality-adjusted life-years). The QALY definition and calculation can be found elsewhere (e.g. [4]) (*see* **Quality of Life and Health Status**). In brief, the number of years spent at a given health status is multiplied by the corresponding weight (typically between zero (death) and one (full health)). The adjusted years are summed and discounted to reflect societal time preference (i.e. the rate that future benefits, and costs, should be adjusted to reflect their present value to society). This rate represents societal willingness to exchange present for future consumption. The number generated represents the equivalent in quality-adjusted life-years of a potential lifetime health profile (i.e. years of life in different health states). The time tradeoff (TTO) technique is one of the methods used to generate the preference weights to be used in the QALY calculations.

The Time Tradeoff Technique

The time tradeoff (TTO) technique was first suggested by Torrance et al. [19] as a substitute for the **standard gamble (SG) technique**, which is seen as the classical method of measuring cardinal preferences [18]. The need for a substitute for the SG technique stems from the empirical observation that subjects sometimes find it difficult to relate to probabilities. Compared with the SG technique, the TTO technique has the advantage of being simpler to use. This technique has been used extensively in many empirical studies to estimate individuals' value preferences for different health states. In this section we describe the TTO as suggested by Torrance et al. [19].

The TTO technique involves a **paired comparison** in which the subject chooses between two alternatives (a more detailed description of the TTO technique can be found in [4]). For simplicity we use the chronic health state (i.e. the case of an individual being in the same health state for the rest of their life) as an example. In this case the individual is presented with two options: alternative 1 (see Figure 1) is to have the health state under consideration (denoted as i) for time t (the remaining **life expectancy** of the individual) followed by death; alternative 2 is a shorter period of time (denoted as $x, x < t$) in full health. The period of time x is varied until the subject is indifferent between the two alternatives. The required preference value for state i (denoted as h_i) is then calculated to be $h_i = x/t$. Props and visual aids are recommended for use to help respondents understand the task.

An example for the use of this procedure is as follows. Suppose one wants to measure the preference value for the health state "severe pain". The first step is to construct scenarios describing the health states of "severe pain" and "full health". These scenarios will be used in the second step. In the second step, individuals are approached and presented with two options: alternative 1 is to have the health state "severe pain" for time t (say 20 years, which is the remaining life expectancy of that individual); alternative 2 is a shorter period of time (denoted as x) in full health. The period of time in full health is varied until the subject is indifferent between the two alternatives. Say $x = 5$ years at the point of indifference. Then, using the equation described above, the required preference value for the health state "severe pain" is then calculated to be $5/20 = 0.25$.

An Indifference Curve Interpretation for the TTO

Unlike the SG method, the TTO technique, suggested by Torrance et al. [19], was not related in a general

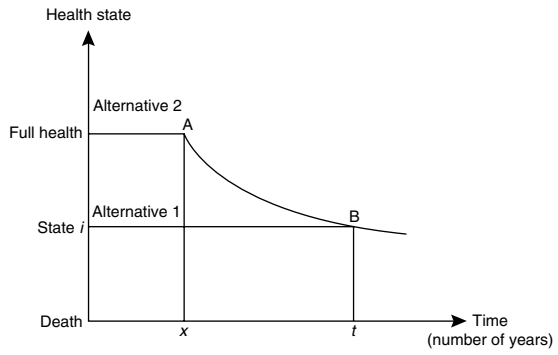

Figure 1 Time tradeoff for a chronic health state

way to any existing behavioral theory. Relating a measure to a behavioral theory is important because it helps us interpret what we measure as well as understand and test the assumptions which underlie the measurement procedure. A general theoretical interpretation for the TTO technique was provided later [10]. If the measure is to be used in the context of an economic evaluation it is also important to make sure that it is consistent with the principles of the discipline. In economics, one starts from choosing a welfare theory as the basis for the analysis. The choice of the underlying welfare theory determines, amongst other things, the types of outcome measure that can be used in the analysis [5] (*see* **Health Economics**).

Mehrez & Gafni [10] argue that the TTO technique is a method which enables us to identify different points on an individual's indifference curve in his evaluation space. An evaluation space is defined as the set of all potential alternatives (or outcomes). An indifference curve is the locus of all points (alternatives) in the individual's evaluation space among which he is indifferent. In other words, following classical utility theory, individuals are assumed to have a mechanism (that can be described as a mathematical function) which associates a real number to each alternative in the evaluation space. This function describes the individual's preferences. The indifference curve is defined as the locus of all points which have the same numerical score.

Following the above, the TTO can be seen as a two-stage procedure. First, a comparison of two alternatives in the individual's evaluation space is performed. Using the concept of indifference curves, this stage can be seen as follows: given one point in the individual's evaluation space (point B in Figure 1; the health state under consideration for period t), we search for another point (point A in Figure 1, full health for period x) which lies on the same indifference curve. In the second stage we attribute a preference score to the health state under consideration using the method described earlier. As shown in [10], in the second step additional assumptions are required about the functional form of the individual's preference function in order to calculate a preference value for the chronic health state. These assumptions, however, are not required for the first step.

To illustrate this important point, let V denote the individual's preference function. By definition, because the individual has indicated indifference between alternatives 1 and 2 (points A and B in Figure 1), then $V_2 = V_2$, i.e. the "numbers" generated by the individual's preference function will be the same for both alternatives. However, the preference value for health state i cannot be calculated without knowing the exact functional form of the preference function. Assume, for example, that the individual has a preference function of the type $V = h_i T$, where h_i and T are the two attributes of concern (h_i = preference value for health state i, $0 \leq h_i \preceq 1$, 1 = full health, 0 = death, and T = years). Using alternatives 1 and 2 in Figure 1, the score of alternative 1 is $V_1 = h_i t$ and of alternative 2 is $V_2 = 1.0x$. With indifference between the alternatives, $h_i = x/t$ (which is the formula currently recommended to calculate h_i [4]). However, if the individual has a different preference function, say $V = h_i T^a (a \not\approx 1)$, it would be incorrect to calculate the value of h_i as being equal to x/t. It is important to note that there is no empirical evidence to support the assumption that all (or most) individuals have a preference function of the functional form of $V = h_i T$. Neither are there appealing normative arguments (e.g. reflecting the discipline view of the world regarding how an individual should behave) why we should impose such preference patterns on individuals.

TTO: Some Empirical Observations

The TTO technique was offered as an empirical substitute to the SG method, and hence it is important to compare the two. From a theoretical perspective it is clear that the two techniques measure different

phenomena [10]. The two techniques have also been compared from an empirical perspective. Torrance [17] and Wolfson et al. [20] reported high **correlations** between health status ratings with SG and TTO. Read et al. [13] found a reasonable correlation between the SG and the TTO rating. However, they also found large systematic differences in the ratings obtained by the two methods. They concluded that the SG and TTO techniques produce different scale values for outcomes of clinical problems, which coincides with the claim made by Mehrez & Gafni [10] on theoretical grounds. In more recent studies, Patrick et al. [12] reported much lower correlations, and Hornberger et al. [7] report even lower correlation. Using other statistical methods, the studies by Stiggelbout et al. [16] and Nease et al. [11] report large discrepancies between TTO and SG scores.

With respect to the added assumptions about the functional form of the preference function, which are needed in the second step, it is important to ask whether they have any empirical support or normative appeal. The answer is No. An important assumption which is made is of a constant proportional tradeoff between years of life and health states. This implies that the weight which is used in the QALY calculation is constant. In other words, the value attached to any given health state is independent of the time spent in this health state. Two recent studies, Stiggelbout et al. [15] and Dolan et al. [3], found that this assumption was violated when tested. Another assumption is that the person has a zero time preference (i.e. s/he is indifferent between benefits (and costs) occurring at present or in the future). This assumption does not have normative appeal [2] or empirical support [6, 9].

Other Ways of Using the TTO Technique

For those who do not want to subscribe to the strong assumptions which are required at the second step, the TTO can still be used as a useful measure of outcome. If we just want to convert years in ill health to years in full health or lifetime health profiles (i.e. allowing individuals to be in different health states over their lifetime) to their equivalent in years in full health, then this can be done using the first step of the TTO method. As shown by Mehrez & Gafni [10], in the first step of the procedure no assumption is made (or necessary) about the functional form of the individual preference function. Hence, this step can be used to measure what Mehrez & Gafni call HYE (healthy years equivalent), i.e. the number of years in full health which is equivalent (preference-wise) to a given lifetime health profile. This measure combines both outcomes of quantity and quality of life and, like the QALY, can serve as a common unit of measurement for all programs, thus allowing comparisons across programs. It also maintains the intuitively appealing meaning of the QALY measure. However, using the TTO base HYE as a measure of outcome at the endpoints of decision trees requires additional assumptions [10].

An alternative version of the TTO technique has been suggested by [14]. This version is identical to the first step of the TTO technique and does not proceed to calculate a preference value for the health state in question. This method is not widely used in empirical studies reported in the literature. Furthermore, the authors do not provide any rationale for their suggestion.

Finally, the major limitation of the TTO technique is that it measures individuals' preferences under conditions of certainty [10]. Because decisions about health interventions at both the individual and the community levels are made under uncertainty [1], we need a measure of outcome that capture individuals' preferences under conditions of uncertainty. Recently, Johannesson [8] suggested a modified TTO question that will enable us to measure the HYE of a risky health profile. Following Johannesson [8], "... the risky health profile to be assessed is framed as a probability distribution and is equated to the certainty equivalent number of healthy years" (p. 47). This approach has not yet been tried empirically. Johannesson questions the practical feasibility of this approach and states that "it is unclear whether that type of information can be processed in a meaningful way" (p. 47). However, as Johannesson acknowledges, this is an empirical question and thus researchers should not be discouraged from trying this method in practice.

Time-by-time Analysis of Longitudinal Data

Graphs such as Figure 1, and the associated analysis, are frequently found in reports of studies in which two groups are observed over time. The main features of the figure are:

1. Profiles based on the mean response at each time are shown.
2. Bars indicating some multiple of a standard error are displayed at each time.
3. The results of testing the equality of the group means at each time are indicated, usually by symbols, such as NS, *, ** for, respectively, $P > 0.05$, $P < 0.05$, $P < 0.01$.

Similar graphs and analogous analyses can be presented when more than two groups are involved. This kind of display, and the analysis it reports, has several serious drawbacks.

One problem is that the structure of the data is ignored: at no stage does this analysis use the information that indicates which observations are from the same individual. Consequently, the standard errors are based on between-subject variation, which for most purposes will be the wrong variance component. It is most unlikely that an analysis that ignores such an important feature of the data will be correct.

Another group of problems concerns the hypothesis tests. Since several tests are performed, the problems of multiple testing arise (*see* **Simultaneous Inference**); moreover, any attempt at interpretation will be complicated further because these tests, being based on the same individuals, are dependent. It is also highly questionable whether the hypotheses being tested; namely, the equality of the group means at each time, are of any interest. To use this collection of hypotheses to assess the equality of two or more curves is unnatural and unhelpful.

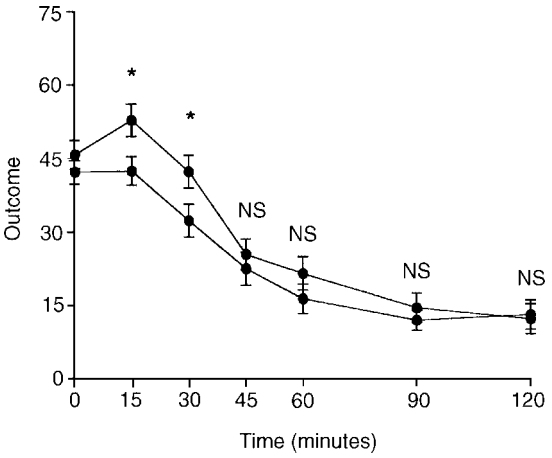

Figure 1 Typical presentation of time-by-time analysis of two groups observed over time

The profiles of the response in each group are summarized by the graph of means. There are applications where the graph of means is misleading, insofar as it may bear little resemblance to the profile of any individual. Whether it is reasonable in a particular application to summarize the response by the profile of means is, to some extent, a matter of judgment for the analyst. In making this judgment it is important that separate plots of the profile of each individual should have been studied.

JOHN N.S. MATTHEWS

Time-dependent Covariate

Introduction

Regression models for survival data are frequently specified via the **hazard** function for the distribution of the survival time X (*see* **Survival Distributions and Their Characteristics**). Thus, the model specifies the conditional probability

$$\alpha(t \mid \mathbf{Z}) \approx \frac{\mathrm{P}(X \leq t + \mathrm{d}t \mid X > t, \mathbf{Z})}{\mathrm{d}t} \qquad (1)$$

of failing just after time t given survival till time t and given the **covariates**, $\mathbf{Z}$. Examples include the **Cox** proportional hazards **regression model** and Aalen's nonparametric **additive hazards model**.

In many cases, some of the covariates change over time.

1. In a medical follow-up study where t refers to time since start of treatment, the current age of the patients, and the current calendar time period are, obviously, time-dependent.
2. In an industrial life-testing experiment, the stress at which the components are tested may be designed to vary over the time period of the experiment.
3. In medical follow-up studies, events may happen to the patients under study in an unpredictable way, which may alter their **prognosis**.

An example of the latter kind is provided by the classical Stanford Heart **Transplantation** Study [17] where the hazard of patients waiting for a transplant (hopefully) changes once a transplantation is carried out.

The specification (1) lends itself to include time-dependent covariates by letting the hazard function at time t

$$\alpha(t \mid \mathbf{Z}(\cdot)) \approx \frac{\mathrm{P}(X \leq t + \mathrm{d}t \mid X > t, (\mathbf{Z}(u), 0 \leq u \leq t))}{\mathrm{d}t} \qquad (2)$$

depend on the entire covariate history over the time interval from 0 to t.

4. An example is a study of the effect of blood pressure on mortality where the blood pressure was recorded continuously and where at time $t(> \Delta t)$ the hazard was modeled to depend on the current blood pressure $Z(t)$ and the change in blood pressure $Z(t) - Z(t - \Delta t)$ over the preceding Δt hours.

Further examples of this type were discussed in [3, 24].

An important complication implied by the added generality of (2) over (1) has to do with the relation between the hazard function $\alpha(\cdot)$ and survival probabilities like

$$S(u \mid t) = \mathrm{P}(X \geq u \mid X \geq t, (\mathbf{Z}(s), 0 \leq s \leq t)), \quad u > t. \qquad (3)$$

In the fixed covariate model (1) this is simply given by

$$S(u \mid t) = \exp\left(-\int_t^u \alpha(s \mid \mathbf{Z})\mathrm{d}s\right), \qquad (4)$$

whereas for the model (2), $S(u \mid t)$ will depend on the stochastic structure of $(\mathbf{Z}(s), t \leq s \leq u)$. Kalbfleisch and Prentice [23, Section 6.3] introduced a classification of (time-dependent) covariates in survival analysis into *external* and *internal* ones. This classification is, in fact, identical to that used in econometrics where one distinguishes between *exogenous* and endogenous variables. One way of thinking of this classification is that external covariates are those for which it makes sense as in (3), at time t, to condition on the path of $\mathbf{Z}(\cdot)$ over the prediction interval from t to u, and internal covariates are those for which it does not make sense. Thus, external covariates include *time-fixed* covariates (constant from t to u), *defined* covariates whose path is fixed from t to u (e.g. current calendar time period in example 1. above), or *ancillary* covariates whose development over (t, u) is not influenced by the failure history of the individual (e.g. the stress level in the life-testing experiment of example 2. above or, as exemplified in [23, p. 197], the level of air pollution as a risk factor for the occurrence of respiratory diseases). In these examples, the survival probability is given by

$$S(u \mid t) = \mathrm{P}(X \geq u \mid X \geq t, (\mathbf{Z}(s); 0 \leq s \leq u)) = \exp\left(-\int_t^u \alpha(s \mid \mathbf{Z}(s))\mathrm{d}s\right). \qquad (5)$$

A mathematical condition on the joint distribution of X and $(\mathbf{Z}(t), t \geq 0)$ for (5) to hold was given in [36].

This may be taken as a formal definition of external covariates.

For *internal* covariates, however, as exemplified in examples 3 and 4 above, one cannot condition on $\mathbf{Z}(s)$ for $s \in (t, u)$ since the mere existence of $\mathbf{Z}(s)$ will imply that $X > s$. In this case, the survival probability is given by

$$S(u \mid t) = \mathrm{E} \exp\left(- \int_t^u \alpha(s \mid \mathbf{Z}(s)) \mathrm{d}s \right), \qquad (6)$$

where the expectation is taken with respect to the conditional distributions of $\mathbf{Z}(s)$ given $X \geq s$ and $\mathbf{Z}(v), 0 \leq v < s$ for $t \leq s < u$. The interpretation is that the (marginal) survival probability at u given the past up to t is the average over the possible paths among survivors for $\mathbf{Z}(s), t \leq s < u$.

For internal covariates, a joint model for X and $\mathbf{Z}(\cdot)$ is, therefore, in general, needed in order to calculate the survival probabilities in (3). Examples with discrete time-dependent covariates modeled as **Markov processes** were given in [4; 6, Section VII.2; 8] and examples with continuous time-dependent covariates in [21, 22, 33, 34, 37] (*see* **Joint Modeling of Longitudinal and Event Time Data**). An alternative approach for estimation of the marginal survival probabilities was discussed in [29].

Furthermore, effects of time-dependent covariates estimated in a model like (2) may only be interpreted as effects on the hazard function for given covariate histories and not as effects on the probability of survival. As a consequence, treatment effects from randomized **clinical trials** adjusted for the effect of a time-dependent covariate $Z(t)$ should be interpreted with great caution since $Z(t)$ may serve as an intermediate variable that may predict survival and whose development over time may be influenced by treatment in such a way that the treatment effect on the hazard function may be masked. (In an epidemiological setting, $Z(t)$ would *not* be a **confounder** variable in this case and should, therefore, *not* be adjusted for when evaluating the treatment effect.)

The Cox Regression Model

The concept of time-dependent covariates was introduced by Cox [14] in the fundamental paper on the **proportional hazards** model where

$$\alpha(t \mid \mathbf{Z}) = \alpha_0(t) \exp(\beta' \mathbf{Z}). \qquad (7)$$

Here, β is a vector of unknown regression coefficients and $\alpha_0(t)$, the baseline hazard, is the hazard function for individuals with $\mathbf{Z} = \mathbf{0}$. Cox's original use of time-dependent covariates was to test the basic assumption in (7) by adding a *defined*, and hence exogenous, time-dependent covariate, for example, $Z_1 \cdot t$, to the time-fixed covariates already in the model and examining whether the corresponding regression coefficient is zero. This is a powerful way of testing for proportional hazards and an important application of time-dependent covariates. Only later were models studied where the effect of certain internal time-dependent covariates was of scientific interest. Early examples are the analyses of the Stanford Heart Transplantation Data [17] and the study [20] of multiple infections. A review was given in [5].

Estimation of β is based on the **Cox partial likelihood**

$$L(\beta) = \prod_{i=1}^{n} \left(\frac{\exp(\beta' \mathbf{Z}_i(T_i))}{\sum_{j \in R(T_i)} \exp(\beta' \mathbf{Z}_j(T_i))} \right)^{D_i}, \qquad (8)$$

[15] where $T_1, \ldots, T_n$ are independent times of observation (T_i being the failure time, X_i, if $D_i = 1$ and a right-**censoring** time if $D_i = 0$) and $R(t) = \{i : T_i \geq t\}$ is the **risk set** at time t. Furthermore, the integrated baseline hazard $A_0(t) = \int_0^t \alpha_0(u) \mathrm{d}u$ is estimated by the Breslow estimator [12]

$$\widehat{A_0(t)} = \sum_{T_i \leq t} \frac{D_i}{\sum_{j \in R(T_i)} \exp(\beta' \mathbf{Z}_j(T_i))}. \qquad (9)$$

The large sample properties of $(\widehat{\beta}, \widehat{A_0(\cdot)})$ were derived in [7]. (Note that the integrated hazard $A_0(t)$ and the estimator (9) are both well-defined in the presence of time-dependent covariates, even though the transformation $S_0(t) = \exp(-A_0(t))$ may not be interpreted as a survival probability; see the Introduction above.

It is seen that in order to compute (8) and (9), the covariate values $\mathbf{Z}_j(T_i)$ for individuals j at risk at time T_i are needed. If, for example, $\mathbf{Z}_j(t)$ is observed as repeated measurements over time for individual j, then the value $\mathbf{Z}_j(T_i)$ may not be measured. If $\mathbf{Z}_j(T_i)$ is (naively) replaced by the latest observation available for individual j before time T_i, then the

estimated coefficients based on (8) tend to be biased [10, 31]. Alternative methods use interpolation on the basis of smoothing of the observed series of repeated measurements of $\mathbf{Z}(\cdot)$ [18, 27, 32] or joint models for X and $\mathbf{Z}$ [21, 22, 34, 35] (*see* **Joint Modeling of Longitudinal and Event Time Data**). A conditional score approach was introduced in [31] while some simpler methods were discussed in [10, 19].

To compute the denominators in (8) and (9) for models with *time-fixed* covariates, a very simple **algorithm** is available. Going backwards in time from the final risk set $R(+\infty) = \emptyset$, one simply adds $\exp(\beta'\mathbf{Z}_j)$ when passing T_j (and if the survival times are left-**truncated**, one subtracts $\exp(\beta'\mathbf{Z}_j)$ when passing the entry time V_j). In models with time-dependent covariates, however, one has to recalculate each sum from scratch and this increases the computing time considerably. This, among other things has led to suggestions to replace the risk set $R(T_i)$ in these sums by some subset of the risk set usually including the individual, i, failing at that time [11, 26, 30]. Such *nested case–control designs* may save computing time and (other resources) without losing much efficiency (*see* **Case–Control Study, Nested**).

Other Regression Models

Aalen [1, 2] introduced and studied a nonparametric regression model with time-dependent effects of covariates and which can also readily take time-dependent covariates into account:

$$\alpha(t) = \beta_0(t) + \beta(t)'\mathbf{Z}(t). \tag{10}$$

Nonparametric estimation of the integrated regression functions $B_j(t) = \int_0^t \beta_j(u)\mathrm{d}u$ are fairly straightforward generalizations of the **Nelson–Aalen estimator**. A simpler version of (10) where $\boldsymbol{\beta}(t)$ is constant was discussed in [25].

The **accelerated failure-time model** for time-fixed covariates is usually defined by

$$\log X = -\beta'\mathbf{Z} + \varepsilon, \tag{11}$$

where ε is an error term and is, thus, not given by its hazard function. If U is a **random variable** distributed as $\exp(\varepsilon)$, that is, as the lifetime of an individual with $\mathbf{Z} = \mathbf{0}$, then, in distribution, $X = \exp(-\beta'\mathbf{Z})U$, or

$$U = \int_0^X \exp(\beta'\mathbf{Z})\mathrm{d}t. \tag{12}$$

On the basis of this, one may study a generalization of (11) allowing for time-dependent covariates by assuming (in the case of no censoring) $U_1, \ldots, U_n$, where

$$U_i = \int_0^{X_i} \exp(\beta'\mathbf{Z}_i(t))\mathrm{d}t, \tag{13}$$

to be i.i.d. A parametric model of this kind was studied in [16, Section 5.2] and a **semiparametric** model with the distribution of U completely unspecified and with estimation based on **linear rank tests** in [28].

Several Timevariables

In the models studied so far, the hazard function has been assumed to depend on a single timevariable but in many examples, more than one time origin may be of relevance (*see* **Time Origin, Choice of**). Thus, one may wish to consider time on study and age, age and calendar time, time on study and time since a given event, and so on.

When using a Cox regression model in such cases, it is necessary to consider one timevariable as the "basic" timescale and to model the effect of other timescales using time-dependent covariates. As an example, we may consider the three-state illness-death model with states 0: healthy, 1: diseased, and 2: dead (*see* **Fix–Neyman Process**). If the three transition intensities $\alpha_{01}(\cdot), \alpha_{02}(\cdot)$, and $\alpha_{12}(\cdot)$ all depend only on a given time, t, the modeled process is **Markov**, but if $\alpha_{12}(\cdot)$ also depends on the duration $d = t - T_{01}$ of time spent in state 1 the modeled process is **semi-Markov** and this may be modeled by including the duration d or some function of it as a time-dependent covariate. A model of this type may also be used for testing the Markov hypothesis in the obvious way. Examples were provided in [6, Section X.1].

In a **Poisson regression** model with a piecewise constant hazard function [13], several timevariables may be modeled simultaneously in a simple way. Dependence on both age and duration may be modeled by assuming the hazard function to be constant in "cells" given by a partition of age and duration,

thus treating the two timescales in "parallel" without considering one of them as basic. Criteria for choosing between Cox and Poisson regression models were discussed in [9, 13].

PER KRAGH ANDERSEN

Time-varying Treatment Effect

Comparing the effects of fixed, time-invariant treatments on a single outcome is basic to biostatistics. In this article we are concerned with the extension to the time-varying situation, i.e. the way that treatments that vary in time within an individual affect outcomes (effects of time-varying treatments). For example, consider the Lipid Research Clinics Coronary Prevention Trial [8], a placebo-controlled, double-blind, randomized trial (*see* **Clinical Trials, Overview**) of the efficacy of cholestyramine for reducing heart disease by lowering the level of cholesterol. The usual approach treats this as a comparison of fixed strategic decisions (treat with cholestyramine or placebo; *see* **Blinding or Masking**), reflected in the **randomization**, and statistical analysis follows the principle of **"intention-to-treat"**. This approach stays close to the experimental basis for **inference** about causal effects of treatment (randomization) and therefore subsumes "noncompliance" or other changes in treatment after randomization under the heading of the "pragmatic" effects of the strategies: "try to give cholestyramine" vs. "try to give placebo". This is not always completely satisfactory to investigators, who may want to know more about the effects of levels of compliance with the active treatment. This involves temporal variation in the treatment, and thus can be seen as a realistic generalization of the causal model that motivates the usual design and analysis of the RCT (*see* **Causation**; **Compliance Assessment in Clinical Trials**; **Pharmacoepidemiology, Adverse and Beneficial Effects**).

For example, an investigator might want to know what would have happened if all patients had been 100% compliant with medication assignment for the entire duration of the study. Efron & Feldman [2] (with commentary) discuss the problem of estimation of the **dose–response** relationship from such a clinical trial with uncontrolled compliance. Another investigator might try to estimate the effects on current cholesterol levels of varying periods of treatment with cholestyramine, or varying total cumulative dose. These are examples of the effects of time-varying treatments. Once the analysis departs from its basis in the randomization, many difficulties arise (see below).

To define these effects more precisely, we introduce some notation. Consider a population of patients U, a set of alternative treatments R, and a collection of possible treatment sequences specifying treatments up to time $s < S$ (an arbitrary upper time horizon):

$$Z(s) = \{z(t)\}_{0 \le t \le s < S}, \quad z(t) \in R. \tag{1}$$

To fix ideas, let U be the population of patients with depression and R be the set of possible doses of antidepressant drug that could be prescribed for some interval. Then, at each time $0 \le t < S$, $z(t)$ specifies the treatment to be given during the intervals $(t, t+1]$, and $Z(s)$ is one particular sequence of treatments specified up to time s. Treatment sequences without arguments define specific treatments for the entire span of time up to S (Z, for example). To define causal effects it is necessary to make a distinction between the set of possible treatment sequences and the one that is actually realized for a given patient. The notation is sufficiently general for realistic purposes, since treatment decisions are effectively discrete time processes, possibly with very short time intervals in some critical care situations.

Let the sequence of outcomes that would be realized up to time s if patient u received treatment sequence Z be denoted by

$$Y_Z(s, u) = \{y_{t,Z}(u)\}_{0 \le t \le s \le S}. \tag{2}$$

For example, each $y_{t,Z}(u)$ could be a vector of symptom scores, **quality of life** scores, and side-effect scores, that would have been observed at time t. If it is necessary to distinguish them from the outcomes, then **covariate** histories $X(s)$ can be specified as well. This generalization to time-varying treatments is implicit in the "potential outcomes" framework due to Rubin [13–15], who explicitly treats such important subtleties as the "stable unit treatment value assumption" (that the response by one patient to a treatment does not depend on the treatment assignments of the other patients). Robins [10, 12] and Lavori et al. [6, 7] exploit these ideas in the context of longitudinal treatments.

We suppose that the treatment decision $z(t)$ specifies the treatment received by the patient for the interval of time starting just after time t, taking effect *after* the measurement of the outcome y_t. Considerations

of causality then make it plausible to assume that the outcomes up to and including time s depend on the given treatment sequence only through its values up to time $s-1$. Thus, if treatment history Z_1 agrees with Z_2 up to and including time $s-1$, then $Y_{Z_1}(s,u) = Y_{Z_2}(s,u)$ and notation such as $Y_{Z(s)}(k,u)$ is well defined for $k \leq s+1$.

Then, following Rubin, define individual causal comparisons of the effects of pairs of treatments Z_1, Z_2 as functionals of $Y_{Z_1}(S,u), Y_{Z_2}(S,u)$. For example, suppose that $y(t)$ is a score measuring severity of depressive symptoms at time t, and Z_1, Z_2 are, respectively, the treatment sequences $\{1,1,1,\ldots,1\}$ and $\{1,1,1,\ldots,1,0,\ldots,0\}$, where there are S 1s in the first sequence, denoting constant treatment with antidepressant, and $s_0 < S$ 1s in the latter sequence. Then we can define one particular individual causal effect (for patient u) of continuous treatment vs. dropping treatment after time s_0 as the difference in time-averaged scores $(1/S)\sum_t y_{t,Z}(u)$ under the particular antidepressant treatment schedules $Z = Z_1$ or $Z = Z_2$.

The problem of inference from observed data arises (just as it does in the fixed-treatment situation) because it is only possible to observe $Y_Z(S,u)$ if Z is the actual realized treatment sequence in patient u. Holland [4] refers to this as the "central problem" of causal effects inference. The statistical approach attempts to estimate some kind of average causal effect (over U) by making assumptions about the nature of the actual assignment of patients to treatment sequences. For example, at time s, the clinician considers the patient's current and past state of depression, level of side-effects of the medication, social functioning, etc. observed under the treatment sequence defined up to the previous assignment (at $s-1$), and then assigns the dosage $z(s)$ that will be taken for the next interval. What do we need to assume about this process to estimate causal effects from the observed outcomes?

Ignorability of Treatment

In the fixed-treatment problem, Rubin [13–15] has defined the requirements for using observed responses to realized treatment conditions to make valid estimates and inferences about average causal effects. These are the "ignorability" conditions, which (for fixed treatments) are guaranteed by randomization of treatments. The crux of the matter is that the treatment actually received should be independent of the potential responses to the treatments being compared (more generally, conditionally independent given measured pretreatment covariates). Generalization of the ignorability conditions to the time-varying case raises a new issue, concerning the intermediate outcomes that may be used as "covariates" to determine subsequent treatment decisions. One omnibus ignorability condition is the following:

$$\begin{aligned}
&\text{for all times } s \text{ and all outcomes } Y(s) \text{ realized up to } s,\\
&\text{for all treatment sequences } Z_0(s-1) \text{ defined up to } s-1,\\
&\text{for all possible treatments } z_1(s), z_2(s), \text{ received at } s,\\
&\text{and for all treatment sequences } Z \text{ agreeing with } Z_0(s-1) \text{ up to } s-1,\\
&\text{for all } t \geq s, \Pr[Y_Z(t,u) | Y_{Z_0(s-1)}(s), Z_1(s)]\\
&\quad = \Pr[Y_Z(t,u) | Y_{Z_0(s-1)}(s), Z_2(s)].
\end{aligned} \tag{3}$$

In words, given any history of treatments and outcomes observed by time s, subgroups defined by the choice of treatment in the interval $(s, s+1]$ have the same distribution of potential future outcomes on any treatment strategy that agrees with the observed treatment history up to $s-1$ and extends it arbitrarily into the future. This would be satisfied if patients were subclassified on treatment and outcome history at s and then randomly assigned to treatment during $(s, s+1]$. Here we sweep all covariates into Y, to avoid unnecessary notation. The idea is that each alternative assignment of treatments during $(s, s+1]$ produces "comparable" patient groups, in the sense of having the same distribution of potential responses to treatment, across all possible treatments determined by arbitrarily extending the observed treatment assignment past s. This assumption is unobservable, and can only be *known* to be true under random assignment, possibly stratified by observables (*see* **Stratification**).

Treatment Strategies and Decision Rules

Fixed treatments can also have effects that apparently vary with time (time-varying effects of treatment).

This is not the focus of the current article, but it is useful to contrast it with the concept of effects of time-varying treatment, since they can easily be confused. Consider the comparison of survival of patients with heart disease under two alternative strategies: (i) immediate surgical treatment vs. (ii) medical treatment at first and then surgical treatment if the patient worsens. The **hazard ratio** may favor medical treatment at first, because of surgical complications, but then the balance may shift over time in favor of surgery. It is commonplace that "all survival curves cross". In our notation, there is only one occasion of treatment decision, defining $z(0)$.

The natural longitudinal extension of the fixed treatment is the fixed strategy, or decision rule. For example, Gelenberg et al. [3] studied the effects on relapse rates in patients in remission from manic depression of two treatment strategies: adjust the dose of lithium carbonate to achieve either a "standard" serum lithium level or a "low" level. The actual prescribed doses of lithium varied in response to the patient's current serum levels, to steer within the target ranges, but the treatment decision was fixed at the outset, and is thus not time-varying in our sense.

In principle, any set of longitudinal treatment strategies can be specified in advance, patients randomized to all of them, and then the outcomes measured and compared. But this breaks down quickly in practice, due to the complexity of possible decision rules. An important exception, when treatments are assigned without regard to previous outcomes, is the standard **crossover design**.

Crossover studies involve explicit use of the variation in treatments within an individual over time to reduce the interindividual variation in response. In the standard crossover study, treatment sequence assignments are randomized, and thus ignorable (barring missing data, dropouts, etc.) The aim is to compare the effects of fixed treatments, and the effects of the longitudinal component of the variation in treatment (carryover, period, and treatment by period **interaction**) are threats to the validity of the analysis rather than explicit targets of estimation. The usual analysis of the two-period two-treatment crossover study tests for the presence of treatment by period interaction effects, and then, given no rejection of the null, goes on to analyze the data as if the order of treatments were immaterial [5]. Thus, the time-varying part of the treatment effect is suppressed. More elaborate and **powerful** designs, with multiple crossovers, essentially suppress higher-order interactions to make better use of the within-individual variation in treatment, but the target is still an effect estimate in the context of a Markovian hypothesis about the irrelevance of some or all of the past history of treatment (*see* **Markov Processes**).

Observational Studies in Medicine

In medicine, simple designs with fixed treatments dominate the experimental literature, partly because of the extreme difficulty in controlling complex patterns of treatments over time in patients whose clinical state demands constant attention and commands instant revision of the individual's treatment protocol when side-effects or worsening exceed tolerance. Represent the clinical decision-making process (*see* **Decision Analysis in Diagnosis and Treatment Choice**) as an iteration of the following single step: measure current outcomes and other covariates, recall past outcomes and treatments, and, on the basis of these facts, determine the next treatment choice by a particular fixed decision rule. No controlled trial can compare many complex versions of the decision rule applied at each step, with randomization among the alternatives. Therefore, time-varying treatment effects appear in nonexperimental studies (*see* **Observational Study**), and in the secondary analysis of data from simple randomized studies when investigators try to define the effects of noncompliance, uncontrolled adjuvant treatments, and other naturalistic complications of controlled experiments.

The study of the effects of time-varying naturalistic treatment is formally identical to the study of the effects of environmental exposures (*see* **Environmental Epidemiology**) that vary in time, and this links the growing literatures in both medical and epidemiologic fields [10]. Since epidemiologists are usually concerned with exposures that are not the result of planned experiments, issues of **confounding** with **time-dependent covariates** are central, including variables that are in the causal pathway from exposure to outcome (intervening variables). An important difference between the epidemiologic and medical treatment contexts is that few epidemiologic exposures are "selected" in order to produce a therapeutic effect. This has

enormous consequences for the likelihood that there are unmeasured **confounders**.

Adjustment for Confounders

There is little controversy over the principles governing adjustment for covariates that are measured prior to treatment (or exposure). In contrast, adjustment for time-varying confounders in the longitudinal setting can yield causally incorrect interpretations (see below). Careful statement of the goals and assumptions is critical to avoiding pitfalls of inference. Mark & Robins give a detailed discussion of this point [9].

For example, in analyzing the effect of dropping antidepressant treatment in patients with major depression in remission, one may suspect that the decision to drop treatment may be influenced by the patient's current state of symptoms, which may vary enough to convince the patient (or clinician) to continue treatment but not enough to qualify as a full relapse. However, adjusting for the patient's current level of symptoms without simultaneously stratifying on the history of treatment can distort the estimation of causal effects on full relapse if the current level of symptoms predicts future relapse and also future treatment, and past treatment predicts current symptoms.

Because of the importance of qualitative changes in health state, such as death, onset of disease, and recurrence of acute illness, survival and other "time-to-event" studies predominate in medicine and epidemiology. Here we concentrate on examples of time-varying treatments in a "survival" setting (including circumstances where the event is not fatal). The survival context offers a substantial statistical simplification: the total probability of the individual trajectory can be factored into a sequence of conditional survival probabilities, with no need to consider the past history of events. This can be generalized by counting process techniques (*see* **Counting Process Methods in Survival Analysis**) to cover situations with reentrance into the risk set [1].

Suppose that measurements of survival and covariates are available, and decisions about a dichotomous treatment are taken, at discrete times 0 (baseline), 1, 2,..., S. Specializing the notation from the first section above to a dichotomous treatment situation, and separating the notation for the survival outcome and possible confounders, let

$$z(t) = \begin{cases} 1, & \text{if patient is treated during } (t, t+1], \\ 0, & \text{otherwise;} \end{cases} \tag{4}$$

$$Z(s) = \{z(t)\}_{0 \le t \le s < S},$$

so that $Z(s)$ defines a particular treatment history. Suppose that each individual u has a set of survival times – one for each possible treatment history – so that $T_{u,Z}$ is the survival time for individual u that would be observed if that individual followed treatment history Z. Note that this is a summary of the sequence of dichotomous indicators of survival at each time: $Y_Z(S, u) = \{y_{t,Z}(u)\}_{0<t\le S}$. (Assume for simplicity that S is larger than any survival time.) Then the obvious individual causal effect of treatment Z_1 vs. Z_2 is just $T_{u,Z_1} - T_{u,Z_2}$, and population average causal effects are functionals of the corresponding survival distributions over U:

$$S_{Z_j}(t) = \Pr(T_{Z_j} > t), \quad j = 1, 2. \tag{5}$$

In the depression maintenance example used above, the "event" could be "relapse into depression", and the treatment dichotomy could be defined by whether the patient continued to receive antidepressant medications during the interval. Some obvious comparisons include "always treat" vs. "never treat" or "treat up to k and then stop". Most possible sequences would be irrelevant or uninteresting; we usually are interested in sequences that are realized naturalistically by many patients.

To introduce possible confounders, let $x(t)$ and $X(t)$ be, respectively, the value of the covariate (vector) measured at time t and the entire history of the covariate up to and including time t. Robins [10] generalizes Rubin's "ignorable treatment assignment" in the following way, stated informally: for each treatment regimen defined up to but not including time s, patients who have survived that regimen and are observed to have the same covariate history up to and including s fall into two groups defined by the actual treatment assignment at time s (treated or not). The assignment is ignorable if the two groups are "comparable" in the sense that their survival distribution from s on would be the same under every treatment history that extends the regimen observed up to but not including s. That is, not only are the groups similar in the unobservable probability of

surviving through $s + 1$, on both the treatment they received and the other option, but also with respect to survival on any future version of the treatment. In symbols,

$$\begin{aligned}&\Pr[T_Z > k | Z_0(s-1), X(s), z(s) = 1] \\ &\quad = \Pr[T_Z > k | Z_0(s-1), X(s), z(s) = 0]\end{aligned} \tag{6}$$

for all Z agreeing with $Z_0(s-1)$, up to $s - 1 < k$.

Robins [10] shows that, under this set of assumptions, causal effects can be calculated by summing (over all possible covariate histories) the joint survival and covariate probabilities of each covariate history, under the two treatment histories being compared. Of course, one must have observed these histories.

Mark & Robins [9] point out that, even with these assumptions and a well-specified time-varying **Cox regression model** for survival given treatment and confounders, the model-based test of the treatment **null hypothesis** does not necessarily test the causal null hypothesis that for each individual the survival times are identical across treatment histories. The example they give involves a hypothetically impotent treatment which has a **correlation** with the discrepancy between the measured confounder and the actual prognostic (latent) variable that it purports to measure. Robins et al. [12] describe an example involving prophylaxis for the intervening variable "onset of pneumocystis carinii infection" in prevention of death from **AIDS**. Lavori et al. [6] investigate a more restricted set of treatment alternatives, defined by the time of cessation of antidepressant therapy, and a "prompt" treatment effect, and find that under these circumstances the time-varying Cox regression model gives valid causal inferences. Robins has also noted that prompt effects can be estimated with the Cox model. Thus, the causal interpretation of the "effect" estimates from the time-varying Cox model depends on more than just the correct specification of the model for the observed data. This is a lively area that should see much activity in the coming years.

Structural Models for Treatment Effect

In the sociological literature, **structural equation models** (*see* **Path Analysis**) are routinely used to model panel data (*see* **Panel Study**) with multiple independent and dependent variables. Such models can be used to analyze time-varying treatment effects, although the assumptions necessary for identification of the parameters include ignorability assumptions that are hidden from view by the structural formulation. Holland [4] contrasts the typical structural equation setup for causal inference with the experiment-based setup described above, which is most familiar to biostatisticians (in its fixed treatment form), and which has come to be known as "Rubin's causal model".

Closely related to the structural equation models used by the sociologists are similar methods used by economists. In particular, **instrumental variables** approaches are often used in econometrics to analyze the structural effects of decisions, inputs, or other variables, which often vary with time. Issues of identification are paramount.

Robins & Tsiatis [11] have proposed an approach to the estimation of causal effects on survival that relies on a structural parametric model for the longitudinal causal effects (an **accelerated failure-time model**). In this model, the strong parametric assumptions make it possible to infer the time to failure of an individual under every possible assignment to treatment, given the observed time to failure under the actual treatment received, and the unknown value of the coefficients of the model. Thus, the parameters have direct causal interpretations. Of course, the method relies on the correct specification of the parametric model for unobservable effects, which is stronger than the usual assumption that the observables are correctly modeled. It will be useful to have several such methods available, to test the sensitivity of conclusions to the specific structural assumptions. This area is currently a focus of intense effort.

Tolerance Interval

Tolerance intervals are statistical intervals that *contain* (or *cover*) at least a proportion β of a population, either on average, or else with a stated *confidence*, γ. Tolerance intervals (and in the multivariate case **tolerance regions**) summarize uncertainty about values of a **random variable**, usually a future observation. This should be contrasted with **confidence intervals** and regions, which provide confidence statements about uncertainty in unknown constants (parameters). Tolerance intervals are sometimes referred to as tolerance bounds or tolerance limits. Prediction intervals and confidence intervals on **quantiles** can be regarded as special cases of tolerance limits.

The statistical theory of tolerance intervals, although conceived to address problems in manufacturing [31, 38], has numerous applications to problems in biostatistics. Some examples include clinical chemistry [9, 30] (*see* **Normal Clinical Values, Reference Intervals for**) and **bioequivalence** [3]. Tolerance interval theory parallels that of confidence intervals in most respects. There is a theory of nonparametric tolerance intervals, a well-developed normal theory, a less complete theory for other parametric families, as well as tolerance limits for linear models. We review some of these areas in this article, with an emphasis on normal theory – which, because of its flexibility, is most important in applications.

Definitions

Let $Y_1, \ldots, Y_n$ denote a sample from a probability distribution with distribution function F. A (β, γ) two-sided β-content tolerance interval is a statistical interval $[L(Y_1, \ldots, Y_n), U(Y_1, \ldots, Y_n)]$ for which

$$\Pr[F(U) - F(L) \geq \beta] \geq \gamma. \tag{1}$$

The constants β and γ are referred to as the *content* (or *coverage*) and the *confidence*, respectively. A two-sided β-expectation interval satisfies

$$\mathrm{E}[F(U) - F(L)] \geq \beta;$$

that is, it has an expected content of at least β. As was first noted by Paulson [26], β-expectation tolerance limits are equivalent to prediction intervals for a future observation.

We define one-sided intervals in the obvious way. A (β, γ) lower tolerance limit is a statistic $L(Y_1, \ldots, Y_n)$ such that

$$\Pr[F(L) \leq 1 - \beta] \geq \gamma.$$

That is, at least a proportion β of the distribution of F exceeds L with confidence at least γ. A (β, γ) lower tolerance limit is thus a lower confidence limit on the $1 - \beta$ quantile of F, with a confidence coefficient of at least γ. Upper tolerance limits are defined similarly.

General References and Bibliographies

The only book-length treatment of statistical tolerance intervals in English is a monograph by Guttman [4], which is particularly useful for its exposition of nonparametric tolerance region theory, and for its discussion of normal and **Bayesian** theory for simple **random samples**. Tolerance intervals are also discussed in some detail in books by Aitchison & Dunsmore [1, Chapters 5 and 6] and, more recently, by Hahn & Meeker [6]. The encyclopedia article by Guttman [5] is also useful for nonparametric, normal, and Bayesian theory for simple random samples, and the article by Noether [20] discusses nonparametric intervals.

The most extensive bibliography of the literature up to 1989 has been published by Jilek, in two parts [10, 11]. Review articles by Patel on tolerance intervals [24] and prediction intervals [25] are particularly useful for their coverage of univariate theory for various parametric families.

An Example: Serum Glucose Measurements

In the remainder of this article we discuss tolerance limits for simple random samples, and briefly review tolerance limits for linear models. We use the following numerical example to illustrate various statistical methods.

At the National Bureau of Standards, measurements were made using isotope dilution/mass spectrometry (ID/MS) of the concentration of glucose in frozen bovine serum. Glucose concentration in frozen serum tends to decrease with time, so these measurements were made on several days over a period of

Table 1 ID/MS concentration of glucose in frozen bovine serum (mg/l)

Serum age (days)				
1	8	15	140	290
1980	1979	1988	1957	1940
1981	1982	1987	1951	1923
1986	1978	1982	1948	1945
1975	1978	1982	1953	1938

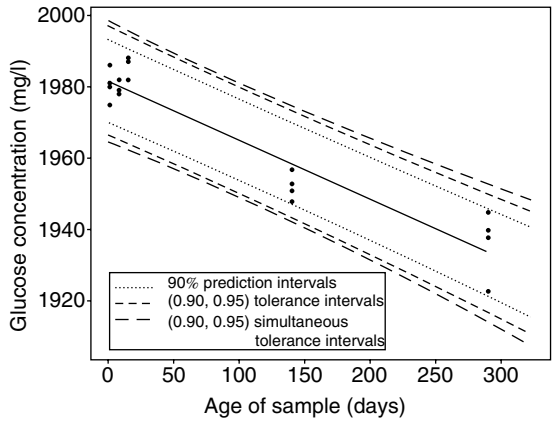

Figure 1 Glucose in bovine serum

months (see Table 1 and [28, p. 14]). A simple plot (e.g. Figure 1 below) of these data suggests that measurements on days 1, 8, and 15 can be pooled, and this is supported by formal tests. However, there is a roughly linear decrease in concentration for the last two sets of measurements.

Simple Random Samples

We begin by assuming that $Y_1, \ldots, Y_n$ are independent and identically distributed (iid). We consider primarily nonparametric tolerance intervals, and tolerance intervals under normality, illustrated using the data in Table 1.

Nonparametric

In one of the earliest papers on tolerance intervals [38], Wilks discusses nonparametric limits (*see* **Nonparametric Methods**). He notes that if $Y_{(1)} \leq Y_{(2)} \leq \cdots \leq Y_{(n)}$ are the **order statistics** of an iid sample from a continuous distribution F, then, for $1 \leq i < j \leq n$, the $\Pr[F(Y_{(j)}) - F(Y_{(i)}) \geq \beta]$ does not depend on F, and can be calculated. This follows from the well-known fact that $F(Y_{(i)})$ and $F(Y_{(j)})$ have **beta distributions**. To determine a (β, γ) tolerance interval, one can select i and j for which

$$\int_0^{1-\beta} \left\{1 - \text{beta}\left[\frac{\beta}{(1-x)}; j-i, n-j+1\right]\right\} \times \text{beta}'(x; i, n-i+1)\, \mathrm{d}x \geq \gamma, \qquad (2)$$

where beta $(\cdot, \lambda_1, \lambda_2)$ denotes the beta distribution with parameters λ_1 and λ_2, and beta$'$ $(\cdot, \lambda_1, \lambda_2)$ denotes the corresponding density. The above integral, derived by conditioning on $F(Y_{(i)})$, is straightforward to evaluate numerically. Some tables (e.g. [6, pp. 318–324]) and graphs (e.g. [19] and [27, p. 123]) are available. Voluminous tables are avoided through the use of the concept of *statistically equivalent blocks* [27, 33], an idea which is central to the theory of multivariate nonparametric tolerance regions. In this univariate case it can be shown that the random variables $C_i = F(Y_{(i)}) - F(Y_{(i-1)})$, where $Y_{(0)} \equiv -\infty$ and $Y_{(n+1)} \equiv \infty$, have the same distribution as the differences of successive order statistics from a sample of size n from a **uniform distribution**. Also, the sum, S_t, of any t of the C_i has a beta $(t, n+1-t)$ distribution. If q denotes the smallest t for which $\Pr(S_t \geq \beta) \geq \gamma$, then $(Y_{(i)}, Y_{(i+q)}), i+q \leq n+1$, is a (β, γ) nonparametric tolerance interval. Since $\mathrm{E}(C_i) = 1/(n+1)$, the expected content of this tolerance limit is simply $q/(n+1)$.

If we pool the data in Table 1 for the first three days, we have $n = 12$, $Y_{(1)} = 1975$, and $Y_{(12)} = 1988$. Substituting $i = 1$, $j = 12$, and $\beta = 0.6613$ into (2) gives $\gamma \doteq 0.9500$; so [1975, 1988] is a (0.6613, 0.95) nonparametric tolerance interval, with expected content $11/13 = 0.846$. Note that for $n = 12$ and $\gamma = 0.95$, nonparametric tolerance intervals of this form do not exist for $\beta > 0.6613$. One-sided nonparametric tolerance limits involving linear combinations of order statistics have been proposed [8, 34]. These limits are valid for a smaller class of distributions than the Wilks limits, but they do not have sample-size limitations.

Normal Distribution

Let $Y_1, \ldots, Y_n$ be an iid sample from a **normal distribution**, and denote the usual sample mean and

standard deviation by $\overline{y}$ and s. We can determine one- and two-sided (β, γ) tolerance limits of the form $\overline{y} - ks$, $\overline{y} + ks$, or $\overline{y} \pm ks$, where k is an appropriate constant. Extensive tables of tolerance limit factors, k, are available; the best source of such tables is Odeh & Owen [21]. For one-sided tolerance limits, the tolerance limit factors are easily shown (e.g. [21, pp. 269–270]) to be proportional to quantiles of a noncentral **Student's *t* distribution**. For two-sided tolerance limits, Wald & Wolfowitz [36] show that $k \approx ru$, where $u = [(n-1)/\chi^2_{n-1,1-\gamma}]^{1/2}$ and r is the solution to

$$\frac{1}{(2\pi)^{1/2}} \int_{r-1/\sqrt{n}}^{r+1/\sqrt{n}} \exp\left(\frac{-t^2}{2}\right) \mathrm{d}t = \beta. \qquad (3)$$

This Wald–Wolfowitz approximation is usually very good, and was used almost exclusively before the advent of modern computing capabilities. Today, exact tolerance limit factors are easy to obtain numerically, and extensive tables are available (e.g. [21]).

Normal tolerance limits for which, with confidence γ, $(1-\beta)/2$ of the population is both less than the lower limit and greater than the upper limit are discussed by Owen [23], and corresponding tolerance limit factors have been tabulated [21, pp. 115–145]. From definition (1), one can see that this symmetry condition is not required for a tolerance limit.

Returning to the example dataset (days 1, 8, and 15), we have $n = 12$, $\overline{y} = 1981.5$ and $s = 3.9196$. To construct, for example, a (0.90, 0.95) two-sided β-content normal tolerance interval, use $k = 2.670$ (e.g. from [21, Table 3.4.1, p. 98]), and calculate the desired limit (1971.0, 1992.0). For a (0.90, 0.95) tolerance limit which controls the probability in both tails, we would use $k = 2.978$ [21, Table 4.4.1, p. 128]. For a β-expectation (i.e. prediction) interval with $\beta = 0.9$, it is easy to show that $k = t_{(1+\beta)/2}(n-1)[n+1)/n]^{1/2} = 1.869$ is appropriate.

Other Distributions

Tolerance interval methods for simple random samples are available for many distributions, continuous and discrete. Patel [24] provides a review. For a **log-normal** model, one need only transform the data by taking logarithms, calculate normal-theory tolerance limits, and exponentiate the result. For the **Weibull distribution** (and, taking logarithms, the **extreme value** distribution), Thoman et al. [32] obtain one-sided tolerance limits using quantiles of pivotal random variables obtained by simulation; a good source for the necessary tables is [2]. Lawless [13] demonstrates that if one conditions on **ancillary statistics**, then one-sided Weibull tolerance limits can be determined numerically, without the need for simulation or tables. One-sided tolerance limits for the log **gamma distribution** are discussed by Jones et al. [12] in an article that emphasizes regression models. For some discussion of discrete distributions, see [24] and [25], and the references cited therein.

Linear Regression

The concept of a tolerance limit can also be applied to **linear regression** models, and the literature in this area is extensive. Let $\mathbf{Y} \sim \mathrm{N}(\mathbf{X}\boldsymbol{\alpha}, \sigma^2\mathbf{I}_n)$, where $\boldsymbol{\alpha}$ is a $p \times 1$ vector of unknown constant parameters, and $\mathbf{X}$ is a known (for convenience, full rank) $n \times p$ matrix of covariates. The **least squares** estimator $\hat{\boldsymbol{\alpha}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$ is normally distributed with expectation $\boldsymbol{\alpha}$. The residual mean square $S = (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\alpha}})'(\mathbf{Y} - \hat{\boldsymbol{\alpha}})/(n-p)$ is σ^2 times a χ^2_{n-p} **(chi-square distributed)** random variable divided by its **degrees of freedom**. For any $p \times 1$ vector $\mathbf{w}$, $\mathbf{w}'\hat{\boldsymbol{\alpha}}$ is normally distributed, and an independent estimate of its variance is proportional to a χ^2 random variable. As a consequence, the theory developed for normal tolerance and prediction intervals for a simple random sample can be applied directly to **fixed-effects** regression problems. This was apparently first demonstrated by Wallis [37], who employed what amounts to the approximation of Wald & Wolfowitz [36]. Although the Wald–Wolfowitz approximation is easy to use, and usually quite accurate, exact computations are straightforward using modern computers.

Similarly, it is reasonable to extend the notion of a prediction interval to a regression setting. Prediction intervals for a single future observation are, of course, classical results in most elementary regression analysis textbooks. Various formulations of multiple prediction problems, along with corresponding solutions, are reviewed by Hahn [7], Hahn & Meeker [6], and Patel [25].

Random-Effects and Mixed-Effects Models

Consider a large (effectively, infinite) population of individuals who respond differently to a treatment,

with each individual having his/her own mean response. Assume that the response for each individual is normally distributed with a common variance σ^2, and that means for individuals are themselves distributed $N(\mu, \sigma_b^2)$. On the basis of, say, J measurements on each of I individuals, one might be concerned with estimating an interval that contains at least a proportion β of the population of potential measurements from a randomly selected member of the population, with confidence γ. Or one might want a prediction interval for a future measurement made on a randomly selected person. This is an example of a **random effects** tolerance limit. Mee & Owen [17] provide conservative methods for one-sided β-content tolerance limits, and Mee [16] treats two-sided tolerance and prediction intervals. Vangel [35] presents an approach for approximate one-sided tolerance intervals for (possibly unbalanced) mixed models having two **components of variance**.

Simultaneous Tolerance Intervals

We now return to the usual regression setup; that is, the data have the form $\mathbf{y} = \mathbf{X}\boldsymbol{\alpha} + \boldsymbol{\varepsilon}$, where $\mathbf{X}$ is a known $n \times p$ matrix of covariates, $\boldsymbol{\alpha}$ is an unknown vector of fixed coefficients, and $\boldsymbol{\varepsilon} \sim N(\mathbf{0}, \sigma^2\mathbf{I}_n)$. Simultaneous prediction intervals constructed for m future $\mathbf{x}$s, when m is large, can often be so wide as to be unusable. For such situations, one would typically use tolerance intervals, or simultaneous tolerance intervals.

A regression tolerance interval covers, for any fixed vector of covariates $\mathbf{x}$, at least a proportion β of future responses $y(\mathbf{x})$, with confidence γ. A *simultaneous* regression tolerance interval is a band about a regression surface such that if $\mathbf{x}_1^*, \mathbf{x}_2^*, \mathbf{x}_3^*, \ldots$ denote arbitrary covariate vectors, and if $y_1^*, y_2^*, y_3^*, \ldots$ denote the corresponding future ys, then at least a proportion β of these future responses will be contained within a tolerance interval, with confidence γ. One can think of the regression sample as being a "training sample" used to estimate a surface, which provides a bound on arbitrarily many future responses. The simultaneous tolerance interval statement means that for at least a proportion γ of repeatedly estimated regression surfaces, at least $100\beta\%$ of all future y^*s will fall within the simultaneous tolerance intervals. Various approximate simultaneous tolerance limit procedures, using different approximations, have been proposed; among these are methods of Lieberman & Miller [14], Limam & Thomas [15], Scheffé [29], and Mee et al. [18].

Regression tolerance intervals, individual and simultaneous, are important in multiple-use **calibration**. In this scenario, a regression curve, once estimated, is to be used many times to obtain estimates and confidence intervals for $\mathbf{x}^*$s based on future y^*s. For a discussion of the use of tolerance intervals in calibration, see the review by Osborne [22]; Lieberman & Miller [14] present an immunoassay example.

An Example Using Serum Glucose Data

In Figure 1, a straight line is fit, and three two-sided tolerance bands are displayed, for the data in Table 1. The innermost band consists of individual 90% prediction intervals (that is, β-expectation tolerance limits) for a single observation, and the outermost bands provide (0.90, 0.95) tolerance intervals: individual and simultaneous. The simultaneous intervals in this figure were calculated using the method of Mee et al. [18].

Tolerance Region

Let $\mathbf{Y}_1, \mathbf{Y}_2, \ldots, \mathbf{Y}_n$ denote iid p-dimensional vectors with distribution function F. A (β, γ) β-content tolerance region is a set $R(\mathbf{Y}_1, \mathbf{Y}_2, \ldots, \mathbf{Y}_n)$ such that

$$\Pr\left(\int_R \mathrm{d}F \geq \beta\right) \geq \gamma.$$

The constants β and γ are referred to as the *content* (or *coverage*) and *confidence* of the tolerance region R, respectively. A β-expectation tolerance region (or *prediction region*) is a region R for which $\mathrm{E}[\Pr(Y \in R)] \geq \beta$. Univariate tolerance regions, often called **Tolerance Intervals**, are discussed in a separate article, which also contains references to bibliographies and reviews on multivariate theory.

The statistical theory on this topic consists mostly of nonparametric and normal theory. We provide an introduction to the main ideas of nonparametric theory below (*see* **Nonparametric Methods**). Some references for **multivariate normal** methods include the monograph by Guttman [3], and articles by Chew [1] and Hall & Sheldon [4].

Nonparametric Regions

Multivariate tolerance regions are determined using *statistically equivalent blocks*, a concept due to Tukey [6], which is introduced in the article on **Tolerance Intervals**, but which we can better appreciate in the multivariate case.

Let $Y_{(1)}, Y_{(2)}, \ldots, Y_{(n)}$ be the order statistics from an iid univariate sample with continuous distribution F. The intervals $C_i = F(Y_{(i)}) - F(Y_{(i-1)})$ (with $Y_{(0)} \equiv -\infty$ and $Y_{(n+1)} \equiv \infty$) are an example of statistically equivalent blocks of **exchangeable** random variables, each of which has the same **beta distribution** as the difference in consecutive uniform **order statistics**. The expectation of each of these random variables is $1/(n+1)$, and the sum of any t of them has the same distribution as the tth order statistic of a uniformly distributed sample of size n. As a consequence, we can easily construct β-content and β-expectation tolerance intervals; this is discussed in some detail in **Tolerance Interval**.

Wald [7] generalizes this idea to multiple dimensions, providing essentially the following **algorithm** for a multivariate tolerance region. First, construct a one-dimensional tolerance interval by ordering the data according to one of the coordinates, keeping only those data values that correspond to blocks chosen to provide a tolerance interval in that coordinate. Repeat this with each coordinate in turn. The region that results is a multivariate tolerance region. Tukey [6] extends Wald's work greatly, introducing the concept of *ordering functions*. Fraser [2] provides further results; Pratt & Gibbons [5] give an elementary introduction.

MARK G. VANGEL

Total Time on Test

Total time on test (TTT) statistics [6] and plots [3, 5] have been discussed quite frequently in the reliability literature on failure-time data as tools for assessing that a **hazard** (or intensity) is constant. The ideas have been phrased in terms of the multiplicative intensity model for counting processes by Aalen & Hoem [1] and Gill [7], and surveyed by Andersen et al. [2]. In this article we introduce this methodology (in counting process notation) with emphasis on biostatistical applications, and present an example of testing constant hazard of death in a follow-up study of liver cirrhosis patients.

We consider a univariate counting process $N(t)$ on an interval $[0, \tau]$ satisfying the **multiplicative** intensity model, i.e. it has an intensity process of the form

$$\lambda(t) = \alpha(t)Y(t),$$

where we want to test the hypothesis that there exists a θ such that

$$\mathrm{H}_0 : \alpha(t) = \theta$$

for all t. Let

$$R(t) = \int_0^t Y(s)\,\mathrm{d}s;$$

then under H_0 the counting process $N(t)$ has $\theta R(t)$ as its compensator and the usual decomposition yields

$$N(t) = \theta R(t) + M(t),$$

with M a (local square integrable) martingale. Therefore, we have

$$\mathrm{E}[R(t)] = \mathrm{E}\left[\frac{N(t)}{\theta}\right]$$

(provided that the expectations exist), and it follows that a plot of $R(t)$ against $N(t)$ should give approximately a straight line with slope θ^{-1}. This plot may be transformed to the unit square by choosing a (possibly random) time T and plotting $R(t)/R(T)$ against $N(t)/N(T)$. This is the TTT plot, the name being due to the fact that $R(t)$ measures the "exposure" or "total time on test" when $Y(t)$ is the size of the risk set. This is, for instance, the case when $N(t) = \sum_i I(X_i \le t, D_i = 1)$ counts the number of failures in $[0, t]$ among independent, identically distributed (iid) (possibly right-**censored**) survival times $X_1, \ldots, X_n$ with D_i being the failure indicator. In this case $Y(t) = \sum_i I(X_i \ge t)$ equals the number at risk at time $t-$. The plot should approximate a straight line with unit slope under H_0, which, for survival data, corresponds to the exponential distribution.

We plot $R(t)/R(T)$ against $N(t)/N(T)$ for all $t \in [0, T]$ and connect the vertical lines one gets in this manner by horizontal lines.

The TTT plot is especially well-suited for situations where the alternative to the hypothesis H_0 of special interest is that $\alpha(t)$ is monotone. Since we have

$$\mathrm{E}[N(t)] = \mathrm{E}\left[\int_0^t \alpha(s)Y(s)\,\mathrm{d}s\right] = \int_0^t \alpha(s)\,\mathrm{dE}[R(s)],$$

it is seen that $\mathrm{dE}[R(t)] = \mathrm{dE}[N(t)]/\alpha(t)$. Therefore, the TTT plot will tend to be concave for an increasing $\alpha(t)$ and convex when $\alpha(t)$ is decreasing.

Closely related to the TTT plot is the cumulative total time on test statistic, defined as $N(T)$ times the area under the TTT plot. According to the just-mentioned properties of the TTT plot, this statistic for testing H_0 tends to take on large values when $\alpha(t)$ is increasing and small values when it is decreasing. One may also use a **Kolmogorov–Smirnov**-type test, i.e. reject the hypothesis when the maximum distance between the TTT plot and the diagonal line $y = x$ is large.

To study formally the properties of the TTT plot, we follow Aalen & Hoem [1] and note that in the new (random) time scale measured by "the total time on test" $R(t)$, N is transformed into a counting process N^* given by

$$N^*(u) = N[R^{-1}(u)],$$

on the (random) interval $[0, R(\tau)]$. Here, $R^{-1}(u) = \inf\{t : R(t) \ge u\}$. This counting process has intensity process $\lambda^*(u) = \alpha[R^{-1}(u)]$, and under H_0 it is a counting process with a constant intensity process θ on $[0, R(\tau)]$, i.e. a randomly stopped **Poisson process** with constant intensity.

As shown by Barlow et al. [4] and Barlow & Campo [3] for certain censoring patterns, and by Gill [7] in greater generality, the asymptotic distribution of the signed area between the TTT plot and the

diagonal line $y = x$, times $[N(T)]^{1/2}$, is the same as that of $\int_0^1 W^0(x)\,dx$, W^0 being the standard Brownian bridge. Therefore, the normalized cumulative total time on test statistic

$$[N(T)]^{1/2}\left[\frac{1}{N(T)}\sum_{i=1}^{N(T)}\frac{R(T_i)}{R(T)} - \frac{1}{2}\right]$$

(with $T_1 < T_2 < \cdots$ being the jump times of N) is asymptotically normally distributed with mean zero and variance 1/12 under the hypothesis. Furthermore, the Kolmogorov–Smirnov-type test for hypothesis H_0 is to reject at the level α when

$$[N(T)]^{1/2}\sup_{0\le t\le T}\left|\frac{R(t)}{R(T)} - \frac{N(t)}{N(T)}\right| > e_\alpha,$$

where e_α is the upper α fractile in the distribution of $\sup_{0\le x\le 1}|W^0(x)|$.

Example

In a **clinical trial** of prednisone vs. placebo treatment of liver cirrhosis, patients entered during 1962–1969 and were followed until September 1974. We consider the survival experience of the 237 placebo patients which could be reevaluated histologically [8]. Figure 1 shows the TTT plot with

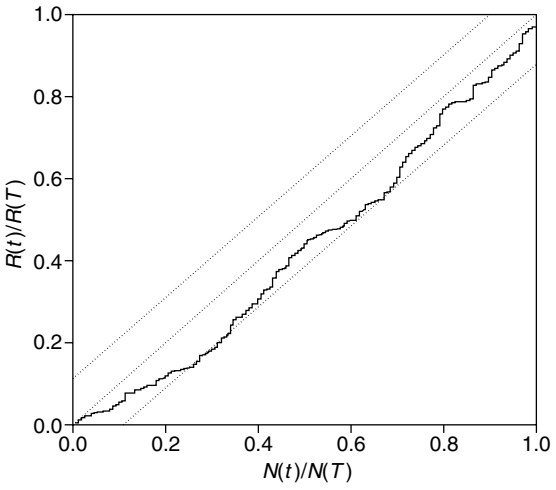

Figure 1 Total time on test plot for mortality of liver cirrhosis patients, including the identity line and boundaries corresponding to the Kolmogorov–Smirnov test

$T = 4892$ days and $N(T) = 150$ observed deaths. The plot is generally *convex*, corresponding to a generally *decreasing* hazard rate. The plot crosses the boundaries $\pm e_\alpha[N(T)]^{1/2}$ around the identity line, where $e_{0.05} = 1.36$ [9, Table 9], indicating significant departure from the hypothesis of exponentiality as judged by a Kolmogorov–Smirnov test at the 5% level. Indeed, the maximal deviation is 0.1214, yielding a Kolmogorov–Smirnov test statistic of $(150)^{1/2} \times 0.1214 = 1.486$, corresponding to $P = 0.024$. The cumulative TTT statistic takes the values -0.8234, corresponding to an approximately normal deviate of $(12)^{1/2} \times (-0.8234) = -2.85$ or a (two-sided) $P = 0.004$.

Transfer Function Models

Time series data arise in a wide range of subject areas; biology and medicine (see, for example, [4]), environment, engineering, economics, etc. To analyze and model such data a number of different tools are available. The simplest is the univariate stochastic model, which associates the value of a variable at time point t to some function of its values at previous time points, i.e. $Y_t = f(Y_{t-1}, Y_{t-2}, \ldots; \boldsymbol{\nu}, \{N_t\})$, where $\boldsymbol{\nu}$ is a vector of parameters and $\{N_t\}$ a noise process. Often the series $\{Y_t\}$ is thought to be related to a second series $\{X_t\}$. A simple example of a *transfer function model* relating the two time series would be

$$Y_t = \nu_0 X_t + \nu_1 X_{t-1} + \cdots + N_t, \tag{1}$$

where $\{X_t\}$ is referred to as the "input" series and $\{Y_t\}$ the "output" series. Transfer function models have proved very useful in the assessment of relationships, if any, between time series measurements, and for prediction and **forecasting** [2, 9]. For example, relating "the daily number of patients attending a clinic for respiratory disease" (output) to "daily pollen count", "daily level of air pollutant", "daily humidity value" (inputs); "monthly employment statistics" related to "inflation rate", "level of investment", etc., in previous months; or, "daily demand for electricity" related to "daily mean temperature" and "mean night temperature".

Assuming there to be no noise (*see* **Noise and White Noise**) in the system, we can write (1) as

$$Y_t = \nu(B) X_t \tag{2}$$

where B is the usual **backward shift operator** $B^h X_t = X_{t-h}$, the operator $\nu(B) = \sum_{i=0}^{\infty} \nu_i B^i$ a polynomial in B known as the *transfer function* of this *linear filter*, and the set of *weights*, $\nu_0, \nu_1, \ldots$ the *impulse response function* of the system.

Note that if $y_t = \nabla Y_t = Y_t - Y_{t-1}$ and $x_t = \nabla X_t = X_t - X_{t-1}$ denote incremental changes in Y and X, then we have

$$y_t = \nu(B) x_t \tag{3}$$

the *same* transfer function model.

Eq. (2) contains a large, possibly infinite, number of parameters and in many systems there may be a time lag, b, in Y_t for a change in X_t. In this case, we can reparameterize the system as

$$Y_t = \delta_r^{-1}(B)\omega_s(B) X_{t-b}, \tag{4}$$

where $\delta_r(B) = (1 - \delta_1 B - \delta_2 B^2 - \cdots - \delta_r B^r)$ and $\omega_s(B) = (\omega_0 - \omega_1 B - \omega_2 B^2 - \cdots - \omega_s B^s)$. Thus, if $\Omega(B) = \omega_s(B) B^b$, the transfer function of this noise-free model is $\nu(B) = \delta_r^{-1}(B)\Omega(B)$, the ratio of two finite-order polynomials, and in this case $\nu_k = 0$ for $k = 0, \ldots, b-1$.

For many practical applications values of r and s that are both ≤ 2 provide suitable models. Box & Jenkins [2] give details of the properties of transfer function models for all combinations of $r = 0, 1, 2$ and $s = 0, 1, 2$.

If multiple input series are available, then the basic model (4) can be generalized to

$$Y_t = \sum_{j=1}^{J} \delta_j^{-1}(B)\omega_j(B) X_{j,t-b_j}, \tag{5}$$

where each input X_{jt} has a transfer function representation the same as for the single-input case, with time lag b_j. The same property for *differencing* as that stated in (3) also applies in this multiple-input case.

For the potential user of transfer function models, the most important task is to identify (*fit*) the model that best describes the process under investigation. This is frequently a mixture of art and science! There are, however, some basic steps to be followed.

Model Identification

An output series $\{Y_t\}$ will almost always be subject to some kind of error. Let us consider the process of identification of a combined transfer function–noise model of the form

$$y_t = \delta_r^{-1}(B)\omega_s(B) X_{t-b} + N_t, \tag{6}$$

where $\{N_t\}$ is a noise process assumed to be generated by an ARIMA (*see* **ARMA and ARIMA Models**) process *statistically independent* of the input process $\{X_t\}$. If $n_t = \nabla^d N_t$, where $\nabla = 1 - B$ denotes the (backward) difference, is a stationary process, then (6) can be rewritten as

$$y_t = \delta_r^{-1}(B)\omega_s(B) x_{t-b} + \phi_p^{-1}(B)\theta_q(B) a_t, \tag{7}$$

where $\{a_t\}$ is a *white noise* process.

In the same way that estimated autocorrelation and partial autocorrelation functions are used to identify univariate ARIMA models, so the estimated *cross correlation function* is used in the identification of transfer function models.

The cross correlation function between two *stationary* series $\{U_t\}$ and $\{V_t\}$ at lag k is defined as

$$\rho_{U,V}(k) = \frac{\gamma_{U,V}(k)}{\sqrt{\sigma_U^2 \sigma_V^2}}, \quad k = 0, \pm 1, \pm 2, \ldots,$$

where $\gamma_{U,V}(k) = \mathrm{E}\{[U_t - \mathrm{E}(U_t)][V_{t+k} - \mathrm{E}(V)]\}$, and σ_U^2 and σ_V^2 are the variances of the input and output series, respectively.

If data $(u_t, v_t; t = 1, \ldots, m)$ is available, then an estimate of the cross correlation function is given by

$$\hat{\rho}_{U,V}(k) = \frac{\hat{\gamma}_{U,V}(k)}{\sqrt{\hat{\sigma}_U^2 \hat{\sigma}_V^2}},$$

where

$$\hat{\gamma}_{U,V}(k) = \sum_{t=1}^{m-k} \frac{(u_t - \overline{u})(v_{t+k} - \overline{v})}{m},$$

$$\hat{\sigma}_U^2 = \sum_{t=1}^{m} \frac{(u_t - \overline{u})^2}{m}, \quad \text{and}$$

$$\hat{\sigma}_V^2 = \sum_{t=1}^{m} \frac{(v_t - \overline{v})^2}{m}$$

are estimates of the covariance and variances, respectively. If the two time series, U and V, are not cross correlated and one is *white noise*, then the standard error for $\hat{\rho}_{U,V}(k)$ is $1/\sqrt{m}$. This result is used to test the statistical significance of cross correlations at each lag k.

Step 1. Identify *univariate* ARIMA models for both the input and output series. The ARIMA model for the input series converts the correlated series $\{X_t\}$ into an approximately independent series $\{\alpha_t\}$. Suppose that this fitted ARIMA model is

$$\alpha_t = \hat{\phi}_X(B)\hat{\theta}_X^{-1}(B)X_t \tag{8}$$

The identical ARIMA model is then applied to the output $\{Y_t\}$ to produce a new series

$$\beta_t = \hat{\phi}_X(B)\hat{\theta}_X^{-1}(B)Y_t; \tag{9}$$

this process is known as *prewhitening* [2].

The transfer function model then becomes

$$\beta_t = \nu(B)\alpha_t + \varepsilon_t, \tag{10}$$

where $\varepsilon_t = \hat{\phi}_X(B)\hat{\theta}_X^{-1}(B)N_t$ is the transformed noise process.

Step 2. Furthermore, it can be shown that $\nu_k = \rho_{\alpha\beta}(k)\sigma_\beta/\sigma_\alpha$. Although statistically inefficient, a reasonable initial estimate for ν_k is $\hat{\nu}_k = \hat{\rho}_{\alpha\beta}(k)\hat{\sigma}_\beta/\hat{\sigma}_\alpha$. Because $\{\alpha_t\}$ is an approximately independent white noise series, the result stated above can be used to identify which cross correlations are significantly different than zero. This step provides an initial estimate of the impulse response function $\{\hat{\nu}_k\}$.

Step 3. The next step is to use $\{\hat{\nu}_k\}$ to "estimate" b, r, and s in (4). The general approach is initially to consider values of $r, s \leq 2$, and to use the results that $\{\nu_k\}$ comprise

1. b zero values $\nu_0, \nu_1, \ldots, \nu_{b-1}$;
2. a further $s - r + 1$ values $\nu_b, \nu_{b+1}, \ldots, \nu_{b+s-r}$, with no fixed pattern;
3. values ν_j, $j \geq b + s - r + 1$, follow the pattern dictated by an rth order difference equation which has starting values $\nu_{b+s}, \ldots, \nu_{b+s-r+1}$. Starting values for ν_j, for $j < b$, will be zero.

Examining the set of values $\{\hat{\nu}_k\}$ in the light of these results, it is possible to obtain preliminary choices for r, s, and b.

Step 4. The identity $\nu(B) = \delta_r^{-1}(B)\Omega(B)$ can be established, and by comparing coefficients of powers of B, preliminary estimates for $\delta' = (\delta_1, \ldots, \delta_r)$ and $\omega' = (\omega_0, \ldots, \omega_s)$ can be obtained.

Step 5. Approximations to the maximum likelihood estimates of parameters δ', ω', ϕ', and θ' are obtained by minimizing the conditional sum of squares function

$$S_0(\delta', \omega', \phi', \theta') = \sum_{t=1}^{m} a_t^2(\delta', \omega', \phi', \theta' | b, x_0, y_0, a_0), \tag{11}$$

where $a_t = \hat{\theta}_X^{-1}(B)\hat{\phi}_X(B)\hat{n}_t$, $\hat{n}_t = y_t - \hat{y}_t$, $\hat{y}_t = \hat{\delta}_r^{-1}(B)\hat{\omega}_s(B)\hat{x}_{t-b}$, and b, x_0, y_0, and a_0 are starting values. This step involves the use of an algorithm to minimize the nonlinear function S_0.

Further details, for each of these steps, can be found in [2] and [9].

Model Checking

The adequacy of any fitted model must be examined. *Residual analysis* is used to do this. Suppose that the identification process gives residuals $\{\hat{a}_t(\hat{\delta}', \hat{\omega}', \hat{\phi}', \hat{\theta}'); t = 1, \ldots, m\}$. The **autocorrelation function** of these residuals, $\hat{\rho}_{\hat{a},\hat{a}}(k) = \gamma_{\hat{a},\hat{a}}(k)/\sigma^2_{\hat{a}}$, should be that of white noise. If this is not the case, then the identified model is not correct.

The inadequacy of either the transfer function or noise process can be checked by examining the cross correlation function, $\hat{\rho}_{\alpha,\hat{a}}(k)$, between the prewhitened input $\{\alpha_t\}$ and the residuals $\{\hat{a}_t(\hat{\delta}', \hat{\omega}', \hat{\phi}', \hat{\theta}')\}$.

If $\hat{\rho}_{\hat{a},\hat{a}}(k)$ exhibits structure – e.g. significant correlations – and $\hat{\rho}_{\alpha,\hat{a}}(k)$ does not, then the noise model alone is incorrect, whilst if both exhibit structure, then the transfer function and noise model are incorrect. Box & Jenkins [2] provide a number of additional diagnostic checks, and statistical tests, that can be carried out to assess the adequacy of various parts of the fitted model.

The application of these models is therefore a cycle of *identification* → *fitting* → *checking* → *re-identification*. A number of software packages are available to assist this process, including BMDP™ [1] and SAS™ [10] (*see* **Software, Biostatistical**).

Examples

Example (A)

Helfenstein [5] (see also [6]) gives an example of the use of a transfer function model to examine the relationship between environmental time series (daily concentrations of SO_2, NO_2, and other factors) and the incidence of respiratory disease in young children (daily number of respiratory symptoms). Measurements were made over a period of approximately one year. Autoregressive models AR(1) were identified for both input series $\ln(SO_2)$ and NO_2, and an autoregressive integrated moving average model ARIMA(0,1,1) identified for the symptoms output series. Transfer function models were identified using the prewhitened cross correlation function for three cases: $\ln(SO_2)$ and $\ln(NO_2)$ as univariate input series, and then both of these as a two-input series.

The paper also gives details of a special case of a transfer function model known as an *intervention model* (*see* **Intervention Analysis in Time Series**). Intervention models incorporate sudden and unusual events into the identification process. In this particular example the sudden event was a chemical spillage.

Example (B)

Crabtree et al. [3] present several examples of the analysis of biomedical time series data. In one of these a transfer function model is identified to describe the relationship between exercise (miles walked per day) and fasting blood glucose concentration (mg/dl). The exercise input series was identified as an autoregressive process with lags at 5 and 8. After prewhitening, the cross correlation function was calculated and revealed a significant negative peak at lag 1. This indicated that exercise significantly reduced blood glucose the following day.

Some other examples of the use of transfer function models in biostatistics can be found in [7, 8], and [11].

Transformations

Statistical analyses make use of transformations which change some quantity into a function of the quantity in a variety of ways. Common transformations are the taking of logarithms, the calculation of powers (*see* **Power Transformations**), and exponentiation but there are many other possibilities. The primary purpose of transformation is frequently to permit the application of standard statistical methodology in a situation in which some features required for the methodology are not present.

In a statistical model, transformations can be applied to a **response variable**, an **explanatory variable**, or to a parameter of the model. The first two situations can be illustrated in the context of **linear regression** which relates a response variable, Y, to an explanatory variable, X. The **normal distribution** assumptions necessary may not be satisfied for the response Y, but may be more reasonably supposed for some transformation of Y such as its logarithm or square root. Furthermore, the linear dependence of the response on X, represented by the linear predictor $\alpha + \beta X$, may be extended to represent a nonlinear relationship between Y and X by adding powers of X to the model. For example, consideration of the quadratic function $\alpha + \beta X + \gamma X^2$ is often used to provide a first test of the assumption of a linear relationship (*see* **Polynomial Regression**). There also may be features of the application which make models which involve nonlinear functions of the explanatory variables particularly appealing (*see* **Nonlinear Regression**). Similar considerations apply in the use of other regression models.

The transformation of a parameter may be required because the natural parameter of interest is not the most convenient for statistical analysis. For example, in epidemiologic studies interest often focuses on **odds ratios**, but inferences are most conveniently undertaken for the logarithm of odds ratios. In this case, the parameter of interest is transformed for the purposes of inference and, most sensibly, the resulting inferences are transformed back to be summarized in terms of the original parameter.

Another illustration of this arises in **generalized linear models** which are based on "linking" a function of the mean of a response to a set of explanatory variables. In the special case of normal theory regression, the mean itself is used but, for example, with **binary data**, the mean of the response is equal to the probability of "success", say, and **logistic regression** links the logarithm of the odds, Pr(success)/Pr(failure), to a linear predictor involving the explanatory variables.

VERN T. FAREWELL

Transfusion Medicine

Transfusion medicine is the branch of medicine concerned with all aspects of the use of blood products and components – from donor selection and care, through testing (blood grouping and microbiology), component preparation, and the indications for their clinical use. The discipline also encompasses pregnancy testing for blood group incompatibilities between mother and baby. New areas in transfusion medicine now overlap with hematology to include tissue banking, stem cells, and immunotherapy. Useful background is provided in references [1, 4, 8, 9].

History of Transfusion

The science of transfusion medicine had a false start for about 2500 years with the mistaken belief that blood letting was actually beneficial for sick patients. Eventually, in the seventeenth century, William Harvey (1578–1657) discovered that blood circulates around the body, and this was the start of experimentation with blood transfusion. In 1666, the English anatomist Richard Lower (1631–1691) found that the pressure difference between an artery and vein would force blood from donor to recipient, and the first successful animal transfusion was achieved, using two dogs as donor and recipient. The first, albeit unsuccessful, human to human transfusion occurred in London in 1818. Although blood transfusion was eventually found to be effective in some recipients, others experienced a severe, sometimes fatal, reaction. This led to the discovery in 1900, by the Austrian biologist Karl Landsteiner (1868–1943), that the blood of one donor was sometimes incompatible with the blood of another and the A, B, and O, blood groups were identified; these are determined by the presence or absence of the antigens A and B in the erythrocytes, and the agglutinating antibodies anti-A and anti-B in the plasma. A fourth group, AB, was discovered two years later. Other blood subgroups were later identified, one of the most important being RhD (Rhesus factor), named after its discovery in Rhesus monkeys, which frequently had fatal implications for foetuses and neonates. These are now rare due to a highly successful prevention programme involving administration of anti-D to RhD negative mothers at delivery to prevent sensitization.

During the Great War, it was discovered that the addition of sodium citrate would stop blood clotting outside the body and prolong its life when refrigerated. The theory of blood transfusion was eventually put into practice during World War II, when thousands of transfusions were needed to save soldiers' lives and the evidence supporting its use was unequivocal. This marked the birth of the specialty of transfusion medicine, which needed to make huge advances to keep up with demand. It was found that albumin and plasma could be used instead of whole blood, and that plasma could be pooled and fractionated to isolate clotting factors, such as factor VIII, for the treatment of hemophilia. Unfortunately, this later led to HIV infection in thousands of sufferers worldwide before HIV screening was introduced (*see* **AIDS and HIV**). Blood clotting is a mechanism to seal the circulatory system after injury. The wound is initially blocked with platelets, some of which rupture to release chemicals that combine with proteins and enzymes in the plasma to form a tough fibrous clot. These clotting factors play an essential role in this mechanism.

Blood Transfusion Today

Whole blood is collected from suitable donors, screened for viral infection, and typed for blood group. As it is inefficient to transfuse whole blood, donations are separated into the three major components of red cells, platelets, and plasma. Leucocytes are discarded to minimize the risk of variant Creutzfeldt-Jakob disease (vCJD) transmission. Individual blood components, such as platelets or plasma, can also be collected by apheresis, where the selected individual components are separated during donation and the remaining components are returned to the donor. The components are stored at blood banks under appropriate conditions until they are either released for transfusion, or expire.

Transfusion of blood products to patients depends on the clinical indication. The evidence base for the efficacy of transfusion lies mainly in clinical experience and laboratory-based research rather than through clinical trials. The key purpose of red cell transfusion is to improve the delivery of oxygen to the tissues, while platelets and plasma are used to

treat and prevent life-threatening bleeding by clotting the blood. Plasma can be fractionated to produce several components, such as clotting factor concentrates, to treat congenital coagulation deficiencies, like hemophilia; immunoglobulins to treat acute infections and to treat immunological disorders; and albumin. This last product was used to treat hemorrhagic shock, although the evidence for this is now doubtful; it is now used for patients with low albumin levels. Transfusions are mostly given without removing blood from the recipient, but exchange transfusions can be performed where the patient's own blood is removed and replaced with donor blood. This is done to counteract the effects of severe jaundice in neonates, or to reduce the proportion of distorted cells in sickle disease.

Millions of blood units are transfused each year, an estimated 23 million in the United States of America, 6 million in Africa, and 2.6 million in the United Kingdom.

The safety of blood is of paramount importance, and safely procedures are in place at every step from donation to transfusion to help prevent transfusion of incompatible blood and infection. There are limits for the shelf life of each component; this depends on the viability of cells and potential for bacterial contamination after prolonged periods. As well as screening for infectious agents, components and recipient blood samples are screened for antibodies that could cause serious allergic reactions in recipients. Numerous safety checks are performed by the nurse at the bedside prior to transfusion to ensure a patient receives correctly matched blood. Despite these safety measures, blood transfusion still carries some risk, and should only be used when absolutely necessary. Several alternatives to transfusion can be considered, such as erythropoietin to improve patient's own red cell production, volume expanders, and red cell substitutes. Techniques to retransfuse the patient's own blood are also employed to minimize the risks of donor transfusion. In the United Kingdom, the Serious Hazards of Transfusion (SHOT) organization exists to audit serious transfusion complications and publishes an annual report on its findings to guide blood safety policies.

Articles on transfusion medicine are published in general medical journals, hematology journals such as *Blood*, and the specialist journals, *Transfusion, Transfusion Medicine,* and *Vox Sanguinis.*

Statistics and Transfusion Medicine

Statistics has had limited use in transfusion medicine, but one of its important practical applications is in quality control, and in studies of transfused versus untransfused patients, to look for associations between perioperative transfusion and adverse clinical outcomes such as risk of cancer recurrence [10]. Parametric models are also employed to determine time to restoration of blood cell concentration, and to select the optimum transfusion time and triggers for transfusion. Models have also been used to estimate induction time of transfusion associated HIV infection and in monitoring survival of transfusion recipients.

Clinical Studies

Blood banks store the products derived from volunteer donations, maintaining meticulous records of vital information, including identity of donors, blood-screening procedures, processing, and dates. They also keep very precise records of the issue of each pack of blood product, including its storage, despatch from blood bank, destination, and the patient who will receive it. Thus, while much information is routinely available about the use of packs of drug products, even within individual hospitals over comparatively short periods, there is a paucity of information about the recipients. Such information is now of vital importance when implementing hemovigilance, a surveillance system for monitoring transfusion safety, through notification of unexpected or adverse events linked to transfusion. This problem was addressed in a landmark study in France by taking a random sample of blood recipients using a complex multistage sampling process [6]. At the first stage, the 39 regional blood centers in France were stratified into small, medium, and large, annual (1997) total of blood units distributed, and five or six centers were randomly selected within each stratum. The selected centers provided lists of the public and private hospitals they each supplied, and the hospitals themselves were then stratified into two groups according to small or medium versus large number of units used. The second stage sampling randomly selected hospitals within these two strata. Within each hospital, all patients who received a transfusion during a specified calendar period of 7 or 14 days were

noted, and details of the first transfusion recorded were analyzed. The recipients were characterized by age, medical history, and ICD-10 diagnostic category, and provided, for the first time, detailed information about transfusions at the population level.

The first population-based survey of the use of red cells in the United Kingdom, was reported in a study confined to north England in 2002 [11]. It was based on transfusion information covering two 14-day periods in 1999 and 2000, and reported broad indications for red cell transfusion, as well as distribution of use among surgical procedures. In addition, it provided age-specific use of red cells, and projected regional demand in 2008. Such surveys will become increasingly important during the next decade, and will require extension to longitudinal designs to assess the consequences of multiple transfusions, and to study survival.

Reducing the amount of unnecessary blood transfused is a key aspect of improving blood safety and can be implemented by the augmentation of current guidelines to rationalize the indications for transfusion. One method is to reduce the trigger for transfusion to lower thresholds. In a Canadian trial, Hébert et al. randomized 838 critical care patients between 1994 and 1997 to either a restrictive red cell transfusion strategy, where they were transfused if their hemoglobin fell to less than 7 g/dL, or a liberal strategy, where transfusion was administered if the hemoglobin fell to less than 10 g/dL [5]. They found no evidence that the restrictive policy was worse in terms of 30-day mortality, with 19% deaths in the restrictive group versus 23% in the liberal arm. Carson et al. carried out a meta-analysis of nine red cell trigger trials in critical care, cardiac, and orthopedic surgery and found that where a lower trigger was used, the probability of receiving a transfusion was reduced without affecting mortality except in patients with serious cardiac disease [2].

The same logic has been applied to other blood components. A trial carried out by Rebulla et al. in Italy randomized 276 patients between 1994 and 1996 with acute myeloid leukemia to either receive platelet transfusions when their platelet count fell below 10×10^9/L, or when it fell below 20×10^9/L [7]. They found no difference in the risk of major bleeding, which was 22% amongst those assigned the lower threshold compared to 20% in the liberal group, with no evidence of a difference in mortality. Of all the blood components, and despite its widespread use, least is known about the efficacy of fresh frozen plasma, useful in treating some congenital deficiencies of clotting factors, and thrombotic thrombocytopenic purpura; its ability to provide benefit in major bleeding remains unconfirmed. A meta-analysis of trials in the use of fresh frozen plasma (FFP) in cardiac surgery found no evidence that its use resulted in reduced blood loss compared to patients receiving no FFP or placebo infusions [3]. Trials in transfusion medicine present more practical issues than standard drug trials, for example, the composition of a component can differ between countries, and timing of randomization also presents difficulties, as a transfusion may not ultimately be needed in all eligible patients. It is also almost always impossible to achieve blinding due to the essential identity checks on the blood bag at the time of transfusion. Clinicians may also be reluctant to randomize patients to receive transfusion or no transfusion, in some clinical situations in which there is limited evidence of benefit; dependent on their perception of risks and benefits involved, some may decide that it is unethical to transfuse, whereas others could take the opposite view.

Limitations of Current Evidence

The clear-cut benefits of transfusing blood in emergency situations, and of routine transfusions in diseases such as leukemia, together with understanding of the severity of outcomes resulting from transfusion of the wrong blood, have led to transfusion medicine becoming a major speciality of medicine. However, the evidence base for current practice is still very limited; there have been very few randomized clinical trials, many of which are underpowered, and poorly designed and conducted.

While there is no question that transfusion can rectify blood loss and imbalances caused by some haematological diseases, or that the biochemical and immunological properties of blood have been proven, it remains to be shown whether the transfusion of blood or blood components is always effective in the treatment of certain diseases and conditions, and whether the benefits of transfusion outweigh its risks.

Transition Models for Longitudinal Data

Suppose that the sequence of random variables $Y_1, Y_2, \ldots, Y_T$ represents the observations from a subject in a longitudinal trial or study. In a transition model, the distribution of each variable is considered *conditionally* on previous outcomes in the sequence. That is, the model represents the behavior of *changes* from the previously established position. More formally, the model is expressed in terms of the **conditional** functions:

$$f(Y_t|y_1, \ldots, y_{t-1}), \quad t = 2, \ldots, T.$$

In practice, a model may use only the most recent history of the process. For example, in a first-order model:

$$f(Y_t|y_1, \ldots, y_{t-1}) = f(Y_t|y_{t-1}), \quad t = 2, \ldots, T.$$

A general discussion of transition regression models can be found in [1].

Such a construction should be contrasted with a *marginal* regression model in which the behavior of Y_t is considered after averaging over the possible outcomes at all other times. Unlike the marginal model, the transition model has no representation in terms of cross-sectional data. Generally, the parameters in analogous regression structures embedded in the two types of model will differ in their interpretation and the choice of the appropriate type should be based on the inferences that are required from the analysis.

Due to the conditional form of the transition model, the associated likelihood is typically easy to construct using the chain rule for probabilities. As a consequence, the models are often comparatively straightforward to use in practice. Applications with binary data, for which the transition models represent **Markov chains**, are widespread. See, for example, [2] and [3]. In contrast, the marginal distribution of Y_t is typically a very complicated function of the parameters of the defining transition model. This may have served to inhibit the theoretical development of the models, which is, at present, less extensive.

M.G. KENWARD

Transplantation

The first successful human corneal transplant was around 1900 by Zirm, corneal xenografting having been tried as early as 1837 but without notable success. From the early 1950s, Calne envisaged kidney transplantation as practicable therapy; and surgical, immunological, and immunosuppressive advances made it so by the mid-1980s. By 1970, Barnard had pioneered heart transplantation; and liver transplantation was also under way. Xenografting from transgenic pigs is the challenge of the next decades, together with improvements in unrelated donor bone marrow transplantation and therapeutic exploitation of stem cell banking. Interventional ventilation has not been proceeded with, and there has been more emphasis on realizing national potentials for living related kidney transplantation together with ethical and matching safeguards for unrelated living renal transplantation.

By 1990, transplantation had achieved one-year graft survival rates of 80% or more for most solid organs, and has done so through surgical innovation, advances in immunosuppression, beneficial and favourable matching of kidney donor to recipient, better preservation solutions, and by studying center variation in donor rates as well as in transplant outcome. In the 1990s, shortage of cadaveric donor organs has been a limiting factor that use of split livers or of domino heart transplants from cystic fibrosis heart-lung block recipients has mitigated only very partially. Epidemiological studies monitor malignancies secondary to immunosuppression. **Quality of life** as well as length of life (*see* **Life Expectancy**) is improved by transplantation.

Statistical science has underpinned most of this progress. Well-conducted randomized controlled trials (*see* **Clinical Trials, Overview**) of new immunosuppression therapies and preservation fluids have been published [26]; there has been occasional but critical early stopping of trials, because of overimmunosuppression, on the basis of **surrogate endpoints** of rejection episodes and major infections [16]. Proposals for the design and analysis of randomized trials with recurrent events [3] have had application in kidney transplantation. Two small trials in bone marrow transplantation were used to illustrate a new statistical measure to aid in the interpretation of published trials [1].

Beneficial matching [9, 12]; that is, the rules by which cadaveric donor kidneys have been exchanged in the UK, had a statistical basis and has persisted for 10 years up to 1997 when extended, also on statistical grounds, to favorable matching. Similar work on matching and matchability (see below) has been done independently by Mickey and colleagues [14, 24]. **Validation studies** have featured, whether in independent data sets (matching effects in distinct epochs of follow-up [11, 29, 31]) or by **meta-analysis** (DR mismatching in corneal transplantation [19]). Matchability score, dependent upon human leukocyte antigen (HLA) phenotype and exchange rules, for patients on the kidney transplant waiting list was introduced by Gilks [8, 10, 12] to summarize a patient's chance of getting a well-matched donor kidney in two or five years, and hence to aid individual decision-making on whether to accept or reject an offered kidney.

Special studies such as Corneal Transplant Follow-up Study (CTFS) and International Marrow Unrelated Search and Transplant (I MUST) Study have been set up to establish the core data that national registries (*see* **Disease Registers**) should seek to collect because they determine either waiting times [20], tissue allocation or prognosis [21] or quality of outcome, for which visual acuity is a natural measure [30]. In the I MUST Study, minimization, as in randomized trials, was adapted to select prospectively a **control** cohort of twice as many HLA-identical sibling transplants to correspond to the unrelated donor transplants in terms of marginal frequency for age group, diagnosis, risk, and transplant center. A second aspect of the design of the I MUST Study is noteworthy: in unrelated bone marrow donor searches, the patients for whom the search procedure finds an unrelated HLA-identical donor are effectively selected by "genetic randomization", which has broader epidemiological application than in studies of transplantation, for example, to understanding environmental determinants of disease [5]. A **time-dependent covariate** indicator (or several to account fully for nonproportionality of hazards (*see* **Proportional Hazards, Overview**) post transplant) can be switched on at that time and, by following all patients for whom an unrelated donor search was initiated, the effect of unrelated HLA-identical bone marrow transplantation against alternative management can be estimated in an **unbiased** manner. Effective **randomization** makes

the proposed analysis even more powerful than the use of a time-dependent indicator to switch patients from "awaiting cardiac transplantation" to "recipient status" [23], leading to appropriate analyses of the cost-effectiveness of heart transplantation (*see* **Health Economics**).

Cardiothoracic transplantation has posed other important statistical problems, including analysis of repeated biopsies after cardiac transplantation [28], informative **censoring** of quality-of-life measurements [4], and individualization of cyclosporine dose by monitoring the variability of cyclosporine blood levels and also the patient's kidney and liver function [2]. Kalman filter techniques [22], applied to weight-adjusted reciprocal creatinine for detection of kidney rejection episodes, were pioneering but did not become routine, perhaps because they were developed before cyclosporine. Sharples [13, 27] used a Gibbs sampling approach (*see* **Markov Chain Monte Carlo**) to modeling the longer-term risk of developing coronary occlusive disease after heart transplantation and thereby showed that there were particularly high transition intensities from mild to severe disease and from severe disease to death; thus, once mild disease developed, a patient's deterioration was rapid and research should focus on reducing progression from mild to severe disease.

Renal graft failure rates have been published in the UK on a center-anonymized basis since the early 1970s. This tradition in transplantation was in contradistinction to center-identified "name and shame" publication of performance data in the public services that took hold in UK in the late 1990s. Dissemination strategies were among the issues reported in October 2003 by a Royal Statistical Society Working Party on Performance Monitoring in the Public Services (see `www.rss.org.uk` for "Performance Indicators: Good, Bad, and Ugly"). Center variation has reduced considerably in the post-cyclosporine era [7] and further analysis by the confidence ranking methods developed by Goldstein & Spiegelhalter [15] would allow comparison of centers over calendar time, with or without adjustment for **case mix**, but taking account of center **covariates** such as whether a department of transplant immunology or transfusion medicine was responsible for tissue typing and cross-matching. In renal transplantation where centers' policies, let alone practice, on acceptance of older or asystolic donors, adherence to favorable matching, and retransplantation of older or diabetic or highly sensitized recipients may differ greatly, there is merit in no adjustment for case mix on the basis that the case mix is effectively center-determined. Ohlssen [25] used center variation in mortality after transplantation as one of three running examples that motivated a predominantly Bayesian analytical framework, easily programmable in WINBUGS, for the identification of unusual performance in a limited number of, versus many, centers.

Donor statistics are as important in transplantation as understanding the determinants of graft outcome. Confidential audit of all deaths in intensive care units in England and Wales in 1989–1990 [17, 18] showed that the second reason, after relatives' refusal, for missed suitable organs differed for the different organs – e.g. failure to ask in the case of kidneys but nonprocurement of offered suitable livers. That confidential audit also showed that even if all potential kidney donors in intensive care units became actual donors the need for cadaveric kidneys would not be met. Since then, the problem of nonprocurement of donor livers has been solved by designation of new centers but the shortage of donor kidneys has been exacerbated by the successful introduction of rear seat-belt legislation which saves lives. UK's most recent donor audit, begun in 2003, additionally records ethnicity because special allocation measures have had to be introduced to achieve better equity for blood group B patients on the kidney transplant waiting list, and differential relatives' consent rate by ethnicity needs to be investigated. Worryingly, preliminary results suggest that, overall, relatives' consent rate in 2003 had reduced markedly compared to 1990. Reduced altruism may be an adverse consequence of an organ-retention scandal emanating from the Royal Liverpool Children's NHS Trust, which has led to a revised Human Tissue Bill [6].

Travel Medicine

The subject of travel medicine is aimed at preventing illnesses associated with travel or travelers. The speciality provides advice and protection for travelers, immigrants, and refugees, and covers issues relating environmental, climatic, physical, and infectious agents during or after a journey. In the nineteenth century, colonial expansion led to the development of the speciality of tropical medicine in order to maintain the health of colonists working in the tropics. As tropical medicine changed with world politics, it became clear that preventing disease dissemination and transmission of cholera, smallpox, and yellow fever required international control and regulation. The **World Health Organization** enacted statutes requiring travelers to show certificates of immunization from registered centers for smallpox, yellow fever, and cholera. On the eradication of smallpox, with control of yellow fever, and with the recognition that cholera was not controlled by immunization, vaccination centers focused on other common travel health problems. Research focused on the epidemiology of diseases imported by travelers, particularly diseases preventable by vaccines or prophylactic drugs. Steffen [6] quantified health problems that afflicted Swiss travelers, and noted that travelers' diarrhea was the most frequent cause of illness. Surveillance studies in travelers revealed that vaccine preventable illnesses such as polio, typhoid, tetanus, and hepatitis B occurred very rarely. Patterns of illness were not always similar across nations; for example, hepatitis A in UK travelers was significantly lower than the incidence of hepatitis A in Swiss travelers [2, 6]. For problems where preventive measures existed, investigators established their effectiveness and safety.

Malaria is important, as it poses a threat to most tropical travelers, and therefore its prevention has attracted much research. Using surveillance reports, Phillips-Howard [5] described the pattern of malaria imported into the UK and factors associated with a high risk of infection. Ethnic travelers visiting West Africa to visit friends and relatives were at particularly high risk. It was also noted that region of travel and the reason for travel and use of a chemoprophylactic regimen had a bearing on the risk of developing malaria. Large-scale questionnaire-based surveillance studies of returning and returned travelers allowed estimates of protective efficacy of various malaria chemoprophylaxis regimens to be made. The largest study, of 145 500 European travelers returning from Mombassa in Kenya, undertaken by Steffen et al. [7], reported comparative prophylaxis effectiveness of mefloquine 91% (95% **confidence interval** 85–94) to chloroquine/proguanil 72% (95% CI 56–82). The study did not report CI between the drug regimens. The authors identified at least six different malaria regimens used by tourists visiting Kenya.

The study was also used to estimate adverse events associated with chemoprophylaxis use. Problems associated with this and other studies of adverse events are in the definitions of an adverse event and in using these definitions across studies. In this cohort, serious was defined as life threatening, disabling, or fatal, and occurred in 1 in 10 000 travelers using mefloquine. In a more recent study of adverse events associated with malaria prophylaxis, Barrett et al. [1] describe severe adverse reactions as those associated with hospital admission and define a disabling reaction as that which interferes with normal daily activity. In relation to mefloquine use, the incidence of severe reactions was 0.5%, and disabling side-effects were reported to occur in 0.7% of users.

Much confusion now exists on the true rate of adverse events and how they should be defined. The size and cost of such projects has restricted subsequent confirmatory or supportive studies. The study relied on adverse events reported on return and on follow-up. This design meant that individuals who developed reactions that prevented them from traveling (most travelers start prophylaxis a week or two before traveling) would not be recognized, a design fault that may have significantly **biased** the true estimates of adverse events. Evaluations of interventions on avoidance of travelers' diarrhea, looking at the impact of advice on food and water hygiene and the benefits of chemoprophylaxis against a problem that affected up to 50% of travelers, have been undertaken by many clinicians. Advice to change travelers' eating and drinking had no impact on diarrhea incidence [4], but antibacterial chemoprophylaxis used in a double blind (*see* **Blinding or Masking**) controlled **clinical trial** in students visiting Mexico had a significant impact. The method of **randomization** was unclear, but two groups received a daily antibacterial agent and the third received a placebo. One third of the placebo group suffered

diarrhea in a 14 day period, while only one of the subjects receiving trimethoprim–sulphamethoxazole had diarrhea [3]. More recent research methodologies have focused on the risk to benefits of interventions (*see* **Data Monitoring Committees**), especially where drugs/vaccines have appreciable toxicity and the risk of infection is variable. As many vaccines and drugs are costly, the cost–benefit [2] of preventive measures is also under investigation (*see* **Health Economics**). Many of the studies examining interventions use standard statistical methods, and the study design is occasionally difficult, as monitoring events in traveling subjects requires innovative techniques.

R.H. BEHRENS

Treatment Delay

Patients showing symptoms characteristic of a life-threatening disease are always advised to report to a physician without delay. Early reporting and subsequent diagnosis permit early treatment intervention. Prognosis is likely to be improved by early diagnosis and treatment, although the benefit may be small or zero if the disease has already progressed irrevocably at the time of diagnosis, or if no effective treatment is available.

The assertions made in the above paragraph cannot be confirmed by randomized trials (*see* **Clinical Trials, Overview**) because it would be both unethical and impracticable to require patients to incur unnecessary delay in reporting symptoms or receiving treatment. However, it seems clear on general grounds that delays in diagnosis or treatment cannot be beneficial except in the unlikely event that the treatment to be offered is actually harmful.

Paradoxically, many data sets appear to show the opposite [3]. Table 1 describes a historically interesting series of 950 cases of breast cancer operated on between 1889 and 1931 [2] (reported in [3]), of whom 420 had died by 1932. The mean duration of survival after operation is related to the preoperative delay. There is little effect of delays less than three years, but four-year delay appears to be associated with longer postoperative survival. The effect is more remarkable when survival is measured from onset of symptoms, since patients in the last group in Table 1 survived some five years longer, after onset of symptoms, than those in the first group.

Other series reported in [3] show higher five-year postoperative survival rates in patients with very short delays or very long delays, with poorer results for the intermediate lengths of delay.

Table 1 Preoperative delay and mean duration of survival after operation, in a series of patients with breast cancer

Preoperative delay (months)	Number of patients	Mean duration of survival after operation (years)
0–	66	3.87
3–	67	2.86
6–	50	3.07
9–	66	2.57
12–	74	3.54
24–	20	3.65
36–48	17	4.91

From [2], quoted in [3, p. 163].

Table 2 Delay in admission to hospital and case–fatality rate, in patients with clinical tetanus

Time from first symptom to admission (hours)	Deaths/total (% fatality rate)
1–9	53/89 (60)
10–18	90/150 (60)
19–36	120/302 (40)
37–72	69/388 (18)
73–144	31/262 (12)
145–	5/90 (6)

Based on [1, Table 3].

It would be easy, but wrong, to conclude from such evidence that patients benefit by deliberate delay in seeking diagnosis and treatment. Long delay will tend to occur with relatively slow progression of disease (for instance, with a slowly growing tumor), and patients with this type of disease will tend to survive longer after onset of symptoms and longer after initiation of treatment. The malignancy of the disease, with the consequent rapidity of progression of symptoms, acts as a **confounder**, being associated negatively with both pretreatment delay and survival. A slight reversal of the positive **correlation** between delay and survival may occur for the group of patients with the very shortest delays, because this group may include some patients whose prognosis is improved by early access to effective treatment.

A similar phenomenon was noted in a study [1] of prognosis in patients with clinical tetanus. Table 2 shows the relation between the time from first symptoms to admission to hospital, and the case–fatality rate. Patients with a delay in admission of less than 10 hours had a fatality rate of 60%, whereas those with a delay longer than 145 hours had a fatality rate of 6%. There is great variation in the rapidity of development of symptoms in clinical tetanus, and mildly affected patients may experience delay in admission but nevertheless have a favorable prognosis.

Treatment-covariate Interaction

A *treatment–covariate interaction* (TCI) is said to exist when the effect of a treatment varies according to the value of a specified **covariate**, the latter being a function of one or more patient characteristics measured at baseline. The existence of such an **interaction** is important for the clinical practice of medicine, because it implies that the optimal choice of treatment differs for different patients. For example, knowledge of aspects of the patient's history and clinical presentation may permit a better treatment selection than would be possible without that knowledge.

The usual objective of a controlled **clinical trial** is to study the effects of a particular treatment given to patients of a particular type. The main conclusion from the trial is usually assumed to relate to any persons who meet the trial's eligibility criteria (*see* **Eligibility and Exclusion Criteria**). For instance, Fischl et al. [4] reported the results of a trial of two drug regimens for delaying disease progression in patients with "advanced" HIV disease, where the investigators defined "advanced" operationally as either symptomatic disease with a CD4 cell count of not more than 300 cells/mm^3 or asymptomatic disease with a CD4 cell count of not more than 200 cells/mm^3.

Two natural questions arise. First, do the results of this trial apply equally to all of the types of persons represented in the study? Because individuals differ in an unlimited number of ways, there is unfortunately no certain answer to the question. However, as we describe below, one can address a more limited question when suitable data are in hand.

Secondly, one might also inquire whether the results of this trial apply to some types of persons who were excluded from entering. For example, do the results apply to individuals with "limited" HIV disease? This second question has to do with study generalizability and involves a somewhat different set of issues.

Interaction Modeling

To approach answering the first question in a limited manner, suppose that the data from the trial include variables indicating not only the treatment and the clinical outcome, but also patient characteristics measured at baseline, such as gender, age, overall health status (such as the Karnofsky performance status score), stage or extent of disease, and other factors that may be prognostic.

A TCI may be defined, estimated, and tested for significance within the framework of commonly used **regression** models. To keep the exposition relatively simple, suppose that the aim of treatment is to affect the average value of outcome which is **normally distributed**, namely, $Y \sim \mathrm{N}(\mu, \sigma^2)$. We choose a model that expresses the influence of the **binary** variable for treatment (x_1, say) and baseline covariates ($x_i, i = 2, \ldots, p$) on outcome through the relationship $\mu = \mathbf{x}'\boldsymbol{\beta}$.

Suppose that the covariate for age is x_2. To introduce an interaction between treatment and age into the model, define the new variable $x_{p+1} = x_1 x_2$, and append it to the list of variables $\mathbf{x}$ in the model $\mu = \mathbf{x}'\boldsymbol{\beta}$. **Mean** outcomes for individuals with covariate values $x_2, \ldots, x_{p+1}$ are $\beta_1 x_{11} + \beta_2 x_2 + \cdots + \beta_p x_p + \beta_{p+1} x_{11} x_2$ and $\beta_1 x_{12} + \beta_2 x_2 + \cdots + \beta_p x_p + \beta_{p+1} x_{12} x_2$, with x_{11} and x_{12} designating the two treatment variable values. The difference between these means, or treatment effects, is $\beta_1(x_{11} - x_{12}) + \beta_{p+1}(x_{11} - x_{12})x_2$, which depends on x_2 unless $\beta_{p+1} = 0$. If x_2 is a continuous covariate, β_{p+1} is the amount by which the treatment effect changes per unit change in x_2. As a special case, if x_2 is binary, taking values 0 and 1, or 1 and 2, say, β_{p+1} is the amount by which the treatment effect changes when the covariate changes from one level to the other. Then, to assess the statistical significance of a particular TCI, one can test the null hypothesis H_0 : $\beta_{p+1} = 0$, using standard methods (*see* **Hypothesis Testing**).

Because the data often include many covariates, one can test many TCIs. One set of choices involves the definitions of covariates to evaluate for characteristics with more than two possible categories, such as age or prior therapy. Another issue is whether to consider higher-order interactions. Note especially for continuous covariates that interactions that appear to be substantial may largely disappear under a **transformation** of the covariate (e.g. from a linear to a logarithmic scale).

Making these choices can leave the analyst with a large multiple testing problem (*see* **Multiplicity in Clinical Trials**), arousing suspicion that any large

observed interaction is spurious. Many writers (e.g. Buyse [1]) recommend limiting the analysis to a small number of TCIs, preferably those identified as plausible before the trial.

Qualitative Interactions

Qualitative interactions are said to exist "when the direction of the true treatment differences varies among subsets of patients" [6, p. 361]. Differences in the magnitudes, when all are in the same direction, are considered to be unremarkable. A change in direction, however, implies a change in recommended treatment. Interactions that are not qualitative are called *quantitative*. Quantitative interactions are model-dependent, because it is sometimes possible to remove them by a monotone transformation of the covariate. Qualitative interactions are model independent [2]. A focus on qualitative interactions will thus: (i) concentrate on cases involving different treatment preferences for different types of patients; (ii) reduce the interactions claimed that are really artifacts of the model chosen; and (iii) limit exposure to multiplicity effects.

Gail & Simon [6] derived a **likelihood ratio test** of the **null hypothesis** that there is no qualitative interaction when the covariate is categoric. Starting with statistically independent estimates $D_i, i = 1, \ldots, I$, of the treatment effect differences in each of I nonoverlapping categories, or subsets, and their **variances** σ_1^2, one calculates $\Sigma(D_i^2/\sigma_i^2)I(D_i > 0)$ and $\Sigma(D_i^2/\sigma_i^2)I(D_i < 0)$, where $I(S)$ is the indicator function for the set S. If both of these quantities exceed a critical value from Table 1 of Gail & Simon [6], which depends on both the nominal type I error rate (*see* **Hypothesis Testing**) and the number of categories being examined, then the null hypothesis is rejected.

Most workers in the field believe that qualitative interactions are quite uncommon. Indeed, it seems implausible that a treatment beneficial in one subgroup (e.g. young patients) would actually be harmful in another (e.g. the old), even though it would not be at all surprising if the average benefit of the treatment varied in magnitude among subgroups. Byar [2] did observe a qualitative interaction concerning the use of diethylstilbesterol (DES) for the treatment of prostate cancer. Patients with advanced stage disease who received DES had lower mortality from prostate cancer than their counterparts not receiving DES, and this was the predominant cause of death in this group. Patients with early stage disease who received DES also had lower prostate cancer mortality but higher mortality from cardiovascular causes than similar patients who did not receive DES. In this early stage disease group, prostate cancer did not predominate as the cause of death, and the increased mortality from cardiovascular diseases became the overriding factor. It would be wrong, Byar concluded, never to look beyond overall results.

Bayesian Approach

A Bayesian approach (*see* **Bayesian Methods**) can be useful in some situations. Starting with estimated regression coefficients at least approximately normally distributed, Dixon & Simon [3] proposed using **exchangeable** normal **priors** centered at zero for the regression coefficients corresponding to TCIs, and vague priors for the other regression coefficients. This model leads to a **shrinking** of estimates of subset-specific treatment differences toward the estimated overall treatment difference. The precision of the estimates, however, need not be reduced on account of multiplicity. Dixon & Simon [3] illustrated this feature of a Bayesian approach using data from a clinical trial of chemotherapy for colorectal cancer.

Subgroup Analysis

As indicated earlier, when describing the parametric model for studying TCIs, the real interest is in detecting subgroups of patients for whom the optimal treatment differs from the overall patient population. An alternative to studying interactions in a parametric model, one that has been used very often in the clinical research literature, is simply to compare treatments in each of a number of patient subsets or subgroups, and to highlight those subgroups in which the treatment difference attains conventional statistical significance.

Uncritical presentation of numerous subgroup-specific tests of a significant treatment effect is certainly to be discouraged. For one thing, clinical trials accrue sufficient participants to provide adequate precision for estimating quantities of primary interest, usually overall treatment effects. Confining attention to subgroups almost always results in

estimates of inadequate precision. Furthermore, the chances of making a type I error increase rapidly with the number of subgroups examined. Provided that the parametric model above holds, there is a one-to-one correspondence between nonzero regression coefficients for interaction terms and a collection of subgroup-specific treatment effects that vary from one subgroup to another. Testing hypotheses about interactions, however, is a much more efficient way to detect these variations than to compare treatments within many different subgroups.

In addition, there is usually good reason for regarding the overall treatment groups as comparable in a randomized trial. Subgroups may not enjoy the same degree of balance in patient characteristics, leading to apparent treatment differences, due to the two treatment groups within a subgroup having markedly different prognoses.

Finally, there are multiple ways to create subgroups. For example, one may examine four mutually exclusive subgroups determined by the cross classification of two binary covariates, as well as two pairs of subgroups determined by the two covariates considered marginally. The choice of subgroups to examine is thus almost boundless, and selection is inevitably somewhat arbitrary.

Gender and Minority Subgroups

In the past few years, assessment of TCIs has assumed new importance because of its relationship to questions of generalizability of findings from clinical trials and access to clinical trials by traditionally under-represented groups. If one assumes no TCIs, one is free to design a study of usual size, or one may even reduce the sample size by favoring volunteers at highest risk of the unfavorable outcome being observed. In the extreme, this leads to omitting whole classes of individuals; for example, women. The problem is that this leaves no possibility of later checking for the existence of TCIs using data from the trial. It therefore seems scientifically sensible to provide reasonable access to clinical trials of new treatments by all segments of the general population.

Unfortunately, a trial just large enough to evaluate an overall treatment effect reliably will almost inevitably lack precision for evaluating differential treatment effects between different population subgroups. **Meta-analyses** of similar trials may carry sufficient **power**, however, especially if one is interested mainly in qualitative interactions. For a thorough exposition of these issues, see Freedman et al. [5].

DENNIS O. DIXON

Trees, Probabilistic Functional

Decision Trees

A decision tree (*see* **Computer-aided Diagnosis**) uses a divide-and-conquer strategy. It attacks a complex problem by dividing it into simpler problems and recursively applying the same strategy to the subproblems. The solutions of subproblems can be combined in a form of a tree to yield a solution of the complex problem. The power of this approach comes from the ability to split the instance space into subspaces and each subspace is fitted with different models. This *recursive partitioning* (*see* **Tree-structured Statistical Methods**) idea is behind well-known decision tree–based **algorithms**, such as CART [4] and C4.5 [17]. More recently several statistical packages, *S-PLUS*, *Statistica*, *SAS*, and *SPSS* (*see* **Software, Biostatistical**) [14] have incorporated functions that implement decision trees for classification and regression problems.

Formally, a decision tree is a direct acyclic graph in which each node is either a *decision node* with two or more successors or a *leaf node*. A *leaf node* is labeled with a *class*. A *decision node* has some *condition* based on attribute values. The hypothesis space of these algorithms is within the *disjunctive normal form* (DNF) formalism. Classifiers generated by those systems encode a DNF for each class. For each DNF, the conditions along a branch represent conjuncts and the individual branches can be seen as disjuncts. Each branch forms a rule with a conditional part and a conclusion. The conditional part is a conjunction of conditions. Conditions are tests that involve a particular attribute, operator (e.g. $=$, $\geq$, etc.) and a value from the domain of that attribute. These kinds of tests correspond, in the input space, to a hyperplane that is orthogonal to the axes of the tested attribute and parallel to all other axis. The regions produced by these classifiers are all hyperrectangles. Each leaf corresponds to a region. The regions are mutually exclusive and exhaustive (i.e. cover all the instance space). It is known that the problem of building a minimal decision tree (in terms of number of nodes), consistent with a set of data, is an *NP hard* problem [18]. Usually, algorithms exploit heuristics that locally perform a one-step lookahead search. Once a decision is taken, it is never reconsidered. This hill-climbing search without backtracking is sensitive to the usual risks of converging to locally optimal solutions that are not globally optimal. However, this strategy allows building decision trees in time *linear* to the number of examples.

The standard algorithm to build univariate trees consists of two phases. In the first phase, a large tree is constructed. In the second phase, this tree is pruned back. The algorithm to grow the tree follows the standard divide-and-conquer approach. The most relevant aspects are the splitting rule, the termination criterion, and the leaf assignment criterion. With respect to the last criterion, the usual rule consists of assignment of a constant to a leaf node. Considering only the examples that fall at this node, the constant is usually the constant that minimizes the **loss function**: the mode of y values in the case of classification problems or the mean of the y values in the regression setting. With respect to the splitting rule, we distinguish between nominal attributes and continuous ones. In the former, the number of partitions is equal to the number of values of the attribute; in the latter, a binary partition is obtained. To estimate the merit of the partition obtained by a given attribute, several heuristics have been used [4, 17]. A nice review appears in [13]. In any case, the attribute that maximizes the criterion is chosen as test attribute at this node. The pruning phase consists of traversing the tree in a depth-first order. At each non–leaf node two measures should be estimated. An estimate of the error of the subtree below this node, which is computed as a weighted sum of the estimated error for each leaf of the subtree, and the estimated error of the nonleaf node if it was pruned to a leaf. If the latter is lower than the former, the entire subtree is replaced to a leaf. All of these aspects have several and important variants (e.g. [4, 17]). Nevertheless, all decision nodes contain conditions based on the values of one attribute, and leaf nodes predict a constant.

Multivariate Trees

One of the most appealing extensions to the basic decision tree algorithm is the use of combinations of attributes in decision tree learning. One of the earliest works is CART [4] where a linear multivariate split is found using a hill-climbing search. An extension to

avoid local minima has been proposed in [15]. Other methods include the use of gradient descent to construct attribute combinations. In [9], in each decision node, a multilayer perceptron is trained with back-propagation leading to a binary split. In [5], in each decision node, a linear machine is trained leading to a k-way splitting. Methods using **linear programming** have been used, for example, in [1, 2]. All these methods are search intensive; they are prone to overfitting and local minima. The most successful methods seems to be those based on **discriminant analysis** that have been used in [6, 7, 11, 12]. A related research line explores the use of functional tree leaves. Functional tree leaves is almost the rule [16, 20, 8], in **regression** problems. In the classification setting, few works explore this idea [22, 10, 19, 8].

Probabilistic Functional Trees

Multivariate trees can be seen as a combination of multiple models. This idea has been fully explored in functional trees. Functional trees combine a standard univariate tree with a discriminant function by means of constructive induction. At each decision node, a discriminant function is built using the examples that fall at that node. Each of these examples is extended with new attributes computed as the probability that the example belongs to a class. The merit of each new attribute is evaluated, in competition with the original attributes, using the meritfunction of the univariate tree. If one of the new attributes is chosen by the merit function, this corresponds to a multivariate split. Functional trees use two types of decision nodes: those based on a test of one of the original attributes, and those based on the values of the discriminant function.

Once a tree has been constructed, it is pruned back. The basic mechanism consists of replacing a decision node by a leaf based on an estimation of the error. Functional trees consider two types of leaves. Those that predict a constant and those that make a prediction using the discriminant function stored at the node before pruning. The pruning algorithm produces two different types of leaves: *ordinary leaves* that predict a constant, and *discriminant leaves* that predict the value of the discriminant function learned (in the growing phase) at this node.

Conclusions

Functional trees extend and generalize multivariate trees. Functional trees generate hybrid models that combine a univariate tree with a discriminant function using a kind of local stacked generalization [23]. The components of the hybrid algorithm use different representation languages and search strategies. While the tree uses a divide-and-conquer method, a discriminant function performs a global minimization approach. While the former performs feature selection, the latter uses all (or almost all) the attributes to build a model. From the point of view of the bias-variance decomposition of the error [3], a decision tree is known to have low bias but high variance, while discriminant functions are known to have low variance but high bias. This is the desirable behavior for components of hybrid models. An extensive experimental study [8] has shown that functional trees are competitive algorithms both in terms of accuracy and learning times. An analysis of the bias-variance decomposition of the error shows that the use of multivariate decision nodes is a bias reduction process, while the use of multivariate leaves is a variance reduction process.

It is interesting to note that there are standard algorithms for topological transformations on decision trees: trees to decision rules [17], multivariate trees to multilayer networks. [21] This is an interesting aspect because it points to a common representation for different generalization languages.

JOÃO GAMA

Tree-structured Statistical Methods

This article is about binary tree-structured methods for biostatistics. The techniques, sometimes called "recursive partitioning," can facilitate the automation of diagnoses and prognoses in clinical contexts. A brief account of the larger topic of rules for clinical prediction provides context for the more specific discussion that follows. Wasson et al. [42] give a broad view of such rules.

Classifying patients is a central element of the physician's work. Typically, the physician asks questions like these. "Is this patient with chest pain suffering a heart attack, or does he simply have a strained muscle? What is the best diagnostic test for this patient with chest pain? During the next year, is this survivor of a heart attack likely enough to die that I should do a costly test that might detect a life-threatening, correctable problem?" Answering questions helps in crafting good care, but it also is essential for matching health care resources to the patients who need them the most.

Until recent decades physicians had no choice but to answer these questions in a subjective, intuitive, idiosyncratic manner. Skill probably depended on clinical experience, but equally experienced physicians varied in their levels of skill. Physicians seldom wrote down the clinical findings that they used to estimate probabilities or their rules for combining findings. As a result, there was, and is, interphysician variability and intraphysician variability in estimating probabilities and in making prognoses. Data-based rules are now available for these purposes. They enable the physician to interpret a patient's findings in quantitative terms by reference to a large number of patients with similar findings and a known diagnosis or clinical outcome. The goal of using a clinical prediction rule is to use clinical findings to place the patient in a subgroup whose disease prevalence, outcome rate, or survival rate is known and to use that placement to infer some aspect of the patient's course.

Clinical prediction rules are, as we have indicated, empirical. Their basis is a cohort of patients with known clinical findings and a known diagnosis or outcome. This cohort, the training set (also called the learning sample), is the set of patients from whom the key clinical predictors and the rule for combining them are discovered. Applying the rule to a separate cohort, the test set, can provide the subgroup-specific disease prevalences or outcome rates that are the basis for estimating probability or prognosis in an individual patient.

There are several steps involved in developing a clinical prediction rule.

Assemble the cohort. The first step is to decide upon the criteria for including the patient in the cohort that will form the training set. The investigator must ask, "What is the problem to be solved? Estimating a probability of coronary artery disease in patients with chest pain? Estimating the one-year death rate in heart attack survivors?" The answers to these questions determine the clinical criteria for admitting a patient to the cohort. One must also pay attention to the generalizability of the findings when defining the cohort. Will the clinical prediction rule apply to all hospitals or clinics? If so, the study must enroll patients from a variety of care settings. Will the findings apply to all patients with the cohort-defining problem (e.g. chest pain) or just those of a certain age, gender, or socioeconomic standing?

The second step in assembling the cohort is to decide on the size of the training set, though circumstances frequently limit the choice. A large cohort maximizes the chance that the clinical prediction rule will be optimal for other populations of patients. One empirical rule is to include five patients in the smallest outcome category for every clinical predictor in the rule.

Decide upon the outcome measure. One must answer this question, "What is the outcome to be predicted?" Then, one must state the criteria for deciding if the outcome has occurred, being sure that it is possible to collect the outcome criteria on all patients. Ideally, the measure is an unequivocal feature of the outcome, such as the result on a reliable indicator that disease is present (the "**gold standard test**") or death from the disease. The outcome should be useful to a clinician, such as an intermediate point on the path to a decision.

Decide which predictors to obtain. The predictors should be pertinent to the clinical problem. Obtaining the information should be feasible. Precise instructions on how to obtain the information are important to the clinician who wants to classify a patient accurately. The list of predictors should include all the clinical findings that could be pertinent, so that the study does not overlook an important predictor.

Collect the data and determine the outcome on a series of patients. It is fundamental here to avoid bias in collecting the data and deciding upon outcome. If the outcome is a clinical diagnosis, then it is all too easy to define it from the predictors for a patient for whom the outcome is not obvious. This can lead to excessive optimism regarding the worth of the predictors at hand. Thus, it is important that, for purposes of the study, predictors and outcome are distinct. Moreover, a source of bias is avoided if the person who assigns the diagnosis is ignorant of any findings that comprise or inform the determination of predictors.

Identify the predictors and the rule for combining them. Most of what remains of the article is a detailed description of this step.

Determine the **misclassification** rate of the rule. The most important principle is to measure the misclassification rate in a new cohort of patient (the test set). If it is not possible to follow this principle, there are several **cross-validatory** techniques by which to estimate misclassification rates on new populations by using the training set patients. By far the best approach is to enroll a new cohort of patients, preferably by a new research group in a new clinical setting. The article by Wasson et al. [42] describes the measurement of the misclassification rates. See, especially, [2] and [14].

The tree-structured statistical techniques we have mentioned are by now widely used in biostatistical inference, e.g. [1, 3, 4, 11, 17, 18, 24, 45–51], and [52]. While there are many approaches, all have in common the successive partitioning of a "feature space" of predictors into subsets. The partitioning is done on the basis of a *learning sample*, and then, if one is fortunate, it is validated by a *test sample*. In this article, it is always the case that a nonterminal node of a tree has only two daughter nodes; thus the trees are *binary trees*. Each node of the trees corresponds uniquely to a subset of the feature space and thus to a unique set of constraints on the predictors of outcome. A decision rule or summary statistic or value of a regression, depending on the application, is the same within the region determined by the terminal node. Learning sample observations have (predictor, outcome) pairs. The hope is to partition so that regions are simple enough to be understandable in terms of the subject matter, yet homogeneous as to outcome. Prediction is made to future data for which predictors are known but outcomes are not. These techniques have been applied with success to classification, regression, survival analysis, and clustering. One popular way to form trees from data is that of *Classification and Regression Trees* (CART^{TM}). Depending on the nature of the response, the techniques may be referred to as classification trees (discrete response), regression trees (continuous response), survival trees (censored positive response), or tree-structured vector quantization (when the predictors and response are the same, univariate, or vectorial but there are constraints on the complexity of the prediction). In the literature, all of them are termed tree-based (or tree-structured) methods or recursive partitioning techniques. Those of the many ideas they have in common are well described by Breiman et al. [2], and Zhang and Singer [48], which has much historical background [8, 15, 16, 19, 32].

In what follows, we first present an early tree-based analysis that will serve to illustrate many aspects of tree-based methodology, not least the simplicity of the ultimate answers. Secondly, we lay out the key and common ground for all of the tree-based methods. Then, we fill in details to distinguish the major types of tree-based methods. In light of the recent surge of the development and use of survival trees, we devote particular attention to this area. Finally, we discuss some common tips, tricks, and traps one encounters in applying the tree-based methods.

An Example

One early notable application of binary classification trees was for the purpose of diagnosing patients who enter hospital emergency rooms with chief complaints of acute chest pain [18]. See also Goldman et al. [17]. Starting with about 100 initial variables that were thought to be predictors of a heart attack, Goldman and colleagues went through a preliminary screening of the predictors and selected 40 of them for further consideration. Their goal was to construct a classification rule that can guide physicians in emergency rooms to decide in a timely manner (i.e. before levels of fundamental enzymes are known) whether a patient has suffered or is suffering a myocardial infarction (MI, or heart attack). Although a definitive diagnosis of heart attack is typically done by

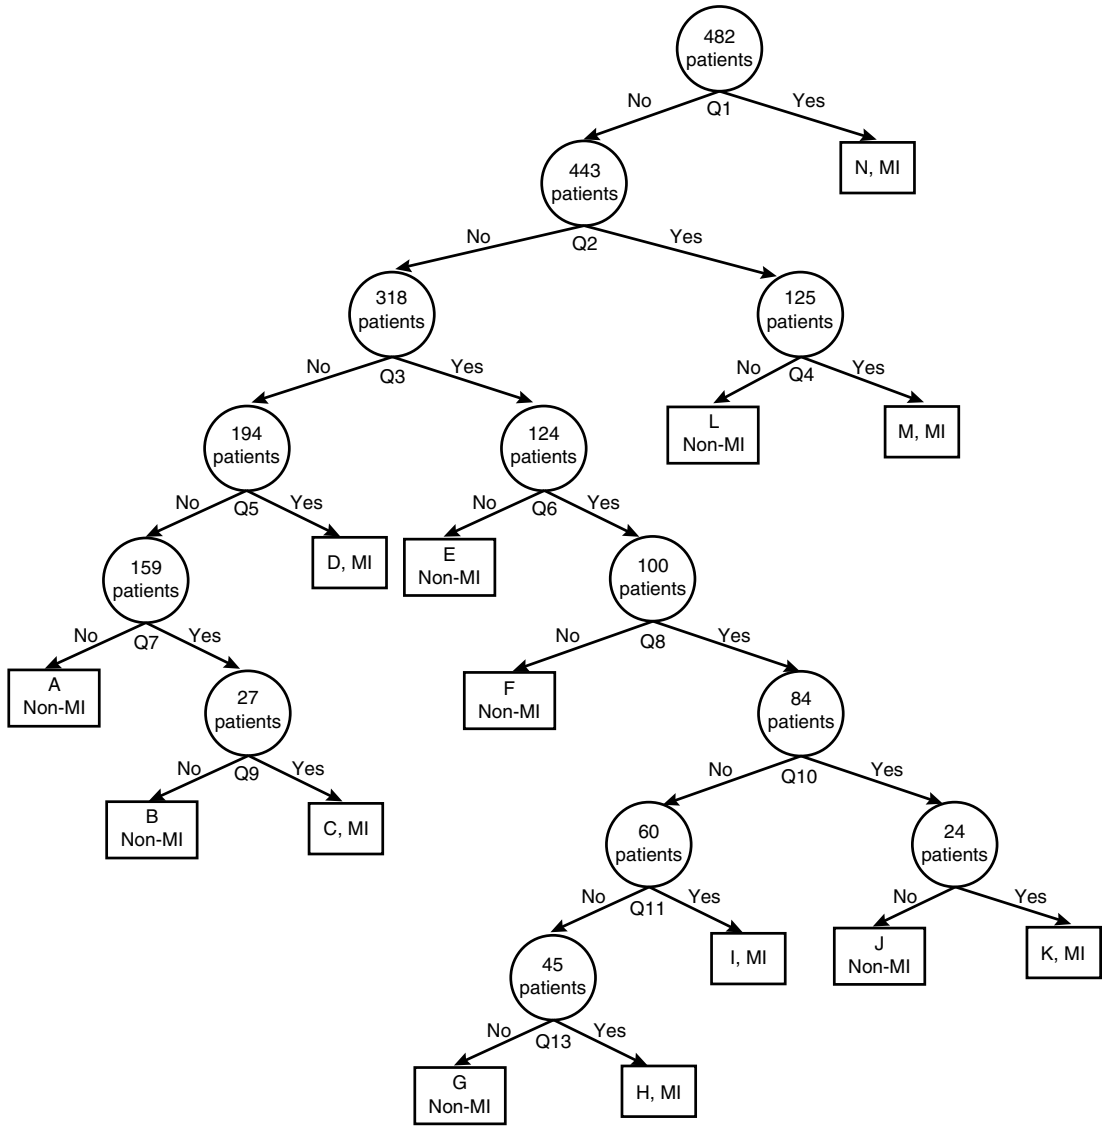

Figure 1 Classification tree for diagnosing heart attack. Table 1 provides the questions (Q1–Q13) used in this tree. This figure is based on Figure 1 of Goldman et al. [18]

testing the levels of these enzymes which tend to be released by damaged heart muscle, the importance of the computerized decision rule is that it is based on clinical measurements that are available almost immediately when a patient is admitted. By answering a maximum of 13 questions (Figure 1), any patient can be classified as having a high or low risk for heart attack.

Outline of the Tree-Based Methods

The Data and the Objective

Suppose that we have observed p covariates $\mathbf{x}$ and a response y for n individuals. For the ith individual, the measurements are

$$\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})' \quad \text{and} \quad y_i, i = 1, \ldots, n.$$

The objective is to model the probability distribution of $\Pr(y|\mathbf{x})$ or some functional of this conditional distribution. Here, $\mathbf{x}$ can be an array of mixed categorical (nominal or ordinal) and continuous variables. Some components may have missing values. It is the nature of y that mandates the choice of methodology. In most applications, the outcome, y, is either a continuous (with or without censoring) or categorical variable. Recently, the tree-based methods have been developed to allow for vectorial y [16, 36, 44]. Here, our discussion focuses on **binary** and **censored** continuous y, for (i) these are the situations where the tree-based methods are applied for the most part in medicine, and (ii) **logistic regression** and **linear discriminant function analysis** (binary case), and the **Cox regression model** for **proportional hazard** modeling (in the case of **survival analysis**) are standard approaches to analyzing such outcomes; it is worthwhile to understand the strengths and limitations of both the more classical and the tree-based methods.

Basics of the Tree-Based Technique

Look again at the tree in Figure 1. This tree has eight layers of nodes. In general, the number of layers varies from case to case. The first layer is always the unique root node, namely, the circle on the top. There are 13 internal (the circle) and 14 terminal (the box) nodes that are scattered among the various layers. The root and the internal nodes are connected to two nodes in the next layer that are called left and right daughter nodes, but terminal nodes do not have "children". Moreover, the tree is not necessarily "balanced" in that not all nodes in the same layer have daughter nodes. The thrust of the tree-based technique is to answer these questions:

1. What are the contents of the nodes and how do we split a node?
2. How do we declare a node terminal?
3. What inferences do we make for the various terminal nodes?
4. What have we learned about our data and the possibly complex relationships among the predictors and outcome as a result of studying the tree?

The subsection below, "Splitting a Node", addresses the first item, and it is followed by a subsection on Terminal Nodes. There, we discuss how to determine terminal nodes. The last question is best answered on a case-by-case basis.

Splitting a Node

The root node contains the learning sample. The learning sample summarizes the information from past experience and allows us to learn the underlying data structure. In Goldman et al. [18], it contains 482 patients. The terminal nodes correspond, as was indicated, to disjoint subgroups of this learning sample. The union of two subgroups in the daughter nodes comprises the subgroup of their parent node. For example, the root node in Figure 1 has 482 patients who are divided into two subgroups: one with 443 patients and the other with 39. So, a node is merely a subgroup of the learning sample.

A critical step of the tree-based technique is to determine the split from one parent node to the two daughter nodes. Since splitting the root node is identical in terms of criterion to that for other nodes, it suffices to explain how to split the root node. Thus, we consider how the 482 patients in the study of Goldman et al. [18] might be divided into two subgroups.

First, the division of the root node is described and implemented by means of a predictor. The purpose of splitting is to generate two offspring whose union is preferred to the root node in some sense. As was mentioned earlier, there were 40 selected potential predictors of a heart attack, denoted by $\mathbf{x}$, that entered into the tree-based analysis. If x_j is an ordered covariate such as age, two subgroups result from the question of the form "Is $x_j > c$?" Here the cutoff point c is in the range of the observed values of x_j. The ith subject goes to the right or left node according to whether or not $x_{ij} > c$. Q2, 8, 9, 12, and 13 in Figure 1 and Table 1 are precisely this type of question. On the other hand, many medical studies involve nominal covariates. For example, the body sites of pain in the present example include the chest, shoulder, and neck. We can send a patient to the left or right node by asking questions such as "is the pain in the neck only?" and "is the pain in the neck and shoulder?" Given the number of covariates (here, it is 40) and the number of possible cutoff points for every covariate, there are many possibilities to split the root node into two nodes. Therefore, we must be specific in what we mean by a desirable split.

Table 1 Questions used in Figure 1

Label	Question
Q1	Does the emergency room EKG show ST-segment elevation or a Q wave that is suggestive of infarction and is not known to be old?
Q2	Did the present pain or episodes of recurrent pain begin 42 or more hours ago?
Q3	Is the pain primarily in the chest but radiating to the shoulder, neck, or arms?
Q4	Does the emergency room EKG show ST-segment elevation or a Q wave that is suggestive of ischemia or strain and not known to be old?
Q5	Is the present pain (a) similar to but somehow worse than prior pain diagnosed as angina or (b) the same as pain previously diagnosed as an MI?
Q6	Does local pressure reproduce the pain?
Q7	Has the chest pain associated with diaphoresis?
Q8	Is the patient 40 years or older?
Q9	Is the patient 70 years or older?
Q10	Was this pain diagnosed as angina (and not an MI) the last time the patient had it?
Q11	Is the pain primarily in the chest but radiating to the left shoulder?
Q12	Did the present pain or episodes of recurrent pain begin 10 or more hours ago?
Q13	Is the patient 50 years or older?

These questions are taken from Figure 1 of Goldman et al. [18]

Table 2

		Non-MI	MI	
Left node (t_L)	$x_j \le c$	n_{11}	n_{12}	$n_{1\cdot}$
Right node (t_R)	$x_j > c$	n_{21}	n_{22}	$n_{2\cdot}$
		$n_{\cdot 1}$	$n_{\cdot 2}$	

If we take age as a tentative splitting covariate and consider its cutoff at 40, as a result of the question "Is x_j(age) $> c$ (40)?", then we have Table 2. What would be desirable in this case? Obviously, we would want to choose a split so that the distributions of y in the daughter nodes are homogeneous. To reflect this idea in the table above, a desirable left (right) node t_L (t_R) should have the property that either n_{11} (n_{21}) is much greater than n_{12}(n_{22}) or vice versa. In other words, we force most of the MI cases to either the left or right node. In a perfect situation where $n_{11} = n_{22} = 0$, the two nodes are pure (or completely homogeneous) because each of them contains only one value of the outcome. In contrast, their parent node includes a mixture of n_{11} non-MI and n_{22} MI patients. This is what we mean by "more desirable" here. Mathematically, one frequently used measure of node homogeneity is defined through the entropy function as follows:

$$h(t_L) = \frac{n_{11}}{n_{1\cdot}} \log\left(\frac{n_{11}}{n_{1\cdot}}\right) + \frac{n_{12}}{n_{1\cdot}} \log\left(\frac{n_{12}}{n_{1\cdot}}\right). \quad (1)$$

Then, we select a split that maximizes the weighted node homogeneity:

$$\frac{n_{\cdot 1}}{n} h(t_L) + \frac{n_{\cdot 2}}{n} h(t_R). \quad (2)$$

It is also interesting to view the criterion (1) from other points of view. Thus, suppose that y in node t_L has a **binomial distribution** with a frequency of θ so that

$$\Pr(y = 1|t_L) = \theta.$$

Then, the log **likelihood** function from the $n_{1\cdot}$ observation in node t_L is

$$n_{11} \log(\theta) + n_{12} \log(1 - \theta).$$

The maximum of this log likelihood function is proportional to (1). Not surprisingly, many criteria of "more desirable" are couched as maxima of certain likelihood functions. See the section "Use of Likelihood Functions" below.

Terminal Nodes

After the node-splitting procedure described above is applied to the root node, the resulting daughter nodes can also be split in the same way, followed by the granddaughter nodes, and so on. This splitting process always terminates because the number of study subjects is finite. For example, the number of possible splits for the data of Goldman et al. [18]

cannot exceed 481. Of course, we can force the process to stop at any point. In usual practice, we end up with a large tree, which is generally too large to be useful. In order that we end up with a useful tree, a rigorous rule for pruning some overfitting nodes is required. Goldman and colleagues did not know a priori the 14 terminal nodes in Figure 1. Initially, these terminal nodes had offspring.

For the purpose of illustration, take a part of Figure 1 as displayed in Figure 2, and use it as if it is an entire initial tree. The question is: "can we prune away some of the nodes?" If we can answer this question in a general way, then we will know how to prune any tree. To this end, we introduce a measure of the quality of a tree. Recall that the objective of the tree-based method is to extract homogeneous subgroups of the study sample. Whether we have achieved it depends on whether the terminal nodes are indeed sufficiently homogeneous. Hence, the quality of a tree, denoted by T, is really the quality of its terminal nodes, and we have

$$R(T) = \sum_{t \in \tilde{T}} p(t) r(t), \tag{3}$$

where $\tilde{T}$ is the set of terminal nodes of tree T, $r(t)$ summarizes the quality of node t, and $p(t)$ is the proportion of subjects falling into node t. For binary outcomes, $r(t)$ is usually taken to be the within-node misclassification cost.

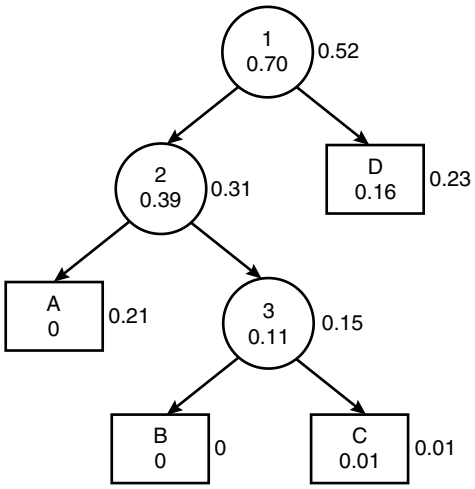

Figure 2 An illustrative tree for pruning. The root node (labeled 1) here comes from the node above the split, Q5, in Figure 1. It contains 194 subjects. Inside each node is the node label and the misclassification cost. The misclassification cost from a test sample is given outside the node

The size of a tree is another important aspect, which here is the fundamental measure of its complexity. Note that the total number of nodes in a tree, T, is $2|\tilde{T}| - 1$, where $|\tilde{T}|$ is the number of the terminal nodes of T. Hence, the complexity of T can be defined directly as $|\tilde{T}|$. Usually, a unit cost, called a complexity parameter, is assigned to each terminal node, and the sum of all costs becomes the penalty for the tree complexity. Therefore, the final quality measure of a tree is the following cost-complexity:

$$R_\alpha(T) = R(T) + \alpha|\tilde{T}|, \tag{4}$$

where $\alpha(> 0)$ is the complexity parameter.

For a given complexity parameter and an initial tree such as the one in Figure 2, there is a unique smallest subtree of the initial tree that minimizes the cost-complexity measure (4). Importantly, if $\alpha_1 > \alpha_2$, then the optimally pruned subtree corresponding to α_1 turns out to be a subtree of the one corresponding to α_2. So, as we increase the complexity parameter, we have a sequence of nested optimally pruned subtrees. This sequence has to have finite length, and the last one is the root node. That the successive optimally pruned subtrees are nested can entail important savings in computation [2].

Here is how pruning works for the tree in Figure 2. Before we start, we must specify a misclassification cost that reflects the severity of the mistake that results when an MI patient is classified to non-MI or vice versa. Let $C(i|j)$ be the misclassification costs that a class j patient is classified as a class i patient. Here, there are two classes of patients: 0 for non-MI and 1 for MI patients. For medical reasons, it is natural to choose $C(0|1) > C(1|0)$ because the consequence is potentially more severe when an MI patient is wrongly diagnosed than when a non-MI patient is. As did the authors, we take $C(1|0) = 1$ and $C(0|1) = 15$, which means that a false positive diagnosis costs as much as 15 false negative ones. Table 3 gives the misclassification costs for all nodes and their designated classes. The third and fourth columns list the misclassification costs as a result of classifying the node as MI and non-MI, respectively. The minimum of these two types of cost determines the final class membership (column 5) of a node. The expected node cost, $r(t)$,

Table 3 Misclassification costs

Node label	Node size	Misclassification costs[a]		Designated class	$r(t)$[b]	Weighted cost[c]
		MI	non-MI			
1	194	185	$9 \times 15 = 135$	Non-MI	0.70	0.70
2	169	154	$5 \times 15 = 75$	Non-MI	0.44	0.39
3	37	22	$5 \times 15 = 75$	MI	0.59	0.11
A	132	132	0	Non-MI	0	0
B	20	20	0	Non-MI	0	0
C	17	2	$5 \times 15 = 75$	MI	0.12	0.01
D	46	31	$4 \times 15 = 60$	MI	0.67	0.16

[a]Number of misclassified subjects multiplied by the cost unit. [b]Misclassification cost divided by the node sample size. [c] $r(t)$ multiplied by $p(t)$, the proportion of subjects in the node.

Table 4 Nested sequence of subtrees

Subtree	Range of α	Nodes in the subtree	Cost complexity
T_0	0–0.1	1, 2, 3, A, B, C, D	$0.01 + 0.16 + 4 \times 0.005 = 0.19$
T_1	0.1–0.215	1, 2, 3, A, D	$0.11 + 0.16 + 3 \times 0.19 = 0.74$
T_2	0.215+	1	$0.70 + 0.28 = 0.98$

is the minimum of the two costs divided by the node size; for instance, $r(D) = \min(31, 60)/46 = 31/46 = 0.67$. The final within-node cost (the last column) is obtained by weighting $r(t)$ by $p(t)$. For example, within node 3, $r(3) = 0.59$ and $p(3) = 37/194 = 0.19$. Hence, the final cost equals $0.59 \times 0.19 = 0.11$.

From Table 3 we calculate the misclassification cost for the tree in Figure 2 as follows. Note that it has four terminal nodes, labeled A, B, C, and D. As is defined in (3), the tree misclassification cost is the sum of the weighted misclassification costs of its terminal nodes. Based on the last column of Table 2, the weighted costs for terminal nodes A through D are, respectively, 0, 0, 0.01, and 0.16. Thus, the tree misclassification cost is

$$0 + 0 + 0.01 + 0.16 = 0.17.$$

The complexity of this tree is 4 because it has four terminal nodes. If we choose a complexity parameter, $\alpha = 0.005$, it follows from (4) that the present tree cost complexity equals $0.17 + 4 \times 0.005 = 0.19$. Table 4 provides three ranges of the complexity parameter that correspond to three nested subtrees. The cost complexities are also given in this table when a complexity parameter is chosen in the range. The thresholds of the range are determined by these considerations. We prune off some terminal nodes only if the tree cost complexity is improved after the pruning. This decision obviously depends on the choice of the complexity parameter, α. For instance, if $\alpha = 0$, then the initial tree, T_0, has a smaller cost complexity than any of its subtrees. Therefore, we cannot prune off any terminal nodes with $\alpha = 0$. What is the smallest α such that some of the terminal nodes can be removed? It turns out to be

$$\min_{t \notin \tilde{T}_0} \frac{r(t)p(t) - R[T(t)]}{|\tilde{T}(t)| - 1},$$

where $T(t)$ is a subtree rooted at node t and the minimization is over all internal nodes of T_0 [2]. Now, T_0 has three internal nodes 1, 2, and 3, and 0.1 is the minimum of the corresponding three numbers: $(0.7 - 0.17)/(4 - 1) = 0.18$, $(0.39 - 0.01)/(3 - 1) = 0.19$, and $(0.11 - 0.1)/(2 - 1) = 0.1$. When $\alpha = 0.1$ is applied, we can prune off terminal nodes B and C without loss of cost complexity, leading to tree T_1 in Table 4. Next, we can ask the same question: what is the smallest α such that some of the terminal nodes of T_1 can be removed? This tree has two internal nodes labeled 1 and 2. It is easy to see that the smallest α equals 0.215 and it leads to the single node tree, T_2. In general, we repeat the same process until we reach the single node tree.

The next step is to select a subtree from the nested sequence. A special aspect of the study of Goldman et al. was that the tree was used to classify patients at another hospital [18]. These additional data constitute a validation data set, also called a test sample. The misclassification costs for the three nested trees were, respectively, $R^{ts}(T_0) = 0.45$, $R^{ts}(T_1) = 0.59$, and $R^{ts}(T_2) = 0.52$. Because $R^{ts}(T_0)$ is the smallest, T_0 is the best choice, implying that we cannot prune any nodes. When an independent test sample is not available, a cross-validation procedure is usually recommended. We refer to Breiman et al. [2] for details; see [28] for a different approach.

Survival Trees

In this Section, we explain how to use the ideas expressed above to analyze censored survival data. Censored survival data arise from many medical studies; see, for example, [1, 3], and [4] for some typical examples. We face the same basic issues. One is to define a splitting criterion by which to divide a node into two, and the other is to choose a "right-sized" tree for subsequent use. Many criteria have been proposed in the literature, but they differ primarily in the way of declaring what daughter nodes are desirable. Segal [37] and Intrator & Kooperberg [23] are two important and helpful reviews. See also LeBlanc & Crowley [27] and Crowley et al. [9].

Gordon and Olshen's Rule

One early proposal was made by Gordon & Olshen [22]. The idea is this: when a node is divided into two, we can compute the **Kaplan–Meier** curves (see, for example, [31]) separately for each. A desirable split can be characterized as one that results in two very different survival functions in the daughter nodes. They used the so-called L^p Wasserstein metrics, $d_p(\cdot, \cdot)$, as the measure of discrepancy between the two survival functions. Specifically, for $p = 1$, the Wasserstein distance, $d_1(S_L, S_R)$, between two Kaplan–Meier curves, S_L and S_R, is the shaded area in Figure 3.

An optimal split is chosen to maximize the distance, $d_1(S_L, S_R)$. Here, S_L and S_R are, respectively, the Kaplan–Meier curves for the left and right daughter nodes. Replacing the quantity (2) with $d_1(S_L, S_R)$ we can produce an initial tree as described above in the section on Splitting a Node.

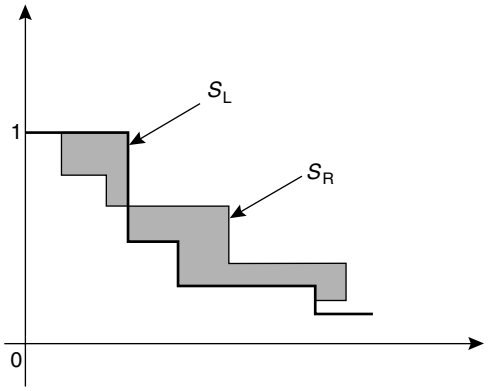

Figure 3 The L^1 Wasserstein distance between two Kaplan–Meier curves. Note that one curve (S_L) is darker than the other (S_R)

To prune an initial survival tree, T, Gordon & Olshen [22] suggested a tree cost complexity as follows. Consider a terminal node, $t \in \tilde{T}$. First, estimate the Kaplan–Meier curve S_t. Secondly, find the closest δ_t to S_t in terms of $d_1(S_t, \delta_t)$; here δ_t must be chosen from piecewise constant survival functions that have at most one point of discontinuity. That is, δ_t has at most two constant pieces. Then, define the within-node cost, $R(t)$, as $d_1(S_t, \delta_t)$. This can be viewed as the deviation of survival times about their median. Finally, applying the same formula (4), we have the tree cost complexity. Obviously, the same principle applies as we use different Wasserstein metrics. It should be noted, however, that when censoring depends on the covariates, the L^p Wasserstein metrics tend to produce splits (due to structure in the censoring) when in fact there is no dependence of survival upon covariates [9].

Use of the Logrank Test

In survival analysis, the **logrank test** is a popular approach for testing the significance of differences between the survival times of two groups. Motivated by this fact, Ciampi et al. [7] and Segal [35] suggested selecting a split that results in the largest logrank test statistic, which is defined as follows. A partition gives a sequence of 2×2 tables at times when failures occurred (Table 5).

Table 5

		Dead	Alive	
Left node (t_L)	$x_j \le c$	a_i		m_{i1}
Right node (t_R)	$x_j > c$			
		n_{i1}		n_i

The logrank test statistic is

$$LR = \frac{\sum_{i=1}^{k}(a_i - E_i)}{\left(\sum_{i=1}^{k} V_i\right)^{1/2}},$$

where k is the number of distinct failure times,

$$E_i = \frac{m_{i1}n_{i1}}{n_i},$$

and

$$V_i = \left[\frac{m_{i1}(n_i - m_{i1})n_{i1}}{n_i(n_i - 1)}\right]\left(1 - \frac{n_{i1}}{n_i}\right).$$

The logrank test (or any similar two-sample test) is a measure of between-node difference. However, with this approach a measure of cost for each node is not readily available for use in pruning. Segal [35] also recommended a practical bottom-up procedure. The basic idea is this. For each internal node (including the root node) of an initial tree, we assign it a value that equals the maximum of the logrank statistics over all splits starting from the internal node of interest. Then, we plot the values for all internal nodes in increasing order and decide a threshold from the graph. If an internal node corresponds to a smaller value than the threshold, then we prune all of its offspring.

LeBlanc & Crowley [26] introduced the notion of "goodness-of-split" complexity as a substitute for cost complexity in pruning the tree. Let $G(t)$ be the value of the logrank test at node t. Then the split-complexity measure is

$$G(T) = \sum_{t \notin \tilde{T}} G(t) - \alpha(|\tilde{T}| - 1).$$

Note that the summation above is over the set of internal (nonterminal) nodes and $|\tilde{T}| - 1$ is the number of internal nodes. The negative sign is a reflection of the fact that G is to be maximized, whereas the cost complexity R is minimized. LeBlanc & Crowley [26] recommend choosing α between 2 and 4 (when the logrank test is expressed in the χ^2 form) and using bootstrap techniques to deflate the value of G. An alternative pruning method based on permutation of ***P* values** for the logrank test is described in LeBlanc & Crowley [27].

In some medical situations such as in cancer, the goal of a tree-based analysis is to arrive at a few (perhaps three or four) groups that define the "stages" of disease. Treatment strategies or randomization algorithms within a **clinical trial** can then be designed with these prognostic groups or stages in mind. Even an optimally pruned tree may have many terminal nodes, so nodes with similar survival need be combined in a final staging system. Ciampi et al. [7] termed this process "amalgamation", and suggested combining terminal nodes based on comparisons using the logrank statistic. LeBlanc & Crowley [26] define an ordered categorical variable (based, for example, on median survival) describing the terminal nodes, and subject that single variable to a recursive partitioning scheme to amalgamate the nodes. Less formal techniques are described in LeBlanc & Crowley [27].

Use of Likelihood Functions

Several likelihood-based splitting and pruning criteria have been proposed. Davis & Anderson [12] assume that the survival function within any given node is an exponential function with a constant hazard. The splitting criterion of LeBlanc & Crowley [25] and Ciampi et al. [6] are both based on the assumption that the hazard functions in two daughter nodes are proportional, but unknown. The difference between their two approaches is whether the full or **partial likelihood** function in the Cox proportional hazards model should be used. For the same logic, these authors defined various tree cost complexities using the likelihood ratio statistic by comparing the survival times in a parent node with those in its daughter nodes. A related method due to Therneau et al. [41] makes use of what are termed martingale residuals from the Cox model as the input to a cost-complexity scheme using least squares as the cost (*see* **Residuals for Survival Analysis**).

A Straightforward Extension

Zhang [43] examined a straightforward tree-based approach to censored survival data. Note that we observe a binary death indicator and the (failure or censored) time. If we treat these two outcomes separately, then we can compute the within-node impurity, i_δ, of the death indicator and the within-node quadratic loss function, i_y, of the time as already defined by Breiman et al. [2]. Then, the within-node impurity for both the death indicator and the time is a weighted combination, $w_\delta i_\delta + w_y i_y$. Some choices of weights w_δ and w_y have been recommended by Zhang [43].

Several applications to real data have indicated that this approach and the use of the logrank test produce very similar tree structures. Perhaps surprisingly, a preliminary simulation suggests that this simple extension outperforms the more sophisticated ones in discovering the underlying structures of data. More extensive simulations are still warranted to study the performance of the various splitting criteria.

Which is Better?

This is still an open question, and perhaps it has no clear answer. Obviously, there is no shortage of splitting criteria for survival analysis. There is, however, very little evidence to suggest which approach is best under what circumstances. Some limited simulations comparing several of the methods have been reported in the literature [9, 10, 43]. Our recommendation is to construct survival trees using a number of approaches. Experts are likely to see, on their own subject matter grounds, which tree makes better sense than others.

Software

The best tested software is the commercial CART program as distributed by Salford Systems, San Diego. It has various versions for Windows, DOS, Macintosh, and Unix systems. A tree function is also available in **S-PLUS** [40]. Free software for survival trees is available, but it is less organized and tested. Four of the splitting criteria introduced above are implemented together in the C language and are available upon request to `heping.zhang@yale.edu`. Specific programs are also available by sending e-mail to various sites, such as `dstein@scott.cts.com` (Salford Systems), `mark@biostat.ucsf.edu` [35], `rdaids@sdac.harvard.edu` [12], and `mikel@fhcrc.swog.org` [26].

Other extensions of the tree-structured method have also been developed to analyze **longitudinal** data and clustered binary responses (*see* **Correlated Binary Data**). Manuscripts and programs are available upon request to `mark@biostat.ucsf.edu` for continuous longitudinal data [36] and `heping.zhang@yale.edu` for multiple correlated binary responses [44]. Also see Dr. Zhang's website (http://peace.med.yale.edu) for additional information.

Discussion

The application of tree-structured methods to many areas of research is growing (see, for example, [1, 3–5, 11, 24, 46–51], and [52]). Nevertheless, logistic regression for binary data and Cox proportional hazard models for censored survival data still dominate applications. The main advantage of tree-based methods is their ability to produce intuitive and appealing tree structures without requiring the users to specify and select conventional models. This advantage is more obvious when the classical, parametric models are not appropriate (see [23] for interesting examples). Several authors have compared the tree-structured methods with other methods [29, 38, 39]. Related programs are available upon request from `wjl@mit.edu` in addition to the sites given above. The computational complexity was an issue, but is no longer. To date, the application of the tree-based methods has been mostly for **exploratory** and secondary analyses. Recently, Zhang & Bracken [46] have demonstrated the use of tree-based methods as an intermediate step in **hypothesis testing**. Tree stability is another important concern. The tree is not a parameter, and it is not necessarily stable to small perturbations in the data. However, the resulting decision rules tend to be. Bayes theory may shed some light on this problem (*see* **Bayesian Methods**). Much work remains to strengthen the basis for statistical inference in this area. The theoretical properties of the tree-structured methods are largely unexplored, but exceptions include [13, 19–21, 26, 30, 33], and [34].

Trend Test for Counts and Proportions

In the comparison of counts or proportions across various populations, it is often important to consider the intrinsic ordering of the populations with regard to some particular characteristic. For example, one may be interested in assessing whether the proportion of women reporting insomnia increases with age group, or whether the number of car accidents is increasing over calendar periods. Such a comparison can be accomplished through the use of a trend test. Trend tests arise naturally within a wide variety of biostatistical applications, such as animal **bioassays**, epidemiologic studies, and evaluations of environmental exposures, in which demonstration of a **dose–response** relationship may be important. The characteristic of the population may be measured on a continuous scale, such as an assigned treatment level, or on an ordinal scale (*see* **Ordered Categorical Data**), such as age group or initial severity of a health condition.

In considering a trend test for counts arising from independent populations, suppose that Y_i is a random variable representing the count of interest and x_i is the quantitative (continuous or ordinal) **covariate** for the ith population. In addition, let w_i be a known design variable for the ith population; this often relates to the sample or population size so that Y_i/w_i represents a "rate" of a certain event. The general data framework for a trend test is shown in Table 1.

We assume that the expected count can be related to the covariate through a continuous function f, as follows:

$$\mathrm{E}[Y_i] = w_i f(x_i).$$

Under the general null hypothesis, there is no difference in expected counts due to differences in x_i, so that the null hypothesis can be stated as:

$$\mathrm{H}_0\colon f(x_i) = f(x_j), \quad \text{for all } i, j.$$

Note that, because the sample or population sizes (or other relevant known weights) w_i may differ across populations, the expected counts themselves may not necessarily be equal even under the **null hypothesis**.

The general **alternative** to this null hypothesis is that $f(x_i) \neq f(x_j)$ for $i \neq j$. However, the trend test considers a narrower alternative, which reflects either an increasing or decreasing ordered alternative. For example,

$$\mathrm{H}_{a1}\colon f(x_i) < f(x_j), \quad \text{for } x_i < x_j$$

reflects an increasing trend alternative, while

$$\mathrm{H}_{a2}\colon f(x_i) > f(x_j), \quad \text{for } x_i < x_j$$

reflects a decreasing (or reverse) trend alternative. When either alternative is true, the trend tests tend to have more power than tests of the general alternative.

Trend tests are typically developed for the situation in which independent random samples are selected from each of the $i = 1, \ldots, k$ populations. However, they can often be applied to data collected under other types of data sampling, such as **cross-sectional studies**, where the sample sizes in each of the k groups become known only after the study is completed. More detail on data sampling plans is provided in Fleiss [14].

The trend test can be developed by considering the function $f(x)$ to be restricted to a linear function of x,

$$f(x) = \alpha + \beta x, \tag{1}$$

or a monotone (increasing or decreasing) continuous function of the above; that is

$$f(x) = g(\alpha + \beta x). \tag{2}$$

Examples of functions commonly used in this context include the normal cdf, **logistic**, arcsine, **extreme value**, and one-hit models. Several of these models, especially the normal and logistic, have been justified in toxicological applications as arising from tolerance distributions, where x represents the dosage (or log dosage) of exposure to a particular chemical [12, 23, 32] (*see* **Logistic Regression**; **Quantal Response Models**). Similarly, the one-hit model $g(x) = 1 - \exp[-(\alpha + \beta x)]$ has been used extensively in cancer

Table 1 Data framework for trend test

Population	Population covariate	Weight	Observed count	Expected count
1	x_1	w_1	y_1	$w_1 f(x_1)$
2	x_2	w_2	y_2	$w_2 f(x_2)$
⋮	⋮	⋮	⋮	⋮
i	x_i	w_i	y_i	$w_i f(x_i)$
⋮	⋮	⋮	⋮	⋮
k	x_k	w_k	y_k	$w_k f(x_k)$

risk assessment (*see* **Dose–Response Models in Risk Analysis**). The inverse of $g(x)$ is referred to as the link function, and allows $g^{-1}[f(x)]$ to be modeled as the linear function $(\alpha + \beta x)$. For example, the link functions for the normal, logistic, and extreme value models are the probit, logit, and complementary log–log links, respectively. Use of such link functions has facilitated the development of trend tests using **generalized linear models**, **quasi-likelihood** methods, and **generalized estimating equations** [32, 41].

After choosing the appropriate model (*see* **Model, Choice of**), a test for trend can be constructed as a test of $H_0 : \beta = 0$, with the alternative of an increasing trend $H_{a1} : \beta > 0$ or decreasing trend $H_{a2} : \beta < 0$. The specific form of the trend test depends on the distribution of the random variables Y_i. Three cases will be considered here:

1. $Y_1, \ldots, Y_k$ are independent **binomial** random variables (see next section);
2. $Y_1, \ldots, Y_k$ follow a **multinomial distribution** (see the section "Trend Tests for Multinomial Counts" below);
3. $Y_1, \ldots, Y_k$ are independent **Poisson** random variables (see the section "Trend Tests for Poisson Counts" below).

The trend test for proportions follows the same form as that for independent binomial random variables, and will be discussed in the next section. For all three cases, it can be shown that the **sufficient statistic** for the trend test is $\sum x_i Y_i$. In the special case in which the covariates x_i are equally spaced or represent ordinal categories, the sufficient statistic for the trend test can be simplified to $\sum_i Y_i$.

Trend Tests for Binomial Counts and Proportions

When $Y_1, \ldots, Y_k$ represent independent binomial random variables, then the design variable w_i is equal to the sample size for the ith population, $w_i = n_i$, and the function of interest is

$$f(x_i) = p_i = g(\alpha + \beta x_i),$$

such that

$$\mathrm{E}[Y_i] = n_i p_i = n_i g(\alpha + \beta x_i).$$

In this situation, the null hypothesis of interest is

$$H_0: p_1 = p_2 = \cdots = p_k \tag{3}$$

and the alternatives of increasing trend and decreasing trend can be written, respectively, as

$$H_{a1}: p_1 < p_2 < \cdots < p_k,$$
$$H_{a2}: p_1 > p_2 > \cdots > p_k.$$

To test these ordered alternatives, the **likelihood** must be specified in terms of the model chosen for p_i. For example, when g is the identity function as in (1), the likelihood becomes

$$\prod_{i=1}^{k} \binom{n_i}{y_i} p_i^{y_i} (1 - p_i)^{n_i - y_i}$$
$$= \prod_{i=1}^{k} \binom{n_i}{y_i} (\alpha + \beta x_i)^{y_i} [1 - (\alpha + \beta x_i)]^{n_i - y_i}.$$

In general, one obtains the **maximum likelihood** estimator $\hat{\boldsymbol{\beta}} = (\hat{\alpha}, \hat{\beta})$ by solving the following score equations:

$$\mathbf{u}(\hat{\alpha}, \hat{\beta}) = \sum_{i=1}^{k} \begin{bmatrix} 1 \\ x_i \end{bmatrix} [y_i - n_i \hat{p}_i] = \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

where $\hat{p}_i = g(\hat{\alpha} + \hat{\beta} x_i)$. For the particular case in which g is the identify function, the maximum likelihood estimator for β is

$$\hat{\beta} = \frac{\sum_{i=1}^{k} x_i (y_i - n_i \tilde{p})}{\sum_{i=1}^{k} n_i (x_i - \overline{x})^2},$$

where $\tilde{p} = \sum y_i / \sum n_i$ and $\overline{x} = \sum x_i n_i / \sum n_i$. Under other models, such as the **logistic regression** model,

$$p_i = \frac{\exp(\alpha + \beta x_i)}{1 + \exp(\alpha + \beta x_i)}, \tag{4}$$

there may be no closed form solution for the maximum likelihood estimators, but iterative techniques such as the Newton–Raphson or Fisher scoring algorithm can be used to identify the MLEs (*see* **Optimization and Nonlinear Equations**).

When p_i can be written as $g(\alpha + \beta x_i)$, then a score test (*see* **Likelihood**) of the null hypothesis $H_0: \beta = 0$ can be constructed as

$$Z^2_{\text{linear}} = \mathbf{u}(\alpha_0, \beta_0)' \mathbf{I}^{-1}(\alpha_0, \beta_0) \mathbf{u}(\alpha_0, \beta_0),$$

where $\beta_0 = 0$, and $\mathbf{I}^{-1}(\alpha_0, \beta_0)$ is the inverse of the **information matrix** evaluated at the null hypothesis. The information matrix can be shown to be:

$$\begin{aligned}
\mathbf{I}(\alpha, \beta) &= \begin{bmatrix} \mathbf{I}_{\alpha^2} & \mathbf{I}_{\alpha\beta} \\ \mathbf{I}_{\alpha\beta} & \mathbf{I}_{\beta^2} \end{bmatrix} \\
&= -\begin{bmatrix} \dfrac{\partial^2 \log L(\alpha, \beta)}{\partial \alpha^2} & \dfrac{\partial^2 \log L(\alpha, \beta)}{\partial \alpha \partial \beta} \\ \dfrac{\partial^2 \log L(\alpha, \beta)}{\partial \beta \partial \alpha} & \dfrac{\partial^2 \log L(\alpha, \beta)}{\partial \beta^2} \end{bmatrix} \\
&= \sum_{i=1}^{k} n_i p_i (1 - p_i) \begin{bmatrix} 1 & x_i \\ x_i & x_i^2 \end{bmatrix} \\
&= \sum_{i=1}^{k} \text{var}(Y_i) \mathbf{x}_i \mathbf{x}_i',
\end{aligned}$$

where $\mathbf{x}_i' = [1 \quad x_i]$. After taking the inverse, we have

$$\begin{aligned}
\mathbf{I}^{-1}(\beta) &= (\mathbf{I}_{\beta^2} - \mathbf{I}_{\alpha\beta} \mathbf{I}_{\alpha^2}^{-1} \mathbf{I}_{\alpha\beta})^{-1} \\
&= p(1 - p) \left[\sum_{i=1}^{k} n_i x_i^2 - \frac{\left(\sum_{i=1}^{k} n_i x_i \right)^2}{\sum_{i=1}^{k} n_i} \right] \\
&= p(1 - p) \sum_{i=1}^{k} n_i (x_i - \overline{x})^2,
\end{aligned}$$

so that the score test can be written as

$$\begin{aligned}
Z^2_{\text{linear}} &= \frac{\mathbf{u}(\beta)^2}{\mathbf{I}^{-1}(\beta)} \\
&= \frac{\left[\sum_{i=1}^{k} x_i (y_i - n_i \tilde{p}) \right]^2}{\tilde{p}(1 - \tilde{p}) \sum_{i=1}^{k} n_i (x_i - \overline{x})^2}. \qquad (5)
\end{aligned}$$

There are many other algebraically equivalent forms of the score test, some of which facilitate numerical computations, including

$$\begin{aligned}
&Z^2_{\text{linear}} \\
&= \frac{\left[\sum_{i=1}^{k} n_i (x_i - \overline{x})(\hat{p}_i - \tilde{p}) \right]^2}{\tilde{p}(1 - \tilde{p}) \sum_{i=1}^{k} n_i (x_i - \overline{x})^2} \\
&= \frac{\left[\sum_{i=1}^{k} n_i (x_i - \overline{x}) \hat{p}_i \right]^2}{\tilde{p}(1 - \tilde{p}) \sum_{i=1}^{k} n_i (x_i - \overline{x})^2} \\
&= \frac{\left[\sum_{i=1}^{k} (x_i - \overline{x})(y_i - n_i \tilde{p}) \right]^2}{\tilde{p}(1 - \tilde{p}) \sum_{i=1}^{k} n_i (x_i - \overline{x})^2} \\
&= \frac{\left[\sum_{i=1}^{k} x_i - \overline{x} \sum_{i=1}^{k} y_i \right]^2}{\tilde{p}(1 - \tilde{p}) \left\{ \sum_{i=1}^{k} n_i x_i^2 - \left[\left(\sum n_i x_i \right)^2 \Big/ \sum n_i \right] \right\}}
\end{aligned}$$

or, in matrix form, as

$$Z^2_{\text{linear}} = \mathbf{x}'(\mathbf{Y} - \mathbf{E})[\mathbf{x}' \mathbf{V} \mathbf{x}]^{-1}$$

where $\mathbf{x} = [(x_1 - \overline{x}), \ldots, (x_k - \overline{x})]'$, $\mathbf{Y} = [y_1, \ldots, y_k]'$, $\mathbf{E} = [n_1 \tilde{p}, \ldots, n_k \tilde{p}]'$, and $\mathbf{V}$ is the diagonal matrix with elements $n_i \tilde{p}(1 - \tilde{p})$ on the diagonal.

For the special case in which g is the identity function, it is also possible to express the Wald test (*see* **Likelihood**) in closed form. When the asymptotic variance is evaluated under the null (i.e. $p_i = p$ for all i), this test statistic is equivalent to the score test, as follows:

$$\begin{aligned}
Z^2_{\text{Wald}, H_0} &= \frac{(\hat{\beta}_0)^2}{\widehat{\text{var}}(\hat{\beta})} \\
&= \frac{\left[\sum_{i=1}^{k} x_i (y_i - n_i \tilde{p}) \right]^2}{\tilde{p}(1 - \tilde{p}) \sum_{i=1}^{k} n_i (x_i - \overline{x})^2}.
\end{aligned}$$

The test statistic Z^2_{linear} is widely known as the Cochran–Armitage trend test, based on the work of Armitage [2] and Cochran [8]. Asymptotically, it follows a **chi-square distribution** with one **degree of freedom**. Alternately, its square root Z_{linear} follows a **normal distribution**. A test of $H_{a1}: \beta > 0$ is constructed by rejecting the null hypothesis of no trend if $Z_{\text{linear}} > z_{(1-\alpha)}$, where $z_{(1-\alpha)}$ is the α-level upper critical value of the normal distribution. Similarly, a test of H_{a2} is constructed by rejecting H_0 for $Z_{\text{linear}} < z_\alpha$. When the values of x_i represent integer **scores** or rankings, then a test of monotone trend can be analogously constructed by replacing x_i with i in (5) to form Z^2_{monotone}. Cox [10] demonstrated that these tests are uniformly **most powerful** for their respective alternatives under the logistic model given by (4). Although Agresti [1] notes that they are not uniformly most powerful (UMP) for any departure from independence, Tarone & Gart [38] showed that both the monotone and linear trend tests are asymptotically locally optimal $C(\alpha)$ tests, provided that g is a twice differentiable monotone function of x. Other extensions of the Cochran–Armitage trend test and associated **power** considerations have been described by Chapman & Nam [7], Gross [21], Tarone & Gart [38], and Wood [44].

Although the maximum likelihood estimators may not have closed form expressions for many choices of the link function g, it is also possible to construct both Wald tests and **likelihood ratio tests** of the null hypothesis of no trend using the appropriate numerical estimates; these test statistics are provided along with the score test in most statistical **software** packages. The Wald test is calculated as

$$Z^2_{\text{Wald},H_a} = \frac{(\hat{\beta})^2}{\widehat{\text{var}}(\hat{\beta})},$$

where the asymptotic variance of $\hat{\beta}$ is estimated under the trend alternative as

$$\widehat{\text{var}}(\hat{\beta}) = \frac{\sum_{i=1}^{k} n_i \hat{p}_i (1-\hat{p}_i)(x_i - \overline{x})^2}{\left[\sum_{i=1}^{k} n_i (x_i - \overline{x})^2\right]^2}$$

and $\hat{p}_i = g(\hat{\alpha} + \hat{\beta} x_i)$ is the estimate of p_i under the alternative. Similarly, a likelihood ratio test statistic for trend can be calculated as

$$\begin{aligned} D^2_{\text{linear}} &= 2\{\log[L(\hat{\alpha}, \hat{\beta})|H_a] - \log[L(\tilde{\alpha}, 0)|H_0]\} \\ &= 2\sum_{i=1}^{k}\left[y_i \log\left(\frac{\hat{p}_i}{\tilde{p}}\right) + (n_i - y_i) \right. \\ &\quad \left. \times \log\left(\frac{1-\hat{p}_i}{1-\tilde{p}}\right)\right], \end{aligned}$$

where $\tilde{\alpha}$ is the MLE for α under the null, and $\tilde{p}_i = g(\tilde{\alpha})$. Like the Cochran–Armitage trend test Z^2_{linear}, the above two test statistics are approximately χ^2_1 in large samples under the null hypothesis of no trend. When some cells of the **contingency table** are sparse or sample sizes are otherwise not adequate for asymptotic approximations, exact tests for trend can be based on the multiple **hypergeometric distribution** [1, 10, 39] (*see* **Exact Inference for Categorical Data**). To accomplish this, one calculates Z^2_{linear} for all tables with the same fixed row and column margins, and then sums the probabilities from the multiple hypergeometric distribution associated with all tables having values of Z^2_{linear} equal to or exceeding that of the observed table.

The **goodness of fit** of the linear model specified by the trend hypothesis can be assessed by comparing the chi-square statistic for testing the hypothesis of independence, that is, the general alternative to the null hypothesis given by (3), to the trend statistic. For example, the difference between the score tests of independence (i.e. the Pearson **chi-square test**) and trend (i.e. the Cochran–Armitage trend test) can be calculated as

$$\chi^2_{\text{gof}} = \chi^2_{\text{ind}} - Z^2_{\text{linear}},$$

where Pearson's chi-square test is given by

$$\chi^2_{\text{ind}} = \frac{\sum_{i=1}^{k} n_i (\hat{p}_i - \tilde{p})^2}{\tilde{p}(1-\tilde{p})}.$$

Similarly, one can construct an analogous goodness of fit test from the corresponding likelihood ratio test statistics:

$$D^2_{\text{gof}} = D^2_{\text{ind}} - D^2_{\text{linear}},$$

where

$$D^2_{\text{ind}} = \sum_{i=1}^{k} y_i \log\left(\frac{y_i}{n_i \tilde{p}}\right).$$

Under the linear trend model, the goodness-of-fit test statistics χ^2_{gof} and D^2_{gof} both follow a chi-square distribution with $k-2$ df.

It can be shown that there is a simple relationship between the Cochran–Armitage Trend test and the Pearson **correlation** coefficient. If the jth individual from sample i is defined to have the binary random variable y_{ij} and covariate x_{ij}, then

$$Z_{\text{linear}} = \frac{\sum_{i=1}^{k} x_i(y_i - n_i\tilde{p})}{\left[\tilde{p}(1-\tilde{p})\sum_{i=1}^{k} n_i(x_i-\overline{x})^2\right]^{1/2}} = N^{1/2}\text{corr}(x_{ij}, y_{ij}),$$

where $\overline{y} = \tilde{p}$ is the sample mean of the y_{ij}s, $N = \sum n_i$, and $\text{corr}(x_{ij}, y_{ij})$ is the Pearson correlation between the individual responses y_{ij} and individual scores x_{ij}. Agresti [1, p. 284] derived a similar formulation, but with $N-1$ in place of N in the above equation. Mantel [30] proposed an extension of this correlation-based statistic for stratified data.

In cases in which the observed $\hat{p}_i$s reflect slight departures from the hypothesized ordering under the trend alternative (e.g. $\hat{p}_i > \hat{p}_j$ for some $i < j$ under H_{a1}), the **isotonic regression** approach of Barlow et al. [3] can be applied. The hypothesis of no trend can be tested by

$$Z^2_{\text{iso}} = \frac{\sum_{i=1}^{k} n_i(\hat{p}^*_i - \tilde{p})^2}{\tilde{p}(1-\tilde{p})},$$

where $\hat{p}^*_i$ is the estimate of p_i under the appropriate order restriction (H_{a1} or H_{a2}). Collings et al. [9] demonstrated that Z^2_{iso} and Z^2_{linear} have the same asymptotic power for rejecting the null in favor of the trend alternative.

Much discussion has surrounded the issue of the appropriate scores x_i to use in constructing the trend test. For example, in a bioassay study with laboratory animals randomly assigned to one of four doses (say 1, 10, 100, and 1000 mg) of a chemical carcinogen, one may question whether to use the actual doses or the dose levels on the $\log_{10}$ scale (i.e. 0, 1, 2, and 3). In general, any set of scores will give a valid test under the null hypothesis and will protect the type I error rate (*see* **Level of a Test**). However, the most powerful scores to assign are those of the true model $p_i = g(\alpha + \beta x_i)$, which may be unknown in practice. Gross [21] has shown that if model (4) holds and the true scores are $x_1, \ldots, x_k$, but the incorrect scores $z_1, \ldots, z_k$ are used in the trend test, then the asymptotic relative efficiency of the Cochran–Armitage trend test is equal to the squared Pearson correlation between the scores, $[\text{corr}(z_i, x_i)]^2$.

Often, the explanatory variable has an underlying continuous scale, but data have been either collected or summarized into groups which specify a range of the continuous variable. For example, a variable such as age may be summarized as 20–29 years, 30–39 years, 40–49 years, and ≥50 years. In such situations, the midpoint of each interval is often chosen as x_i. When the highest or lowest category is specified only as above or below a certain cutoff, as in the previous example, one possible choice is to use the median level of x_i among the individuals in that group (if such data is available) (*see* **Categorizing Continuous Variables**). An alternate selection of scores for ordinal covariates can be provided by the approach of ridit analysis, as described by Bross [6], Fleiss [14], and Mantel [31]. Further discussion of the choice of scores is given by Agresti [1], Armitage [2], Cochran [8], Graubard & Korn [20], Snedecor & Cochran [35], and Yates [45] (*see* **Scores**).

Analysis of animal bioassay data was one of the original applications and motivations for development of trend tests (*see* **Tumor Incidence Experiments**). In a typical bioassay, animals are randomized to various exposure or "dose" levels of a drug, chemical, or other stimulus, and the proportion exhibiting the response of interest is observed. An example of bioassay data and associated trend tests is shown in Table 2. In this study, female mice were administered one of three doses of the chemical 1, 2-dichloroethane, and the proportion with lung tumors was observed. The Cochran–Armitage trend test yields $Z^2_{\text{linear}} = 10.64$ (df = 1, $P = 0.001$). A goodness of fit test for the linear model is calculated as $\chi^2_{\text{gof}} = 11.09 - 10.64 = 0.45$ (df = 1, $P = 0.650$), where $\chi^2_{\text{ind}} = 11.09$ is the Pearson chi-square test for independence; the nonsignificance of χ^2_{gof} suggests that the linear model is appropriate. A logistic regression model fit to this data yields likelihood ratio and Wald tests for trend of $D^2_{\text{linear}} = 11.51$ (df = 1, $P = 0.001$) and $Z^2_{\text{Wald},H_a} = 9.54$ (df = 1, $P = 0.002$), respectively. Based on these results,

Table 2 Binomial counts for lung tumors in female mice exposed to 1,2-dichloroethane

Dose (mg/kg)	Number exposed	Number with tumor	Percentage with tumor(%)
0	40	2	5
1	50	7	14
2	48	15	31

Test statistics

Test statistic	Label	Chi-square statistic	df	P value
Cochran–Armitage trend test	Z^2_{linear}	10.64	1	0.001
LR test of trend	D^2_{linear}	11.51	1	0.001
Wald test of trend	$Z^2_{\text{Wald,H}_a}$	9.54	1	0.002

we can conclude that the data provide evidence of an increasing trend in tumor rates with higher 1, 2-dichloroethane doses.

There is a wealth of literature on the application of trend tests to bioassay data. Bliss [4, 5] and Finney [12, 13] provided some of the original treatises on the subject of logit and probit models for analyzing trend in bioassays. More recent texts include those by Gart et al. [18], Govindarajulu [19], Hubert [23], and Morgan [32]. Adjustments to trend tests for bioassay data have been proposed by Gart et al. [17] to account for differential survival, and by Ibrahim & Ryan [24], Ryan [34], and Tarone [36] to incorporate information on historical controls into trend tests.

Extensions of the trend test have been suggested for stratified analysis, multiple outcomes, clustered data, and missing data. Using an example of combining information from animal bioassays conducted in several different sex-species groups, Tarone & Gart [38] described how the trend test for a general $(2 \times k)$ contingency table can be extended to incorporate **stratification** factors. Trend tests are also applied routinely to data from developmental toxicity bioassays, in which pregnant dams are exposed but primary interest lies in assessment of the effects of exposure on development and growth of their offspring. Since there are typically multiple outcomes of interest, trend tests in this setting must take into account both the clustering induced by litter effects and the correlation between multiple outcomes measured on the same embryo (*see* **Correlated Binary Data**). A test for global trend was proposed by Lefkopoulou & Ryan [29]; this test evaluates the overall effect of exposure on multiple correlated outcomes which may also be clustered. Williams & Ryan [42] adapted this test to account for missing data, and examined the efficiency of such global trend tests under various patterns of missing data. Because of the complexity of maximum likelihood analysis in such settings, use of quasi-likelihood methods and generalized estimating equations (GEEs) has become very popular in evaluating trends in proportions in the context of clustered binary data [32, 33, 43] (*see* **Quasi-likelihood**). An example of fitting three different types of models – logit, probit, and extreme value – to the probability of fetal malformation resulting from exposure to ethylene glycol is shown in Figure 1. These models were fit using both standard estimation methods and GEEs. While the parameter estimates for α and β were actually fairly similar, the standard errors for the standard models (which ignored clustering) were underestimated and led to inflated trend test statistics; for example, the trend Z statistic for the logit model was 14.6 based on the standard method and 8.4 using the GEE method.

Trend Tests for Multinomial Counts

In the case in which $(Y_1, \ldots, Y_k)$ represents a vector of counts following a multinomial distribution with $\sum_{i=1}^{k} Y_i = N$ and corresponding probabilities $p_1, \ldots, p_k$, we again assume that the probabilities p_i are linked to ordinal or continuous covariates x_i which are monotonically increasing or decreasing. Lee [26] described a method for testing the null hypothesis that the probability of falling into any

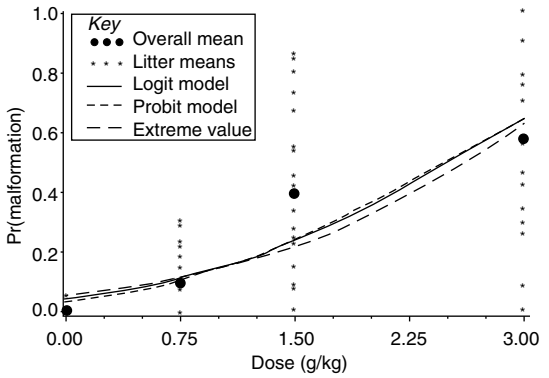

Figure 1 An illustration of logit, probit, and extreme value models fitted to the EG data on malformation

level is equal, that is,

$$H_0: p_1 = p_2 = \cdots = p_k = 1/k$$

vs. the increasing trend alternative

$$H_a: p_1 \leq p_2 \leq \cdots \leq p_k.$$

In fact, a slightly narrower alternative than H_a is considered by Lee as H_a^*: $p_{i+1} \geq \lambda_i p_i$, where $\lambda_i \geq 1$, $i = 1, \ldots, k-1$, with strict inequality for at least one λ_i. The trend statistic was then developed by choosing the test which maximized the minimum power over the parameter space $\Omega(\lambda)$, i.e. a **minimax** test.

This approach was later generalized, again by Lee [27], to one that allows incorporation of weights for each p_i. The test for trend is specified in terms of the related probabilities π_i which are subject to weights w_i, such that

$$p_i = f(w_i, \pi_i),$$

where $\sum w_i = 1$. Consider, for example, a cross sectional sample of N subjects summarized in a $(2 \times k)$ contingency table, with the first row representing the response of interest and the columns indicating the levels of the covariate $(x_1, \ldots, x_k)$. Since each of the N subjects can fall into only one of the $2k$ cells, the vector $(Y_{11}, Y_{21}, \ldots, Y_{1k}, Y_{2k})$ follows a multinomial distribution. In addition, conditional on $\sum_{i=1}^{k} Y_{1i}$, the vector of counts $(Y_{11}, \ldots, Y_{1k})$ also follows a multinomial distribution with probabilities $(p_1, \ldots, p_k)$. The weights w_i in this case are the proportion of the total sample N falling into the ith covariate level, that is $w_i = (Y_{1i} + Y_{2i})/N$, and the functional relationship is $p_i = w_i \pi_i$, where $\pi_i = \delta_i / \sum_{i=1}^{k} w_i \delta_i$ and δ_i is the conditional probability of response given the subject has covariate level x_i. The values of π_i can be related to the covariates via the function g, so that $\pi_i = g(x_i)/N$. The null hypothesis and alternative hypotheses are then stated as

$$H_0: \pi_1 = \pi_2 = \cdots = \pi_k$$

vs.

$$H_{a1}: \pi_1 < \pi_2 < \cdots < \pi_k$$

or

$$H_{a2}: \pi_1 > \pi_2 > \cdots > \pi_k,$$

with $\sum_{i=1}^{k} w_i \pi_i = 1$. Lee showed that the linear trend test for multinomial counts is:

$$Z_{\text{linear}} = \frac{\sum_{i=1}^{k} x_i (y_i - N w_i)}{\left\{ N \left[\sum_{i=1}^{k} w_i (x_i - \overline{x})^2 \right] \right\}^{1/2}},$$

where $\overline{x} = \sum w_i x_i / \sum w_i$. The monotone trend test Z_{monotone} can be constructed by replacing x_i with i in Z_{linear}. These test statistics follow an asymptotic standard normal distribution, and are both minimax tests. Like the tests derived in the binomial count setting, they are asymptotically efficient. Lee recommends use of the monotone trend test statistic, since it is more generally applicable regardless of the values of λ_i or the functional form of g. Tiwari & Sen [40] derived a rank statistic which incorporates historical control data for testing for a trend in multinomial proportions.

An example is shown in Table 3 for a sample of 1178 HIV-infected patients enrolled in a clinical trial comparing treatments for prevention of *Mycobacterium avium* complex (MAC) disease, a serious opportunistic infection contributing towards mortality

Table 3 Multinomial counts for MAC disease by pre-entry CD4 count

	CD4 lymphocyte level (cells/mm^3)				
	<25	25–50	50–75	>75	Total
MAC disease	78	25	11	7	121
No MAC disease	473	251	150	183	1057
Total	551	276	161	190	1178

Table 4 Estimated multinomial probabilities by pre-entry CD4 count

CD4 level	Number with MAC (Y_{1i})	Estimated multinomial probability ($\hat{p}_i$)	Weight (w_i)	Estimated conditional probability (δ_i)	Estimated trend value (π_i)
<25	78	0.645	0.467	0.142	1.378
25–50	25	0.207	0.234	0.091	0.882
50–75	11	0.091	0.137	0.068	0.665
>75	7	0.058	0.161	0.037	0.359
Total	121	1.000	1.000	–	–

in this population. The 1178 patients are cross-classified as to their MAC disease status and pre-entry CD4 lymphocyte count (cells/mm^3). Conditional on the 121 total observed cases of MAC disease, the vector of counts of patients with MAC disease in each of the four CD4 categories follows a multinomial distribution. While the estimated multinomial probabilities shown in Table 4 appear to follow a decreasing trend, such a comparison neglects the fact that the overall proportions of patients in the four CD4 levels are not equal. Instead, the appropriate trend test is based on the conditional probabilities of response δ_i given CD4 level x_i. This can be formulated as a test of trend in $\pi_i = p_i/w_i$; the values of π_i are proportional to δ_i but satisfy the constraint that $\sum p_i = \sum w_i \pi_i = 1$. For the data shown in Table 3, the linear trend test based on setting x_i equal to the median values of CD4 for each level (10, 36, 63, and 93, respectively) yields $Z_{\text{linear}} = -4.210$ ($P < 0.0001$). Since the values of x_i are almost evenly spaced, this result is very similar to that of the monotone trend test $Z_{\text{monotone}} = -4.227$. Either test indicates a significant departure from the null hypothesis of equal values of π_i in favor of the reverse trend alternative H_{a2}.

Trend Tests for Poisson Counts

For the case in which $Y_1, \ldots, Y_k$ are independent Poisson random variables, we still assume that $E[Y_i] = w_i f(x_i)$ where x_i is an ordered covariate, but now $f(x_i) = \lambda_i$ is the mean of the Poisson variable Y_i. Lee [28] has noted that we may consider the weights w_i arising from one of two scenarios: either (i) Y_i may be the number of rare events during an interval of length w_i, where λ_i is the event rate per unit time; or (ii) each Y_i may be a sum of w_i independent Poisson random variables, that is $Y_i = \sum_{j=1}^{w_i} Y_{ij}$, where $Y_{i1}, \ldots, Y_{iw_i}$ are identically distributed with mean λ_i. The former situation may also be relevant when w_i is the cumulative exposure in units such as person-years. Examples of Poisson data in biostatistical applications include incidence of new AIDS or cancer cases per calendar year, number of injuries or accidents over a set time period, number of bacteria per unit volume of suspension, number of revertants in microbial mutagenesis assays, or number of tumors observed in w_i animals exposed to dose x_i in an animal bioassay.

Our interest is again in testing for an increasing or decreasing trend in the means $\lambda_i = E[Y_i]/w_i$ with increasing levels of x_i. The relationship between λ_i and x_i is specified as

$$\lambda_i = g(\alpha + \beta x_i), \tag{6}$$

where g is a twice-differentiable monotone function. Commonly used functions in the context of Poisson data include g equal to the identity function or $g(x) = \exp(x)$, with the latter implying the loglinear regression model (*see* **Poisson Regression**)

$$\log(\lambda_i) = \alpha + \beta x_i. \tag{7}$$

The special case in which g is the identity and the intercept is zero, resulting in the regression through the origin $\lambda_i = x_i \beta$, has been considered by Frome et al. [15], Gart [16], and Jorgensen [25]. The test of trend developed by Gart in this context is exact, while the other two rely on asymptotic approximations.

Armitage [2] derived a chi-square test for trend in frequencies based on the asymptotic distribution of β in the model

$$\lambda_i = \alpha + \beta x_i,$$

and Cochran demonstrated that this test was valid for Poisson data under the assumption of equal weights,

$w_i = w$ for all i. For the more general model given by (6), the likelihood can be written as

$$\mathcal{L} = C(y_1, \ldots, y_k) \prod_{i=1}^{k} \exp\{-w_i g(\alpha + \beta x_i)\} \times \{g(\alpha + \beta x_i)\}^{y_i},$$

where C is a constant not involving α or β. The maximum likelihood estimators $\hat{\alpha}$ and $\hat{\beta}$ are found by solving the score equations $\partial \log \mathcal{L}/\partial\alpha = 0$ and $\partial \log \mathcal{L}/\partial\beta = 0$ simultaneously, but iterative numerical methods such as the Newton–Raphson approach or Fisher scoring algorithm are necessary. Frome et al. [15] described iterative approaches for obtaining estimates by the methods of maximum likelihood, weighted least squares, and minimum chi-squared criteria leading to "best asymptotically normal" **(BAN) estimates** of parameters, and noted that these estimates are computationally equivalent under certain conditions.

Since score tests only require MLEs under the null, this approach proves more practical for deriving tests of trend which have a closed form representation. Tarone [37] showed that a score test of the null hypothesis $H_0: \beta = 0$ in (6) could be derived as

$$\chi^2_{\text{Poisson}} = \frac{\left[\sum_{i=1}^{k} x_i(y_i - w_i\overline{y})\right]^2}{\overline{y}\sum_{i=1}^{k} w_i(x_i - \overline{x})^2}, \qquad (8)$$

where $\overline{y} = \sum_{i=1}^{k} Y_i / \sum_{i=1}^{k} w_i$. Asymptotically, χ^2_{Poisson} is distributed as chi-square with one degree of freedom under H_0. While this statistic is identical to that proposed by Armitage [2], Tarone [37] provided a more rigorous justification for its use by demonstrating that it was asymptotically locally optimal against any smooth monotone alternative, i.e. regardless of the choice of g, provided g was a smooth monotone function on $[0, x_k]$. In addition, Tarone noted that when $g(x) = \exp(x)$ as in (7), the chi-square test proposed in (8) is an asymptotic approximation to the UMP test of $H_0: \beta = 0$. Because the Poisson distribution is the limiting distribution of the binomial for small p_i and large n_i, the efficiency properties described for tests of trend for binomial proportions extend to the Poisson setting.

A number of computational difficulties can arise when applying the BAN method or other estimation approaches which require inversion of the information matrix, particularly if the values of $E[Y_i]$ are small [28]. When sample sizes are moderate to large, however, maximum likelihood estimates of α and β can be obtained from statistical **software** packages such as GLIM and Stata. These estimates and their associated asymptotic standard errors can be used as the basis for constructing a Wald or likelihood ratio test of trend, using methods analogous to those described for binomial data in an earlier section.

Lee [28] suggested that an alternative approach is first to condition on the sum of the Poisson random variables, $\sum_{i=1}^{k} Y_i$, and then use the methods derived for multinomial data. Since the vector of Poisson random variables $(Y_1, \ldots, Y_k)$ follows a multinomial distribution conditional on $\sum Y_i$, the tests Z_{linear} and Z_{monotone} of the previous section can be considered as conditional minimax tests when applied to tests of trend for Poisson means.

Jorgensen [25] extended the trend tests for Poisson regression to multiple variables, and both linear and nonlinear extensions of the zero-intercept model are addressed by Frome et al. [15]. Both Gart [16] and Frome et al. [15] have discussed methods for evaluating the goodness of fit of the Poisson regression model. Tarone [37] used an approach similar to that employed for binomial data [36] to incorporate historical control data into tests for trend in Poisson means; this technique is appropriate for dose–response experiments which include a control group. El-Sayyad [11] described a Bayesian method and a related Bayesian approximation to test for trends in Poisson-distributed data. Hakulinen & Dyba [22] have described use of trend models for Poisson data to predict future disease incidence, and developed associated prediction intervals for new cases of melanoma and lung, stomach, or colon cancer. In cases in which the variance of Poisson counts appears to be inflated relative to the mean, quasi-likelihood methods can be used to account for such overdispersion ([1, pp. 456–457], and *see* **Overdispersion**; **Quasi-likelihood**).

An example of Poisson data for which a trend test is of interest is presented in Table 5. This table shows the number of cases of melanoma reported between 1969 and 1971 for six age groups, along with the person-years of employment in each age group. Also

Table 5 Poisson counts of melanoma cases by age group

Age group midpoint (x_i)	Number of observed melanoma cases (Y_i)	Person-years of exposure (w_i)	Observed rate per 100 000 person-years ($y_i/w_i \times 10^5$)	Predicted rate per 100 000 person-years ($\hat{\lambda}_i \times 10^5$)
30	61	2 880 262	2.12	3.90
40	76	564 535	13.46	6.64
50	98	592 983	16.53	11.29
60	104	450 740	23.07	19.22
70	63	270 908	23.26	32.70
80	80	161 850	49.43	55.66

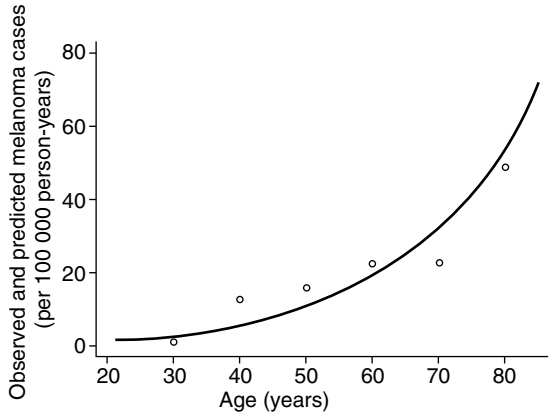

Figure 2 An illustration of Poisson regression to melanoma data

shown is both the observed rate of melanoma per 100 000 person-years, and the predicted rate based on fitting the loglinear model in (7) (see Figure 2). The MLE for β is 0.0532 with associated asymptotic standard error of 0.0025, yielding a Wald test of trend of $Z_{\text{Wald},H_a} = 21.2$. The score test of trend is calculated as 23.5, leading to a similar conclusion that the data indicate a significant increasing trend in rates of melanoma with increasing age level.

PAIGE L. WILLIAMS

Trigonometric Regression

This is essentially a method of fitting a periodic regression function to data of the form $\{y_i, t_i; i = 1, 2, \ldots, n\}$, where y is a response variable and t usually denotes time. Common applications arise in modeling biological cycles that are tied to environmental cycles such as the 24 h solar day, the approximately 25 h lunar day, or the annual cycle of 12 months (seasonal variation; *see* **Circadian Variation**). In such cases the fundamental period is determined a priori. Other biological cycles, such as the menstrual period in women, have no clear link to the environment and may vary in length between individuals; so it may be of interest to estimate the length of the cycle in addition to its amplitude and phase. Furthermore, many diurnal cycles may be slightly changed in length by changes in the environment, such as exposure to continuous light (or dark). Applications where t is spatial rather than temporal arise in modeling variation with orientation on a circle (*see* **Circular Data Models**). Bliss [2, Chapter 17], gives examples and references.

Consider a model equation

$$y_i = g(t_i) + e_i, \tag{1}$$

where g is periodic with period τ, i.e. $g(t + \tau) = g(t)$ for all t, and e_i are error random variables with zero mean. In the simplest nontrivial case, $g(t)$ is a single cosine (or sine) wave with amplitude ρ, angular frequency, ω, and phase angle ϕ. This may be written in the equivalent forms

$$g(t) = \rho \cos(\omega t - \phi) \tag{2}$$

$$= \rho \sin(\omega t - \phi + \frac{\pi}{2}) \tag{3}$$

$$= \alpha \cos \omega t + \beta \sin \omega t, \tag{4}$$

where $\alpha = \rho \cos \phi$ and $\beta = \rho \sin \phi$. Expressing ρ and ϕ in terms of α and β gives

$$\rho = (\alpha^2 + \beta^2)^{1/2} \quad \text{and} \quad \phi = \tan^{-1}\left(\frac{\beta}{\alpha}\right).$$

The function $g(t)$ given by 2, 3, or 4 is periodic with period $\tau = 2\pi/\omega$ time units; ω is the angular frequency in radians per unit time, and $\omega/2\pi = 1/\tau$ is the frequency in cycles per unit time. The value of $g(t)$ cycles between ρ and $-\rho$ and reaches its first peak after $t = 0$ at time $t_\phi = \phi/\omega$. The parameters α and β are useful for fitting models; they may then be transformed to ρ and t_ϕ for interpreting results.

The model equation (1) for a constant term plus a single cosine wave becomes

$$y_i = \alpha_0 + \alpha \cos \omega t_i + \beta \sin \omega t_i + e_i. \tag{5}$$

When the period τ (and hence the frequency ω) is known, this is equivalent to an ordinary linear regression model with a constant term and explanatory variables $x_{1i} = \cos \omega t_i$ and $x_{2i} = \sin \omega t_i$. Note that, unless the phase is known, it is not sensible to include one of these terms without the other. The constant term α_0 can be regarded formally as a trigonometric function 4 with $\omega = 0$, $\alpha = \alpha_0$, and $\beta = 0$.

A cosine wave is limited in shape, but in principle a periodic function of any shape can be expressed as a linear combination of sine and cosine terms with frequencies $\omega, 2\omega, 3\omega, \ldots$, see, for example, [8, p. 11]. Here ω is called the fundamental frequency and $2\omega, 3\omega, \ldots$ are higher harmonics. Thus consider

$$g(t) = \alpha_0 + \sum_{j=1}^{m} (\alpha_j \cos j\omega t + \beta_j \sin j\omega t). \tag{6}$$

This is still periodic with period $\tau = 2\pi/\omega$, because a function that repeats itself every $2\pi/j\omega$ time units also does so every $2\pi/\omega$ time units. Again, when ω is known, and with the usual assumptions about the errors e_i, (1) is an ordinary linear regression model once we have fixed which terms to include.

In applications where the cycle varies about a nonstationary trend, the model equation may need to be generalized further – for example, by adding to 6 a parametric trend function, such as a low-order polynomial in t or a low-frequency trigonometric function to be fitted along with the cyclic function, or alternatively by removing the trend nonparametrically before fitting (6).

When the period τ (or frequency ω) is regarded as an unknown parameter, then (1) with $g(t)$ given by 6 is no longer a linear regression model. However, a natural approach is to fit 6 by linear regression for each of a range of values of ω and to choose ω to optimize the fit. If the e_i are assumed to be independent and normal, then **maximum likelihood** estimates for ω and the other parameters may be obtained by this method.

There are obvious extensions to **generalized linear models**, or types of error models other than

independent normal. For example, y_i might have a **Poisson distribution** with mean $\exp\{g(t_i)\}$, independently for each i, where $g(t)$ is given by 6. When ω is known, this is a standard **loglinear model**. For a single trigonometric term, the frequency and phase have the same meaning as before, but ρ is now the amplitude on a log scale, so that $\mathrm{E}[y(t)]$ cycles between $\mu_0 e^{\rho}$ and $\mu_0 e^{-\rho}$.

Another type of extension of the model is to nonindependent errors. Particularly when $y_1, y_2, \ldots, y_n$ is an observed **time series**, it may sometimes be more reasonable to assume that the e_i are correlated, perhaps described by a low-order **moving average** or autoregressive process (*see* **ARMA and ARIMA Models**).

When observed at a sufficient number of reasonably spaced times, different trigonometric functions are nearly orthogonal. These **orthogonality** properties are exact for the equally spaced times and frequencies discussed in the next section, which makes trigonometric functions particularly convenient for modeling periodic phenomena.

Equally Spaced Times and Fourier Frequencies

Often y is observed at n equally spaced times. We now take unit time to be the sampling interval and denote the data by $\{y_t, t; t = 1, 2, \ldots, n\}$ to avoid possible confusion with the complex number i which is sometimes used in the derivation of the orthogonality results used here and in related representations.

The shortest period that can be observed is $\tau = 2$, corresponding to $\omega = 2\pi/2 = \pi$, so without loss of generality we consider frequencies in the range $0 \le \omega \le \pi$. A trigonometric function 4 with $\omega = \pi$ may be written as

$$\alpha \cos \pi t + \beta \sin \pi t = \alpha(-1)^t, \tag{7}$$

which is represented by just one parameter, α. The absolute value of α is the amplitude and the sign of α determines the phase ($t_\phi = 0$ or 1). Thus, to fit a function with period 24 h one would need to observe it at least every 12 h; and observing it every 12 h would just allow one to fit (7).

For reasonably large n, the frequency range $0 \le \omega \le \pi$ is well spanned by the set of *Fourier frequencies*

$$\omega_j = \frac{2\pi j}{n}, \quad j = 0, 1, 2, \ldots, m, \tag{8}$$

where $m = n/2$ when n is even and $m = (n-1)/2$ when n is odd. Furthermore, the sampling interval is usually chosen so that the frequencies of interest are a subset of 8. For these frequencies it can be shown (see, for example, [1, p. 95]) that the functions

$$\cos \omega_j t, \sin \omega_j t, \cos \omega_k t, \sin \omega_k t$$

for $j \ne k$, are mutually orthogonal. That is, the sum over $t = 1, 2, \ldots, n$ of products of any pair of these is zero.

We present results for the case n even, so $m = n/2$. The formulas for n odd are the same except that there is no one-parameter term corresponding to $\omega = \pi$. The saturated model equation, including sine and cosine terms at all frequencies 8, is now

$$y_t = \alpha_0 + \sum_{j=1}^{m-1} (\alpha_j \cos \omega_j t + \beta_j \sin \omega_j t) + \alpha_m \cos \pi t + e_t. \tag{9}$$

This has n coefficients. If these are all estimated by **least squares**, then the data will be fitted exactly. In practice, a model with a subset of these terms, corresponding to the fundamental frequency and some higher harmonics for each underlying periodicity, will be of interest. Because of the orthogonality, such a model may be fitted simply by selecting the relevant terms from the saturated model, analogously to using orthogonal polynomials (*see* **Orthogonality**) in **polynomial regression**.

The least squares estimates for $j = 1, 2, \ldots, m-1$, are

$$\hat{\alpha}_j = \frac{2}{n} \sum_{t=1}^{n} y_t \cos \omega_j t, \; \hat{\beta}_j = \frac{2}{n} \sum_{t=1}^{n} y_t \sin \omega_j t, \tag{10}$$

and for $j = 0, m$, are

$$\hat{\alpha}_0 = \frac{1}{n} \sum_{t=1}^{n} y_t, \qquad \hat{\alpha}_m = \frac{1}{n} \sum_{t=1}^{n} (-1)^t y_t. \tag{11}$$

These estimates are unaffected by omitting other terms from the model. Under the usual sampling model for linear regression, where the errors e_t are uncorrelated with mean 0 and variance σ^2, all of the estimates (10) and (11) are mutually uncorrelated.

Table 1 Harmonic analysis of variance

Source frequency (cycles per n time units)	Degrees of freedom (df)	Sum of squares (ss)
0	1	$n\bar{y}^2$
1	2	$(n/2)(\hat{\alpha}_1^2 + \hat{\beta}_1^2)$
2	2	$(n/2)(\hat{\alpha}_2^2 + \hat{\beta}_2^2)$
...	...	...
$m-1$	2	$(n/2)(\hat{\alpha}_{m-1}^2 + \hat{\beta}_{m-1}^2)$
m	1	$n\hat{\alpha}_m^2$
Total	n	$\sum_{t=1}^{n} y_t^2$

Each of the estimates (10) has variance $2\sigma^2/n$, and each of 11 has variance σ^2/n.

There is a corresponding harmonic **analysis of variance**, described in Table 1. Sources of variation are the different frequencies j in cycles per n sampling intervals, or corresponding periods in numbers of sampling intervals. The frequency $j = 0$ corresponds to the constant term; this is usually omitted from the analysis of variance table, but is included here for completeness. The sums of squares are proportional to the squared amplitude of each fitted cosine wave.

The n coefficients $\frac{1}{2}\hat{\alpha}_j$, $\frac{1}{2}\hat{\beta}_j$, $\hat{\alpha}_0$, and $\hat{\alpha}_m$ given by 10 and 11 constitute the *discrete Fourier transform* of the data, and the sums of squares in Table 1 constitute the *periodogram*. These are basic statistics used in the frequency domain analysis of **time series**.

Example

As an illustrative example consider the data in Table 2. The height of the tide at a point on a tidal river in West Scotland has been measured every 62 min for $n = 24$ times.

The interval between successive high tides at the relevant time of year is known to be 12 h 24 min, so there should be exactly two tidal cycles in these data. Here it is convenient to take the time unit as 62 min. Strictly speaking, two successive tidal cycles within a day are not identical, but as the data are limited to just one lunar day we fit a single function with period 12.

Table 3 shows the analysis of variance (cf. Table 1) along with the parameter estimates for the saturated model, and hence for any submodel.

To fit a model with period 12, one would include only terms with j even. The remaining terms ($j = 1, 3, 5, 7, 9, 11$) can be pooled to provide a residual mean square of 1.53 with 12 degrees of freedom. Including all of the even terms (12 parameters) effectively fits an arbitrary periodic function with period 12. The $j = 2, 4$, and 8 mean squares are individually significantly large by an F test. The pooled mean square for $j = 6$, 10, and 12 is only 1.97 with five degrees of freedom, so the tidal variation is well explained by just the 2, 4, and 8 terms. This leads to the fitted model:

$$\begin{aligned} y_t = 10.07 &+ 7.04\cos(t - 23.6)\frac{\pi}{6} \\ &+ 2.58\cos(t - 0.81)\frac{\pi}{3} \\ &+ 1.62\cos(t - 1.01)\frac{\pi}{3} + e_t, \end{aligned}$$

with error standard deviation σ estimated (from the pooled mean square for $j = 6$, 10, 12 and j odd) to be 1.29 feet.

Figure 1 shows a time plot of the data along with each component cosine wave separately and fitted models with and without the $j = 8$ term. The higher harmonics $j = 4$ and 8 have no particular meaning on their own. The $j = 4$ term has the effect of shaping the basic wave so that it spends 8 time units dropping from maximum to minimum

Table 2 Height of tide y_t (ft) at 24 equally spaced times t

t	1	2	3	4	5	6	7	8	9	10	11	12
y_t	19.8	18.1	12.7	13.5	10.5	10.5	6.8	2.4	1.4	4.7	6.0	13.6

12	2	0.067		0.00	0.067	1	0.11

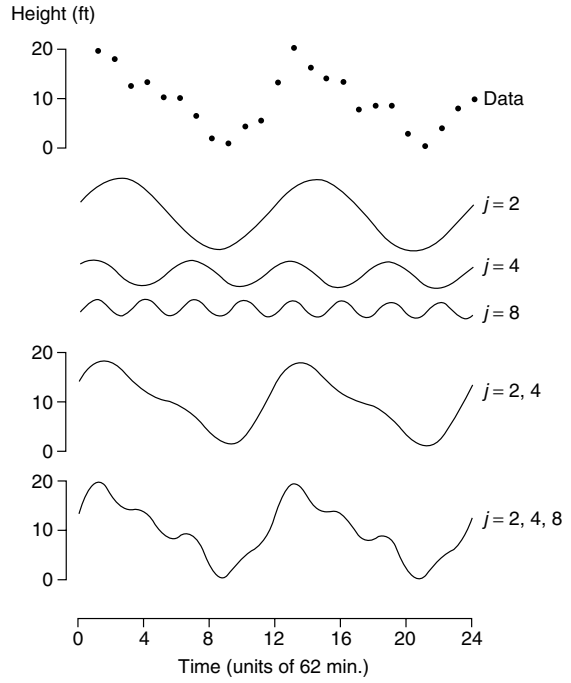

Figure 1 Plot of height of tide vs. time, individual trigonometric terms with j = 2, 4, and 8 cycles per 24 time units, and fitted regression functions with $j = 2, 4$ and $j = 2, 4, 8$

and 4 time units climbing back to the maximum. This is presumably due to the flow of the river. The $j = 8$ term puts steps into the wave to that it does not decrease monotonically. This seems physically implausible, though not impossible; for example, it might be due to local currents caused by a sandbank. Although there is some hint of this feature in both cycles of the data, one should beware of reading too much detail into the fitted curve.

Extensions and Further Material

This topic is discussed in [2, Chapter 17] and in books on time series analysis, particularly [1, Chapter 4] and [3, Chapter 2]. Related Encyclopedia articles include [6] and [7].

There is a generalization of 9, minus the error term, that is fundamental to the frequency domain theory of stationary time series, i.e. when the coefficients α_j and β_j are independent (or in some contexts merely uncorrelated) random variables with zero means and variances given by $\text{var}(\alpha_j) = \text{var}(\beta_j) = \sigma_j^2$. The second-order properties of the model are defined by the set of variances σ_j^2, which constitute the (discrete, nonnormalized) spectral density function (*see* **Spectral Analysis**). It can be shown that, when this model is extended to the continuous range of frequencies $0 \leq \omega \leq \pi$, it defines the class of *all* second-order **stationary** processes (with zero mean).

For cyclic phenomena that are not strictly periodic there are other types of model that may be more **parsimonious**. Perhaps the simplest is the second-order autoregression

$$y_t = \mu_0 + \alpha_1 y_{t-1} + \alpha_2 y_{t-2} + e_t,$$

where μ_0 is a constant term, e_t are independent errors with zero means and common variance σ^2, and the

coefficients α_1 and α_2 are such that $-1 < \alpha_2 < 0$ and $\alpha_1^2 + 4\alpha_2 < 0$ (see, for example, [4, Section 3.2.4]). Such a process displays pseudo-periodic behavior, oscillating with varying frequencies around ω_0 given by $\cos\omega_0 = |\alpha_1|/2\sqrt{-\alpha_2}$, i.e. a large amount of the variation in y_t comes from frequencies in the neighborhood of ω_0. Among published examples of such modeling are several analyses of data on annual trappings of the Canadian lynx, including two discussion papers: Tong [9] fitted an autoregression of order 11, while Campbell & Walker [5] fitted a superposition of a pure sine wave and a second-order autoregression.

Trimming and Winsorization

There are several practical problems with the population mean, μ, and its usual estimator, the sample mean, $\overline{X}$. First, μ is not **robust**. Roughly, this means that a small proportion of a distribution can dominate its value. Also, very small shifts in a distribution can result in large changes in μ. For example, μ might correspond to the 0.8 **quantile**, in which case, at least in some situations, it provides a poor reflection of the typical subject under study. The sample mean is not resistant (*see* **Robustness**), meaning that a single unusual observation can completely dominate its value. Another problem is that slight departures from normality can inflate its **standard error**, which in turn can result in relatively low **power** for **hypothesis testing**. Also, a single unusual value, or **outlier**, can inflate the estimate of the standard error. It might be hoped that these problems rarely arise in applied work, but the exact opposite seems to be true.

The contaminated normal distribution provides the classic example of how small departures from normality can inflate the standard error of $\overline{X}$. The distribution is given by

$$H(x) = (1 - \varepsilon)\Phi(x) + \varepsilon\Phi(x/k),$$

where $\Phi(x)$ is the standard **normal distribution**. That is, with probability $1 - \varepsilon$, an observation is sampled from a standard normal distribution; otherwise, sampling is from a normal distribution having standard deviation k. The standard normal and contaminated normal distributions for $\varepsilon = 0.1$ and $k = 10$ are shown in Figure 1. The distributions are similar (as measured by the Kolmogorov distance function; *see* **Kolmogorov–Smirnov Test**), yet the contaminated normal has variance 10.9 versus a variance of 1 for the standard normal.

When **testing hypotheses** or computing **confidence intervals**, more problems arise. First, standard methods for computing confidence intervals can have probability coverage substantially different from the nominal level. The probability coverage can be too low when sampling from **skewed**, light-tailed distributions, and it can be too high when distributions have heavy tails. The left panel of Figure 2 illustrates the first problem by showing the distribution of the one-sample **Student's *t* statistic**

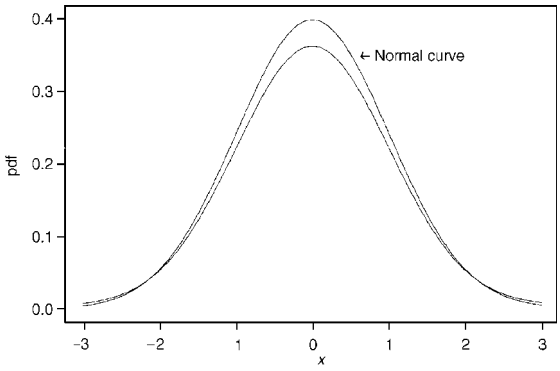

Figure 1 Normal and contaminated normal distributions

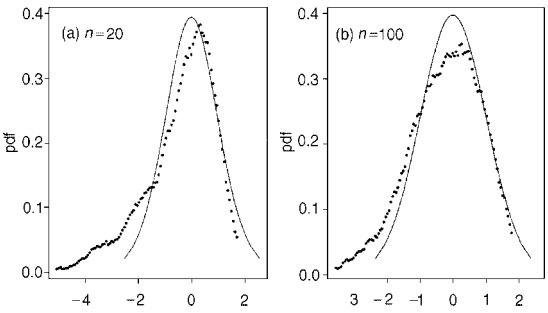

Figure 2 The probability density function of Student's t when sampling from a lognormal distribution (the solid line is the assumed distribution)

when sampling from a **lognormal distribution**. Under standard assumptions, the distribution is symmetric about zero, as shown by the solid line in Figure 2. In actuality, the left tail is too thick, the right tail is too thin, and the mean of the test statistic is approximately -0.5, not zero as is commonly assumed. The result is that power can go down as we move away from the null hypothesis, although eventually it goes up. For a lower-tail test at the 0.05 level, the actual probability of a type I error is approximately 0.15. The right panel of Figure 2 shows that the tail of the actual distribution is still too thick when $n = 100$. Just how large the sample size has to be, to ensure accurate probability coverage, is unknown. From [4], $n = 160$ is not large enough. In the comparison of two or more distributions, similar problems arise when distributions have unequal skewnesses. The second problem arises because sampling from heavy-tailed distributions inflates the sample variance, resulting in

confidence intervals that are too long, which, in turn, can mean poor power.

When attention is focused on making inferences about distributions using some measure of location, trimming and Winsorization provide one approach that has been found to be relatively effective for dealing with the problems just described. (M-estimators (*see* **Robustness**) represent another approach.) The resulting measure of location is more robust than the mean, efficiency is not overly sensitive to small changes in the tails of the distributions, and accurate confidence intervals can be computed for a wider range of situations vs. methods based on means, particularly when distributions are skewed.

Trimming deals with problems associated with the tails of a distribution by removing them. That is, it concentrates on the "middle" portion of the distribution. For example, 20% trimming means that a distribution would be trimmed at the 0.2 and 0.8 quantiles. This is not to say that observations in the tails are uninteresting or unimportant, but for certain purposes they do more harm than good. For a random sample, $X_1, \ldots, X_n$, let $X_{(1)} \leq \ldots \leq X_{(n)}$ be the **order statistics** (the observations written in ascending order). The sample trimmed mean is

$$\overline{X}_t = \frac{X_{(g+1)} + \cdots + X_{(n-g)}}{n - 2g},$$

where $g = [\gamma n]$, the notation $[\gamma n]$ meaning that γn is rounded down to the nearest integer, and γ is the desired amount of trimming. The optimal amount of trimming varies from one situation to another. A common recommendation is $\gamma = 0.2$ (20%), because it maintains reasonably high efficiency under the normal model, and it can have substantially higher efficiency, vs. the sample mean, when distributions have heavy tails. In terms of probability coverage for confidence intervals, there are advantages to having γ close to 0.5, but a negative consequence is low **efficiency** under normality. Also, it seems that as the amount of trimming increases, problems in obtaining accurate confidence intervals diminish substantially up to about $\gamma = 0.2$.

A common misconception is that trimming is equivalent to randomly discarding $2g$ observations. Another common mistake is to apply standard methods for means after trimming. The problem is that the order statistics $X_{(g+1)}, \ldots, X_{(n-g)}$ are dependent random variables, so application of the usual estimate of the standard error of the sample mean to these $n - 2g$ values, to estimate the standard error of $\overline{X}_t$, is inappropriate. If $2g$ observations are randomly removed, the remaining observations would be independent, which differs from trimming. The result is that some of the practical advantages of trimming are not intuitive to many researchers.

A practical problem is to find an appropriate estimate of the standard error of the trimmed mean, and there are theoretical results that supply a useful solution. The resulting estimator depends in part on the Winsorized sample mean (named after the American statistician, C.P. Winsor),

$$\overline{X}_w = \frac{1}{n}\Sigma W_i,$$

where

$$W_i = \begin{cases} X_{(g+1)}, & \text{if } X_i \leq X_{(g+1)}, \\ X_i, & \text{if } X_{(g+1)} < X_i < X_{(n-g)}, \\ X_{(n-g)}, & \text{if } X_i \geq X_{(n-g)}. \end{cases} \quad (1)$$

An estimate of the squared standard error of $\overline{X}_t$ is

$$\frac{1}{n^2(1-2\gamma)^2}\sum(W_i - \overline{W})^2.$$

Another, nearly equivalent, estimate, that seems to have a slight practical advantage in certain situations, is

$$\frac{1}{nh}\sum(W_i - \overline{W})^2,$$

where h, the so-called effective sample size, is $n - 2g$, the number of observations left after trimming. Both estimates are slightly biased, but a Winsorized unbiased estimate can be obtained by replacing n^2 in the first estimate with $n(n-1)$. (See [5] for details.)

Methods for comparing trimmed means have been examined by **simulations** for many problems including one-way and two-way designs, repeated measures (*see* **Longitudinal Data Analysis, Overview**), **random effects** models and **multiple comparisons**. Extensions to **split plot** and higher-way designs are relatively straightforward. Trimming and Winsorization also play a role in **correlation** and **regression**. Details about all of these methods, with related techniques, are summarized in [5]. For relevant theoretical results, see also [1–3].

Truncated Survival Times

Truncation of survival data arises when observation of an experimental subject can only occur if the value of the failure time (survival time) lies within a certain interval, (l, r), where l or r may be infinite. When the failure time is outside the truncation interval, no information about the subject is observable; hence the subject is said to be "sampled from a conditional distribution". This feature distinguishes truncation from **censoring**; in the latter situation, subjects are known to have failure times greater (or less) than some fixed constant. An important example of truncation in the analysis of data on **AIDS** arose from investigation of blood transfusions contaminated with the human immunodeficiency virus (HIV) [11] published in 1986. Data from an AIDS registry that included date of onset of AIDS and retrospective determination of transfusion times were used to estimate the distribution of latency times from HIV infection to onset of clinical disease (*see* **Latent Period**). Lui et al. [11] were able to observe only latency times short enough to result in onset of AIDS before the end of the observation period, December 1985. For example, they knew about only those contaminated transfusions from June 1982 that were associated with latency periods of less than 3.5 years. These data are said to be *right-truncated* with a truncation time equal to the difference between the end of the observation period and time of transfusion. Because AIDS was not identified until 1981, latency periods of greater than 2 years were required for transfusions that took place in 1979 to be included in the AIDS registry. When failure times must exceed a certain value for the subject to be observable, such data are said to be *left-truncated*. In the transfusion case, truncation times are equal to the difference between the beginning of the observation period and the time of transfusion. Thus, some transfusion dates result in data that are only right-truncated; other dates yield data that are left- as well as right-truncated. The following sections describe estimation procedures for data that are only right-truncated, or both left- and right-truncated; for methods for data that are only left-truncated, *see* **Delayed Entry**.

Nonparametric Maximum Likelihood Methods

Methods for closed-form **nonparametric maximum likelihood estimation** are available when data are truncated only on one side; the simplest situation occurs when data are only left-truncated. Following an approach described by **Kaplan & Meier** [7] and the formalization of Keiding [8], let $l_1, \ldots, l_n$ be arbitrary left-truncation times, and X be the underlying **random variable** (latency period in our example) with continuous distribution function F. Consider $Y_1, \ldots, Y_n$ to be independent failure times, with Y_i following the conditional distribution of X given $X > l_i$. Here and throughout this section we assume there are no ties (*see* **Tied Survival Times**). We can calculate the number at risk at time x as

$$R(x) = n(l_i \leq x) - n(Y_i < x),$$

where $n(\cdot)$ refers to the number of subjects. The product-limit estimator of F is given by

$$1 - \hat{F}(x) = \Pr(X > x) = \prod_{Y_i \leq x} \left(\frac{1 - 1}{R(Y_i)} \right).$$

Left truncation is equivalent to delayed entry into the risk set. The **Nelson–Aalen estimator** may be used to estimate the integrated hazard under left truncation

$$\hat{\Lambda}(x) = \sum_{Y_i \leq x} \frac{1}{R(Y_i)}.$$

When data are right-truncated, F is **identifiable** only if the longest right-truncation time, $r_M = \sup\{r_i\}$, exceeds the longest possible time of failure. Otherwise one can identify only $G(x) = F(x)/F(r_M)$ [10]. Let z_i denote the chronologic time of transfusion, and R_* denoted the end of the observation period. The right-truncation times r_i are equal to $R_* - z_i$. Once again, we let Y_i denote the observed failure times (latency in our example), sampled from X given $X < r_i$. Nonparametric maximum likelihood estimation in the setting where only right truncation occurs can also be performed using a product-limit estimator. Once again, the presence of right censoring can easily be accommodated. Intuition into the approach is

provided by considering the problem in reverse time. Consider a "reverse time" transformation, $S = R_* - X$, which transforms right truncation into (easier to deal with) left truncation. We define a risk set at (reverse) time s

$$R(s) = n(R_* - r_i \le s) - n(R_* - Y_i < s).$$

Thus, $R(s)$ consists of subjects who have z_i, such that $z_i \le s$ (or $r_i \ge x$), and failure times such that $R_* - Y_i \ge s$ or $(Y_i \le x)$. The product-limit estimator is then

$$\Pr(S > s | S \ge 0) = \prod_{R_* - Y_i \le s} \left(\frac{1-1}{R(R_* - Y_i)} \right)$$

for $R_* - Y_M \le s \le R_*$, and 1 for $0 \le s \le R_* - Y_M$, where Y_M is the maximum of the observed failure times. Since

$$\begin{aligned} \Pr(S > s | S \ge 0) &= \Pr(X < R_* - s | X < R_*) \\ &= G(R_* - s), \end{aligned}$$

$$\hat{G}(x) = \prod_{Y_i \ge x} \left(\frac{1-1}{R(R_* - Y_i)} \right),$$

for $0 \le x \le Y_M$, and 1 for $Y_M \le x \le R_*$. In practice one can compute these estimates with software for product-limit estimates that permit left truncation (delayed entry). Subjects enter the risk set at time z_i and fail at time $R_* - Y_i$. Asymptotic properties of the estimators have been studied by Woodroofe [19], Wang et al. [18], and Keiding & Gill [9].

Example 1

Lagakos et al. [10] have considered the problem of estimating and comparing the induction-time distribution for 258 adults (group 0) and 37 children (group 1) infected by blood transfusion, diagnosed by June 30, 1986, and reported to the Center for Disease Control before January 1, 1987. The data were been condensed by grouping dates of infection and AIDS into 3-month intervals beginning April 1, 1978. Thus $z = 0$ denotes an infection occurring between April 1, 1978 and June 30, 1978, $z = 0.25$ denotes an infection occurring between July 1, 1978, and September 30, 1978, and $R_* = 8$. The data are right-truncated because only cases (z_i, Y_i) such that $z_i + Y_i \le R_*$ were observed. Since there are ties of Y_is in this example, we have to modify the methodology described above. Following [10], let $v_1 < \ldots < v_m$ denote the distinct values of $(Y_1, \ldots, Y_n)$, let $u_j = R_* - v_j$, and define $n_j = n(Y_i = v_j)$, for $j = 1, \ldots, m$. Notice that N_j in [10] is the risk set $R(R_* - v_j)$. The nonparametric maximum likelihood estimator of $G(x)$ is

$$\hat{G}(x) = \prod_{v_j \ge x} \left(\frac{1 - n_j}{N_j} \right),$$

for $0 \le x \le v_m$, and 1 for $v_m \le x \le R_*$.

Figure 1 shows the estimates $\hat{G}(x)$ for the groups of adults and children. Conditional on being less than 8 years, the induction times for children tend to occur sooner than those for adults, with estimated medians of about 3 and 5.5 years, respectively. To compare to the above nonparametric results, Lagakos et al. [10] also used a parametric likelihood method to estimate F. They fit the **Weibull** model $F(x) = 1 - \exp\{-(\theta x)^r\}$ to the adult data, giving a **likelihood** function that is extremely flat over a range of parameter values representing a wide range of induction distributions. Figure 1 also displays the maximum likelihood estimates of G corresponding to Weibull distributions with medians of 8.5 years and 210 years. Both parametric maximum likelihood

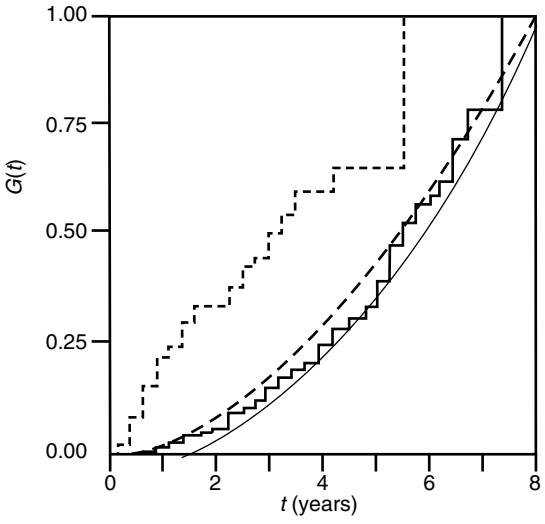

Figure 1 Nonparametric estimates of G based on data in Table 1: - - - - - children; ——— adults. Parametric estimates of G based on Weibull distributions with medians of: – – – 8.5 years; ——— 210 years. Reprinted from [10] by permission of *Biometrika*

estimates agree with the nonparametric maximum likelihood estimate $\hat{G}(x)$ reasonably well, indicating that very different $F(\cdot)$ distributions can have similar $G(\cdot)$ components. See also [5, 9], and [13].

When both left and right truncation occur, closed-form solutions are not possible. A method for obtaining the nonparametric maximum likelihood estimate (NPMLE) was proposed by Turnbull [17], that also accommodates left, right, and interval censoring (*see* **Turnbull Estimator**). Turnbull described a self-consistent approach to estimation that turns out to be a version of the **EM algorithm**. In the presence of both arbitrary censoring and truncation, however, Turnbull's self-consistent algorithm has to be modified [3]. Alioum & Commenges [1] provide a detailed correction of Turnbull's method and an extension to the regression analysis. Here, we consider only the problem of truncation, and assume that the failure times are uncensored. Let the observed times of failure be at $Y_i, i = 1, \ldots, N$. Let the probabilities of failure associated with Y_i be p_i. The likelihood can be written as

$$L(p_1, \ldots, p_N) = \prod_{i=1}^{N} \frac{p_i}{\sum \beta_{ij} p_j},$$

where β_{ij} is 1 for all Y_j that are within the truncation interval for the ith person. Each observed individual might be considered to represent others–Turnbull called them "**ghosts**"–whose events occurred outside the truncation interval. For example, in the transfusion example above, the ghosts corresponding to case i would include people infected by transfusion at time z_i but who had latencies longer than $R_* - z_i$. The expected number of such subjects who will have disease onset at time Y_j is

$$\mathrm{E}(I_{ij}) = \frac{(1 - \beta_{ij}) p_j}{\sum \beta_{ik} p_k}. \tag{1}$$

Once again, in order for F to be identifiable, r_M must exceed the longest possible failure time.

Expression (1) permits construction of an EM algorithm. The complete data log likelihood (if I_{ij} were known) is

$$\log L_{\mathrm{c}} = \sum_{ij} (\alpha_{ij} + I_{ij}) \log \ p_j,$$

where $\alpha_{ij} = 1$ if the ith subject is observed to fail at time j and 0 otherwise. Therefore the rth iteration of the E-step is evaluation of

$$\mathrm{E}^r(\log \ L_{\mathrm{c}} | p, Y) = \sum_{ij} (\alpha_{ij} + \mathrm{E}^r(I_{ij})) \log \ p_j$$

using (1); and the M-step maximizes this simple expectation to obtain

$$p_k^{r+1} = \frac{\sum_i \alpha_{ik} + \mathrm{E}^r(I_{ik})}{\sum_{ij} \alpha_{ij} + \mathrm{E}^r(I_{ij})}.$$

Regression Models

Regression models have also been developed for settings in which the effect of **covariates** on failure time is of interest. Suppose that we are interested in determining whether a covariate, **Z**, such as age at transfusion, chronologic time of transfusion, or region, affected the time from transfusion to onset of AIDS. We divide the time interval $[0, R_*]$ into units of equal length, where 0 is the time of the earliest transfusion. Let $A(j|\mathbf{z})$ denote the number of cases corresponding to covariate $\mathbf{z}$ that have latency j for $0 \le j \le T$, where T is the longest latency time that can be reliably estimated. Since the observed cases have different transfusion times and are observed in the same chronologic time interval $[0, R_*]$, the observed portion of $A(j|\mathbf{z})$, denoted $A(j|\mathbf{z}, r) (0 \le j \le r)$, depends on the truncation interval $[0, r]$.

If the $A(j|\mathbf{z})$ are regarded as multiple responses at $0 \le j \le T$, models in **categorical data analysis** can be used to model $A(j|\mathbf{z})$. A number of investigators have considered the following **multinomial** response model (also with censoring), where failure time X takes only discrete values j. The probability that failure time, X, equals j, given covariate $\mathbf{Z}$ is

$$p(j|\mathbf{Z}) = \Pr(X = j|\mathbf{Z}) = \frac{\exp(\eta_j(\mathbf{Z}))}{\sum \exp(\eta_k(\mathbf{Z}))},$$

where

$$\eta_j(\mathbf{Z}) = \begin{cases} 0, & \text{if } j = 0, \\ \alpha_j + \mathbf{Z}'\boldsymbol{\beta}_j, & \text{if } 1 \le j \le T. \end{cases}$$

An alternative is the discrete **proportional hazards model** [15]:

$$\Pr(X = j|\mathbf{Z})$$

$$= \begin{cases} (p_0, \ldots p_{j-1})^{\exp(\mathbf{Z}'\boldsymbol{\beta})}[1 - p_j^{\exp(\mathbf{Z}'\boldsymbol{\beta})}], \\ \quad \text{if } j < T, \\ (p_0, \ldots p_{T-1})^{\exp(\mathbf{Z}'\boldsymbol{\beta})}, \\ \quad \text{if} j = T, \end{cases}$$

where

$$p_j = \Pr(X > j + 1 | X > j), \quad \text{for } 0 \leq j \leq T - 1.$$

This model implies that the probability that a case is reported at lag time j conditional on being reported at time j or later is given approximately by

$$P(X = j | \mathbf{z}, X \geq j) = \exp(\alpha_j + \mathbf{z}'\boldsymbol{\beta}),$$

where $\alpha_j = \log(-\log(p_j))$.

We let $\boldsymbol{\theta} = (\alpha, \beta)$ and denote the dependence of $p(j|\mathbf{Z})$ on $\boldsymbol{\theta}$ by $p(j|\mathbf{Z}, \boldsymbol{\theta})$. We also denote the truncation interval for the ith subject as $[0, r_i]$. The log likelihood under a chosen model and an observed sample of size N, denoted $\{A(j|\mathbf{z}_i, r_i)\}_{1 \leq j \leq r_i; 1 \leq i \leq N}$, is given by

$$\log\ L(\theta) = \sum_i^N \sum_j^{r_i} A(j|\mathbf{z}_i, r_i) \times \left\{ \log[p(j|\mathbf{z}_i, \boldsymbol{\theta})] - \log \left[\sum_{j=0}^{r_i} p(j|\mathbf{z}_i, \boldsymbol{\theta}) \right] \right\}. \quad (2)$$

Note that the second term above is the result of right truncation and disappears if the data are not truncated.

Estimation of model parameters as well as the variance–**covariance matrix** can be obtained by maximizing the log likelihood above using the Newton–Raphson method (*see* **Optimization and Nonlinear Equations**). When the data are not truncated, the analytical calculations of the first- and second-order derivatives, necessary for the Newton–Raphson method, are simplified. In this case, some standard **software** packages can be utilized to obtain the estimates. For example, estimation of the parameter vector $\boldsymbol{\theta}$ for the multinomial response model can be consistently estimated by using the loglinear model

$$\log[\mu_j(\mathbf{z})] = \phi(z) + \alpha_j + \mathbf{z}^{\mathrm{T}}\boldsymbol{\beta}_j, \quad 0 \leq j \leq T, \quad (3)$$

with the error following a **Poisson** distribution, where $\mu_j(z) = \mathrm{E}[A(j|z)]$ and the **nuisance parameter** ϕ (**z**) is termed *incidental* [12]. So statistical packages such as GLIM, which also implement the complementary log-log model (*see* **Quantal Response Models**), are easily utilized to estimate the parameter vector $\boldsymbol{\theta}$. The simplicity of estimation in the absence of truncation suggests using the EM algorithm for estimation under either model, in the presence of truncation [14].

Some other discrete-time regression models for right-truncated data have been developed and applied in the analysis of AIDS incidence and induction-time distributions [2, 4, 6, 16]. Alioum & Commenges [1] discussed methods for fitting a continuous proportional hazards model for truncated and censored data.

Example 2

We illustrate the use of regression models for right-truncated data by applying these methods to a problem that arises in analyses of data on AIDS surveillance (*see* **Surveillance of Diseases**) in the US. A data set released by the US Centers for Disease Control in the first quarter of 1990 includes AIDS diagnosis date and reporting date in six geographic regions: Northeast, Central, West, South, Mid-Atlantic, and Other. In this setting, R_*, the end of the observation period, is the first quarter of 1990, and the observed portion of $A(j|\mathbf{Z}), 0 \leq j \leq r$, depends on the truncation interval $[0, r]$, where $r = R_* - x$ and x is the chronologic time of AIDS diagnosis. To adjust for reporting delay, we first model the covariate effects of the chronologic time of AIDS diagnosis and region by fitting the multinomial response model [14] with

$$\eta_j(Z) = \alpha_j + \text{region} \times \gamma_j + x\zeta_j + (\text{region} \times x)\psi_j, \quad 0 \leq j \leq T,$$

where x is the year of diagnosis, and "region" is a vector of five indicator variables that designate any five of the six regions. When $\psi_j = 0$, for $0 \leq j \leq T$, there is no interaction between region and x and the delays have the same trend across the regions.

The reported cases were grouped on quarterly intervals, and cases reported with a delay time of more than 12 quarters were grouped into one category, $T = 12$. The EM algorithm was used for estimation under the model, as described above. The median reporting delays for the six geographic regions obtained from the above model are plotted in Figure 2. The reporting delays appear to have

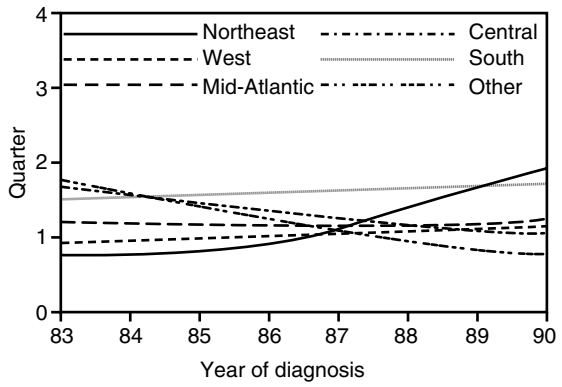

Figure 2 Reporting delays for six geographic regions. Reprinted from *Biometrics*, with permission

lengthened in the late 1980s, except for the Central region and Other, in which the delays seem to have shortened from 1983 to 1990. The South region has the longest delay in reporting. Figure 2 also shows strong interaction between the chronologic time trend and geographic regions. Such analyses allow us to distinguish between trends in reporting and in AIDS incidence; without reporting delay estimates, AIDS surveillance data are uninterpretable. The estimated AIDS incidence can be obtained by dividing the AIDS incidence at each chronologic time period by the estimated probability that an AIDS case would be reported in time for inclusion in the data base.

VICTOR DE GRUTTOLA & Q. LIAO

Tukey, John Wilder

Born: June 16, 1915, New Bedford, Massachusetts.
Died: July 26, 2000, New Brunswick, New Jersey.

John Wilder Tukey (JWT) was one of the most influential statisticians of the twentieth century. The combination of his unorthodox education, scientific interests, and exposure to a diverse range of applied problems facing scientists and engineers across many disciplines, enabled him to make significant contributions in many areas and to advance a new basic philosophy for how statisticians approach data. He may be best known to statisticians for founding the field of exploratory data analysis [70], for introducing the jackknife as a tool for characterizing the uncertainty in a statistic [63], and for guiding and contributing to research in robust methods [3, 8, 67]. But his name is familiar to scientists in many other fields for diverse reasons: Tukey's lemma (mathematics); fast Fourier transform, or FFT (digital computing, engineering, and medicine), for which he received the Medal of Honor from the Institute of Electronic and Electrical Engineers (1982); multiple comparisons (psychology and education); principles of sampling (social science and medicine); binomial probability paper (quality control); cloud seeding experiments (meteorology); spectrum and cepstrum estimation (geophysics); smoothing (science and engineering); and coining the word "bit" (computer science).

Tukey had tremendous vision, addressing problems with solutions whose need was recognized, sometimes only years or decades later. Two notable examples are **exploratory data analysis** [70], with its emphasis on statistical graphics (*see* **Graphical Displays**), and *Index to Statistics and Probability* [69], forerunner to the present *Current Index to Statistics* [2]; both foreshadowed needs to cope with the data explosion of the 1990s. He believed that solving the *exact* problem, even with only an *approximate* solution, was better than solving the convenient and easier (but only approximate) problem with the exact solution: "Far better an approximate answer to the *right* question, which is often vague, than an *exact* answer to the wrong question, which can always be made precise" [68, p. 13]. Consequently, an important theme throughout his work is the validity of **inference** that does not depend heavily on assumptions (e.g. Gaussian-distributed errors). He published over 300 papers (nearly 100 of which appeared after his federally mandated retirement in 1985), graduated 55 Ph.D. students, and advised countless others, both undergraduate (e.g. David L. Donoho, William F. Eddy, Paul A. Tukey) and graduate (e.g. Frederick Mosteller, Marvin L. Minsky, Yoav Benjamini).

Tukey received numerous awards, including honorary doctorates from seven universities; Deming and Shewhart Medals (American Society for Quality); S.S. Wilks Medal (American Statistical Association); James Madison Medal (Princeton University); and the National Medal of Science from President Nixon in 1973, "for his studies in mathematical and theoretical statistics. . .and for his outstanding contributions to the applications of statistics in the physical, social, and engineering sciences". His entire career was devoted to academic, government, and public service, through his association with Princeton University (1937–2000), employment and consultant for the Bell System (1945–2000), membership in the National Academy of Sciences (1961–2000), and participation on numerous government panels and academic committees. He was a member of the President's Scientific Advisory Committee (PSAC) for Presidents Eisenhower and Kennedy, and headed PSAC working groups for Presidents Johnson and Nixon (environment, 1964–1965; chemicals and human health, 1971–1972). He was also a member of Technical Working Group 2 of the Conference on the Discontinuance of Nuclear Weapons Tests in Geneva (1959) and the United Nations Conference on the Human Environment in Stockholm (1972) for the US State Department. Retired Chairman of the Board of Bell Laboratories William O. Baker commented on his influential contributions to the labs and to science at large, saying, "We have watched at least four Presidents of the United States listen to him and heed his counsel" [38, p. 335].

Tukey's career included a variety of projects that led to important methodological developments in biometry and biostatistics:

The National Halothane Study. This study [16, 42] was conducted under the auspices of the National Research Council in response to concerns about a possible association between the use of halothane as an anesthetic in surgical operations and fatal hepatic necrosis (liver failure). The critical statistical issue was the quantitative comparison of death rates for

various anesthetics (halothane, ether, cyclopropane, nitrous oxide-barbiturate, "other"), in the presence of unavoidable **confounding** variables (e.g. type of operation; hospital where operation was performed; length of operation; and age class in 10-year intervals, gender, ethnicity, and physical status of the patient), whose effects grossly dominated the differences among the anesthetics. With millions of **covariate** combinations and only 800 000 cases, Tukey and his colleagues developed a method to standardize rates (*see* **Standardization Methods**), or adjust for the joint effects of suitably selected combinations of variables, which they called "smear-and-sweep analysis" [48]. Similar issues arose in quantifying the effect of sulfinpyrazone after myocardial infarction [5]. Tukey returned to the important issue of adjustment in the 1980s in connection with the US decennial census [25]: in the spirit of approximate solutions to right problems, he wrote, "adjustment to reduce bias cannot wait for perfection but must be considered as soon as we recognize that it will help. Incomplete adjustment to reduce bias, since that is all we can ever do, is desirable and not to be denigrated" [76, p. 127].

Multiple Comparisons. The widely circulated 1953 manuscript, "The problem of multiple comparisons," appeared in Volume VIII of *The Collected Works of John W. Tukey* [80]. It set out the concepts of "error rate per comparison/determination", "error rate per family/batch", and "error rate familywise/batchwise", as well as "error rate budgeting" [80, p. 5], which guided the research into these methods for the next 40 years. He advocated the "wholly significant difference" (WSD), for the allowance when comparing any two means in a **fixed-effects**, one-way analysis of variance (*see* **Experimental Design**) or **linear regression** model (based on the **Studentized range** statistic, and later called "honestly significant difference" (HSD); see [41, p. 92]), as opposed to the "least significant difference" (LSD), which is based on the F-statistic (*see* ***F*** **Distributions**) in a one-way analysis of variance; see also [9] for a broad overview. With increasing volumes of data (e.g. microarrays, county rates of disease mortality and incidence), Tukey returned to this area in the 1990s, in his advisory role on committees for the National Assessment of Education Progress (NAEP), which involved thousands of comparisons of measures among various states in the United States [1], and for presenting results of plant breeding experiments [7] and of animal studies [22, 82]. He acknowledged "the usefulness of – and need for – a variety of procedures reflecting the *varied strength* of different experiments" [81, p. liv].

Jackknife. In perhaps the most oft-cited abstract in the statistics literature, Tukey described, in only six sentences, the **jackknife** as a procedure for assessing the uncertainty in a statistic [63]. By leaving out one observation (or one group of observations) at a time, one can recompute the statistic, and then calculate the usual sample **standard deviation** of these "leave-out-one" statistics, to obtain an estimate of the **standard error** of the statistic computed on the entire sample (see also [43, Chapter 7]). The use of the jackknife had a huge impact on statistical practice intervals. Efron later analyzed the bias and **variance** of such jackknifed estimates of the standard error, leading him to propose the **bootstrap** [23, 24]. Fernholz, Morgenthaler, and Tukey [27] later combined jackknife samples using principles of experimental design and Hadamard matrices (*see* **Response Surface Methodology**) to derive methods of "nominating" **outliers**.

Clinical Trials. Tukey's recommendations for the design and analysis of **clinical trials** included the unequivocal value of the focused randomized clinical trial and the ethical consequences of lesser, unfocused alternatives [71], the combination of covariates in assessing treatment effects [77], problems of **multiplicity** [78], and designs whose analysis relies on "probability statements that depend on only exactly how the trial was conducted – not at all on assumptions", which he termed the "platinum standard" [79, p. 266]. Several of the ideas recommended by Brillinger, Jones, and Tukey [15], for the design of cloud-seeding experiments, are applicable to the design of clinical trials with tight constraints.

Statistical Problems of the Kinsey Report. In the appendix to their evaluation of the "Kinsey report" [17], **Cochran**, Mosteller, and Tukey discussed important principles in survey sampling (*see* **Sample Surveys in the Health Sciences**), such as sample selection, generalization from sample to population, accuracy of interview data, systems of interviewing,

methods of checking and analyzing data, and the reporting of results [17–19].

Statistical Mapping. Tukey emphasized graphical displays and used them heavily in all his work, particularly for geographical data. In "Statistical mapping: what should *not* be plotted" [74], he argued that chloropleth ("patch") maps inappropriately draw too much attention to region size and political boundaries, and that displayed rates, adjusted properly for age, should be further adjusted for other variables known to have strong effects (e.g. lung cancer and smoking, or a proxy for smoking such as urbanization; see [31]), and then smoothed [72, 74]. The *Atlas of United States Mortality* [44] implemented many of these ideas.

Tukey was famous for parallel processing; rarely did he engage in only one activity at a time. Seminar speakers recall seeing him in the audience, working on an entirely different project or even seemingly completely asleep, yet rising at the end to deliver insightful comments on the presentation [37, p. xlv] – often telling the speaker not only what he did wrong, but also how he might do it right the next time [32]. He was a large man, often seen wearing a black polo shirt, whose pocket bulged with his address book and four-color pens. He relaxed by frequenting mystery book stores and organizing birding expeditions in various places where meetings took him, all over the world. He was able "to carry out two or three times the load of ordinary men" [12]. He was also known for "making up words" – but those who worked with him knew that he proposed a new word only when he was absolutely certain that no other word (in any of the large number of languages that he knew) precisely matched his intended meaning (e.g. "hinge" or "fourth" versus "sample quartile"; "batch" versus "random sample"; [34, p. 4]).

Tukey was born in New Bedford, Massachusetts, the only child of Adah M. (Tasker) and Ralph H. Tukey, both 1898 graduates (first and second) of Bates College (Lewiston, Maine), and both educators (his father earned a Ph.D. degree in classics and chaired the Latin department at New Bedford High School). Recognizing JWT's genius at age 3, they educated him at home. He did attend high school "for one term in French and some mechanical drawing" [14, p. 26], and spent much time in the New Bedford public library, reading the *Journal of the American Chemical Society* and the *Transactions of the American Mathematical Society*. He was admitted to Brown University in 1933 on the basis of his College Board Examinations. He received the Sc.B. and Sc.M. degrees in chemistry in 1936 and 1937 and entered the Ph.D. program in chemistry at Princeton in September 1937. His concurrent interest in mathematics flourished around the stimulating environment at Fine Hall and the Institute for Advanced Study at Princeton, so he soon transferred to the Mathematics Department, passed his oral examinations in May 1938, and completed his dissertation the following spring (Tukey [52], published by Princeton University Press as *Convergence and Uniformity in Topology*, [53]). During his years as a graduate student, his friends and later collaborators included physicists Richard Feynman and Lyman Spitzer [49, 50]; mathematicians Ralph Boas [11] and Arthur Stone [51]; William Baker, later chairman of the board of Bell Laboratories; and Frederick Mosteller, a lifelong friend and frequent collaborator (of four books and 24 articles). Tukey joined on the mathematics faculty at Princeton, as Instructor (1939–1941), Assistant Professor (1941–1948), Associate Professor (1948–1950), Professor (1950–1965), and later as Professor of Statistics (1965–1985), Donner Professor of Science (1976–1985), and Professor Emeritus and Senior Research Statistician (1985–2000).

During World War II and while teaching at Princeton, Tukey held the position of Research Associate in the Fire Control Research Office (1941–1944). He worked closely with his mentor, Charles P. Winsor, for whom he later named the robust location estimate, "Winsorized mean" [30, 66], and to whom he dedicated the book *Exploratory Data Analysis* [70]. Tukey and his colleagues worked on projects related to the war effort, including stereoscopic range finders and testing of rocket powders. In 1945, he joined Bell Laboratories, first as a Member of the Technical Staff (MTS), working on anti-aircraft guided missiles (later Nike and Nike-Ajax). Samuel S. Wilks in the Mathematics Department at Princeton asked him to teach statistics, and Tukey remained part-time at both institutions for the next 40 years. His dual career at Bell Labs proceeded from MTS to Assistant Director of Research in the Department of Communications Principles (1958–1961), and then as Associate Executive Director of Research in Information Sciences (1961–1985) and consultant (1985–2000), working on problems of signal processing, communications

engineering, and information retrieval and interpretation. *The Measurement of Power Spectra from the Point of View of Communications Engineering* [10] was the leading authoritative work on spectrum analysis (*see* **Spectral Analysis**); its principles were used even more widely after Tukey introduced computer scientists to an **algorithm** that permitted fast and efficient computation of **fast Fourier transforms (FFT)**; [20].

In the 1950s and 1960s, Tukey wrote papers on concepts in mathematical statistics, **regression** and **analysis of variance**, and methodology that assume no particular distributional form (i.e. **nonparametric**); for example, population **tolerance** limits and **confidence** bands for a continuous, cumulative, distribution function [46, 47]; **means**, variances, and covariances of **order statistics** for small samples from Gaussian (*see* **Normal Distribution**) and non-Gaussian distributions [33]; a useful bound on the ratio of the variance of the *mis*-weighted mean to the variance of the *optimally* weighted mean [54]; the robustness of **Student's t** confidence intervals (Tukey [55]; see also [6]).

His numerous contributions in **Biometrics** have had important consequences for later practice and research in statistics. Tukey [56] derived the allowance for comparing all pairwise differences among several means in a one-way analysis of variance based on the studentized range distribution (distribution of the range of Gaussian random variables all having the same variance, estimated by the **mean square for error**), now called "Tukey's method of multiple comparisons." In "One degree of freedom for nonadditivity" [57], Tukey developed a test for an **interaction** term (of a specific form) between the two factors in a two-way layout with no replication. McNeil and Tukey [40] proposed diagnostic plots for estimating this interaction parameter (see also [43, Chapter 9], and [35, Chapter 3]). A short abstract published in *Biometrics* [65] contained technically advanced theory for the development of highly fractionated and saturated experimental designs (*see* **Fractional Factorial Designs**) to investigate many factors in very few runs (see also [64]), potentially applicable to the design of clinical trials today. Several other papers addressed the analysis of single and higher-order classifications [59–61] Papers on **transformations**, which he later called reexpressions (which later included combinations of two or more transformations to different segments of the data), also have had a lasting impact on statistical practice ([28, 62]; see also [34]).

Tukey's association with Winsor led him to distrust analyses that relied heavily on often unverifiable assumptions about the data. Many of his papers provide methods with minimal reliance on distributional assumptions. Cornfield and Tukey [21] concentrated on the expectation of mean squares in crossed and nested classifications, "based on a model of sufficient generality and flexibility that the necessary assumptions concern only the selection of the levels of the factors [e.g. fixed or random] and not the behavior of what is being experimented upon [e.g. the underlying distributions]" (p. 907). In "Components in regression," Tukey was "principally concerned with simple linear regression where both variates are subject to 'error"' [58, p. 34], and laid out the problems later addressed by the field now known as "**errors in variables**." In a seminal paper, "A survey of sampling from contaminated distributions," Tukey [82] showed that the asymptotic variance of the mean absolute deviation from the mean is *less* than that of the sample standard deviation if the underlying distribution is a contaminated normal, when the fraction of the contamination by a normal distribution having three times the standard deviation of the target normal, is as small as 0.0018 (less than two observations per thousand). This paper guided the development of robust methods (*see* **Robustness**) for the next two decades, including the "Princeton Robustness Study" [3], which investigated the performance of 65 estimators of location. A by-product of this research was the development of a clever **simulation** algorithm, called the Monte Carlo Swindle, described in Andrews et al. [3, § 4D, pp. 61–63]. Later, Beaton and Tukey [8, p. 151] proposed the "biweight" as a robust estimator of location; (see also [43, pp. 205–206]). Beaton and Tukey were concerned with a regression coefficient, but the biweight has been shown to be remarkably efficient and to perform extremely well in a variety of other contexts.

Tukey's extensive experience with data and association with Charles P. Winsor and Edgar Anderson led him to develop a more flexible approach to data, "exploratory data analysis", which he later described as "an attitude, a state of flexibility, a willingness to look for those things that we believe are not there, as well as for those we believe might be there. Except for emphasis on graphs, its

tools are secondary to its purposes" [73]. His book, *Exploratory Data Analysis*, or *EDA* [70] describes many such tools, including stem-and-leaf displays; boxplots (extended by McGill, Tukey, Larsen [39], and by Rousseeuw, Ruts, Tukey [45]); letter value displays; robust smoothing by running medians; median polish; and resistant line fitting. Subsequent books [34–36] emphasized the exploratory approach in practice. His methods were designed to extract the "fit" in the data decomposition $data = fit + residual$, with special emphasis on graphical displays. "Projection pursuit," an algorithm to identify interesting unexpected structure in higher-dimensional data [29], has a similar goal. In contrast, "confirmatory analysis" emphasized fitting specific models and testing particular hypotheses. Despite the distinction between these two approaches, Tukey nonetheless believed that, "We need both exploratory *and* confirmatory" [75].

Even after this age-mandated retirement from AT & T and Princeton in 1985, Tukey's commitment was unflagging. He continued to write, attend conferences and workshops, and discuss statistical problems until his final days. He consulted extensively for various organizations, including Xerox Palo Alto Research Center (1985–2000), which led to 10 patents on which his name appears as coinventor; Health Effects Institute, which sponsors epidemiological studies on matters related to health; Merck Laboratories (1952–2000); Educational Testing Service (1965–2000); Schering-Plough; and Pfizer. He remained generous with his time and ideas to both students and colleagues, and the research ideas that he conceived continue to be pursued today. Upon his death, a press release from Princeton University (26 July 2000) quoted Princeton Emeritus Professor of Physics John A. Wheeler as saying: "I believe that the whole country – scientifically, industrially, financially – is better off because of him and bears evidence of his influence."

Further information about his life appears in various sources: *The Collected Works of John W. Tukey* (brief biography by Frederick Mosteller); *The Practice of Data Analysis* ([14]; biography, pp. 5–8; interview conducted by L.T. Fernholz and S. Morgenthaler, pp. 26–45), [13], interviews conducted by Anscombe [4] and Fernholz and Morgenthaler [26], and special issues of *Technometrics* (August 2001), *The Annals of Statistics* (May 2002), and *Statistical Science* (August 2003).

Acknowledgments

The author expresses sincere thanks to Dr. David C. Hoaglin and Mr. F. R. Anscombe for their comments and suggestions on an earlier version of this article, which led to several important corrections and additions, and also to Dr. Barry I. Graubard and Dr. Michael Cohen, for copies of Tukey's less easily obtained articles. (The author takes responsibility, with regret, for remaining errors and omissions.)

Tumor Growth

Since the control of tumor growth is the purpose of cancer treatment, it is natural to ask: What are the characteristics of that growth which can be measured in a quantitative fashion for prognostic, diagnostic or explanatory purposes? Loosely, there are three different types of measurements that might be made to describe the growth of a tumor. The simplest measure of total growth is a series of sequential size measurements to produce an overall growth curve. At the cellular level, measurements can be made of proliferative markers related to the growth of the tumor and, possibly, to the mechanisms controlling growth. Finally, at the molecular level, measurements are made of genes and gene products controlling the proliferation of a tumor. Each of these measurements has limitations, but can be of great interest.

Tumor Growth Curves

Of the different types of measurements, that of the total tumor growth is undoubtedly the most important, but often unavailable for analysis in the clinical setting. Indeed, if the future growth of a tumor could be predicted then it might be possible to develop individualized treatments for patients depending on the specific properties of their tumors. In practice, comparing the growth patterns of tumors induced in animals following treatment is a standard method for screening potential anti-cancer agents prior to clinical use and for the study of carcinogenesis (*see* **Animal Screening Systems**; **Tumor Incidence Experiments**).

There are several reasons why total tumor growth measurements may not be possible. Normally, unless the patient chooses otherwise, treatment begins as soon as the tumor is discovered. While retrospective studies of earlier diagnostic procedures, e.g. mammograms, can sometimes be done with detection of the tumor at an earlier size [9], it is more likely that only bounds on the rate of growth can be found. Even in animal studies, the growth rate of tumors can usually be followed only for short periods of time because of ethical considerations or early death of the animal. For example, in murine tumors, commonly used in **radiation** biology studies, the tumors seldom can be measured for much more than four volume doublings so that a comparison of growth rates is usually determined among murine experimental tumors on the basis of growth between 4.0 mm mean geometric diameter and 12.5 mm [12]. (Methods do exist for obtaining estimates at smaller sizes, but these are less precise.) Inferential estimates on tumor growth rates can be made also on the basis of size at detection [2] and as done in some carcinogenesis studies [15].

While the actual form of the total growth curve is unknown, it is generally accepted that tumors, unlike cells in tissue culture, do not increase exponentially. (A detailed study of different models has been made in model systems by Marusic et al. [8].) The key question then is to understand and predict the changing nature of tumor growth. Generally, it is agreed [10, 11] that there are three cellular determinants of the population growth. First is the **cell cycle** time T_C, or the minimal time required for a cell to grow, duplicate its DNA, and divide. Second is the fraction of cells in a tumor actively dividing, known as the growth fraction, GF. Third is the rate of death or cell loss from the tumor. Since the tumor doubling time of an individual tumor is not accessible, a variety of methods have been devised to identify **surrogate** markers of proliferation in the population reflecting the overall growth of the tumor on the basis of measurements made at a single time, such as at biopsy or surgery.

Proliferation Markers

At the cellular level, the methods of analytical cytometry [3] are employed to identify subpopulations of tumor cells having specific markers associated with growth such as DNA content. Since cells go through a regular progression of DNA contents or phases, known as G_1 (post-mitotic and the state of the majority of cells in tissues), S (actively synthesizing DNA), G_2 (pre-mitotic), and M (mitosis), it is possible to measure the fractions of cells in a population in any given state of the division cycle. If we assume that the population is in a steady state where the fraction of cells in each phase is constant, from **branching process** theory [6] we assert that the phase fractions are proportional to the time spent in each phase. Thus, one

can, for example, compare the fractions of cells in the S-phase in two tumors and argue that the tumor with the greater fraction synthesizing DNA will be the faster growing. Unfortunately, these methods only give the relative fractions in each phase and two tumors with widely differing cycle times might appear identical [13]. There is an extensive literature on the validity of such markers as **prognostic factors** [3, 4].

An alternative approach to obtaining dynamic markers of proliferation, including specific times for each tumor, is based on the fact that certain halogenated thymidine analogs, e.g. bromodeoxyuridine, which label cells exclusively during DNA synthesis, can be detected by monoclonal antibodies. It is thus possible to identify a cell's bivariate analysis of DNA content and label. The duration of the S-phase, T_S, can then be estimated from the change in DNA content of the labeled cells [1]. Using the phase fractions and the known T_S, an estimate of the doubling time, known as the potential doubling time or T_{pot}, can be computed [14]. T_{pot}, introduced by Steel [11], is related to T_C by $T_{pot} = \ln(1 + GF)T_C / \ln 2$ and is considered to be the doubling time that would occur without the presence of cell loss. Usually the GF cannot be measured so that T_C cannot be determined, but T_{pot} may provide a useful dynamic estimate of the state of a tumor. As such T_{pot} has formed the basis for a series of prospective trials for assigning patients to altered radiotherapy treatments [12].

Other proliferation markers, such as Ki67 and PCNA, are commonly studied and new ones [5] are continually being developed. The advantage of these markers is that they can be determined in individual cells so that population averages may be determined, but in many cases, such as DNA content, these markers are removed from the molecular machinery controlling cell proliferation and may not be closely associated with long-term tumor growth.

Molecular Markers

Most recently, at the molecular level, a series of methods are being employed to determine the growth status on the basis of the occurrence of aberrant gene products. In this methodology, specific genes or gene products known to control cell regulation are measured in cells obtained from tumors. Unfortunately, the tools are largely qualitative, leaving one with a series of statements such as p53 is overexpressed or BCL is upregulated in a tumor without it being possible to describe the fraction of cells actively involved in this process. The advantage of this methodology is that it provides a systematic approach for gene therapy to suppress specific genes and possibly control the tumor growth. For a current overview of these approaches, see [7].

Tumor Incidence Experiments

The primary purpose of a typical tumorigenesis study is to evaluate the rate at which new tumors develop. Thus, the focal point in the analysis of such an experiment should be the tumor **incidence rate**. Consequently, the ideal statistical analysis treats tumor onset as the endpoint of interest, estimates the tumor incidence rates, and formally compares treatment groups with respect to these incidence rates.

In practice, several factors complicate what otherwise might be a straightforward failure-time (or survival) analysis. Among the complexities are: no uncensored onset times (*see* **Censored Data**), differential survival, and tumor lethality. Some of the proposed solutions, which introduce complications of their own, include: focusing on a different endpoint (*see* **Response Variable**), assuming a particular level of tumor lethality, assigning individual **causes of death**, requiring some animals to be sacrificed, specifying parametric models, and imposing functional restrictions. This article summarizes the advantages and disadvantages associated with these approaches, and gives a short description of each method.

Background

Tumor Incidence

Tumor incidence refers to the rate of tumor onset during a given time period, where onset is the earliest stage of tumor development at which the lesion could be detected microscopically. The time interval over which new tumors are accrued can vary in length from infinitesimal to an entire lifetime. If time is treated as continuous, the incidence rate is the **hazard rate** for tumor onset, which is an instantaneous (conditional) failure rate. Often, the timescale is partitioned into intervals, and a discrete incidence rate can be defined for each interval. Here, the incidence rate is the probability that tumor onset occurs in a particular interval, conditional on being alive and tumor-free upon entering that interval. If time is completely ignored, by treating the entire study as one large time interval, the incidence rate reduces to the lifetime probability of developing a tumor.

Study Design

Generally, studies involve both sexes of two rodent species, usually one strain of mice and one strain of rats. Exposures often begin when animals are 6–8 weeks of age and typically continue for two years, which corresponds to late middle age in these rodents, at which point all live animals are killed and necropsied. Some two-year studies incorporate interim sacrifices, which call for randomly selected subsets of animals to be killed and examined at intermediate times (*see* **Serial-sacrifice Experiments**). For each sex/species combination, the study usually includes one control group and several (e.g. three) exposed groups. For a single type of exposure, the treatment groups differ, in theory, only with regard to the dose level of exposure. After being stratified on weight, typically 50 animals are randomly assigned to each group, with perhaps ten more animals per group for each interim sacrifice planned.

Conditions and Assumptions

We focus on a single sex/species combination and we restrict attention to tumors at a single site. All tumors are assumed to be irreversible and, except for illustrating the ideal analysis, all tumors are assumed to be occult (unobservable in live animals). When multiple tumors occur at the site of interest, we do not adjust for multiplicity; we simply classify animals as tumor-free or tumor-bearing. In these situations, tumor onset refers to the onset of the first tumor. The time variables are measured from a common origin, such as birth, weaning, or study initiation. The term "sacrifice" refers to the intentional killing of a randomly selected animal, which acts as a random censoring mechanism with respect to the failure times, where failure might represent either tumor onset or death.

Stochastic Model

The simplest way to view the problem is in terms of a **competing risks** framework, in which each animal is subject to two competing risks: tumor onset or death without the tumor. Each animal is initially tumor-free, but eventually either develops the tumor or dies without the tumor. Thus, we can imagine a three-state stochastic model with one initial state (alive and tumor-free), one transient state (alive and tumor-bearing), and one absorbing state (dead)

(*see* **Fix–Neyman Process**). If followed long enough, each animal would travel from the initial state to the absorbing state, either directly or through the transient state. We observe which of the two paths is taken from birth to death, as well as the sojourn time for the overall journey, but not the sojourn times for the transitions to and from the intermediate state.

Notation

Let X denote the time to the first event, either tumor onset or tumor-free death, and let T denote the time to (natural) death. Sacrifices randomly censor both X and T. Define an indicator $Y(t)$ (*see* **Dummy Variables**) that is 1 if the tumor is present at time t and 0 otherwise. Let Y indicate whether the tumor is present or absent at death, either from natural causes or sacrifice.

Suppose that X and T are continuous variables. The transition intensities associated with the two competing risks can be expressed as event-specific hazard functions:

$$\lambda(t) = \lim_{\varepsilon \to 0} \Pr(t \le X < t + \varepsilon, Y(X) = 1 | X \ge t)/\varepsilon, \tag{1}$$

$$\beta(t) = \lim_{\varepsilon \to 0} \Pr(t \le X < t + \varepsilon, Y(X) = 0 | X \ge t)/\varepsilon, \tag{2}$$

where $\lambda(t)$ represents the tumor incidence rate and $\beta(t)$ is called the tumor-free death rate. Once an animal develops a tumor, say at time x, the risk of death at time t is

$$\alpha(t|x) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon | T \ge t, Y(t) = 1, X = x)/\varepsilon, \tag{3}$$

where $t \ge x > 0$. Some analyses involve a simplified version of this conditional death rate:

$$\alpha(t) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon | T \ge t, Y(t) = 1)/\varepsilon, \tag{4}$$

which can be regarded as an average rate of death among all animals having the tumor.

Define the following "pseudo" survivorship functions:

$$S_\lambda(t) = \exp\left[-\int_0^t \lambda(u)\,du\right],$$

$$S_\beta(t) = \exp\left[-\int_0^t \beta(u)\,du\right], \tag{5}$$

$$S_\alpha(t|x) = \exp\left[-\int_x^t \alpha(u|x)\,du\right],$$

which are used purely for notational convenience and have no particular interpretation.

Observed Data

The basic information that we observe for each animal is the time of death and an indicator of whether a tumor was found at the organ site of interest. In particular, we observe $\{T = t, Y(t) = y\}$ if an animal dies of natural causes, and $\{T > t, Y(t) = y\}$ if an animal is sacrificed ($y = 0, 1$). Note that among animals that die of natural causes, $Y(t)$ generally is not observable for $t < T$, except in special situations such as when tumors are palpable or visible in live animals. Occasionally, we have access to additional information, such as the tumor's role in causing death, but these extra data are not routinely available.

Suppose that there are $K \ge 1$ exposed groups and a single control group. Let N_k denote the number of animals randomized to the kth group ($k = 0, 1, \ldots, K$). Let $d_0 < d_1 < \cdots < d_K$ denote the ordered dose levels, where the control value is assumed to be $d_0 = 0$. Often, transforms of the dose levels are used, such as logarithms or equally spaced scores, in which case d_k represents the transformed value. Let J be the number of distinct natural death times across all groups, with $t_1 < t_2 < \cdots < t_J$ denoting their ordered values.

Likelihood Contributions

Sacrifice times randomly censor tumor onset times and natural death times. Thus, an animal sacrificed at time t and found to be tumor-free contributes only the information that the time to the first event exceeds $t : \Pr(X > t)$. In terms of the underlying transition intensities, the **likelihood** contribution from such an animal can be expressed as

$$S_\lambda(t) S_\beta(t). \tag{6}$$

Similarly, a tumor-free animal that dies of natural causes at time t contributes

$$\beta(t) S_\lambda(t) S_\beta(t). \tag{7}$$

The likelihood contributions from animals having an occult tumor are more complicated, as the components must be integrated over all possible (unobserved) tumor onset times. Thus, an animal sacrificed at time t and found to have an occult tumor contributes

$$\int_0^t \lambda(x)S_\lambda(x)S_\beta(x)S_\alpha(t|x)\,\mathrm{d}x, \tag{8}$$

whereas the corresponding contribution for a natural death with an occult tumor is

$$\int_0^t \lambda(x)S_\lambda(x)S_\beta(x)S_\alpha(t|x)\alpha(t|x)\,\mathrm{d}x. \tag{9}$$

The overall likelihood is the product of contributions such as those in (6)–(9).

If tumors were observable, contributions for tumor-bearing animals would simply be the integrands in (8) and (9), and maximization of the likelihood would be much easier. For occult tumors, the likelihood often is simplified by making assumptions about tumor lethality, cause of death, parametric models, or functional restrictions. With enough sacrifices, these additional assumptions are unnecessary and the likelihood can be maximized nonparametrically by treating certain failure times as discrete.

Goals

The main objective of a carcinogenicity study is to compare treatment groups with respect to tumor incidence and to provide summaries of the incidence rates within these groups. Thus, the analysis should focus on estimating the incidence rate in the kth group, say $\lambda_k(t)$, as well as testing the **null hypothesis** of equal incidence rates across groups

$$\mathrm{H}_\lambda : \lambda_0(t) = \lambda_1(t) = \cdots = \lambda_k(t), \tag{10}$$

against certain **alternative hypotheses** of interest. The usual choices are the general alternative that not all incidence rates are identical (i.e. group heterogeneity) and the specific alternative that incidence rates increase linearly with dose (i.e. a positive linear trend). Often, pairwise comparisons of each exposed group with the control group are performed. These comparisons can be viewed as special cases of testing H_λ against either of the above alternatives when there are only two groups ($K = 1$).

Lifetime Incidence Rates

The simplest incidence analysis focuses on lifetime incidence rates, comparing the group-specific proportions of animals that develop the tumor during the experiment. The lifetime incidence rate, say θ, can be expressed in terms of the age-specific incidence rate, $\lambda(t)$, and the tumor-free death rate, $\beta(t)$:

$$\begin{aligned}\theta &= \Pr(X \le T^*, Y(X) = 1)\\ &= \int_0^{T^*} \lambda(x)S_\lambda(x)S_\beta(x)\,\mathrm{d}x,\end{aligned} \tag{11}$$

where T^* is the time at which the study ends.

No Survival Adjustment

The standard nonparametric estimate of the lifetime incidence rate in the kth group, denoted by θ_k, is the overall group-specific proportion of tumor-bearing animals:

$$\hat{\theta}_k = \sum y_{ik}/N_k, \tag{12}$$

where y_{ik} is the observed value of Y for the ith animal in the kth group and the summation is over all i from 1 to N_k. In general, the null hypothesis of equal lifetime incidence rates across groups neither implies, nor is implied by, the hypothesis of equal age-specific incidence rates, H_λ. Usually, pairwise comparisons are based on **Fisher's exact test**; an overall assessment of group heterogeneity is based on an omnibus **chi-square test**; and dose-related changes are judged on the basis of the linear trend test of Cochran [11] and Armitage [3] (*see* **Trend Test for Counts and Proportions**). See Haseman [26] and Gart et al. [25] for a review of these tests and for some worked examples based on data from real carcinogenicity studies.

The primary advantage of this approach, in addition to using well known statistical methods, is that it does not rely on the usual simplifying assumptions. The analysis of lifetime tumor incidence rates does not make tumor lethality assumptions; occult tumors pose no problems; and there is no need for sacrifice data, cause-of-death information, parametric models, or functional restrictions. The major drawback is that the lack of any time adjustment can lead to biased inferences when mortality rates differ across groups.

Tests regarding lifetime incidence rates assume that all animals in the same group have the same

lifetime risk of developing a tumor, which clearly is violated if some die earlier than others. Even so, if mortality patterns are similar across groups, then these unadjusted tests are valid [24], though possibly less powerful than survival-adjusted tests [48] (*see* **Power**). Misleading results can be obtained, however, when mortality rates differ across groups. For example, if exposure causes animals to die early, then unadjusted tests can miss true carcinogens if treated animals die before having a chance to develop many tumors. In fact, tumorigenesis analyses should focus on $\lambda(t)$ rather than θ, and tests comparing lifetime incidence rates will tend to reject H_λ less often than desired when exposure is toxic because θ is a decreasing function of β. Again, true carcinogens can be missed when no survival adjustments are incorporated, and thus all analyses discussed subsequently make some adjustment for survival.

Adjusting for Survival

One simple way to adjust for survival when analyzing lifetime incidence rates is to modify the number of animals at risk by reducing the denominator of each rate. Rather than giving equal weight to all animals, less weight can be assigned to those dying early without a tumor. For example, Gart et al. [24] assign a weight of zero to any animal dying without the tumor at a time before the first death with the tumor, while assigning all other animals a weight of one. Extending this idea, Bailer & Portier [5] assign a weight of one to animals dying with the tumor and otherwise assign a weight proportional to a fixed power of the time on study, where the choice of the time exponent depends on the assumed shape of the tumor onset distribution. Bieler & Williams [7] propose a variance correction for the Bailer–Portier procedure. Often, the survival adjustment made by these methods is helpful; but, generally, an analysis focusing on age-specific incidence rates is preferable to one focusing on lifetime incidence rates, as inferences about the latter are not necessarily well correlated with inferences about the former.

Age-Specific Incidence Rates

There are various ways to adjust for survival, but no one method is appropriate in all situations. Several factors complicate the adjustment, and the proper analysis depends on what additional data can be obtained or which extra assumptions are plausible. For example, unless tumors are observable in live animals, all onset times are censored. Tumor lethality worsens the problem; if animals with the tumor die at a different rate than those without the tumor, then deaths from natural causes do not randomly censor tumor onset times. Thus, without direct observations on the onset times, survival adjustments usually are accomplished at the expense of additional data or assumptions.

Observable Tumors

Ideally, an incidence analysis should focus on the tumor onset times directly, which is only possible for observable tumors, such as visible skin tumors or palpable mammary tumors. When event times are observable, most analyses use standard nonparametric survival methods (see Kalbfleisch & Prentice [28]), which typically treat event times as discrete random variables. If X is discrete, then the tumor incidence rate at time t_j is

$$\lambda_j = \Pr(X = t_j, Y(X) = 1 | X \geq t_j). \tag{13}$$

Within the kth group, let O_{jk} be the (observed) number of animals developing a tumor at time t_j and let R_{jk} be the number of animals at risk of developing a tumor at time t_j:

$$\begin{aligned} O_{jk} &= \#\{X_{ik} = t_j, Y(X_{ik}) = 1\} \quad \text{and} \\ R_{jk} &= \#\{X_{ik} \geq t_j\}, \end{aligned} \tag{14}$$

where $\#\{e\}$ is the number of animals experiencing event e and X_{ik} is the value of X for the ith animal in the kth group. Under H_λ, the expected counts and variance–covariance terms associated with O_{jk} are

$$\begin{aligned} E_{jk} &= R_{jk}\left[\frac{O_{j+}}{R_{j+}}\right] \quad \text{and} \\ V_{jkm} &= \left[\frac{O_{j+}(R_{j+} - O_{j+})}{(R_{j+} - 1)}\right]\left[\frac{R_{jk}}{R_{j+}}\right] \\ &\quad \times \left[A_{km} - \frac{R_{jm}}{R_{j+}}\right], \end{aligned} \tag{15}$$

where the plus sign indicates the summation over all $K + 1$ groups and A_{km} is an indicator that equals 1 if $k = m$ and 0 otherwise. For each k (and m), create

group-specific summaries for the observed counts, expected counts, and variance–covariance terms:

$$O_k = \sum O_{jk}, \quad E_k = \sum E_{jk}, \quad V_{km} = \sum V_{jkm}, \tag{16}$$

where the summations are over all J times. Let $\mathbf{D}' = (d_1, \ldots, d_K)$ be the vector of dose levels, let $\mathbf{O}' = (O_1, \ldots, O_K)$ be the vector of observed counts, let $\mathbf{E}' = (E_1, \ldots, E_K)$ be the vector of expected counts, and let $\mathbf{V}$ be the matrix of variance terms $V_{km} (k = 1, \ldots, K; m = 1, \ldots, K)$. Note that these arrays do not include the summary terms from the control group ($k = 0$).

The nonparametric estimate of the incidence rate at time t_j in group k is

$$\hat{\lambda}_{jk} = O_{jk}/R_{jk}. \tag{17}$$

The usual test for heterogeneity of groups is based on the statistic:

$$\chi^2_{\mathrm{H}} = (\mathbf{O} - \mathbf{E})'\mathbf{V}^{-1}(\mathbf{O} - \mathbf{E}), \tag{18}$$

which follows asymptotically the **chi-square distribution** on K **degrees of freedom** (df) under H_λ. Often, the test for a dose-related trend in incidence rates is based on the **logrank** statistic

$$\chi^2_{\mathrm{T}} = [\mathbf{D}'(\mathbf{O} - \mathbf{E})]^2/(\mathbf{D}'\mathbf{V}\mathbf{D}), \tag{19}$$

which is also distributed asymptotically as chi-square under H_λ, but on a single df. Finally, a test for departures from linearity can be based on the statistic

$$\chi^2_{\mathrm{D}} = \chi^2_{\mathrm{H}} - \chi^2_{\mathrm{T}}, \tag{20}$$

which is distributed asymptotically as chi-square on $K - 1$ df under the null hypothesis that tumor incidence rates increase linearly with dose. For details on these tests and other related analyses, see Tarone [50], Tarone & Ware [51], Kalbfleisch & Prentice [28], and Gart et al. [25].

The only disadvantage of this approach is that most tumor types are unobservable in live animals. Thus, in the remaining sections we discuss methods that require additional data or assumptions to overcome the complications associated with occult tumors.

Rapidly Lethal Tumors

We assume that lethality refers to an intrinsic property of the tumor type and does not change on an individual animal basis, as opposed to the concept of cause of death, which allows each tumor's effect on death to vary across animals. The presence of a nonlethal tumor does not alter the risk of death, whereas a lethal tumor increases the risk of death. Conceivably, a tumor can be protective if it lessens the risk of death, although such instances are rare and are not considered here. The degree of tumor lethality is often characterized by how much a tumor's presence hastens death.

Suppose that a tumor type is rapidly lethal, which means that post-onset survival is short and thus time to death with the tumor is a good **surrogate** for time to tumor onset. If this rapid lethality assumption is accurate, then the analysis can focus on time to death with the tumor, which is an observable event. Therefore, as with the observable tumors discussed previously, ordinary **life table** analyses based on the estimates in (17) and the tests in (18)–(20) are reasonable when tumors are rapidly lethal.

The main problem with this approach is that few tumor types are instantly lethal, and life table analyses perform worse as tumor lethality decreases, especially as the mortality patterns across groups become more disparate. Tests comparing the rates of death with the tumor can yield biased conclusions about tumor incidence rates when the post-onset survival times are relatively long. The bias is in the opposite direction of the bias in the unadjusted analysis, and Gart et al. [24] characterize this effect as an over-adjustment for survival. For example, if exposure is toxic and causes treated animals to die sooner than controls, then nonlethal tumors will be discovered earlier in the exposed groups and a life table analysis might falsely conclude that exposure is carcinogenic even when the tumor incidence rates are identical across groups. Thus, a life table test applied to data on tumors that are not rapidly lethal rejects too often [34].

Nonlethal Tumors

Suppose that the tumor type of interest is strictly nonlethal, so that tumor presence has no effect on the risk of death. In this situation, the incidence rate is a one-to-one function of the **prevalence** rate, which in turn equals the response rate. Therefore, a standard

prevalence analysis of tumor response rates, which are directly observable, allows us to make inferences about the incidence rates of nonlethal tumors.

The tumor prevalence rate, say $\pi(t)$, is the expected proportion of animals having a tumor among those *alive* at time t, which can be expressed as

$$\pi(t) = \Pr(Y(t) = 1 | T > t). \tag{21}$$

In general, $\pi(t)$ is a function of the incidence rate, $\lambda(t)$, and the death rates, $\beta(t)$ and $\alpha(t|x)$:

$$[1 - \pi(t)]^{-1} = 1 + \int_0^t \lambda(x) \exp\left\{ \int_x^t [\lambda(u) + \beta(u) - \alpha(t|u)]\, \mathrm{d}u \right\} \mathrm{d}x. \tag{22}$$

When the tumor type is nonlethal, the conditional death rates for tumor-free and tumor-bearing animals are equal, $\alpha(t|x) \equiv \beta(t)$, and thus $\pi(t)$ reduces to a function of $\lambda(t)$ only:

$$\pi(t) = 1 - S_\lambda(t). \tag{23}$$

Similarly, the tumor response rate, say $p(t)$, is the expected proportion of animals having a tumor among those *dying* at time t, which can be expressed as

$$p(t) = \Pr(Y(t) = 1 | T = t). \tag{24}$$

In general, $p(t)$ is a slightly different function of the three underlying transition rates:

$$[1 - p(t)]^{-1} = 1 + \beta(t)^{-1} \int_0^t \lambda(x) \exp\left\{ \int_x^t [\lambda(u) + \beta(u) - \alpha(t|u)]\, \mathrm{d}u \right\} \alpha(t|x)\, \mathrm{d}x, \tag{25}$$

but when tumors are nonlethal, $p(t)$ also reduces to $1 - S_\lambda(t)$, and thus equals $\pi(t)$.

For stabilization purposes, a nonparametric analysis of the response rates usually groups the data into time intervals. Within the jth interval, say I_j, the response rate is

$$p_j = \Pr(Y(T) = 1 | T \in I_j). \tag{26}$$

The nonparametric estimate of the jth tumor response rate in the kth group is simply

$$\hat{p}_{jk} = \#\{T_{ik} \in I_j, Y(T_{ik}) = 1\} / \#\{T_{ik} \in I_j\}. \tag{27}$$

Depending on the intervals, these estimates can fluctuate greatly. Of course, there is no consensus on the best way in which to choose intervals. Some analyses specify fixed intervals, while others use data-dependent intervals that contain equal numbers of deaths. As the response rates are nondecreasing when tumors are nonlethal and irreversible, Hoel & Walburg [27] apply the pool-adjacent-violators algorithm [4] to estimate $p(t)$ under a monotonicity constraint. The resulting **isotonic regression** estimate of $p(t)$ is constant over data-dependent intervals, with step heights of the form given in (27).

Hoel & Walburg [27] propose a survival-adjusted prevalence analysis that uses intervals to stratify on death times, compares observed and expected counts within time intervals, and applies **Mantel–Haenszel methods** [39] to combine results over the intervals. Regardless of how time intervals are determined, the test statistics still are given by (18)–(20), except that now for group k the observed count (O_{jk}) is the number of deaths in I_j with a tumor and the number at risk (R_{jk}) is the total number of deaths in I_j.

One potential problem is that differential mortality can yield time intervals within which all (most) of the deaths come from the same group and thus these intervals make no (little) contribution to the test statistics. With this in mind, Dinse & Lagakos [22] model tumor response as a **logistic regression** on age and dose. Likelihood methods can be used to estimate and to compare prevalence rates. This regression approach avoids the arbitrariness of choosing time intervals at the expense of parameterizing the time term. Despite its parametric nature, however, the logistic analysis is fairly robust. For example, linear age and dose terms produce a test with operating characteristics that match or exceed those of the interval-based tests [14].

Similar to the problems that arise when a life table analysis is applied to nonlethal tumors, the use of a prevalence analysis when the tumors are lethal also can produce misleading results, except that the bias is in the opposite direction. Once again, suppose that exposure is toxic and causes the treated animals to die sooner than the controls. As the tumor response rate, $p(t)$, is a decreasing function of the tumor-free death rate, $\beta(t)$, a prevalence test oriented toward detecting an increase in $p(t)$ will not reject as often as a test appropriate for assessing H_λ should reject, unless

tumors are nonlethal. Therefore, a prevalence test applied to data on lethal tumors will not reject often enough [34], which could result in a true carcinogen being missed.

Fixed Intermediate Lethality

In general, it is unlikely that death always follows tumor onset immediately or that death is completely unaffected by tumor onset. More realistically, all tumors of a given type might have a fixed but intermediate level of lethality, which could even vary with age. Formally, lethality usually is defined as some function of the conditional death rates, $\beta(t)$ and $\alpha(t|x)$. If this lethality function is known, then $\lambda(t)$ is identifiable, and thus appropriate incidence estimators and tests can be derived [40].

Typically, tumor lethality is unknown. Often, both life table and prevalence methods are applied in hope that the two procedures will give similar results [26]. While this approach has some intuitive appeal, the two tests do not always give the same results. Lagakos & Louis [35] show that the significance levels from life table and prevalence analyses need not bracket the P value from a test based on an intermediate lethality. Alternatively, Lagakos & Louis suggest a sensitivity analysis, which evaluates the data for various assumed lethalities and illustrates the range of possible inferences. A more definitive solution, however, requires additional data or assumptions.

Cause of Death

Rather than assuming that lethality is an intrinsic property of the tumor type itself, suppose that an individual context of observation [43, 44] can be specified for each tumor discovered, which characterizes that tumor's effect on the risk of death. Within this framework, tumors that do not alter longevity and are observed merely as the result of a death from an unrelated cause are classified as *incidental*. Conversely, tumors that affect mortality either by directly causing death, or by indirectly increasing the risk of death from other causes, are classified as *fatal*. This information on context of observation commonly is referred to as data on cause of death.

The availability and reliability of cause-of-death data are subject to debate. Many pathologists will not make these assessments and several investigations have shown that cause-of-death data, when available, can be inaccurate [33, 36]. Nevertheless, suppose that accurate cause-of-death data are provided, at least for a subset of the animals. Note that any tumor found in a randomly sacrificed animal is observed in an incidental context.

Information on cause of death allows us to identify the tumor onset distribution and perform a survival-adjusted incidence analysis without lethality assumptions, sacrifices, parametric models, or functional restrictions. Let C denote cause of death. We extend the three-state model to four states by replacing the single absorbing state with two absorbing states: death from the tumor ($C = 1$) and death from other causes ($C = 0$). Deaths without the tumor must be due to other causes; thus, the tumor-free death rate is

$$\beta(t) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon, C = 0 | T \ge t, Y(t) = 0)/\varepsilon. \tag{28}$$

The death rates with fatal and incidental tumors among the tumor-bearing animals are

$$\gamma(t|x) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon, C = 1 | T \ge t, Y(t) = 1, X = x)/\varepsilon, \tag{29}$$

$$\delta(t|x) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon, C = 0 | T \ge t, Y(t) = 1, X = x)/\varepsilon. \tag{30}$$

Note that the death rate for tumor-bearing animals is the sum of two cause-specific death rates, $\alpha(t|x) = \gamma(t|x) + \delta(t|x)$. Define a marginal rate of death from the tumor among all of the tumor-bearing animals:

$$\gamma(t) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon, C = 1 | T \ge t, Y(t) = 1)/\varepsilon. \tag{31}$$

Finally, as an incidental tumor does not affect mortality, the associated death rate is the same as the death rate in the absence of the tumor:

$$\delta(t|x) \equiv \beta(t), \quad \text{for all } t \ge x > 0. \tag{32}$$

Kodell & Nelson [31] propose a parametric estimator for the incidence rate by assuming **Weibull** models for all of the transition rates. Later, within a nonparametric framework, Kodell et al. [32] derive an estimator for the tumor onset distribution under the assumption that tumor prevalence is a nondecreasing

function of age. Dinse & Lagakos [21] and Turnbull & Mitchell [53] generalize this analysis to allow nonmonotonic prevalences (see also [16]).

Peto [43] and Peto et al. [44] describe a testing procedure that simultaneously compares groups with respect to tumor prevalence and tumor mortality. This approach applies a prevalence analysis to the subset of animals dying from other causes, applies a life table analysis to all animals, and combines these two components to obtain an overall assessment of group differences. The life table component treats deaths from the tumor as uncensored events and deaths from other causes as censored events. Regression extensions of this combined analysis have been proposed [22, 23], based on a logistic model for the prevalence part and a **proportional hazards** model [12] for the life table part (*see* **Cox Regression Model**). Lagakos & Louis [35] derive the Peto test as a **partial likelihood** score test under linked **proportional-odds** and proportional hazards models for the prevalence and mortality rates, respectively (see also [9]).

Pathologists are reluctant to label every tumor as definitely incidental or definitely fatal, and classification errors can produce biases [34, 47]. Peto et al. [44] suggest adding categories for probably fatal and probably incidental. In practice, however, the analysis often combines categories to form a new dichotomy and then proceeds as usual. Lagakos [34] considers a single intermediate category to allow an unknown cause of death and proposes two strategies: (i) relabel the unknowns as incidentals and fatals according to the proportions observed in those categories; or (ii) relabel all unknowns as incidentals in the lifetable component and as fatals in the prevalence component. Alternatively, analyses can formally account for uncertain contexts of observation either by having a pathologist assign a probability to each category [47] or by estimating these probabilities from the data [2, 15, 16, 30].

There are several difficulties with cause-of-death analyses. Most studies do not provide information on cause of death, and even when these data are available, they are often unreliable. Furthermore, even if data on cause of death are available and accurate, most tests are oriented toward prevalence and mortality rather than incidence, and H_λ does not always correspond to $\pi_0(t) = \pi_1(t) = \cdots = \pi_K(t)$ and $\gamma_0(t) = \gamma_1(t) = \cdots = \gamma_K(t)$. In fact, the prevalence portion of a Peto type test focuses on $p(t)$ rather than on $\pi(t)$, and thus its validity depends on whether tumor patterns in animals that die from other causes are representative of those in live animals, an assumption that is not always true [1, 36]. Finally, given that representativeness holds, McKnight & Wahrendorf [41] discuss situations in which these cause-of-death tests should provide appropriate inferences about tumor incidence.

Random Sacrifices

The intentional killing and examination of a random sample of healthy animals gives a cross-sectional view of the tumorigenic process. The proportion of animals having the tumor among those sacrificed at time t provides an unbiased estimate of $\pi(t)$. Therefore, together with observations on time to death and tumor response, sacrifice data permit an analysis of tumor incidence. The advantage of having sacrifice data is that lethality assumptions, cause-of-death data, parametric models, and functional restrictions are not necessary. The survival adjustment improves with the number of sacrifice times and the number of animals killed at each sacrifice time. The main disadvantages of multiple sacrifices are the extra expense and complexity associated with a large experiment.

McKnight & Crowley [40] state that without knowledge of how tumor incidence affects the risk of death, sacrifice data are needed to identify $\lambda(t)$. They express the tumor incidence rate in terms of the prevalence rate, its derivative, and two death rates:

$$\lambda(t) = [\pi'(t) + g(t) - \pi(t)h(t)]/[1 - \pi(t)], \quad (33)$$

where $\pi'(t)$ is the derivative of $\pi(t)$, $g(t)$ is the rate of death with the tumor

$$g(t) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon, Y(T) = 1 | T \ge t)/\varepsilon, \quad (34)$$

and $h(t)$ is the overall death rate:

$$h(t) = \lim_{\varepsilon \to 0} \Pr(t \le T < t + \varepsilon | T \ge t)/\varepsilon. \quad (35)$$

Lacking further structure, however, the prevalence rate is estimable only at the sacrifice times and thus the "resolution" of a nonparametric incidence analysis is limited by the number of sacrifice times. For example, a nonparametric analysis is generally based on intervals with endpoints at the sacrifice times. The amount of age adjustment increases with the number of sacrifice times and most experiments have few, if

any, in addition to the terminal sacrifice. Even carcinogenicity studies with one or two interim sacrifices would yield very coarse nonparametric estimates of the derivative of the prevalence rate, and thus poor estimates of the incidence rate.

McKnight & Crowley [40] describe the advantages of multiple sacrifice times, discuss identifiability, and give nonparametric estimators and tests for the incidence rates. Dewanji & Kalbfleisch [13] propose an iterative maximum likelihood analysis, while Malani & Van Ryzin [38] suggest a closed form solution that coincides with the maximum likelihood analysis when the data are well behaved, but otherwise can produce negative incidence estimates. Williams & Portier [54, 55] derive similar explicit nonparametric estimators, with and without restricting the incidence rates to be positive.

Many other authors have dealt with survival/sacrifice experiments, but most have assumed parametric models or have not focused on tumor incidence rates. Turnbull & Mitchell [52] consider the simultaneous analysis of several diseases, but they use **loglinear** and logistic models to investigate tumor prevalence and lethality rates (see also [6] and [42]). On the basis of a piecewise constant model for the transition rates, Borgan et al. [8] show that multiple sacrifices can greatly increase efficiency. In rare cases, such as in the ED_{01} study [10], an experiment is large enough and has a sufficient number of sacrifices to support a reasonable nonparametric analysis of tumor incidence rates, but this is clearly the exception rather than the rule. In practice, an analysis should not rely on routinely having numerous sacrifice times.

Parametric Models

Kalbfleisch et al. [29] discuss a fully parametric setting and suggest that a maximum likelihood analysis is complicated, but feasible, if the assumed models are identifiable. Borgan et al. [8] describe a special case in which the underlying intensities are piecewise constant. By reformulating in terms of more easily estimable quantities, Dinse [17] uses simple, flexible models to produce reasonable estimates of the incidence rate and a measure of tumor lethality. Without additional data, though, such as from multiple sacrifices, the modeling assumptions in a parametric analysis are untestable. Conclusions based on one model can differ greatly from those based on another. Thus, one must take care to select a biologically sensible model, or at least a general model that is fairly robust to misspecification.

Several recent analyses combine the benefits of parametric models and sacrifice data. That is, much information on tumor incidence can be gained through relatively few sacrifices as a result of the increased structure provided by a parametric model. For example, Portier [45] proposes a semiparametric analysis that assumes a **Weibull distribution** for the tumor onset times, which gives incidence rates of the form

$$\lambda(t) = bct^{c-1}, \tag{36}$$

but imposes no parametric model on the conditional death rates and requires only two sacrifice times (see also [16] and [46]).

Functional Restrictions

Rather than assuming particular distributions for the underlying random variables or modeling the components of the onset/death process, constraints can be placed on the way in which the components relate to each other. For example, Dinse [18] proposes a constant risk difference model, which assumes that the difference between the death rates for animals with and without the tumor in the kth group is constant over time:

$$\alpha_k(t|x) - \beta_k(t) \equiv \Delta_k. \tag{37}$$

Dinse [18] also considers a constant risk ratio model, which assumes that the ratio of these death rates is constant over time:

$$\alpha_k(t|x)/\beta_k(t) \equiv \rho_k. \tag{38}$$

Although multiple sacrifice times are useful, only one is needed to fit these models.

Under either restriction, the tumor incidence rates and tumor-free death rates can vary with each death time t_j; which, together with Δ_k or ρ_k, can yield as many as $2J + 1$ unknowns per group in this nonparametric setting. The number of unknowns can be reduced by modeling either $\lambda_k(t)$ or $\beta_k(t)$ as a function of time t. In fact, any of the quantities $\lambda_k(t)$, $\beta_k(t)$, Δ_k, or ρ_k can be modeled as functions of dose and other covariates. Lindsey & Ryan [37] describe a constant risk ratio model with piecewise constant tumor incidence rates and tumor-free death

rates. Ryan & Orav [49] propose a constant risk ratio model and suggest incorporating covariates such as tumor size and histology, although they focus on tumor prevalence rather than tumor incidence.

This approach enjoys several advantages, as it adjusts for differential mortality, allows for occult tumors, avoids lethality assumptions, and does not require information on cause of death. Only one sacrifice time is necessary, in theory, and certain functional constraints seem less restrictive than many parametric models. One downside is that the validity of any functional constraint can not be tested without additional information, such as data from multiple sacrifices. Thus, the appropriateness of such methods in general must be judged on the basis of simulations and large data sets, such as the ED_{01} study [10]. The estimates and the operating characteristics of tests derived under the constant risk difference model appear promising [18–20].

Discussion

Our understanding of the tumor onset/death process has evolved over time, as has our appreciation of which endpoints are important, what data must be collected, and how studies should be designed. If our goal is to analyze tumorigenesis, then we must focus on the time to tumor onset, which is characterized by the tumor incidence rate. In the vast majority of organ sites, however, tumors simply are not observable in live animals and thus the experiment provides no direct observations on the primary endpoint of interest. Consequently, we must either focus on secondary endpoints, collect additional data, design studies differently, or make unverifiable assumptions.

If our goal is to estimate and to compare tumor incidence rates, an analysis oriented toward some other endpoint is unacceptable, unless a clear equivalence exists between tumor incidence and the other endpoint. The common alternatives, such as time-specific tumor prevalence, time to death with tumor, and time to death from tumor, suffer various shortcomings. Except in special situations, an analysis based on one of these other endpoints can produce biases with respect to inferences about tumor incidence. The best strategy, in general, is to focus on tumor incidence if at all possible.

In a perfect world, with no budgetary limits, the ideal study would have many interim sacrifices. Given enough sacrifice data, the analysis could focus on tumor incidence without worrying about tumor lethality, cause of death, parametric models, or functional restrictions. Unfortunately, such studies are extremely rare, and thus analyses that rely on an abundance of sacrifices are not routinely applicable, regardless of how satisfying they are conceptually. In general, cost and other practical considerations demand an approach that can be applied with few sacrifice times.

Assumptions about tumor lethality provide the simplest survival-adjusted analysis of tumor incidence rates. In this case, however, simplicity comes at the expense of general applicability. Most researchers would agree that there are few organ sites for which all tumors are strictly nonlethal or all tumors are instantly lethal. Consequently, analyses based on either of these extreme lethality assumptions produce biased inferences with regard to tumor incidence when that lethality assumption is false. Techniques that rely on cause-of-death determinations, which are not commonly available, experience similar problems due to misclassification errors.

The last resort seems to be the use of parametric models or functional constraints. Without sacrifice data, or other extraordinary information such as reliable cause-of-death data, parametric assumptions typically are untestable. Methods that rely on unverifiable assumptions must be used with caution. The increased structure of a parametric model, however, provides many benefits and thus such models should be considered carefully.

In conclusion, perhaps the most promising approach is based on a combination of some sacrifice data and some type of formal structure. Although multiple sacrifice times are rare, most studies are terminated after a fixed period of time, at which point all of the remaining animals are killed. In many cases, the data from this terminal sacrifice can provide enough information about the overall tumorigenesis puzzle to allow an analysis that makes limited parametric assumptions or imposes some functional restrictions. The terminal sacrifice data permit the incidence function to be identified even when only a subset of the underlying transition intensities is modeled parametrically or constrained in some way. For example, assuming a constant difference between the death rates for animals with and without the tumor

is sufficient to provide an otherwise nonparametric analysis of the tumor incidence rates. This approach and other similar methods appear to be the most fruitful avenues for future research.

GREGG E. DINSE

Tumor Modeling

Introduction

There are various stages in the development of a particular cancer into a life-threatening disease. In the first of these, one or more mutations occur within an individual cell. The uncontrolled division of that cell leads to the growth of a (small) avascular tumor, which may then remain dormant unless and until it acquires its own blood system by the process of angiogenesis (*see* **Tumor Growth**). The resulting vascular tumor is relatively well-supplied by nutrients and may grow to a much larger size. Finally, malignant tumors are able to invade the surrounding tissue, leading to metastatic spread, with secondary tumors arising elsewhere in the host. Further mutations within the population of tumor cells, including drug resistance, may underpin these later stages of development.

Tumorigenesis, the process by which normal cells transform into cancer cells, is associated with the progressive loss of function of a range of regulatory genes, including repair genes that correct mutations and DNA damage before cell division and tumor suppressor genes that signal for cell-cycle arrest or induce programmed cell death (apoptosis) if substantial genetic damage is detected.

Once a solid tumor has developed and been detected, it may be categorized in many ways, such as: according to the tissue and cell-type of origin, the fractal dimension of its periphery [24] and whether it is benign or malignant.

A further classification is based on whether it possesses a blood supply: vascular tumors have a blood supply, whereas avascular ones do not. Diffusion controls the delivery of nutrients (e.g. oxygen and glucose) to, and the removal of waste products from, avascular tumors [13, 43]. The diameter to which avascular tumors grow is thus limited to several millimeters and they are relatively harmless. By contrast, vascular tumors are life-threatening for two reasons. Firstly, being connected to the host's blood supply, they have access to an almost limitless supply of nutrients. The consequent rapid growth of such tumors may impair the function of neighboring vital organs.

Second, tumor fragments that enter the vasculature may be transported to other parts of the body where they may establish secondary tumors (metastases) that further jeopardize the host. The switch from avascular to vascular growth is effected by angiogenesis [12]. During this process, the tumor cells secrete a range of diffusible chemicals (e.g. vascular endothelial growth factor and tumor necrosis factor-β), which are known collectively as angiogenic factors. The angiogenic factors stimulate neighboring blood vessels to proliferate and migrate towards the tumor, eventually furnishing it with a circulating blood supply so that vascular growth may commence.

Invasion of the surrounding tissue is another key feature of solid tumors: contact with the tissue stimulates the production of enzymes such as matrix metallo-proteases, which digest the tissue. This creates spaces into which the tumor cells may then migrate [40].

At a cellular level, the sequence of events that are needed to establish a well-developed, vascularized tumor may be associated with genetic mutations. For example, mutations in the tumor suppressor gene p53 have been linked with tumor angiogenesis and cell immortality, the latter being a hallmark of many tumors [37, 39].

Tumorigenesis

As stated above, disruption of a number of regulatory genes is necessary for tumorigenesis (the initiation of tumor growth), the number and type of genes required remaining open questions [19]. The earliest models of tumorigenesis were **stochastic** and developed to investigate the age-specific incidence rates for certain adult cancers [3]. These **multistage carcinogenesis models** were extended to distinguish between inherited and spontaneous cancers [22, 29] and adapted to investigate the effects of apoptosis [46] and variable mutation rates [47]. More recently, Plotkin and Nowak [36] developed a stochastic model that investigates the extent to which loss of DNA repair genes and tumor suppressor genes contribute to tumorigenesis.

The corresponding literature for deterministic models is less well developed. Coldman and Goldie develop **compartmental models** in which reversible mutations may occur [10]. Thompson and Royds [45] study competition between subpopulations of tumor cells that differ in the status of the tumor suppressor gene p53 (the gene functions normally in

one population and gives a survival advantage under low oxygen to the second population). Norris [33] has extended these concepts to allow for the effects of spatial variation within avascular tumors.

Avascular Growth

During avascular growth, nutrients that enter the tumor are consumed by live, proliferating cells as they diffuse towards the tumor center. As the tumor grows, the amount of nutrient reaching the center declines until there is insufficient to sustain viable cells. There ensues the formation of a central core of dead (necrotic) cellular material whose size increases as the tumor continues to grow. Thus, a well-developed avascular tumor comprises an outer rim of nutrient-rich, proliferating cells and a central core of nutrient-starved, necrotic debris. These regions may be separated by a layer of oxygen-poor (hypoxic) cells, which are quiescent (viable but nonproliferating).

Many mathematical models of avascular tumor growth that reproduce the phenomena described above have been developed and shown to exhibit good qualitative and quantitative agreement with experimental data. Probabilistic models that focus on individual cells and their interactions with neighboring cells use concepts ranging from **Markov chain** processes [17], through cellular automata [11] to stochastic energy minimization techniques [42]. By contrast, deterministic models tend to focus on cell populations or continua and are formulated as systems of ordinary differential equations [30], spatiotemporal partial differential equations [6, 15, 16, 30, 50] or age-structured partial differential equations [16].

Angiogenesis

Deterministic models of angiogenesis, the process by which an avascular tumor acquires a blood supply from the host tissue, have successfully reproduced many macroscopic features of the developing vascular network. These include: the acceleration of the vascular network and the increase in the number of capillary tips as the vascular network approaches the tumor [7] and regression of the vasculature in response to angiogenic inhibitors such as angiostatin [27].

However, such deterministic models are unable to provide details of microscopic features, such as vessel lengths and distances between buds or anastomoses, that can be obtained using stochastic models [41] and hybrid deterministic-stochastic models in which certain processes (e.g. nutrient diffusion and its consumption by the tumor cells) are viewed deterministically while others (e.g. cell proliferation, death and migration) are treated probabilistically [2].

Vascular Growth

Once a tumor has acquired its own blood supply by angiogenesis (see [28], for example, for an approach to modeling the onset of vascularization), it is able to grow to a large (ultimately life-threatening) size. There has been relatively little modeling work on this crucial stage of tumor development, in part reflecting the complexities that arise; these include the following: the interactions between angiogenesis and the growing tumor (e.g. [32, 34]); the balance between nutrient delivery by the vasculature and nutrient consumption by the tumor (e.g. [1]); the complexities of the immature vascular networks through which the nutrients are delivered, in terms both of their highly tortuous geometry and of the interactions between blood flow and interstitial fluid pressures within the tumor (see [31, 38, 52], for instance); and the complex microenvironments (as described in [5, 23], for example), involving both spatial and temporal variations in oxygen tension and pH in particular, which arise because of nonuniformities in nutrient delivery and waste product removal [35] by the vasculature. These effects have important implications for the effectiveness of different, blood-borne treatment protocols [21].

Invasion

One of the earliest approaches to the modeling of tumor invasion and metastatic spread, pioneered by Greenspan [15], involves linear stability studies of existing models for the growth of radially symmetric tumors; the growth of fingers due to the instability of the symmetric state provides a mechanism for a tumor to invade the surrounding tissue. Such studies, which typically involve an analysis of the interactions between nutrient-limited growth and the physical properties of a growing tumor, remain an active

area of research (see [8], for instance). However, numerous additional complexities have also now been incorporated, including: the role of degradative proteases, for example, in leading to a distinction between noninvasive (benign) tumors, which are often confined by a capsule comprised of connective tissue, and malignant ones (see, for example, [20, 25, 26]); the role of pH (e.g. [51]); interactions with the immune system (surveyed in [4]); interactions with the underlying tissue matrix (e.g. [49]); interactions between primary and secondary tumors (e.g. [14]); and the implications of "diffuse" invasion for imaging and therapy (see [44]). Because cellular mutation may enhance a tumor's invasiveness and because a single cell can lead to metastatic spread, stochastic effects have a crucial role to play in invasion; [48] provides a discussion of the role of deterministic and stochastic models.

Conclusions

The modeling of tumor growth continues to present enormous challenges. A vast range of scales is involved, from subcellular through cellular and tumor to patient. Numerous phenomena are thus of interest, from stochastic effects relating, in particular, to the mutation or survival of single cells to mechanical ones, which may not only influence the interactions of a growing tumor with the surrounding tissue [9, 18] but may also create difficulties in, say, delivering drugs against an adverse pressure gradient [52]. Multiple (and age-structured) populations of cell types are present and three-dimensional effects can be crucial, leading to severe computational challenges. The value of the insights, which experimentally validated modeling can provide is nevertheless, increasingly widely recognized.

Turnbull Estimator

The Turnbull estimator [27] is a **nonparametric maximum likelihood estimator** (NPMLE) of the distribution function F of a real-valued **random variable** X based on N independent, arbitrarily interval-censored and/or truncated observations $(X_1, X_2, \ldots, X_N)$ of X. The observation X_i is said to be truncated by a set B_i if X_i is drawn from the conditional distribution $F(x : B_i) = \Pr(X \leq x | X \in B_i)$, and X_i is said to be **interval-censored** if X_i is only known to lie in an interval $[L_i, R_i]$.

Interval censoring occurs naturally when X_i represents the time to an event of interest and there is intermittent monitoring for this event. For example, in **AIDS** studies interval-censored data arise in connection with the time of infection with human immunodeficiency virus (HIV) in individuals exposed to the virus. Since only periodic assessment of HIV status is feasible, the time to infection with HIV will be known only to lie in an interval specified by the last negative and the first positive assessment, or it will be right-censored if no positive assessment was made by the time of last examination.

Truncation occurs if X_i is drawn from the population in which observations with values outside truncating set B_i have been removed (*see* **Truncated Survival Times**). For example, if X is a survival time associated with a chronic disease, and individuals suffering from the disease are not followed from the time of diagnosis, but instead are recruited into a study at some later times, then X_i will be included in the sample only if $X_i > V_i$, where V_i is the time from the diagnosis to the time of recruitment (*see* **Delayed Entry**). Thus, X_i is drawn from the population of observations with the same time of diagnosis but from which observations with survival times shorter than V_i were removed. The observation X_i is then said to be left-truncated by $B_i = (V_i, \infty)$.

The observations can be both truncated and interval-censored as in [2, Example I.3.11]. In this example, the data set includes interval-censored and left-truncated observations on the time from the diagnosis of diabetes to the onset of severe complications associated with diabetes.

The sample of truncated and interval-censored observations is then represented by N pairs $(A_1, B_1), (A_2, B_2), \ldots, (A_N, B_N)$, where X_i is truncated by B_i and furthermore is censored by $A_i = [L_i, R_i] \subseteq B_i$. In particular, X_i is right (left) censored if $R_i = +\infty$ ($L_i = -\infty$) and is known exactly if $L_i = R_i$. Interval, right, and left truncation are defined in a similar manner. The truncating sets, B_i, and censoring sets, A_i, can be either fixed or random. Turnbull's method of estimation is also applicable when A_i is a union of disjoint closed intervals.

We note that grouped data are a special case of interval-censored data in which, for each i, the censoring interval $[L_i, R_i]$ is a member of a known, fixed partition of the range of X.

Interval-censored and/or truncated data arise in a wide range of research areas including AIDS studies (see e.g. [4, 5, 7], and [25]) and cancer research (see for example, [12] and [24]). Examples of studies which involve application of the Turnbull estimator to medical data are [21, 22], and [24].

Derivation of the Turnbull Estimator

We sketch the derivation of $\hat{F}$, the NPMLE of F. Assuming that either (A_i, B_i) are fixed, or that they were generated by a random mechanism independent of X_i, the **likelihood** function is proportional to

$$L(F) = \prod_{i=1}^{N} \frac{[F(R_i+) - F(L_i-)]}{P_F(B_i)}, \qquad (1)$$

where $P_F(B_i) = \Pr(X \in B_i)$.

The estimator is derived in two steps. In the first step it is shown that $\hat{F}$ increases on only a finite number of disjoint intervals. This characterization of the support of $\hat{F}$ is used in the second step to compute the estimator. For the case of nontruncated, interval-censored data Peto [23] proposed a Newton–Raphson algorithm (*see* **Optimization and Nonlinear Equations**) for computation of $\hat{F}$. Turnbull [27] developed a simple and intuitively appealing self-consistency algorithm for obtaining $\hat{F}$.

The Support of the Turnbull Estimator

When data are not truncated, i.e. $P_F(B_i) = 1, (1 \leq i \leq N)$, the intervals on which $\hat{F}$ may increase are derived as follows. Let $L = (L_i, 1 \leq i \leq N)$ and $R = (R_i, 1 \leq i \leq N)$, be the sets of left and right endpoints of censoring intervals. The form of (1) indicates that $L(F)$ will be maximized when the values of $F(x)$ are as large as possible for $x \in R$

and as small as possible for $x \in L$ subject to the constraint that F is the distribution function. Accordingly, let $C = \bigcup_{j=1}^{m}[q_j, p_j]$, where $q_1 \le p_1 \le q_2 \le p_2 < \ldots < q_m \le p_m$, be a union of disjoint, closed intervals whose left and right endpoints lie in the sets L and R, respectively, and which contain no other members of L or R. Then on examination of $L(F)$ it can be seen that the support of $\hat{F}$ is contained in C, and that for fixed values of $F(p_j+)$ and $F(q_j-)$, $L(F)$ is independent of the behavior of F within each interval $[q_j, p_j]$. Thus, $\hat{F}$ is flat outside C and is only unique up to the class of distributions with the same values of $\hat{F}(p_j+) - \hat{F}(q_j-)$, $1 \le j \le m$.

When data are also truncated the described construction is in general not valid. The necessary modification of Turnbull's construction of the support of $\hat{F}$ in the presence of truncation involves endpoints of truncation intervals and is discussed by Frydman [14]. In the following we assume that, if data are truncated, the set C is constructed as in [14].

Let $s_j = F(p_j+) - F(q_j-)$, for $1 \le j \le m$. The foregoing discussion shows that the problem of finding the NPMLE of F reduces to one of maximizing

$$L(\mathbf{s}) = \prod_{i=1}^{N}\left(\sum_{j=1}^{m}\alpha_{ij}s_j \Big/ \sum_{j=1}^{m}\beta_{ij}s_j\right) \qquad (2)$$

with respect to $\mathbf{s} = (s_1, \ldots, s_m)$, subject to $\sum_{j=1}^{m} s_j = 1$ and $s_j \ge 0$, $1 \le j \le m$, where $\alpha_{ij} = 1$ if $[q_j, p_j] \in A_i$, 0 otherwise, $\beta_{ij} = 1$ if $[q_j, p_j] \in B_i$, 0 otherwise.

The Self-Consistency Algorithm

Turnbull proposed an **algorithm** for the maximization of $L(\mathbf{s})$ based on the idea of self-consistency. This idea was introduced by Efron [11] and is described, for example, by Cox & Oakes [6]. We briefly describe the algorithm. For $1 \le i \le N$ and $1 \le j \le m$, let $I_{ij} = 1$ if $X_i \in [q_j, p_j]$ and 0 otherwise. Also let J_{ij} be the number of individuals corresponding to the observation X_i who were never observed because their X-values are in the complement of B_i and which have X-values in $[q_j, p_j]$. Turnbull termed these X_is **"ghosts"**. Because of censoring I_{ij} is in general not known but its expectation conditional on the observed data computed under a given value of $\mathbf{s}$ is equal to

$$\mathrm{E}(I_{ij}|\text{data}, \mathbf{s}) = \alpha_{ij}s_j \Big/ \sum_{k=1}^{m}\alpha_{ik}s_k \equiv \mu_{ij}(\mathbf{s}). \qquad (3)$$

The expectation of J_{ij} conditional on the observed data, under $\mathbf{s}$, is given by

$$\mathrm{E}(J_{ij}|\text{data}, \mathbf{s}) = (1 - \beta_{ij})s_j \Big/ \sum_{k=1}^{m}\beta_{ik}s_k = \nu_{ij}(\mathbf{s}). \qquad (4)$$

A self-consistent estimate of $\mathbf{s}$ is defined as a solution to the following system of equations

$$s_j = \sum_{i=1}^{N}[\mu_{ij}(\mathbf{s}) + \nu_{ij}(\mathbf{s})] \Big/ \sum_{i=1}^{N}\sum_{j=1}^{m}[\mu_{ij}(\mathbf{s}) + \nu_{ij}(\mathbf{s})], \quad 1 \le j \le m. \qquad (5)$$

It can be demonstrated that (5) are simply loglikelihood equations for the maximization of $L(\mathbf{s})$ with respect to $\mathbf{s}$. This shows that $\hat{\mathbf{s}}$, the **maximum likelihood estimator** (MLE) of $\mathbf{s}$, is a self-consistent estimator of $\mathbf{s}$. The algorithm for finding the MLE of $\mathbf{s}$ starts with the initial value $\mathbf{s}^0 > 0$, and the improved estimate $\mathbf{s}^1$ is obtained from the right-hand side of (5) evaluated at $\mathbf{s}^0$. One iterates in this fashion until convergence is achieved. We note that the described algorithm is an example of the EM algorithm [9]. The complete data likelihood function is based on the fact that the random variables $\sum_{i=1}^{N}(I_{ij} + J_{ij})$, $1 \le j \le m$, have a **multinomial** distribution with cell probabilities $(s_1, \ldots, s_m)$. Combining the E-step, where the expectations are computed as in (3) and (4), with the M-step gives self-consistency equations in (5). The convergence of the algorithm was demonstrated by Turnbull [27], but it is also assured by the theory of the EM algorithm for an **exponential family** of distributions of which the multinomial distribution is a member.

The Turnbull estimator of F is given by

$$\hat{F}(x) = \begin{cases} 0, & \text{if} \quad x < q_1, \\ \hat{s}_1 + \hat{s}_2 + \cdots + \hat{s}_j, & \text{if} \quad p_j < x < q_{j+1}, \\ & \quad 1 \le j \le m-1, \\ 1, & \text{if} \quad x > p_m, \end{cases}$$

and is undefined for $x \in [q_j, p_j]$, $1 \le j \le m$, so that the way an increase $\hat{s}_j$ occurs over an interval $[q_j, p_j]$ is arbitrary. Thus, when plotted, $\hat{F}$ is a step function with gaps which occur over the intervals in C.

Special Cases

For some special cases of interval-censored data an NPMLE of F has an explicit representation. If all observations are exact or right-censored only, then $\hat{F}$ is the well known **Kaplan–Meier estimator** [17]. Current status data arise when all observations are either right- or left-censored; see the survey by Diamond & McDonald [10]. In this case, $\hat{F}$ also has an explicit representation [3, 16]; see also [18] for an exposition.

Asymptotic Properties

Groeneboom & Wellner [16], using an elegant approach based on **isotonic regression** theory, demonstrated **consistency** and developed asymptotic distribution theory (*see* **Large-sample Theory**) for an NPMLE of F derived from current status data. They also demonstrated consistency and presented partial asymptotic distribution results for an NPMLE of F obtained from "case 2" interval-censored data. The "case 2" interval censoring is the same as arbitrary interval censoring except that exact observations can never be observed.

The asymptotic distribution result obtained by Groeneboom & Wellner [16] for an NPMLE of F derived from current status data is nonstandard and involves $\sqrt[3]{n}$ norming. This shows that there will never be a completely general asymptotic result for the Turnbull estimator of F derived from arbitrarily interval-censored data.

However, assuming that exact observations occur with some positive probability, Li et al. [20] presented an EM algorithm for obtaining a self-consistent estimator of F defined on $(0, \infty)$. The obtained estimator is a smoothed version of the Turnbull estimator. The authors state that consistency and asymptotic normality of the smoothed estimator are established in [28].

Generalizations

Turnbull's method has been generalized by a number of authors to the estimation of multistate survival models in which times of transitions to states may be interval-censored and/or truncated (*see* **Multivariate Survival Analysis**). Many generalizations were motivated by the problems encountered in AIDS studies (unknown time of infection with HIV, left truncation of the **incubation period** of AIDS, and delays in the reporting of AIDS cases), where the typical framework is an irreversible three-state disease model (state 1, not infected; state 2, infected; state 3, clinical AIDS). For example, De Gruttola & Lagakos [7] simultaneously estimated the distribution of the time of infection with HIV, and the distribution of the incubation time (time between infection and the appearance of clinical symptoms of AIDS; *see* **Latent Period**), assuming independence between these times, in the case where the time of infection is interval-censored and there is no truncation. Assuming that a three-state disease model is a time-nonhomogeneous Markov process, Frydman [13] proposed a self-consistent algorithm for estimating the cumulative transition intensities for data of the same form as in [7]. Other generalizations are given by De Gruttola et al. [8], Sun [25], and Frydman [15]. The generalizations by Kim et al. [19], Tu et al. [26], and Alioum & Commenges [1] incorporate covariates.

Twin Analysis

The first use of twin resemblance as a means of resolving alternative hypotheses about the causes of human differences appears to have been in 426 AD by Augustine of Hippo in Book V of the *City of God*. Augustine argued that since twins, who were highly correlated in their times of birth, nevertheless had such discrepant life histories, there was little empirical support for planetary influence on human destiny. For Augustine's purpose, it was sufficient that at least some twin pairs showed markedly different life histories. In the nineteenth century, **Sir Francis Galton** suggested the etiologic basis of the distinction between identical (monozygotic or "MZ") and fraternal (dizygotic or "DZ") twins [15] (*see* **Heterozygosity**). He viewed twins as a unique natural experiment which allowed the resolution of the effects of heredity and environment on human development. These effects had been **confounded** in his studies of hereditary human traits in nuclear families and derived pedigrees [16]. Galton solicited letters from twins describing some of their experiences and characteristics. Based on these anecdotal data, Galton likened the developmental trajectories of identical twins to the path of two sticks dropped simultaneously into a stream. Although the eddies of the stream meant that the sticks would probably alternate in relative position as they flowed downstream, the overwhelming pressure of the current, corresponding to hereditary influences on human development, ensured that, on average, the sticks moved at essentially the same rate.

Galton's data, and his approach to data analysis, would receive little recognition today. In the century since Galton's pioneering studies, the twin study, though still subject to many inherent difficulties, has played a critical part in establishing the prima facie case for a significant role of genetic factors in a wide range of human traits and disorders. This article outlines some of the principal contours of past and current thought on the analysis of twin data.

Basic Analytic Method for Continuous Measures

Although the study of twins separated at birth (*see* **Adoption Studies**) has obvious appeal [48], practical issues of obtaining large and representative samples have dictated that the majority of twin studies employ twins reared together. Furthermore, although there are reports of other kinds of twins [3], we focus on the two most frequent classes: monozygotic (MZ) and dizygotic (DZ) twins, who most often have been reared together since birth.

Currently, there is no single perfect method of twin data analysis. The approach taken will depend somewhat on the kinds of data being analyzed and the genetic and environmental issues being explored. It is convenient, however, to begin with the approach laid down by Jinks & Fulker [24], as this is based on the familiar **analysis of variance**. Twin pairs are regarded as **random samples** from a population of pairs, and hence as a random sample of the genetic and environmental factors creating variation in the population of interest. Twins within a pair are assumed to sample at random the **genes** segregating within a family and the environmental differences operating within families. Birth order notwithstanding, there is no reason a priori to order the twins within a pair, so the data for each kind of twin pair may be summarized (Table 1) by a nested analysis of variance recognizing sources of variation within and between pairs or by the derived intraclass **correlation** coefficient. The strength of the twin method stems from the fact that the **components of variance** within and between pairs involve different proportions of the genetic and environmental contributions in MZ vs. DZ pairs.

Under the simplest model, which assumes no **genotype × environment interaction** (G × E) and no genotype–environment covariance (CGE), the contributions of genes and environment to the components of variance are shown in Table 2, where G_1 and G_2 are, respectively, the components of variance due to genetic differences within and between sibships, and E_1 and E_2 are, respectively, the components due to environmental differences within and between sibships.

Table 1 Expectations under a nested analysis of variance of n families of size m, in terms of between (σ_b^2) and within (σ_w^2) components of variance

Source	df	Expected MS
Between families	$n-1$	$\sigma_w^2 + m\sigma_b^2$
Within families	$n(m-1)$	σ_w^2

Table 2 Variance components for MZ and DZ twin pairs, reared together or apart, under a simple genetic model. Subscripts 1 and 2, respectively, denote within- and between-family components of genetic (G) and environmental (E) variance; $G = G_1 + G_2$ and $E = E_1 + E_2$. These components contribute to within (σ_w^2), between (σ_b^2), and total (σ_t^2) variance components in the analysis of variance

Component	Reared together		Reared apart	
	MZ twins	DZ twins	MZ twins	DZ twins
σ_w^2	E_1	$G_1 + E_1$	$E_1 + E_2$	$G_1 + E_1 + E_2$
σ_b^2	$G + E_2$	$G_2 + E_2$	G	G_2
σ_t^2	$G + E$	$G + E$	$G + E$	$G + E$

Other authors sometimes use different notations, especially for the between-families environmental component (also known as "common" environment, "CE", "shared" environment, or "family" environment). The total variance is $G + E$ for all relatives under the model. The expectations of the intraclass correlations $t = \sigma_b^2/(\sigma_b^2 + \sigma_w^2)$ for MZ and DZ twins reared together are

$$t_{MZT} = G_1^* + G_2^* + E_2^*,$$
$$t_{DZT} = G_2^* + E_2^*,$$

where the asterisks denote the components of variance expressed as proportions of the total.

The proportion of the total variance attributable to genetic differences (the "broad **heritability**") is $G_1^* + G_2^*$. Early twin researchers proposed a number of tests for the importance of genetic effects in twin studies and ratios intended to summarize the relative importance of genetic factors. Holzinger [23] proposed using the ratio $H = (r_{MZ} - r_{DZ})/(1 - r_{DZ}) = G_1/(G_1 + G_2)$. Similarly, Vandenberg [51] proposed a statistic $F = 1/(1 - H) = (G_1 + E_1)/E_1$ that measures the relative contribution of genes and environment to differences within families. Significance levels and **confidence intervals** could be obtained from the sampling distribution of the intraclass correlation coefficient and variance ratio as appropriate. However, under the model above, it is clear that neither of these ratios corresponds to the broad (or narrow) heritability understood by geneticists.

Genetic Meaning of Statistical Parameters

Two components of variance G_1 and G_2 are merely convenient ways of partitioning the genetic variance in twin pairs into those effects that arise as a result of **segregation** (G_1) and those that arise because of the sampling of parents (G_2). They do not correspond directly to the additive, dominant, or epistatic effects of the genes contributing to variation. Considering only the additive (V_A) and dominant (V_D) components of genetic variance, it may be shown (e.g. 32) that $G_1 = \frac{1}{2}V_A + \frac{3}{4}V_D$ and $G_2 = \frac{1}{2}V_A + \frac{1}{4}V_D$ when mating is random. Thus, in the absence of dominance, $G_1 = G_2 = \frac{1}{2}V_A$.

Discontinuous Traits

Univariate analysis of discontinuous data, specifically concordance rates and **relative risks**, is described in the article on **Twin Concordance**. **Multivariate analysis** of both continuous and discontinuous traits is described below.

Structural Equation Model for Twin Resemblance

Although the biometric genetic model allows for the specification of additive and nonadditive genetic components, it does not deal well with the effects of **assortative mating** and the various forms of nongenetic inheritance. The approach of **path analysis**, though not ideal for the specification of nonlinear effects, provides a convenient way of representing family resemblance in the presence of assortative mating and cultural inheritance [12, 49]. The basic path model for the similarity of MZ and DZ twins reared together is shown in Figure 1 (cf. [39]). The model allows for the additive and dominance effects of genes (A and D), and for the common (shared) family environment (C) and the unique (within-family) environment (E). The basic model assumes **polygenic** autosomal inheritance, random mating, and the additivity and independence of genetic and environmental effects. In the simplest model, it is assumed that genes and environment have the same effects in males and females.

Model Fitting

If MZ and DZ twins are random samples of the genetic and environmental effects in the population,

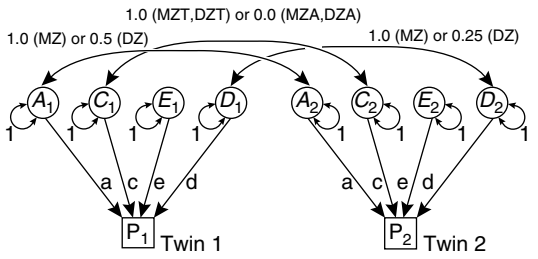

Figure 1 Univariate model for data from monozygotic (MZ) or dizygotic (DZ) twins reared together (T) or apart (A). Additive (A_i) and dominant (D_i) genetic, and common (C_i) and specific (E_i) environment latent variables cause the phenotypes P_i in a linear additive structural equation model

then there should be no difference between the means of MZ and DZ twins, nor any difference between their total phenotypic variances. Some types of social interaction, such as sibling contrast effects [5, 9], can produce zygosity differences in mean or variance or both, as can nonrandom sampling. The model of Figure 1 yields the following predicted values for the **covariance matrices** of phenotypic values in pairs of MZ and DZ twins:

$$\boldsymbol{\Sigma} = \begin{bmatrix} a^2 + c^2 + e^2 + d^2 & \alpha_i a^2 + \beta_i c^2 + \delta_i d^2 \\ \alpha_i a^2 + \beta_i c^2 + \delta_i d^2 & a^2 + c^2 + e^2 + d^2 \end{bmatrix}, \tag{1}$$

where a, c, e, and d are path coefficients for additive genetic, common environment, random environment, and genetic dominance effects, respectively; $\alpha_i = 1.0$ for MZ and 0.5 for DZ twins; $\delta_i = 1.0$ for MZ and 0.25 for DZ; and $\beta_i = 1.0$ for twins reared together and 0.0 for twins reared apart.

The parameters of the **structural equation model** for the pattern of MZ and DZ covariance may be estimated by several approaches, including **maximum likelihood** and weighted **least squares**. Parameters a, d, c, and e cannot be estimated simultaneously from the "classical twin study", which consists of data on MZ and DZ twins living together. Dominance effects tend to reduce the DZ correlation relative to that of MZ pairs, whereas the common environment tends to increase the DZ correlation relative to that of MZs. If d and c are both zero, then the DZ correlation is predicted to be exactly half that of MZs as long as mating is random. Typically, a set of reduced models (omitting either c or d) is fitted to the covariances to explore the major contributions of genes and environment to family resemblance. Where appropriate, **likelihood ratio tests** of **alternative hypotheses** may be conducted (e.g. that c or d is zero) and confidence intervals obtained for the parameter estimates [44]. These operations can be conducted efficiently, with many programs currently available for the structural equation modeling of covariance matrices. Recently, Mx [38] has been widely used in twin and adoption studies. It has the advantage of being able to fit models to raw data, which enables appropriate treatment of data missing completely at random or missing at random [30] (*see* **Missing Data**) as well as the detection of **outliers**.

Multiple Variables and Developmental Change

The univariate model for the analysis of twin data directly extends to the multivariate case. Multivariate path analysis [52] may be used to derive predicted covariances between relatives measured on several variables. In Figure 1, every latent and observed variable is replaced by a vector of variables. Thus the path coefficients are replaced by matrices of path coefficients, which are organized such that column variables cause row variables. The predicted covariances among twins are then:

$$\boldsymbol{\Sigma} = \begin{bmatrix} \mathbf{AA}' + \mathbf{CC}' + \mathbf{EE}' + \mathbf{DD}' & \alpha_i \mathbf{AA}' + \beta_i \mathbf{CC}' + \delta_i \mathbf{DD}' \\ \alpha_i \mathbf{AA}' + \beta_i \mathbf{CC}' + \delta_i \mathbf{DD}' & \mathbf{AA}' + \mathbf{CC}' + \mathbf{EE}' + \mathbf{DD}' \end{bmatrix}.$$

The form of the matrices **A**, **C**, **E**, and **D** dictates the form of the multivariate model for each component. One simple form is the Cholesky decomposition, in which all matrices are square and lower triangular. This decomposition provides a **robust** way to estimate the genetic and environmental sources of variation in, and covariation between, multiple measures. Covariance due to additive genetic sources is simply $\mathbf{AA}'$, and this matrix may be standardized to obtain additive genetic correlations between traits. The genetic variances and covariances may be expressed as proportions of the total (phenotypic) covariances, to obtain a multivariate analog of the narrow heritability coefficient, yielding information on the relative importance of genetic vs. environmental factors to covariation between traits. Some caution is required because it is possible for some sources of covariance to be negative while others are

positive. Such estimates might arise, for example, if the phenotypic covariance between traits is zero, but the cross-twin cross-trait covariance is positive. Thus the multivariate twin study has a remarkable potential to identify relationships between traits that are uncorrelated within individuals.

The Cholesky decomposition is not a theory-based model – it merely factorizes the covariance matrices **A**, **D**, **C**, and **E**. Other forms of the path coefficient matrix can be used to test alternative (usually simpler) models. A natural example from confirmatory **factor analysis** is to postulate that a single latent factor is responsible for all genetic (or environmental) covariation between traits, along with residual factors specific to each trait. Models of this type are called *biometric factor* or *independent pathway* models. Matrix **A** would be specified as a partitioned matrix **F**:**D**, where **F** is an $m \times 1$ vector of paths from the latent factor and **D** is an $m \times m$ diagonal matrix of residual factors. The form of the environmental factor matrices might be similarly constructed, but there is no obligation to keep the factor structure the same for the different variance components. If specific environmental variation consists of **measurement error**, a diagonal form for **E** would be sufficient.

Another natural branch of multivariate model is the *phenotypic factor*, or *common pathway*, model [26, 33], in which the genetic and environmental factors combine to form a latent factor which subsequently causes variation and covariation between the phenotypes. In addition, there may be trait-specific genetic and environmental factors. This common pathway model predicts that the cross-trait variation and covariation due to the general genetic and environmental factors is proportionate for all traits. Usually, this model has fewer parameters than the biometric factor model and does not fit as well by the χ^2 criterion. However, the model may prove to be a simpler, more **parsimonious**, account of the data, as judged by other indices of fit such as **Akaike's information criterion** [1].

Understanding of the sources of variance and covariance between traits gleaned from multivariate analyses can greatly enhance our knowledge of the role of risk factors in the interplay between genotype, environment, and phenotypic outcome. In studies of complex disorders, it is not good practice to assume that a risk factor is purely environmental, nor that it is a cause rather than a consequence of liability to a disorder. Multivariate genetically informative studies are particularly useful for the identification of risk factors and for the quantification of their effects.

Longitudinal Genetically Informative Studies

Just as the measurement of twins on many variables at a single occasion can provide information about the proportion of covariance between traits that is due to genetic vs. environmental factors, so can multiple measures made on the same twins at several points in time yield information about the sources of longitudinal stability and change. One starting point for analysis is the use of the Cholesky decomposition, which has a good conceptual basis if the variables $P_1, \ldots, P_t$ are ordered chronologically from occasion 1 to t. The first Cholesky factor F_1 causes variation at all occasions. The second causes variation at all occasions *except the first*, and may be conceived of as sources of variation not present at the first occasion, i.e. new variance or "innovations" at the second occasion. All subsequent Cholesky factors $F_{i=3,\ldots,t}$ represent innovations which occur at time i of measurement. In the context of twin studies, this distinction between persistent and innovation variance can be made separately for genetic and environmental components. Either genetic or environmental factors or both may account for patterns of stability and change over time, and the longitudinal twin study allows us to test alternative hypotheses about the origins of individual differences in change over time.

In 1986, Eaves et al. [10] described a number of alternative models of genetic and environmental stability and change. Because data are collected at several points in time, and because **causation** by definition operates from earlier to later events, it is natural to think of earlier variables causing later ones, and not vice versa. Such models are known as **Markov chain**, or Simplex, and have been used in psychological science for at least half a century [18]. In the context of a twin study, each of the components of variation may have a Simplex form, so that, for example, environmental variance at each occasion is partitioned into that due to previous occasions, and that due to innovation since the previous measurement. Application of the genetic Simplex to twin data is described in [39].

A novel component to the Eaves et al. [10] approach was the development of methodology to deal with irregular spacing of intervals between study.

Though not widely used, these methods are valuable for taking into account differences in age between subjects, which is particularly useful when the twin study is expanded to include other relatives.

Application to Discontinuous Data

In the univariate case, data analysis may proceed by maximum likelihood analysis of the **contingency tables** of twin 1 against twin 2 (*see* **Twin Concordance**). Most analyses assume that there is an underlying **normally distributed** liability continuum on which there are one or more abrupt thresholds that subdivide the population into ordinal classes. In principle, it is possible to analyze multivariate data this way, but the likelihood computations require the computation of **multivariate normal** integrals over twice (for twins) as many dimensions as there are variables in the analysis. Beyond-bivariate analysis of twin data (requiring four-dimensional integration) is numerically tedious at this time, even with advanced integration methods [17].

As an alternative to direct maximum likelihood analysis of multivariate ordinal data, it is possible to fit models to matrices of polychoric and polyserial correlations computed using software such as PRELIS [25], together with a weight matrix based on fourth-order **moments** [4]. These methods are practical only when the sample sizes are very large relative to the number of variables being analyzed; with small sample sizes the departure of the fit statistics from chi-square can be substantial.

Other Models

There are many approaches to the analysis of twin data, only some of which involve more elaborate structural equation models. To some extent, any multivariate statistical method can be applied to twin data, often yielding tests of salient genetic and environmental hypotheses. However, it is rare that a statistical method developed for unrelated subjects can be directly applied to data collected from twins. Methodologic development is usually required to specify that the subjects are related and that while certain parameters may be expected to be equal, others may need reparameterization to reflect the a priori knowledge from Mendelian (*see* **Mendel's Laws**) or Fisherian theory of the degree of genetic relatedness.

Continuous Indices of the Environment

A common misconception is that variation for something that seems environmental – like socioeconomic status – is purely environmental. Often, empirical inquiry with a twin or adoption study reveals substantial genetic variability for such traits. Therefore, it is wise to collect genetically informative data on all variables, wherever possible, before exploiting one or other variable as an environmental index. If a suitable environmental index does exist, it is possible (in principle) to identify genetic variance in an otherwise confounded design [36]. Such situations are relatively rare, so the multivariate twin or adoption study – which does not require the existence of an environmental index and is therefore of ubiquitous utility – is more widely used.

$G \times E$ and $G \times$ Sex Interactions

A common question is whether the set of relevant genetic and environmental factors, and the sizes of their effects, remain the same under different conditions [32]. One example would be examination of exposure to stressful experiences (though this may not be entirely environmental). Another example is male vs. female sex. In both cases multigroup structural equation modeling is a viable statistical approach. Twin pairs may be subclassified as concordant for exposure, discordant, or concordant for nonexposure. The basic procedure is to fit models in which parameters are allowed to differ between the subsamples, and to compare them, by likelihood ratio tests, with models in which the parameters are constrained to be equal across all groups. This comparison tests whether the magnitude of the parameters is the same under different environmental conditions. It is possible to carry out this test separately for one or more of the genetic or environmental sources of variation, to test whether, for example, differences in genetic effects alone are sufficient to account for differences in phenotypic variability. The subtler question of whether the same genetic and environmental factors are operating in the different groups may be addressed by developing a more elaborate model, which involves genetic and environmental factors that only operate on those individuals exposed to the environment (see Figure 2). In the special case of sex interactions, the twin study is limited to assessing sex-specific effects for either additive or dominance

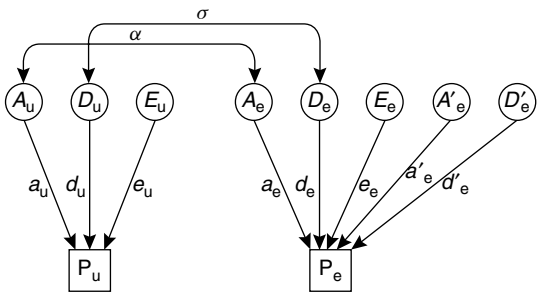

Figure 2 Path diagram of genotype × environment interaction in twins discordant for environmental exposure. For MZ pairs, $\alpha = 1.0$ and $\beta = 1.0$; for DZ pairs, $\alpha = 0.5$ and $\delta = 0.25$. The subscripts u and e identify variables and parameters for unexposed and exposed twins, respectively

(or common environment) genetic effects but not both (a'_e or d'_e in Figure 2). This limitation is because the identical twins are always of the same sex.

While the method may in principle be extended to test simultaneously the effects of several environmental variables, the number of subgroups increases quadratically, requiring an even greater increase in sample size to maintain sufficient numbers in the less frequent subgroups. To some extent this problem – which also occurs when more than a **binary** subclassification of twin pairs is used – can be mitigated by the analysis of the raw data instead of summary statistics [38].

Age Effects

Age can affect parameter estimates in a twin study in many different ways. Perhaps the simplest way, and one that is easiest to correct, is where there is a linear relationship between age and the phenotype. Assuming that the age distribution is equivalent in the MZ and DZ pairs, that the members of a twin pair are measured at the same age, and that twin pairs span a variety of ages, the linear effects of age will inflate the estimate of c^2. Neale & Martin [42] showed how the linear effects of age could be added to the structural equation model for twin data to control for, and estimate, the effects of age. Another approach is to regress out the effects of age on the phenotype prior to structural equation modeling. This latter technique is useful when nonlinear effects of age are of concern. Failure to correct for age in extended twin designs (twins plus their parents, children, or other relatives) where age difference is unequal for different types of relationship (such as parent–offspring vs. twin) can give rise to **biased** parameter estimates.

Similar to genotype × environment interaction, the impact of genes and the environment may vary between ages. In addition, different genetic and environmental factors may be operating at different ages. Such age × genotype or age × environment interactions are best resolved with longitudinal, genetically informative studies (see above).

A further recent development in genetic studies is the use of growth curve modeling [43]. Based on dynamical systems theory, specific functional forms for asymptotic growth or decay are specified. It is then possible, in a single-step analysis, to estimate genetic and environmental components to variation in initial level, rate of growth, and final asymptote components of variation in growth. Such models have great economy for predicting means, variation, and covariation of relatives across many points in time.

Censoring

A common statistical problem concerns the nonrandom observation of test scores. For example, examination scores from a sample of students may be available only for those who passed. Such a sample is termed **censored**. Uncorrected analysis of data from twin pairs in which both members passed the examination would yield biased estimates of genetic and environmental components of variation for the population. Typically, such censoring biases correlations towards zero, but in a nonlinear fashion [46], so the impact on additive genetic and common environment estimates depends on their true population values.

Correction for censoring requires knowledge of the proportion of the sample that has been censored, and, in the case of twins, some assumption about the underlying distribution so that the correlated **ascertainment** can be controlled. Assuming that a variable is normally distributed in the population, the likelihood for a pair of censored observations is

$$\frac{\phi(x_i)}{A}, \tag{2}$$

where $\phi(x_i)$ is the **bivariate normal** pdf

$$|2\pi\,\mathbf{\Sigma}|^{-n/2} \exp\left[-\tfrac{1}{2}(\mathbf{x}_i - \boldsymbol{\mu}_i)'\mathbf{\Sigma}^{-1}(\mathbf{x}_i - \boldsymbol{\mu}_i)\right],$$

in which $\mathbf{\Sigma}$ is the population covariance matrix, $\boldsymbol{\mu}_i$ is the (column) vector of population means of x_1 and x_2,

and $|\mathbf{\Sigma}|$ and $\mathbf{\Sigma}^{-1}$ denote the determinant and inverse of the matrix $\mathbf{\Sigma}$, respectively. The divisor A in (2) is the ascertainment correction, and is the probability that a pair will both have passed the examination. If the passing grade is t, the correction term is

$$A = \int_t^\infty \int_t^\infty \phi(x_i)\, \mathrm{d}x_2\, \mathrm{d}x_1.$$

In a similar fashion, data from the pairs discordant for passing the examination may be analyzed jointly. These data increase the precision of the estimates of the means and variances of the examination scores, but add little to the precision of the estimated covariances between the twins, and hence add little to the precision of estimates of heritability or common environmental variance.

Nonrandom Sampling

Similar to the analysis of data from censored samples, other forms of nonrandom sampling are sometimes used to increase statistical **power**. For example, in "four corners" sampling, pairs are selected because both members have scores either above a cutoff point t or below $-t$. This design will, after correction, yield estimates of genetic and environmental effects that are more precise (i.e. have smaller confidence intervals) than those from a random sample of equal size. By itself, this observation is of little practical use because scores on the whole sample are required in order to effect the nonrandom sampling, in which case the data from the whole sample should be used. However, the method gains value when subjects are being screened for a more expensive measurement protocol such as genotyping (see below).

Another common source of nonrandom samples in twin data occurs when all patients at a hospital are asked if they are a twin. In this case a key concept is the *probability of ascertainment*, usually denoted as π. Maximum likelihood based methods for estimating π and twin concordances are available [2]. Especially for rare disorders, nonrandom sampling, such as that through hospital records, can yield large gains in statistical power [45]. However, nonrandom sampling may suffer from nonrepresentativeness, if, for example, hospital cases do not constitute a random sample of cases in the population.

Co-Morbidity and Causation

An interesting feature of the classical twin study is its ability, under certain conditions, to test causal models of the relationship between traits or disorders [8, 22, 39] (*see* **Causation**). The principle can be seen in a simplified example, in which trait A correlates between twins, and trait B does not. However, trait A and trait B correlate within individuals. If trait A causes trait B, then we would predict a cross-correlation between trait A in twin 1 and trait B in twin 2. On the other hand, if B causes trait A, then the cross-twin, cross-trait correlation would be predicted to be zero. This simple example extends to the more general case; identification of the model requires that the twin correlation (either MZ or DZ) for trait A differs from the twin correlation for trait B. A limitation of this method is that, to avoid incorrect inferences about causation, measurement error variance should be approximately equal for the two traits.

Simple causation is only one of a variety of possible sources of covariation between traits, or of *co-morbidity* between disorders. We discussed above several multivariate models of resemblance based on genetic and environmental correlations between traits. In addition to these, there are a number of other models of co-morbidity that are clinically relevant [28, 41]. In particular, there is the idea that succumbing to a disorder in and of itself causes an increase in liability to a second disorder. This is quite distinct from simple correlation or causation between the liabilities to two disorders, and has different implications for etiology and treatment.

Other models of co-morbidity are based on hypotheses that two disorders are either a single-liability dimension, two correlated dimensions, or three independent dimensions, where excess co-morbid cases are a third, independent disorder [41]. All the models described in this section can be assessed with a maximum-likelihood or minimum χ^2 goodness-of-fit function. When cell frequencies are low, minimum χ^2 often performs better than maximum likelihood.

Dimensionality

Biostatisticians and psychometricians frequently rely on the joint distribution of the items on a test to

discern the dimensionality of a trait. Item response theory, **latent class analysis**, and **multidimensional scaling** are all examples of devices to assess dimensionality with multivariate data. Twins offer a unique perspective on dimensionality, gleaned from the pattern of covariance between twins measured *on a single scale*. A simple example of this is for cigarette smoking, where individuals may be current smokers, ex-smokers, or nonsmokers [21]. The question is whether these categories represent an ordinal scale based on a single underlying continuum of liability or whether there are different processes involved in initiation vs. persistence of tobacco use. Data from twins may be summarized as contingency tables, and used to test against frequencies predicted under a bivariate normal model with two thresholds and a polychoric correlation coefficient. This single-liability dimension model may be compared with two main alternatives. First is a model of two independent normally distributed liability dimensions in which one dimension discriminates between those who initiate and those who do not, and the second dimension discriminates between those who quit smoking and those who persist. Second is a combined model, which is the same as the two-dimensional model except that those intermediate on the initiation dimension invariably become ex-smokers. Empirically, the combined model has the greatest support, and the single-liability dimension model is usually statistically rejected, indicating that smoking status cannot be regarded as a unitary trait.

Latent Class Analysis

It is possible to extend latent class analysis [34] for use with twin data by constraining the pattern of joint class frequencies in pairs of twins [11] to accord with various models of twin resemblance. A simple form of patterning allows members of a twin pair to correlate for class membership. The usual reparameterization to estimate variation due to additive genetic, shared environmental, and random environmental components can be applied to class membership frequencies, assuming some ordering of classes (polychoric correlation) or nonparametric association such as Cramer's C [6]. Of greater interest from a biometric genetic standpoint is the patterning of classes according to **gene frequencies** under a major locus model (see Table 3). Optionally, these cell frequencies may be multiplied by **penetrance** parameters, which estimate the probability that each genotype gives rise to the three latent classes. Not all penetrance parameters can be estimated in this model.

Table 3 Pairwise class membership frequencies for MZ and DZ twins under a single biallelic major locus model, with gene frequencies p and $q = 1 - p$

		MZ twin 1			DZ twin 1		
		1	2	3	1	2	3
Twin 2	1	p^2	0	0	p^4	$2p^3q$	q^2p^2
	2	0	$2pq$	0	$2p^3q$	$4p^2q^2$	$2pq^3$
	3	0	0	q^2	q^2p^2	$2pq^3$	q^4

Extending the Twin Design

The classical twin study should be regarded only as a good starting point for **genetic epidemiologic** investigations. It is clearly limited in a number of ways, several of which can be overcome by extending the twin design to include other relatives. As noted above, data from either MZ or DZ twins reared apart enable the joint estimation of the effects of both dominance genetic factors and the common environment, along with the effects of additive genes and specific environment. However, data from adoptees are themselves subject to a number of critical assumptions (*see* **Adoption Studies**), so it is worthwhile to consider extended twin designs.

A simple and practical extension is to assess twins and their parents [13, 47]. Parents yield two new types of data: marital and parent–offspring covariances. The marital covariance provides information about the presence of **assortative mating**. Usually, assortment is assumed to be phenotypic [12]. The consequences for the twin study are an increase in total phenotypic variance, the same increase in MZ covariance (hence no increase in correlation) and the same increase for DZ twins. Functionally, with the MZ and DZ covariances increasing by equal amounts, assortative mating will be estimated as part of the shared environment variance in the uncorrected classical twin study. It should be noted that appropriate modeling of twin–parent data will yield estimates of heritability that include a portion due to the effects of assortment.

Parent–offspring covariances can be used to identify several alternative parameters. When environmental transmission between generations is assumed

to be absent, the parent–offspring covariance may be used to identify genetic dominance, as parents and their offspring do not share genetic dominance deviations (*see* **Genotype**). It seems naive to the behavioral scientist to suppose that human parents, who expend much effort in rearing their offspring, do not influence the environment of their children. A genetically informative design, such as twins and their parents or a full adoption study, is required to discriminate between genetic and environmental transmission from parent to child. Path models for mixed environmental and genetic transmission in the twin–family design appear to have been described first by Fulker [13]. Of these models, those that involve an effect of the parents' phenotypes on their offspring ($P \rightarrow$ E transmission) generate *genotype–environment covariance* because the genes and the environment have a common origin (parental genes affect both parental phenotype, and hence children's environment as well as children's genotypes). Genotype–environment covariance is typically assumed to be at equilibrium over generations, yielding a nonlinear constraint among the parameters of the model.

Much parent–child environmental transmission is modeled in a univariate fashion, e.g. a parent's body mass is assumed to form part of the environment for their children's body mass. Transmission might, however, operate indirectly via other variables, e.g. a parent's dietary preference forms part of the environment for their children's body mass. Multivariate models which overcome this limitation have been described [47]. Twin–parent data are still limited by the assumption that heritability is the same in both generations. While this may be defensible for adult populations where the age of the children from some families overlaps that of the parents in others, it is much more questionable in studies of juvenile twins and their parents.

Beyond twins and parents, the next most obvious extension is twins, their spouses, and their children. Interestingly, twins and their spouses – and in-law data in general – allow the resolution of several alternative models of assortative mating [20]. Of particular note is the distinction between phenotypic homogamy – a matching of the phenotypes of spouses – from social homogamy, where there may be some social stratification or other environmental basis for spouse similarity. These models have quite different consequences for genetic and environmental sources of variation, so incorrect modeling of marital resemblance can give rise to biased estimates, especially when the mate resemblance is high.

A great advantage of twins and their children is that both generations contain a genetically informative design – the classical twin study in the parental generation, and siblings, cousins, and half-siblings related through MZ twins in the offspring generation. Thus a test of equality of heritability over generations is possible by a likelihood ratio test. If heritability varies continuously over the lifespan, and different genetic and environmental factors operate at different ages, then longitudinal data would be needed to quantify these changes.

Recently, models for twins, their parents, spouses, siblings, and children have been devised and applied [50]. Initially, these models were fitted to z-transformed correlations using a weighted least-squares procedure, but more recently Mx has been used to fit the models to the raw data, enabling statistically appropriate maximum likelihood analysis of pedigrees of irregular size and structure.

Measured Genotypes in Studies of Twins

Assessments of the genotype, such as **blood groups**, have long been used to help distinguish MZ from DZ twins [35]. More recently, greater precision has been obtained through **polymorphic** markers, against which questionnaire methods have proved approximately 95% accurate. Beyond **zygosity determination**, DZ twins can be regarded as a special type of sibling, where age and intrauterine effects have been matched. As such, they are suitable for studies of genetic **linkage** and association.

Genetic marker studies fall into three broad categories: studies of candidate loci, studies of linkage, and studies of association. A candidate locus is a specific region of the genome that is thought to cause phenotypic variation. DZ twins, who may share zero, one, or two genes identical by descent (IBD) at this locus, can yield information about the locus' effects, but MZ twins, who share two alleles IBD at every locus (somatic mutations notwithstanding), are uninformative about the effects of the candidate locus [37].

Studies of genetic linkage use data from highly polymorphic genetic markers approximately evenly

spaced along the genome. Two branches of linkage studies concern binary traits – especially putative genetic disorders – and quantitative traits. Again, DZ twins are informative for linkage, whereas MZ twins provide information to resolve background genetic from common environment effects. Several approaches to the analysis of linkage data have been described, from the **regression** methods of Haseman & Elston [19] to recent multipoint maximum-likelihood methods [29]. All rely on estimating the probabilities, $p(0)$, $p(1)$, and $p(2)$, that a sib-pair shares zero, one, or two alleles IBD, and the association of these probabilities with the phenotypic resemblance. These probabilities may be estimated by a variety of methods; those of Kruglyak & Lander [29] are currently popular. There are two main ways of using the probabilities: separately to weight the likelihood under different models, or jointly using the summary statistic $\hat{\pi} = 0.5p(1) + p(2)$. In addition, there are two main ways to utilize univariate data from sib-pairs or DZ twins: signed intrapair differences or raw data. Intrapair differences may be convenient when selected samples are used, but they carry a cost of loss of information and hence statistical power. Similarly, use of $\hat{\pi}$ can simplify data analysis but lose statistical power, although – in some cases at least – less so than the use of intrapair differences [14].

Structural equation modeling can clarify the use of genetic marker data to detect the effects of quantitative trait loci, and provides a straightforward extension to the multivariate case. Figure 3 shows path diagrams for the alternative approaches with $\hat{\pi}$ and weighted models. The likelihood maximized with the $\hat{\pi}$ approach is based on the multivariate normal pdf, but the predicted population covariance matrix $\mathbf{\Sigma}$ changes for each sib-pair, according to the $p(i)$ values. The log likelihood of the weighted model is given by

$$L_{\mathrm{M}} = \log \sum_{i=0}^{2} p_i L_i,$$

where L_i is the likelihood under the model for siblings that share i alleles IBD, and p_i is the probability based on the marker data that the siblings share i alleles IBD. Likelihood for mixtures of

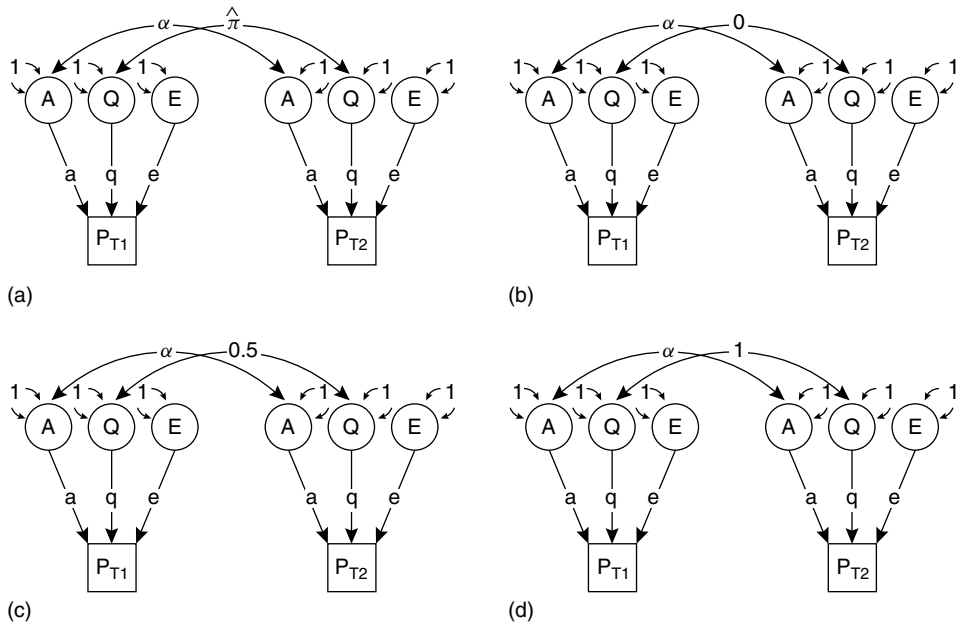

Figure 3 Models for quantitative trait locus effects (Q) in data from monozygotic (MZ) or dizygotic (DZ) twins reared together. Additive polygenic background (A_i) and specific (E_i) environment latent variables also cause the phenotypes (P_i) in a linear additive structural equation model. Figure (a) shows the use of $\hat{\pi}$ as an estimate of the correlation between QTL effects of siblings; models (b) through (d) are used jointly to compute the likelihood from weighted mixture distributions

normal distributions can be evaluated in the structural equation modeling program Mx [38].

Estimates of the path coefficient in Figure 3 from **Q** to the phenotype give an indication of the impact of the putative QTL on the phenotype, and likelihood-based confidence intervals may be obtained to judge their statistical significance. A formal likelihood ratio test may be used for this purpose by fixing the parameter q to zero and comparing the **goodness of fit** under the two models. An alternative test is available through the LOD score, being the log of the odds under the model where the sibling IBD 0, 1, and 2 probabilities are fixed at 0.25, 0.5, and 0.25, respectively, against the model where the probabilities are set to their estimated values. The log likelihood has well-known distributional properties for the multivariate case (where **Q** affects multiple traits) and is therefore a natural choice. It should be noted that there remain problems with the method in that the likelihood ratio does not asymptote exactly to χ^2, so alternative methods using **bootstrapping** may be preferred.

Problems of the Twin Method

Several assumptions of the twin method are open to question. Most of these may be tested empirically either within the twin study itself, by reference to population statistics, or through expansion of the twin study to include other relatives.

Representativeness

A general problem with any **observational** or **experimental study** is that the sample collected may not be representative of the population, and therefore any conclusions drawn would not necessarily generalize to the population. Of course, studies that use volunteer samples always run the risk of being unrepresentative of nonvolunteers. In twins, some information concerning the degree of volunteer bias can be obtained by comparison of pairs discordant for study participation with concordant participating pairs [40]. This method requires nonzero correlation between twins for volunteering, which is commonly observed.

Obstetric Complications

A particular concern with twin data is that their uterine development is unusual, and that this has lasting effects on development. However, these effects, if they exist, are hard to detect because the means and variances of twins are comparable with population norms in many different domains, from personality and psychopathology to body mass index and cardiovascular function. There is evidence that twins have lower than average verbal abilities, but this seems to be associated with the social aspect of having a same-aged companion rather than biological complications [35]. One possibility that has not yet been tested thoroughly is the effects of chorionicity (MZ twins may occupy either one or two amniotic sacs, depending on the time in development at which the zygote splits). Systematic ascertainment of twins during pregnancy – such as currently occurs in Belgium – may help address this question.

Sibling Interaction

As mentioned above, twins may have a direct influence on one another during development. If they do, we would predict differences in total variance of twins compared to nontwins [9]. Even within the twin study, if the MZ and DZ correlations differ prior to interaction, then we would expect differences in their total variance. Structural equation modeling of twin data implicitly tests few these effects, for substantial sibling interaction will cause the model to fit badly. Few cases of sibling effects have been observed in empirical studies. Few parental ratings of activity in their children interaction seems to exist, but multivariate analyses and those of behavioral observations suggest that this is a parental contrast (rater bias) effect rather than genuine interaction.

Equal Environments

The "equal environments" assumption requires that MZ and DZ twins share environmental experiences to the same extent. It is often found that MZ twins are dressed more similarly and are treated more similarly than are DZ twins. However, the important factor here is whether or not these similarities lead to appreciable variation in measured phenotypes. Usually this is tested by examining the correlation of absolute intrapair differences with the measure of treatment similarity (contact between twins is amenable to similar methods). More recently, treatment effects have been incorporated into structural equation models [27]. In general, the assumption appears valid for

psychopathology and other behavioral traits [27, 31]. Furthermore, to the extent that MZ twins elicit more similar treatment by others than do DZ twins, variation is correctly estimated as, and is ascribed to, genetic factors, albeit that they are acting through the environment. Effects of this type are sometimes referred to as those of the *extended phenotype* [7].

No Genetic Dominance

The **confounding** of genetic dominance with the common environment is a difficult problem which is best overcome by the addition of further types of family relatives, as described above. Failure of the assumption without test will cause an underestimation of the effects of the common environment; however, twice as much genetic dominance as common environment would be needed to mask it completely.

No Assortative Mating

Tests for assortative mating are best carried out by assessing a sample of parents; as noted above, the parents of twins make an excellent sample for this purpose.

Linearity

Almost all models considered to date assume a linear effect of genotype on phenotype. Nonlinear effects are entirely plausible, but are difficult to test in data from human subjects. In practice, most nonlinear effects carry a substantial linear component, and it is good scientific practice (Occam's razor) to keep the models simple unless further complications are warranted.

The Future of the Twin Method

The rise of molecular genetics led some researchers to infer that the twin study is dead. As may be seen from this article, we believe such reports to be a great exaggeration. While the proportion of funds and research effort devoted to molecular genetics has clearly grown to dwarf that spent on twin studies, the latter continues to grow in absolute terms. Indeed, the effort spent on twin studies seems to be growing faster than traditional epidemiologic areas. Twin studies have the advantage that linkage studies which include MZ and DZ twins can assess the proportion of QTL and non-QTL genetic variance. In addition, there are large **databases** of twin data that have been gathered on a variety of phenotypes worldwide. These are valuable resources from which samples may be specially selected (for extreme phenotypic values) to increase the power of linkage studies.

Finally, it should be said that the best way to study the environment is to use a genetically informative design. Without controlling for genotype – which the twin study allows us to do statistically – putative environmental factors almost always may have a biological component. Thus the twin study will likely play a significant role in the assessment of environmental as well as genetic causes of individual differences and disease.

Twin Concordance

The comparison of similarity, or concordance, for a **binary** trait between monozygotic (MZ) and dizygotic (DZ) twin pairs can be used to test the null hypothesis that genetic factors do not influence the variance of that trait. Under the classic twin model it is assumed that nongenetic factors relevant to the trait variance are shared to the same extent within MZ pairs as they are within DZ pairs, so that greater concordance within MZ pairs is evidence against the null nongenetic hypothesis and in favor of a genetic alternative.

For binary traits there are several measures of association within twin pairs, such as the Pearson **correlation** (which is related to the classic test for independence in a **two-by-two table**), the tetrachoric correlation, the **odds ratio**, and several probabilities conditional on the trait status of one or both twins. The latter conditional probabilities have been referred to traditionally in the twin literature as "concordance rates".

Some methods of estimation allow adjustment for measured factors that might influence trait **prevalence**. This is important. For example, if the expression of the trait depends on age, methods that do not take this into account will give higher estimates of concordance. This is because twins within a pair are perfectly matched for age, whereas twins from different pairs may differ in age. In the classic twin method, failure to adjust for such putative factors would be misleading if those factors were not independent of zygosity. Crude measures that use only the numbers of twins in the cells of the 2×2 table implicitly assume that the MZ and DZ pairs are comparable for such factors.

Statistical Framework and Definitions

Let Y_1 and Y_2 be random variables representing the binary trait status of twin 1 and twin 2, respectively, within the same pair. Often the trait represents disease status, and this situation will be used for illustrative purposes. Let $Y_j = 1$ if twin j is affected, otherwise let $Y_j = 0$, for $j = 1, 2$. For simplicity, let the probability that a twin is affected be the same for both members of a pair, i.e. let $P = \Pr(Y_j = 1)$ be independent of j. Define the joint probabilities as: $P_{11} = \Pr(Y_1 = 1, Y_2 = 1)$, $P_{10} = \Pr(Y_1 = 1, Y_2 = 0) = \Pr(Y_1 = 0, Y_2 = 1) = P_{01}$, and $P_{00} = \Pr(Y_1 = 0 \text{ and } Y_2 = 0)$. Note that

$$P_{11} + P_{10} + P_{01} + P_{00} = 1 \quad \text{and}$$
$$P = P_{11} + P_{10} = P_{11} + P_{01}. \tag{1}$$

The *casewise concordance*, P_c, the probability that one member of a pair is affected given that the other twin is affected, is

$$\begin{aligned} P_c &= \Pr(Y_2 = 1 | Y_1 = 1) \\ &= \Pr(Y_1 = 1 | Y_2 = 1) \\ &= \frac{P_{11}}{P}. \end{aligned} \tag{2}$$

The *pairwise concordance*, P_p, the probability that both members of a pair are affected given that at least one member is affected, is

$$\begin{aligned} P_p &= \Pr(Y_1 = 1 \text{ and } Y_2 = 1 | Y_1 = 1 \text{ or } Y_2 = 1) \\ &= \frac{P_{11}}{P_{11} + 2P_{10}}. \end{aligned} \tag{3}$$

Therefore, casewise and pairwise concordance are two different measures, and the decision of which to work with depends on the question(s) being asked. For example, if as in **genetic counseling** one wants to know the probability that a twin will become affected, given that the other twin is affected, then casewise concordance is appropriate. However, if interest is in predicting the pair disease status when all one knows is that at least one twin is affected, then pairwise concordance is relevant.

The *Pearson correlation* is

$$\begin{aligned} \rho &= \frac{\operatorname{cov}(Y_1, Y_2)}{[\operatorname{var}(Y_1)\operatorname{var}(Y_2)]^{1/2}} \\ &= \frac{P_{11} - P^2}{P(1 - P)} \\ &= \frac{P_c - P}{1 - P}. \end{aligned} \tag{4}$$

Note that

$$P_{jk} = \Pr(Y_1 = j) \Pr(Y_2 = k) + \delta_{jk} \rho D, \tag{5}$$

where $D = P(1 - P)$ and $\delta_{jk} = 1$ if $j = k$, else -1.

The **odds ratio** is

$$\psi = \frac{P_{11} P_{00}}{P_{10} P_{01}}. \tag{6}$$

It can be shown from (1), (5), and (6) that

$$\rho^2 - \rho\left(2 + \frac{1}{K}\right) + 1 = 0, \tag{7}$$

where $K = (\psi - 1)P(1 - P)$.

The *tetrachoric correlation* is the Pearson correlation of a presumed underlying normally distributed "liability" score, which, when dichotomized at appropriate cut-points, gives expected proportions in the four cells that best approximate the observed numbers in the 2×2 table (*see* **Genetic Liability Model**).

Estimation

If all twin pairs in a defined population are sampled at random, estimation of the above measures of association is straightforward. If pairs are studied only because (at least) one twin is affected, the correlations and odds ratio cannot be estimated. The concordances may be estimable, but to do so the process whereby the pairs were "ascertained" needs to be known. If there is complete **ascertainment**, the concordance rate estimator one would naturally use when all pairs are randomly sampled is appropriate; it is an unbiased estimator of the respective conditional probability. When there is incomplete ascertainment, however, this natural estimator is no longer unbiased.

Under Random Population Sampling

Let n_{ij} be the number of twin pairs with $Y_1 = i$ and $Y_2 = j$, $n_{\,\mathrm{d}} = n_{01} + n_{10}$ be the number of pairs discordant for disease, and n be the total number of pairs observed.

The **maximum likelihood** estimates of P and P_{c} are, respectively,

$$\hat{P} = \frac{2n_{11} + n_{\,\mathrm{d}}}{2n} \tag{8}$$

and

$$\hat{P}_{\mathrm{c}} = \frac{2n_{11}}{2n_{11} + n_{\,\mathrm{d}}}. \tag{9}$$

The asymptotic variances of these estimates are

$$\frac{\hat{P}(1 - \hat{P})}{n} - \frac{n_{\,\mathrm{d}}}{4n^2}$$

and

$$\hat{P}_{\mathrm{c}}^2(1 - \hat{P}_{\mathrm{c}})\left[\frac{1}{n_{11}} - \frac{1}{n_{\,\mathrm{d}}}\right],$$

(see [1, Appendix C], where in addition an expression for the asymptotic variance of the maximum likelihood estimate of ρ is given).

Smith [2] presents methods for interpreting the casewise concordance (referred to there as the "proband concordance rate"; see below) in terms of an estimate of the tetrachoric correlation, and a standard error.

The square of the maximum likelihood estimator of ρ is X^2/n, where $X^2 = (n_{11}n_{00} - n_{10}n_{01})^2 n \div [(n_{00} + n_{01})(n_{00} + n_{10})(n_{01} + n_{11})(n_{10} + n_{11})]$ is Pearson's χ^2 statistic (*see* **Chi-square Tests**) for the 2×2 table of disease in pairs with $n_{10} = n_{01} = 1/2n_{\,\mathrm{d}}$. This provides a simple approximate χ_1^2 test of the hypothesis $\rho = 0$.

Sampling of Affected Pairs Only

Suppose that pairs are observed only if one or both twins are affected. Under complete ascertainment, the maximum likelihood estimate of P_{c} is

$$\hat{P}_{\mathrm{c}} = \frac{2n_{11}}{2n_{11} + n_{\,\mathrm{d}}}, \tag{10}$$

and for large samples the standard error is approximately $[\hat{P}_{\mathrm{c}}(1 - \hat{P}_{\mathrm{c}})(2 - \hat{P}_{\mathrm{c}})/[2n_{11} + n_{\,\mathrm{d}})]^{1/2}$.

The maximum likelihood estimator of P_{p} is

$$\hat{P}_{\mathrm{p}} = \frac{n_{11}}{n_{11} + n_{\mathrm{d}}}, \tag{11}$$

with standard error $[\hat{P}_{\mathrm{p}}(1 - \hat{P}_{\mathrm{p}})/(n_{11} + n_{\mathrm{d}})]^{1/2} = [n_{11}n_{\mathrm{d}}/(n_{11} + n_{\mathrm{d}})^3]^{1/2}$.

Under incomplete ascertainment, for the n_{11} pairs concordant for disease a distinction must be made between those $n_{11\mathrm{D}}$ *doubly* ascertained pairs in which both twins were found to be affected in the original sampling from the population, and those $n_{11\mathrm{S}}$ *singly* ascertained pairs in which only one member was found to be affected in the original sampling, and the other was subsequently found to be affected only on further examination, for whatever reason. Therefore $n_{11} = n_{11\mathrm{D}} + n_{11\mathrm{S}}$. The ascertainment probability, π, is the probability that an affected twin will be identified from the original sampling from the population. Its maximum likelihood estimator is

$$\hat{\pi} = \frac{2n_{11\mathrm{D}}}{2n_{11\mathrm{D}} + n_{11\mathrm{S}}}. \tag{12}$$

The *probandwise estimator* is

$$\hat{P}_{\mathrm{pr}} = \frac{2n_{11\mathrm{D}} + n_{11\mathrm{S}}}{2n_{11\mathrm{D}} + n_{11\mathrm{S}} + n_{\mathrm{d}}}. \tag{13}$$

Therefore, whereas under complete ascertainment $\hat{P}_{\mathrm{c}}$ is the maximum likelihood estimator of the casewise concordance, P_{c}, under *incomplete* sampling the maximum likelihood estimator of P_{c} is $\hat{P}_{\mathrm{pr}}$. $\hat{P}_{\mathrm{c}}$ given in (10) becomes $(2n_{11\mathrm{D}} + 2n_{11\mathrm{S}})/(2n_{11\mathrm{D}} + 2n_{11\mathrm{S}} + n_{\mathrm{d}})$, which is not equal to $\hat{P}_{\mathrm{pr}}$. This shows that under incomplete ascertainment $\hat{P}_{\mathrm{c}}$ is a biased estimator of P_{c}. If π is close to 1, however, the bias is small.

The asymptotic variances of $\hat{\pi}$ and $\hat{P}_{\mathrm{pr}}$ are

$$\hat{\pi}^2(1-\hat{\pi})^2\left[\left(\frac{1}{n_{11\mathrm{D}}}\right) + \left(\frac{1}{n_{11\mathrm{S}}}\right)\right]$$

and

$$\hat{P}_{\mathrm{pr}}(1-\hat{P}_{\mathrm{pr}})^2\left\{1 + \left[(4n_{11\mathrm{D}} + n_{11\mathrm{S}})n_{\mathrm{d}} / (2n_{11\mathrm{D}} + n_{11\mathrm{S}})^2\right]\right\}/n_{\mathrm{d}}.$$

Unfortunately, the difference between the concordance in the population (in statistical parlance a *parameter*) and the concordance *estimator* based on the observed numbers of pairs sampled, has usually been obfuscated in the twin literature through use of the same notation for both entities.

In summary, therefore:

1. Under random or complete ascertainment:
   (a) the casewise estimator is unbiased for the casewise concordance, and
   (b) the pairwise estimator is unbiased for the pairwise concordance.
2. Under incomplete ascertainment:
   (a) the casewise estimator is biased for the casewise concordance, and
   (b) the pairwise estimator is biased for the pairwise concordance, but
   (c) the probandwise estimator is unbiased for the casewise concordance.

Taking into Account Main Effects of Measured Variables on the Trait Mean

As mentioned at the start, the trait mean may depend on measured factors, and inference about the binary trait covariance (concordance) may differ depending on whether or not these are taken into account. The maximum likelihood methods can be extended to allow the parameter P to depend on these factors, introducing a new set of parameters. By using a numerical maximization routine all parameters can be straightforwardly estimated, allowing the twin concordance to be estimated while adjusting the trait prevalence for covariates. Furthermore, the twin concordances can also be estimated as functions of measured factors, such as zygosity, age, sex, cohabitation status, years living apart; see [1]. This allows for a more critical appraisal of the null and alternate genetic hypotheses.

Twin Registers

Twins offer unusual and interesting opportunities for biomedical research [7, 19]. In the classic (and widely used) twin study design the degree of similarity (concordance) of identical (presumed monozygotic) and like-sex nonidentical (presumed dizygotic) twin pairs are compared [7] (*see* **Zygosity Determination**). This approach indicates an upper limit to the relative importance of genetic factors, in the context of the prevailing lifestyle and environment, although it has long been recognized that the method cannot rigorously prove genetic causation [14]. However, potential uses of twins extend well beyond the classic twin method to studies in molecular genetics, **environmental epidemiology**, developmental biology and behavioral science. In combination, such research can address the influence of both genetic and environmental factors, and their interaction [3, 8, 17].

Dizygotic twins who are concordant or highly discordant for disease or a quantitative trait may be studied for **genetic markers** as a special case of the *sib-pair technique* [5, 15]. Monozygotic pairs who are discordant for a particular condition, however rare, offer powerful evidence for nongenetic determinants of disease [4]. Experimental studies based on monozygotic twin pairs are particularly informative for outcomes where a powerful **gene–environment interaction** is suspected [2]. Twins differ from singletons in both intrauterine environment and upbringing. Comparison of adult characteristics of twins and singletons may point to long-term effects of these unusual early experiences [1]. Certain experiences which are unique to twins, such as the occurrence of death or disease in a co-twin, may also deserve special study.

The rarity of twins in general population samples poses a problem for research studies focusing on dichotomous disease outcomes, rather than continuously measured physiological, psychological or other variables. Twin series based on volunteers or respondents to mass media appeals may be **biased** in important respects [7, 14, 19], in particular towards an excess of females and identical pairs concordant for behavioral and disease characteristics [10]. To overcome these problems, national twin registers have been compiled in Sweden [13], Norway [11], Finland [9], and Denmark [6, 12]. No national twin register exists in the UK, although the UK shares with Scandinavian countries the basic ingredients required to create one: a near-complete population register and identity numbers allocated at birth or in other ways which are informative with regard to twin status [18].

Work with the Scandinavian registers has shown that, among adults and older children, zygosity can be determined reliably in most cases by postal questionnaire, enquiring about the visual identity of co-twins [16]. Twins who are visually identical are almost always monozygotic, although a few monozygotic pairs are sufficiently dissimilar to be considered visually nonidentical. This simple method of estimating zygosity can be validated by more objective methods, such as tissue typing or DNA "fingerprinting" (*see* **DNA Sequences**), techniques which may be required to ascertain zygosity reliably in infants and younger children. These more expensive and invasive techniques have yet to be applied systematically to national twin registers, although a selective application, to pairs in whom the questionnaire information is equivocal, may be considered.

DAVID PETER STRACHAN

Two-by-Two Table

A two-by-two table is a 2×2 array of frequencies, obtained by classifying items according to two dichotomous characteristics. We denote by n_{ij} the frequency in row i and column j $(i, j = 1, 2)$. The marginal row totals are $n_{i\cdot} = n_{i1} + n_{i2}$ $(i = 1, 2)$, the marginal column totals are $n_{\cdot j} = n_{1j} + n_{2j}$ $(j = 1, 2)$ and the total frequency is $n = n_{11} + n_{12} + n_{21} + n_{22}$

n_{11}	n_{12}	$n_{1\cdot}$
n_{21}	n_{22}	$n_{2\cdot}$
$n_{\cdot 1}$	$n_{\cdot 2}$	n

Two-by-two tables arise very often in biomedical studies. The following are three examples:

Example 1 Consider a clinical trial (*see* **Clinical Trials, Overview**) to compare two treatments. If the outcome variable has only two categories, say "recovered" and "not recovered", then the results can be displayed in a 2×2 table with rows corresponding to the treatments and columns to the outcomes. For example, n_{11} is the number of patients who received the first treatment and have recovered.

Example 2 Consider a study to compare men and women with respect to cigarette smoking. Samples of $n_{1\cdot}$ men and $n_{2\cdot}$ women are drawn from the target population, and each person is classified as "smoker" or "nonsmoker". The results can be summarized in a 2×2 table where the rows represent males and females, and the columns represent the two outcome categories.

Example 3 To investigate the association between smoking and a certain lung disease, a sample of n persons is drawn from the target population and each sampled individual is classified with respect to both smoking status (smoker or nonsmoker) and disease status (diseased or nondiseased).

It is important to note a difference between the first two examples and the last one. Examples 1 and 2 represent comparative studies, where the row totals $n_{i\cdot}$, which are the number of patients in each treatment group in Example 1, and the number of persons from each gender in Example 2, have been determined before the beginning of the study. However, Example 3 represents a cross-sectional study, where only the total sample size, n, is fixed in advance, while the marginal totals $n_{i\cdot}$ and $n_{\cdot j}$ are random. We refer to these two situations as case 1 (row totals are fixed, column totals are random) and case 2 (both row and column totals are random), respectively. While most analytical methods for 2×2 tables are the same in both cases, it is important to understand the differences between the two cases for the sake of formulating the questions regarding a specific table and for the interpretation of the results of the statistical analysis. In case 1, the main interest is to compare the two rows with regard to the probability of a specific outcome (i.e. the probability of being in a specific column of the table). Denote by p_i the probability of the first column for an individual in row i $(i = 1, 2)$. Then the main interest is the comparison of p_1 and p_2. In case 2, one is mainly interested in the association between the two characteristics. The natural null hypothesis in this case is that of independence, i.e. that the probability p_{ij} of falling into row i and column j equals the product of the marginal probabilities $p_{i\cdot}$ of row i and the marginal probability $p_{\cdot j}$ of column j. An equivalent formulation of this hypothesis is $p_{11}p_{22} = p_{12}p_{21}$.

Measures of Association and Agreement

Numerous measures of the strength of the association (*see* **Association, Measures of**) between the row and column classifications in a 2×2 table have been proposed over the years. In case 1, one may be interested in the difference $p_1 - p_2$ or in the ratio p_1/p_2. When the first category of the outcome variable represents a disease, then these measures are known as the *risk difference* and the *risk ratio*, respectively (*see* **Relative Risk**). To estimate these measures, one simply replaces each p_i by its natural estimator $n_{i1}/n_{i\cdot}$. In case 2, the most important measure of association in medical applications is the **odds ratio** $p_{11}p_{22}/p_{12}p_{21}$, which can be estimated by the observed odds ratio, $n_{11}n_{22}/n_{12}n_{21}$. The odds ratio is also a useful measure in case 1, where it is defined as $p_1(1 - p_2)/[p_2(1 - p_1)]$. For example, in case-control studies the odds ratio is used as an approximation to the risk ratio, which cannot be measured directly in this kind of study.

A measure of a different type is the **kappa** *coefficient of agreement*. It is used to assess the

amount of agreement between two raters who assign the same item to one of two (or more) categories. This coefficient, which is often used in reliability studies (*see* **Reliability Study**), is defined as follows:

$$\kappa = \frac{p_0 - p_e}{1 - p_e},$$

where $p_0 = p_{11} + p_{22}$ is the probability that both raters classify an item to the same category, and $p_e = p_{1\cdot}p_{\cdot 1} + p_{2\cdot}p_{\cdot 2}$ is the probability of agreement expected by chance.

Tests of Hypotheses

The main hypothesis of interest in case 1 is that the probability of an item being classified into the first column is the same in both rows, i.e. H_0: $p_1 = p_2$. The most commonly used test for this hypothesis is based on the statistic comparing the observed proportions in the two groups:

$$Z = \frac{\hat{p}_1 - \hat{p}_2}{[\hat{p}(1-\hat{p})(1/n_{1\cdot} + 1/n_{2\cdot})]^{1/2}},$$

where $\hat{p}_i = n_{i1}/n_{i\cdot}$ is the estimated probability of the first column in row i, and $\hat{p} = n_{\cdot 1}/n$ is the estimated pooled probability of the first column under H_0. The denominator in the expression for Z is the standard error of the numerator, hence the distribution of Z under H_0 is approximately standard normal as long as the sample sizes are not too small. A one-sided test against the alternative H_1: $p_1 > p_2$ rejects H_0 when $Z \geq z_{1-\alpha}$, where $z_{1-\alpha}$ is the upper 100α percentile of the standard normal distribution. A two-sided test against the alternative H_1: $p_1 \neq p_2$ rejects H_0 when $|Z| \geq z_{1-\alpha/2}$.

From a computational viewpoint, it is more convenient to use *Pearson's χ^2 statistic* (*see* **Chi-square Tests**), defined as:

$$\chi^2 = \frac{n(n_{11}n_{22} - n_{12}n_{21})^2}{n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2}}.$$

The two-sided test rejects H_0 when χ^2 exceeds the upper 100α percentile of the χ^2 distribution with one degree of freedom. Since $\chi^2 = Z^2$, the two tests are equivalent when the alternative is two-sided. In the one-sided case, it is more natural to use the Z test.

In case 2, the main hypothesis of interest is that of independence of the row and column classification variables, i.e. H_0: $p_{ij} = p_{i\cdot}p_{\cdot j}$. It can be shown that Pearson's χ^2 test is appropriate in case 2 as well.

The adequacy of the use of the χ^2 distribution as an approximation to the exact sampling distribution of Pearson's statistic has been investigated by several statisticians. A conservative rule of thumb requires all the expected frequencies under H_0, $e_{ij} = n_{i\cdot}n_{\cdot j}/n$, to exceed 5. A more liberal rule allows one of the expected frequencies to be as small as 1, as long as the other three are at least 5. Other statisticians suggested modifications to Pearson's statistic in attempts to improve the χ^2 approximation for small samples. The most frequently used modification is **Yates's continuity correction**. The Yates-corrected χ^2 statistic is defined as

$$\chi^2_C = \frac{n\left(|n_{11}n_{22} - n_{12}n_{21}| - \frac{n}{2}\right)^2}{n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2}}.$$

This correction is obtained by subtracting $\frac{1}{2}$ from the two frequencies n_{ij} which are larger than the corresponding expected frequencies e_{ij}, and adding $\frac{1}{2}$ to the other two frequencies (which are smaller than the expected frequencies under H_0). Since χ^2_C is always smaller than χ^2, the test based on Yates's correction is more conservative.

An alternative approach to the small sample problem is the use of an *exact test* (*see* **Exact Inference for Categorical Data**). One should note that the term "exact" does not mean that the test has a probability of exactly α of rejecting H_0 when this hypothesis is true. All it means is that the test is based on the exact sampling distribution (under H_0) of a particular test statistic. An exact test may be conditional or unconditional. The difference between these two types of exact tests will be explained in the context of case 1. Under the null hypothesis, the distribution of the observations n_{ij}, and therefore the distribution of every test statistic, depends on the unknown common value of p_1 and p_2, denoted by p. Let T be a test statistic, and suppose that H_0 is rejected for large values of T. Then one must determine a critical value, say $t_{1-\alpha}$, such that $\Pr_{H_0}(T \geq t_{1-\alpha}) \equiv \alpha$. However, this last probability depends on the unknown value of p; hence, it is usually impossible to determine a single critical value which will guarantee a type I error probability of exactly α for every p. One way to overcome this problem is to use the *conditional* distribution of T when the marginal column totals, $n_{\cdot j}$, are fixed at their observed values. This

distribution is independent of p and hence one can find a critical value such that $\Pr_{H_0}(T \geq t_{1-\alpha}|n_{\cdot j}) \equiv \alpha$. Alternatively, one can calculate the conditional P value as $\Pr_{H_0}(T \geq t_0|n_{\cdot j})$, where t_0 is the value of T for the observed table, and then reject H_0 when this conditional P value is less than the nominal α.

The conditional distribution of the cell frequencies when the marginal totals are held fixed is hypergeometric (*see* **Hypergeometric Distribution**):

$$\Pr(n_{11}, n_{12}, n_{21}, n_{22}|n_{\cdot 1}, n_{\cdot 2}) = \frac{\binom{n_{\cdot 1}}{n_{11}}\binom{n_{\cdot 2}}{n_{12}}}{\binom{n}{n_{1\cdot}}}.$$

Therefore, the conditional P value can be calculated as the sum of the hypergeometric probabilities of all the possible 2×2 tables (with the same marginal totals as the observed table) for which the value of T is greater than or equal to the observed value, t_0. The most popular conditional exact test for 2×2 tables is **Fisher's exact test**, where the test statistic T is Pearson's statistic χ^2. It is easy to see that if another test statistic, T' is a monotonic function of T in the conditional sample space, then the conditional exact tests based on T and T' are equivalent. For the one-sided test, n_{11} is a monotonic function of χ^2; hence, the one-sided Fisher test can be based on n_{11}. In the two-sided case, Fisher's test can be based on the absolute difference between the observed and the expected frequencies, $|n_{11} - e_{11}|$, which is a monotonic function of χ^2. (The absolute difference is the same for all four cells.)

To derive the *unconditional* distribution of a test statistic under H_0 one uses the fact that when the column totals are considered random, then n_{11} and n_{21} are independent binomial variables (*see* **Binomial Distribution**) with a common probability p of success. Thus:

$$\Pr(n_{11}, n_{12}, n_{21}, n_{22}; p) = \binom{n_{1\cdot}}{n_{11}}\binom{n_{2\cdot}}{n_{21}} p^{n_{11}+n_{21}} (1-p)^{n_{12}+n_{22}}.$$

If T is, as before, a test statistic and H_0 is rejected for large values of T, then the type I error probability associated with a critical value c is

$$\alpha(c, p) = \sum_{T \geq c} \Pr(n_{11}, n_{12}, n_{21}, n_{22}; p).$$

The summation is over all the possible 2×2 tables (with the fixed values of the row totals and any values of the column totals) for which the test would reject H_0. This critical value depends on the unknown value of the nuisance parameter p. One way to eliminate p is by averaging according to some prior distribution. Alternatively, one can substitute the estimate $\hat{p}$ for p. However, in order to stay within the traditional framework of the theory of testing hypotheses, it seems more natural to require that the size of the test, i.e. the maximum (over p) of the type I error probability, will never exceed the nominal significance level α. Thus, the critical value for the unconditional exact test based on T is the smallest value of c for which

$$\max_{0 \leq p \leq 1} \alpha(c, p) \leq \alpha.$$

Unconditional tests of this type have been discussed and compared by McDonald et al. [10], Suissa & Shuster [11], and Haber [6].

The development of computation technology enabled statisticians to investigate the properties of asymptotic and exact tests for 2×2 tables. Actual type I error probabilities and powers were calculated either by complete enumeration of all possible outcomes or via simulations. The results of these computations lead to a controversy regarding the use of conditional exact tests. The opponents of the conditional exact tests argue that these tests are very conservative and, as a result, their power is much lower as compared with unconditional exact tests. The proponents of the conditional approach have raised several arguments, four of which are presented here:

1. The correct sample space should be the conditional one, since once a particular 2×2 table has been observed, the only other 2×2 tables of interest are those with column totals equal to the observed values of $n_{\cdot 1}$ and $n_{\cdot 2}$. The conditional exact tests are not too conservative when their *conditional* type I error and power are calculated.
2. The column totals do not provide any relevant information regarding the equality of p_1 and p_2, and hence conditioning on these marginal totals should not result in any loss of information.
3. Fisher's exact test, when supplemented by a randomization process to ensure that the size

of the test will be equal to the nominal level of significance (α), is uniformly most powerful among the unbiased tests (UMPU) (*see* **Most Powerful Test**), and therefore the conditional approach provides the "optimal" test.

4. Fisher's exact test seems conservative when one uses a fixed nominal α. However, for most practical purposes one is interested in the P value as a measure of the degree to which the data support H_0, rather than as a tool for deciding whether to "accept" or "reject" the null hypothesis. When tests are compared with regard to their attained P values, Fisher's test is no longer conservative or powerless.

The first argument is a philosophical matter; there is no "correct" or "incorrect" sample space. The second argument seems unconvincing, as the lack of information provided by the column totals is not a sufficient reason to consider them as fixed. The third argument has two major flaws: (i) in practice, nobody uses a random device to decide whether to accept or reject H_0 when the test statistic equals the critical value; (ii) the optimality property in this case is meaningless, since none of the tests used in practice is unbiased. (An unbiased test is one for which the probability of rejecting H_0 is always larger when $p_1 \neq p_2$ than when $p_1 = p_2$.) In fact, there are situations when an unconditional biased test has a larger power than the UMPU test [6]. The fourth argument is incorrect. Calculations have shown [7] that when tests are compared with respect to their attained P values, Fisher's test is still conservative and has a low relative efficiency compared to other tests.

Despite all this, there are two pieces of evidence that suggest that conditioning on the column totals per se is not the cause for conservatism of the conditional tests: (i) the conservatism (and the resulting lack of power) almost completely disappears when larger tables (e.g. 2×3 tables) are considered; (ii) a simple modification of Fisher's test has adequate power even though it is still a conditional test [5]. For an exact test which rejects H_0 for large values of a statistic T, this modified test defines the P value as

$$\Pr(T > t_0) + \tfrac{1}{2}\Pr(T = t_0),$$

where the probabilities are calculated in the conditional sample space. It rejects H_0 when this P value is less than α. This procedure is known as the *mid P value test*. Thus, it seems that the main reason for the conservatism of Fisher's exact test is the very small number of points in the conditional sample space for a 2×2 table, rather than any loss of information resulting from conditioning. For example, when $n_{1\cdot} = n_{2\cdot} = 10$, and a table with $n_{\cdot 1} = 5$ and $n_{\cdot 2} = 15$ is observed, then the conditional sample space has only six points, compared with 121 points in the unconditional sample space. Therefore, one can expect a large difference between $\Pr(T > t_0)$ and $\Pr(T \geq t_0)$, both of which could be used as measures of the amount of evidence for or against H_0.

In summary, is seems that the mid P value test should be acceptable to both proponents and opponents of the conditional approach. It is based on the conditional distribution of the test statistic, but its attained type I error probability is usually close to the nominal significance level and its power is similar to that of unconditional tests.

Sample Size Determination

A common question asked by investigators when designing a study is "How large should our sample be?" Determination of the sample sizes (*see* **Sample Size Determination**) will be discussed here in the context of a comparative study, i.e. case 1. The row totals $n_{1\cdot}$ and $n_{2\cdot}$ represent the sizes of the samples drawn from the two groups compared. It is assumed that Pearson's χ^2 statistic is used to test the null hypothesis $p_1 = p_2$ at a given significance level α, and that the desired power of the two-sided test is $1 - \beta$ when the actual absolute difference between p_1 and p_2 is δ. If nothing is known about the probabilities p_1 and p_2, then the total sample size is minimized with $n_{1\cdot} = n_{2\cdot}$ [9]. However, if the relative magnitude of p_1 and p_2 is known, then it is advantageous to take a larger sample from the group whose p is closer to zero or one [1]. The following discussion is limited to the case of equal sample sizes.

Let m denote the common value of $n_{1\cdot}$ and $n_{2\cdot}$. Suppose first that one has some rough estimates of p_1 and p_2 and let $\overline{p} = (p_1 + p_2)/2$. Then a first approximation to the required sample sizes is [3]

$$m' = \left\{ z_{1-\alpha/2}[2\overline{p}(1-\overline{p})]^{1/2} + z_{1-\beta}[p_1(1-p_1) + p_2(1-p_2)]^{1/2} \right\}^2 \Big/ \delta^2.$$

It turns out that the actual power attained with this value of m is less than the specified value of

$1 - \beta$. Casagrande et al. [2] suggested to adjust m' as follows:

$$m = \frac{m'}{4}\left[1 + \left(1 + \frac{4}{m'\delta}\right)^{1/2}\right]^2.$$

This value of m provides a close approximation to the desired power. Fleiss [3] gives tables of the values of m derived by this method for various combinations of α, $1 - \beta$, p_1, and p_2.

If nothing is known about the actual values of p_1 and p_2, then one can obtain a conservative estimate of the required sample size for each group, m, by replacing each of the three products of the form $p(1 - p)$ in the expression for m' by $\frac{1}{4}$[since $p(1 - p) \leq \frac{1}{4}$ for all $0 \leq p \leq 1$].

There are several other methods for determining the required sample sizes (see [4] for a recent review). A computer program that calculates the sample sizes based on the arcsine transformation is included in the NCSS-PASS package [8]. Software for calculating sample sizes for exact tests can be found in StatXact (see www.cytel.com).

MICHAEL HABER

Two-mutation Carcinogenesis Model

Stochastic models of carcinogenesis were first proposed in the 1950s [1, 2, 34] to explain the observation that the age-specific incidence curves of many human carcinomas increase roughly with a power of age (*see* **Multistage Carcinogenesis Models**). In the four decades since the introduction of these models our understanding of the processes underlying malignant transformation has increased considerably. Yet the basic assumption – that a malignant tumor arises from a single cell that has sustained a small number of critical insults to its genetic apparatus – on which these early models were predicated remains valid today. From the perspective of carcinogenesis modeling, perhaps the most important insight has been the realization that, in addition to heritable changes to the genome (mutations), the kinetics of cell division and apoptosis (programmed cell death) play an important role in carcinogenesis (*see* **Cell Cycle Models**).

In 1971, on the basis of epidemiologic observations, Knudson proposed a model for retinoblastoma, a rare tumor of the retina in children [16]. In contrast to earlier models of carcinogenesis, Knudson's model took explicit account of cell proliferation kinetics. Subsequent work in molecular biology leaves little doubt that the salient features of Knudson's model for retinoblastoma are correct [3]. Knudson's so-called recessive oncogenesis model has been generalized and applied to analyses of both epidemiologic [14, 18, 25, 31] and experimental data [17, 22, 30]. In its modern garb, this model is often referred to as the two-mutation clonal expansion model. The main goal of this article is a brief discussion of this model.

Although there is much that we do not understand about the biological events underlying carcinogenesis, there are some things we do know. Disruption of normal cell proliferation and differentiation are the *sine qua non* of the malignant state. Conversely, as indicated above, there is accumulating evidence that the kinetics of cell proliferation and differentiation in normal and premalignant cells are important in the carcinogenic process. Increases in cell division rates may lead to increases in the rates of critical mutational events, and an increase in cell division without a compensatory increase in differentiation or death leads to an increase in the size of target cell populations, leading to increased probability of malignant transformation. It is these important aspects of the process of carcinogenesis that the two-mutation clonal expansion model attempts to capture.

The two-mutation clonal expansion model has been used for analyses of time-to-tumor data in epidemiologic and experimental studies (*see* **Tumor Incidence Experiments**), and for analyses of data on the number and size distribution of intermediate lesions on the pathway to malignancy in initiation-promotion experiments. The requisite mathematical and statistical development required for these applications is briefly described.

The Model

The version of the two-mutation model discussed here has been widely used for data analysis. Similar models were considered by Armitage & Doll [2], Neyman & Scott [33] and Kendall [15]. A detailed description of the model can be found in Moolgavkar & Luebeck [26]. The development here follows the development in that paper and uses the same notation. The fundamental biological assumptions are: (i) In any tissue there is a pool of cells susceptible to malignant transformation. This pool is generally identified with the stem cell pool in the tissue of interest and may change in size during life. (ii) Malignant tumors are clonal, i.e. they arise from a single progenitor cell that has become malignantly transformed. (iii) Malignant transformation of a susceptible cell is the result of two specific, rate-limiting, hereditary (at the level of the cell) and irreversible events. For a discussion of the biological interpretation of the two events, see Moolgavkar & Luebeck [26] and Moolgavkar & Knudson [25]. The model also provides a natural framework for the interpretation of initiation and promotion, as discussed in [25] and [26]. Succinctly, the first rate-limiting event is identified with initiation, the second rate-limiting event with progression, and the clonal expansion of initiated cells with promotion.

The following assumptions are used in the mathematical development. Let $X(s)$ represent the number of normal susceptible cells in the tissue of interest at time (age) t, and suppose that intermediate cells, i.e. cells that have sustained the first rate-limiting event on the pathway to malignancy, arise from normal

cells as a nonhomogeneous **Poisson process** with intensity $\nu(s)X(s)$, where $\nu(s)$ is the first event rate. Note that although ν and X are not separately **identifiable**, it is preferable to model the two separately because information on one or the other may be available from independent sources. In the time interval $(s, s+\Delta s)$, an intermediate cell divides into two intermediate cells with probability $\alpha(s)\Delta s + o(\Delta s)$; it dies or differentiates with probability $\beta(s)\Delta(s) + o(\Delta s)$ (note that death and differentiation are equivalent events for carcinogenesis because both events remove the cell from the pool of susceptible cells); it divides into one intermediate cell and one cell that has sustained the second event (malignant cell) with probability $\mu(s)\Delta s + o(\Delta s)$; the probability of more than one event is $o(\Delta s)$. In many applications the parameters are assumed to be constant or piecewise constant. In particular, this implies that the distribution of waiting times to cell division and cell death is assumed to be **exponential**.

Some comments on these mathematical assumptions are in order. The cell kinetics of intermediate cells are modeled in primitive fashion. There are entire tomes on the mathematical modeling of the cell cycle and it is clear that cells do not divide or die with exponential waiting times. Nevertheless, in the context of carcinogenesis modeling these simplifications appear to be entirely appropriate as a first approximation. Once a malignant cell is generated it is assumed to give rise to a detectable tumor after a suitable lag time. This assumption is clearly false and there is clearly a time-to-detection distribution. Furthermore, malignant cells undoubtedly execute a birth–death process and as a consequence become extinct with nonzero probability.

The Hazard Function

Let $Y(t)$ and $Z(t)$, represent the number of intermediate and malignant cells, respectively, at time t and let

$$\Psi(y, z; t) = \sum_{j,k} P_{j,k}(t) y^j z^k$$

be the probability **generating function**, with

$$P_{j,k}(t) = \Pr[Y(t) = j,\ Z(t) = k | Y(0) = 0, Z(0) = 0].$$

Then $(Y(t), Z(t))$ is a **Markov Process**, and Ψ satisfies the Kolmogorov forward differential equation

$$\begin{aligned}\Psi'(y, z; t) = \frac{\partial \Psi(y, z; t)}{\partial t} &= (y-1)\nu(t)X(t)\Psi(y, z; t) \\ &+ \{\mu(t)yz + \alpha(t)y^2 + \beta(t) \\ &- [\alpha(t) + \beta(t) + \mu(t)]y\}\frac{\partial \Psi}{\partial y} \qquad (1)\end{aligned}$$

with initial condition $\Psi(y, z; 0) = 1$ [26] (*see* **Stochastic Processes**). $\Psi(1, 0; t)$ is the survival function for this model, and the **hazard** (incidence) function is given by

$$h(t) = -\frac{\Psi'(1, 0; t)}{\Psi(1, 0; t)}. \qquad (2)$$

It follows immediately from the Kolmogorov equation that

$$\Psi'(1, 0; t) = -\mu(t)\frac{\partial \Psi}{\partial y}(1, 0; t)$$

and thus

$$h(t) = \mu(t)\mathrm{E}[Y(t) | Z(t) = 0] \qquad (3)$$

where E denotes the expectation and we have used the relationship

$$\mathrm{E}[Y(t) | Z(t) = 0] = \frac{\partial \Psi}{\partial y}\frac{1, 0; t}{\Psi(1, 0; t)}.$$

If the probability of tumor is small enough, then $\mathrm{E}[Y(t)] \approx \mathrm{E}[Y(t) | Z(t) = 0]$ and $h(t) \approx \mu(t)\mathrm{E}[Y(t)]$. The differential equation, derived from the Kolmogorov equation, for $\mathrm{E}[Y(t)]$ can be readily solved to yield

$$\begin{aligned}h(t) \approx \mu(t) \int_0^t \Bigg\{ &\nu(s)X(s) \\ &\times \exp \int_s^t [\alpha(u) - \beta(u)]\, \mathrm{d}u \Bigg\}\, \mathrm{d}s. \qquad (4)\end{aligned}$$

This approximate solution sometimes has been used for the analysis of epidemiologic data. It is reasonably accurate when tumors are rare, as in epidemiologic data. However, even with epidemiologic data, this approximation could yield misleading results (see below).

The exact hazard function can be obtained by solving the characteristic equations associated with

the Kolmogorov equation. The survival function is given by

$$\Psi(1,0;t) = \exp \int_0^t [y(u,t) - 1]\nu(u)X(u)\,\mathrm{d}u, \quad (5)$$

where, for each $t > 0$, $y(u,t)$ satisfies the Riccati equation

$$\frac{\mathrm{d}y}{\mathrm{d}u} = -\{\mu(u)yz + \alpha(u)y^2 + \beta(u) - [\alpha(u) + \beta(u) + \mu(u)]y\},$$

with $y(t,t) = 1$.

The hazard function is then given by

$$h(t) = -\frac{\Psi'(1,0;t)}{\Psi(1,0,t)} = -\int_0^t \nu(u)X(u)y_t(u,t)\,\mathrm{d}u, \quad (6)$$

where y_t denotes the derivative of y with respect to t.

Suppose now that $0 = t_0 < t_1 < \cdots < t_k = t$, and suppose that the parameters α, β, and μ are piecewise constant, i.e. on (t_{i-1}, t_i) the parameters are α_i, β_i, and μ_i. Suppose, furthermore, that A_i and B_i are the two roots of the polynomial $\alpha_i x^2 - [\alpha_i + \beta_i + \mu_i]x + \beta_i$. It can be easily shown that $0 < A_i < 1 < B_i$. Then, for $u \in (t_{i-1}, t_i)$, $y(u,t)$ can be defined inductively by

$$y(u,t) = \frac{B_i - A_i \dfrac{y(t_i,t) - B_i}{y(t_i,t) - A_i} \exp[\alpha_i(A_i - B_i)(u - t_i)]}{1 - \dfrac{y(t_i,t) - B_i}{y(t_i,t) - A_i} \exp[\alpha_i(A_i - B_i)(u - t_i)]}, \quad (7)$$

with $y(t_k,t) = 1$. The derivative $y_t(u,t)$ is now straightforward, albeit cumbersome, to compute by repeated use of the chain rule. The equations for $\Psi(1,0;t)$ and $h(t)$ can be integrated using the values of $y(u,t)$ and $y_t(u,t)$ computed above. If $\nu(u)$ is piecewise constant too and if, as is often the case, $X(u)$ is taken to be constant, then, in principle, these equations can be integrated in closed form.

Sometimes, the time-scale of interest is not the age of the animal, or time since start of treatment, but the age of *individual* intermediate clones. Then, $(Y(t), Z(t))$ is not Markovian, and the Kolmogorov differential equation does not exist. A second approach, described in [29] can then be used.

Properties of the hazard function are discussed in detail in [11] and [29]. See also [36]. A brief summary is given here. For a general class of multistage models, the hazard function for the kth malignant transformation (given that $k-1$ malignant transformations have already occurred) is given by an expression that is analogous to (3) above:

$$h_k(t) = \mu_n(t)\mathrm{E}[Y_{n-1}(t)|Z(t) = k-1],$$

where $Y_{n-1}(t)$ represents the number of cells in the penultimate stage on the pathway to malignancy and $\mu_n(t)$ is the last mutation rate, i.e. the rate of transition from the penultimate stage into the malignant stage [6]. Then $h_1(t)$ is just the usual hazard function. It can be quite easily shown that, for any k, $h_k(t) > h_{k-1}(t)$. This inequality implies, for example, that the hazard function for a second malignancy is higher than that for the first. This phenomenon has been observed and attributed to biological changes (decrease in resistance) associated with the first malignancy. While this may well be true, it is worth remembering that an increased hazard for a second malignant tumor is a logical consequence of a multistage process.

The approximate expression $h(t) = \mu_n(t)\mathrm{E}[Y_{n-1}(t)]$ has often been used. The Armitage–Doll approximation, for example, retains only the first nonzero term in the Taylor series expansion of this approximate expression [23]. While replacing the conditional expectation in the exact hazard function with the unconditional expectation would appear, at first glance, to lead to a good approximation if the probability of tumor is low, the qualitative behavior of the approximate hazard function is quite different. For example, consider exposure to an environmental carcinogen that increases the hazard by affecting one or more of the parameters of the model. When exposure stops, the exact hazard function eventually approaches the background hazard, whereas the approximate hazard function never returns to background levels [11, 18, 29]. This has important implications for interpretation of epidemiologic data. For example, the relative risk of lung cancer among smokers who quit declines with time since smoking cessation (*see* **Smoking and Health**). It is not

generally appreciated that this phenomenon, which is often attributed to repair, is predicted by multistage carcinogenesis.

For **likelihood** construction and applications to analyses of time-to-tumor data, the reader is referred to the original papers [22, 28, 32]. Identifiability of parameters of the two-mutation clonal expansion model is discussed in publications [8–11]. Likelihoods for case–control studies are discussed in [13, 24]. The impact of covariate measurement errors on parameter estimates is discussed in [12]. Extensions of the model to incorporate more than two mutations can be found in [18, 20, 27, 36, 37].

Number and Size Distribution of Intermediate Lesions

In the two-mutation clonal expansion model, clones of cells in the intermediate compartment can be identified with premalignant lesions that arise in initiation–promotion experiments, which are typically done with the mouse skin or the rodent liver as the target organs. In the rodent liver the lesions of interest are microscopic foci that exhibit typical enzyme alterations characterized by specific stains. The number and sizes of these altered foci (in two-dimensional sections) are generally reported as functions of the doses of agents of interest and time since beginning of exposure. The requisite mathematical quantities for analyses of such lesions have been developed [7, 19], and used for analyses of substantial data sets (e.g. [21, 26], and [32]). Since the observations are made in two-dimensional sections of three-dimensional objects (the foci) stereologic considerations play an important role in the analyses (see, for example, [5] and [35] and the references above). In the mouse skin system, the intermediate lesions are papillomas. These lesions are directly observable, so that the animal does not have to be sacrificed for the data to be collected. Typically, several observations are made on the same animal over the course of the experiment. This leads to correlated longitudinal observations. The reader is referred to the articles by Kopp-Schneider & Portier [17] and Dewanji et al. [4] for more details.

SURESH H. MOOLGAVKAR

Two-phase Sampling

Historical Background

Suitably enough, the theory of two-phase sampling was created by Jerzy Neyman [8] in response to a problem posed at a conference on sampling human populations in April, 1937. Neyman [8] introduces his solution "by describing the problem in much the same form as it was stated to me, without using any mathematical symbols": Simply put, a field survey is to be undertaken to determine the average value of some character of a population; for example, the amount of money families spend on food. As the collection of data requires long interviews by specially trained enumerators, the cost per family is quite high. The cost of the survey is constrained within a specified amount but the sample does not appear to yield an estimate of desired precision because of the great variability of the character. Nevertheless, the character is correlated with a second character that can be determined at a lower cost per family so that a precise estimate of the distribution of this second character is readily obtained. Hence, a more precise estimate of the original character can be found by first estimating the distribution of the second character alone from a large random sample, then dividing this sample, as in stratified sampling, into classes or strata according to the value of the second character and to draw at random from each of the strata a small sample for the costly procedure of measuring the first character.

Neyman [8] called this method *double sampling*, and this term remains in use among statisticians working in the area of quality control and assurance. Survey statisticians, however, tend instead to use the term *two-phase sampling* so that this method is distinguished from *two-stage sampling*. Two-phase sample designs differ from two-stage sample designs in that the stratification occurs after the first sample is collected (i.e. *post hoc*) in the case of two-phase designs rather than before the first sample is collect (i.e. *ante hoc*) in the case of two-stage designs. It is understandably regrettable and a source of confusion that the biometrics literature refers to a two-phase survey sampling design as a two-stage design, as noted by Whittemore [13].

In the case of **genetic epidemiology**, the interest lies primarily with the estimation of means associated with Bernoulli distributed random variables, such as disease prevalence and allele frequencies (*see* **Gene**), rather than economic variables. Nevertheless, two-phase sampling designs are applicable to quantitative phenotypes.

Formulation and Allocation

Assume a finite population size N of which n' are to be selected by a simple random sample without replacement at the first phase of the design. Suppose that there are determined to be K strata with (possibly unknown) population size N_h for the hth stratum. Suppose n'_h sample units are observed to be in the hth stratum in the first phase sample with a sample mean of $\overline{y}_h$. Let $\overline{Y}_h$ denote the population mean and S_h^2 the population variance for the hth stratum. Let s_h^2 denote the usual **unbiased** estimator of S_h^2 based on the n'_h sample units in the first phase. Let n_h denote the sample size for the hth stratum at the second phase. For convenience, let $W_h = N_h/N$, $w_h = n'_h/n'$, and $\nu_h = n_h/n'_h$ with $0 < \nu_h \leq 1$ for all h. Assuming that $\Pr(n'_h = 0) = 0$ for all h, Rao [9] showed that an unbiased estimator of the population mean $\overline{Y} = \Sigma W_h \overline{Y}_h$ is $\overline{y} = \Sigma w_h \overline{y}_h$ with **variance**

$$\operatorname{var}(\overline{y}) = \left(\frac{1}{n'} - \frac{1}{N}\right) S^2 + \sum_{h=1}^{K} \frac{W_h S_h^2}{n'} \left(\frac{1}{\nu_h} - 1\right),$$

where S^2 is the population variance. These results are available elsewhere in the literature, but Rao [9] obtained them under the assumption that the second-phase sample sizes $\{n_h\}$ for the strata are random variables, unlike Cochran [1] who assumed that they are fixed values. Rao [9] further showed that a nonnegative unbiased estimator of $\operatorname{var}(\overline{y})$ is

$$v(\overline{y}) = \frac{1}{Nn'} \left[\left(\frac{N-1}{n'-1}\right) \sum_{h=1}^{K} n'_h s_h^2 \left(\frac{1}{\nu_h} - 1\right) + \left(\frac{N-n'}{n'-1}\right) \left(\sum_{h=1}^{K} \frac{1}{\nu_h} \sum_{j=1}^{n_h} y\{h_j\}^2 - n' \overline{y}^2 \right) \right],$$

provided n' is sufficiently large so that $\Pr(n_n \geq 2) = 1$ for all h. Särndal & Swensson [10] showed that the result for $v(\overline{y})$ continues to be valid if K is a random variable or if there is random nonresponse at the second phase described by a Bernoulli distribution with a fixed but unknown probability of inclusion

within each stratum with the possibility that the probability of inclusion varies among strata.

With respect to the optimal allocation of the first-phase sample size n' and the second-sample sampling fractions $\{\nu_h\}$, the cost function is taken as

$$C = n'c' + \sum_{h=1}^{K} n_h c_h,$$

where c' is usually much smaller than c_h. Since C is a random variable, we take

$$C^* = \mathrm{E}(C) = n' \left(c' + \sum_{h=1}^{K} W_h c_h \nu_h \right).$$

From the Cauchy inequality, the optimal ν_h for the hth stratum for given C^* and $\mathrm{var}(\overline{y})$ is

$$\nu_h = S_h \left[\frac{c'}{c_h \left(S^2 - \sum W_h S_h^2 \right)} \right]^{1/2}.$$

As noted by Singh & Singh [12], it is important to realize that the upper limit on the second-phase sample size is n'_h if randomly sampled without replacement from the first-phase sample. As suggested by Rao [9] in this case for which $\nu_h > 1$, set the corresponding $\nu_h = 1$ and repeat the procedure until all the $\nu_h \leq 1$.

By Rao [9], if the strata weights $\{W_h\}$ are not known, then the subsampling fraction $\nu_h = n_h/n'_h$ varies as a function of the observed value of n'_h. Nevertheless, in this case, replace W_h by its estimate w_h.

Bayesian Approaches

Draper & Guttman [3] assumed that the observations $\{y_{hj}\}$ are normally distributed with independent improper prior distributions for the mean μ_h and variance σ_h^2 of the hth stratum given by

$$p(\mu_h)\,\mathrm{d}\mu_h \propto \mathrm{d}\mu_h, \qquad p(\sigma_h^2)\,\mathrm{d}\sigma_h^2 \propto \frac{\mathrm{d}\sigma_h^2}{\sigma_h^2}.$$

Draper & Guttman [3] further assumed that C, K, and $\{n'_h\}$ are fixed with $\Sigma n_h c_h < C$ but with the prior information concerning the means and variances of the strata available before the first phase and showed that the posterior distribution of

$$T_h = \frac{(n'_h + n_h - 1)(\mu_h - \tilde{\mu}_h)}{\tilde{\sigma}_h}$$

is student's t with $n'_h + n_h - 1$ degrees of freedom where, if $\{x_{hj}\}$ denotes the observations from the first phase,

$$\tilde{\mu}_h = \frac{n'_h \overline{x}_h + n_h \overline{y}_h}{n'_h + n_h},$$

and

$$\tilde{\sigma}_h^2 = \frac{1}{n'_h + n_h} \left[\left(\frac{n'_h n_h}{n'_h + n_h} \right) (\overline{x}_h - \overline{y}_h)^2 + (n'_h - 1)s_h^2 + (n_h - 1)t_h^2 \right]$$

with $\overline{x}_h$ and s_h^2 the usual unbiased estimators of the mean and variance of the h stratum from the first phase and $\overline{y}$ and t_h^2, respectively, from the second phase. Furthermore, Draper & Guttman [3] showed that the posterior distribution of $(n_h - 1)s_h^2/\sigma_h^2$ is $\chi^2_{n'_h - 1}$. From these results concerning the posterior distributions, the posterior exception of $\mu = \Sigma_h W_h \mu_h$ is

$$\sum_{h=1}^{K} W_h^2 \frac{(n'_h - 1)s_i^2}{(n'_h + n_h)(n'_h - 3)}.$$

Choosing the sample size n_h for the h stratum at the second phase subject to $n_h \geq 0$ for all h leads to

$$n_h = \frac{C}{c_h} q_h - n'_h,$$

where

$$q_h = \frac{\left(\frac{n_h - 1}{n_h - 3} \right)^{1/2} W_h s_h \sqrt{c_h}}{\sum_h \left(\frac{n_h - 1}{n_h - 3} \right)^{1/2} W_h s_h \sqrt{c_h}}.$$

There is the possibility that this allocation rule will lead to negative n_h for some strata. This merely indicates that the hth statum has been oversampled. Draper & Guttman [3] discussed an algorithmic adjustment to the optimal allocation rule to compensate for this.

If, on the other hand, the posterior after the first phase is used to provide the prior for the second

phase, then by Draper & Guttman [3], the optimal allocation rule becomes instead $n_h \propto Cq_h/c_h$. Compare this with the optimal allocation rule

$$C\frac{W_h S_h}{\sum_h W_h S_h}$$

of Neyman [8] assuming $\{W_h\}$ are known with n' and $\sum_h n_h$ fixed. This so-called *Neyman allocation* can also be obtained from the expression derived by Rao [9] for $\text{var}(\overline{y})$ using the Lagrange multiplier.

Draper & Guttman [3] also considered the situation when the strata weights $\{W_h\}$ are no longer known but rather follow a Dirichlet prior distribution with parameter v_h corresponding to the hth stratum. In this case, the answer is the same as the case for $\{W_h\}$ known except that the unbiased estimator

$$\tilde{w}_h = \frac{n'_h + v_h}{\sum_h (n'_h + v_h)}$$

replaces W_h everywhere. Note that Jeffrey's prior coincides with the uniform prior (all $v_h = 1$).

For a **multivariate normal** extension to this approach, see Draper & Guttman [4]. Although the approach of Draper & Guttman [3, 4] is suitable for quantitative phenotypes with a normally distributed **likelihood**, it is not suitable for estimation of disease prevalence or allele frequencies for which a solution is given by Zacks [15] assuming a hypergeometric likelihood and a discrete uniform prior distribution for the number of successes out of the number of trials for the hth stratum. For a heterogeneous situation in which the prevalence varies among strata, see the optimal allocation rules of Newbold [7] which assumes the invariant Jeffreys' prior distribution

$$p(P_h) \propto P_h^{-1/2}(1 - P_h)^{-1/2}$$

and a binomial likelihood for the parallel cases comparable to those of Draper & Guttman [3].

Prevalence Estimation and Practical Considerations

For a Bayesian solution to the problem of estimation of prevalence in a two-phase sampling design using a **Markov chain Monte Carlo** method for a Dirichlet conjugate prior distribution for **sensitivity**, **specificity**, and prevalence jointly with a beta posterior distribution, see Erkanli et al. [5].

On the other hand, the results of Neyman [8] and Rao [9] do not assume a distributional form for the likelihood and thus apply to the problem of estimation of disease prevalence. While these results do assume a finite population, the hypothetical case of an infinite population is easily derived as a limiting case.

As discussed by Deming [2], a two-phase design is not necessarily more efficient than a one-phase design, nor is Neyman allocation necessarily more efficient than *proportional allocation*: $n_h \propto w_h$ for all h.

Calculations in Deming [2], suggest that, as a rule-of-thumb, it is only when the ratio of interview cost per sampling unit at the second phase compared with screening cost per sampling unit at the first phase exceeds $6:1$ that two-phase sampling will be more advantageous. Note that the ratio is likely to be high when the screening and stratification is done on the basis of records, typically on the order of $40:1$ or $100:1$ according to Deming [2].

A sample design using Neyman allocation that incorporates an estimate of the proportion of false negatives that is wide of the mark may well yield an estimate of the prevalence with greater variance than the estimate by proportional sampling. Deming [2] also noted that it is easy "to fall into the trap in the planning stages by putting unwarranted credence into an advance estimate" of the proportion of false positives when in fact a large sample or a long history of usage of the exact plan of screening is required. The example of the heavy workload encountered by a psychiatrist interviewing 30 subjects for a pilot study is cited despite the fact that the estimate of a small proportion of false positives in such a small sample is subject to a wide standard error. Whereas, a fairly large preliminary sample will often reveal problems that one would not otherwise foresee, for example, a set of admission records intended to contain individuals only aged 21 to 60 but actually including admissions of age 20 and under.

For a discussion of two-phase sampling designs in the context of prevalence for a rare disease for which all those screened positive in the first phase must ethically be included in the second phase, see Shrout & Newman [11].

For a discussion concerning the estimation of disease prevalence with nonresponse at the second phase, see Särndal & Swensson [10], and Gao et al.

[6] for a representation incorporating a logistic model for nonresponse that is not completely random.

A **maximum likelihood** approach for the multinomial distribution with discussion of options involving the **EM algorithm** and the **bootstrap method** are given in Zhou et al. [16] together with a **likelihood ratio test** for the null hypothesis of completely random nonresponse.

Multistage Sampling in Genetic Epidemiology

One of the greatest challenges to successfully concluding a **disease–marker association** study is heterogeneity in the distribution of alleles among races, ethnic and regional groups (*see* **Bias in Case–Control Studies**). For example, cystic fibrosis (CF) can be caused by many different mutations. The most common mutation in the North American non-Ashkenazi population is $\Delta 508$. The proportion of CF genes that are $\Delta 508$ varies widely among different countries, within a country, and among different ethnic and racial groups. But in the case of CF, these observations were noted after the gene was successfully cloned.

A case–control study using a two-phase design is discussed by Whittemore & Halpern [14] in which men were asked whether they were diagnosed with prostate cancer and whether they had a first degree male relative with prostate cancer at the first phase. The subjects are stratified according to diagnosis and family history in preparation for second-phase sampling. The parameters of interest in this study were prostate cancer hazard rates in carriers and noncarriers and the probability that an arbitrary allele contains a deleterious **mutation**. The study budget could accommodate a second-phase sample of size 570 from the first-phase sample of size 1500. Calculations showed that Neyman allocation of 570 sampling units resulted in little loss of efficiency compared with a complete one-phase sample of 3000 with respect to the variances of the three parameter estimators.

With respect to the theoretical discussion in Whittemore & Halpern [14], the use of the Horvitz–Thompson estimating equation for multiphase sampling is treated in greater detail in Whittemore [13] where it is noted that although it can yield estimates less efficient than the maximum likelihood estimates, substantial efficiency loss appears to occur chiefly when multiphase sampling is unnecessary.

Two-stage Least Squares Regression

This procedure is widely used in econometrics where ordinary **least squares** regression (OLS) gives inconsistent estimators (*see* **Consistent Estimator**) for systems of simultaneous equations if some **explanatory variables** are correlated with errors. Two-stage least squares (2SLS) was proposed by Theil [5] to overcome this difficulty. A description for extensive systems is given by Amemiya [1] but the principle may be illustrated by a two-equation econometrics model. This is discussed more fully by Johnston [3].

If y_t represents consumption expenditure, x_t income and z_t nonconsumption expenditure in period t, where z_t (often called an exogenous or instrumental variable) is determined by external influences such as taxation, interest rates, savings, or mortgage contracts, it may be reasonable to model income and expenditure by the equations

$$y_t = \beta_0 + \beta_1 x_t + \varepsilon_t, \tag{1}$$

$$x_t = y_t + z_t. \tag{2}$$

In more general cases, (2) may contain coefficients and an error term.

We assume that the ε_t for different t are independent and that for all t, $\mathrm{E}(\varepsilon_t) = 0$ and $\mathrm{var}(\varepsilon_t) = \sigma^2$, and that z_t is independent of ε_t. Then, using (1) to eliminate y_t from (2) gives

$$x_t = \frac{\beta_0}{1-\beta_1} + \frac{z_t}{1-\beta_1} + \frac{\varepsilon_t}{1-\beta_1},$$

whence

$$\mathrm{E}(x_t) = \frac{\beta_0}{1-\beta_1} + \frac{z_t}{1-\beta_1}$$

and

$$\mathrm{E}\{\varepsilon_t[x_t - \mathrm{E}(x_t)]\} = \frac{\sigma^2}{1-\beta_1},$$

implying that ε_t and x_t are correlated. The OLS estimate of β_1, obtained from (1) is easily shown to be inconsistent.

In 2SLS, the first stage is to form the OLS estimators, say p_0 and p_1, of intercept and slope, for the regression of x_t on z_t and use this fitted regression to give estimators $\hat{x}_t$ of x_t. In the second stage, these estimators are inserted in (1) in place of x_t, and OLS is applied to the amended equation to estimate β_1. In practice, the two stages may be telescoped and a direct estimate of β_1 obtained as $b = s_{yz}/s_{xz}$, where s_{yz} and s_{xz} denote the usual sums of products of deviations from the mean. Estimators with this structure also occur in procedures described by Barnett [2] which involve instrumental variables in models that allow for errors in explanatory variables (*see* **Errors in Variables**).

Applications outside econometrics are not common, but Permutt & Hebel [4] applied 2SLS using a slightly different model to results of a clinical trial designed to estimate the effect of smoking by pregnant women upon birth weight of offspring. The smokers were randomly allocated to a control and treatment group, and in the latter group intervention measures to discourage smoking were used. Although the original analysis indicated higher birth weights among the treatment group, it did not give an accurate measure of birth weight gain associated with giving up smoking because, despite the intervention, not all women in the treatment group gave up smoking. The authors proposed and justified an alternative model:

$$B = \beta_{01} + \beta_{11} S + \varepsilon_1,$$

$$S = \beta_{02} + \beta_{12} I + \varepsilon_2,$$

where S is the number of cigarettes smoked per day during the eighth month of pregnancy, B the birth weight and I an indicator variable for control or treatment group. Although B does not occur explicitly in the second equation, I, which is related to B, does. A 2SLS analysis was recommended on the basis of evidence that ε_1 and ε_2 were correlated for some individuals because heavy smokers with the same intervention status may tend systematically to have lighter (or perhaps heavier) offspring for reasons other than smoking. This introduces correlation between S and ε_1. Details of the analysis using 2SLS are given in [4].

P. SPRENT

Type-specific Covariates in Survival Analysis

The presentation will be in terms of the **Cox regression model** [3] for survival data, though the concept of type-specific covariates is equally relevant for other regression models.

The Cox regression model in its simplest form states that the **hazard** function $\alpha(t)$ for an individual with covariates $\mathbf{Z}$ has the form

$$\alpha(t) = \alpha_0(t) \exp(\boldsymbol{\beta}'\mathbf{Z}), \tag{1}$$

where $\boldsymbol{\beta}$ is a vector of unknown regression coefficients and the baseline hazard, $\alpha_0(t)$, is an unknown and unspecified hazard function for individuals with covariates $\mathbf{Z} = 0$.

In some cases, however, individuals may experience several types ($h = 1, \ldots, k$) of events, the intensities of which may all be of scientific interest. Examples include the **competing risks** model, where $h = 1, \ldots, k$ refers to different causes of failure, and the Markov illness–death model for a chronic disease, with states $0 =$ healthy, $1 =$ diseased, and $2 =$ dead, and where the types of events may be $h = 01$ (occurrence of disease), $h = 02$ (death without disease), and $h = 12$ (death while diseased) (*see* **Stochastic Processes**). In such cases, an immediate extension of the model (1) would be

$$\alpha_h(t) = \alpha_{h0}(t) \exp(\boldsymbol{\beta}'_h\mathbf{Z}) \tag{2}$$

for events of type h. If, however, some regression coefficients are the same for different types of events, then it is often more convenient to define *type-specific covariates* $\mathbf{Z}_h$, $h = 1, \ldots, k$, and formulate the model as

$$\alpha_h(t) = \alpha_{h0}(t) \exp(\boldsymbol{\beta}'\mathbf{Z}_h) \tag{3}$$

(see, for example, Andersen et al. [1, Section VII.1]).

To illustrate this, consider an example of a competing risks model with two causes of death (A and B) and with covariates sex (S), age (A), and treatment (T). Suppose that S has different effects on causes A and B, A has the same effect on causes A and B, while T only affects A. Then the model formulated as (2) would be

$$\alpha_{\mathrm{A}}(t) = \alpha_{\mathrm{A}0}(t) \exp(\beta_{\mathrm{A}1}S + \beta_{\mathrm{A}2}A + \beta_{\mathrm{A}3}T)$$

and

$$\alpha_{\mathrm{B}}(t) = \alpha_{\mathrm{B}0}(t) \exp(\beta_{\mathrm{B}1}S + \beta_{\mathrm{B}2}A),$$

where $\beta_{\mathrm{A}2} = \beta_{\mathrm{B}2}$. To write the same model in the form (3), type-specific covariates for A and B are defined as follows: for cause A, let

$$Z_{\mathrm{A}1} = S, \qquad Z_{\mathrm{A}2} = 0, \qquad Z_{\mathrm{A}3} = A, \qquad Z_{\mathrm{A}4} = T,$$

and for cause B, let

$$Z_{\mathrm{B}1} = 0, \qquad Z_{\mathrm{B}2} = S, \qquad Z_{\mathrm{B}3} = A, \qquad Z_{\mathrm{B}4} = 0.$$

Then the covariate vector $\boldsymbol{\beta}$ in (3) is

$$\boldsymbol{\beta}' = (\beta_{\mathrm{A}1}, \beta_{\mathrm{B}1}, \beta_{\mathrm{A}2} = \beta_{\mathrm{B}2}, \beta_{\mathrm{A}3}).$$

To test the hypothesis $\beta_{\mathrm{A}1} = \beta_{\mathrm{B}1}$ of identical effects of S for causes A and B, one may replace the model above with one where both $(Z_{\mathrm{A}1}, Z_{\mathrm{A}2})$ and $(Z_{\mathrm{B}1}, Z_{\mathrm{B}2})$ are replaced by S. It is seen that, to formulate the model using type-specific covariates, one has to define, for all types $h = 1, \ldots, k$, a p-dimensional covariate vector where p is the total number of regression coefficients to be estimated.

Type-specific covariates provide a flexible means for analyzing multistate survival regression models. Since model (3) is formally identical to a stratified Cox regression model, estimates may be obtained using standard software for this model. Thus, to analyze the model exemplified above based on competing risks survival data, we create a new input file by duplicating each patient's data in the following way: in version A, we include the survival/censoring time, the indicator for failure of type A, and the type-specific covariate vector $\mathbf{Z}_{\mathrm{A}}$, and set the stratum variable to A; in version B, we include the survival/censoring time, the indicator for failure of type B, and the type-specific covariate vector $\mathbf{Z}_{\mathrm{B}}$, and set the stratum variable to B. An example of this is described in detail by Andersen & Keiding [2].

PER KRAGH ANDERSEN

Unbiasedness

The term *unbiasedness* is used in somewhat different senses in the theories of **estimation** and **hypothesis testing**, with a unified interpretation in **decision theory**.

Unbiased Estimation

There is usually more than one way to estimate a parameter. Applying alternate estimation procedures to the same data set, it is possible to obtain distinct estimates of the same quantity. Making an informed choice among such estimates may be difficult or impossible if the choice is to be made simply on the basis of the estimates themselves, particularly if little is known about the quantity being estimated (the *estimand*). The choice must be governed by the typical performance of the estimators that produced the estimates.

It is helpful to imagine a large collection of hypothetical data sets, replicates obtained under essentially similar conditions to those which generated the data at hand. In application to these, a single estimator produces a collection of replicate estimates of the same estimand; summaries of these hypothetical replicates provide means for evaluating the performance of the estimator.

In particular, it is desirable that the average of the values produced by an estimator be close to the value of the estimand. The difference between the average value of an estimator and the estimand is called *bias*; an estimator is said to be unbiased if its bias is zero.

The existence of an unbiased estimator depends, in varying degrees, on the parameter being estimated and on the nature of the data. We illustrate this in the following examples, supposing that $X_1, X_2, \ldots, X_n$ is a sample of random variables with common distribution function $F(x) = \Pr(X \leq x)$.

Example 1

If F has a finite mean μ, then the sample mean $\overline{X} = (1/n)\sum_i X_i$ is unbiased for μ, without making any assumptions on the parametric form of F, or even whether the Xs are independent.

Example 2

If F has a finite variance σ^2, then the sample variance $S^2 = \sum(X_i - \overline{X})^2/(n-1)$ is unbiased for σ^2 provided that the Xs are independent. However, if the Xs are not independent, S^2 is likely to be biased. For example, if $\mathrm{corr}(X_i, X_j) \equiv \rho$ for all $i \neq j$, the expected value of S^2 is $\mathrm{E}(S^2) = (1-\rho)\sigma^2$.

Example 3

If F is an **exponential distribution**, then $T_p = -\overline{X}\ln(1-p)$ is unbiased for the pth **quantile** of F. The unbiasedness of this estimator is a consequence of the relation between means and quantiles of exponential random variables; T_p is likely to be biased if F is not an exponential distribution.

The criterion of unbiasedness is not without inadequacies, some of which are discussed in the next set of examples (see also [6] and [9]).

Example 4

Unbiasedness is not maintained by transformation. $\mathrm{E}[g(X)]$ is rarely the same as $g[\mathrm{E}(X)]$; this is true if $g(\cdot)$ is linear, but seldom otherwise. Consequently, if $\hat{\theta}$ is unbiased for θ, it is not to be anticipated that $g(\hat{\theta})$ is unbiased for $g(\theta)$: the opposite is usually the case. For example, the unbiasedness of S^2 for σ^2 in Example 2 guarantees that S is biased for σ; $0 < \mathrm{var}(S) = \mathrm{E}(S^2) - [\mathrm{E}(S)]^2 = \sigma^2 - [\mathrm{E}(S)]^2$ implies that $\mathrm{E}(S) < \sigma$.

Example 5

Unbiased estimators may not exist. If X is a **binomial** random variable with index N and success parameter p, unbiased estimators of $\psi(p)$ exist if and only if ψ is a polynomial of degree $\leq N$. Thus, for example, there does not exist an unbiased estimator of the expected number of trials until the next success; that is, $\psi(p) = 1/p$.

In cases such as this, a reasonable biased estimator can be constructed by considering a surrogate parameter for which an unbiased estimator does exist. Setting $\theta = 1/p$, it is easily demonstrated that $\theta = \theta^* - B$, where

$$\theta^* = \sum_{i=0}^{N} (1-p)^i$$

and

$$B = \frac{-(1-p)^{N+1}}{p}.$$

Since θ^* is a polynomial of degree $\leq N$ in p, an unbiased estimator of θ^* exists; namely, $\hat{\theta}^* = (N+1)/(X+1)$. Considered as an estimator of θ, $\hat{\theta}^*$ has bias $B < 0$, which is readily seen to be a negligible fraction of the estimand, for large N. It can be shown that $\hat{\theta}^*$ is a consistent estimator of θ.

The bias of an estimator can sometimes be reduced through the use of **bootstrap** or **jackknife** techniques [2, 3, 8].

Example 6

When unbiased estimators exist, they may be obviously unreasonable. Let X be a **Poisson** random variable with mean λ. We consider the problem of estimating $\theta_a = \exp(a\lambda)$, for some known value $a \neq -1$. The unique unbiased estimator of θ_a is $T_a(X) = (a+1)^X$.

For negative values of a, $0 < \theta_a < 1$. However, $a < 0$ implies that $\Pr[0 < T_a(X) < 1] < 1$; there is a chance that the estimator will not fall within the range of the estimand. In fact, for $a \leq -2$, $\Pr[0 < T_a(X) < 1] = 0$, so the estimator never falls within the range of the estimand. A similar problem can occur in estimating **variance components**: unbiased estimators of variance sometimes produce negative estimates.

An alternative estimator of θ_a is $S_a(X) = \exp(aX)$. It can be shown that if $a < 0$, the average squared distance from θ_a to $S_a(X)$ is smaller than that from θ_a to $T_a(X)$. Thus, even though $S_a(X)$ is biased, it has a smaller **mean square error** (MSE) than $T_a(X)$.

Example 7

More than one unbiased estimator may exist. If $X_1, X_2, \ldots, X_n$ are independent and **uniformly** distributed on $(0, \theta)$, then the following estimators are all unbiased for θ : $\hat{\theta}_1 = (n+1)X_{\min}$, $\hat{\theta}_2 = 2X_1$, $\hat{\theta}_3 = 2\overline{X}$, $\hat{\theta}_4 = X_{\min} + X_{\max}$, and $\hat{\theta}_5 = [(n+1)/n]X_{\max}$.

When more than one unbiased estimator exists, selection can be made on the basis of the variance of the estimators. The variances of estimators $\hat{\theta}_1, \ldots, \hat{\theta}_5$ can be shown to be in the proportions

$$n^2 : \frac{n(n+2)}{3} : \frac{n+2}{3} : \frac{2n}{n+1} : 1 ;$$

on this basis, the estimator $\hat{\theta}_5$ is clearly the best. In fact, it can be shown that $\hat{\theta}_5$ is a *uniformly minimum variance unbiased estimator* (UMVUE): no unbiased estimator exists having smaller variance.

Under regularity conditions, a lower bound for the variance of an unbiased estimator is available; an estimator with variance equal to this lower bound is therefore a UMVUE. This "**Cramér–Rao** lower bound" [1] is the reciprocal of the Fisher **information** number $\mathcal{I}(\theta)$: in words, $\mathcal{I}(\theta)$ is the expectation of the squared derivative with respect to θ of the log likelihood. It is possible, however, that a UMVUE does not attain this bound. Construction of UMVUEs is facilitated by the Lehmann–Scheffé theorem, which states that the conditional expectation of an unbiased estimator given a complete **sufficient statistic** is a UMVUE [1].

The existence of a UMVUE does not rule out consideration of other estimators. It is easily demonstrated that if T is unbiased for θ and $\mathrm{var}(T) = a\theta^2$, then $S = T/(1+a)$ has smaller MSE than does T. This result can be used to show that the UMVUE of a normal variance, S^2, has larger MSE than does $[(n-1)/(n+1)]S^2$: in Example 7, the UMVUE $\hat{\theta}_5$ has larger MSE than does $[(n+2)/(n+1)]X_{\max}$.

Other considerations may weigh against the choice of a UMVUE. In Example 7, the UMVUE $\hat{\theta}_5$ has a **skewed** distribution so that, for any sample size $n > 5$, there is a better than 60% chance that the UMVUE exceeds θ. Thus, $\hat{\theta}_4$, while more variable than $\hat{\theta}_5$, may be deemed superior on the basis of the symmetry of its distribution. Since $\Pr(\hat{\theta}_4 \leq \theta) = 0.5$, $\hat{\theta}_4$ is said to be median unbiased.

Unbiased Hypothesis Testing and Risk Unbiasedness

Let $\mathcal{F}_0$ and $\mathcal{F}_1$ denote disjoint collections of distribution functions. A test of $\mathrm{H}_0 : F \in \mathcal{F}_0$ is said to be unbiased against $\mathrm{H}_1 : F \in \mathcal{F}_1$ if, for any $F_0 \in \mathcal{F}_0$ and $F_1 \in \mathcal{F}_1$, $\Pr(\text{Reject } \mathrm{H}_0 | F_0) \leq \Pr(\text{Reject } \mathrm{H}_0 | F_1)$; one is at least as likely to reject the null hypothesis when the alternative is true, as when the null is true. This criterion of unbiasedness is of importance in the theory of uniformly most powerful tests [7].

Unbiased estimation, unbiased hypothesis testing, and other optimal procedures for testing and estimation are unified by the general decision-theoretic concept of *risk unbiasedness* [4, 5] (*see* **Decision**

Theory). Given data $\boldsymbol{X}$ and a **loss function** $L(\theta, d)$, a decision rule $\delta(\boldsymbol{X})$ is said to be risk unbiased if $\mathrm{E}_\theta[L(\theta^*, \delta(\boldsymbol{X}))] \geq \mathrm{E}_\theta[L(\theta, \delta(\boldsymbol{X}))]$ for all θ, θ^*. For example, choosing a squared-error loss function, $L(\theta, d) = [\psi(\theta) - d]^2$, risk unbiasedness of $\delta(\boldsymbol{X})$ is equivalent to unbiasedness of $\delta(\boldsymbol{X})$ as an estimator of $\psi(\theta)$.

Uniform Distribution

We can distinguish between the *discrete* and *continuous* uniform (or *rectangular*) distributions.

Discrete Uniform Distribution

Let X be a **random variable** taking integer values from m_1 to m_2 with the probability function

$$\Pr(X = j) = \frac{1}{m_2 - m_1 + 1}, \quad m_1 \le j \le m_2.$$

There are many examples where a uniform distribution is appropriate. For example, observing a number from tossing a die, or drawing a random digit from 0 to 9, are two common examples.

Mean and Variance

$$\mathrm{E}(X) = \frac{m_1 + m_2}{2},$$

$$\mathrm{var}(X) = \frac{(m_2 - m_1 + 1)^2 - 1}{12}.$$

Continuous Uniform Distribution

Let X be a random variable taking real values from a to b with probability density function (pdf)

$$f(x) = \frac{1}{b - a}, \quad a \le j \le b.$$

It is common to denote $X \sim \mathrm{U}(a, b)$.

Properties

Mean and variance:

$$\mathrm{E}(X) = \frac{a + b}{2},$$

$$\mathrm{var}(X) = \frac{(b - a)^2}{12}.$$

Linear transformation:
For any constants $c > 0$ and d,

$$Y = cX + d \sim \mathrm{U}(ac + d, bc + d).$$

In particular,

$$Y = \frac{X - a}{b - a} \sim \mathrm{U}(0, 1).$$

More Properties of U*(0, 1)*

1. *Probability integral transformation*. Let $F(x)$ be the cdf of a continuous random variable X, then $Y = F(X) \sim \mathrm{U}(0, 1)$.

2. *Inverse cdf transformation*. If the $F(x)$ in point 1 is strictly increasing, then for $Y \sim \mathrm{U}(0, 1)$, $F^{-1}(Y)$ is a random variable with cdf $F(x)$. This result enables us to simulate observations of a continuous random variable that has as its cdf $F(x)$. For example,
   (i) $-\ln Y$ has an **exponential distribution** with mean 1;
   (ii) $\ln[Y/(1 - Y)]$ has a **logistic distribution**;
   (iii) $Y^{1/n}$ has a **beta(n, 1) distribution**.
3. We can also use $Y \sim \mathrm{U}(0, 1)$ to **simulate** observations of a discrete random variable. In particular,
$$X = m_1 + [(m_2 - m_1 + 1)Y]$$
will have a discrete uniform distribution from m_1 to m_2. Here $[x]$ is the largest integer $\le x$.

For additional properties and references related to the uniform distribution, see [2, 3], and [4].

Characterization

For two independent random variables, U and V, Deng & George [1] gave some characterizations of a function g such that $g(U, V) \sim \mathrm{U}(0, 1)$ is independent of V if and only if $U \sim \mathrm{U}(0, 1)$. They also studied several classes of function $g(u, v)$ which yield a U(0, 1), if U and/or V follows a uniform distribution. Examples of such functions are

1. $g_1(u, v) = \min[u/v, (1 - u)/(1 - v)]$,
2. $g_2(u, v) = u + v \bmod 1$,
3. $g_3(u, v) = \min(u, v)/\max(u, v)$,
4. $g_4(u, v) = \log u/(\log u + \log v)$.

Uniform Random Numbers

The use of empirical studies based on computer-generated **(pseudo)-random numbers** has become a common practice in the development of statistical methods, particularly when the analytical study of a statistical procedure becomes intractable. Often there are several generating methods that can be used to produce a random number sequence for a given distribution. Most often these methods are based on the generation of independent variates from the **uniform distribution**, U(0, 1). Usually, pseudorandom integers from 0 to m are generated and then they are transformed into [0, 1] by a scale of $1/m$. Several common uniform number generators are presented here.

Linear Congruential Generator (LCG)

The congruential method, proposed by Lehmer [19], is the most commonly used pseudorandom number generator. A sequence of random numbers is obtained by setting

$$X_i = (BX_{i-1} + A) \bmod m, \quad i \geq 1,$$

where X_i, B, A, and m are nonnegative integers. The quality of the generator is determined by the choice of the increment A, multiplier B, initial seed X_0, and modulus m.

Case 1

If $A = 0$, then it is called a *multiplicative linear congruential generator* (MLCG), in which case it becomes

$$X_i = BX_{i-1} \bmod m, \quad i \geq 1.$$

The maximum period of the sequence $\{X_0, X_1, X_2, \ldots\}$ generated depends on the choice of the modulus m [14, p. 20]:

1. $m = 2^t$, $t > 3$. The maximum period attainable is 2^{t-2}.
2. $m = p > 3$, a large prime number. The maximum period attainable is $p - 1$.
3. Any composite modulus. See Knuth [14, p. 21] for a formula of the maximum period attainable. However, a composite modulus (other than 2^t) is rarely used for a MLCG.

Case 2

If A is not zero, it is possible to achieve the full period m [14, p. 16]. However, according to Marsaglia [24], the "effective period" cannot be greater than the period of the corresponding MLCG. The value of A does not have any effect on the structure of the random number sequence. For example, different values of A give the same results in the spectral test [14, p. 91] and the lattice test [4, p. 28].

In the early days, a popular choice of m was 2^{w-1} (w is the machine word-size) for efficiency considerations. For example, the IBM generator RANDU used $m = 2^{31}$, $B = 65539$, and $A = 0$. However, sequences generated using $m = 2^t$ have a serious drawback: the lower-order bits of X_i are not very random. The Lth least significant bit of the X_i has period equal to $\max(1, 2^{L-2})$. The lowest-order bit is always 1 (odd); the second-lowest-order bit has an order of 1 (if $B = 8k - 3$) or 2 (if $B = 8k + 3$).

Recently, $m = 2^{31} - 1$, a well-known Mersenne prime number [14, p. 390], has become the most popular modulus. It is also the maximum positive number representable in a 32-bit computer. The multiplier $B = 16807$ was suggested by Lewis et al. [20]. It is also used in the scientific library from IMSL. Payne et al. [28] suggested the use of $B = 630360016$, which is commonly used in the SIMSCRIPT II simulation programming language.

Marsaglia [23] was the first to show that successive overlapping sequences of k random numbers fall on at most $(k!m)^{1/k}$ planes, where m is the modulus chosen. This shortcoming may yield grossly wrong results for certain applications, such as in the **Monte Carlo** multiple-integration method.

Shift Register Generator (SRG)

Tausworthe [29] suggested combining L-bits of a binary sequence generated by the linear recurrence relation

$$X_i = (\alpha_1 X_{i-1} + \cdots + \alpha_k X_{i-k}) \bmod 2, \quad i \geq k,$$

for any initial nonzero binary vector $(X_0, \ldots, X_{k-1})$, where $\alpha_j = 0$ or 1 for $1 \leq j \leq k - 1$ and $\alpha_k = 1$.

The necessary and sufficient condition for achieving the maximum period $2^k - 1$ is that the polynomial $f(x)$,

$$f(x) = x^k - \alpha_1 x^{k-1} - \cdots - \alpha_k,$$

is a primitive polynomial over the finite field consisting of $\{0, 1\}$ and $\gcd(L, 2^k - 1) = 1$. For computing efficiency, we usually consider only the primitive trinomial

$$f(x) = x^k + x^h + 1, \quad 1 \le h \le k - 1.$$

Watson [30] tabulated primitive polynomials with degree ≤ 100. A more comprehensive listing of primitive trinomials with modulus 2 was given in [34] and [35].

The advantage of the Tausworthe generator is that if we choose parameter values carefully, then the generated sequences are guaranteed to have a nice property of equidistribution over some multidimensional space. The disadvantage is that it is not efficient because it requires L to be big enough to resemble a continuous random variable over [0, 1]. Lewis & Payne [21] proposed a more efficient method known as the generalized feedback shift register (GFSR) in which numbers are formed by phase-shifted elements of the binary sequence generated by a primitive trinomial. One of the shortcomings of the GFSR is that no theoretical equidistribution over multidimensional space can be proved for all GFSRs. Fushimi & Tezuka [9] gave a necessary and sufficient condition for the k distribution of the GFSR.

Although the Tausworthe shift register generator has a k-space equidistribution property, its empirical performance gives poor results (see, for example, [25]).

Multiple Recursive Generator (MRG)

The MRG is a natural extension of the SRG. It is generated from a degree k primitive polynomial [14, pp. 28–29]

$$f(x) = x^k - \alpha_1 x^{k-1} - \cdots - \alpha_k,$$

with period $p^k - 1$, by

$$X_i = (\alpha_1 X_{i-1} + \cdots + \alpha_k X_{i-k}) \bmod p, \quad i \le k,$$

for any initial nonzero vector $(X_0, \ldots, X_{k-1})$, where p is a large prime number. A polynomial of degree k is said to be a "primitive polynomial modulo p" if this polynomial has a root that is a primitive element of the field with p^k elements. Knuth [14], Zierler [33], Golomb [10], and Lidl & Niederreiter [22] proved and summarized several very important properties about the primitive polynomial and the MRG. The main difference is that the classical SRG uses the modulus $p = 2$, large L (decimation), and large degree, k, whereas the MRG uses small k, $L = 1$, and very large modulus p. Clearly, when $k = 1$, the MRG is reduced to the LCG. Therefore, the MRG includes both the LCG and the SRG as special cases.

Knuth [14, p. 29, conditions (i)–(iii)] gave a search algorithm for finding primitive polynomials. L'Ecuyer & Blouin [17] implemented Knuth's algorithm into a computer program using the generalized spectral tests [14] to find the MRG. The main drawback of Knuth's algorithm is that it involves polynomial modulus arithmetic, and it needs some additional programming work. Deng et al. [7] proposed an efficient search algorithm using only usual arithmetic and no polynomial arithmetic was required.

Example Modulus $m = p = 2^{31} - 1$

A listing of two MRGs and their periods for $k \le 3$ is given in Tables 1–3. For additional listings with other prime modulus and/or a larger k, see [7].

When $k = 1$, period $= 2^{32} - 2 = 2,147,483,646$. As mentioned before, the MRG is reduced to the LCG when $k = 1$. When $k = 2$, period $= 4,611,686,014$,

Table 1 $k = 1$

No.	α_1
1	16 807
2	630 360 016

Table 2 $k = 2$

No.	α_1	α_2
1	7 732	19 398
2	1 644 975 444	1 454 071 610

Table 3 $k = 3$

No.	α_1	α_2	α_3
1	34 482	41 200	20 226
2	1 090 176 785	2 064 992 429	1 835 451 531

132, 420, 608. When $k = 3$, period = 9, 903, 520, 300, 447, 984, 150, 353, 281, 022.

Matrix Congruential Generator (MCG)

The matrix generator, considered by Franklin [8], Grothe [11], and Niederreiter [26], is defined by

$$\mathbf{X}_i = \mathbf{B}\mathbf{X}_{i-1} \bmod p, \quad i \geq 1,$$

where the $\mathbf{X}_i$s are k-dimensional vectors, $\mathbf{B}$ is a $k \times k$ matrix, and p is usually chosen as a large prime number. The maximum period of the MCG is $p^k - 1$. A brief review of the matrix generator is given by L'Ecuyer [16]. Niederreiter [27] derived the "discrepancy" of the sequence generated by the matrix generator. The procedure proposed in Grothe [11] of finding the matrix multiplier $\mathbf{B}$ with the maximum period depends on the availability of the primitive polynomial of degree k. Deng et al. [7] also proposed an efficient algorithm for searching the MRG and MCG.

Example: Modulus $m = p = 2^{31} - 1$

A sample listing of the matrix $\mathbf{B}$ for two MCGs and their periods for $k \leq 3$ is given below. When $k = 1$, the MCG is again reduced to the LCG. When $k = 2$, period = 4 611 686 014 132 420 608.

$$\begin{pmatrix} 17\,943 & 43\,665 \\ 9\,283 & 33\,768 \end{pmatrix},$$

$$\begin{pmatrix} 1\,238\,321\,839 & 1\,336\,529\,607 \\ 995\,629\,446 & 359\,802\,910 \end{pmatrix}.$$

When $k = 3$, period = 9 903 520 300 447 984 150 353 281 022.

$$\begin{pmatrix} 1\,853 & 8\,475 & 32\,652 \\ 25\,307 & 36\,979 & 23\,868 \\ 39\,567 & 34\,683 & 41\,419 \end{pmatrix},$$

$$\begin{pmatrix} 1\,347\,553\,617 & 1\,521\,896\,970 & 1\,565\,253\,766 \\ 1\,454\,071\,610 & 1\,644\,975\,444 & 1\,616\,800\,968 \\ 519\,234\,310 & 1\,463\,044\,428 & 2\,045\,396\,196 \end{pmatrix}.$$

Combination Generator

Consider the following n multiplicative linear congruential generators (MLCGs), proposed by Lehmer [19]:

$$X_{j,i+1} = B_j X_{j,i} \bmod m_j, \quad i \geq 0,$$
$$j = 1, 2, 3, \ldots, n,$$

where $X_{j,0}$ (initial seed), B_j (multiplier) are positive integers and m_j (modulus) are different prime numbers. Wichmann & Hill [31] suggested adding three MLCGs and take the fractional part:

$$U_{W,i} = \sum_{j=1}^{3} \frac{X_{j,i}}{m_j} \bmod 1.$$

Through a simple example, they claimed that this procedure "ironed out" the imperfections in the component variates.

Example

Listed in Table 4 are the three MLCGs used in Wichmann & Hill [31]. The period of this generator is 1cm, $(m_1 - 1, m_2 - 1, m_3 - 1) \approx 6.95 \times 10^{12}$. Zeisel [32] observed that a linear combination of several MLCGs with different moduli is equivalent to another MLCG with a large multiplier ($B = 16\,555\,425\,264\,690$) and a large modulus ($m = 27\,817\,185\,604\,309$).

L'Ecuyer [15] considered a variation of Wichmann & Hill's method:

$$U_{L,i} = \sum_{j=1}^{n} \frac{\delta_j X_{j,i}}{m_1} \bmod 1,$$

where $\delta_j = (-1)^{j-1}$. He proved that if generators are independent of each other and if one of the generators is uniformly distributed, then the combined generator will also be uniformly distributed. L'Ecuyer & Tezuka [18] studied the structural properties for these two classes of the combined random number generators (RNGs) and extended the observation by Zeisel [32].

Table 4

j	B_j	m_j
1	170	30 323
2	171	30 269
3	172	30 307

Empirical and Statistical Justifications

The technique of combining several random number generators to obtain a "more random" generator has been suggested by many authors. Wichmann & Hill [31], Marsaglia [25], Collings [3], L'Ecuyer [15], and Anderson [1] all suggested the use of the combination generator. In fact, as pointed out in [7] the, MRG (and MCG) can also be considered as a combination generator. Marsaglia [25] concluded that the combination generator seems to be the best, according to his empirical study of several popular generators. Several other authors also performed empirical studies about the combination generator. Collings [3], L'Ecuyer [15], and Anderson [1] also found good empirical performance of the combination generators.

Some theoretical support for the combination generator is given in the literature. See, for example, Horton [12], Horton & Smith [13], Brown & Solomon [2], Marsaglia [25], and Deng & George [5]. However, they all made an unrealistic assumption that the individual generators are independent of each other. Deng et al. [6] proved the (asymptotic) uniformity and independence of the combined generator without assuming independence between the generators. Deng et al. [7] also gave some intuitive explanations on the excellent performance of the combination generators.

LIH-YUAN DENG

Unimodality

Let X be an absolutely continuous **random variable** with density function $f(x)$ and corresponding distribution function $F(x)$. We say that X is unimodal if $f(x)$ is either decreasing, increasing, or, more typically, increasing to the **mode** m and then decreasing (in other words, $F(x)$ is convex if $x < m$ and concave if $x > m$). For example, **normal** and **gamma** random variables are unimodal.

Often we are interested in some characteristic θ of X (e.g. **median**, 95th percentile; *see* **Quantiles**). If we know $f(x)$, then θ is easily calculated. If we know that $f(x)$ belongs to some parametric family, then θ is a function of the parameters of the family. If we have no information on $f(x)$, then little can be said about θ.

The question we entertain is: If we know that $f(x)$ belongs to the class of unimodal density functions, what can be said about θ? Two results are described:

1. *Chebyshev's inequality*. If we know that $f(x)$ is unimodal, what can we say about $\Pr(|X - \mu| > x)$?
2. *Interpolation*. If we know that $f(x)$ is unimodal and the values of $F(x)$ at selected points; $F(a_i) = p_i$ for $i = 1, \ldots, n+1$, what can be said about $F(b)$ or $F^{-1}(p)$ for some b and p of interest?

Chebyshev's inequality states that $\Pr(|X - \mu| \geq x) \leq \sigma^2/x^2$. Camp [2] and Meidell [9] showed that, if X is unimodal with mode at 0, then, for any $x > 0$,

$$\Pr(|X| \geq x) \leq \left(\frac{r}{r+1}\right)^r \frac{\mathrm{E}(|X|^r)}{x^r} \quad \text{for any } r > 0. \tag{1}$$

The result for $r = 2$ dates back to Gauss [6]. If X is unimodal and symmetric about μ (i.e. has a mode at μ), then (1) provides the following modification to Chebyshev's inequality:

$$\Pr(|X - \mu| \geq x) \leq \frac{4}{9}\frac{\sigma^2}{x^2}. \tag{2}$$

For example, if $x = 2\sigma$, then Chebyshev's bound is 1/4, while the bound in (2) is 1/9. This bound is achieved by mixing a point mass at $x = \mu$ with a **uniform** density function. In [1] this bound is further refined if, in addition to unimodality and symmetry, smoothness conditions in the form of bounds on $|f'(x)|$ are assumed. Specifically, if $|f'(x)|$ does not exceed the maximum of $|f'(x)|$ for a normal random variable, then the bound is further reduced from 1/9 to 0.067. Similar results for restrictive classes of distributions also appear in [3, 10].

The interpolation result appears in [8]. We present the result for a nonnegative random variable with decreasing density; the result for unimodal densities, which appears in [8], is more complicated and in the same spirit.

Assume that the p of interest is in the jth interval (i.e. $p_j \leq p \leq p_{j+1}$). The bound on the pth quantile is determined by the line connecting (a_i, p_i) to (a_{i+1}, p_{i+1}) with slope $s_i = (p_{i+1} - p_i)/(a_{i+1} - a_i)$. This line crosses the line $y = p$ at $t_{i,p} = (p - p_i)/s_i + a_i$:

$$F^{-1}(p) \geq LB \equiv \begin{cases} \max(0, t_{2,p}), & \text{if } j = 1, \\ \max(t_{j-1,p}, t_{j+1,p}), & \text{if } 2 < j < n, \\ t_{n-1,p}, & \text{if } j = n, \end{cases} \tag{3a}$$

and

$$F^{-1}(p) \leq UB \equiv t_{j,p}. \tag{3b}$$

A reasonable estimate for $F^{-1}(p)$ is $(LB+UB)/2$. The results for the **exponential** random variable with $\lambda = 1$, where $a_i = 0.5i$, $i = 1, \ldots, 8$, are presented in Table 1.

Two other questions have been raised regarding unimodal densities. The first is: When is the sum of two unimodal densities unimodal? If the modes of the two random variables are not the same, then the sum need not be unimodal. For example, the sum of two normal random variables with different means (i.e. modes) is not unimodal if the means are sufficiently different. Even if the modes are the same then it is also necessary (see the example in [5]) and sufficient [11] that the random variables are symmetric.

The other question that has received attention is: What is the relationship between the mode (m), **mean** (μ), and the median (ν) for unimodal densities? Groeneveld & Meeden [7] showed that if $F_{Y_1}(y) \leq F_{Y_2}(y)$, where $Y_1 = (X - \nu)^+$ and $Y_2 = (\nu - X)^+$, then $m \leq \nu \leq \mu$ (*see* **Skewness**).

The reader is referred to Dharmadhikari & Joagdev [4] for a more mathematical treatment of the

Table 1 Interpolation of exponential quantiles

p	$\theta = F^{-1}(p)$	LB	UB	$\hat{\theta} = (LB + UB)/2$	$(\hat{\theta} - \theta)/\theta$
0.5	0.693	0.635	0.723	0.679	−0.020

Union Internationale Contre le Cancer (UICC)

The International Union Against Cancer (UICC) is devoted to all aspects of the worldwide fight against cancer (*see* **Oncology**). Its objectives are to advance scientific and medical knowledge in research, diagnosis, treatment, and prevention of cancer, and to promote all other aspects of the campaign against cancer throughout the world. Founded in 1933, the UICC is a nongovernmental, independent association of more than 270 member organizations in about 80 countries. Members are voluntary cancer leagues and societies, cancer research and/or treatment centers and, in some countries, ministries of health. The UICC has played a major role in the field of cancer biostatistics, notably by creating the TNM committee and the Controlled Clinical Trials Committee.

The TNM committee was created in 1954 with the aim of characterizing and classifying malignancies. The TNM system, devised by Pierre Denoix, was based on:

1. the tumor (T),
2. regional lymph nodes (N), and
3. distant metastases (M).

Precise clinical description and classification of malignant neoplasms by anatomical extent of disease may serve a number of related objectives, namely:

1. to aid the clinician in the planning of treatment.
2. to help the clinician to making a prognosis.
3. to facilitate the exchange of information between treatment centers.
4. to pursue studies on the natural history of cancer.

Finally, the TNM classification improved the quality of **clinical trials**; first, by precisely defining the type of patients concerned, and secondly, by enabling the comparison of treatment efficacy between groups, the stage of malignancy being controlled. The TNM staging system is still being actively developed by UICC.

The Controlled Clinical Trials Committee, created in 1966, was composed of a dozen members (clinicians, surgeons, and biostatisticians) of various nationalities. I was the first President, later succeeded by Robert Flamant. There were two main aims.

The first was to analyze the different methodologic, ethical, and practical problems encountered during clinical trials, and to offer solutions. Committee meetings were held yearly to discuss new aspects. UICC technical reports on a large number of methodologic points were prepared and distributed.

The committee's second objective was to establish a list of all randomized cancer trials throughout the world, either completed or ongoing. This information was aimed at avoiding redundancy: teams planning duplicate trials could either withdraw or join forces. In 1968 the International Information Office was set up under the direction of Robert Flamant; five compilations of clinical trials were published. The International Information Office only ceased its activity when the US National Cancer Institute (*see* **National Institutes of Health (NIH)**) created the International Data Bank (ICRDB), a body with the same vocation.

Independently of these actions, the UICC has conducted and is still conducting a program on epidemiology and prevention. Current studies include in particular Chernobyl Disaster Follow-up, Evaluation of Primary Prevention of Cancer, Familial Cancer and Prevention, and Nutrition, Diet, and Cancer.

In these and other fields of cancer research UICC has made an important contribution.

D. SCHWARTZ

Union–Intersection Principle

Multivariate analysis refers to the branch of statistics in which we attempt to analyze multiple response (or dependent) variables simultaneously. This is in contrast to the simpler situation of univariate analysis in which we focus on only one response variable. Not surprisingly, multivariate analysis is more complex than univariate analysis and this is especially true for **hypothesis testing**. Roy [8] developed the *union–intersection principle* as a tool for solving statistical inference problems in multivariate analysis.

We illustrate the applicability of the union–intersection principle with an example. Suppose we have an experimental situation in which we measure pretreatment and posttreatment values of p response variables on each of n subjects, and we are interested in determining whether the treatment has an effect. For convenience, we let $\boldsymbol{\mu} = [\mu_1 \ldots \mu_p]'$ denote the $p \times 1$ vector of population means for the post- minus pretreatment responses. A treatment effect is apparent if $\boldsymbol{\mu}$ is different from the null vector. Therefore, we form our hypothesis testing problem as

$$\mathrm{H}_0 : \boldsymbol{\mu} = \mathbf{0} \text{ vs. } \mathrm{H}_1 : \boldsymbol{\mu} \neq \mathbf{0} \tag{1}$$

We let $\mathbf{X}_1, \ldots, \mathbf{X}_n$ denote the $p \times 1$ vectors of responses for the subjects $1, \ldots, n$, respectively, and we let $\overline{\mathbf{X}} = (1/n) \sum_{i=1}^{n} \mathbf{X}_i$ denote the $p \times 1$ vector of sample means. We attempt to determine from $\overline{\mathbf{X}}$ whether there is enough evidence to reject H_0 in favor of H_1. If our situation consisted of only one response variable ($p = 1$) that followed a **normal distribution**, then we could apply the **paired *t* test**,

$$t = \sqrt{n} \frac{\overline{X}}{s}, \tag{2}$$

where s is the sample standard deviation. The statistic t in (2) follows a t_{n-1} distribution (**Student's *t* distribution** on $n - 1$ **degrees of freedom**).

However, for the multivariate testing problem in (1) we want to test the **null hypothesis** that simultaneously p response means are different from zero. To apply the union–intersection principle, we let $\mathbf{b} = [b_1 \ldots b_p]$ be any nonnull $p \times 1$ vector. Then $\boldsymbol{\mu} = \mathbf{0}$ if and only if $\mathbf{b}'\boldsymbol{\mu} (= \sum_{i=1}^{p} b_i \mu_i) = 0$ for every nonnull vector $\mathbf{b}$. Analogously, $\boldsymbol{\mu} \neq \mathbf{0}$ if and only if $\mathbf{b}'\boldsymbol{\mu} \neq 0$ for at least one nonnull vector $\mathbf{b}$. This suggests that we consider the following hypothesis testing problem for each nonnull vector $\mathbf{b}$:

$$\mathrm{H}_0(\mathbf{b}) : \mathbf{b}'\boldsymbol{\mu} = 0 \text{ vs. } \mathrm{H}_1(\mathbf{b}) : \mathbf{b}'\boldsymbol{\mu} \neq 0. \tag{3}$$

Over all nonnull vectors $\mathbf{b}$, the null hypothesis described in (1) is equivalent to the intersection of all the null hypotheses described in (3), and the alternative hypothesis in (1) is equivalent to the union of all the **alternative hypotheses** described in (3). In other words,

$$\mathrm{H}_0 \equiv \bigcap_{\mathbf{b}} \mathrm{H}_0(\mathbf{b}) \quad \text{and} \quad \mathrm{H}_1 \equiv \bigcup_{\mathbf{b}} \mathrm{H}_1(\mathbf{b}). \tag{4}$$

This decomposition of the null and alternative hypotheses leads to the chosen nomenclature of the union–intersection principle.

For a particular nonnull vector $\mathbf{b}$, we let $T(\mathbf{b})$ be a statistic for the hypothesis testing problem in (3) and we let $R(\mathbf{b})$ denote its critical region. If we observe $T(\mathbf{b})$ within $R(\mathbf{b})$, then we reject $\mathrm{H}_0(\mathbf{b})$ in favor of $\mathrm{H}_1(\mathbf{b})$. In general, we strive to select a statistic $T(\mathbf{b})$ that has optimal properties, such as uniformly **most powerful**, **unbiased**, etc. If large values of $T(\mathbf{b})$ lead to the rejection of $\mathrm{H}_0(\mathbf{b})$, then H_0 is rejected if any $T(\mathbf{b})$ is in the **critical region** $R = \cup R(\mathbf{b})$. However, this is equivalent to rejecting H_0 for large values of

$$T = \sup_{\mathbf{b}} \{T(\mathbf{b})\}, \tag{5}$$

which we label as the *union–intersection statistic*.

With respect to our particular example, under the assumption that the post- minus pretreatment responses follow a **multivariate normal distribution**, we select $T(\mathbf{b})$ as the paired t statistic, described in (2). For convenience, we use

$$T^2(\mathbf{b}) = \frac{n\mathbf{b}'\overline{\mathbf{X}}\overline{\mathbf{X}}'\mathbf{b}}{\mathbf{b}'\mathbf{S}\mathbf{b}}, \tag{6}$$

where $\mathbf{S}$ is the sample $p \times p$ variance–**covariance matrix**,

$$\mathbf{S} = \frac{1}{n-1} \sum_{i=1}^{n} (\mathbf{X}_i - \overline{\mathbf{X}})(\mathbf{X}_i - \overline{\mathbf{X}})'. \tag{7}$$

It turns out that the vector $\mathbf{b} = \mathbf{S}^{-1}\overline{\mathbf{X}}$ yields the union–intersection statistic

$$T^2 = n\mathbf{X}'\mathbf{S}^{-1}\overline{\mathbf{X}}. \tag{8}$$

The statistic in (8) is known as **Hotelling's T^2** and $(n-p)T^2/p(n-1)$ follows an ***F* distribution** with $(p, n-p)$ degrees of freedom. In the same context, if we let $T^2_{1-\alpha,p,n-p}$ denote the $100\,(1-\alpha)$ upper percentile from Hotelling's T^2 distribution, then the union–intersection principle leads to the following simultaneous probability statement for all linear combinations $\mathbf{b}'\boldsymbol{\mu}$:

$$\Pr\left\{\mathbf{b}'\overline{\mathbf{X}} - \left[\left(\frac{1}{n}\right)\mathbf{b}'\mathbf{S}\mathbf{b}\right]^{1/2} \times T_{1-\alpha,p,n-p} \le \mathbf{b}'\boldsymbol{\mu} \le \mathbf{b}'\overline{\mathbf{X}} + \left[\left(\frac{1}{n}\right)\mathbf{b}'\mathbf{S}\mathbf{b}\right]^{1/2} \times T_{1-\alpha,p,n-p}\right\} = 1-\alpha. \qquad (9)$$

The above examples with multivariate paired data are the simplest applications of the union–intersection principle. The union–intersection principle also provides test statistics and **simultaneous confidence** regions in the context of the multivariate two-sample problem, **multivariate multiple regression**, and **multivariate analysis of variance** [7]. Other applications of the union–intersection principle include testing sphericity of the variance matrix, i.e. proportionality of the variance matrix to the identity matrix [6, 11], and hypothesis testing in multivariate settings when the alternative hypothesis imposes restrictions on the model parameters [1–5, 9, 10, 12].

Unit of Analysis

The *unit of analysis* in a given study is the type of item on which data values are summarized in order to draw statistical **inferences**. It is what "*n*" counts. In **hierarchical** data sets, the unit of analysis specifies a level of aggregation.

Introductory Examples

In many research situations, there is one obvious choice for the unit of analysis. In a simple two-arm **clinical trial**, for example, individual patients are assigned at random to either of two treatments, and an outcome is observed for each patient. The results are expressed in terms of how many patients received each treatment and the distribution of outcomes among the patients in each treatment group. The patient is the unit of allocation, the unit of measurement, and thus the natural unit of analysis.

Ambiguity about the unit of analysis may arise, however, in more complex study designs. Consider the following situations.

1. *Community intervention trials*. A multicommunity study to determine whether a mass-media campaign motivates smokers to quit smoking might involve allocating entire communities *en bloc* to intervention or control groups. The primary endpoint, however, may be whether a person who smoked at baseline had quit smoking by the end of the study period, which is determined at the individual-person level. Communities are the units of allocation, while individual people nested within those communities are the units of observation. Is the unit of analysis the community or the individual? A similar question may arise in **group-randomization** studies more generally.
2. *Multilevel observational studies*. A study that seeks to identify the determinants of compliance with guidelines on mammographic screening in a large managed care plan might measure characteristics of individual female enrollees, attributes and care practices of these women's physicians, and local barriers or conveniences at several clinic sites at which these physicians practice. Individual women are nested within physician practices, which are nested within clinic sites. Data are obtained at all three levels. What is the appropriate unit of analysis (*see* **Multilevel Models**)?
3. *Longitudinal studies*. A study of prognosis among **AIDS** patients may seek to model time trends in CD4 lymphocyte counts, which reflect the effects of AIDS on the immune system. If the CD4 counts are obtained in the course of routine clinical care of each patient rather than at fixed time points dictated by a common protocol, then the number and timing of CD4 count values will vary among patients, and measurement occasions can be considered as nested within (rather than crossed with) patients. Is the unit of analysis the individual CD4 count or the patient?

Study Design Features That Lead to Uncertainty About Unit of Analysis

Four features seem to characterize studies such as these, in which ambiguity arises about the unit of analysis. First, they involve nested (or hierarchical) data arrangements in which there is clustering of subunits within aggregates (*see* **Cluster Sampling**). In the three examples above, individuals are clustered within communities, patients within provider panels within clinic sites, and CD4 test measurements within patients. In general terms, the issue is whether the subunit or the aggregate should be the unit of analysis. Some studies involve two or more levels of nesting, as in the mammography example; however, the underlying analytic issue does not depend critically on the number of levels of nesting, and the discussion here will consider only the simplest, two-level case.

Secondly, at least some of the observations are made at the subunit level. Thus, subunit-level data can either be collapsed to the aggregate level or not, depending on the choice of a unit of analysis. (If only aggregate-level data were available, this decision would not arise; *see* **Ecologic Study**.)

Thirdly, aggregate-level effects on outcome are likely. This phenomenon can be viewed equivalently in two ways: (i) greater variability in outcomes among aggregates than would be expected based on within-aggregate variation; or (ii) less variability within aggregates than would be expected from total variation among subunits across all aggregates. In other words, observations on subunits within a

given aggregate tend to be **correlated**, for any of several reasons. One mechanism is *self-selection*. In the community-trial context, people can choose to reside in a certain community because they share attributes of other community residents and thus "fit in", and those shared characteristics may in turn be predictors of the outcome variable. *Contagion* is another mechanism. Attitudes, norms, and behaviors may be transmissible from person to person within a community, leading to homogeneity. *Shared exposures* constitute yet another mechanism. Patients of a certain physician are all subject to his or her individual practice style. Similarly, observations on the same patient over time are influenced by systematic differences between that patient and other patients as well as by temporal **autocorrelation**. Regardless of the mechanism, because of this kind of clustering, subunit-level observations cannot be assumed to be statistically independent across aggregates.

Fourthly, the particular aggregates studied represent, in some sense, a sample from a universe of similar aggregates to which we may wish to generalize the study findings. In **analysis of variance** parlance, the aggregate-level design factor can be considered a **random effect** rather than a **fixed effect**.

Approaches to Analysis

An Incorrect Approach: Treat Subunit-level Data as Statistically Independent

A naive and incorrect approach to analysis of data from studies fitting this description is to analyze data at the subunit level, treating the subunits as though they were statistically independent across aggregates. Failure of the data to conform to this independence assumption leads to inflated type I error rates (*see* **Hypothesis Testing**), sometimes substantially so [2, 9, 11]. Unfortunately, reviews of published medical research suggest that this incorrect practice is all too common [3, 9, 10].

Analysis Based on Aggregate-level Means

An alternative approach that avoids this pitfall is to use the aggregate, rather than the subunit, as the unit of analysis. Subunit-level data are combined to yield a **mean** value for each aggregate, and these means are then treated as elementary data points to be compared across aggregates. (If there are two or more levels of nesting, further aggregation may be necessary to reach a level of aggregation at which the independence assumption is likely to be satisfied.)

Applying this method to the community-trial smoking-cessation example, a "quit rate" for each study community would first be obtained. These quit rates can be regarded as community-specific mean values of an individual-level indicator variable that takes the value 1 for each smoker who quits smoking and 0 for each smoker who continues to smoke. The success of the community-level intervention would then be assessed by comparing the location of the distribution of quit rates between all intervention and all control communities, possibly using a t-test (*see* **Student's *t* Statistics**) or a **nonparametric** analog.

Basing the analysis on group means has long been advocated for group-randomized studies, such as community intervention trials. It follows the classical Fisherian principle to "analyze as you randomize" [4, 6]. Under the **null hypothesis, randomization** justifies an assumption of independence among the communities within a treatment group, even if no such assumption holds among individuals within each community.

But while analysis based on aggregate-level means circumvents some difficulties, it has important shortcomings. If the number of subunits varies markedly among aggregates, then estimates of aggregate-level means based on many subunits will be more precise than those based on fewer subunits. This difference in precision implies violation of the homoscedasticity assumption (*see* **Scedasticity**) behind many standard statistical tests. In principle, this problem can be circumvented by conducting a weighted analysis, weighting each mean in proportion to the inverse of its estimated **variance** (taking care to include both subunit- and aggregate-level components), but other superior methods of analysis described below obviate the need to do so.

A second major difficulty is that subunit-level **covariates** are not easily accommodated in an analysis based on aggregate-level means. Their omission from the analysis may prevent the removal of **bias** due to subunit-level **confounding** factors and may be a lost opportunity to enhance **power**. For example, if women in some physicians' practices are generally younger than those in other practices, then differences in mammographic screening practices may

Table 1 Abridged ANOVA tables

Source of variation	Symbol	df	MS	E(MS)
For the model given in (1)				
Treatment group	G_i	$g-1$	MS_G	$\sigma_P^2 + p\sigma_C^2 + pc\Sigma G_i^2$
Community	$C_{j(i)}$	$g(c-1)$	MS_C	$\sigma_P^2 + p\sigma_C^2$
Person	$P_{k(ij)}$	$gc(p-1)$	MS_P	σ_P^2
For the model given in (2)				
Treatment group	G_i	$g-1$	MS_G	$\sigma_*^2 + \sigma_C^2 + c\Sigma G_i^2$
Community	$C_{j(i)}$	$g(c-1)$	MS_C	$\sigma_*^2 + \sigma_C^2$

be partly due to patient age differences rather than to practice style. In addition, the ability to detect treatment effects can be enhanced if otherwise unexplained variability in outcomes can be reduced by including patient-level predictors of outcome. Finally, absence of subunit-level covariate data from the main analysis sacrifices the ability to consider **interaction** effects involving those factors.

Multilevel Analysis

Fortunately, several analytic methods are now available that obviate the need to choose between using subunits or aggregates as units of analysis. They accommodate data from two or more levels at once and account properly for the nonindependence of subunits within aggregates.

The *mixed-model analysis of variance* is historically the oldest of these methods, being based on classical analysis of variance (ANOVA) theory. Both subunits and aggregates are treated as random effects. In a community-trial context, a simple statistical model for a continuous outcome variable Y would be:

$$Y_{ijk} = \mu + G_i + C_{j(i)} + P_{k(ij)}, \qquad (1)$$

where Y_{ijk} is the outcome value for person k ($k = 1, \ldots, p$) within community j ($j = 1, \ldots, c$) within treatment group i ($i = 1, \ldots, g$), μ is the grand mean, G_i is the effect of being in treatment group i, $C_{j(i)}$ is the effect of being in community j within treatment group i, and, $P_{k(ij)}$ is the effect of being person k within community j within treatment group i. Basically, a particular value of Y is regarded as the sum of treatment-group, community, and individual-person effects.

Because there is only one observation per person, variation among individuals within a community is implicitly combined with **measurement error** in $P_{k(ij)}$. The model includes two random effects, one at the subunit level and one at the aggregate level: $P_{k(ij)} \sim \mathrm{N}(0, \sigma_P^2)$ and $C_{j(i)} \sim \mathrm{N}(0, \sigma_C^2)$. The one fixed effect is for treatment group: G_i. This simple model includes no covariates at the subunit (person) or aggregate (community) levels.

If the number of individuals per community, p, is assumed to be constant across communities and the number of communities per treatment group, c, is constant across treatment groups, then an abridged ANOVA table for the model given in (1) is shown in the top panel of Table 1. A test of the main study hypothesis about treatment effectiveness ($\mathrm{H}_0 : G_i = 0$ for all i) would be $F = MS_G/MS_C$, with $g-1$ and $g(c-1)$ **degrees of freedom** in the numerator and denominator, respectively, neither of which depends on p.

It is interesting and satisfying to note that, for a balanced study design and in the absence of covariates, an analysis based on community-level means yields the same test statistic for the main study hypothesis. In particular, the corresponding additive statistical model for a community-level mean would be:

$$\overline{Y}_{ij} = \mu + G_i + C_{j(i)} + e_{j(i)}, \qquad (2)$$

where $\overline{Y}_{ij}$ is the mean outcome value for community j within treatment group i, $e_{j(i)}$ is the random error of a community-specific mean, and other symbols are as defined above for the model given in (1). Here, $e_{j(i)} \sim \mathrm{N}(0, \sigma_*^2)$. Because there is only one "observation" (a mean value of Y) per community, σ_*^2 and σ_C^2 cannot be separately estimated, and the expected mean square for community is their sum. But σ_*^2 is the sampling variance of an estimated community-specific mean based on p randomly chosen individuals, while σ_P^2 is the variance of Y in the community from which those individuals were

sampled. Hence $\sigma_*^2 = \sigma_P^2/p$. With this substitution, the F statistics for a treatment-group effect become equivalent in the top and bottom panels of Table 1.

Modern statistical software (*see* **Software, Biostatistical**), such as PROC MIXED in SAS, substitute **restricted maximum likelihood** estimation for classical **least squares** estimation, thus relaxing the need for a balanced study design in order to estimate the parameters of the model given in (1) and to calculate a valid test of the null hypothesis of no treatment-group effect [8].

The flexibility and utility of multilevel modeling is illustrated in several sources describing closely related statistical approaches that accommodate covariates at both the subunit and aggregate levels to explain variation at those levels. Bryk & Raudenbush [1] describe how *hierarchical linear modeling* combines subunit- and aggregate-level linear models into a single framework, with an emphasis on continuous response variables. Hedeker et al. [5], describe *random-effects regression* methods that have been developed to accommodate clustered data with unbalanced designs. **Generalized estimating equations** [7] offer yet another way in which to create multilevel models for outcome variables with nonnormal distributions in a **general linear model** framework.

THOMAS D. KOEPSELL

Univariate Response

The term univariate response is used to refer to a single **response variable** and contrasts with a multivariate response which refers to a number of response variables. Traditionally, **multivariate analysis** considers a number of response variables jointly, and univariate analysis considers a single or univariate response variable.

Many analyses, however, examine the relationship between a response variable and one or more **explanatory variables**. A univariate response may be related to a single, or to multiple, explanatory variables, as can a multivariate response. It is increasingly common in the medical literature to use the term *univariate analysis* to refer to analyses which examine only a single explanatory variable's relationship to a response variable. Similarly, multivariate analysis is often used to refer to analyses like **multiple linear regression** which examine a number of explanatory variables jointly. The term *multifactorial* is sometimes used in the latter situation to avoid confusion, but the context usually makes the intention clear.

VERN T. FAREWELL

University Group Diabetes Program (UGDP)

The University Group Diabetes Program (UGDP) was one of the first **multicenter clinical trials** designed and implemented to evaluate treatments for a chronic disease. It was designed to test the accepted and widely used methods available in the late 1950s and early 1960s for treating adult-onset, noninsulin-dependent diabetes. The three major objectives were: (i) evaluation of the effects of different hypoglycemic treatments (diet, insulin, and oral agents) on the development of vascular complications in patients with adult-onset diabetes; (ii) study of the **natural history** of vascular disease in noninsulin-dependent diabetics; and (iii) development of methods appropriate for the design and conduct of cooperative clinical trials.

Twelve clinics, two lipid laboratories, and a Coordinating Center participated in the study. Each clinic was responsible for recruiting patients, for collecting observations on these patients according to a common study protocol (*see* **Clinical Trials Protocols**) and for providing medical care to each patient enrolled in that clinic. The Coordinating Center was the data repository for all study forms and data. The Coordinating Center staff helped to design the study, were responsible for the inventory, filing, editing, and storing of all study material and had major responsibility for the analysis of study data. The study was funded by grants from the National Institute of Arthritis, Metabolism and Digestive Diseases, US Public Health Service.

Patient recruitment was started in February 1961 and was completed in February 1966, after 1027 patients were enrolled. Follow-up examinations were scheduled through the end of August 1975. Thus patients were followed for 10.0–14.5 years; the mean follow-up for all patients was 12.25 years.

Methods

Patient Eligibility

Patients were considered for enrollment only if the diagnosis of diabetes had been established within the 12-month period preceding the date of the screening examination. In addition, the diagnosis of diabetes had to be confirmed by a glucose tolerance test performed during the screening examination. Each clinic physician was asked to use his best judgment to screen prospective study candidates for absence of life-endangering diseases so as to select patients with a good prognosis for five-year survival. The study design was described in detail in several study reports [9, 10, 11, 13, 16] (*see* **Eligibility and Exclusion Criteria**).

Candidates for the study were placed on a diet with caloric content designed to achieve or to maintain the patient's body weight within $\pm 15\%$ of his/her desirable body weight. The prescribed diet consisted of a fixed proportion of calories derived from fat, protein, and carbohydrates. Each patient was observed for four weeks on treatment with diet alone and only those patients who did not develop major diabetic symptoms, in particular ketosis, were asked to participate in the study. Only the patients who met all of the above requirements and who indicated a willingness to participate, including a willingness to accept any of the treatments under study, were enrolled and allocated to treatment. Initially, patients were asked to give verbal consent after a detailed explanation of the study had been given. Later, all patients including those already enrolled were asked to sign a consent form after the study design and methods were reviewed in detail (*see* **Ethics of Randomized Trials**).

Treatments

Patients were randomly assigned to one of the five treatments listed in Table 1 (*see* **Randomized Treatment Assignment**). There were two insulin treatment groups. The insulin variable treatment was designed to resemble as much as possible the use of insulin in clinical practice. Adjustments in the insulin dosage for patients assigned to the insulin variable treatment group during the course of the study were based on blood glucose values from an abbreviated glucose tolerance test (short GTT). The insulin dosage was to be increased by at least two units per day whenever the fasting blood glucose value obtained from this test was 110 mg per 100 ml or greater and the one-hour value from this test was 210 mg per 100 ml or greater. The fasting value for this test was based on a blood sample drawn from the patient after a

Table 1 Study treatments

Treatment	Abbreviation	Dosage
Insulin variable (U-80 Lente Iletin or other insulins)	IVAR	Amount required to maintain "normal" blood glucose; minimum dose five units per day
Insulin standard (U-80 Lente Iletin insulin)	ISTD	10, 12, 14, or 16 units per day, depending on the patient's body surface
Tolbutamide (Orinase)	TOLB	1.5 g per day
Phenformin[a] (DBI-TD)	PHEN	100 mg per day
Placebo	PLBO	Dosage schedules similar to those used for the oral agents

[a]Added to the study 18 months after patient recruitment started for the other four treatment groups.

12-hour fast. The one-hour value for this short GTT was based on a blood sample drawn 1.5 hours after the patient took his assigned study medication and one hour after ingesting a drink containing 50 g of glucose. The insulin dosage was to be decreased if hypoglycemic episodes were reported by the patient. In the second insulin group, each patient was given a prescription which was based solely on an estimate of the individual's body surface (function of height and weight). The range of dosage was 10–16 units per day.

Two oral agents were studied: tolbutamide, a member of the sulfonylurea family of compounds, and phenformin, a member of the biguanide family of compounds. Tolbutamide was selected because in 1960 clinical experience with this agent was greater than with any of the other sulfonylurea drugs. A dose of 1.5 g per day (1 g in the morning and 0.5 g in the evening) was used for all patients. The dosage of phenformin was 100 mg per day (50 mg before breakfast and 50 mg before the evening meal).

Phenformin was added to the study approximately 18 months after the study had started for the other four treatment groups. When the decision was made, six of the original seven UGDP clinics were so far along with patient recruitment that it was decided not to include phenformin as one of the study treatments in these six clinics. Five additional clinics were recruited for the study when phenformin was added. These five clinics, along with one of the original seven clinics, had allocation schedules providing for assignments to all five treatment groups. In these clinics, three times the number of assignments were made to phenformin as were made to each of the remaining treatment groups. This procedure was used to provide almost the same total number of assignments to phenformin in these six clinics as were made to each of the other four treatment groups in all 12 clinics at the end of patient recruitment. This design feature required that the evaluation of phenformin effects be based on the results for patients in the six clinics administering phenformin rather than the results from all 12 clinics.

Separate **randomization** schedules were used for each clinic, and these schedules were designed to provide balance in the number of patients assigned to the different treatment groups at specified intervals throughout the period of patient recruitment. All treatment allocations were issued by the Coordinating Center. The oral agents were administered in a double-blind fashion; that is, neither the patient nor the physician knew whether the patient was receiving an active drug or placebo.

Examination Schedule

Patients were given an extensive battery of examinations at the time of enrollment and at three-month intervals thereafter. A general clinical review as well as a detailed examination of the eyes, heart, kidney function or peripheral vascular and neurologic systems was performed in conjunction with each quarterly follow-up visit to the study clinic.

Results for Tolbutamide Therapy

The use of tolbutamide therapy was discontinued in June 1969 when it became apparent that there was

an excess cardiovascular mortality for patients in the tolbutamide treatment group compared with the mortality experience for patients in the placebo treatment group as well as compared to patients in either of the two insulin treatment groups (*see* **Excess Mortality**). As soon as possible after June 1969 patients assigned to tolbutamide or placebo tablets were recalled by the clinics to discontinue the prescription for these tablets. A closing date of October 7, 1969, was used for the evaluation of tolbutamide therapy for the first published report on findings for patients treated with tolbutamide [10].

A total of 89 deaths was reported for the four treatment groups considered in the analysis of tolbutamide findings. The number and percentage of patients who died in each of the treatment groups by cause are given in Table 2. As indicated, more patients in the tolbutamide group were observed to have died from all causes, as well as from cardiovascular causes, than in the other groups. The cumulative annual mortality rates per 100 population at risk were computed with **life table** methods, and the results are shown in Figure 1 for all causes as well as for cardiovascular causes. The final judgment regarding the principal cause of death of each deceased study patient was made by a special review team without knowledge of the treatment group to which the patient had been assigned. Their decision regarding principal cause of death was based on information provided in a detailed death report prepared at the clinic (*see* **Cause of Death, Underlying and Multiple**).

Except for blood glucose levels, few differences in evaluations made at scheduled follow-up examinations were observed among the groups treated with placebo and diet, tolbutamide and diet, or insulin and diet [10, 11, 14]. The fasting blood glucose levels in the tolbutamide treated group were lower than the levels in the placebo group and about the same as the levels in the group treated with a fixed dose of insulin. The patients treated with variable doses of insulin had consistently lower levels than the patients in the other three groups (Figure 2).

Most of the excess mortality observed in the tolbutamide treated group over that of patients treated with diet or diet plus insulin appeared to be a result of increased mortality due to myocardial infarction among the tolbutamide treated patients [14]. The mortality for all patients who had at least one myocardial infarction during the course of follow-up was 50% for patients in the tolbutamide group, and 18% for patients in the placebo group, 35% for patients in the insulin standard group, and 40% for patients in the insulin variable group.

Results for Phenformin Therapy

The observed mortality for all causes and from cardiovascular causes for patients assigned to phenformin was higher than the mortality in any of the other treatment groups about two years after the decision concerning tolbutamide. Also, there was no evidence that phenformin was more effective than any of the other treatments in preventing nonfatal

Table 2 Number of deaths by cause, October 7, 1969

Cause	PLBO, $N = 205$	TOLB, $N = 204$	ISTD, $N = 210$	IVAR, $N = 204$

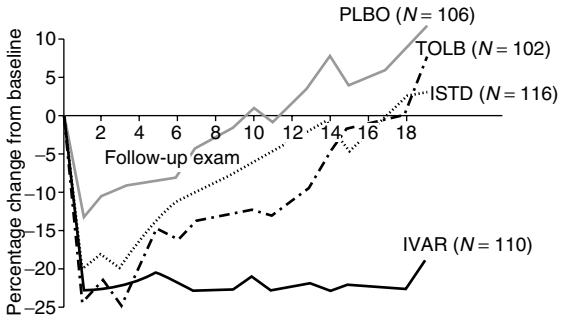

Figure 2 The percentage change in fasting blood glucose levels from baseline to each follow-up examination for the cohort of patients followed through the 19th follow-up examination, as of October 7, 1969

vascular complications. For these reasons, all patients originally assigned to phenformin and those assigned to the corresponding placebo were recalled by the UGDP clinics for a special examination in order to discontinue phenformin or placebo capsules as soon as possible after May 15, 1971, the date of the UGDP decision to discontinue this therapy in the UGDP. A preliminary report on these findings was published based on mortality findings through January 6, 1971, shortly after the decision was made to discontinue phenformin [12]. A more complete report based on data through October 7, 1971, was published later [13], and these results are summarized here.

The number and percentage of patients who died in each treatment group by cause are given in Table 3. The cumulative annual mortality rates per 100 population at risk calculated with life table methods are shown in Figure 3. The mortality results for patients in the two insulin groups were quite similar although the amount of insulin received was different, as specified by protocol. Furthermore, there was no evidence of beneficial or adverse effects for either of the insulin therapies compared to diet alone (placebo group). Therefore, the results in these three treatment groups were pooled to obtain a larger population for comparison with the patients in the phenformin treated group. In the phenformin group, one death was attributed to lactic acidosis, there were also two reported cases of nonfatal lactic acidosis. The possibility that this side effect is a consequence of phenformin therapy had been reported in the literature previously, although there was no convincing proof of causal relationship.

The changes in fasting blood glucose levels during the course of follow-up are shown in Figure 4. There was a large drop in blood glucose levels in all treatment groups after the initiation of treatment, but

Table 3 Number of deaths by cause, October 7, 1971

Cause	PLBO, $N = 64$	PHEN, $N = 204$	ISTD, $N = 68$	IVAR, $N = 65$	PL + INS, $N = 197$

the changes did not persist except in the insulin variable group. Patients in the phenformin-treated group had an increase in both systolic and diastolic blood pressure levels and in heart rate. These adverse effects of phenformin on blood pressure and heart rate in addition to the observed excess mortality led to the discontinuation of phenformin in the UGDP.

Results for Insulin Therapy

A preliminary report of the findings for the two insulin groups was published in 1978 [15] and a more detailed report in 1982 [16]. The number and percentage of patients who died in the two insulin groups are shown in Table 4. The cumulative mortality rates per 100 population at risk are shown in Figure 5. Almost the same number of cardiovascular deaths was observed in the three treatment groups; more cancer deaths were reported for placebo patients than for patients in either of the two insulin groups.

The changes in fasting blood glucose levels observed during the course of follow-up for each treatment group are presented in Figure 6. There was a large drop in blood glucose levels in all

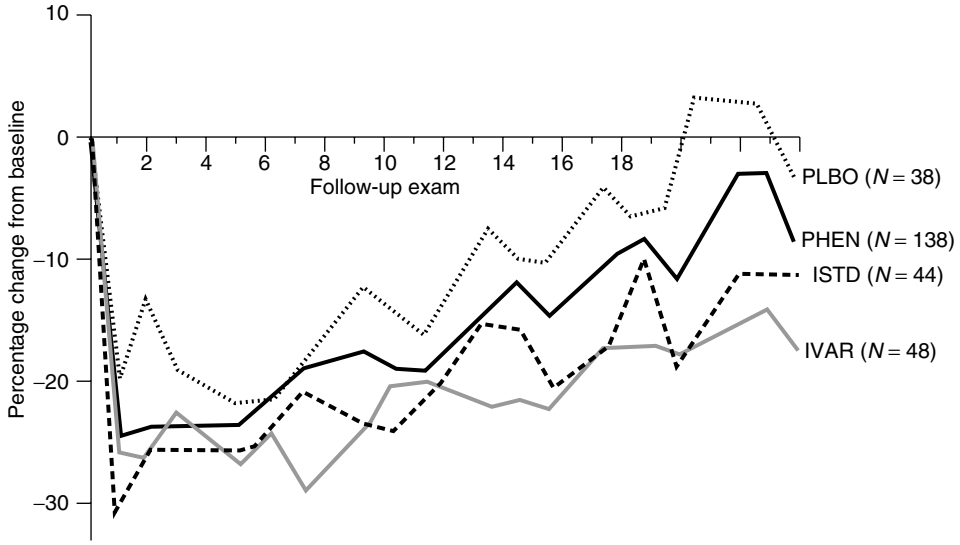

Figure 4 The percentage change in fasting blood glucose levels from baseline to each follow-up examination for the cohort of patients followed through the 23rd follow-up examination, as of October 7, 1971

All causes	29.3	24.8	25.5

treatment groups after the initiation of treatment. However, the fasting blood glucose levels for patients in the placebo and insulin standard treatment groups showed a trend toward baseline and then exceeded baseline values. The lower fasting blood glucose levels in the insulin variable treatment group were maintained during the course of the study by increasing the mean number of units of insulin from ten units at the first quarterly follow-up examination to 47 units at the 39th quarterly follow-up examination in the cohort followed for 39 quarters.

The occurrence of microvascular complications such as diabetic retinopathy and diabetic nephropathy was remarkably low during the course of follow-up and there were no differences among the three treatment groups. The UGDP investigators pointed out

> ... the 12–14 years of observations on the course of vascular complications in patients with type II disease in the UGDP show that in spite of the gradual progression of the carbohydrate abnormality and in spite of a relatively high incidence of cardiovascular risk factors, the overall mortality and the proportion of mortality due to cardiovascular complications were not significantly greater than would be expected in a nondiabetic population of comparable age, race and sex [16].

Discussion

Meinert [5] provided a detailed chronology of the University Group Diabetes Program as well as a summary of criticisms of the UGDP and comments on these criticisms. He also provided an assessment of the impact of the UGDP on prescribing practices in the United States. Meinert concluded that the study did have some effect on treatment practices, but perhaps the most important result was that it had led physicians to reexamine the underlying rationale for treatment of noninsulin-dependent diabetics.

The methods and procedures used in the UGDP Coordinating Center provided a framework for standards of operations for such Coordinating Centers in multicenter clinical trial. The Coordinating Center investigators (C.R. Klimt, C.L. Meinert, G.L. Knatterud, and P.L. Canner) utilized the UGDP experience to further the development of clinical trial methodology and the development of procedures for Coordinating Center operations in the implementation of many multicenter clinical trials conducted after the UGDP was initiated. Two statistical procedures, **Monte Carlo** monitoring procedures and a **likelihood** approach, were used to evaluate the effects of tolbutamide [10] and the effects of phenformin therapy [13]. The monitoring approach developed by Canner and colleagues [2, 3] used a computer **simulation** procedure to generate boundaries to evaluate a test statistic at different times during the course of a study (*see* **Data and Safety Monitoring**). The likelihood approach was developed by Cornfield [3, 4] and this **Bayesian method** was designed to evaluate treatment effects. The value generated by this approach was called "relative betting odds" (*see* **Relative Odds**) and for a drug–placebo comparison estimated the odds in favor of the **null hypothesis** of no difference relative to a specified set of alternatives. In the case of tolbutamide, these procedures were applied after the investigators realized that there was an unfavorable trend for patients treated with tolbutamide. It is perhaps worth pointing out that the UGDP did not have an independent Data Monitoring Committee (*see* **Data Monitoring Committees**) to review accumulating results for adverse or beneficial trends. The strategies used in the UGDP have been replaced by other methods, but perhaps their use in the UGDP pointed out the need for approaches to take account of interim monitoring in the assessment of treatment effects.

Few clinical trials have generated such an unusually acerbic and long lasting controversy as the UGDP. Every aspect of the design, execution, analysis and results of the trial have been subjected to extraordinary scrutiny. Two audits (Bilstad et al. [1], and Report of Committee for the Assessment of

Biometric Aspects of Controlled Trials of Hypoglycemic Agents [7]) of the UGDP were conducted. Both of these identified some shortcomings that had already been acknowledged by the UGDP investigators. The two audits concluded that any errors in data reporting or processing that did occur were infrequent and no more than might be expected in a long-term multicenter clinical trial.

The UGDP findings which precipitated this controversy were the results for tolbutamide which were first presented at the American Diabetes Association annual meeting and subsequently published in *Diabetes* [10]. The UGDP investigators review of mortality and occurrence of nonfatal events had led to formulation of the following conclusion:

> All UGDP investigators are agreed that the findings of this study indicate that the combination of diet and tolbutamide therapy is no more effective than diet alone in prolonging life. Moreover, the findings suggest that tolbutamide and diet may be less effective than diet alone or than diet and insulin at least insofar as cardiovascular mortality is concerned. For this reason, use of tolbutamide has been discontinued in the UGDP. . . . It should be noted that any conclusion reached in this study pertains only to the type of patient studied and the specific hypoglycemic agents and dosage schedules used. Extrapolation of findings to other dosage schedules of the same drug or to other chemically related hypoglycemic agents not included in this study must be made on a judgmental and nonstatistical basis.

It is remarkable that such a conservative conclusion should have generated such controversy. The UGDP investigators responded to several of the criticisms of the study in 1972 [6].

The results of phenformin were released to the medical community by a short report in the *Journal of the American Medical Association* [12] rather than by means of a presentation at a national meeting. This report did not generate the same controversy. The results for the two insulin treatment groups were initially released at the time of the presentation of the tolbutamide findings and the lack of differences among the insulin groups and the diet alone group did not change substantially from that time through the end of follow-up. The reports on insulin therapy reopened the challenges to the study. The UGDP investigators' perspective on the extended controversy was summarized in the detailed report on the insulin findings [16].

Since the last UGDP major report was published in 1982, the Diabetes Control and Complication Trial [8] has provided strong evidence that control of blood glucose by diet and insulin will delay microvascular diabetic complications. Such evidence has not yet been provided from a study of oral hypoglycemics or adult-onset noninsulin-dependent diabetics.

Up-and-Down Method

In biological experiments, often the response is dichotomous (or **binary**); for example, death or survival of an animal exposed to a toxic substance. In the standard situation, there are k levels of exposure, where, at the ith level, $n_i + m_i$ animals are placed, of which n_i show a positive response, for instance by death. The probability of a positive response, p_i, is a function of the exposure level, Z_i. If, over the k levels of response, animals are independent within and among these levels, the **likelihood** over the entire experiment is

$$L = \prod_{i=1}^{k} \binom{n_i + m_i}{n_i} p_i^{n_i}(Z_i) q_i^{m_i}(Z_i), \qquad (1)$$

where $q_i(\cdot) = 1 - p_i(\cdot)$, $i = 1, \ldots, k$.

It should be noted, concerning (1), that Z_i, instead of being a scalar quantity such as exposure level, is more generally a vector that includes other covariates related to response. Furthermore, $p_i(Z_i)$ can be represented by a plethora of possible models (*see* **Quantal Response Models**). Three examples are probit analysis [11], **logistic regression** [19], and reliability growth [16].

Dixon & Mood [10] describe a modification of (1), for which the response of the ith animal at exposure level Z_i determines the next exposure level. More precisely, assume that the first animal receives a particular stimulus at a dose level Z_0. Should the animal respond positively, the next animal receives a smaller dose Z_{-1}, whereas a negative response implies that the next animal receives a larger dose Z_1. This process is then repeated, sequentially, with either Z_{-1} or Z_1 as the dose for the next animal, depending on whether the first animal responded positively or negatively to Z_0. (Compare this with the play-the-winner rule [36] (*see* **Adaptive and Dynamic Methods of Treatment Assignment**) and **sequential analysis** [34].)

The basic theory assumes an initial dose level Z_0 and dose increments of amount d. Hence, the ith dose level (or logarithm thereof) is

$$Z_i = Z_0 + jd, \qquad (2)$$

$i = 0, 1, \ldots$, where j is the excess of negative over positive responses at doses 0 to $i - 1$, inclusive. The likelihood is

$$L(n, m|Z_0) = K \prod_i p_i^{n_i} q_i^{m_i}, \qquad (3)$$

where $q_i = 1 - p_i$ and K is a constant, independent of the p_i and q_i. Furthermore, in probit analysis the tolerance (dose or logdose at which an animal would respond positively; *see* **Quantal Response Models**) is assumed to be normally distributed with mean and variance μ and σ^2, respectively.

Hence, if Z_i is the dosage metameter that is normally distributed,

$$q_i = \Phi\left(\frac{Z_i - \mu}{\sigma}\right), \qquad (4)$$

$i = 0, 1, \ldots$. The parameters μ and σ^2, and hence p_i and q_i, are estimated by **maximum likelihood**. Details of the procedure are found in [10]. (*See* **Median Effective Dose**.)

Example

Table 1 displays a hypothetical up-and-down experiment to estimate the LD_{50} (the dose that produces a response in 50% of all subjects under test) of a new analgesic. First, a series of concentrations of 1%, 4%, 8%, 16%, 32%, and 64% was used. Furthermore, the number of tests performed in this series is $N' = 8$. However, as Dixon [7, 8] indicates, it is convenient to reduce the nominal sample size by one less than the number of like responses at the commencement of the trial. This provides a nominal sample size of $N = 6$. There is no loss in information in estimating an appropriate dosage level since all early responses are used in the tabled estimates.

In this example, an estimate of the LD_{50} is obtained as $Z_f + \theta d$ where Z_f is the final dose that

Table 1 Example of testing an analgesic

Log dose	Results of tests[a]

	Pain measurement	[4]

is administered, d is the common interval between doses and θ is obtained from [9, Table 19–3], or [8, Table 1]. Thus, $\theta = 0.831$ and $Z_f = 1.153$.

Applications

The up-and-down (or "staircase") method is a very practical and useful technique that has enjoyed a wide variety of scientific applications. In particular, many biomedical applications are featured. Most of these applications indicate that the up-and-down method saves both time and money as well as providing improved subject tolerance when compared with alternate sampling methods. Table 2 indicates a selection of the type and number of biomedical studies that have used the up-and-down method. While Table 2 is not an all-inclusive list of the biomedical applications of the up-and-down method, it does indicate the wide application and usefulness of this technique.

U-Shaped Distribution

A U-shaped distribution is a **probability** distribution or **frequency distribution** shaped, more or less, like a letter U, although not necessarily symmetrical. Such a distribution has its greatest frequencies at the two extremes of the range of the variable. An example of a variable which commonly has a U-shaped distribution and is often encountered in medical research is the Barthel index; this is a **quality-of-life** measure used to assess the ability of a patient to perform daily activities. A score of zero corresponds to complete dependence on others (and, in some investigations, to the death of a patient), and a score of 100 implies that the patient can perform all usual daily activities without assistance. An example of the distribution of the Barthel index for the patients in a particular investigation is shown in Figure 1.

Variables having U-shaped distributions, such as the Barthel index, are sometimes referred to in the statistical/medical literature as *bounded scores* (see [2]); that is, scores bounded below and above, in which the bounds can and will be attained in a nontrivial proportion of the population. Such variables might be analyzed by considering patients scoring zero (or the lower bound) separately from the others. In some cases, this will correspond to analyzing the mortality rate separately from the values of the variable amongst survivors. Alternately, the two-sample **Wilcoxon–Mann–Whitney** rank sum test might be used to test for a difference between, for example, a group given an active treatment and one given a placebo. Some discussion of the appropriateness of this approach is given in [1].

The problem of calculating sample sizes in studies with bounded outcome scores having U-shaped distributions is taken up in [2].

U-Statistics

Given a **random sample** (a sequence of independent **random variables** $X_1, \ldots, X_n$ with common distribution function F), the study of the statistical properties of the sample mean, $\overline{X}_n = n^{-1} \sum_{i=1}^{n} X_i$, is a well-established part of probability theory. The notion of averaging over the observations has been generalized by Hoeffding [14] in the following way: given a measurable real-valued function h, symmetric in its m arguments, a *U-statistic* is obtained by averaging over the outcomes $h(X_{i_1}, \ldots, X_{i_m})$ where $(i_1, \ldots, i_m) \in C_{nm} = \{(i_1, \ldots, i_m) \in IN^m : 1 \leq i_1 < \ldots < i_m \leq n\}$, i.e.

$$U_n = \binom{n}{m}^{-1} \sum_{C_{nm}} h(X_{i_1}, \ldots, X_{i_m}).$$

Note that, because of the symmetry of h (a nonrestrictive assumption), it is sufficient to average over the *ordered* m-tuples. U_n is called a U-statistic with *kernel* h of *degree* m. We assume, of course, that $n \geq m$.

Many statistics in estimation and testing theory can be represented as U-statistics. We give two illustrations.

Example 1

Assume $0 < \sigma^2 = \mathrm{var}(X_1) < \infty$. The sample variance $S_n^2 = (n-1)^{-1} \sum_{i=1}^{n} (X_i - \overline{X}_n)^2$, the **minimum variance unbiased estimator** for σ^2, can be rewritten as

$$S_n^2 = \binom{n}{2}^{-1} \sum_{1 \leq i < j \leq n} \frac{(X_i - X_j)^2}{2}.$$

Therefore, the sample variance is a U-statistic with kernel $h(x, y) = (x - y)^2/2$. In general, we have that the minimum variance unbiased estimator of the mth central **moment** is a U-statistic with kernel of degree m. See, for example, Hoeffding [14, p. 295] and Serfling [21, p. 176] for details.

Example 2

The Cramér–von Mises statistic (*see* **Kolmogorov–Smirnov and Cramer–Von Mises Tests in Survival Analysis**), a **goodness-of-fit** statistic to test if the unknown distribution function F equals some specified distribution function F_0, is given by

$$V_n = \int_{-\infty}^{+\infty} [F_n(x) - F_0(x)]^2 \, \mathrm{d}F_0(x),$$

with $F_n(x) = n^{-1} \sum_{i=1}^{n} \mathrm{I}\{X_i \leq x\}$, the empirical distribution function of the sample $X_1, \ldots, X_n$. With

$$h(x, y) = \int_{-\infty}^{+\infty} [\mathrm{I}\{x \leq t\} - F_0(t)][\mathrm{I}\{y \leq t\} - F_0(t)] \, \mathrm{d}F_0(t)$$

we can write $V_n = n^{-2} \sum_{i=1}^{n} \sum_{j=1}^{n} h(X_i, X_j)$. An asymptotically equivalent statistic is the U-statistic

$$U_n = \binom{n}{2}^{-1} \sum_{1 \leq i < j \leq n} h(X_i, X_j).$$

See de Wet [7] for a detailed discussion.

For both examples we have that the parameter of interest is of form

$$\theta(F) = Eh(X_1, X_2) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} h(x, y) \, \mathrm{d}F(x) \, \mathrm{d}F(y).$$

With h as in Example 1 we have $\theta(F) = \sigma^2$, and with h as in Example 2 the goodness-of-fit parameter is $\theta(F) = \int_{-\infty}^{+\infty} [F(x) - F_0(x)]^2 \, \mathrm{d}F_0(x)$. Under the null hypothesis $F = F_0$ we have $\theta(F_0) = 0$. If, in general, a real-valued functional θ defined on a set $\mathcal{F}$ of distribution functions can be written as the expectation with respect to $F \in \mathcal{F}$ of a properly chosen kernel h of degree m, the functional θ is called a *regular functional*. Such functionals have U-statistics as minimum variance unbiased estimators. See Lee [19, Chapter 1] for details. His book also includes a variety of further examples (Chapter 6).

Note that a naive estimator for $\theta(F)$ can be obtained by the plug-in method (replace F by F_n), i.e. use $\theta(F_n)$ as an estimator for $\theta(F)$. The resulting (biased) estimator is the von Mises statistic. The goodness-of-fit statistic, V_n, in Example 2 is a plug-in estimator. U-statistics and von Mises statistics are closely related.

A U-statistic with kernel of degree m can be written in terms of uncorrelated U-statistics of degree $1, \ldots, m$. In fact,

$$U_n - \theta(F) = \sum_{c=1}^{m} \binom{m}{c} U_{cn},$$

with

$$U_{cn} = \binom{n}{c}^{-1} S_{cn} = \binom{n}{c}^{-1} \sum_{C_{nc}} h_c(X_{i_1}, \ldots, X_{i_c}).$$

See Lee [19, Section 1.6] for the explicit expression of h_c and an excellent further discussion. This *H-decomposition* is due to Hoeffding [15]. Other important structural properties are the *forward martingale structure* of $\{S_{cn}, \mathcal{F}_n\}_{n \geq c}$, with $\mathcal{F}_n = \sigma(X_1, \ldots, X_n)$ and the *reverse martingale* structure of $\{U_n, \tilde{\mathcal{F}}_n\}_{n \geq m}$, with $\tilde{\mathcal{F}}_n = \sigma(X_{1:n}, \ldots, X_{n:n}, X_{n+1}, X_{n+2}, \ldots)$ and $X_{i:n}$ the ith **order statistic** of $X_1, \ldots, X_n$ [19, Section 3.4] (*see* discussion of martingales in **Counting Process Methods in Survival Analysis**).

So far we have demonstrated that many statistics are in fact U-statistics and we have discussed some structural properties. Also highly relevant is the appearance of U-statistics as terms in stochastic approximations of smooth statistics. U-statistics are, for example, extremely useful to approximate important estimators in nonparametric **density estimation** and **nonparametric regression** theory (see, for example, [13] and [20]) and **survival analysis** (see, for example, [5]). The basic idea is that the estimator of interest can be approximated by a sum of uncorrelated U-statistics. This idea is closely related to the H-decomposition of a U-statistic (see [19, Section 4.1] and [9]) and to von Mises expansions, a generalization of the projection method (a technique discussed in more detail below). For further reading we refer to [21, Chapter 6] and [10].

A more detailed discussion would require a number of technical concepts and definitions. We therefore restrict ourselves to one illustration.

Example 3

Let $T_1, \ldots, T_n$ denote iid nonnegative survival times with a continuous distribution function F and let $C_1, \ldots, C_n$ denote iid nonnegative censoring times with a continuous distribution function G. For $i = 1, \ldots, n$, we denote $X_i = \min(T_i, C_i)$ and $\delta_i = \mathrm{I}\{T_i \leq C_i\}$. Let $\hat{F}_n(t)$ denote the product-limit or **Kaplan–Meier estimator** for $F(t)$. With $\hat{\Lambda}_n(t)$ the **Nelson–Aalen estimator** and $\Lambda(t)$ the cumulative hazard function, a U-statistic representation has been established in [5] for $\hat{\Lambda}_n(t) - \Lambda(t)$. On the basis of the relation

$$\hat{F}_n(t) - F(t) = \exp[-\Lambda(t)] \times \{1 - \exp[-(\Lambda_n(t) - \Lambda(t)]\}$$

and using Taylor expansion ideas, a U-statistic representation for the Kaplan–Meier estimator can be obtained.

Asymptotic Properties

A basic contribution to the study of the asymptotic behavior of U-statistics (*see* **Large-sample Theory**) is the following result.

Theorem 1. If $E|h(X_1, \ldots, X_m)| < \infty$, then $U_n \to \theta(F)$ almost surely (a.s.).

This theorem states that the classical strong **law of large numbers** for the sample mean generalizes to U-statistics. Different proofs are available. They rely on the martingale structure of U-statistics mentioned above. For full proofs and references to the original papers, see Lee [19, Section 3.4].

Next, we briefly discuss the asymptotic distribution theory for U-statistics. The limit distribution of a (properly standardized) U-statistic will be Gaussian if we can obtain a stochastic approximation, $\hat{U}_n$, of iid structure that is close to U_n (in the sense that U_n inherits the asymptotic distributional behavior of $\hat{U}_n$). The appropriate approximation is obtained from the projection technique, which is in fact the first term in the H-decomposition. We have

$$\hat{U}_n = \sum_{i=1}^{n} \mathrm{E}(U_n | X_i) - (n-1)\theta(F).$$

With

$$h_1(x) = \int_{-\infty}^{+\infty} \cdots \int_{-\infty}^{+\infty} h(x, x_2, \ldots, x_m)\, \mathrm{d}F(x_2) \ldots \times \mathrm{d}F(x_m) - \theta(F)$$

we can write

$$\hat{U}_n - \theta(F) = \frac{m}{n} \sum_{i=1}^{n} h_1(X_i).$$

If $h_1 \equiv 0$, then the U-statistic is called *degenerate* or *pure*; otherwise, the U-statistic is *nondegenerate*. Pure U-statistics do not admit an iid approximation,

and as a consequence the limit distribution is not Gaussian. For nondegenerate U-statistics the following central limit result is valid.

Theorem 2. [14]. If $Eh^2(X_1, \ldots, X_m) < \infty$ and $\zeta_1 = \text{var}h_1(X_1) > 0$ (U_n is nondegenerate), then

$$\frac{\sqrt{n}[U_n - \theta(F)]}{(m\zeta_1^{1/2})} \xrightarrow{d} Z,$$

with Z a standard normal random variable.
A simple calculation shows that

$$\zeta_1 = \text{E}\{[h(X_1, X_2, \ldots, X_m) - \theta(F)] \times [h(X_1, X_{m+1}, \ldots, X_{2m-1}) - \theta(F)]\}.$$

For a pure U-statistic (the first term in the H-decomposition vanishes and $\zeta_1 = 0$) with $\zeta_2 = \text{E}\{[h(X_1, X_2, X_3, \ldots, X_m) - \theta(F)]\ [h(X_1, X_2, X_{m+1}, \ldots, X_{2m-2}) - \theta(F)]\} > 0$, the H-decomposition is

$$U_n - \theta(F) = \frac{m(m-1)}{n(n-1)} \sum_{1 \le i < j \le n} h_2(X_i, X_j) + \sum_{c=3}^{m} \binom{m}{c} U_{cn}.$$

For h_2, define the operator

$$Az(x) = \int_{-\infty}^{+\infty} h_2(x, y) z(y)\, \mathrm{d}F(y)$$

with z square integrable with respect to F. Let $\lambda_1, \lambda_2, \ldots$ denote the (not necessarily distinct) **eigenvalues** corresponding to the distinct solutions $z_1, z_2, \ldots$ of the equation $Az = \lambda z$.

Theorem 3. [12]. If $\text{E}[h^2(X_1, \ldots, X_m)] < \infty$ and $\zeta_1 = 0 < \zeta_2$, then

$$n[U_n - \theta(F)] \xrightarrow{d} \frac{m(m-1)}{2} Y,$$

with Y a random variable of the form $Y = \sum_{j=1}^{\infty} \lambda_j [\chi_j^2(1) - 1]$, where $\chi_1^2(1), \chi_2^2(1), \ldots$ are independent $\chi^2(1)$ random variables (*see* **Chi-square Distribution**; **Convergence in Distribution and in Probability**).

Example 1 (Continued)

For the sample variance an application of Theorem 2 yields (with μ_k the kth central moment): if $\mu_4 < \infty$ and $\mu_4 - \mu_2^2 > 0$, then $\sqrt{n}(S_n^2 - \mu_2)$ has a limiting normal distribution with mean zero and variance $\mu_4 - \mu_2^2$.

Example 2 (Continued)

Under the null hypothesis $F = F_0$ the Cramér–von Mises statistic is easily seen to be a pure U-statistic. Theorem 3 is applicable, the eigenvalues are $\lambda_j = (j\pi)^{-2}$. See [7] for details.

Remarks and Extensions

1. For U-statistics with a kernel of degree $m > 2$, more terms in the H-decomposition might vanish (higher order degeneracy). Asymptotic distribution theory has been established. The resulting limit distributions are characterized in terms of multiple Wiener integrals [8].
2. We reviewed some basic results for one-sample U-statistics. Extensions to multisample or generalized U-statistics are available. See the books by Lee [19], Koroljuk & Borovskich [18] and Borovskikh [4] for details. These books also deal with other variations on the theme: incomplete U-statistics, random U-statistics, weighted U-statistics, generalized L-statistics, Edgeworth expansions for U-statistics, etc.
3. **Bootstrap** theory for U-statistics is reviewed in Janssen [17]. Bickel & Freedman [3] is a basic reference.
4. A further important topic, especially for applications in nonparametric density and regression estimation, is the study of U-statistics with the kernel depending on the sample size n. Key references are Jammalamadaka & Janson [16] and Mammen [20]. We also mention the work by Frees [11] on infinite order U-statistics.
5. In Serfling [22] the study of U-processes and U-**quantiles** is initiated. Important recent contributions on U-processes and U-quantiles include Arcones & Giné [2], Stute [23], and Arcones [1]. Key words in the development of new results for U-processes are martingales and decoupling. For details we refer to the book by de la Peña & Giné [6].

PAUL JANSSEN

Utility in Health Studies

Utility is a technical term from economics and **decision theory** with a very precise meaning based on an underlying theory to be described later. However, in a general way, utility can be thought of as a measure of strength of preference. Utilities are applicable, and are used, in all sectors of the economy including business, defense, environment, education, and health. Applications of utility in **pharmacoepidemiology** do not differ from applications of utility to health in general. Accordingly, the utility material described in this article applies not just to pharmacotherapy but equally well to all interventions or programs designed to improve health.

In health applications the preferences generally relate to different outcomes that can be achieved, but could equally well refer to different programs or treatments. As an example of utilities for outcomes, if a particular individual prefers outcome A to outcome B, and in turn prefers outcome B to outcome C, cardinal numbers can be assigned to each outcome such that they represent the preferences of the individual on an interval scale. For example, if the numbers so assigned are $A = 12$, $B = 6$, and $C = 4$, then they would indicate that the individual prefers A to B and B to C, and that their preference difference between A and B (6 units) is three times as great as their preference difference between B and C (2 units). Note that it would not indicate that the person prefers A twice as much as B, because the preference scale is only an interval scale and not a ratio scale (*see* **Measurement Scale**).

More formally, utility can be defined by a precise set of axioms that form the foundation of expected utility theory [36, 64, 71]. The axioms represent a fundamental statement or definition of consistent and rational decision making under uncertainty. That is, they represent compelling rules that are widely seen as logical and appropriate for rational decision making when there are uncertainties regarding the outcomes. Clearly this applies to decision making in health – hence the view that utilities can play a useful role in the analysis of alternative courses of action in the field of health (*see* **Decision Analysis in Diagnosis and Treatment Choice**).

When utility is defined formally on the basis of the axioms mentioned above, it is properly referred to as "von Neumann–Morgenstern utilities", or NM utilities for short. NM utilities are measured using a technique called the **standard gamble**. The standard gamble is a direct application of one of the fundamental axioms of expected utility theory. In the standard gamble an individual expresses his or her preference by choosing between two alternatives. For example, the individual described above, who preferred A to B to C, would be asked to choose between one alternative in which outcome B would be received with certainty and a second alternative in which outcome A would be received with probability p and outcome C with probability $(1 - p)$. The probability p would then be varied until the individual was indifferent between these two choices. The indifference probability is used to calculate the NM utility that the individual has for outcome B relative to the utilities for outcomes A and C. Details of the methods are widely available [6, 24, 48, 62].

In addition to the technical and precise use of the term utility to represent NM utilities measured according to the fundamental theory, the term is also used broadly to refer simply to preferences, however measured. This is unfortunate, and causes considerable confusion in the literature. When readers come across the term utility they should first determine whether it is being used in the technical NM sense or in the broader sense of preferences.

We prefer to use the term preference to refer to the broad construct, and the term utility to refer to NM utilities. We also prefer to make a distinction between preferences that are measured with a standard gamble instrument, which contains uncertainty, and other instruments such as the **time trade-off** and rating scales that do not. The former are called utilities, while the latter are called values. However, readers should beware that many writers fail to make this distinction.

Utility as a Measure of Health-Related Quality of Life

Quality of life is an extremely broad concept that includes health, wealth, freedom, environment, political system, family, future prospects, and indeed an endless list of all-encompassing considerations. However, within this list is a subset that is generally known as "health-related quality of life". It is widely accepted that the goal of the health system is to improve both the quantity of life **(life expectancy)**

and the health-related quality of life. Accordingly, many health status instruments have been developed to measure health-related quality of life. A useful taxonomy for these instruments is that developed by Guyatt and colleagues in which the instruments are partitioned into three major sets: specific instruments, generic profiles, and utility measures [18, 28, 30].

Specific instruments include those that are disease-specific, such as the Functional Living Index–Cancer [12] or the Western Ontario–McMaster Osteoarthritis Index [5]. Specific instruments also include those designed for individuals in a particular age group, for example, the Care and Resource Evaluation Tool for the elderly [23]. Specific instruments are generally felt to be the most sensitive and responsive, but they clearly lack generalizability [29].

Generic profiles include instruments such as the Short Form 36 [72], the Sickness Impact Profile [13], and the Nottingham Health Profile [43]. These instruments produce **scores** on a number of different dimensions (profile of scores), are applicable to a wide variety of diseases and individuals, and accordingly are more generalizable but probably less responsive than specific instruments [29].

The third category, utility measures, produces a single summary index that represents health-related quality of life by a cardinal number. Like the generic profiles, these approaches are applicable to a wide variety of diseases and individuals and thus are highly generalizable. However, they are likely to be the least responsive of the three approaches [29].

A major advantage of the utility approach is that the single cardinal score for health-related quality of life can be combined with quantity of life to provide an integrated measure of health improvement that captures both the impact on quantity of life and the impact on quality of life. The usual method of combining quality and quantity of life is to calculate the quality-adjusted life years (QALY) involved, although alternative measures such as the healthy years equivalent [44] or the disability-adjusted life years (DALY) [45] have been suggested. The single measure of QALY, or its alternative, can be used in economic evaluation studies such as cost-effectiveness analysis and cost–utility analysis (*see* **Health Economics**) and can also be used as an **outcome measure in clinical trials** [27, 63].

Which measure of health-related quality of life should be used in a study? Our general answer to that question is that if health-related quality of life is an important outcome for the study, then the study should contain one instrument from each of the three types. The specific instrument is likely to be the most informative at a detailed level, particularly to clinicians interested in the impact on the disease and in specific patients. The generic profile will be useful in comparing the health impact more broadly to other types of patients and other diseases. The utility measure is necessary if one wishes to undertake economic evaluations such as cost–effectiveness or cost–utility analyses. The utility measure is also necessary if the intervention has an impact on both quantity and health-related quality of life and one wishes to have a single effectiveness measure that aggregates both of these effects.

Utility for Economic Evaluation Including Pharmacoeconomics

The primary application of utility is for use in economic evaluation. Economic evaluation is the comparative analysis of the costs and consequences of two or more alternative treatments or programs to improve health [15]. The techniques of economic evaluation include cost analysis, cost–effectiveness analysis, cost–utility analysis, and cost–benefit analysis (*see* **Cost–Benefit Analysis, Willingness to Pay**). When these approaches are applied to pharmacotherapy they have been labeled as pharmacoeconomics. However, the methods are the same whether the intervention being evaluated is a pharmaceutical product or a nondrug therapy.

When quantity of life and health-related quality of life are both important, the principal approach in economic evaluation is to use the utility approach, broadly defined. That is, utilities may be measured according to expected utility theory using the standard gamble instrument, or they may be measured more generally using other instruments such as the time trade-off or rating scales. The most common approach is to use the utility score to combine the quantity and health-related quality of life into a single outcome measure, the quality-adjusted life year (QALY) gained. This is then used as the denominator to determine the cost per QALY gained for one intervention or program as compared to another. The approach is known as cost–effectiveness analysis or cost–utility analysis, depending upon the writer.

CUA is a special case of CEA, and some researchers, including ourselves, distinguish it with its own title, while others do not [27]. Methods for calculating QALYs and for undertaking economic evaluation are widely available [15, 27, 56, 63, 64].

Utility as an Outcome Measure for Clinical Studies

Because utilities can be used to combine the impact on quantity of life and health-related quality of life, it makes an ideal outcome measure for clinical studies that affect both. Utilities have been used in this way as secondary measures of effectiveness for some time [1, 3, 8, 49, 50, 59, 61]. Recently, utility has been designated as the primary effectiveness measure for a planned Canadian randomized **multicenter trial** of lung volume reduction surgery for patients with pulmonary emphysema [46]. We expect that use of utility as a primary clinical endpoint in trials will become more common in the future.

How to Measure Utility

Utilities can be measured directly or indirectly; see [67] for a comprehensive review.

Direct Measurement of Utility

As mentioned above, and discussed elsewhere, utilities can be measured directly using a number of different instruments: the standard gamble, the time trade-off, and the rating scale with its variant, the visual analog scale. The conventional approach to using these instruments is to interview the respondent face-to-face, with a carefully trained and scripted interviewer leading the respondent through a highly structured interview, complete with visual aids and props to elicit the relevant preferences (*see* **Interviewing Techniques**). This approach is elaborate and costly, but has been included in many studies to date [11, 14, 37, 40, 41, 42, 49, 51, 54, 55, 58, 68, 69, 73]. Recently, a number of new and more efficient approaches have been developed and are being tested. These include telephone administration [35], self-administration by pencil and paper [47], and self-administration by an interactive computer program [27, 52]. In fact, a number of commercial systems are now available to provide computer interactive self-administered interviews for utility assessment. Although these are recent developments, they are likely to become the standard approach for direct measurement of utility in the future on many types of respondents.

Indirect Measurement of Utilities

An alternative approach that is being increasingly and widely used in studies is to use one of the multiattribute health status classification systems that include a utility scoring formula [31]. Three such systems are the Quality of Well-Being [30, 31], the Health Utilities Index [17, 22, 25], and the EQ-5D [39, 53]. All of these systems are similar in that they consist of attributes of health status (such as physical function, emotional function, or cognitive function) and levels on each attribute ranging from good function to bad or no function. Patients in studies, or populations under study, are classified into the system, and a scoring formula provides the utility score for the particular combination of levels across attributes. The systems differ in terms of the attributes included, the levels described for each attribute, and the type of scoring formula provided. As one example of the systems, we will describe the Health Utilities Index.

The Health Utilities Index (HUI) has developed through a series of studies over a number of years [9, 10, 19, 20, 65, 66]. The studies defined and refined the attributes and levels in the system, and the methods for determining the utility scoring formula. Currently there are two versions of the system, which are closely interrelated – the HUI2 (Table 1) and the HUI3 (Table 2). Scoring formulae are available for each [22, 69]. HUI2 and HUI3 have been widely used in clinical studies, and HUI3 has also been used widely in population health studies [7, 32, 57, 70, 74]. Thus, population norm data are available for HUI3. Currently, our recommendation is that studies incorporate both systems by using a combined questionnaire, which we have developed. The self- administration version consists of 15 questions and provides all of the information required to map the health status of the respondent into both HUI2 and HUI3. The questionnaire is available in a number of formats: self-administered, interviewer-administered face-to-face, and interviewer-administered by telephone. It is currently available in a wide range of languages, and

Table 1 Health status classification system for HUI2

Attribute	Level	Level description
Sensation	1	Ability to see, hear, and speak normally for age
	2	Requires equipment to see or hear or speak
	3	Sees, hears, or speaks with limitations even with equipment
	4	Blind, deaf, or mute
Mobility	1	Able to walk, bend, lift, jump, and run normally for age
	2	Walks, bends, lifts, jumps, or runs with some limitations but does not require help
	3	Requires mechanical equipment (such as canes, crutches, braces, or wheelchair) to walk or get around independently
	4	Requires the help of another person to walk or get around and requires mechanical equipment as well
	5	Unable to control or use arms and legs
Emotion	1	Generally happy and free from worry
	2	Occasionally fretful, angry, irritable, anxious, depressed, or suffering night terrors
	3	Often fretful, angry, irritable, anxious, depressed, or suffering night terrors
	4	Almost always fretful, angry, irritable, anxious, depressed
	5	Extremely fretful, angry, irritable, or depressed, usually requiring hospitalization or psychiatric institutional care
Cognition	1	Learns and remembers schoolwork normally for age
	2	Learns and remembers schoolwork more slowly than classmates as judged by parents and/or teachers
	3	Learns and remembers very slowly and usually requires special educational assistance
	4	Unable to learn and remember
Self-care	1	Eats, bathes, dresses, and uses the toilet normally for age
	2	Eats, bathes, dresses, or uses the toilet independently with difficulty
	3	Requires mechanical equipment to eat, bathe, dress, or use the toilet independently
	4	Requires the help of another person to eat, bathe, dress, or use the toilet
Pain	1	Free of pain and discomfort
	2	Occasional pain; discomfort relieved by nonprescription drugs or self-control activity without disruption of normal activities
	3	Frequent pain; discomfort relieved by oral medicines with occasional disruption of normal activities
	4	Frequent pain, frequent disruption of normal activities; discomfort requires prescription narcotics for relief
	5	Severe pain; pain not relieved by drugs and constantly disrupts normal activities
Fertility[a]	1	Ability to have children with a fertile spouse
	2	Difficulty in having children with a fertile spouse
	3	Unable to have children with a fertile spouse

[a]Fertility attribute can be deleted if not required. Contact developers for details. Source: Table II in [19]

further translations are under way. The questionnaire takes from 2 min (interviewer-administered telephone version) to under 10 min (self-administered written version) to administer, has been used on thousands of respondents, and is simple to complete. Proxy respondents can be used for patients who are unable to answer the questions on their own.

The HUI system is useful in clinical studies in two ways. First, the classification is useful in its own right and has been widely used as a systematic method

Table 2 Health status classification system for HUI3

Attribute	Level	Level description
Vision	1	Able to see well enough to read ordinary newsprint and recognize a friend on the other side of the street, without glasses or contact lenses
	2	Able to see well enough to read ordinary newsprint and recognize a friend on the other side of the street, but with glasses
	3	Able to read ordinary newsprint with or without glasses but unable to recognize a friend on the other side of the street, even with glasses
	4	Able to recognize a friend on the other side of the street with or without glasses but unable to read ordinary newsprint, even with glasses
	5	Unable to read ordinary newsprint and unable to recognize a friend on the other side of the street, even with glasses
	6	Unable to see at all
Hearing	1	Able to hear what is said in a group conversation with at least three other people, without a hearing aid
	2	Able to hear what is said in a conversation with one other person in a quiet room without a hearing aid, but requires a hearing aid to hear what is said in a group conversation with at least three other people
	3	Able to hear what is said in a conversation with one other person in a quiet room with a hearing aid, and able to hear what is said in a group conversation with at least three other people with a hearing aid
	4	Able to hear what is said in a conversation with one other person in a quiet room without a hearing aid, but unable to hear what is said in a group conversation with at least three other people even with a hearing aid
	5	Able to hear what is said in a conversation with one other person in a quiet room with a hearing aid, but unable to hear what is said in a group conversation with at least three other people even with a hearing aid
	6	Unable to hear at all
Speech	1	Able to be understood completely when speaking with strangers or friends
	2	Able to be understood partially when speaking with strangers but able to be understood completely when speaking with people who know the respondent well
	3	Able to be understood partially when speaking with strangers or people who know the respondent well
	4	Unable to be understood when speaking with strangers but able to be understood partially by people who know the respondent well
	5	Unable to be understood when speaking to other people (or unable to speak at all)
Ambulation	1	Able to walk around the neighborhood without difficulty, and without walking equipment
	2	Able to walk around the neighborhood with difficulty, but does not require walking equipment or the help of another person

(*continued overleaf*)

Table 2 (*continued*)

Attribute	Level	Level description
	3	Able to walk around the neighborhood with walking equipment, but without the help of another person
	4	Able to walk only short distances with walking equipment, and requires a wheelchair to get around the neighborhood
	5	Unable to walk alone, even with walking equipment; able to walk short distances with the help of another person, and requires a wheelchair to get around the neighborhood
	6	Cannot walk at all
Dexterity	1	Full use of two hands and ten fingers
	2	Limitations in the use of hands or fingers, but does not require special tools or help of another person
	3	Limitations in the use of hands or fingers, is independent with use of special tools (does not require the help of another person)
	4	Limitations in the use of hands or fingers, requires the help of another person for some tasks (not independent even with use of special tools)
	5	Limitations in use of hands or fingers, requires the help of another person for most tasks (not independent even with use of special tools)
	6	Limitations in use of hands or fingers, requires the help of another person for all tasks (not independent even with use of special tools)
Emotion	1	Happy and interested in life
	2	Somewhat happy
	3	Somewhat unhappy
	4	Very unhappy
	5	So unhappy that life is not worthwhile
Cognition	1	Able to remember most things, think clearly and solve day to day problems
	2	Able to remember most things, but having a little difficulty when trying to think and solve day to day problems
	3	Somewhat forgetful, but able to think clearly and solve day to day problems
	4	Somewhat forgetful, and having a little difficulty when trying to think or solve day to day problems
	5	Very forgetful, and having great difficulty when trying to think or solve day to day problems
	6	Unable to remember anything at all, and unable to think or solve day to day problems
Pain	1	Free of pain and discomfort
	2	Mild to moderate pain that prevents no activities
	3	Moderate pain that prevents a few activities
	4	Moderate to severe pain that prevents some activities
	5	Severe pain that prevents most activities

of describing and comparing patients and monitoring their changes over time [1–4, 21, 26, 38, 60]. In addition, the scoring formula for the HUI is based directly on NM utilities measured on a **random sample** of the community. Thus the HUI scores represent both appropriate utility weights (NM utilities) for calculating quality-adjusted life years and undertaking cost–effectiveness or cost–utility analyses, and they represent the appropriate source of these preferences, i.e. the community at large [27].

Given the ease and simplicity of using these multiattribute systems in clinical studies, we generally recommend their use, rather than the direct measurement of utilities using a standard gamble or other instrument. The latter is generally reserved for studies in academic centers that also have methodologic hypotheses about the utilities being measured. Investigators who simply wish to use utilities are generally better served by using one of the multiattribute systems.

Conclusions

Utilities are being incorporated increasingly into clinical studies. They can be used as a measure of health-related quality of life, as an outcome measure for the trial either in terms of health-related quality of life or in terms of a combined index of quality and quantity of life, and they can be used to undertake economic evaluations of interventions or programs. For most studies the simplest and most appropriate method of obtaining utilities is to use a multiattribute health status classification system that includes a utility scoring formula. In some studies the researchers may wish to measure the utilities directly using one of the preference measurement tools available.

GEORGE W. TORRANCE

Utility

Utility theory is concerned with the quantitative representation of individual preferences for the outcomes of a decision. In biomedical research, utility theory is used to provide guidance for individual and sometimes societal decisions regarding health, and to provide a rational foundation for the choice of appropriate **experimental designs** and data analysis strategies (*see* **Decision Theory**).

The ideas underlying modern utility theory arose during the Age of Enlightenment with the work of Daniel Bernoulli [3, 5] (*see* **Bernoulli Family**). Bernoulli analyzed the behavior of rational individuals in the face of risk from a Newtonian perspective, viewing science as an operational model of the human mind. His empirical observation that prudent and thoughtful individuals do not necessarily take the actions that maximize their expected monetary return, as in the St Petersburg's paradox [3, 11], led him to investigate a formal model of individual choices based on the direct quantification of value, and to develop a prototypical utility function for wealth.

Quantification of value has been a central component of economic thought since then, and has more recently gained an important role in the theories of decision making under uncertainty, both descriptive and normative. (Descriptive theories aim at portraying the way individuals or groups make decisions, while normative theories aim at guiding decision making based on adherence to accepted fundamental principles. While descriptive theories are important in public health areas such as risk communication (*see* **Risk Assessment**) and patient counseling, this article is concerned with normative theories.)

Most utility theories consider the problem of representing an individual's preferences for the elements of a set R of possible outcomes. Examples of outcomes relevant for biomedical applications are the health states following a treatment or intervention, the consequences of marketing a drug, the change in the exposure to a toxic agent that may result from a regulatory change, the knowledge gained from a study design, and so forth. If r_1 and r_2 are two outcomes in R, then $r_1 \prec r_2$ indicates that r_2 is preferred to r_1. Formally, $\prec$ is a binary relation on R, usually taken to be asymmetric. Indifference between two outcomes (neither $r_1 \prec r_2$ nor $r_2 \prec r_1$) is indicated by $r_1 \sim r_2$.

A cardinal utility function is a real-valued score u assigned to the outcomes in R, so that

$$r_1 \prec r_2 \iff u(r_1) < u(r_2). \tag{1}$$

Not all preferences are amenable to this kind of representation, but, for example, if R is a countable set, and if both $\prec$ and $\sim$ are transitive relationships, then a u that represents these preferences can be constructed. An in-depth discussion of conditions for the existence of such cardinal utility representations of preferences is in [6].

Expected Utility Theory

One contribution of utility theory to decision making is in the possibility of characterizing preferences over complex sets of options in terms of much simpler utility specifications. In the prototypical problem of decision under uncertainty, a decision maker must choose an action whose consequences are uncertain. Each action is then described by a given probability distribution p over the set R of possible outcomes. A simple operational approach is to assign a utility score $u(r)$ to each of the outcomes, and choose the action p that maximizes the expected value of the utility of the outcome, or

$$u(p) = \sum_{r \in R} p(r)u(r). \tag{2}$$

A fundamental contribution to the foundations of this approach is the work of von Neumann & Morgenstern [21], who showed how the expected utility representation (2) can be derived from conditions on the ordinal relationships among the set of all actions P. In particular, they provided necessary and sufficient conditions for preferences over a convex set P of options to be representable by a utility function of the form (2). These conditions can be thought of as basic rationality requirements, and are taken to be the primitives, or axioms, in the von Neumann & Morgenstern theory of utility. To gain a basic understanding of these axioms, assume that R is countable and that P is the set of all probability distributions on R. The decision maker has preferences over elements of P. The axioms, in the format given in [10], are:

1. *Weak order axiom.* Both $\prec$ and $\sim$ are transitive.
2. *Archimedean axiom.* If $p_1 \prec p_2 \prec p_3$, then there are α and β in (0, 1) such that $\alpha p_1 + (1 -$

$\alpha)p_3 \prec p_2 \prec \beta p_1 + (1-\beta)p_3$. Here $\alpha p_1 + (1-\alpha)p_3$ indicates the action that leads to outcome r with probability $\alpha p_1(r) + (1-\alpha)p_3(r)$. In words, p_3 can be preferred to p_2, but not so strongly that mixing p_3 with p_1 cannot lead to a reversal of preference. So p_3 cannot be incommensurably better than p_2. Likewise, p_1 cannot be incommensurably worse than p_2.

3. *Independence axiom.* If $p_1 \prec p_2$, then, for every p_3 in P and α in (0, 1), $\alpha p_1 + (1-\alpha)p_3 \prec \alpha p_1 + (1-\alpha)p_2$. In words, the two composite lotteries should be compared solely based on the component that is different.

Axioms 1, 2, and 3 hold if and only if there is a real-valued utility u such that the preferences for the options in P can be represented as in (2). A given set of preferences identifies a utility function u only up to a linear transformation with positive slope.

The von Neumann & Morgenstern theory also provides the basis for practically assessing an individual decision maker's utilities for outcomes. A widely used approach is the so-called **"standard gamble"**, illustrated here in the case of a finite set of outcomes R. If we avoid the trivial case in which all outcomes are equally valued by the decision maker, then the weak ordering assumption permits us to identify a worst outcome r_1 and a best outcome r_2. For example, in assessing the utility of health states, "death" is often chosen as the worse outcome and "full health" as the best, although in some problems there are health outcomes that could be ranked worse than death [20]. Worst and best outcomes need not be unique. Because all utility functions that are positive linear transformations of the same utility function lead to the same preferences over P, we can arbitrarily set $u(r_1) = 0$ and $u(r_2) = 1$, leading to a convenient and interpretable utility scale.

Then a decision maker's utility for outcome r can be inferred by eliciting the value of π such that the decision maker is indifferent between the following two actions:

p_1: outcome r for certain;

p_2: outcome r_1 with probability $1-\pi$ and outcome r_2 with probability π.

The existence of a value of π reaching indifference is implied by the Archimedean and independence properties of the decision maker's preferences. It is easy to check that the expected utility of both actions p_1 and p_2 is π, and that therefore $u(r) \simeq \pi$. Alternative assessment methods used in health sciences are reviewed by [20].

Expected utility maximization proved to be a fundamental tool in guiding practical decision making under uncertainty, including clinical decision making (*see* **Decision Analysis in Diagnosis and Treatment Choice**) and cost-effectiveness analysis (*see* **Health Economics**). The literature on the extensions of this characterization is extensive. Good entry points are [13, 8], and [9]. Because of the centrality of the expected utility paradigm, the von Neumann–Morgenstern axiomatization and its derivatives have been deeply scrutinized and criticized from both descriptive and normative perspectives. Empirically, it is well documented that individuals sometimes violate the independence axiom [1, 12, 13, 19]. Normative questions have also been raised about the weak ordering assumption [17, 18].

Subjective Expected Utility Theory

A more general decision setting occurs when outcomes depend on uncertain events, whose probabilities are not given externally, as in the theory of von Neumann–Morgenstern, but must be assessed by the decision maker together with the utilities. An action can then be described as a function $a(s)$ from states $s \in S$ to outcomes $r \in R$: the states describe the alternative realizations of the uncertain events that affect the outcome of the decision. For example, consider deciding whether to be vaccinated against influenza in anticipation of the cold season. The two actions are "vaccine" and "no vaccine". A simple description of the problem could include four states, defined by the combinations of the events "adverse reaction to the vaccine" and "influenza is contracted later in the winter". To each state S there corresponds an outcome $r(s)$ that could be a description of health states, costs, and so forth, ensuing from state s.

Extending the results of von Neumann & Morgenstern, and echoing earlier groundbreaking work by Ramsey [14], **L.J. Savage** [15] developed a system of axioms for preferences over the type of actions exemplified above. These axioms hold if, and only if, there is a utility function u over outcomes and a probability distribution p over states that represent

the agent preferences by

$$u(a) \simeq \sum_{s \in S} p(s)u[r(s)]. \tag{3}$$

Savage's theory is based on seven axioms [15]. As an alternative to the rewarding but demanding reading of Savage's fundamental book, one can consult [13] or [7]. Some of the axioms are similar in spirit to those of von Neumann & Morgenstern. An important additional requirement is the so-called state independence of utilities, which in essence requires the decision maker to give the same value to identical outcomes ensuing from different states. A critical appraisal of the consequences of this assumption is in [16]. Later work on subjective expected utility theory is reviewed in [7].

In addition to having direct implications for decision making under uncertainty, Savage's theory aims at providing a rational foundation for statistical **inference**. The actions represent the results of a statistical analysis, such as rejecting a hypothesis; the states are the alternative values of the parameters of interest such as the **null** and the **alternative hypotheses**; the outcomes represent the rewards, or losses, resulting from the analysis. If an agent's preferences satisfy the axioms, then the agent's choices will be consistent with assigning a **subjective probability** distribution to the states and a utility function to the outcomes, and choosing the action that maximizes the resulting expected utility. In particular, all Bayesian optimal procedures (*see* **Bayesian Methods**) are consistent with Savage's system of rationality axioms.

GIOVANNI PARMIGIANI

Validation Study

Validation studies obtain information on **measurement errors** in exposures and other **covariates** used in epidemiologic studies by comparing the conventional exposure measurements with "**gold standard**" measurements. **Reliability studies**, unlike validation studies, provide information on the measurement error process by replicating the conventional exposure measurements. Validation studies can be applied to study a broader range of error processes than reliability studies, which are based on a special error model. Data from validation studies or reliability studies are needed to correct relative **risk** estimates for **bias** and to obtain valid **inference** in the presence of measurement error (*see* **Misclassification Error**).

To define these ideas more precisely, let $\mathbf{Y}$ be the response variable, and let $\mathbf{X}$ be the true value(s) of the covariate. In some cases, $\mathbf{X}$ can never be observed and can be thought of as a *latent* variable. In other cases, $\mathbf{X}$ is a "gold standard" method of covariate assessment which is infeasible and/or expensive to administer to large numbers of study participants. Usually, instead of observing $\mathbf{X}$, an error-prone measurement $\mathbf{W}$ is observed. Finally, there may be covariates $\mathbf{Z_1}$ upon which the model for response depends that are never misclassified or measured with error. In main study/validation study designs, the main study yields the data $(\mathbf{Y}_i, \mathbf{W}_i, \mathbf{Z}_i), i = 1, \ldots, n_1$. If the validation study is *internal*, it yields the observations $(\mathbf{Y}_i, \mathbf{W}_i, \mathbf{X}_i, \mathbf{Z}_i), i = n_1 + 1, \ldots, n_1 + n_2$. If the validation study is *external*, it produces observations $(\mathbf{W}_i, \mathbf{X}_i, \mathbf{Z}_{2i}), i = n_1 + 1, \ldots, n_1 + n_2$ observations. There may be covariates, denoted $\mathbf{Z}_2$, upon which the measurement error and/or misclassification model depend but of which the model for response is independent; we denote the unique elements of $\mathbf{Z}_1$ and $\mathbf{Z}_2$ by $\mathbf{Z}$. An external validation study is a useful option only when there are a priori reasons to believe that measurement error/misclassification is **nondifferential**, i.e. that $f(\mathbf{Y}|\mathbf{W}, \mathbf{X}, \mathbf{Z}) = f(\mathbf{Y}|\mathbf{X}, \mathbf{Z})$. This definition can be rewritten as $f(\mathbf{W}|\mathbf{Y}, \mathbf{X}, \mathbf{Z}) = f(\mathbf{W}|\mathbf{X}, \mathbf{Z})$, in which form the nondifferential error feature is more apparent.

Without validation or reliability data, it is possible only to perform **sensitivity analyses** under hypothesized scenarios for measurement error and/or misclassification. Without information about the nature and extent of the measurement error and/or misclassification, sensitivity analyses yield wide ranges of the parameter(s) estimates, and cannot assess the true uncertainty of the estimates. It is possible in certain instances to test hypotheses about $\mathbf{X}$, however, even in the absence of validation data. For **generalized linear models** with $\dim(\mathbf{X}) = \dim(\mathbf{W}) = 1$, the usual score test, based upon the main study data alone, will have the correct size, although its **power** will be reduced unless $\mathbf{X}$ is linearly related to $\mathbf{W}$ and $\mathbf{Z}$ [16]. The same results apply for the global **null hypothesis** about $\mathbf{X}$. Validation and/or reliability data are required for valid **estimation** and inference in nearly all other circumstances. An exception occurs when the model for $\mathbf{Y}$ given $(\mathbf{X}, \mathbf{Z}_1)$ is **logistic** and the model for $\mathbf{X}$ given $(\mathbf{W}, \mathbf{Z}_2)$ is Gaussian (*see* **Normal Distribution**). In this case, when $\dim(\mathbf{X}) = \dim(\mathbf{W}) = 1$, the parameters of both models are **identifiable** from the main study alone [10], although as yet unpublished work by Spiegelman & Rosner indicates that estimates of these parameters are difficult to obtain, and when obtained, are usually very imprecise.

A reliability study can be used to estimate **variance components** in the classic, random within-person, measurement error model

$$\mathbf{W} = \mathbf{X} + \mathbf{U}, \tag{1}$$

where $\mathbf{U}$ is a mean zero error term with variance–covariance Σ. It is only when (1) applies that replicate data, as would be obtained in a reliability study, can be used for valid estimation and inference in the presence of covariate measurement error. Eq. (1) has been applied to the assessment of measurements of blood pressure, serum hormones, and other serum biomarkers such as vitamin concentrations.

A validation study can be used for a wide range of error models. A validation study may be expensive or infeasible because it requires that the true value $\mathbf{X}$ be observable, at least in some small sample of n_2 study participants. That is, a "gold standard" technique for measuring the quantity of interest without error must be available. In most situations, it is impossible to measure exposure perfectly. If measurement error/misclassification methods are used with an "alloyed" or imperfect gold standard, $\mathbf{X}'$, the results of the analysis can be misleading. If $\mathbf{X}'$ and $\mathbf{Z}$ are uncorrelated, however, the results may be interpreted as those which would have been obtained had

the (imperfect) gold standard measurements $\mathbf{X}'$ been available for all study participants, rather than just those in the validation study. Under certain circumstances, if the errors in $\mathbf{X}'$ and $\mathbf{W}$ are uncorrelated, the regression calibration estimate will provide **unbiased** measurement error correction for the gold standard, $\mathbf{X}$ [14, 18]. In some realistic examples, the bias in regression calibration estimates is small even when the errors are moderately correlated.

In this article it is assumed, unless stated otherwise, that the validation study is sampled completely at random. That is, if V is a **random variable** which equals 1 if a participant is in the validation study and 0 otherwise, we assume $\Pr(V = 1|\mathbf{Y}, \mathbf{X}, \mathbf{W}, \mathbf{Z}) = \pi$, independent of $\mathbf{Y}$, $\mathbf{X}$, $\mathbf{W}$, and $\mathbf{Z}$.

Two-stage designs (*see* **Case–Control Study, Two-phase**) allow V to depend upon $\mathbf{Y}$, $\mathbf{W}$ and $\mathbf{Z}$. Two-stage designs allow one to control the selection of validation study participants so as to increase statistical efficiency or reduce cost. These options require the validation study to be *internal*. Two-stage designs have several limitations. Many validation studies yield data on numerous covariates. For example, in a prospective **cohort study** yielding information on cancer and cardiovascular endpoints, it may be necessary to validate many nutrient measures simultaneously. An optimal design for one response/covariate pair may be inefficient for another. Although some authors have found that the optimal sampling probability function, π depends on $\mathbf{Y}$ ([17] and as yet unpublished work by Holcroft & Spiegelman) in cohort studies and many **nested case–control** studies, it will not be possible to identify the optimal π as a function of $\mathbf{Y}$, since covariate status is best ascertained before observing $\mathbf{Y}$.

The remainder of this article will discuss strategies for optimizing (n_1, n_2), assuming that the validation sample is taken completely at random. Solutions to this problem are mathematically complex, and software is not widely available. In a two-stage design, $(n_1 + n_2, \pi)$ must be optimized, which poses an even more difficult theoretical and computational problem. Nevertheless, further research on two-stage designs may lead to improvements on the designs presented below.

The valid use of an external validation study requires that the measurement error model $f(\mathbf{X}|\mathbf{W}, \mathbf{Z}_2)$ is the same in the external population as in the main study. This assumption is necessarily true for an internal validation study, supplied completely at random. By **Bayes' Theorem** $f(\mathbf{X}|\mathbf{W}, \mathbf{Z}_2) = f(\mathbf{W}|\mathbf{X}, \mathbf{Z}_2) f(\mathbf{X}, \mathbf{Z}_2)/f(\mathbf{W}, \mathbf{Z}_2)$. Although in many instances it may be reasonable to assume that $f(\mathbf{W}|\mathbf{X}, \mathbf{Z}_2)$ may be "transportable" from one population to the next, provided the instruments used to measure $\mathbf{X}$ and $\mathbf{W}$ are identical, it is less reasonable to assume that the unobservable marginal density $f(\mathbf{X}, \mathbf{Z}_2)$ in the main study population is the same as that in an external validation population. Thus, an internal validation study is more convincing than an external validation study.

Two recent epidemiologic textbooks devote a chapter to the design and analysis of validation and reliability studies. Armstrong et al. [1, Chapter 4] focus primarily on the design and analysis of reliability studies, but there is some consideration of validation studies as well. Willett [19] discusses validation study design for dietary intake questionnaires (*see* **Nutritional Exposure Measures**). Willett gives a simple formula for calculating the sample size of a validation study, based on the criterion of testing $\mathrm{H}_0 : \rho = \rho_0$ vs. $\mathrm{H}_\mathrm{a} : \rho = \rho_A$ with prespecified power $1 - \beta$ and nominal size α, where ρ is the **correlation** between the usual exposure method ($\mathbf{W}$) and the gold standard ($\mathbf{X}$):

$$n = 3 + \frac{(Z_\alpha + Z_\beta)^2}{|\rho_A - \rho_0|},$$

where Z_α and Z_β are the **standard normal deviates** for α and β, respectively (*see* **Sample Size Determination**). This criterion for validation study sample size is not designed to ensure adequate sample size for measurement error correction, and is strictly useful only when the estimation of the correlation between $\mathbf{X}$ and $\mathbf{W}$ is the end goal. Willett reports some otherwise unpublished data which examined the influence of validation study sample size on the precision of **odds ratio** corrected for measurement error by regression calibration, where it had been found that for "realistic conditions" $(0.5 < \rho < 0.7)$, validation studies with more than 150–200 subjects provide little additional precision.

Design of Main Study/Validation Studies

Choice of the Optimization Criterion for Efficient Study Designs

In the biomedical research setting, research proposals will usually not be approved for funding unless the

proposed study has power of 80% or more to test the central scientific hypothesis. The study design process seeks to minimize the proposed budget while assuring adequate statistical power. Because the unit cost of measuring **X** can be 100 or more times that of measuring **W**, validation studies can be expensive, and efficient main study/validation study designs are essential. Incorporating these design features is important, because it is seldom possible to collect validation data after the main study has been completed. Calculation of a point estimate, typically an odds ratio or **hazard ratio**, and the construction of **confidence intervals** around this estimate are often primary analytic goals in observational biomedical research, where measurement error and misclassification frequently arise. Greenland proposed the *discriminatory power* criterion [5] for these settings. One specifies the two sample sizes needed, respectively, to test the **null hypothesis**, $H_0 : \beta = \beta_L$ against the **alternative**, $H_a : \beta = \beta_U$, each with prescribed size and power. According to the discriminatory power criterion, the required sample size is the maximum of these two sample sizes. In **relative risk models**, because the **variance** of the estimate of the parameter of interest, $\hat{\beta}$, depends on the value of the parameter of interest, β, typically the log odds ratio or log hazard ratio, the discriminatory power criterion will usually produce optimal sample sizes larger than those produced by the traditional power criterion. An alternative criterion is to specify the expected confidence interval width at a specified relative risk, but this criterion may produce designs with unknown, possibly subnominal confidence levels for different, equally plausible values of the relative risk.

Given unit costs $r_{\mathbf{Y}}, r_{\mathrm{W}}$, and r_{X} for a single measurement of **Y**, **W**, and **X**, respectively, the optimization criterion we prefer minimizes the total study cost, C, with respect to (n_1, n_2), subject to minimum discriminatory power requirements. In a main study/external validation study design,

$$C(n_1, n_2) = (r_{\mathbf{D}} + r_{\mathbf{W}})n_1 + (r_{\mathbf{W}} + r_{\mathbf{X}})n_2$$

and maximization over (n_1, n_2) is subject to the constraints

$$1 - \Phi\left[\frac{Z_{1-\alpha/2}[V_L(n_1, n_2)]^{1/2} - \beta_U + \beta_L}{[V_U(n_1, n_2)]^{1/2}}\right] \geq \Pi,$$

and

$$\Phi\left[\frac{-Z_{1-\alpha/2}[V_U(n_1, n_2)]^{1/2} - \beta_L + \beta_U}{[V_L(n_1, n_2)]^{1/2}}\right] \geq \Pi.$$

Here $V_L(n_1, n_2)$ and $V_U(n_1, n_2)$ are the expected values of the variances of $\hat{\beta}$ evaluated at β_L and β_U, respectively, over the distribution of (**D**, **X**, **W**) for the study population to be investigated, Π is the minimal acceptable discriminatory power, and z_γ is γth quantile of the standard normal distribution. For a main study/internal validation study design, the cost function

$$C(n_1, n_2) = \min[(r_{\mathbf{D}} + r_{\mathbf{W}})n_1 + (r_{\mathbf{W}} + r_{\mathbf{X}} + r_{\mathbf{D}})n_2, (r_{\mathbf{D}} + r_{\mathbf{X}})n_2^*]$$

is used, since there may be a discontinuity point in the main study/internal validation study design optimization equations at which the fully validated design, consisting only of observations $(\mathbf{Y}_i, \mathbf{W}, \mathbf{Z}_{1i})$, $i = 1, \ldots, n_2$, is optimal.

Within this framework, one must supply the necessary design specifications, which will vary from one setting to another, and substitute the appropriate formulas for V_L and V_U to obtain the optimal values of n_1 and n_2. Even with a simple formula for $\mathrm{var}\hat{\beta}$, the solution cannot be written in closed form because the constraints are complex. Numerical solutions can be found using a nonlinear multiparameter optimization subroutine such as DNCONF in IMSL [8], with a call to an application-specific subroutine implementing the appropriate variance formula.

Although the design criteria discussed above are all functions of the variance of $\hat{\beta}$ as well as other parameters, the expected confidence interval width criterion is simply proportional to the square root of this variance. A limitation of most of the papers on validation study design is that they investigate design issues only by the criterion of expected confidence interval width.

Optimal Study Design for Misclassified Binary Exposure Variables

When **binary** exposure variables are subject to misclassification, the simplest misclassification model, $f_2(\mathbf{X}|\mathbf{W}; \theta)$, can be completely described with two parameters, $\theta = (\omega, \varphi)$, namely the **sensitivity**

$$\omega = \Pr(\mathbf{W} = 1|\mathbf{X} = 1),$$

and the **specificity**

$$\varphi = \Pr(\mathbf{W} = 0|\mathbf{X} = 0).$$

This model is less restrictive than the measurement error model (1), since the error distribution depends on **X**, except in the special case when $\omega = 1 - \varphi$. Further complexity in the misclassification model can be introduced by allowing that ω and/or φ vary with **Y**, as in the case of **recall bias** in a **case–control study**, or allowing ω and/or φ to vary with some other covariate(s), **Z**. In most instances, optimal study designs will depend on the underlying true exposure **prevalence**, $\Pr(\mathbf{X} = 1)$.

Palmgren [11] studied internal validation designs for case–control studies and with the same proportions of the sample allocated to validation for cases and controls. Palmgren found the optimal allocation proportion, $n_2/(n_1 + n_2)$, to minimize the null variance of the estimated log odds ratio, $\hat{\beta}$, subject to fixed cost. She also determined the optimal allocation proportion to minimize the variance of $\hat{\beta}$ subject to fixed cost. She did not base her designs on a classical power criterion nor on the discriminatory power criterion.

To use Palmgren's formulation, the investigator must specify the odds ratio, the sensitivity and specificity for measuring exposure, the exposure prevalences in cases and controls, and the costs of measuring **W** and **X**. When $\beta = 0$ and the sensitivity and specificity are assumed to be the same for cases and controls, the optimal design for minimizing the variance of $\hat{\beta}$ is the fully validated design, $(n_1 = 0)$, unless the square of the correlation between **W** and **X** is greater than the cost ratio $r_{\mathbf{W}}/r_{\mathbf{X}}$, in which case the optimal design is the main study only $(n_2 = 0)$. When sensitivity and specificity are allowed to depend upon case status, the optimal allocation ranges between 0 and 1, depending on the other design parameters. Palmgren also provided some results for minimizing the variance of the **maximum likelihood** estimator of β, for $\beta \neq 0$, subject to fixed cost, under the assumptions that the sensitivity and specificity are equivalent for cases and controls and for a one-to-one case–control ratio. It is shown that for small β, case–control ratios near one-to-one and in most cases when the cost ratio, $r_{\mathrm{X}}/r_{\mathrm{W}}, \geq 4$, the main study/internal validation study design is more efficient than the fully validated design. When the exposure is rare, the optimal design depends more heavily on the value of the specificity parameter, and when the exposure is common, the optimal design depends more heavily on the sensitivity parameter.

A useful contribution of [11] are equations (A1) and (A2), which give the nonnull and null formulas for the variance of the maximum likelihood estimator of β.

Greenland [6] also minimized the variance of $\hat{\beta}$ subject to fixed cost, but he used the matrix method for estimating β [2, 7, 12], rather than maximum likelihood. Greenland found that the optimal proportion allocated to the validation study increases dramatically when **differential** misclassification is assumed. He concluded that the fully validated design is optimal or near optimal in many cases and has the additional advantages of permitting standard methods of data analysis and of assuring representativeness of the validation sample. Although Greenland's recommendations are clearly appropriate for low cost ratios ($r_{\mathbf{X}}/r_{\mathbf{W}}$ ranging between 3 and 12) and high case–control ratios (e.g. where $\Pr(\mathbf{Y}) \approx 0.50$), it is not clear at what point this recommendation no longer applies. For cost ratios, $r_{\mathrm{X}}/r_{\mathrm{W}}$, above 100, or lower case–control ratios, the main study/validation study design is likely to be preferable.

Chernoff & Haitovsky [4] and Zelen & Haitovsky [20] considered optimal design in the estimation and testing settings, respectively. They admitted as the class of optimal designs a linear combination of the eight designs derived from four possibilities for case and controls: (i) main study only; (ii) validate all subjects with $\mathbf{W} = 1$; (iii) validate all subjects with $\mathbf{W} = 0$; and (iv) validation study only. Designs were optimized by minimizing the variance of the estimate of $\Pr(\mathbf{X} = 1|\mathbf{Y} = 1) - \Pr(\mathbf{X} = 1|\mathbf{Y} = 0)$, for fixed cost, and differential misclassification was assumed at known misclassification rates. They found that the optimal design was a combination of two of the eight sampling plans, one for cases and the other for controls. As long as the sensitivity, specificity, and costs of collecting the data are the same for cases and controls, the same type and sample size of design for cases and controls is optimal.

Optimal Study Designs for a Continuous Covariate Measured with Error

Buonaccorsi [3] provided optimal allocation formulas for minimizing the variance of the estimate of the

odds ratio subject to specified cost, when $\dim(\mathbf{X}) = \dim(\mathbf{W}) = 1$, $\dim(\mathbf{Z})$ is arbitrary, and $\mathbf{Y}$ is a binary outcome. These formulas apply when ($\mathbf{X}$, $\mathbf{W}$, $\mathbf{Z}$) are jointly **multivariate normal** given $\mathbf{Y}$ but where the measurement error model, $f_2(\mathbf{X}|\mathbf{W})$, may be a function of $\mathbf{Y}$ or dependent on other covariates $\mathbf{Z}_2$. Under these assumptions, the odds ratio can be validly and efficiently estimated through the normal **discriminant analysis** model instead of the **logistic regression** model. Buonaccorsi derived a closed-form expression for the optimal proportion of study subjects validated under the main study/internal validation study design, $n_2/(n_1 + n_2)$, as a function of six quantities: (i) unit costs for $\mathbf{Y}$, ($\mathbf{W}$, $\mathbf{Z}$) and $\mathbf{X}$ ($r_{\mathbf{Y}}$, $r_{\mathbf{W}}$, and $r_{\mathbf{X}}$); (ii) total cost for the study (C); (iii) value for the log odds ratio of $\mathbf{Y}$ from a unit change in $\mathbf{X}$ (β); (iv) multiple correlation between $\mathbf{X}$ and ($\mathbf{W}$ $\mathbf{Z}$) (this quantity can be taken to represent the extent of measurement error resulting from failure to observe $\mathbf{X}$); (v) the variance of $\mathbf{X}$ (σ_x^2); and (vi) the **marginal probability** of $\mathbf{Y}$ [Pr($\mathbf{Y}$)]. With the exception of the measurement error parameter and the quantities relating to cost, all of these quantities would be required for study design calculations even when $\mathbf{X}$ were perfectly measured. Buonaccorsi gave a simple formula for the variance of the measurement-error corrected estimate of β.

Spiegelman & Gray [13] also investigated optimal study design for binary **regression** in the case of a single continuous covariate measured with error but, unlike Buonaccorsi, they relied on the discriminatory power criterion. In addition to considering the main study/internal validation study design paradigm, they also considered the main study/external validation study designs. Since external validation study data will often be obtained as an afterthought at the end of a prospective study, choosing the optimal sample sizes, n_1 and n_2, is of less practical importance. However, it is instructive to compare cost, power, and sampling ratios as given by optimal internal and external validation study settings. From efficiency considerations, it was shown that an internal validation study is optimal. However, as Pr($\mathbf{Y}$) becomes small, the efficiency advantage of the main study/internal validation study design virtually disappears relative to the main study/external validation study design.

Rather than assuming that ($\mathbf{W}$, $\mathbf{X}$, $\mathbf{Z}$) are jointly normal given $\mathbf{Y}$, Spiegelman & Gray assume that $\mathbf{X}|\mathbf{W}$ is multivariate normal. Unlike Buonaccorsi, they did not consider the presence of additional perfectly measured exposure variables $\mathbf{Z}$, and they require that $\mathrm{E}(\mathbf{X}|\mathbf{W})$ is linear. Without the joint multivariate normality assumption, the normal discriminant model cannot be used to obtain an **unbiased** estimate of β. Instead, the logistic regression model must be used. This is the model upon which Spiegelman & Gray based their sample size calculations. Iterative methods must be used to find optimal main study and validation study sample sizes when $f_2(\mathbf{X}|\mathbf{W})$ is normal and $f_1(\mathbf{Y}|\mathbf{X})$, the model for the outcome conditional on the true exposure, is logistic. In order to find the optimal design in this framework, the investigator needs to identify six quantities: (i) $r_{\mathbf{Y}}, r_{\mathbf{X}}$, and $r_{\mathbf{W}}$; (ii) Pr($\mathbf{Y}$); (iii) β_{L} and β_{U}, the two values of the log odds ratio between which the study is designed to discriminate; (iv) the mean and variance of $\mathbf{W}$; (v) the parameters for the conditional mean of $\mathbf{X}$ given $\mathbf{W}$, α', and γ, where $\mathrm{E}(\mathbf{X}|\mathbf{W}) = \alpha' + \gamma\mathbf{W}$, and $\mathrm{var}(\mathbf{X}|\mathbf{W})$; and (vi) the desired confidence level, α, and the required discriminatory power, Π.

Spiegelman & Gray found that the fully validated design is optimal only when $r_{\mathbf{X}}/r_{\mathbf{W}}$ is small, Pr($\mathbf{Y} = 1$) is large, and the magnitudes of β_{U} and $\beta_{\mathbf{L}}$ are relatively far from the null but close together. They found that the optimal percent allocation to the validation study increased as the unit cost of $\mathbf{Y}$ increased. Figure 1 shows the cost of the optimal main study/internal validation study designs for sample disease frequencies [Pr($\mathbf{Y}$)] equal to 0.005. In

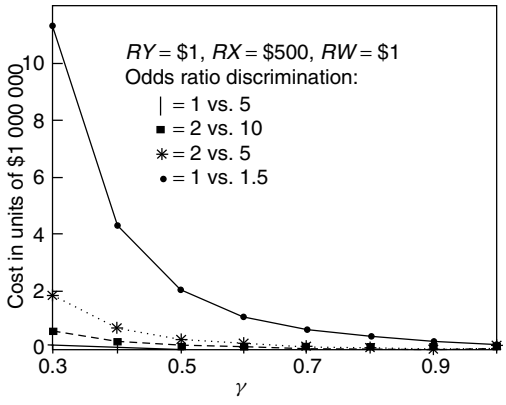

Figure 1 Plot of minimized cost to discriminate between two hypothesized odds ratios, against γ, where $\mathrm{E}(\mathbf{X}|\mathbf{W}) = \alpha' + \gamma\mathbf{W}$. When $\mathbf{X}$ and $\mathbf{W}$ are standardized, γ is corr ($\mathbf{W}$, $\mathbf{X}$)

this figure RY, RX, and RW are the unit costs for measuring **Y**, **X**, and **W**, respectively, and, when **X** and **W** are standardized, γ corresponds to the correlation between **X** and **W**. Designs are optimized to discriminate with 95% power between two hypothesized values of the odds ratios, and the scenarios considered are given in the legend. Cost increases dramatically as the distance between the two hypothesized odds ratios decreases, and as measurement error increases.

In the context of **nutritional epidemiology**, two additional papers on validation study design have appeared. Stram et al. [15] considered validation study design for minimizing the variance of the regression calibration estimate of the odds ratio, under the constraint of fixed total cost for an external validation study. They derived equations for the optimal choice of the number of subjects and the number of days per subject of diet records or diet recalls ($\mathbf{X}'$) when the food frequency questionnaire (**W**) is used to assess diet in the main study. It is assumed that the relationship between **X** and $\mathbf{X}'$ is given by the assumption of random within-person variation, following (1). They found that the optimal validation study size and number of replicates per subject depend on the ratio between the costs of the initial and subsequent 1-day diet records, and on the ratio of the variance in a single replicate of $\mathbf{X}'$ to the variance of the true underlying diet. The authors concluded that, in most settings, the optimal study design will rarely require more than five 1-day diet records per validation study participant. Kaaks et al. [9] derived a closed-form expression for the increase due to measurement error in the number of cases needed in a main study/external study design using regression calibration, as a function of the validation study sample size, the correlation between **X** and **W**, the odds ratio, and the conditional variance of **X** given **W**. They inverted this expression to optimize n_2 as a function of these other parameters, subject to a specified degree of precision in the regression calibration estimate of β per subject.

Conclusion

In main study/validation study design, the criterion used for design optimization should be carefully chosen. For both validity and efficiency considerations, internal validation studies are preferred over external ones. Particularly when the sample disease frequency is not rare and when the cost of the gold standard is not prohibitive, completely validated designs may be optimal. Owing to the lack of user-friendly software, it does not appear that explicitly optimized main study/validation study designs have been used by scientific investigators. Further work could involve making the identification of optimal designs more accessible in the field.

Validity and Generalizability in Epidemiologic Studies

The validity of a study of human subjects is often separated into two components: the validity of the **inferences** drawn as they pertain to members of the source population (*internal validity*), and the validity of the inferences as they pertain to people outside that population (*external validity* or *generalizability*). Internal validity parallels the statistical concept of generalizing from sample to source population, while generalizability involves more informal inference beyond a source population to **target populations**.

Scientific generalization extends beyond statistical generalization of study results to the formulation of abstract concepts relating the study factors. The concepts are abstract in the sense that they are not tied to specific populations; instead they amount to the specification of a more general scientific theory. Internal validity is a prerequisite for the study to contribute usefully to this process of abstraction, but the generalization process is otherwise separate from the concerns of internal validity and the mechanics of the study design.

Validity

Internal validity implies validity of inference for the study subjects themselves. Specifically, it implies an accurate measurement apart from **random errors**. Numerous types of **biases** can detract from internal validity; for examples, see [19]. The distinction among these biases is occasionally difficult to make, but three general types can be identified: **selection bias**, **confounding**, and information bias. These categories are not always clearly demarcated; factors that appear to be responsible for a selection bias can also be viewed, under some circumstances, as confounding factors. Occasionally, certain information biases can also be construed as confounding.

Selection Bias

Most epidemiologic studies involve a comparison of two or more groups with regard to either disease or exposure frequency. Bias is a distortion of the effect that is measured. Selection biases are distortions that result from procedures used to select subjects, and from factors that influence study participation.

Self-Selection Bias. One form of such bias is *self-selection* bias. When the **Centers for Disease Control (CDC)** investigated subsequent leukemia incidence among troops who had been present at the Smoky Atomic Test in Nevada [3], 76% of the troops identified as members of that cohort (*see* **Cohort Study**) had known outcomes. Of this 76%, 82% were traced by the investigators, but the other 18% contacted the investigators on their own initiative in response to publicity about the investigation. This self-referral of subjects is ordinarily considered a threat to validity, since the reasons for self-referral may be associated with the outcome under study [6]. In the Smoky study, there were four leukemia cases among the $0.18 \times 0.76 = 15\%$ of cohort members who referred themselves and four among the $0.82 \times 0.76 = 62\%$ of cohort members traced by the investigators, for a total of eight cases among the 76% of the cohort with known outcomes. These data indicate that self-selection bias was a small but real problem in the Smoky study. If the 24% of the cohort with unknown outcomes had a leukemia incidence like that of the subjects traced by the investigators, then we should expect that only $4(24/62) = 1.5$ or about one or two cases occurred among this 24%, for a total of only nine or 10 cases in the entire cohort. If, however, we assumed that the 24% with unknown outcomes had a leukemia incidence like that of subjects with known outcomes, then we would calculate that $8(24/76) = 2.5$ or about two or three cases occurred among this 24%, for a total of 10 or 11 cases in the entire cohort.

Self-selection can also occur before subjects are identified for study. For example, it is routine to find that the mortality of active workers is less than that of the population as a whole [9, 15]. This "healthy-worker effect" presumably derives from a screening process, perhaps largely self-selection, that allows relatively healthy people to become or remain workers, whereas those who remain unemployed, retired, disabled, or otherwise out of the active worker population are as a group less healthy [23] (*see* **Occupational Epidemiology**).

Diagnostic Bias. Another type of selection bias occurring before subjects are identified for study is

diagnostic bias [19]. When the relation between oral contraceptives and venous thromboembolism was first investigated with **case–control studies of hospitalized patients**, there was concern that some of the women had been hospitalized with a diagnosis of venous thromboembolism because their physicians suspected a relation between this disease and oral contraceptives and had known about oral contraceptive use in patients who presented with suggestive symptoms [20]. A study of hospitalized patients with thromboembolism could lead to an exaggerated estimate of the effect of oral contraceptives on thromboembolism if the hospitalization and determination of the diagnosis were influenced by the history of oral contraceptive use.

Many varieties of selection bias could be described. The common element of such biases is that the relation between exposure and disease is different for those who participate and those who should be theoretically eligible for study, including those who do not participate. The result is that associations observed in the study represent a mix of forces determining participation as well as forces determining disease. It is sometimes (but not always) possible to disentangle the effects of participation determinants from those of disease determinants using analytic methods for the control of confounding.

Confounding. The term **confounding** has been used for several different concepts. Although this bias can occur in experiments, it is a considerably more important issue in nonexperimental research.

On the simplest level, confounding may be considered a confusion of effects. Specifically, the apparent effect of the exposure of interest is distorted because the effect of an extraneous factor is mistaken for or mixed with the actual exposure effect (which may be null). The distortion introduced by a confounding factor can be large, and it can lead to overestimation or underestimation of an effect depending on the direction of the **associations** that the confounding factor has with exposure and disease. Confounding can even change the apparent direction of an effect.

A more precise definition of confounding begins by considering the manner in which effects are estimated. Let us assume that we wish to estimate the degree to which exposure has changed the frequency of disease in an exposed cohort. To do so, we must estimate what the frequency of disease would have been in this cohort had exposure been absent. To accomplish this task, we observe the disease frequency in an unexposed cohort. But rarely could we take this unexposed frequency as fairly representing what the frequency would have been in the exposed cohort had exposure been absent, because the unexposed cohort would differ from the exposed cohort on many factors that affect disease frequency besides exposure. To express this problem, we say that the comparison of the exposed and unexposed is *confounded*, because the difference in disease frequency between the exposed and unexposed results from a mixture of several effects, including (but not limited to) any exposure effect.

The extraneous factors responsible for difference in disease frequency between the exposed and unexposed are called **confounders**. In addition, factors associated with these extraneous causal factors that can serve as surrogates for these factors are also commonly called confounders. The most extreme example of such a surrogate is chronologic age. Increasing age is strongly associated with *aging* – the accumulation of cell mutations and tissue damage that lead to disease – but increasing age does not itself cause such pathogenic changes, for it is just a measure of how much time has passed since birth.

Regardless of whether a confounder is a cause of the study disease or merely a surrogate for such a cause, its chief characteristic is that it would be predictive of disease frequency within the unexposed (reference) cohort – otherwise it could not explain why the unexposed cohort fails to represent properly what the exposed cohort would experience in the absence of exposure. For example, suppose all the exposed were men and all the unexposed women. If unexposed men would have the same incidence as unexposed women, then the fact that all the unexposed were women rather than men could not account for any confounding that is present.

Information Bias

Once the subjects to be compared have been identified, the information to be compared must be obtained. Bias in evaluating an effect can occur from errors in obtaining the needed information. Information bias can occur whenever there are errors in the measurement of subjects, but the consequences of the errors are different depending on whether the distribution of errors for one variable (for example,

exposure or disease) depends on the actual value of other variables. and errors in other variables.

For discrete variables, **measurement error** is usually called classification error or **misclassification**. Classification error that depends on the values of other variables is referred to as *differential misclassification* (*see* **Differential Error**). Classification error that does not depend on the values of other variables is referred to as *nondifferential misclassification* (*see* **Nondifferential Error**).

Differential Misclassification. Suppose a cohort study were undertaken to compare incidence rates of emphysema among smokers and nonsmokers. Emphysema is a disease that may go undiagnosed without unusual medical attention. If smokers, because of concern about health-related effects of smoking or as a consequence of other health effects of smoking (such as bronchitis), seek medical attention to a greater degree than nonsmokers, then emphysema might be diagnosed more frequently among smokers than among nonsmokers simply as a consequence of the greater medical attention. Unless steps were taken to ensure comparable follow-up, an information bias would result: a spurious excess of emphysema incidence would be found among smokers compared with nonsmokers that is unrelated to any biologic effect of smoking. This is an example of differential misclassification, since the underdiagnosis of emphysema, a classification error, occurs more frequently for nonsmokers than for smokers. Unlike the diagnostic bias in the studies of oral contraceptives and thromboembolism described earlier, it is not a selection bias, since it occurs among subjects already included in the study. Nevertheless, the similarities between some selection biases and differential misclassification biases are worth noting.

In case–control studies of congenital malformations, the etiologic information may be obtained at interview from mothers. The case mothers have recently given birth to a malformed baby, whereas the vast majority of control mothers have recently given birth to an apparently healthy baby. Another variety of differential misclassification, referred to as **recall bias**, can result if the mothers of malformed infants recall exposures more thoroughly than mothers of healthy infants. It is supposed that the birth of a malformed infant serves as a stimulus to a mother to recall all events that might have played some role in the unfortunate outcome. Presumably such women will remember exposures such as infectious disease, trauma, and drugs more accurately than mothers of healthy infants, who have not had a comparable stimulus. Consequently, information on such exposures will be ascertained more frequently from mothers of malformed babies, and an apparent effect, unrelated to any biologic effect, will result from this recall bias. Recall bias is a possibility in any case–control study that uses an anamnestic response, since the cases and controls by definition are people who differ with respect to their disease experience, and this difference may affect recall.

The bias that is caused by differential misclassification can either exaggerate or underestimate an effect. In each of the examples above, the misclassification serves to exaggerate the effects under study, but examples to the contrary can also be found. Because of the relatively unpredictable effects of differential misclassification, some investigators go through elaborate procedures to ensure that the misclassification will be nondifferential, such as **blinding** of exposure evaluations with respect to outcome status. Unfortunately, even in situations when blinding is accomplished or in cohort studies in which disease outcomes have not yet occurred, collapsing continuous or categorical exposure data into fewer categories can induce differential misclassification [8, 21].

Nondifferential Misclassification. Nondifferential exposure or disease misclassification occurs when the proportion of subjects misclassified on exposure does not depend on disease status, or when the proportion of subjects misclassified on disease does not depend on exposure. When the misclassification is independent of other errors, bias introduced by such nondifferential misclassification of a **binary** exposure or disease is predictable in direction, namely toward the null value [5, 11, 12, 17] (*see* **Bias Toward the Null**). Contrary to popular misconceptions, however, nondifferential exposure or disease misclassification can sometimes produce bias away from the null, especially if the errors in exposure and disease classification are correlated [4, 7, 13, 22]. If the misclassification is extreme, the misclassification can go beyond the null value and reverse direction.

When the exposure is **polytomous** (that is, has more than two categories) and there is nondifferential misclassification between two of the categories and no others, the effect estimates for those two categories will be biased toward one another [1,

22]. In particular, the effect estimate for the lower exposure category will be shifted toward that of the higher exposure category, and away from the null value. It is also possible for independent nondifferential misclassification to bias trend estimates away from the null or reverse a trend [7]. Such examples are unusual, however, because trend reversal cannot occur if the **mean** exposure measurement increases with true exposure [24].

Nondifferential Misclassification of Disease. The effects of nondifferential misclassification of disease resemble those of nondifferential misclassification of exposure. In most situations, nondifferential misclassification of a binary disease outcome will produce bias toward the null, provided that the misclassification is independent of other errors. There are, however, some useful special cases in which such misclassification produces no bias in the risk ratio (*see* **Relative Risk**); in addition, the bias in the risk difference is a simple function of the **sensitivity** and **specificity**. For a discussion, see Rothman & Greenland [18].

Pervasiveness of Nondifferential Misclassification. Since the bias from independent nondifferential misclassification of a dichotomous exposure is always in the direction of the null value, historically it has not been a great source of concern to epidemiologists, who have generally considered it more acceptable to underestimate effects than to overestimate effects. Nevertheless, such misclassification is a serious problem: the bias it introduces may account for certain discrepancies among epidemiologic studies. Many studies ascertain information in a way that guarantees substantial misclassification, and many studies use classification schemes that can mask effects in a manner identical to nondifferential misclassification.

Suppose aspirin transiently reduces risk of myocardial infarction. The word *transiently* implies a brief induction period. Any study that considered as exposure aspirin use outside of a narrow time interval before the occurrence of a myocardial infarction would be misclassifying aspirin use: there is relevant use of aspirin, and there is use of aspirin that is irrelevant because it does not allow the exposure to act causally under the causal hypothesis with its specified induction period. Many studies ask about "ever use" (use at any time during an individual's life) of drugs or other exposures. Such cumulative indices over an individual's lifetime inevitably augment possibly relevant exposure with irrelevant exposure, and can thus introduce a bias toward the null value through nondifferential misclassification.

In cohort studies in which there are disease categories with few subjects, investigators are occasionally tempted to combine outcome categories to increase the number of subjects in each analysis, thereby gaining precision. This collapsing of categories can obscure effects on more narrowly defined disease categories.

Nondifferential exposure and disease misclassification is a greater concern in interpreting studies that seem to indicate the absence of an effect. Consequently, in studies that indicate little or no effect, it is crucial for the researchers to consider the problem of nondifferential misclassification to determine to what extent a real effect might have been obscured. On the other hand, in studies that describe a strong nonzero effect, preoccupation with nondifferential exposure and disease misclassification is rarely warranted, provided that the errors are independent. Occasionally, critics of a study will argue that poor exposure data or a poor disease classification invalidate the results. This argument is incorrect, however, if the results indicate a nonzero effect and one can be sure that the classification errors produced bias towards the null, since the bias will be in the direction of underestimating the effect.

Generally speaking, it is incorrect to dismiss a study reporting an effect simply because there is substantial nondifferential misclassification of exposure, since an estimate of effect without the misclassification could be even greater, provided that the misclassification probabilities apply uniformly to all subjects. Thus, the implications of nondifferential misclassification depend heavily on whether the study is perceived as "positive" or "negative". Emphasis on measurement instead of on a qualitative description of study results lessens the likelihood for misinterpretation, but even so it is important to bear in mind the direction and likely magnitude of a bias.

Misclassification of Confounders. If a confounding variable is misclassified, the ability to control confounding in the analysis is hampered [2, 10, 14]. While independent nondifferential misclassification of exposure or disease usually biases study results in the direction of the null hypothesis, independent nondifferential misclassification of a confounding

variable will usually reduce the degree to which confounding can be controlled and thus can cause a bias in either direction, depending on the direction of the confounding. For this reason, misclassification of confounding factors can be a serious problem.

If the confounding is strong and the exposure–disease relation is weak or zero, misclassification of the confounding factor can lead to extremely misleading results. For example, a strong causal relation between smoking and bladder cancer, coupled with a strong association between smoking and coffee drinking, makes smoking a strong confounder of any possible relation between coffee drinking and bladder cancer. Since the control of confounding by smoking depends on accurate smoking information, and since some misclassification of the relevant smoking information is inevitable no matter how smoking is measured, some residual confounding is inevitable [16]. The problem of residual confounding would be even worse if the only available information on smoking were a simple dichotomy such as "ever smoked" vs. "never smoked", since the lack of detailed specification of smoking prohibits adequate control of confounding. The resulting confounding is especially troublesome because to many investigators and readers it may appear that confounding by smoking has been controlled.

Generalizability

Many epidemiologists and statisticians have taught that generalization from a study group depends on the study group being a representative subgroup of the target population, in the sense of a sample. If scientific generalization were simply a matter of statistical generalization, however, it would be limited literally to those individuals who might have been included, through sampling, as study subjects. If this notion were correct, there would be no application to humans of any results obtained from animal research. In addition, every population would require its own set of studies, and these studies would have to be repeated for every new generation.

The tendency to use "representative" study groups probably derives from early experience with **surveys** for which the inferential goal was only description of the surveyed population. Social scientists often rely on statistical inference because decisions about what is relevant for generalization are more difficult in the **social sciences**, and populations are considerably more diverse in sociologic phenomena than in biologic phenomena. In the biologic sciences, however, investigators conduct experiments using animals with characteristics selected to enhance the validity of the experimental work rather than to represent the target population. Epidemiologic study designs are usually stronger if subject selection is guided by the need to make a valid comparison, which may call for severe restriction of admissible subjects to a narrow range of characteristics, rather than by an attempt to make the subjects representative, in a sampling sense, of the potential target populations.

Ultimately, the goal of a purely scientific study is to contribute to scientific knowledge. The process of synthesizing knowledge from observations is, after centuries of examination, not yet well understood. In most sciences, however, the process involves moving from the particulars of a set of observations to the abstraction of a scientific hypothesis or theory that is more or less divorced from time and place: the abstractions apply to a broader domain of experience than that observed or sampled from. Such scientific generalization amounts to moving from time- and place-specific observations to an abstract "universal" hypothesis, such as "cigarette smoking causes lung cancer". This process is neither mechanical nor statistical, nor does it involve specific target populations (although the hypothesis may be limited to certain biological subgroups, such as a specific **genotype**). In this sense, the term external validity is a misnomer, and the term generalization must be interpreted as abstraction. Selection of study groups that are representative of larger populations in the statistical sense will generally not enhance the ability to abstract universal statements from observations, but selection of study groups for characteristics that enable a study to distinguish effectively between competing scientific hypotheses will do so.

In addition to scientific goals, some studies also have a goal of measuring effects and predicting the impact of interventions in a specific target population. In contrast to scientific inference, these pragmatic goals may depend more closely on the representativeness of study subjects with respect to the target population. For example, if a **clinical trial** is conducted using patients with a good **prognosis**, the results from the trial may not predict well the results when the new intervention is applied to patients with a poor prognosis. Thus, some effort may be needed

in the study design to ensure that enough subjects are included from each of several major subgroups of the target, such as males and females. Even in this situation, complete representativeness is not always desirable, for a more efficient study might be obtained by oversampling some subgroups and then standardizing the study estimate to the target population.

Variable Selection

Automated variable selection is often used for the selection of **explanatory variables** in regression (*see* **Multiple Linear Regression**). This may be in the context of linear or nonlinear models with continuous or categorical data. More broadly, variable selection concerns the choice of variables derived from an original set of available explanatory variables, including **interaction** and nonlinear terms, and orthogonal series decompositions (principal components (*see* **Principal Components Analysis**), Fourier series, **splines**, **wavelets** (*see* **Orthogonality**). This involves substantive considerations of the application, and cannot necessarily be based on automated means. In short, it concerns the modeling process.

The most common use is for the selection of explanatory variables in least squares linear regression, often by automated means, to arrive at a single "best" model. Variables are included or excluded on the basis of:

1. Statistical tests that regression coefficients or groups of regression coefficients are zero.
2. Model choice criteria (*see* **Model, Choice of**), e.g. **Mallows' C_p statistic**, **Bayes** information criterion (BIC) (see the section "Bayes Selection" below).
3. **Cross-validation** or **bootstrap** prediction.

The first of these broadly relates to **estimation** accuracy, whereas the latter two relate to **prediction** accuracy.

Many caveats need to be attached to such automated procedures, and we discuss some of them later in this article. With k explanatory variables there are 2^k possible regression models, depending on whether or not each variable is included. When k is more than about 15 (or perhaps less) a complete search of all models is often abandoned in favor of a restricted automated search, broadly categorized as:

1. backward, forward, and stepwise selection
2. using a branch-and-bound **algorithm**
3. using a stochastic algorithm for finding a good model.

The search algorithms may also aim to provide a subset of models, all of which may be judged to be alternative good models. One may then wish to choose from within this primitive subset a model which makes physical sense or alternatively report the range of suitable models, or even provide predictions based on averaging the range of good models; see, for example, [6] and [18]. The use of stochastic algorithms is mushrooming, especially in the area of Bayesian variable selection (*see* **Bayesian Methods**), using **Markov chain Monte Carlo** (MCMC).

Before considering these aspects in more detail we illustrate some simple selection algorithms with data on the factors associated with infant birth weight, collected from Baystate Medical Centre, Massachusetts, during 1986, given by Hosmer & Lemeshow [12]. The birth weights of the 189 infants ranged from 709 g to 4990 g. It was thought that variation in birth weight might be explained by nine variables: *AG*e of mother (years), *W*eigh*T* in pounds at last menstrual period, *SM*oking status during pregnancy, number of *PR*evious premature births, *HY*pertension presence, uterine *IR*ritability, number of physician *VI*sits during first trimester, and two race dummy variables to define *BL*ack and *OT*her to cover the three categories, White, Black, and Other. Our purpose here is not to examine whether these are the most sensible variables to employ, but rather to illustrate some of the selection issues elaborated on in the following sections of this article. The regression equation for all nine variables included is

$$\begin{aligned} Birthwt = {} & 2928 - 3.57AG + 4.35WT - 352SM \\ & - 48PR - 593HY - 516IR - 14.1VI \\ & - 488BL - 355OT. \end{aligned} \quad (1)$$

Only 24% of the variation is explained, and Student's t-ratios on individual coefficients range from 3.72 on IR to 0.30 on VI (in absolute terms), with three <2: AG, PR, and VI. If one successively removes the most insignificant variable, refitting the remaining variables and stopping when all remaining variables are significantly different from zero on the basis of a nominal 5% F test, then a six-variable model results. This model is

$$\begin{aligned} Birthwt = {} & 2837 + 4.24WT - 356SM - 585HY \\ & - 526IR - 475BL - 348OT. \end{aligned} \quad (2)$$

The t ratios for the six variables (based on newly estimated residual error) range from 2.53 to 3.90 in absolute terms with 24% variation explained. In

fact, this model contains all the variables significant at the 5% level. None of the remaining variables, either singly or in combination, explains significant variation. It also happens to be the preferred model of the various search methods based on statistical testing as well as C_p model choice. In this example it hardly leads to an impressively well-fitting model, and has a sizable residual standard deviation of 646, and yet at least has coefficients which are plausible in direction. A more detailed summary of alternative models is given in Table 1, with the best two models of each size from 1 to 8 together with the full nine-variable model.

The residual standard deviation in the full model, $\hat{\sigma} = 650.3$, is used for

$$C_p = \frac{\text{RSS}_p}{\hat{\sigma}^2 + 2p - n} \tag{3}$$

in all p variable models fitted, $p = 1, \ldots, 9$. Here, RSS_p is the residual sum of squares for the particular p-variable model, and the estimated residual variance for this model is $s^2 = \text{RSS}_p/(n - p - 1)$.

If one were to base choice of model on percentage of variation explained (R^2), then the full nine-variable model is best. Adjusted R^2, given as

$$\text{adj. } R_p^2 = 1 - \left(1 - R_p^2\right) \frac{n}{(n - p)}, \tag{4}$$

suggests a six-variable model with WT, SM, PR, IR, BL, and OT included. Mallows' C_p leads to the same six-variable model.

The hoped for advantage of subset models rests with reduced **mean square error** loss, to be achieved by reduction of variance at the expense of minimal increase in bias. It may offer prediction or estimation robustness by avoiding those variables whose effect is nonlinear or which interact with other variables. Occasionally there is real benefit in terms of reduced cost in not needing to measure particular variables, and this may be particularly true in the medical context where some measurements may be invasive to the patient.

Automatic selection procedures are perhaps most appropriate when there is a large number of candidate variables and no clear prior knowledge of variables likely to be related to the response. These procedures are built into many statistical packages (*see* **Software, Biostatistical**). With least squares multiple regression they provide perhaps the most heavily used, and abused, statistical technique. Focusing on just one model often ignores other good models and the uncertainty, due to the process of sifting, that ought to attach to that selection. Some of the technical aspects are described below. For further discussion of strategic considerations both in the choice of measurement and **measurement scale**, and choice

Table 1 Best two models of each size for predicting birth weight from nine explanatory variables, percentage variation explained (R^2), adjusted R^2, Mallows' C_p, and residual standard deviation

					Variables								
Size	R^2	Adj. R^2	C_p	s	AG	WT	SM	PR	HY	IR	VI	BL	OT
1	8.1	7.6	32.3	701						X			
1	3.6	3.1	42.8	718			X						
2	11.2	10.3	26.8	691					X	X			
2	11.1	10.1	27.2	691			X			X			
3	14.8	13.4	20.4	679		X			X	X			
3	14.7	13.3	20.6	679			X			X			X
4	18.9	17.1	12.7	664			X			X		X	X
4	17.7	16.0	15.4	669			X		X	X			X
5	21.4	19.2	8.9	655			X		X	X		X	X
5	20.5	18.3	11.0	659		X	X			X		X	X
6	24.0	21.5	4.6	646		X	X		X	X		X	X
6	21.6	19.0	10.3	656			X	X	X	X		X	X
7	24.2	21.2	6.3	647		X	X	X	X	X		X	X
7	24.1	21.2	6.3	647	X	X	X		X	X		X	X
8	24.2	20.9	8.1	649	X	X	X	X	X	X		X	X
8	24.2	20.8	8.1	649		X	X	X	X	X	X	X	X
9	24.3	20.5	10.0	650	X	X	X	X	X	X	X	X	X

of variables, see [5]. Raab [22], in a cross-sectional study of blood lead levels on children's abilities, emphasizes the importance of study design to separate **confounders** from exposure variables and the desirability of purposeful predetermined inclusion of some covariates. Related topics are **Model, Choice of**, **Parsimony**, **Akaike's Criteria**, **Model Checking**, **Diagnostics**, and **Residuals**.

Restricted Search Methods

Forward, Backward, and Stepwise Selection

These methods are all based on significance tests as to whether to enter or delete a variable. The estimated residual variance is usually kept constant during the search, either being specified from the full model with k variables or from replicates or near replicates in the data. For stepwise selection there are two quantities, *FADD* and *FDROP*, and these may be specified by the appropriate value of the tabulated F distribution (*see* ***F*** **Distributions**) to test whether the coefficient can be assumed to be zero for the candidate variable in the context of the currently entertained model involving p of the k regressors, typically on 1 and $n-k-1$ degrees of freedom. Suppose the model currently includes explanatory variables $X_1, X_2, \ldots, X_p$. For each of these p variables the F statistic (= square of t statistic) is compared with *FDROP*. If the minimum F statistic is less than *FDROP*, then that variable is removed from the current model, $p \leftarrow p-1$, and the variable goes into the pool of variables not currently used, otherwise no variable is dropped at this stage. Each variable in this pool of unused variables is examined now in turn to see whether it should be added to the current model. If the largest F statistic from augmenting the model with a variable from the available pool is greater than *FADD*, then the variable is added to the current model and $p \leftarrow p+1$, otherwise no variable is added at this stage. Clearly, to make sense, $FADD \geq FDROP$. The process of adding or subtracting variables continues until the model no longer changes, and all variables included have F statistics greater than *FDROP* and all variables not included have F statistics for inclusion less than *FADD*. The stepwise algorithm may start from either no variables in the model and build up the model, or from all variables in the model and strip down the model. It might also start from some arbitrarily specified model with some of the main variables included, or even a randomly chosen starting set. The build-up mode is the only feasible option when there are more variables than observations and the full variable model is overparameterized, and fits perfectly, with zero residual variation.

Often in stepwise regression one chooses $FADD = FDROP$. A value around 4 corresponds to a 5% significance test ($1.96^2 = 3.84$) for infinite error degrees of freedom and consequent normality of the estimated regression coefficient. For moderate or few degrees of freedom on the residual error estimate, then the *FADD*, *FDROP* pair ought to be correspondingly larger than 4. The use of Mallows' C_p as a criterion for subset choice implies $FADD = FDROP = 2$ since the residual sum of squares for the candidate p variable model, divided by estimated residual variance, is penalized by adding $2p$, that is 2 per new variable added. Thus Mallows' C_p will tend to choose larger models than arising out of 5% significance tests. However, C_p was not designed by Mallows [19] as an automatic selection procedure, but rather as a graphical method of comparing models of differing dimensions exhaustively.

Forward selection and backward elimination may be thought of as special cases of the stepwise algorithm. Forward selection starts with no variables in the model and has $FDROP = 0$, so that variables are added one at a time until no variable not in the equation has an F statistic for entry greater than *FADD*. There is no guarantee that the variables in the final equation all have F statistics greater than *FADD*, since once entered in the sequential process they are not considered for removal at any future stage.

Backward elimination corresponds to the stepwise algorithm with $FADD = \infty -$ in practice, some chosen large number. It starts from all variables in the equation. The procedure stops when no variable in the model has an F statistic less than *FDROP*.

None of these methods guarantees that the model chosen is the best out of the 2^k possible models. Particular combinations of variables may be missed completely. The attraction of the algorithms is that they are very fast, whereas a complete enumerative search of the 2^k models becomes infeasible for k much greater than about 15.

A number of issues are raised by adoption of one of these automatic procedures, aside from whether they find the "best" model. First, the idea of finding a single best model is suspect because there may

be other near "best" models which are much more plausible and substantively interesting. Secondly, the extent of the sifting process with repeated significance tests and search for the maximum F statistic is not quantified in terms of increased uncertainty that the optimal model is best or even good. This is discussed in some detail by Miller [20, Chapter 3]. Breiman & Spector [3] evaluate backward selection techniques in terms of prediction error with special emphasis on a bootstrap and cross-validation choice of model. Bootstrap and 5-fold cross-classification choices fare particularly well.

Branch-and-Bound Algorithms

Criteria such as minimizing the residual sum of squares or prediction error have a particular monotonicity property. If $\mathcal{A}$ is a set of variable labels and $\mathcal{B}$ is a subset of $\mathcal{A}$, then

$$\mathrm{RSS}(\mathcal{A}) \leq \mathrm{RSS}(\mathcal{B}).$$

Many of the criteria used in identifying the "best" subset of variables are monotone in RSS given subsets with the same number of independent variables. These include adjusted R^2 and Mallows' C_p; exceptions are the bootstrap procedures of Breiman & Spector [3] and the leave-one-out cross-validatory statistic PRESS of Allen [2], although the latter is asymptotically equivalent to C_p [25].

The branch-and-bound algorithm, in its most satisfying form given by Furnival & Wilson [9], relies on this simple monotonicity. If a model with $p < p^*$ variables has a smaller RSS (and cannot therefore be a subset), then the model with p^* variables and *all* its submodels must be inferior to the model with the alternative set of p variables. If models are thought of as being generated by a binary tree, then the branch with the particular set of p^* variables can be cut off and all its submodels ignored. Furnival & Wilson's approach provides a clever exploitation of this with an implementation that simultaneously creates two tableaux, one being for bounds, moving through the tree in complementary directions (*see* **Tree-structured Statistical Methods**).

The procedure can be readily modified to provide, say, the five best subsets of each size. Whilst all-subsets regression is only feasible for up to around 15 variables, the branch-and-bound algorithm can extend this to 30 or more variables, although its benefits reduce with increasing correlation between the independent variables. It cannot begin to tackle data generated by modern instruments used for chemometrics in the pharmaceutical industry, where 700 explanatory absorbances/reflectances at 700 wavelengths are not unusual. See [4, Chapter 7] for a variety of graphical and algorithmic techniques for such high dimensions.

Non-Gaussian Models

The techniques described readily extend to nonnormal models, common in medical studies. The residual sum of squares for a Gaussian model considered above is equal to $-2 \times$ ln likelihood maximized over the regression parameters, aside from a scale factor of $1/\sigma^2$. In the non-Gaussian case this so-called deviance (*see* **Generalized Linear Model**, or [7]), can be used as a basis of using **likelihood ratio tests** for comparison of two models, with either an assumed asymptotic **chi-square distribution** or an ***F* distribution** when the scale factor is estimated, in direct analogy with the Gaussian case.

In moving from Gaussian to non-Gaussian models, there is usually the need for iterative methods in fitting models by **maximum likelihood** (*see* **Optimization and Nonlinear Equations**). This imposes a considerable computational overhead. Lawless & Singhal [14] use a first-order approximation to the log likelihood of the submodel to speed up computations. Nordberg [21] shows how to incorporate such approximations so that standard least squares regression computer packages may be used, together with their associated best subsets/stepwise selection routines.

Bayes Selection

Model Choice

Suppose M_1 and M_2 denote two different regression models, with p_1 and p_2 variables and nonzero regression parameters β_1 and β_2, e.g. 1 and 2 above, respectively. The *Bayes factor* for M_1 vs. M_2 is

$$B_{12} = \frac{P(Y|X, M_1)}{P(Y|X, M_2)},$$

where

$$P(Y|X, M_i) = \int P(Y|X, \beta_i, M_i) P(\beta_i|M_i)\, \mathrm{d}\beta_i$$

is the probability of the data n-vector Y averaged over the prior distribution of the regression vector β_i. One way of comparing models is through Bayes factors. In fact under a wide set of model assumptions and prior assumptions, as n becomes large, it may be shown that

$$2 \ln B_{12} \approx \Lambda - (p_1 - p_2) \ln(n).$$

Here Λ is the generalized log likelihood ratio, and the relative error of the approximation implied for B_{12} is $O(1)$; see [13]. Large values of B_{12} support model 1 compared with model 2, and if $p_1 > p_2$ then the log likelihood ratio is penalized by $\ln(n)$ times the difference in dimensions. This $\ln(n)$ factor, known as the Bayes information criterion (BIC) [23], contrasts with the value 2 (AIC) argued by Akaike [1], and corresponds to Mallows' C_p in the special case of least squares multiple regression. The adjusted R^2 of 4 involves a factor $(1 - p/n)^{-1} \doteq 1 + p/n$ and therefore penalizes by 1 rather than the 2 of Mallows' C_p. The F test 5% significance method described earlier produces a penalization factor of around 4. Both AIC and BIC penalize maximum likelihood for overfitting. For large n the BIC penalization is much greater and leads to smaller models being promoted. For n smaller than $e^2 = 7.4$, AIC tends to favor smaller models. The BIC procedure is consistent as $n \to \infty$, whereas AIC is not [24], but BIC is not asymptotically efficient as $p \to \infty$. Consistency requires at least a penalization factor that increases with n. A factor of $2c \ln \ln(n)$, $c > 1$, is necessary and sufficient in the special case of autoregression; see [11]. Consistency may be regarded as less important when the aim is prediction rather than estimation.

Bayes Averaging

Whether the focus be estimation or prediction, any reasonable loss function (apart from 1–0 loss) will lead to model averaging rather than selection of a single "best" model if applying Bayesian decision theory. One exception is where costs on observing variables are included, as in [17], leading to a minimum expected posterior loss submodel. For prediction of a future Y_f at x_f,

$$P(Y_f | x_f, D) = \sum \int P(Y_f | X, \beta_i, M_i) P(\beta_i, M_i | D) \, \mathrm{d}\beta_i,$$

where D represents the n observation data. When there are 2^k models and k is large, this involves summation over a very large number of models. Madigan & Raftery [18] propose an Occam window principle (*see* **Parsimony**) which reduces the summation to be over the subset of models that are more probable *a posteriori*. Interestingly, **ridge regression** may be viewed as a particular weighted average of all subset models; see Leamer & Chamberlain [16].

Other Prior Distributions

A class of **prior distributions** with equiprobability contours proportional to

$$\prod_i (\gamma + |\beta_i|^\delta)$$

has been shown [15] to generate a range of densities which generate modal models favoring subsets. The idea seems to have been rediscovered by Frank & Friedman [8] to lend insight into a variety of chemometric regression tools, and taken up in a particular instance by the lasso of Tibshirani [26], corresponding to a double exponential prior distribution, with $\delta = 1$, $\gamma = 0$.

An approach gaining sway and more in keeping with model averaging is based on mixture models. Each regression parameter β_i is thought to come from one of two distributions, each one centered on zero, but one having a much smaller variance than the other, and may even be zero corresponding to a spike of probability at zero. There is an indicator random variable γ_i which determines whether the parameter has large variance ($\gamma_i = 1$) or small variance ($\gamma_i = 0$). The posterior distribution of the k-vector γ gives all the information about probable subset models. With a natural conjugate prior distribution and Gaussian errors, direct computation is feasible provided 2^k is not too large, say with $k < 20$. Otherwise Markov chain Monte Carlo (MCMC) allows one to summarize the posterior distribution by simulation; see [10].

Variance Component Analysis

Fisher [7] introduced the concept of environmental and **genetic correlations and covariances** in 1918. He assumed that a trait could be influenced by unmeasured genetic factors transmitted from parent to offspring in accordance with Mendelian inheritance (*see* **Mendel's Laws**), and showed that under certain conditions these factors would result in *genetic components of variation* that would make a stable contribution to population **variance**. It is also possible to develop models for *environmental components of variation* to represent the effects on trait covariation of sharing nongenetic factors.

These variance component models can be fitted to data collected on sets of individuals, generally referred to as pedigrees. Each pedigree could consist of a single individual on its own, a twin pair, a nuclear family or a multigenerational kinship. Pooled pedigrees need not all be of the same size and structure; see, for example, [9]. Although some methods for fitting variance components may be applicable to pedigrees that are "regular", in that they are all of the same size and structure (such as twin pairs), more general methods are needed to analyze data from sets of "irregular" pedigrees.

Even if a variance component model appears to give a good or parsimonious fit to the data, this does not necessarily imply that the hypothesized components correctly represent the true causes. The ability to differentiate the effects of shared (usually unmeasured) **genes** from those of (usually unmeasured) shared environment is strongly dependent on the design and the ability to model correctly the putative causes of familial associations.

A General Model

Within each pedigree, let $\mathbf{Y} = (Y_1, \ldots, Y_n)'$ be a vector of possibly dependent measures on a continuous trait. Let $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)'$ be the vector of conditional trait means expressed as a not necessarily linear function, f, of measured covariates specified by a set of parameters $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \ldots)'$. Similarly, for any two individuals i and j, let the covariance $\mathrm{cov}(Y_i, Y_j) = \boldsymbol{\Omega}_{ij}(\boldsymbol{\beta})$ be a not necessarily linear function of measured **covariates** specified by a set of parameters $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots)'$. The covariance matrix can be modeled in terms of variances and **correlations**, or the covariances themselves, or it can be modeled in terms of variance components. It can also be modeled in terms of path coefficients derived from path diagrams; although this approach is often referred to as **path analysis**, it is essentially the same as variance component analysis.

A Descriptive Model for Familial Associations

The covariance between relatives can be modeled by, for example, letting $\mathrm{cov}(Y_i, Y_j) = \sigma^2$ if $i = j$, $\rho_{\mathrm{sib}}\sigma^2$ if i and j are siblings, $\rho_{\mathrm{PO}}\sigma^2$ if i and j are parent and offspring, $\rho_{\mathrm{sp}}\sigma^2$ if i and j are a spouse pair, and so on, where ρ_{sib}, ρ_{PO}, and ρ_{sp} are the correlations between sibling, parent–offspring, and spouse pairs, respectively. Note that σ^2 can itself be modeled in terms of measured characteristics of the individuals, such as their age and sex. In this case, the expression above for the covariance must be adjusted to allow two individuals, i and j, to have different variances by replacing σ^2 by $(\sigma_i^2\sigma_j^2)^{1/2}$, and allowing σ_i^2 and σ_j^2 to depend on those variables.

A Basic Variance Component Model

A basic variance component model is represented by

$$Y_i = \mu_i + C_{\mathrm{i}} + E_{\mathrm{i}}, \tag{1}$$

where C_i and E_i are independent random variables with zero mean, and variances σ_{c}^2 and σ_{e}^2 representing factors common to a group of individuals, and factors specific to the individual, respectively. That is, for $i, j = 1, \ldots, n$, $\mathrm{cov}(C_i, C_j) = c_{ij}\sigma_{\mathrm{c}}^2$, where $c_{ii} = 1$ and $-1 \le c_{ij} \le 1$, while $\mathrm{cov}(E_i, E_j) = \sigma_{\mathrm{e}}^2$ if $i = j$, and 0 otherwise. If C and E are independent, then $\mathrm{cov}(Y_i, Y_j) = \mathrm{cov}(C_i, C_j) + \mathrm{cov}(E_i, E_j)$, and the variance of Y is $\sigma^2 = \sigma_{\mathrm{c}}^2 + \sigma_{\mathrm{e}}^2$. This model can be extended to include multiple variance components representing independent familial factors, $C^1, C^2, \ldots$, in which case $\mathrm{cov}(Y_i, Y_j) = \mathrm{cov}(C_i^1, C_j^1) + \mathrm{cov}(C_i^2, C_j^2) + \cdots + \mathrm{cov}(E_i, E_j)$, and the total variance of Y is $\sigma^2 = \sigma_{\mathrm{c1}}^2 + \sigma_{\mathrm{c2}}^2 + \cdots + \sigma_{\mathrm{e}}^2$.

The model can be extended by letting c_{ij} take different values depending on the characteristics of the individuals i and j, such as their relationship to

one another, or whether they actually live together and for how long, and how often they see each other. The coefficients c_{ij} can also be considered as parameters, and estimated rather than fixed a priori. They can also be estimated as a function of measured variables (see below).

The descriptive model can be represented as a variance component model as follows: let C represent factors common to, for example, siblings, so that $c_{ij} = 1$ if i and j are siblings, otherwise 0. The correlation between siblings, ρ_{sib}, is therefore σ_c^2/σ^2. The variance component E encompasses measurement error, which sets an upper limit on the ratio σ_c^2/σ^2, "the amount of variation attributed to the variance component" C.

Note that in the descriptive model above, and in this simple variance component model, the causes of familial aggregation need not be specified. The correlations between relatives, and the variance components representing factors common to relatives, could be caused by genetic and/or nongenetic factors shared by the relatives.

A More General Variance Component Model

A more general model that allows interpretation of variance components is given by

$$Y_i = \mu_i + G_i + C_i + E_i, \tag{2}$$

where G, C and E are independent with zero mean, and represent genetic factors, factors common to relatives, and factors specific to an individual (including measurement error), respectively.

The variance of G, or *genetic variance* σ_g^2, can be decomposed into σ_a^2, the additive genetic variance, representing the additive effects of alleles at a locus, and σ_d^2, the dominance genetic variance, representing the nonadditive effects of alleles at a locus [7]. This applies whether there is one, several or a multitude of loci influencing the trait. It has traditionally been used to model the effects of one or more putative genetic loci that have not been measured, and is used to make inferences about the existence and magnitude of genetic etiologies, even though the genes responsible are not identified. The model can be extended to include epistasis (*see* **Genotype**), and there are a number of ways of expressing the genetic correlations and covariances in terms of **identity coefficients**. Furthermore, the components of variance themselves can be modeled as a function of measured covariates, in particular age and sex. Variations in the genetic variance with age or, for example, with geographic location, are consistent with **gene–environment interactions**.

The dominance component is difficult to detect in the presence of additive genetic factors, even with a large number of observations on relatives (e.g. twin pairs), because in most designs the correlation between the estimate of σ_a^2 and the estimate of σ_d^2 is typically close to -1 (for an example, see the section "Statistical Power" below). Although in theory a dominance effect can occur at a single locus without there being an additive effect [in which case the heterozygote must be on a different side of the mean than the homozygote(s)], a polygenic dominance component is implausible without a polygenic additive component (*see* **Polygenic Inheritance**).

Even when there is a "purely" dominant or recessive effect (in that one homozygote and the heterozygote have the same residual value about the mean that is different to the residual value of the other homozygote) there is both an additive and a dominance variance component. That is, "dominance variance" is not the same concept as "dominant inheritance"; one refers to a variance component and the other to a pattern of (expected) trait values for given genotypes. Furthermore, estimates of the dominance component are strongly confounded with those of a common sibling environment component in most designs.

As indicated above, the *environmental variances* that represent the effects of factors common to relatives, C, can be defined in a number of ways. For example, $\text{cov}(C_i, C_j) = \sigma_c^2$ if i and j live in the same household, or 0 otherwise, represents a common household effect. An effect related to length of cohabitation and to time spent living apart might take the form

$$\text{cov}(C_i, C_j) = \begin{cases} \sigma_c^2(1 - e^{-\lambda t}), & \text{if } t \le t', \\ \sigma_c^2(1 - e^{-\lambda t'})e^{-\nu(t-t')}, & \text{if } t > t', \end{cases} \tag{3}$$

where t represents time measured from when i and j begin living together possibly up to and beyond a time t', when i and j begin to live apart. The parameters λ and ν can be allowed to vary across relationships. Some theoretical justifications have been proposed [5, 14, 19].

Example 1: Blood Lead Levels

The lead content of blood was measured in 617 individuals from 80 families of two or three generations [14, 15]. After extensive descriptive modeling, which examined the shape of correlations as a function of type of relationship and ages of pairs, the following model was fitted to the log transformed blood lead levels: $Y_i = \mu_i + G_i + C_i^1 + C_i^2 + E_i$, where G, C^1, C^2 and E are independent with zero mean, and represent additive genetic factors, factors common to siblings, factors related to cohabitation, and factors specific to an individual (including measurement error), respectively, with variance components σ_a^2, σ_{c1}^2, σ_{c2}^2 and σ_e^2, respectively. For two members i and j of the same family, $\mathrm{cov}(G_i, G_j) = 2\phi_{ij}\sigma_a^2$ (i.e. it is assumed there are no dominance effects so that $\sigma_d^2 = 0$), $\mathrm{cov}(C_i^1, C_j^1) = \sigma_s^2$ if i and j are siblings, otherwise 0, and $\mathrm{cov}(C_i^2, C_j^2)$ follows (3) with t' set at 16 years.

A parsimonious model gave the following estimates (standard errors in parentheses): $\sigma_{c1}^2 = 0.008$ (0.005), $\sigma_{c2}^2 = 0.037$ (0.009), $\sigma_e^2 = 0.042$ (0.017), with $\sigma_a^2 = 0$. [When σ_a^2 was fitted it was estimated to be 0.007 (0.008), justifying its exclusion.] Referring to (3), the estimates were: $\lambda = 0.072$ for parent–offspring pairs, ∞ for sibling pairs, and 0 for spouse pairs; and $\nu = 0.140$.

The predicted correlations between parent–offspring and between sibling pairs based on this fit are depicted in Figure 1, across the possible range of cohabitation times and times spent living apart of pairs of study subjects. For sibling pairs both under 16 years the predicted correlation was $(\sigma_{c1}^2 + \sigma_{c2}^2)/\sigma^2 = (0.008 + 0.037)/0.087 = 0.52$, where $\sigma^2 = \sigma_{c1}^2 + \sigma_{c2}^2 + \sigma_e^2$, while for older sibling pairs the effect of C^1 halved every $\log 2/\nu = 5$ years towards the asymptote $\sigma_{c1}^2/\sigma^2 = 0.09$. For parent–offspring pairs the correlation was $[1 - \exp(-0.072a)]\sigma_{c1}^2/\sigma^2$ for offspring of age a, being 0.22 for $a = 10$, and peaking at 0.30 for $a = 16$, then halving for every 5 years thereafter. When sibling correlations were estimated from pairs of specific ages they were about 0.5 for siblings aged 11–18, 0.2 for siblings both aged 30 or older, and 0.1 for siblings both over the age of 50, in general accord with the predicted values displayed in Figure 1.

The factor C can also be used to represent measured genetic factors. Suppose a genetic **marker** is measured using **DNA** from individuals i and j; an additive effect could be modeled by $\mathrm{cov}(C_i, C_j) = \sigma_c^2$ if i and j share both alleles, $\frac{1}{2}\sigma_c^2$ if i and j share one allele, 0 otherwise, so that trait similarity is equated with the number of shared alleles [14, 17, 25]. By considering sharing of alleles both within and across pedigrees, in which case alleles are said to be shared "identity-by-state", the factor C represents a random association effect. If i and j are in the same pedigree, then it may be possible to determine how many of the alleles are shared identical-by-descent (ibd), or at least the probability that 0, 1 or 2 alleles are shared ibd. With c_{ij} equal to either half the observed number of alleles shared ibd, or half the expected number based on the probabilities, the factor C represents a random linkage effect (see below).

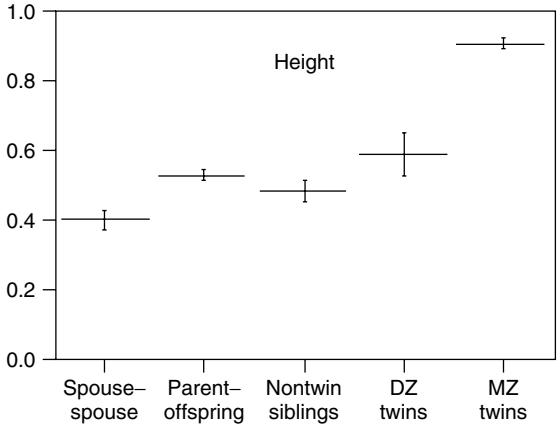

Figure 1 Predicted values of correlation in blood lead levels as a function of years, t, since cohabitation began, based on the fitted model. For sibling pairs, t is the age of the younger sibling, while for parent–offspring pairs t is the age of the offspring. It is assumed that individuals live in the same household as their parents up until the age $t' = 16$ years. Reproduced from [16] with permission from Blackwell Science

A Model for Twin and Family Data

Data from pairs of monozygous (MZ) and dizygous (DZ) twins can be used to test if there is evidence for a genetic component of variance, under the assumptions of the classic twin model (*see* **Twin Analysis**). By including data from relatives of the twins, or by supplementing the twin data with data from nontwin families, more critical assessment can be made of the underlying causes of familial aggregation. For

example, the coefficients of a common environment component can be defined by $c_{ij} = 1$ if i and j are members of the same twin pair, irrespective of zygosity (*see* **Zygosity Determination**), c_{sib} if i and j are siblings, c_{po} if i and j are a parent–offspring pair, c_{sp} if i and j are spouse of one another, etc. Unlike Fisher's model for the genetic components of variance, which are defined in terms of the identity coefficients, there is no established model for the relationship between these environmental coefficients, $c_{\text{sib}}, c_{\text{po}}, c_{\text{sp}}, \ldots$. Nevertheless, within the limitations of the design, the coefficients can be estimated [9]. This model presumes that the common environment effects are strongest within twin pairs, and the effects within other pairs of individuals are the same, or a proportion of, those effects. If, for example, the correlation within spouse pairs is more than can be explained by this parameterization of a common environment, then the model may not be realistic (e.g. there could be spouse-specific effects not shared by twins or other relatives), or there could be effects of **assortative mating**.

Example 2: Height

Height was measured in 2959 adult individuals in 783 families, including 89 MZ and 86 DZ twin pairs [9]. Figure 2 shows that the correlations for age- and sex-adjusted height. Independent of the sex of the parent or offspring, or the sexes of sibling pairs, the correlations in parent–offspring pairs were no different to the sibling correlations with all estimates in the range 0.4–0.5. The correlation in DZ pairs was 0.6 (standard error about 0.1). For MZ pairs the correlation was more than 0.9, adhered closely to the pattern anticipated under a model that attributes most familial aggregation to additive genetic factors with a small component to shared environment, and includes assortative mating (the correlation in spouse pairs was 0.4). After taking into account assortative mating [7], 55% of variance was attributed to additive genetic factors, 15% to the effects of environmental factors common to siblings, twins and parent–offspring pairs while they cohabited in the past, and the remainder to effects specific to individuals.

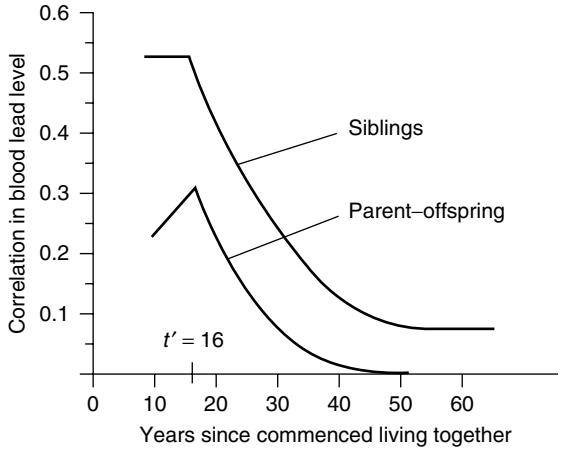

Figure 2 Correlation coefficients and their standard errors for the following pairs of family members: spouse–spouse, parent–offspring, nontwin siblings, DZ twins, MZ twins for height, Victorian Family Heart Study, 1990–1996. Reproduced from [9] by permission of Oxford University Press

Estimation, Statistical Inference and Model Fitting Under Multivariate Normality

Least squares analysis of variance (ANOVA), **maximum likelihood** and Bayesian methods have all been used to estimate variance components from samples of pedigrees [11, 12, 23, 31]. For simple balanced or "regular" designs, such as collections of twin pairs, the mean squares between and within pairs are sufficient statistics to estimate variance components. For more complex pedigree structures and unbalanced designs, ANOVA-type methods do not use the data efficiently and have unknown sampling properties, so that maximum likelihood (ML) methods are usually preferred because of the desirable asymptotic properties of estimates.

Perhaps the most flexible and practically useful approach, given the current wide availability of high-speed computers, assumes that $\mathbf{Y}$ has an n-variate normal distribution with mean $\boldsymbol{\mu}$ and variance–covariance matrix $\boldsymbol{\Omega}$, and uses ML estimation to simultaneously estimate mean and (co)variance parameters [23, 31]. Within a pedigree, the log likelihood (LL) of the observed values $\mathbf{y} = (y_1, y_2, \ldots, y_n)'$ is, to a constant,

$$\text{LL} = -\tfrac{1}{2}\log|\boldsymbol{\Omega}| - \tfrac{1}{2}(\mathbf{y}-\boldsymbol{\mu})'\boldsymbol{\Omega}^{-1}(\mathbf{y}-\boldsymbol{\mu}), \qquad (4)$$

where $\boldsymbol{\mu}$ is a function of fixed effects parameters $\boldsymbol{\alpha}$ and the covariance matrix $\boldsymbol{\Omega}$ defined by a set of

parameters $\boldsymbol{\beta}$. For a sample of k independent pedigrees, not necessarily of the same size and structure, asymptotically **unbiased** parameter estimates can be obtained by maximizing the sum of LLs over all pedigrees. Asymptotic standard errors can be calculated from the inverse of the observed **information matrix**. The (Fisher) information matrix contains minus the second differentials of LL with respect to the parameter estimates. A choice between nested models, the selection of a parsimonious model, and hypothesis testing can be carried out using the **likelihood ratio** criterion.

Typically the size of pedigrees is of the order of 2 to 20, and small relative to the total number of pedigrees, which is often in excess of 100. In such instances the negative bias in ML estimates of variance components is small, even when within pedigree correlations are large.

The ML estimation of variance components in effect assumes that the fixed effects are known without error, which leads to biased estimates of the variance components. [In the simplest case of $Y_i = \mu_i + E_i$ and n observations, the ML estimate of σ_e^2 is $\sum(y - \overline{y})^2/n$, which is biased by a factor of $n/(n-1)$.] When the number of observations is large relative to the number of fixed effects or covariates to be estimated, this bias is small. In residual (or restricted) maximum likelihood (REML) [27], only the part of the likelihood that is independent of fixed effects is maximized, by taking into account the loss in degrees of freedom by estimating fixed effects. In balanced designs, REML estimates are identical to ANOVA estimates of variance components. For the analysis of samples from human populations, the number of covariates is usually small relative to the number of observations, so that the use of either ML or REML is likely to lead to the same statistical inference.

Transformation of Data

In order to apply the above methodology, the distribution of the residuals about the mean $\boldsymbol{\mu}$ must be approximate multivariate normal. If this condition is not satisfied, then it may be after scale **transformation** and modeling of the mean, for example using a **power transformation** [3]. Transformation may have other desirable properties, such as stabilizing the variance.

Tests of Fit and Detection of Outliers

Under a fitted model, the observed trait of an individual can be compared with its expected distribution independent of, or conditional on, all or a subset of the observed traits of other individuals in the pedigree [14, 16]. The conditional residuals can be orthogonally transformed to approximately independent univariate normal variates. These can reveal potential outliers, and such individuals may have trait values that are typical for the population but atypical given the trait values of their relatives and the patterns of within-family associations evident in the pooled data. **Goodness of fit** can be assessed by comparing the overall distribution of these residual variates with the standard normal distribution, and by examining a plot of expected vs. observed normal order statistics.

Outlying pedigrees may be identified by noting that, after replacing $\boldsymbol{\mu}$ and $\boldsymbol{\Omega}$ by their estimated values, the observed quadratic form for a pedigree, $Q = (\mathbf{y} - \boldsymbol{\mu})'\boldsymbol{\Omega}^{-1}(\mathbf{y} - \boldsymbol{\mu})$, has an approximate χ^2 distribution with n degrees of freedom. For each pedigree, $P = P(\chi_n^2 > Q)$ should have a uniform distribution on [0, 1]. An excess of small values for P can be detected by counting the number of values less than a particular cutpoint, e.g. 0.1, 0.05 or 0.01, and comparing with the binomial distribution defined by the number of pedigrees and the cutpoint [2]. The detection of outliers is important not only because of the implications for valid statistical inference, but also because of the potential biologic insights that can follow, e.g. evidence for a genetic locus with a major influence.

Robustness of Statistical Inference

It is well known that outliers can be masked when estimation is based on normal theory, under which standard tests on means are influenced by skewness while tests on variances are influenced by **kurtosis**. Departures from normal theory influence statistical inference on the genetic regressions between relatives [4]. Under non-normality, ML estimates of components of variance and correlation are robust in the sense of being not greatly biased, but are inefficient [29]. Standard errors are under- or over-estimated when there is positive or negative kurtosis, respectively [30].

One robust approach to calculating standard errors for variance components is based on the observed

covariance matrix of the score vectors [1]. Although the likelihood ratio test is not robust, the score test may be modified using a consistent estimate of the variance to allow hypotheses regarding specific components to be tested without relying directly on the assumption of multivariate normality.

Other robust procedures exist. One involves downweighting observations with large standardized residuals [18]. Another involves replacing the **multivariate normal distribution** by a multivariate t distribution [22]. In theory this approach can be extended to other non-normal distributions, including nonsymmetric ones.

Adjustment for Ascertainment

If pedigrees are sampled (ascertained) through one or more individuals (probands) with particular features, e.g. having an extreme value on the trait, then the data are no longer a random sample (*see* **Ascertainment**). Suitable adjustments must be made to avoid major biases in estimates. One approach is to maximize the LL conditional on the observed trait value of proband p, y_p, $\mathrm{LL_c} = \mathrm{LL} - \mathrm{LL}_p$, where LL is given by (4), μ_p is the expected mean, and $\mathrm{LL}_p = -\frac{1}{2}\log|\Omega| - \frac{1}{2}(y_p - \mu_p)^2/\sigma^2$. However, if it is known that probands have trait values above a given threshold, or have been selected by a specific criteria, then the conditional LL should reflect that information. This may be problematic in practice, however, because it would necessitate computation of an area under the multivariate normal density. Conditioning on the observed value of a proband can lead to biased estimates if probands are selected under specific criteria [2, 6].

Estimability

An important issue in the estimation of multiple (co)variance parameters is whether there is sufficient information to estimate each parameter. Although models containing a number of components can be specified, the components may not be identifiable from a given data set. For example, from twin data alone it is not possible to estimate uniquely σ_a^2, σ_d^2, σ_c^2 and σ_e^2, where σ_c^2 represents the variance due to common environmental effects shared by twins independent of their zygosity, under the classic twin model. Often lack of identifiability is obvious from the design, or becomes evident during model-fitting computations due to matrix singularities, or by correlations between estimates being close to -1. Problems arise, however, when researchers ignore realistic components, or model them simplistically or poorly.

Perhaps the most important issue is the confounding between the additive genetic factor and a shared environment factor. For both these factors, theoretical considerations and common sense predict that the associated correlation between relatives will decrease the weaker is their relationship to one another. Often model fits attribute this pattern of correlations in pedigree data to a genetic, rather than a shared environment, component. This could be a consequence of the genetic model predicting a more detailed pattern of correlations within a pedigree than that predicted by the usual simplistic model of the shared features of the environment (such as a dichotomous "common family" or "common household" effect, presumed to be independent of the age, sex, cohabitational status, etc. of pedigree members). The classic twin model, where any increase in the MZ pair correlation over the DZ same-sex pair correlation can only be attributed to genetic effects, is an extreme case of this bias. There are a number of other reasons why the typical modeling paradigm used historically to fit genetic and environmental components of variance to twin data tends to conclude that familial aggregation is due to genetic factors, and not to the effect of shared environment [13].

Note that if it is presumed that common environment effects do not exist, then the standard error of the genetic component(s) of variance will be greatly reduced from what they would be if it was assumed that common environment effects do exist, even though they may not be nominally statistically significant. For example, consider the classic twin model and suppose there exists a common environment effect even though it may not be highly likely to go undetected given the sample size. When fitting both an additive genetic component and a common environment component, the estimate of σ_a^2 is based on twice the difference in covariance between MZ and DZ pairs. Its standard error must be greater than the sum of the standard errors of the MZ and DZ covariance estimates. If, instead, it is assumed that there is no common environment effect, then the estimate of σ_a^2 is based on a weighted pooling of the MZ and DZ covariance estimates, and will therefore have a considerably smaller standard error.

For human traits for which it is known that environment or lifestyle factors influence the mean values, and that these factors are themselves familial (i.e. correlated in individuals within families), it would be hard to argue that there are definitely no effects of common environment on variation in trait values across the population. Furthermore, real deviations from the assumption of the effect of common environment is independent of zygosity (in that MZ pairs actually share those effects more strongly than DZ pairs) will result in overestimating the additive genetic component, and consequently underestimating the common environment component and making it more likely to be "not significant". Therefore it would seem prudent always to quote a confidence interval for the genetic component, or for the **heritability**, by reference to the fits of a variance components model that included a common environment effect, even if the estimate of that variance component were negative.

A negative estimate of a variance component designed to represent factors causing similarities between individuals may occur if, in reality, there are factors causing dissimilarities between individuals. The existence of such "competition" effects has been recognized in behavioral studies, where for example outgoing or extroverted behavior in an individual may induce introverted behavior in a close relative. Note, however, that many software packages that estimate (co)variance components using ML have inbuilt constraints that allow only positive-definite covariance matrices. With these packages one would not be able to observe a negative estimate of a variance component.

Analysis of Multivariate Traits

The likelihood framework is easily extended to multiple traits, allowing the estimation of genetic and environmental correlations and covariances between traits [20]. The main difficulty regarding multitrait analysis is computational, because many parameters are estimated and they may be strongly negatively correlated. For an analysis of k traits and I random effects per trait, a total of $l * k(k+1)/2$ parameters are estimated.

Another approach to considering the genetic and environmental links between multiple traits is to conduct a univariate analysis of a "primary" trait, and to fit the effect of one or more "secondary" traits as fixed effects on the mean of the primary trait. As each secondary trait is entered into the equation representing that mean, the residual variance will decrease. The extent to which the genetic or environmental components of variance decrease reflects the pathways through which the secondary trait(s) influence the primary trait. The approach of adjusting the mean of a trait for different factors and observing the relative reductions in variance components can also be applied to multivariate analyses.

Example 3: Bone Density and Lean Mass

Hip bone density and lean mass were measured in 56 MZ and 56 DZ female twin pairs [28]. After adjusting mean bone density for age, the correlation (standard error in parentheses) was 0.62 (0.08) in MZ pairs and 0.33 (0.11) in DZ pairs. When a variance component model was fitted the estimates were 109 for σ_a^2 and 65 for σ_e^2 (for this exercise, σ_c^2 was set at zero). After adjusting mean lean mass for age, the correlations were 0.87 (0.03) and 0.30 (0.11) for MZ and DZ pairs, respectively, and the same variance component modeling gave estimates of 17.4 and 2.5 for σ_a^2 and σ_e^2, respectively. After also adjusting mean lean mass for height, the variance component estimates became 8.6 and 2.2 for σ_a^2 and σ_e^2, respectively, indicating that about half the genetic variation in lean mass for age was explained by the association between lean mass and height.

The (cross-trait) correlation between age-adjusted hip bone density and age-adjusted lean mass in the same individual was 0.43 (0.06). The (cross-trait cross-twin) correlation between these two measures in different members of a twin pair was 0.31 (0.07) in MZ pairs and 0.09 (0.09) in DZ pairs (one-sided P value $= 0.05$). This is consistent with about 75% of the covariance between the two traits being attributable to genetic factors that influence variation of both traits.

After adjusting the means of both traits for height as well as age, the cross-trait correlation reduced to 0.26 (0.07), suggesting that about 40% of the original within-person association between the two traits was explained by their height being associated with both traits. The cross-trait cross-twin correlations, however, were no longer different between MZ and DZ pairs, becoming 0.16 (0.08) and 0.13 (0.09), respectively. This suggests that, after also adjusting for

height, genetic factors no longer explained the residual correlation between hip bone density and lean mass. Furthermore, the genetic factors that explained the original association between the two age-adjusted traits must be associated with height.

Variance Component Linkage Analysis

Fisher introduced the concept of variance, and its partitioning into causal components, partly to separate unmeasured genetic from unmeasured nongenetic sources of variance [7]. With the advent of molecular genetics, it is now possible to decompose the genetic variance further, in contributions from individual loci [quantitative trait loci (QTL)]. The above theory and estimation procedures readily lend themselves for this extension. The essence of detection of a QTL is that *observed* proportions of alleles shared ibd at genetic marker loci are used instead of (co)variances among relatives based upon the *expected* proportion of alleles shared ibd. This allows the estimation of within-family genetic variance and therefore the partitioning of genetic variance into components due to individual trait loci. One way has already been described above as the last example of a More General Variance Component Model.

Haseman & Elston [10] proposed a simple least-squares method to detect linkage between a QTL and a marker locus for collections of sibling pairs, essentially by estimating a variance component associated with a marker locus. For each pair of siblings i and j, let $Z_i = Y_i - \mu_i$ and $Z_j = Y_j - \mu_j$, and use all pairs to fit the linear regression model $(Z_i - Z_j)^2 = a + b\pi_{ij}$, where π_{ij} is the proportion of alleles shared ibd between individuals i and j, at a marker locus. For a fully informative marker, π takes the values 0, $\frac{1}{2}$ or 1. The expected value of the regression coefficient is $b = -2(1-2\theta)^2\sigma_q^2$, where θ is the recombination fraction between the marker and QTL, and σ_q^2 the variance component due to the QTL. ML variance component methods have subsequently been proposed for linkage analysis in sib pairs and in more complex pedigrees [32]. The mixed linear model [(3)] is readily extended to incorporate random QTL effects. The difficulty in estimating QTL variance for complex pedigrees is in deriving the probabilities of sharing 0, 1 or 2 alleles ibd for all pairs of members within a pedigree from multiple marker loci, when individual marker loci are not fully informative and when marker genotypes are available on a subset of the pedigree only.

Statistical Power

The statistical power of a balanced random-effect ANOVA design to estimate variance components has been addressed [24] by assuming a general random-effect model and considering the test statistic $F = MS_x/MS_y$, where MS_i is the mean squares for stratum i. Let $n(x)$ and $n(y)$ be the degrees of freedom pertaining to each stratum. Then, to obtain a power of $(1-\beta)$, a sample size is needed such that $F_{n(x),n(y),[1-\alpha]} = [E(MS_x)/E(MS_y)]F_{n(x),n(y),[\beta]}$.

As a simple example, consider a sample of n pairs under the basic variance component model $Y_i = \mu_i + C_i + E_i$ given by (1), with $c_{ij} = 1$ for all $i, j = 1, 2$. Assume that $C_i \sim \mathrm{N}(0, \sigma_c^2)$ and $E_i \sim \mathrm{N}(0, \sigma_e^2)$, and let $c^2 = \sigma_c^2/(\sigma_c^2 + \sigma_e^2)$. The test statistic $F = MS_C/MS_E$ is distributed as $F \sim [1 + 2c^2/(1-c^2)]F_{n-1,n}$, and the power of the test is $\Pr[F_{(n-1),n} > (F_{n-1,n,[1-\alpha]})/(1 + 2c^2/(1-c^2))]$.

Another approach is to consider the ML estimate of the correlation between two traits, Pearson's product moment correlation coefficient, r. When estimated from n pairs, r estimates c^2 and has an asymptotic variance of $(1-r^2)^2/(n-1)$. The sampling distribution tends to normality slowly, so that even if the two traits follow a bivariate normal distribution the distribution of r is not normal, especially if the true value correlation is close to 1 or -1 when it has substantial **skewness**. The Fisher z-transform, $z = \frac{1}{2}\log[(1+r)/(1-r)]$, has an approximate variance $1/(n-3)$ and a distribution that tends to normality rapidly as the sample size increases, irrespective of the true value of r. Provided the true values of r is between -0.4 and 0.4, there is little difference between r and z (i.e. if $r = 0.4$, $z = 0.42$), but as r increases in absolute value, the difference increases rapidly (i.e. if $r = 0.6$, $z = 0.69$, and if $r = 0.8$, $z = 1.10$). For 80% power at the 0.05 level of significance (one-sided) the true value must be 2.45 times the standard error of the test statistic. Therefore, at least for true correlations or values of c^2 in the range of -0.4 to 0.4, a sample size of about $n = (2.45/c^2)^2 + 3$ is needed (compare with Table 1).

That is, the number of pairs required is small if the correlation between members of the pairs is large, or equivalently if the variance component representing

Table 1 Number of pairs, n, needed to detect a variance component that explains the proportion c^2 or more of total variance, or a correlation between members of the pair of r, with 80% or more power at the 0.05 level of significance (one-sided)

c^2	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
n	617	152	66	36	22	15	10	7	5

effects common to the pair is large relative to the overall variance. When the correlation is small, which may particularly apply to effects of a QTL, the sample size to detect even a substantial variance component can become very large.

For the classic twin model, let the sample size be sufficiently large that the total variance, σ^2, is estimated with negligible error. Let A and C be the estimates of $a^2 = \sigma_a^2/\sigma^2$ and $c^2 = \sigma_c^2/\sigma^2$, respectively so that $A = 2(r_{MZ} - r_{DZ})$ and $C = 2r_{DZ} - r_{MZ}$ [and the correlation between A and C is $-(0.9)^{0.5} = -0.95$]. Given that the twin pairs are independent, however, the standard errors of A and C are $2[\mathrm{var}(r_{MZ}) + \mathrm{var}(r_{DZ})]^{0.5}$ and $[4\mathrm{var}(r_{DZ}) + \mathrm{var}(r_{MZ})]^{0.5}$, respectively. (Note that most of the variance of C comes from the variance of r_{DZ}, which can only be reduced by increasing the number of DZ pairs.) Let the correlations within both MZ and DZ pairs be < 0.4, say, and let there be the same number, n, of MZ pairs as there are DZ pairs, so their sampling variances are each approximated by $1/(n-3)$. The standard error of A is then about $2.83(n-3)^{0.5}$, and the standard error of C is about $2.24(n-3)^{0.5}$. Therefore, if c^2 is zero or small, one would need more than 4800, 1200, 500 or 300 pairs of each zygosity to detect values of $a^2 = 0.1$, 0.2, 0.3 and 0.4, respectively. Similarly, if a^2 is zero or small, one would need more than 3000, 750, 330 or 200 pairs of each zygosity to detect values of $c^2 = 0.1$, 0.2, 0.3 and 0.4, respectively. Conversely, if $n = 1000$, say, and the true situation is that $a^2 = 0.3$ and $c^2 = 0.2$, then the standard error of A will be about 0.09 and the standard error of C about 0.07, so there would be about 95% power of detecting the additive effect, and about 90% power of detecting the common environment effect. If $n = 100$, the standard errors would be 0.29 and 0.25, respectively, and the powers would be reduced to about 25% and 20%, respectively. That is, failure to detect evidence for a genetic effect, or for a common environment effect, must be interpreted carefully after consideration of sample sizes. For a further discussion of power in twin studies, see [26].

Statistical Software Packages

There are a great many statistical packages capable of being used for variance component analysis in general. For specific applications to pedigree data, the multivariate normal model can be fitted by ML using the program FISHER [21]. REML can be fitted using ASREML [8]. Mx is specifically written for structural equation modeling of pedigree data, in particular for regular designs [26]; see [`http://views.vcu.edu/mx`].

Variance Components

In a **simple random sample**, one observation is made on each of a number of separate individuals and the variation is assumed to be represented by independent and identically distributed **random variables**, one for each individual. This forms the basis of **regression** and other models widely used in biostatistics. However, there are two ways in which the assumption of a single random component corresponding to each individual might fail to be adequate. In the first, the random variation may have a more complex structure arising from several identifiable sources. The variation is then considered to have multiple components, which we call *components of variance*. This is the classical field of variance components and has a long history dating from the nineteenth century. The second way in which the assumption can fail is when the parameters describing the systematic part of the variation may themselves change randomly, for example, between individuals or groups of individuals. This forms the basis of **hierarchical** or **multilevel modeling** in which the emphasis is on **computer intensive** methods for handling unbalanced or nonnormal data.

We begin this article with three examples to illustrate the key concepts and objectives involved in variance component analysis. Example 1 presents the simplest situation of the balanced one-way model. Example 2 describes a more complex model for microarray data, which involves *nesting* and *cross-classification* and helps distinguish these features. Examples 1 and 2 are classical variance component models. Example 3 outlines a linear **random effects** regression for a marker of HIV/**AIDS** disease and is an example of a multilevel model.

Example 1 *One-way balanced model*. Consider a group of patients, each of whom has a 'true' value of cholesterol say, or blood pressure, denoted by μ_j, $j = 1, \ldots, n_J$. For each patient, one measurement is made by a conditionally unbiased method; this means that for a given patient, μ_j has corresponding observation $Y_j = \mu_j + \varepsilon_j$, where the random term ε_j has mean zero and variance σ_ε^2. We call σ_ε^2 the *component of variance within patients*, which usually represents sampling or measurement error or some such.

Suppose now that the n_J patients are to be regarded as a random sample from a hypothetical infinite population of patients of true mean μ. This situation could arise, for example, in a **clinical trial** in which a homogeneous group of patients has been **randomized** to a treatment and interest centers on the efficacy of that treatment. The mean for patient j becomes a random variable, which can be written as the sum of the overall population mean, μ, and an independent random contribution from the patient, ξ_j. This gives $Y_j = \mu + \xi_j + \varepsilon_j$, where ξ_j has mean zero and variance σ_ξ^2. The latter is called the *component of variance between patients*. It follows that the variance of Y is the sum of two components, $\sigma_\xi^2 + \sigma_\varepsilon^2$, which are not separately estimable without either an external estimate of σ_ξ^2 from other studies or repeated measurements on each patient.

Suppose that several measurements are made on each patient for whom the response is assumed to remain stable. This gives observations

$$Y_j = \mu + \xi_j + \varepsilon_{js} \tag{1}$$

in which n_S, $s = 1, \ldots, n_S$, repeat observations are nested within patients. This means that observation 1 on patient i is assumed to have no special connection with observation 1 on a different patient k, and so on. The simplest situation assumes that all the random variables ξ and ε are mutually uncorrelated, but such an assumption should not be made uncritically. For example, errors would be uncorrelated if repeated samples were taken from a patient, homogenized, then split into n_S subsamples. Many such considerations relate to the design of the investigation.

This is the balanced one-way model in which there are two components of variance, between-patients and within-patients, each with zero mean. The random variables are usually, although by no means necessarily, assumed independently normally distributed. Repeat observations for a randomly chosen patient are correlated in the one-way model with *intraclass* **correlation** *coefficient* $\rho = \sigma_\xi^2/(\sigma_\xi^2 + \sigma_\varepsilon^2)$. This is a dimensionless measure and such measures are in general useful for formal inference, such as in genetics, but the variance components themselves are more informative as a basis for comparing the spread between and within patients.

Some statisticians prefer to represent variance component models via **covariance matrices** rather than random variables. The covariance matrix of the full $n_J n_S \times 1$ random vector formed by stacking the

rows of $\{Y_{js}\}$ into a single column is a block diagonal matrix of the form

$$(\tau_\xi J_{n_S} + \tau_\varepsilon I_{n_S}) \otimes I_{n_J} = \tau_\xi U_\xi + \tau_\varepsilon U_\varepsilon, \qquad (2)$$

where $\otimes$ denotes the Kronecker product [27], and I_{n_S} and J_{n_S} are the $n_S \times n_S$ identity matrix and the matrix all of whose elements are one, respectively; U_ξ, U_ε are associated matrices connected with indicator matrices defining the contribution of the component random variables to the observations (*see* **Matrix Algebra**). This formulation paves the way for a very general version with each separate component of variance identified with its own associated matrix. For interpretation and inference, however, we regard the representation in terms of component random variables as primary and this is the focus of the present article.

Example 2 *A model for cDNA microarray data* (*see* **DNA Sequences**). In cDNA microarrays, known single-stranded DNA clones are robotically spotted out and fixed onto a glass microscope slide. At the same time, two mRNA samples from the cell populations to be compared are reversed transcribed into cDNA and separately labeled with dyes, usually red (Cy5) and green (Cy3). The two labeled targets are mixed together and applied to the microarray slide. During hybridization, single strands in the target solution competitively combine with their complementary base-pair nucleotide sequences spotted on the slide. The relative intensities of red and green at a spot are extracted by image processing the scanned microarray images. The motivation for the technique is that the mRNA in the original cell sample reflects which genes are being used by the cell, and that the intensity ratio at a spot is a measure of the relative abundance of that gene in the two samples. The intensity ratios are usually adjusted for background noise on the slide, normalized to remove systematic sources of variation, transformed to log base 2 to induce approximate normality and additivity of effects, and denoted by the random variable M. For a detailed description of the biological and technical background, see [29].

In a study of osteoarthritis, n bone samples from diseased patients are compared to n bone samples taken from the same site in nondiseased control cadavers. The aim of the investigation is to identify which genes are differentially expressed in the osteoarthritis and control bone samples. In a simplified situation, the patients are assumed to be homogeneous for the **risk factors** age and sex. There is no shortage of slides so each case i is hybridized with each control j, m times. Replicates are assumed to be independent. One model for the observed log intensity ratio for gene g is

$$M_{gijk} = \mu_g + \xi_{gi}^D + \varepsilon_{gi}^D - \xi_{gj}^N - \varepsilon_{gj}^N + \varepsilon_{gijk}, \qquad (3)$$

where μ_g represents the true mean difference in expression of gene g in the two samples and all the remaining terms are independent random variables with zero means. In particular, ξ_{gi}^D and ξ_{gj}^N are crossed random effects specific to the diseased and control individuals with variances $\sigma^2_{g\xi D}$ and $\sigma^2_{g\xi N}$, respectively. The random variable ε_{gi}^D is an error term with component of variance $\sigma^2_{g\varepsilon D}$ specifically associated with the ith diseased case and believed to arise from random errors accumulating through the mRNA extraction, amplification, and labeling steps prior to hybridization; $\sigma^2_{g\varepsilon N}$ is the analogous component of error for the jth control sample. Finally, ε_{gijk} is the measurement error associated with the hybridization, scanning and image processing of patient i with control j and is assumed to have variance $\sigma^2_{g\varepsilon}$ for gene g. The k replicates across slides are nested within the disease-control classification (i, j). The variance of M_{gijk} is then

$$\mathrm{var}(M_{gijk}) = \sigma^2_{g\xi D} + \sigma^2_{g\varepsilon D} + \sigma^2_{g\xi N} + \sigma^2_{g\varepsilon N} + \sigma^2_{g\varepsilon}. \qquad (4)$$

In practice, it may not be feasible to estimate the separate components of variance in the model, not least because many sources of systematic and random variation in microarray experimentation are still not well understood. In this example, it would be adequate for determining differential expression to combine the sources of error into a single variance component term corresponding to the variability between log intensity ratios across slides for gene g. This illustrates an important general point that it is often adequate to use a model in which many sources of error are combined into a single variance term.

Microarray data analysis is receiving increasing attention from statisticians. Speed and Yang [44] are among the first researchers to critically examine the assumption of independent random variables and replication in this context.

Example 3 *A random effects regression model*. Suppose that a marker of disease progression such as log viral load or CD4 cell count in individuals infected with HIV varies roughly linearly over time in each individual. An initial analysis might be reasonably based on a linear regression with time, in which each individual j has intercept and slope parameters β_0 and β_1, that is,

$$Y_{jt} = \beta_0 + \beta_1 x_t + \varepsilon_{jt}. \quad (5)$$

(*see* **Nonlinear Mixed Effects Models for Longitudinal Data**).

However, a cohort of infected individuals would be very unlikely to have the same parameters. The next step might then be to regard the intercept and slope as responses regressed on individual characteristics, or to consider models in which the parameters themselves have random structure; that is, to model the slope for individual j as $\beta_{1j} = \beta_1 + \xi_{1j}$, where β_1 is the mean slope and ξ_{1j} is a random term, and similarly for the intercept, which we write as $\beta_{0j} = \beta_0 + \xi_{0j}$. In this model, interest focuses on the magnitudes of the random variation of individual responses about their regression line, in the variation in the intercepts and slopes, as well as on explanatory determinants of the regression parameters. The random effects themselves are often assumed to be normally distributed although it may not be possible to test the assumption, and it will nearly always be essential to allow these random terms to be correlated so that σ_ξ^2 denotes the covariance matrix of (ξ_{0j}, ξ_{1j}). These ideas generalize to nonnormal response data and to binary **logistic regression** models in particular.

There are only really two key ideas involved in these examples and in variance component problems generally. The first is the distinction between nesting and cross-classification. This is a qualitative rather than a statistical issue, and is to do with the design and logical structure of the data under study and not with any probabilistic or distributional model assumptions (*see* **Experimental Design**). The second key idea is statistical: are we going to treat the levels of factors as intrinsically interesting (i.e. as **fixed effects**) or are the factors to be regarded as random variables (i.e. as **random effects**) where interest might be in their variances? For example, in genetics, an investigator may want to partition the variability into environmental versus inherited components (*see* **Twin Analysis**).

Both dichotomies are subject-matter considerations. There are some general principles, which can be helpful in deciding whether a factor should be regarded as fixed or random. If the levels of a factor are treatments, for example, different therapies for breast cancer, they would usually be treated as fixed effects. Exceptions arise, such as in a clinical trial comparing the effects of many antibiotics.

The key to variance component analysis is to build models that represent different situations and explain levels of variability that are plausible approximations of what we actually observe. The motivation may be intrinsic interest in the variance components themselves, such as in a comparison of different measuring techniques, or on estimating the precision of the mean or other model parameters. Alternatively, the motivation may be the design of further studies via a *synthesis of variance*, which we discuss below.

History

The idea of partitioning variability can be traced at least as far back as Airy's interest in errors of measurement in astronomy [1]. The more recent systematic study of splitting variation into components dates from R.A. Fisher's introduction of the **analysis of variance**; his original motivation was to improve on the intraclass correlation. There followed periods of intense activity during the last century in biometrical genetics as described by Bulmer [6] (*see* **Polygenic Inheritance**), in the analysis of variability in industrial processes dating from the 1930s work in the cotton industry by Tippett [46] and in the wool industries by Daniels [12], and on error structures especially in randomized experimental designs in the 1950s [8]. Eisenhart made explicit the distinction between fixed and random interpretations of an analysis of variance and introduced this terminology [13].

Much of the early work dealt with balanced data. Henderson, in a long series of papers starting in the 1950s, gave noniterative methods for handling unbalanced data based on equating suitable quadratic forms to their expectation [18, 19]. This more intuitive approach has now largely been replaced by **likelihood**-based methods. Hartley and Rao [17] gave a general matrix formulation and **maximum likelihood** estimation for the unbalanced linear model. The important subsequent generalization of maximum likelihood to REML (reduced, **restricted or**

residual maximum likelihood, which we discuss in the next section) for unbalanced data was developed in detail by Patterson and Thompson [30]. Searle et al. [38] provide a very detailed and systematic account of the normal theory formulations and the associated matrix algebra for balanced and unbalanced data. Rao gives a broad account of normal theory aspects too [35]. Rao and Kleffe [34] emphasize the point **estimation** of variance components using quadratic error **loss**, and we discuss this and other methods of estimation in the next section.

Variance component problems with discrete response data have a long history going back to the Lexis urn models of dispersion associated with the **binomial** distribution; see, for instance, [20] (*see* **Overdispersion**). For an early paper on the **beta-binomial distribution**, see [40]. Greenwood and Yule [16] derived the **negative binomial distribution** as a **Poisson distribution** with an additional source of variation in connection with an analysis of accidents to London bus drivers (*see* **Accident Proneness**). Anscombe [2] compared the theoretical properties of various methods of estimation of its parameters. Cox [9] proposed simple methods for variance components in multiplicative models for Poisson variables.

The literature on multilevel modeling has been steadily growing over the past decade and is now very large. See Goldstein [15] for a thorough discussion. In addition to the references already mentioned, Snijders and Bosker [41] contains important computational work and guidance for fitting random effects and other models and Verbeke and Molenberghs [48] give an extremely thorough account of **linear mixed** models. McCulloch and Searle [28] discuss **generalized, linear, and mixed models** as do Fahrmeir and Tutz [14]. Pinheiro and Bates [32] focus on nonlinear normal theory models (*see* **Nonlinear Mixed Effects Models for Longitudinal Data**).

Variance components arise implicitly or explicitly in many problems in sampling and experimental design. Important applications include industrial processes and reliability studies, genetics, animal and plant breeding, econometrics, the design and analysis of interlaboratory standardization trials, epidemiology, psychometric testing, and education. Khuri and Sahai [23] review developments in variance components analysis to the mid-1980s and include a comprehensive bibliography, and a recent issue of *Statistical Methods in Medical Research* was devoted to variance components [42].

Estimation

The most important and often most difficult issue in variance component problems is the appropriate formulation of a model, or equivalently, the formulation of an analysis of variance table. We begin with the simplest situation described in Example 1. It is well known from the analysis of variance that for balanced systems, there are parallel **orthogonal** decompositions of the data vector, of sums of squares of the components, and of the **degrees of freedom**. The observation vector is decomposed into orthogonal components as

$$Y_{js} = \overline{Y}_{..} + (\overline{Y}_{j.} - \overline{Y}_{..}) + (Y_{js} - \overline{Y}_{j.}), \qquad (6)$$

and if we write the data as one long vector, orthogonality implies that the cross-product terms on the right-hand side vanish.

It is conventional to write out the analysis of variance table for the components and this is shown in Table 1, in which MS denotes Mean Square. Roughly, the mean square measures the sum of squares per dimension for the component. The analysis of variance formulation is entirely structural and does not involve model or distributional assumptions. For interpretation, we bring in the probability model, although we still only need the theory of a simple random sample to derive the key properties, in particular, for equating mean squares to their expected values.

For the one-way balanced arrangement, the first important property is that $E(\mathrm{MS}_\varepsilon) = \sigma_\varepsilon^2$, which only concerns how repeat observations for an individual vary around the true mean for that individual. It is also straightforward to show that $E(\mathrm{MS}_\xi) =$

Table 1 Analysis of variance table for the one-way balanced variance component model

Source	SS	df	
Mean	$\Sigma_{j,s}\overline{Y}_{..}^2$	1	MS
Between individuals	$\Sigma_{j,s}(\overline{Y}_{j.} - \overline{Y}_{..})^2$	$n_J - 1$	MS_ξ
Within individuals	$\Sigma_{j,s}(Y_{js} - \overline{Y}_{j.})^2$	$n_J(n_S - 1)$	MS_ε
Total	$\Sigma_{j,s}Y_{js}^2$	$n_J n_S$	

$n_S\sigma_\xi^2 + \sigma_\varepsilon^2$, from which we deduce σ_ξ^2 is estimated via $(\mathrm{MS}_\xi - \mathrm{MS}_\varepsilon)/n_S$.

If we are interested in the overall mean μ, for instance, to compare the means in two or more groups treated in different ways, we want $E(\overline{Y}_{..}) = \mu$ and $\mathrm{var}(\overline{Y}_{..}) = \sigma_\xi^2/n_J + \sigma_\varepsilon^2/(n_J n_S)$. Hence, a pivot for the estimation of μ is

$$\frac{\overline{Y}_{..} - \mu}{\sqrt{\mathrm{MS}_\xi/(n_J n_S)}}.$$

Assuming the pivot is approximately normally distributed, we can also obtain (approximate) confidence limits for μ.

These estimates are sometimes called the least-squares–based estimators and are **unbiased** estimates of the variance components. The overall approach can be generalized to more complex situations in which estimating equations are formed by equating suitable functions of the data (here sums of squares) to their expectations under the assumed model (*see* **Estimating Functions**). Alternative (biased) estimators are given by the method of maximum likelihood and these are discussed below.

If we make the further assumption that all the random variables are independently normally distributed, several important properties follow that also extend to general balanced cases. The most important is that the two sums of squares and the sample mean are minimal sufficient statistics implying various strong optimum properties, and in particular, that as long as the model is adequate, all we need for analysis are the sums of squares and the mean. The assumption of normality should not be made uncritically however, and some effort should be expended on investigating the sensitivity of the conclusions. We discuss ways of assessing model adequacy later.

Certain exact inferential procedures for the three unknown parameters μ, σ_ξ^2, and σ_ε^2 follow from the assumption of normality. For example, a technical refinement of the pivot for μ is that it then has the **Student *t* distribution** with $n_J - 1$ degrees of freedom. However, only certain combinations of the parameters can be tackled by these procedures, which may not be of substantive interest. For example, we can obtain exact confidence limits for the ratio of variances $\sigma_\xi^2/\sigma_\varepsilon^2$, but not for σ_ξ^2 itself, which is of interest in comparing estimates from two or more similar sets of data, subject to checks of homogeneity. The safest general procedure for doing this is the use of **profile likelihood** or one of its generalizations. There are however simpler and essentially equivalent methods. For example, if T is an approximately unbiased estimate of a positive parameter θ with effective degrees of freedom d, then $\log T$ is approximately normally distributed around mean $\log\theta$ with variance $2/d$, and further issues of analysis are in a normal theory least-squares framework. See [11] for a more thorough discussion of these less standard procedures.

Example 4 *Angiogenesis microarray data*. In a collaborative study, the author has been investigating genes involved in the growth of blood vessels, a process known as angiogenesis. The ability to stimulate new blood vessel growth is a prerequisite for the expansion of a solid tumor and future anticancer treatments are postulated to involve therapy directed to both cancer cells and the expanding vascular system. COX2 (Prostaglandin endoperoxide synthase 2) is a gene known to regulate angiogenesis and cell migration, and served as a control gene in a cDNA microarray experiment comparing mRNA samples from time three hours with time zero. The microarray consisted of a subtracted library of 10 400 clones, each duplicated on the slide. The duplicate spots were printed next to each other and are therefore spatially correlated, but we will ignore this special feature of the data. Four slides were hybridized and we assume that the hybridized slides are independent.

The observed log intensity ratios for COX2 are given in Table 2, which illustrates the data structure for the simple one-way model with two replicate observations. Note that in general, the ordering of the observations within rows is arbitrary. In the notation of Table 1, $n_J = 4$ and $n_S = 2$. The appropriate analysis is based on the pivot for the mean, μ, which under the null hypothesis of no differential expression and the assumption that the log ratios are normally distributed, is t with 3 degrees of freedom.

Table 2 Log intensity ratios for a COX2 in a cDNA microarray experiment with four slides and duplicate spots within slides

Slide	Log ratios M	
1	3.5040	3.4757
2	3.7160	3.7896
3	3.6215	3.7496
4	2.9467	2.8873

Thus, $T = 3.4613/(0.3796/2) = 18.23$ on 3 degrees of freedom. The associated P value is 0.00036 with an estimated 95% confidence interval for the true mean difference in expression (2.8572, 4.0654), indicating that COX2 is significantly upregulated at three hours.

We are ignoring here issues of multiple testing, which can be important in microarray experiments when many thousands of genes are analyzed simultaneously (*see* **Multiple Comparisons**).

Negative estimates: All variances are by definition nonnegative. However, the standard least-squares estimates of the upper variance component in the one-way balanced model are based on differences of mean squares and hence may sometimes be negative. The simplest way to deal with negative estimates arising from this and similar situations is to replace them by zero. For example, we would take $\max\{(\mathrm{MS}_\xi - \mathrm{MS}_\varepsilon)/n_S, 0\}$ as an estimate of σ_ξ^2. There are two qualifications to this recommendation. Firstly, if the mean square between individuals is substantially smaller than the mean square within individuals, this indicates that the data are inconsistent with the model and may be a warning that a systematic effect has been omitted. Alternatively, it may be a warning that important correlations between the random variables have been ignored. Secondly, in an analysis that synthesizes an estimate of σ_ξ^2 from several separate sets of data, such as in a **meta-analysis** of **case–control** studies, then negative values should be retained to avoid systematic error in the pooled estimate.

The procedures described so far extend directly to more complex models provided the data are balanced. In practice, however, data are often not balanced, either by design or as a result of various forms of missingness. The concepts involved are not affected by lack of balance, but the analytical details are. In particular, the decompositions for the balanced case no longer hold and the underlying algebra is more complicated. It is not always obvious how to find the variance estimates for more complicated models and general procedures are required. One very powerful procedure is maximum likelihood for which we find algebraically, or more commonly numerically, the combination of parameter values that maximize the likelihood.

Maximum likelihood and REML: It is well known that the maximum likelihood estimate of the variance in a simple random sample is biased, having divisor n_S rather than $n_S - 1$. In more complex models, the resulting estimates of variance may be entirely unsatisfactory especially if the number of **nuisance parameters** is large, and alternative methods of estimation need to be deployed. The most widely used method and preferred basis for the formal analysis of unbalanced normal models is REML, which maximizes the likelihood of judiciously chosen parts of the data, rather than that of all the data.

REML may be formulated as follows for the one-way analysis. We may apply an **orthogonal** transformation to each individual (or sample) to replace the n_S values by the quantity $\overline{Y}_{j.}\sqrt{n_S}$ and $n_S - 1$ variables, which are independently normally distributed with zero mean and variance σ^2. The contribution of the individual to the likelihood is thus the product of two factors, one depending on μ_j and σ^2, and the other depending only on σ^2 and involving the data only via $\sum(Y_{js} - \overline{Y}_{j.})^2$. In many problems, especially when little is known initially about μ_j, the first factor contains little or no information about σ^2. Thus, for inference about σ^2, we use only the second factor. This leads to a loglikelihood based on $n_J(n_S - 1)$ observations that are independently normally distributed with mean zero and variance σ^2. The corresponding maximum likelihood estimate then has the correct divisor, which is the degrees of freedom within individuals. The same idea can be applied to the general linear mixed model with fixed and random effects.

REML has the advantage of returning the usual least-squares estimates of the variance components for balanced data. It is a particular case of the use of **marginal likelihood** and **conditional** likelihood; see [21] for a general study of both. Barndorff-Nielsen and Cox [3] show that REML is a special case of modified profile likelihood.

Alternative methods of estimation: Powerful and efficient methods for model fitting are important. Indeed, the lack of such methods for unbalanced data held the subject of variance components back until relatively recently. A disadvantage of these developments, however, is that the relationship between the data and the conclusions can be obscure, and for complicated problems, simpler methods may be useful for conceptual clarity and interpretation.

For the unbalanced one-way arrangement, the two simplest procedures are to base the estimation of the upper-level variance component σ_ξ^2 on either the unweighted sum of squares $\sum(\overline{Y}_{j.} - \overline{Y}_{..}^{(u)})^2$, where $\overline{Y}_{j.}$ is the mean of the r_j responses for individual j

and $\overline{Y}_{..}^{(u)}$ is the unweighted average of these means, or on the usual analysis of variance sum of squares $\sum r_j(\overline{Y}_{j.} - \overline{Y}_{..}^{(r)})^2$, where $\overline{Y}_{..}^{(r)}$ is the average of the $\overline{Y}_{j.}$ weighted by the group size. The idea is to decide informally whether the upper or lower component of variance is dominant and to use the unweighted or standard analysis of variance sum of squares as a basis for examining the upper-level component of variance. The same idea can be extended to general models. These simpler approaches are related to the various methods of estimation proposed by Henderson and are described in detail in [38].

An important special case is when $T_1, \ldots, T_{n_J}$ are estimates of a parameter θ obtained from independent sets of data, each with its own internal estimate of error. For example, in combining the results of a number of case–control studies, θ could be the log **odds ratio** for treatment versus control after adjustment by maximum likelihood logistic regression for imbalance with respect to **explanatory variables**, which might be different in the different studies. Note that it is not necessary that the same model is fitted to each group of data, only that the parameter θ has the same interpretation. The estimates may vary more than would be expected on the basis of internal error and it may not be feasible to explain the extra variability as systematic. In this case, we may represent the additional variability as random, and in particular, take as a reasonable approximation $T_j = \theta + \xi_j + \varepsilon_j$, where the ξ and ε are approximately normally distributed and independent. The idea is that a simple analysis helps decide whether a component of variance σ_ξ^2 is necessary, whether there are **outlying** groups, and which of the weighted or unweighted estimates of θ are likely to have high efficiency. Similar arguments apply if θ is a vector. Cox [10] outlines the approach and Cox and Solomon [11] give details of these simpler procedures in applications to nonnormal response data and random effects logistic regression.

We mention briefly another class of methods for estimating variance components known as minimum norm quadratic unbiased estimators (MINQUE) described in detail in [34]. In this and related criteria, low moment assumptions are made about the component random variables and attention focusses on quadratic point estimates that satisfy conditions such as unbiasedness and minimum variance (*see* **Minimum Variance Unbiased (MVU) Estimator**).

Synthesis of Variance

This refers to the process of putting the variance components back together with a view to determining what the variability would be in different sampling situations, or the variance that should be attached to a nonstandard type of comparison. Calculations of this sort are particularly important in designs of systems to achieve a balance between the number of groups or individuals that need to be studied and the number of replicates within each individual.

The simplest example is to estimate the variance of a mean if n_{S_1} repeat observations are to be made on each of n_{J_1} individuals. This is $(\sigma_\varepsilon^2 + n_{S_1}\sigma_\xi^2)/(n_{J_1}n_{S_1})$, which can be estimated. We may be interested to know how much better will the precision be if we take three or four repeat observations on each individual rather than one, say. If the different individuals are very different, that is, σ_ξ^2 is large, then there is little point in replicating more within individuals. But if σ_ε^2 is large relative to σ_ξ^2, there will be an $n_{J_1}n_{S_1}$ effect and increasing the number of replicates will improve the precision of the overall mean.

The estimated synthesized variance of the mean under the new design with n_{S_1} rather than n_S repeated observations within each individual is

$$\frac{1}{n_{S_1}n_{J_1}}\left(\mathrm{MS}_\varepsilon + n_{S_1}\frac{\mathrm{MS}_\xi - \mathrm{MS}_\varepsilon}{n_S}\right),$$

where the observed mean squares and degrees of freedom are those from the original data.

Example 4 revisited: *Angiogenesis microarray data*. The estimated components of variance for the gene COX2 in Example 4 are 0.3731 for the between-slide component and 0.0131 for the within-slide component. In view of the considerations outlined above, increasing the number of replicate spots within a slide would have little impact on the precision as compared with increasing the number of slides hybridized in the experiment.

Components of Covariance and Regression

In the simplest case of a number of groups with a regression of Y, say, on X within each group, work on multilevel modeling has tended to stress the effect of the correlation and additional variation

within groups on the regression coefficient of Y on X and its standard error. But if the groups represent **bivariate** populations, there are two regression coefficients, one within groups and another that would be defined by a scatterplot of the means of X and Y. In an early exposition of **analysis of covariance**, Pearson stressed the distinction between these coefficients [31].

To formulate the issues explicitly, consider the bivariate one-way balanced model in which each observation Y_{js} is a 1×2 row vector giving an $n_J n_S \times 2$ data matrix Y. The pairs of observations are

$$Y_{js} = \mu_Y + \xi_j^Y + \varepsilon_{js}^Y,$$
$$X_{js} = \mu_X + \xi_j^X + \varepsilon_{js}^X, \tag{7}$$

for which there are four variances $\sigma^2_{Y\xi}$, $\sigma^2_{X\xi}$, $\sigma^2_{Y\varepsilon}$ and $\sigma^2_{X\varepsilon}$ as well as covariances $\mathrm{cov}(\xi_j^Y, \xi_j^X)$ and $\mathrm{cov}(\varepsilon_{js}^Y, \varepsilon_{js}^X)$. In the general case with p response variables, each observed random variable is replaced by a set of p components.

As explained above, we can view the bivariate decomposition in two different ways. If Y and X are treated on an equal footing, we have two covariance matrices for the interpretation of associations at the two different levels. Sometimes it may be helpful to estimate separately the two **correlations** $\mathrm{corr}(\xi_j^Y, \xi_j^X)$ and $\mathrm{corr}(\varepsilon_j^Y, \varepsilon_j^X)$. The second possibility is that X should be considered as explanatory to the response Y. Then there are two regression coefficients of Y on X, namely, $\beta_{\xi,YX}$ and $\beta_{\varepsilon,YX}$, regression coefficients from the between- and within-group structure, respectively.

Suppose as an illustration that on a large sample of subjects of stable health and in a narrow age range, measurements are made of blood pressure, Y, and sodium (Na) intake, X. For each subject, the observations are repeated some months later. If we ignore possible time trends, we may consider a one-way analysis. The regression coefficient $\beta_{\varepsilon,YX}$ measures the mean increase in blood pressure Y when the Na intake, X, of a particular subject varies by one unit, for example, 10 mg per day. By contrast $\beta_{\xi,YX}$ is the average difference in the mean blood pressure of two different subjects whose long-run mean Na intakes differ by 10 mg per day. The naive interpretation of $\beta_{\xi,YX}$ would imply that if subjects changed their long-run mean Na intake by 10 mg per day, then there would be a corresponding change in long-run mean blood pressure as determined by $\beta_{\xi,YX}$. The naive interpretation of $\beta_{\varepsilon,YX}$ would imply that individuals increasing their Na intake by 10 mg per day would on average have an increase in blood pressure determined by the regression coefficient.

In an observational study, both interpretations involve substantial assumptions and would be quite speculative. If individuals had been randomized to Na levels on the other hand, the interpretation of the regression coefficients would be unambiguous. In the absence of randomization, however, there may be explanatory variables, observed or unobserved, and long-run features of individuals that are themselves explanatory to both Y and X. These arguments extend to more complicated structures. The difficulties of applying aggregate-level conclusions to individuals in this way is often called **ecological**.

Empirical Bayes

When a frequency probability analysis is based on empirical data with structural assumptions, for example, that certain terms in a regression are random, we call the analysis **empirical Bayes**. No special conceptual issues to do with defining a suitable **prior** probability and so forth are involved.

Classical empirical Bayes analysis proceeds as follows. Consider the univariate one-way model again where, as before, the ξ_j and the ε_{js} are independently normally distributed with zero mean. There are three unknown parameters in the model, $\theta = (\mu, \sigma_\xi^2, \sigma_\varepsilon^2)$. Suppose θ is known and that interest is in the mean of the first group, $\mu + \xi_1$; ξ_1 is an unobserved random variable, which itself partly determines the distribution of the observations. It is therefore appealing, and can be justified formally from various points of view that information about ξ_1 is best summarized by its conditional distribution given the data. This is derived by **Bayes's theorem**. We can show [11, Chapter 3] that the required conditional distribution is normal with mean of the form of an optimally weighted mean obtained from combining the information from the data $\overline{y}_{1\cdot}$ and that from the distribution of ξ_1 around μ, denoted $\tilde{\xi}_1$. In effect, the sample mean $\overline{y}_{1\cdot}$ is shrunk towards the general mean (*see* **Shrinkage**). By the same argument, the estimate of any contrast is obtained by shrinking the sample contrast towards zero (*see* **Shrinkage Estimation**).

It can be shown that if in the originating model, the random variables are not normally distributed, then the above estimates are in a sense the best linear estimates. Viewed as a point predictor of ξ_1, the quantity $\tilde{\xi}_1$ has a property summarized in the term *best linear unbiased predictor* (BLUP; see [37]).

Nonnormal Models

There are broadly parallel developments for the Poisson and binomial distributions with one extra level of variability to those discussed above for continuous random variables. An alternative approach to analysis may be to use (approximate) weighted least-squares methods on the basis of an empirical **transform** of the response variable, for example, the square root or logarithm of Poisson variables and the empirical logistic, probit, or log−log transform of binomial variables.

There may be some loss of efficiency in these approximate procedures. But a more general discussion of variance component models for **generalized linear models** and normal theory **nonlinear regression** is difficult, primarily due to the fact that formally efficient methods of estimation involve high-dimensional integration. The general form of the full likelihood is given by

$$\int \mathrm{lik}(\theta \mid \xi; y)\, \mathrm{d}F(\xi; \tau),$$

where $F(\xi; \tau)$ is the distribution function of ξ depending on parameters τ, which are typically components of variance and their generalizations. In cases without **time series** or similar structure, ξ will consist of independent components so that $F(\xi; \tau)$ factorizes into a product component by component. The integral will factorize into subintegrals but, even so, the dimension of each may be large.

In the special case in which, given the random terms ξ, the observations have an **exponential family** distribution, we obtain a **generalized linear mixed model**. In the simplest formulation, the random effects ξ_j are independently and identically normally distributed with zero mean and q-dimensional variance matrix $D(\tau)$, where τ is a vector of unknown variance components; D is often called the *dispersion matrix*. The conditional independence of the observations within an individual or cluster allows us to write the exact marginal likelihood

$$\mathrm{lik}(\beta, \tau; y) = \prod_{j=1}^{n_J} \int \prod_{s=1}^{r_j} f(y_{js} | \xi_j; \beta) g(\xi_j; \tau)\, \mathrm{d}\xi_j, \tag{8}$$

where g is the link function for the generalized linear model.

Formal inference can be based on maximum likelihood or on **Bayesian** considerations, and there are currently three ways to approach the **numerical integration** problem. The most direct and appealing method is direct or preferably adaptive quadrature. The second, applicable when the integrals can be resolved into a sequence of one-dimensional integrals, is to use an analytical approximation, usually based on a few terms of a Laplace expansion [5, 39, 43]. Such expansions are based on the idea that integrals involving an exponential of a function are dominated by behavior of that function near its maximum. This method can sometimes yield relatively simple interpretable results. Calculation of higher terms in the expansions may be feasible, especially if aided by **computerized algebra**. Higher terms are important to give at least a partial check on the adequacy of the approximations but there is often some uncertainty about the range of applicability of the approximations.

The third method is **Markov chain Monte Carlo (MCMC)**. In the Bayesian version, a **Markov chain** is defined, which has as its equilibrium distribution, the posterior distributions of interest. The chain is then simulated a very large number of times and if the realizations appear to have converged to stationarity, the frequency distribution of realized values, excluding a run-in period, is used to estimate the posterior distributions. MCMC is a powerful and general technique but there is the possibility, in theory at least, that apparent convergence to a stationary state is illusory. Some protection can be achieved by starting the **simulations** from very different initial states.

There are also at least two other approaches to these problems. Lee and Nelder [25, 26] study a notion of h-likelihood in which, in effect, realized values of individual random variables representing portions of variability are treated like unknown parameters. This is likely to be effective when there is substantial information about each such realized value. Another mode of analysis called *penalized*

quasi-likelihood concentrates on the underlying estimating equations and their justification in a broader setting than a fully parametric one [4, 5, 24, 45] (*see* **Penalized Maximum Likelihood**; **Quasi-likelihood**). Rabe-Hesketh et al. [33] provide a valuable comparison of methods for estimation in generalized linear mixed models.

In **survival** or **event history** data, a random term for each individual with an associated variance component is often called *frailty*. The terminology arises from applications in which the randomly occurring events are failures or adverse reactions of some kind. See **Frailty** for a detailed discussion of these and related models.

Model Assessment and Prediction

Although there is a very large literature on formal and informal tests of model adequacy, little of it is directly relevant to variance component models (*see* **Model Checking**). The most important type of failure of a model stems from omitting a substantial effect, for example, treating a cross-classification as if nested. This destroys the independence assumptions underlying the discussion and is likely to be detected by anomalous behavior of the mean squares, possibly leading to substantial negative estimates of variance.

Outlying observations or individuals can influence the usual quadratic estimates of variance. For example, in the one-way arrangement, an anomalous single observation has a large effect on the estimated component of variance within individuals, but relatively little effect on the estimated component between individuals. In more complex situations, the distinction between outliers at the different levels becomes harder to detect empirically. **Robust** methods provide one way of dealing with outlying observations but do not retain key parameter properties, which are central to variance component analysis, in particular, the additivity of variance as a parameter.

Other important departures from the standard formulation include nonnormality of one or more of the component random variables, or dependence between the variability within an individual and the individual mean. Mild nonnormality of the variances within or between individuals may be of relatively minor concern, but the dependence described above may lead to inappropriate predictions or supplementary analyses. Solomon and Cox [43] suggested a formal analysis in which the nonnormal variances and dependence features are separated.

Further, special topics on model criticism and improvement include the prediction of exceedances, the analysis of **panel** data, fitting more elaborate models, transformations, and study of the distributional form of the underlying random variables. Many of these methods and ideas are discussed in detail in [11]. An important general point when assessing model adequacy is that the analysis should focus on issues that are of substantive importance. For example, discriminating between heterogeneous variances versus constant variances with differing individual means is only worth attempting if the distinction can be given a physical interpretation.

Generalizations and Further Topics

There are many additional areas of current work related to variance components including the following.

Measurement error models: The main emphasis in this article has been on the estimation of variance components as parameters of intrinsic interest. One situation where the real emphasis lies elsewhere and the components of variance are of concern because they affect this primary aspect, is the effect of measurement error in explanatory variables on regression analysis (*see* **Errors in the Measurement of Covariates**). **Measurement error models** have a long history and an extensive literature; see, for example, [7, 36] for a recent application.

Design of investigations: The objective of variance components analysis is the study of patterns of variation as they exist rather than the assessment of interventions under controlled conditions, which is the purpose of formal design of experiments. However, many of the general principles of **experimental design**, and especially those common with the principles of sampling (*see* **Sample Surveys in the Health Sciences**), apply. Khuri [22] gives a systematic review and bibliography of work on design for the estimation of variance components, and Cox and Solomon [11, Chapter 3] present some new ideas.

Finite population aspects: Occasionally, the individuals are not regarded as individuals or as sampled from an infinite population but as from an existing **finite population** of known size, or in particular, as forming the whole of the population in which

variation is to be assessed. The finite population variance component is relevant only in very special situations, and in some industrial problems in particular. The importance of distinguishing between finite and infinite populations when defining variance components was first stressed by Daniels in the context of studies of variation in industrial processes [12]. Tukey [47] extended these ideas to sampling a finite population. A formulation relevant to the industrial context is outlined in [11].

Synthesis of studies: In many fields of application, the synthesis of information from several studies is crucial. Variation between studies and interactions of such variation with the treatment effects under investigation may involve representation by components of variance. In biostatistics, the term *overview* or **meta-analysis** is often used and is an integral part of evidence-based medicine. A representation in terms of random effects would only be indicated if no direct explanation of important observed variation in treatment effect is apparently available, such as nonconstancy of the treatment effect being confined to certain contrasts. The use of variance components in meta-analysis is not without controversy.

Acknowledgments

Example 2 is based on joint work in progress with G. Glonek and N. Fazzalari. Example 4 is from collaborative work with C. Hahn, J. Gamble and A. Tsykin. I am grateful to Sir David Cox, FRS, for helpful comments.

Variance

The variance of a random variable X is a measure of the variable's spread or dispersion around its mean. The **mean** is the average or expected value of X, and is a measure of the center of its distribution. The mean can also be viewed as a "typical" value of X. By definition, however, the outcome of a **random variable** is unpredictable and will vary from one trial to the next; the variance describes the amount of variation that can be expected around the average value. If the mean of X is represented by $\mathrm{E}(X)$, then its variance is defined by

$$\begin{aligned}\operatorname{var}(X) &= \mathrm{E}[X - \mathrm{E}(X)]^2 \\ &= \mathrm{E}(X^2) - [\mathrm{E}(X)]^2,\end{aligned}$$

provided that $\mathrm{E}(X)$ exists. The mean of a random variable X is often denoted by μ and its variance by σ^2.

From the preceding definition, the variance of X is the average value of the squared deviation of X from its mean. Since a quantity which is squared cannot be negative, the variance is never less than 0. If X is a measurable quantity such as length or temperature, then the units of measurement for the variance are the square of the units for X. If X is measured in meters, for example, then the variance of X is measured in meters squared. This is a major drawback in the variance's use a measure of dispersion – it is difficult for most people to think in terms of squared units. Nevertheless, a large variance indicates that the outcomes of X are widely distributed around its mean, while a small variance means that the outcomes cluster tightly around the center. In practical applications, a measure of dispersion called the **standard deviation** is often used in place of the variance; the standard deviation is the positive square root of the variance and is denoted by σ.

To calculate the variance of a random variable, it is necessary to know the probability distribution of X. If X is a discrete random variable with mean $\mathrm{E}(X) = \mu$, then

$$\begin{aligned}\operatorname{var}(X) &= \sum_i (x_i - \mu)^2 \Pr(X = x_i) \\ &= \left[\sum_i x_i^2 \Pr(X = x_i)\right] - \mu^2,\end{aligned}$$

where $x_1, x_2, \ldots x_i \ldots$ are all outcomes of X such that $\Pr(X = x_i) > 0$. If X is a continuous random variable with probability density function $f(x)$ and mean $\mathrm{E}(X) = \mu$, then

$$\begin{aligned}\operatorname{var}(X) &= \int_{-\infty}^{\infty} (x - \mu)^2 f(x)\,\mathrm{d}x \\ &= \left[\int_{-\infty}^{\infty} x^2 f(x)\,\mathrm{d}x\right] - \mu^2.\end{aligned}$$

A linear transformation of the random variable X affects the variance in a straightforward manner. If a and b are constants and if the random variable $Y = aX + b$, then

$$\operatorname{var}(Y) = a^2 \operatorname{var}(X).$$

A constant has variance 0.

In practice, the variance of a distribution can be estimated using the information contained in a sample of observations drawn from that distribution. If $x_1, x_2, \ldots, x_n$ is a **random sample** of size n selected from a population with mean μ and variance σ^2, then the sample variance is represented by s^2 and is defined by

$$\begin{aligned}s^2 &= \frac{\sum_{i=1}^{n} (x_i - \overline{x})^2}{n-1} \\ &= \frac{\sum_{i=1}^{n} x_i^2 - \dfrac{\left(\sum_{i=1}^{n} x_i\right)^2}{n}}{n-1},\end{aligned}$$

where $\overline{x}$ is the sample mean

$$\overline{x} = \frac{\sum_{i=1}^{n} x_i}{n}.$$

Just as σ^2 describes the dispersion of a distribution around its mean μ, s^2 describes the spread of a sample of values around the sample mean x. It can be thought of as the average squared deviation of each observation from the sample mean. While it might seem more natural to estimate σ^2 by the true average

squared deviation, or

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^{n}(x_i - \overline{x})^2}{n},$$

this estimator is seldom used in practice. This is because s^2 is an **unbiased** estimator of σ^2 over all possible random samples of size n – meaning that $\mathrm{E}(s^2) = \sigma^2$ – while $\hat{\sigma}^2$ is not unbiased.

Varimax Rotation

Varimax rotation is probably the most popular **orthogonal rotation** procedure for use with **principal components analysis** and **factor analysis**. Given a matrix $\mathbf{V}$ of dimension $p \times k$ consisting of a set of k vectors defining a set of principal components or factors, a new set of transformed variables is obtained by an orthogonal rotation of $\mathbf{V}$, namely $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$. $\boldsymbol{\Theta}$ is a $k \times k$ matrix determined such that the coefficients of $\mathbf{B}$, a $p \times k$ matrix, will maximize the quantity

$$Q = \sum_{j=1}^{k} \left[\sum_{i=1}^{p} b_{ij}^4 - \left(\frac{1}{p}\right) \left(\sum_{i=1}^{p} b_{ij}^2 \right)^2 \right],$$

where p is the number of original variables and k is the number of retained components or factors. Varimax rotation is a special case of *orthomax* rotation with $c = 1.0$ (*see* **Factor Analysis, Overview**; **Rotation of Axes**) In this procedure, the sums of squares of $\mathbf{B}$ are maximized *columnwise* as contrasted with **quartimax rotation**, which maximizes them *rowwise*. Varimax is due to Kaiser [3, 4] and was used in the original Little Jiffy of Kaiser & Rice [5]. It is the default in some computer packages. The form above is referred to as *raw varimax* and, in this form, the effect of each variable on the rotation is a function of the amount of the variability in that variable accounted for by the retained components or factors. To put the variables on an equal footing, the individual b_{ij}^2 may be divided by the corresponding diagonal element of $\mathbf{VV}'$. The resultant form is called *normal varimax*, and is the default in some other computer packages. To deal with some pathological situations which could arise, Cureton & Mulaik [2] introduced another version called *weighted varimax*. The standard errors for the vector coefficients produced by varimax rotation were given by Archer & Jennrich [1].

For the decathlon example introduced in the articles on **Rotation of Axes** and **Factor Analysis, Overview**, $\mathbf{V}$ and $\mathbf{B}$ are repeated here in Table 1.

Variogram

The variogram is a description of the second-order dependence properties of a **stochastic process**. It was first proposed by Jowett [4] in the context of industrial sampling and subsequently popularized by the French geostatistical school [5], where it is a fundamental ingredient in the method of spatial prediction known as kriging. Its importation to the field of longitudinal data analysis stems from Diggle [2]. In this article we will describe the variogram in the context of longitudinal data analysis. For a counterbalancing view emphasizing spatial applications, see [1].

For a stochastic process $Y(t)$, where t denotes time, the *covariance function* is the function $\gamma(t, s) = \text{cov}\{Y(t), Y(s)\}$. If $Y(t)$ is **stationary**, the covariance between $Y(t)$ and $Y(s)$ only depends on $u = |t - s|$, in which case we write the covariance function as $\gamma(u)$. The *variogram* of $Y(t)$ is the function

$$V(u) = \tfrac{1}{2}\text{Var}\{Y(t) - Y(t-u)\}, \qquad (1)$$

if this function exists. Note that if $\text{E}[Y(t)] = \mu$, a constant for all t, then

$$V(u) = \text{E}[\tfrac{1}{2}\{Y(t) - Y(t-u)\}^2].$$

Some authors call $V(u)$ the *semivariogram*. The variogram exists for all stationary processes $Y(t)$ and for a limited class of nonstationary processes. In the stationary case, $V(u) = \gamma(0) - \gamma(u)$.

One practical advantage of the variogram over the covariance function is that estimation from observed data is more straightforward, especially when the underlying stochastic process is observed at irregular time-points. Consider a set of longitudinal data in the form $(t_{ij}, y_{ij}) : j = 1, \ldots, n_i; i = 1, \ldots, m$, in which y_{ij} denotes the jth of n_i observations on the ith of m subjects, and t_{ij} the corresponding observation times. We assume that y_{ij} is a realization of $Y(t_{ij})$ and that observations from different subjects (different values of i) are independent.

The *empirical variogram* is the set of points (u_{ijk}, v_{ijk}): $k > j$; $i = 1, \ldots m$, where $u_{ijk} = |t_{ij} - t_{ik}|$ and $v_{ijk} = \frac{1}{2}(y_{ij} - y_{ik})^2$. A scatterplot of the points (u_{ijk}, v_{ijk}) is called a *variogram cloud*. In principle, the variogram cloud can be used to suggest a parametric model for $V(u)$, and to obtain quick, if inefficient, estimates of the parameters of $V(u)$ by nonlinear ordinary least squares regression, the justification for this being that $\text{E}(v_{ijk}) = V(u_{ijk})$. The usefulness of the variogram cloud for exploratory data analysis is limited by the fact that the sampling distributions of the empirical variogram ordinates v_{ijk} are typically highly variable and highly skewed. For example, if $Y(t)$ is a Gaussian process, then $v_{ijk}/V(u_{ijk})$ has a χ^2_1 sampling distribution. Furthermore, pairs of variogram ordinates from the same subject are typically dependent.

A more useful graphical display is the *sample variogram*, defined by averaging empirical variogram ordinates v_{ijk} at common values of u_{ijk}. In most designed longitudinal studies there is a high degree of commonality amongst the observation times associated with the different subjects, and the averaging imparts a high degree of stability to the sample variogram by comparison with the empirical variogram. When each of the subjects have their own unique set of observation times, an alternative graphical display can be obtained by averaging the v_{ijk} corresponding to *approximately* equal values of u_{ijk}, or by applying a nonparametric scatterplot smoother to the points (u_{ijk}, v_{ijk}). See, for example, [3, p. 53].

Because variogram ordinates from different subjects are independent, in the stationary case an estimate of $\gamma(0) = \text{var}\{Y(t)\}$ can be obtained as the average of all quantities of the form $\frac{1}{2}(y_{ij} - y_{i'k})^2$ for all j, k and $i' > i$.

Mathematically legitimate forms for the theoretical variogram $V(u)$ are constrained by the need for $V(u)$ to correspond to a legitimate covariance structure. An algebraic condition that a variogram must satisfy is that $\sum_{i=1}^{n}\sum_{j=1}^{n} a_i a_j V(t_i - t_j) \leq 0$, for any positive integer n, set of times $t_i; i = 1, \ldots, n$, and real numbers $a_i, i = 1, \ldots, n$, such that $\sum_{i=1}^{n} a_i = 0$. For examples of variogram models for longitudinal data, see [3, Chapter 5]. Common features of $V(u)$ in the longitudinal setting are the following:

1. *A nonzero value at the origin*. We interpret $V(0)$ as the expectation of one half the squared difference between two independent determinations of $Y(t)$ from the same subject. If we think in terms of a model in which $Y(t)$ is observed with additive measurement errors, $V(0)$ is the variance of the measurement error. In the spatial setting, $V(0)$ is called the *nugget effect*.

2. *Increasing trend*. An increasing function $V(u)$ corresponds to a decreasing $\gamma(u)$. Most models for the serial correlation in longitudinal (or spatial) data assume that correlation decreases monotonically with increasing time-separation.
3. *Limiting behavior at large time-separation*. The difference between the estimated variance of $Y(t)$ and the limiting value of $V(u)$ as $u \to \infty$ arises because of variation between subjects, which is included in var$\{Y(t)\}$ but excluded from $V(u)$.

Often, in practice, the available data are generated by a model of the form $y_{ij} = \mu_i(t_{ij}) + z_{ij}$ where the function $\mu_i(t)$ represents the mean response for subject i at time t and z_{ij} is a realization at time t_{ij} of an underlying **stationary** random process $Z(t)$. In this case, we estimate the unobservable z_{ij} as $\hat{z}_{ij} = y_{ij} - \hat{\mu}_i(t_{ij})$ and use the $\hat{z}_{ij}$ as the basis for calculating the empirical or sample variogram. In a designed experiment with a common set of observation times for all subjects, the effects of estimating the $\mu_i(t_{ij})$ can be minimized by fitting a saturated model for the mean response. More generally, the recommended practice is to base the estimates $\hat{\mu}_i(t_{ij})$ on a deliberately over-parameterized model. For further discussion, see [3, Chapter 5].

Figure 1 shows the sample variogram derived from a set of data on the log-bodyweights of 27 cows, allocated amongst four treatment groups. Each cow was weighed at 23 unequally spaced time-points over a period of approximately two years. The variogram was computed using the residuals from a saturated treatments-by-times model for the mean response. The horizontal line denotes the estimate of the variance of the residual process, assuming that this process is stationary. The large number of plotted points is a consequence of the fact that time intervals between successive weighings were not common to all cows, which limits the opportunities for averaging the empirical variogram ordinates. The other salient features of Figure 1 are:

1. *Behavior near the origin*. Simple extrapolation suggests that $V(0)$ is close to zero, which in turn suggests, reasonably, that the measurement error in determining the log-bodyweight is negligible.
2. *Increasing trend*. Log-bodyweights at different times become less correlated as the time-separation increases; the shape of this rising trend conveys information about the shape of the underlying covariance function $\gamma(u)$; note, however, that the sampling fluctuations in $\hat{V}(u)$ are substantial, and increase with u.
3. *Difference between the estimated variance and the values of $\hat{V}(u)$ at large values of u*. Assuming that $V(u)$ has leveled out within the plotted range of u, this difference appears to be substantial, suggesting a large component of variance between cows.

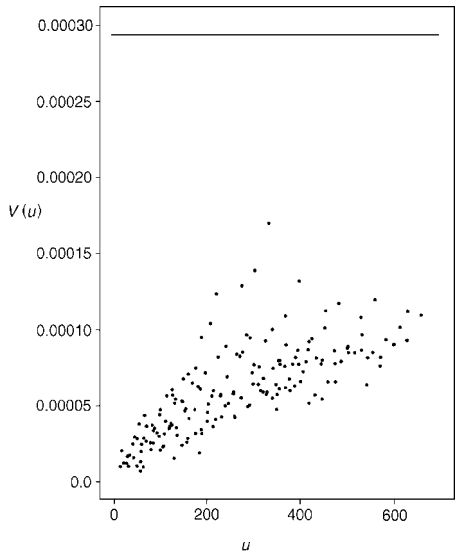

Figure 1 The sample variogram of ordinary least squares residuals from a saturated treatment-by-times model fitted to data on the log-bodyweights of cows

PETER J. DIGGLE

Vector Field Plot

Slope Fields

One may think of a slope field as a scatterplot (*see* **Graphical Displays**) where at each selected pair (x, y) denoting a location with respect to abscissa and ordinate axes is plotted the expected change in y for a one unit change in x as indicated by a short line segment of that slope. As an example, suppose a variable y were related to its slope with respect to time t such that

$$\frac{\Delta y(t)}{\Delta t} = \beta(y(t) - C), \tag{1}$$

where $y(t)$ is some time varying score, $\Delta y(t)/\Delta t$ is the expected change in $y(t)$ over some fixed interval of time Δt, β is some fixed coefficient, and C is some asymptotic value (i.e. *fixed point equilibrium*). From this equation, a slope field may be plotted such that on each point in a grid of pairs of values of Y and t a line segment is centered with the expected slope given that pair of values (i.e. *initial conditions*)(see Figure 1). The lengths of the line segments are all equal to one another. Three salient characteristics of the slope field shown are that (a) since each row of line segments has no variance in slope, the slopes are independent of time, (b) since each column of line segments has variance in slope, the slope is not independent of y, and (c) since the slopes are near zero when y is near 60, the equilibrium C in this plot must be near 60.

Slope fields may be plotted in which one variable represents time, or may also be plotted so as to visualize the expected slope of two variables with respect to each other. The expected slope could potentially vary with respect to the value of one, both, or neither of the two variables.

Vector Fields

Vector fields differ from slope fields in that they are directional, implying some evolution of the slope (i.e. first derivative) with respect to time. Vector fields are useful for visualizing the implications of differential equations over a range of initial conditions [5, 10]. A vector field is composed of a grid of arrows that may vary in direction and length. Direction and length

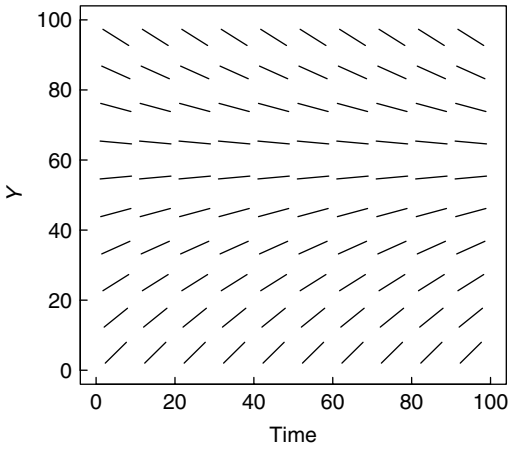

Figure 1 Slope field plotted for Equation 1

may be mapped to a variety of concepts. The most commonly used vector field display maps the vectors so that given the values of the variables in a system at time t plotted as the base of a vector, the length and the direction of the vector point to the values of those variables after some chosen interval τ has elapsed.

As an example in continuous time, the relationship between two variables X and Y might be modeled as a set of simultaneous differential equations

$$\begin{aligned} \frac{\mathrm{d}X}{\mathrm{d}t} &= \alpha_x + \beta_x X(t) + \gamma_x Y(t) \\ \frac{\mathrm{d}Y}{\mathrm{d}t} &= \alpha_y + \beta_y Y(t) + \gamma_y X(t), \end{aligned} \tag{2}$$

where the coefficients $(\alpha,\ \beta,\ \gamma)$ for each variable are used to describe the instantaneous trajectory of the bivariate processes. Or equivalently in discrete time might be formed a set of simultaneous difference equations

$$\begin{aligned} &\frac{\Delta X(t)}{\Delta t x \alpha_x} + \beta_x X(t - \Delta t) + \gamma_x Y(t - \Delta t) \\ &\frac{\Delta Y(t)}{\Delta t x \alpha_y} + \beta_y Y(t - \Delta t) + \gamma_y X(t - \Delta t), \end{aligned} \tag{3}$$

where Δt is defined by the application, and the coefficients for each variable describe the step-by-step trajectory of the bivariate processes [4, 6, 9]. Such a system is plotted in Figures 2 (a) and (b).

Vector field plots such as that shown in Figure 2b can be read to provide several forms of information.

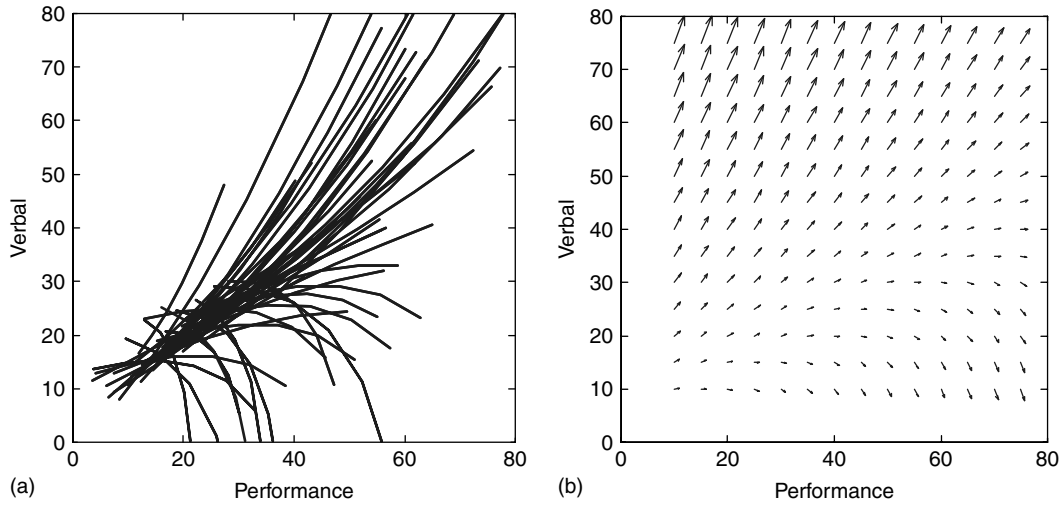

Figure 2 Trajectories and vector field generated from coefficients estimated from WISC data from $N = 204$ Children aged 6–11 [7]. (a) Hypothetical individual trajectories evolving over a lifetime from a few selected initial conditions. (b) A vector field plotting the evolution of a grid of initial conditions over a short interval of time

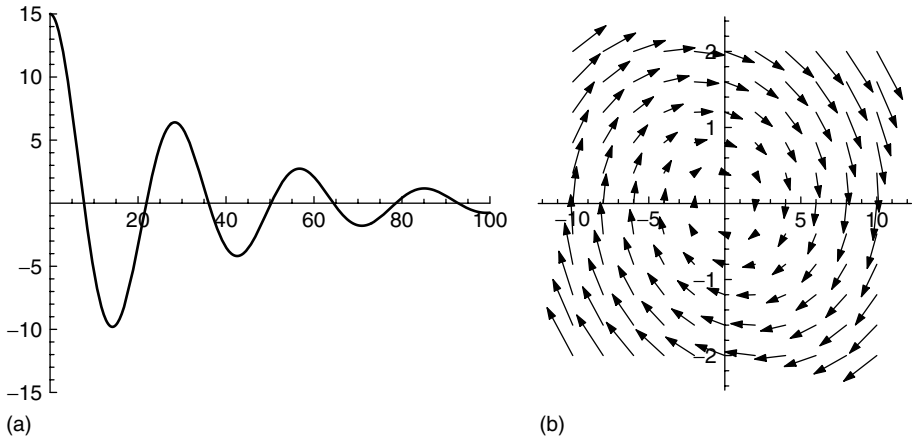

Figure 3 (a) Time series plot and (b) vector field plot of a damped linear oscillator conforming to Equation 4

In areas of the graph where vector lengths are small, the system is near an equilibrium. If vectors point away from an equilibrium, then that equilibrium is unstable. If vectors point towards an equilibrium, then that equilibrium is stable. If vectors appear to "circle" an equilibrium, then the system may oscillate under some initial conditions.

Vector fields are also used to visualize the relationship between a variable and its first and second derivatives with respect to time [1, 3]. The vector field in Figure 3 plots the expected change in x and its first derivative $\dot{x}$ over a short interval of time for the damped linear oscillator system

$$\ddot{x} = \eta x + \zeta \dot{x} \tag{4}$$

when η and ζ are both negative. This system has a stable equilibrium at $x = 0$ and oscillates about that equilibrium for a time that is dependent on its initial conditions.

Statistical Slope Fields

When performing **exploratory** analyses on **longitudinal data**, it is often useful to visualize the expected change of one variable with respect to another or in a variable with respect to time. Statistical slope fields employ **nonparametric methods** of local aggregation or smoothing to develop local estimates of the derivatives of systems and then plot these empirically derived estimates. Typically, a statistical slope field appears similar to a parametric slope field, but varies the length of the line segment as a means of displaying the relative proportion of the data near to the center of the line segment.

As an example, suppose a random sample of 100 individuals of different ages were drawn from a population whose scores were evolving according to the autoregressive system from (1) (*see* **ARMA and ARIMA Models**). Suppose each of these individuals were measured at two occasions separated by 15 years and that the measured score were the sum of a true score and **normally distributed** independent

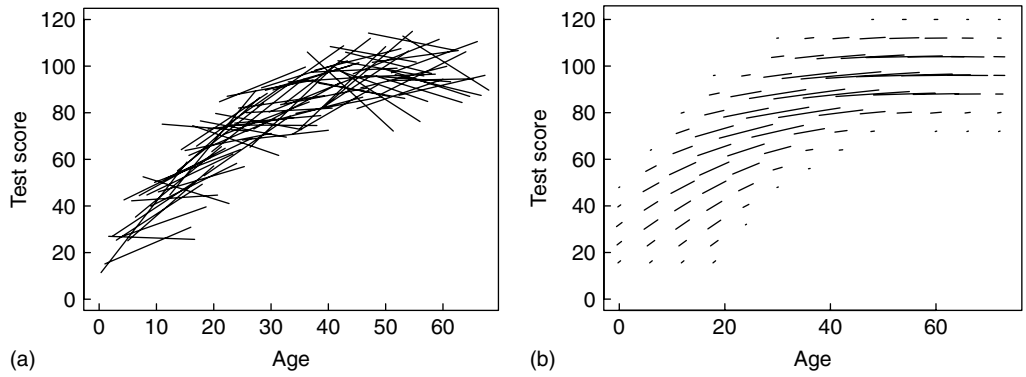

Figure 4 (a) Longitudinal time series plot and (b) statistical slope field plot of an autoregressive process conforming to Equation 1

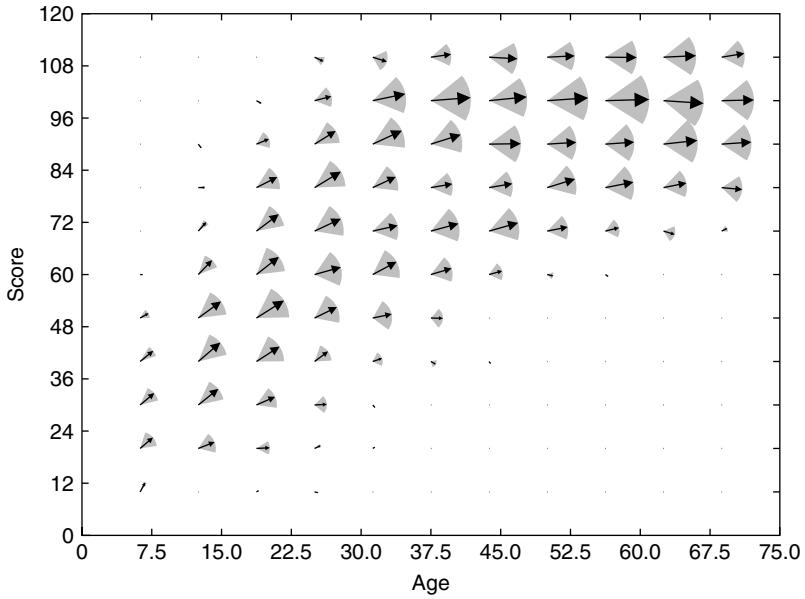

Figure 5 A statistical vector field plot of data from an autoregressive process conforming to Equation 1

error. These longitudinal scores could be plotted as in Figure 4(a). The statistical slope field of the same data was calculated using loess smoothing (*see* **Graphical Displays**) to locally estimate the derivative of the score with respect to time at the center of each point in a grid of age and score pairs. In some areas, there is no data and thus no estimate is made. Derivative estimates with larger Ns are plotted as longer line segments.

Statistical Vector Fields

A statistical vector field [2] is similar to a statistical slope field except that there is a time direction of the evolution of the system and an estimate of the variability of the slopes is made in the locality of each initial condition pair. The direction of the vector represents the expected change in the value of the variable shown on the ordinate axis with respect to a unit change in the variable shown on the abscissa. The length of the vector plots the proportion of the data in the vicinity of the initial condition pair at the base of the vector. The estimated **standard deviation** of this slope is plotted as a gray arc centered around the vector. An example statistical vector field of data conforming to (1) is plotted in Figure 5 [8, 9].

Viral Population Growth Models

Viruses are amongst the most dangerous and devastating threats to human health. They may invade a human or animal population and spread rapidly amongst its members, sometimes causing a large number of fatalities, possibly on a recurrent basis. A well-known case is the influenza virus, a new strain sweeping the globe and causing approximately 25 million deaths in 1919. At the present time, there are several countries, particularly in Africa, with up to 35% of their populations between the ages of 15 and 50 years infected by human immunodeficiency virus (HIV) (*see* **AIDS and HIV**). Throughout the world, already over 16 million deaths have been caused by this virus. More recently, a corona virus causing SARS (severe acute respiratory syndrome) [9] has created panic and economic chaos in certain southeast Asian countries. Renewed interest in the dynamical processes involved in the spread of viruses has also arisen recently because of the threat of bioterrorist attacks, especially with such viruses as smallpox [6], which was eradicated many years ago. We will first briefly describe in a simplified fashion some of the processes that determine the outcome of a viral invasion [14].

Viral Reproduction

Viral reproduction depends on host cells. The sequence of steps after the virus has penetrated the body's initial physical barriers (skin, mucosal lining) is

(a) the virus attaches to a host cell at a receptor on the cell surface,
(b) penetration occurs,
(c) the virus sheds its protein coat and releases its nucleic acid (RNA or DNA) into the cell,
(d) transcription occurs followed by replication of the virus genetic material and the production of proteins for new coats, and
(e) virus particles are assembled and released and may infect new host cells; the original host cell may die.

The time taken for some of these steps is extremely variable. For HIV, replication is unpredictable but may occur in a few hours; with herpes virus there may be a delay of weeks or up to many years, which seems to be an evolutionary strategy [25].

Models of viral population growth may be distinguished by whether they consider the within-host population, or the total across all individuals. To determine the latter, the dynamics of transmission amongst members of the host population are needed and this is usually the domain of classical models such as **SIR** (susceptible infected, recovered). These are discussed, for example, in Bailey [2] and Hethcote [8]. Recently, we have formulated nonlinear dynamical spatial network models for determining the total viral load (see [28], and references therein). In this work, we only consider within-host dynamics.

Deterministic Models

Since the growth of a viral population depends on the ability of the virus to penetrate new host cells, the simplest growth model has the following three components for a given volume of tissue: $x(t) =$ number of uninfected cells; $y(t) =$ number of infected cells; and $v(t) =$ number of free virus particles. Then,

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \lambda - \mu x - \beta v x \tag{1}$$

$$\frac{\mathrm{d}y}{\mathrm{d}t} = \beta v x - \alpha y \tag{2}$$

$$\frac{\mathrm{d}v}{\mathrm{d}t} = cy - \gamma v - \beta v x, \tag{3}$$

where uninfected host cells are supplied at rate λ and have a per cell death rate of μ, the parameter β describes the rate at which virus infects host cells, c is the rate at which free virions are produced per infected cell, and α and γ are the "per capita" rates of attrition of infected cells and virions, respectively. Equation (3) is a slightly modified version of the standard model formulated by Herz et al. [7], which is analyzed in [18]. The modification, suggested by Tuckwell and Le Corfec [27] and others consists of the additional term $-\beta v x$ in (3) to allow for the fact that whenever a cell is attacked, a free virus must disappear. The more complete model (1)–(3) is analyzed in detail by Tuckwell and Wan [29].

The system (1)–(3) has two equilibrium points:

$$P_1 = \left(\frac{\lambda}{\mu}, 0, 0\right),$$
$$P_2 = \left(\frac{\alpha\gamma}{\beta c}, \frac{\lambda}{\alpha} - \frac{\gamma\mu}{\beta c}, \frac{c\lambda}{\alpha\gamma} - \frac{\mu}{\beta}\right). \quad (4)$$

For $\lambda > 0$, P_1 is either a saddle point or an asymptotically stable node, but for usual parameter values, the former. P_2 is usually an asymptotically stable spiral point. Note that P_2 is unphysical when $\beta c\lambda < \alpha\gamma\mu$. When P_2 is in the first octant, solutions of the system (1)–(3) approach this point in an oscillatory fashion so that eventually there remain infected cells, virions, and uninfected cells in equilibrium. In the less usual case that P_2 is unphysical, the free virus must be extinguished.

The above model does not include an "immune response". The presence of infected cells may stimulate the production of cytotoxic T-cells, which attack infected cells. If these have concentration $z(t)$, then a plausible model system is given by (1) and (3) with (2) changed by the addition of a term representing the removal of infected cells

$$\frac{\mathrm{d}y}{\mathrm{d}t} = \beta vx - \alpha y - \rho yz \quad (2')$$

and an additional equation for the cytotoxic cells:

$$\frac{\mathrm{d}z}{\mathrm{d}t} = kyz - \delta z, \quad (5)$$

where δ is their natural death rate. In (2′), ρ is the per capita rate of removal of infected cells per immune cell, and k is the per capita rate of production of immune cells per infected cell. Some dynamical properties of the model (1),(2′),(3) (without the correction term) and (5) are also discussed in [18].

HIV

The virus that has attracted the most dramatic attention in the previous two decades is HIV (human immunodeficiency virus, usually type 1). A distinguishing feature of this virus is that the infected cells are those of the immune system itself, being CD4+ T-cells (helper cells). After infection, there is a rapid initial rise of virion density followed usually by a similarly paced fall, the latter being originally ascribed to an immune response. Modeling indicated that the early dynamics might be reasonably explained without invoking such a response [12, 21], and this has been mainly vindicated by subsequent studies. However, fitting the data on viral loads after the primary peak in some patients seemed to require the introduction of more complex dynamics such as the inclusion of cytotoxic T lymphocytes [23]. There is a large number of models that have been posited to describe these phenomena, and they may be distinguished by whether they address only the early phases or the later phases of the disease – Perelson and Nelson [20] and Nowak and May [18] can be consulted for numerous references.

The general model of McLean et al. [12] was later used in a different context by Phillips [21] to explain the decline in viral load in HIV after the initial rise to about 5000 per mm^3. Two classes of infected cells [17] are introduced because the insertion of viral genetic material may be followed by a delay before virions emerge. Thus, $x(t)$ is the density of uninfected CD4+ T-cells, but now $u(t)$ is the density of latently infected cells and $w(t)$ is the density of infected cells producing virus. With $v(t)$, the density of free virions in the plasma we have, with an added correction term for $\mathrm{d}v/\mathrm{d}t$:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \lambda - \mu x - \beta vx \quad (6)$$
$$\frac{\mathrm{d}u}{\mathrm{d}t} = \beta pvx - (\mu + \alpha)u \quad (7)$$
$$\frac{\mathrm{d}w}{\mathrm{d}t} = \beta(1-p)vx + \alpha u - aw \quad (8)$$
$$\frac{\mathrm{d}v}{\mathrm{d}t} = cw - \gamma v - \beta vx. \quad (9)$$

Here, p is the fraction of infected cells, which become latent, α is the rate of conversion of latent to actively infected cells, and a is the death rate of actively infected cells. The term λ in (6) gives the rate at which new T-cells are created from sources in the body. Another term may be added, such as a logistic, to represent growth due to the proliferation of existing T-cells. The parameters are possibly time-varying so that, for example, if the immune response is weakening, then γ may decrease. A long-term model not dissimilar to the above and which leads to the break down of immunity (AIDS) was analyzed in [24].

In all the above dynamical models, not only for HIV but also for other viruses, the law of "mass action" is assumed to operate giving a rate of

new infections proportional to the product of viral and host cell numbers. However, there are strong grounds for sometimes questioning the validity of this assumption. For such a law to apply, there must be homogeneous mixing and the latter is unlikely if there are only one or two virions and say 10^{11} host cells. The law may, nevertheless, be accurate for a very restricted volume of tissue or fluid. It is also worth mentioning that the viral density in plasma may be low, or essentially zero, but that due to the continued existence of latently infected host cells, the viral density may increase at a later time, making the disease extremely difficult to eradicate.

Other Viruses

There has been a considerable effort to model the invasion and within-host growth of influenza virus populations, sometimes with very complex systems [3]. Although there have been many epidemiological studies of the spread of such viruses as smallpox, measles, herpes, and so on, mathematical models for the growth of their within-host viral populations have been sparse. Nowak and May [18] have described simple differential equations for the hepatitis B virus, which presently afflicts about 300 million people, and Neumann et al. [15] have analyzed the dynamics of the hepatitis C virus.

Stochastic Dynamical Models for HIV

As pointed out by Tan and Wu [26], a stochastic description of viral population growth is more realistic than a deterministic one because of the nature of the subcellular processes. Furthermore, it is expected that a stochastic approach can provide a more accurate quantitative basis for evaluating the efficacy of drug treatments in infected host populations. Nevertheless, relatively little attention has been given to stochastic dynamical viral growth models. From an analytic viewpoint, this is probably due to the complexity of the systems. The general viral growth model (1)–(3) does not have a stochastic counterpart, though one could easily be developed using approaches similar to those described below for HIV. One of the first stochastic models for HIV was a simple **branching process** [13].

In general, the following effects are stochastic:

(a) generation and fluctuations in the rate of appearance of new host cells,
(b) contacts between viruses and the host cell and random attachment,
(c) transition to active or latent infected cell,
(d) time for the emergence of new virions,
(e) number of new virions emerging from a host cell,
(f) death process for infected and uninfected host cells and virions,
(g) mutation to other viral strains, and
(h) appearance and action of immune system components, which assist in the removal of virions.

Models for a Single Viral Genotype

Here, it is assumed that all virus particles have the same genetic properties. Vector valued **Markov process** models for the growth of HIV populations have been introduced by Tuckwell and Le Corfec [27] and Tan and Wu [26]. Both models have the same four biological components. A comparison of these models was made in Kamina et al. [10], but the nature of the boundaries for the diffusions (see e.g. [4]) needs further investigation. The Tuckwell–Le Corfec model is a four-dimensional diffusion process and as it is simpler than Tan and Wu's model, it will be described first, after a consideration of a more fundamental model involving **Poisson processes**.

Stochastic Model for Early HIV Growth. In this work, emphasis is on the early period (to several weeks) after infection and not on the later progression to the acquired immune deficiency syndrome, which may follow. The stochastic properties included are (b) and (c) in the above list, so that emphasis is on the viral production process. It is assumed that the number of virions produced by each actively infected cell and the birth and death rates of the various components take fixed mean values, so variability is underestimated but with the advantage of simplification and far fewer parameters.

Letting the components be X_k, $k = 1, 2, 3, 4$, we have that at time t (days) after initial infection, for a fixed and relatively small (in order to enhance the validity of the mass action principle) volume of plasma, $X_1(t)$ is the number of uninfected CD4+ T-cells (called "activated" by Phillips [21]), $X_2(t)$ is

the number of latently infected cells, $X_3(t)$ is the number of actively infected cells, and $X_4(t)$ is the number of circulating HIV-1 virions. The attachment of virus to CD4+ T-cells (assumed to be one on one) occurs according to a Poisson process $N = \{N(t), t \geq 0\}$ with rate $\beta X_1 X_4$ so that the system of stochastic differential equations corresponding to the above deterministic model is

$$\mathrm{d}X_1(t) = (\lambda - \mu X_1(t)\,\mathrm{d}t - \mathrm{d}N(t) \tag{10}$$

$$\mathrm{d}X_2(t) = -(\mu + \alpha)X_2(t)\,\mathrm{d}t + \mathrm{d}X(t) \tag{11}$$

$$\mathrm{d}X_3(t) = (\alpha X_2(t) - aX_3(t))\,\mathrm{d}t + \mathrm{d}Y(t) \tag{12}$$

$$\mathrm{d}X_4(t) = (cX_3(t) - \gamma X_4(t))\,\mathrm{d}t - \mathrm{d}N(t). \tag{13}$$

The random variable $X(t)$ is **binomial** with parameters $N(t)$ and p and $Y(t)$ is binomial with parameters $N(t)$ and $1 - p$. That is, at time t for each of $N(t)$ virus-uninfected cell interactions, the probability of a transition to a latently infected cell is p; and the probability of a transition to an actively infected cell is $(1 - p)$. Note that N has different units in, for example, (10) and (13), but equal numerical values. In a diffusion approximation [27] (*see* **Brownian Motion and Diffusion Processes**), the evolution of the system is described by

$$\begin{aligned}\mathrm{d}X_1 &= (\lambda - \mu X_1 - \beta X_1 X_4)\,\mathrm{d}t \\ &\quad - \sqrt{(\beta X_1 X_4)}\,\mathrm{d}W \end{aligned} \tag{10A}$$

$$\begin{aligned}\mathrm{d}X_2 &= [\beta p X_1 X_4 - (\mu + \alpha)X_2]\,\mathrm{d}t \\ &\quad + \sqrt{(\beta p X_1 X_4)}\,\mathrm{d}W \end{aligned} \tag{11A}$$

$$\begin{aligned}\mathrm{d}X_3 &= [\beta(1 - p)X_1 X_4 + \alpha X_2 - aX_3]\,\mathrm{d}t \\ &\quad + \sqrt{(\beta(1 - p)X_1 X_4)}\,\mathrm{d}W \end{aligned} \tag{12A}$$

$$\begin{aligned}\mathrm{d}X_4 &= (cX_3 - \gamma X_4 - \beta' X_1 X_4)\,\mathrm{d}t \\ &\quad - \sqrt{(\beta' X_1 X_4)}\,\mathrm{d}W. \end{aligned} \tag{13A}$$

The model parameters are as defined above for the deterministic model. The prime on β indicates that this parameter has different units from those of β. Note that there is only one primary Wiener process, not four as portrayed in [10] as each component carries the same one, derived from the Poisson process N.

For the four-component diffusion process (10A)–(13A), the transition probability density function $P(\mathbf{y}, t; \mathbf{x}, s)$, $s < t$, where $\mathbf{y}$ is a 4-vector of forward variables and $\mathbf{x}$ is a 4-vector of corresponding backward variables, satisfies the following backward Kolmogorov equation [5]

$$\frac{\partial P}{\partial s} + L_{\mathbf{x}} P = 0, \tag{14}$$

where the operator $L_{\mathbf{x}}$ is defined through

$$\begin{aligned} L_{\mathbf{x}} &= \left[\lambda - \mu x_1 - \beta x_1 x_4\right]\frac{\partial}{\partial x_1} \\ &\quad + \left[\beta p x_1 x_4 - (\mu + \alpha)x_2\right]\frac{\partial}{\partial x_2} \\ &\quad + \left[\beta(1 - p)x_1 x_4 + \alpha x_2 - a x_3\right]\frac{\partial}{\partial x_3} \\ &\quad + \left[c x_3 - \gamma x_4 - \beta' x_1 x_4\right]\frac{\partial}{\partial x_4} \\ &\quad + x_1 x_4 \Bigg[\frac{1}{2}\left\{\beta\frac{\partial^2}{\partial x_1^2} + \beta p\frac{\partial^2}{\partial x_2^2}\right. \\ &\quad \left. + \beta(1 - p)\frac{\partial^2}{\partial x_3^2} + \beta'\frac{\partial^2}{\partial x_4^2}\right\} \\ &\quad + \beta\sqrt{p}\frac{\partial^2}{\partial x_1 \partial x_2} + \beta\sqrt{1 - p}\frac{\partial^2}{\partial x_1 \partial x_3} \\ &\quad - \sqrt{\beta\beta'}\frac{\partial^2}{\partial x_1 \partial x_4} + \beta\sqrt{p(1 - p)}\frac{\partial^2}{\partial x_2 \partial x_3} \\ &\quad - \sqrt{\beta\beta' p}\frac{\partial^2}{\partial x_2 \partial x_4} - \sqrt{\beta\beta'(1 - p)}\frac{\partial^2}{\partial x_3 \partial x_4}\Bigg]. \end{aligned}$$

For the diffusion model, some simulated sample paths obtained with a strong Euler scheme for X_1, X_2, and X_4 are shown in Figure 1. Good agreement with the time course and variability of the acute phase of HIV-1 infection is found. In addition, it was found useful to find the times at which the virion density attains levels corresponding to the thresholds for detection of the virus in plasma samples; a typical distribution is shown in the bottom part of Figure 1. Such results are useful in ascertaining the risks in tests of blood donations for infection by HIV [11].

It is possible to find the properties of the distribution of the time to detection by using first passage time theory for diffusion processes, which results in the following analytical framework. Let the threshold level of detection of the virus be θ/mm^3. Let A be a set in R^4 containing the initial value $\mathbf{x}$ of the process such that $x_4 \in (0, \theta)$. In particular, let $A = (x_1', x_1'') \times [0, x_2'') \times [0, x_3'') \times (0, \theta)$. Then, we consider the time to detection as the first exit time, $T_\theta(\mathbf{x})$,

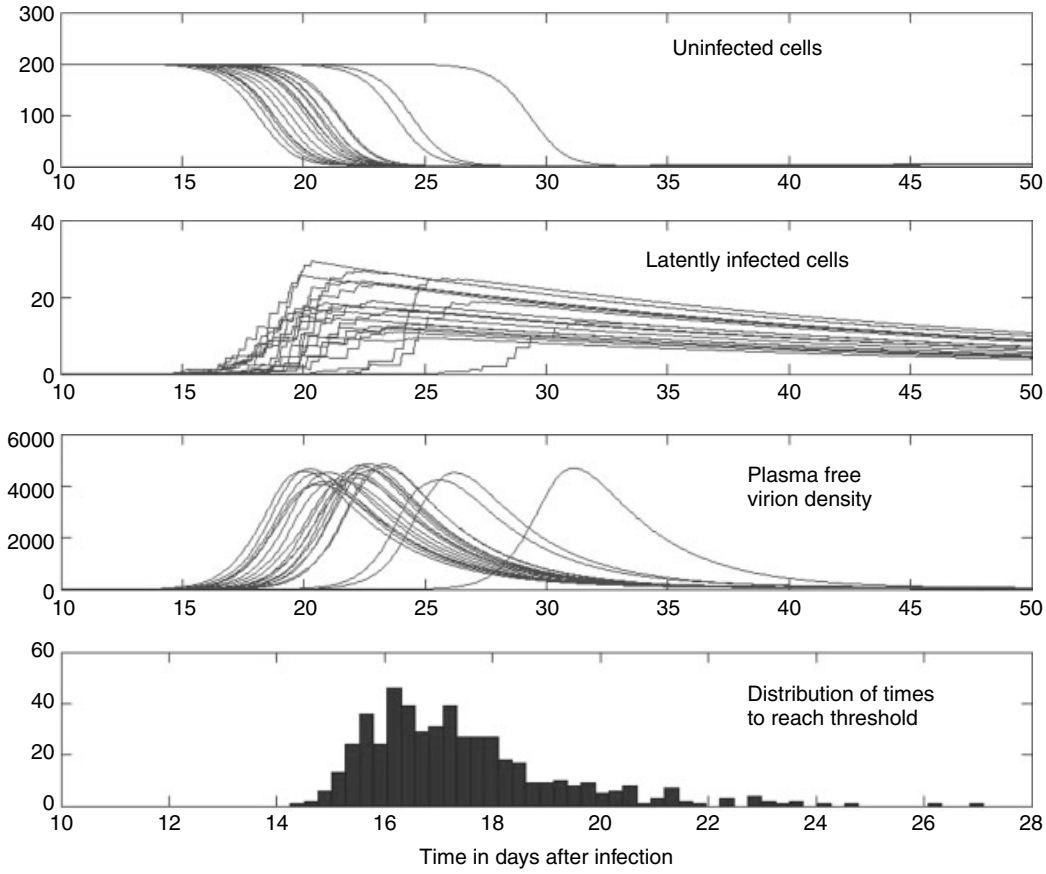

Figure 1 Numerical solutions of the stochastic differential equations (10A)–(13A), showing 20 sample paths for the components X_1, activated uninfected cells, X_2, latently infected cells, and X_4, free plasma virus. For more details, see Tuckwell and Le Corfec [28]. An estimate of the distribution of the time to reach an assumed detection threshold (100 virions/cubic millimeter) is also shown, based on 500 trials

of the process (X_1, X_2, X_3, X_4) from A. Here, x_1' is chosen small enough and both x_2'' and x_3'' are chosen large enough so that escapes through $x_1 = x_1'$ or $x_2 = x_2''$ or $x_3 = x_3''$ are extremely unlikely. Also, the actual initial value of X_1 must be less than x_1''.

The distribution function of this quantity, $F_{\boldsymbol{\theta}}(\mathbf{x}; t) = Pr\{T_\theta(\mathbf{x}) \leq t\}$, satisfies

$$\frac{\partial F_{\boldsymbol{\theta}}}{\partial t} = L_{\mathbf{x}} F_{\boldsymbol{\theta}}, \tag{15}$$

with initial condition $F_{\boldsymbol{\theta}}(\mathbf{x}; 0) = 0$, if $\mathbf{x} \in A$ and $F_{\boldsymbol{\theta}}(\mathbf{x}; 0) = 1$, if $\mathbf{x} \notin A$, with boundary condition $F_{\boldsymbol{\theta}}(\mathbf{x}; t) = 1$, $\mathbf{x} \notin A, t \geq 0$. Furthermore, the **moments** $\mu_n = E\left[T_\theta^n(\mathbf{x})\right]$, $n = 1, 2, \ldots$, satisfy the recursive system

$$L_{\mathbf{x}} \mu_n = -n\mu_{n-1}, \tag{16}$$

for $\mathbf{x} \in A$, with boundary conditions $\mu_n(\mathbf{x}) = 0, \mathbf{x} \in \partial A$. Here, $\mu_0 = 1$ is the probability of ever leaving A. There may be some escape of probability mass at zero virion level but this is expected to be insignificant compared to that associated with paths, which attain level θ, so $T_\theta(\mathbf{x})$ will be very close to the time to detection.

Approximation for Small Times. The above four-component framework can be simplified to a two-component one at early times by not distinguishing

between latently and actively infected CD4+ T-cells, as in [7], and by considering the number of uninfected CD4+ T-cells as constant. Neglecting also the interaction term in the viral dynamical equation, one obtains a simplified stochastic model for the very early (less than 15 days) period of HIV-1 dynamics [30].

Long-term Stochastic HIV Model. The mathematical model of Tan and Wu [26] has the same four components as above, but the dynamics of the uninfected cells are more complicated. These are generated by a means of a (possibly temporally nonhomogeneous) Poisson process with rate $s(t)$ (replacing the constant λ), the rate declining as free virion level increases. Furthermore, these cells are stimulated by HIV and antigen to produce new X_1 by a stochastic logistic birth process with rate $r(t) = r_0[1 - (X_1 + X_2 + X_3)/T_{\max}]$, where r_0 is a constant and $T_{\max}$ is the saturating level of host cells in all stages. The proportion of infected cells that become latent is possibly time dependent and given by $\omega(t)$ and the number of virions released by an actively infected cell is (possibly) random and given by $M(t)$. Furthermore, the three kinds of host cells and free HIV die according to simple death processes with rates μ_1, μ_2, μ_3 and μ_4, respectively (*see* **Stochastic Processes**). The stochastic equations take the form

$$\mathrm{d}X_1 = s(t)\,\mathrm{d}t + r(t)X_1\,\mathrm{d}t - X_1[\mu_1 + k_1X_4]\,\mathrm{d}t + \varepsilon_1(t)\,\mathrm{d}t \tag{17}$$

$$\mathrm{d}X_2 = \omega(t)k_1X_1X_4\,\mathrm{d}t - X_2[\mu_2 + k_2]\,\mathrm{d}t + \varepsilon_2(t)\,\mathrm{d}t \tag{18}$$

$$\mathrm{d}X_3 = [1 - \omega(t)]k_1X_1X_4\,\mathrm{d}t + k_2X_2\,\mathrm{d}t - \mu_3X_3\,\mathrm{d}t + \varepsilon_3(t)\,\mathrm{d}t \tag{19}$$

$$\mathrm{d}X_4 = M(t)\mu_3X_3\,\mathrm{d}t - k_1X_1X_4\,\mathrm{d}t - \mu_4X_4\,\mathrm{d}t + \varepsilon_4(t)\,\mathrm{d}t. \tag{20}$$

The constants k_1 and k_2 are the interaction rate between HIV and uninfected cells and the transition rate from X_2 to X_3. Note that here virions are released (only) whenever an X_3 cell "dies". The terms ε_k, $k = 1, \ldots, 4$, are "random noises". The means of the X_k's are not the same as the deterministic model. By means of simulation, Tan and Wu were able to distinguish three regimes: (a) an early infection period; (b) a transition period; and (c) a steady state period. Using parameters estimated from patient data, in both their simple and complex models, they found there was a positive probability of approaching a noninfected state ($X_3 = X_4 = 0$), even in the absence of drug treatments.

Models with Mutant Virus Strains

It is important to address the effects of the appearance of mutant strains of virus, which may lead to ineffective or less effective drug treatments [1, 16, 18, 22]. Abundo and Rossi [1] consider a multicomponent diffusion process model. In addition to distinguishing viral strains, $V_i, i = 1, \ldots, n$, each of which has its own unique growth rate r_i, it was assumed that there are associated specialized classes of CD4+ T-cells, X_i. There are also an uninfected cell population Y and a nonspecific class of activated cells, X. A virus of any strain may attack host cells. The drift terms correspond to the deterministic model of Nowak *et al.* [19]. The process of viral mutation does not appear explicitly in the model, which seems undesirable. However, in the simulated solutions of the diffusion model, explosions of viral load eventually occur, accompanied by the collapse of the immune system. For a perspective on the ramifications for strategies of drug treatment, see [22].

Statistical Models and Drug Treatments

Using simple differential equations, similar to those in the section "Deterministic Models", modified to incorporate the effects of drug treatments, patient data on CD4 cell counts and HIV loads may be used to estimate model parameters from explicit solutions. For example, using **nonlinear regression** analysis, the viral clearance rate constant, and the rate of loss of virus-producing cells were estimated for each of a group of patients [20]. However, as there is presently no suitable long-term HIV model, Wu and Zhang [32] have applied a class of semiparametric nonlinear mixed-effects models developed for longitudinal data [33] (*see* **Random Coefficient Repeated Measures Model**). At the population level, combination antiretroviral therapies (ARV) are widely used to treat HIV, but drug-resistant strains have quickly evolved and the overall impact that ARV will have on HIV epidemics remains unclear. Velasco-Hernandez et al. [31] used a mathematical model to determine the effectiveness of current therapies in reducing the severity of HIV epidemics. They claimed that even

a high-prevalence HIV epidemic could be eradicated using current ARV.

Conclusions

Mathematical models of viral dynamics are potentially very useful for understanding the progression and treatment of virally induced diseases. Simple statistical models and the incorporation of mutant viral strains can lead to optimized drug treatments for HIV, which ameliorate the disease but do not eliminate it. The stochastic modeling of viral dynamics is in its infancy, and existing models omit many important agents and properties of both virus, host cell and immune response.

Vital Statistics, Overview

Vital statistics, as a scientific discipline, is a subdomain of **demography**, the study of the characteristics of human populations. Vital statistics comprises a number of important events in human life including birth, death, fetal death, marriage, divorce, annulment, judicial separation, adoption, legitimation, and recognition. The term "vital statistics" is also applied to individual measures of these vital events. Thus, a birth rate is an example of a vital statistic and an analysis of trends in birth rates is an example of an application in the field of vital statistics. A vital statistics system is the total process of collecting by civil registration, enumeration, or indirect estimation, information on the frequency of occurrence of vital events, selected characteristics of the events and the persons concerned, and the compilation, analysis, evaluation, and dissemination of these data in summarized statistical form. Other life events of demographic importance such as change of place of residence (migration), change of citizenship (naturalization), and change of name are not included, mainly because information on these is usually derived from other statistical systems such as population registers [1].

Systems for Collecting Vital Statistics

It is generally accepted that the preferred method for individual countries to collect vital statistics is through a civil registration system. This is recognized by the United Nations (UN) and other international organizations, as well as by the many countries that have had civil registration laws and regulations in place and in operation for many years [1, 2]. Nevertheless, a number of newly emergent and developing nations, facing the difficulties and length of time it takes to create a satisfactory civil registration system, have instituted alternative procedures to acquire statistical data to describe the levels and trends for key vital events, particularly for fertility and mortality measurements. The UN recognizes the importance of a civil registration system for each country as the preferred source of vital statistics data for the long run. However, use of an alternative data collection system is recommended as an interim measure for meeting needs for essential information where a civil registration system of acceptable quality does not yet exist. Other systems include, for example, probability area samples (*see* **Probability Sampling**), purposeful area samples, records-based **surveys**, and **record linkage**. Furthermore, the UN recommends a priority order for the types of vital statistics data to be collected. The highest need is given to data on births and deaths, followed in order by marriages, divorces, fetal deaths, annulments, judicial separations, adoptions, legitimations, and recognitions [1].

Uses of Vital Records and Vital Statistics

Vital records created through a civil registration system have two classes of use. They have value individually as legal documents for the persons named thereon; they also constitute the input, when aggregated, for the various vital statistics measures that are used to study the demographics and health of populations and population subgroups.

For the individual, a birth record is a legal document establishing name, parentage, birth data, order of birth for multiple births, legitimacy, and citizenship, nationality, or geographic place of birth. A wide variety of individual rights and civil entitlements depends on these facts, including proof of age for school entrance, motor vehicle drivers' licenses, military service and other age-related activities, establishment of eligibility for family allowances, insurance benefits, tax benefits, inheritance rights, issuance of passports, etc. The death record provides documentary proof of the facts of death needed for social security and insurance purposes such as time and place of death and the medical cause of death. Proof of death and the associated facts are also used for property inheritance rights, for remarriage rights of surviving spouses, etc. Marriage and divorce records serve to document rights to special social and economic programs and benefits for the married, including tax privileges for couples, alimony, change of nationality based on marriage, and the right to remarry. Many rights of children, their parents, and their guardians are dependent on records of adoption, legitimation, and recognition.

Individual vital records may also be used administratively as the basis for initiating maternal and child health services, including child immunization programs, or for epidemiologic investigations into disease outbreaks or assessments of causes of accidents and injuries. Another important administrative

use of individual vital records especially of death records (*see* **Death Certification**), is for the updating or clearing of files such as electoral rolls, social security files, **disease registers**, cohort follow-up studies, tax registers, etc.

In aggregated form, vital records become a collection of vital statistics, most often in the form of **means**, **medians**, and various ratios such as proportions and **rates**. Whether collected by civil registration or by other means, vital statistics serve as key demographic variables in the analysis of population size, growth and geographic distribution, especially when used in conjunction with periodic population **censuses**. When census data are used as a base, current intercensal estimates of population size can be made, and projections into the future can be prepared using estimates of future trends in fertility, natality, and mortality linked with estimates of net migration. In addition to the importance of vital statistics to the study of population size and growth trends, other national and subnational economic and social concerns such as health, welfare, education, occupation, housing, urbanization, family structure, and income are also affected by these measures. In the fields of public health and medicine, for example, levels and trends of **infant and perinatal mortality** are often used as surrogate measures of levels and trends in the overall health and well-being of nations. **Life expectancy** at birth is also frequently used to compare the overall effects of mortality and its determinants. **Cause of death** information provides a foundation upon which much research into diseases and disease prevention is based.

Differentials in mortality by sex, age, racial groups, and other variables are often the basis for the planning of health and medical intervention programs. In addition, the planning and provision of public and private housing, educational facilities, social security and private insurance plans, medical facilities, and consumer goods of all kinds are examples of activities dependent on vital statistics data. At the international level, vital statistics provide a basis for comparing important demographic, social, and economic differences and trends over time among countries or regions of the world.

Definitions of Selected Vital Events

Standard statistical definitions of vital events have been promulgated by international agencies [1, 5]. In some cases, legal definitions may differ from the international standards in varying degrees, but, in many cases, national vital statistics reports are either based on the standard statistical definitions or do not differ in principle. In cases where comparability among countries is compromised because of the use of nonstandard definitions, international agencies and others presenting national comparisons of tabular, graphical or descriptive vital statistics usually provide appropriate cautions to users. Nevertheless, users of vital statistics data need to ascertain the comparability of the data before drawing reliable conclusions about national differences. The **World Health Organization (WHO)** promulgates a number of vital statistics definitions as part of the **International Classification of Diseases (ICD)**. These definitions are incorporated in regulations adopted by the World Health Assembly and which each WHO member country has agreed to follow [4]. Nevertheless, it is still necessary to ensure that the standard definitions have been followed for a given data set. The international standard definitions for selected vital events are given below.

Live Birth. This is the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of the pregnancy, which, after such separation, breathes or shows any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached; each product of such a birth is considered liveborn [5].

Fetal Death. This is death prior to the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of pregnancy; the death is indicated by the fact that after such separation the fetus does not breathe or show any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles [5].

Maternal Death. This is the death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and the site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes. Maternal deaths may be subdivided into two groups: direct obstetric

deaths which are the result of obstetric complications of the pregnant state (pregnancy, labor, and the puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of these; and indirect obstetric deaths which are the result of previously existing disease or disease that developed during pregnancy and which was not due to direct obstetric causes, but which was aggravated by physiologic effects of pregnancy [5].

Infant Death. This is the death of a liveborn infant who dies before completing its first year of life.

Neonatal Death. This is the death of a liveborn infant who dies during the first 28 completed days of life. These may be subdivided into early neonatal deaths, occurring during the first seven days of life, and late neonatal deaths, occurring after the completion of the seventh day but before the completion of 28 days [5].

Perinatal Death. This is the death of a fetus or newborn infant occurring after 22 completed weeks (154 days) of gestation (the time when fetal weight is normally about 500 g), but prior to the completion of seven days after birth [5].

Marriage. This is the act, ceremony or process by which the legal relationship of husband and wife is constituted. The legality of the union may be established by civil, religious, or other means recognized by the laws of each country [1].

Divorce. This is a final legal dissolution of a marriage which confers on the parties the right to remarriage under civil, religious, or other provisions, according to the laws of each country [1].

Definitions of Selected Vital Statistics Measures

Raw vital statistics most often are comprised of counts of how often a specified vital event has occurred, rather than on measurements of continuous variables such as height, weight, or blood pressure. The analysis of vital data depends mainly on the conversion of observed frequencies into indices, ratios, and probabilities. Counts of vital events often do have utility, but, for the majority of uses, absolute frequencies are not sufficient and it becomes necessary to compute relative numbers, including crude rates, various types of specific rates, percentages, probabilities, and other ratios.

Some of the more commonly encountered vital statistics relative numbers are defined and calculated as follows.

Crude Death Rate

The most common form of mortality measurement is the crude death rate. It is computed from the following formula [3]:

$$m_{\mathrm{cd}} = \left(\frac{D}{P}\right) k,$$

where m_{cd} is the crude death rate, D is the total number of deaths for a given area and time period, usually a calendar year, P is the size of population at risk of dying, usually taken as the estimated population at the midpoint of the calendar year, and k is a constant, usually taken as 1000.

The crude rate is so named to differentiate it from various specific and adjusted rates and represents the total or overall death rate without regard to the various component elements which combine to produce the total figure. The crude death rate is usually expressed as "the number of deaths per 1000 persons" for a specified place (country, city, state, etc.) for a given year.

Specific Death Rate

Detailed analyses of vital statistics frequently go beyond the overall risk of death in the population as a whole. Many studies deal with subsets of the population or with particular classes of deaths. Epidemiologists often focus on deaths from a particular disease or class of diseases. Actuaries and demographers are concerned with differences in mortality by sex and in different age groups within the population. Environmental and **occupational health** specialists are interested in the differential risks of dying in selected occupations, and in different geographic subdivisions such as urban and rural areas. To meet these kinds of needs, various specific death rates are calculated. Specific rates for different age groups are called *age-specific death rates*; rates for males and females

are called *sex-specific death rates*, rates for particular causes of death are called *cause-specific death rates*. Rates may be specific for combinations of characteristics. For example, age–sex–race-specific death rates are computed separately for each age group by race and sex. Specific death rates are approximations of true probabilities. That is, the denominator of the ratio is an estimate of the total number of events of a particular type that could happen, while the numerator is a count of those that did happen.

Specific death rates are computed as follows [3]:

$$m_{\mathrm{sd}} = \left(\frac{d_i}{p_i}\right) k,$$

where m_{sd} is the specific rate for any defined ith class, d_i is the number of deaths occurring in the ith class for a given area and time, p_i is the number of persons in the ith class of the population for the same area and time, and k is a constant, usually 100 000.

For cause-specific death rates, the denominator, p_i, in the above formula is replaced by P, the total population exposed to the risk of death. Therefore, a cause-specific death rate measures the risk in the total population of dying from a specified cause of death.

Infant Mortality Rate

The infant mortality rate is considered by many as one of the important indicators of the overall level of health and social well-being of a country or other geopolitical area. This is, in part, because a large proportion of deaths in the first year of life are considered to be preventable through adequate prenatal care, good nutrition for women and infants, and improved control of the environment, including injury prevention.

The infant mortality rate is computed as follows [3]:

$$m_i = \left(\frac{d_{<1}}{B}\right) k,$$

where m_i is the infant mortality rate, $d_{<1}$ is the number of deaths to liveborn infants under one year of age during a specified time period, usually one year, B is the total number of live births during the same time period, and k is a constant, usually 1000.

The infant mortality rate is a proxy for the age-specific death rate for the "under one year of age group" and is intended to be a measure of the risk of dying during the first year of life. The numerators of the infant mortality rate and the "under one year of age" age-specific death rate are the same. For a denominator, however, a reliable estimate of the size of the population under one year of age for a given time period is hard to obtain, even in a census year. As a proxy measure, the denominator may be considered to be the number of births occurring during the period. For either of these choices of denominator, there is some mismatch with the numerator in terms of a true probability number. Not all events in the numerator arise from the events in the denominator. For example, in the infant mortality rate, some of the deaths under one year of age in a given year and counted in the numerator were actually born in the previous year and are not represented in the denominator, while some of the births represented in the denominator will die before their first birthday but the deaths will occur in the next year and are not included in the numerator. However, when the birth rate is fairly stable from one year to the next, calculation of the infant mortality rate results in a ratio that closely approximates the probability of a live-born infant dying within the first year of life. When the birth rate is not stable from year to year, a more accurate mortality rate may be computed by following each live birth occurring during a one year period and measuring how many of them die before their first birthday.

Neonatal, Early Neonatal and Postneonatal Mortality Rates

The *neonatal mortality rate* is defined as follows [5]:

$$m_{\mathrm{n}} = \left(\frac{d_{<1\ \mathrm{mo}}}{B}\right) k,$$

where m_{n} is the neonatal mortality rate, $d_{<1\ \mathrm{mo}}$ is the number of deaths of infants under 1 month of age during a specified time period, B is the number of live births occurring during the same time period, and, k is a constant, usually 1000.

The neonatal mortality rate, like the infant mortality rate, is a proxy for an age-specific death rate. It approximates the risk of dying in the first month of life. The relative importance of an infant mortality rate compared with the corresponding neonatal mortality rate depends on the proportionate age distribution of the deaths under one year of age. Generally, when the infant mortality rate is low, a large proportion of infant deaths occur during the first month

of life. The neonatal mortality rate then reflects an important measure of the mortality risk for infants. Conversely, when the infant mortality rate is high, larger proportions of deaths fall into the older age groups under a year. Often it is useful to partition the deaths of infants under one year of age into two groups: those dying before one month of age, and those dying between one month and their first birthday. The former comprise the numerator, $d_{<1\ \mathrm{mo}}$, of the neonatal mortality rate, while the latter can be used to calculate the *postneonatal mortality rate*:

$$m_{\mathrm{pn}} = \left(\frac{d_{1\ \mathrm{mo}-1\ \mathrm{yr}}}{B} \right) k,$$

where m_{pn} is the postneonatal mortality rate, $d_{1\ \mathrm{mo}-1\ \mathrm{yr}}$ is the number of deaths occurring between 1 month and 1 year of age during a specified time period, B is the number of live births occurring during the same time period, and k is the same constant used in the neonatal mortality rate, usually 1000.

In similar fashion, the neonatal deaths may be partitioned into those dying within the first week of life and the remainder that survive the first seven days but die before one month of age. The risk of dying in the first week of life is measured by the *early neonatal mortality rate*, m_{en}, as follows [5]:

$$m_{\mathrm{en}} = \left(\frac{d_{<7\ \mathrm{days}}}{B} \right) k,$$

where the components of the calculation are the same as in the neonatal and postneonatal mortality rates, except that the numerator contains only those deaths to infants occurring during the first week of life.

Perinatal Mortality Rate

The perinatal period, as defined earlier, is the period of time surrounding the event of birth. It includes the time that a fetus spends in utero after it has reached 22 weeks of gestation and continues through the birth process until the end of the first week of life after birth. The perinatal mortality rate measures mortality occurring during this period. The rate, therefore, combines deaths of fetuses of specified **gestational age** with deaths of liveborn infants who die in their first week of life. The determination of whether a fetus is born dead or whether it shows any sign of life before expiring is not always clear-cut; social, economic, and cultural factors, as well as medical and biological considerations, tend to push the fetal death rate in one direction or the other in different societies, thus making comparisons of neonatal or infant mortality among countries difficult. By using the perinatal mortality rate for comparisons, this difficulty is minimized since fetuses dying just before or during the birth process as well as those born alive but dying shortly thereafter are all included in the calculation [5]:

$$m_{\mathrm{peri}} = \left[\frac{d_{\mathrm{peri}}}{F + B} \right] k,$$

where m_{peri} is the perinatal mortality rate, d_{peri} is the number of deaths of fetuses of 22 or more weeks of gestation plus deaths of liveborn infants of less than 7 days of age during a specified period, usually a calendar year, F is the number of fetal deaths of 22 or more weeks of gestation during the same period, B is the number of live births during the same period, and, k is a constant, usually 1000.

Note that, unlike the infant and neonatal mortality rates, the denominator of the perinatal mortality rate combines both the number of live births and the number of fetal deaths of 22 or more weeks of gestation. This denominator is called "total births" and better approximates the population from which the numerator could arise than would a denominator restricted to only live births. On the other hand, it is recognized that it is easier to collect reliable counts of live births than of fetal deaths, thus introducing another source of error into the calculation of the perinatal mortality rate.

Maternal Mortality Rate

The **maternal mortality** rate is calculated as follows [5]:

$$m_{\mathrm{m}} = \left[\frac{d_{\mathrm{md}} + d_{\mathrm{mi}}}{B} \right] k,$$

where m_{m} is the maternal mortality rate, d_{md} is the number of direct maternal deaths in a specified time period, usually 1 year, d_{mi} is the number of indirect maternal deaths in the same period, B is the number of live births in the same period, and k is a constant, usually 10 000 or 100 000.

A related measure, the *direct obstetric mortality ratio*, may be calculated from the above formula

but using in the numerator only the direct maternal deaths, d_{md}.

Proportionate Mortality

Proportionate mortality, sometimes known as the death ratio (*see* **Proportional Mortality Ratio (PMR)**), is defined as [3]:

$$p_d = \left(\frac{d_i}{D}\right) k,$$

where p_d is the proportionate mortality, d_i is the number of deaths in a specified class during a stated time period, D is the total number of deaths in the same time period, and k is a constant, usually 100 or 1000.

Proportionate mortality ratios may be calculated for any class of deaths, but their most common uses are for given causes or group of causes of death expressed as percentages of deaths from all causes, or for deaths at a specified age expressed as percentages of deaths at all ages.

Crude Birth Rate

The crude birth rate is the most frequently used overall measure of the reproduction of a population. Like its counterpart, the crude death rate, it is influenced by many factors and represents a proxy for more specific fertility measurements. It is calculated as follows [3]:

$$m_{cb} = \left(\frac{B}{P}\right) k,$$

where m_{cb} is the crude birth rate, B is the total number of live births for a given area and time period, P is the total population at the midpoint of the time period, and, k is a constant, usually 1000.

Comparing Vital Statistics Data

Aggregated vital statistics data, whether in tabular or graphical form, often appear as time trends for particular variables such as causes or groups of causes of death, or for age and sex groups of the population. They also appear frequently as comparisons between countries or other geographical entities for a point in time, usually a particular year. In either case, great care must be taken to ensure that the quality of the data in the groups being compared warrants making the comparisons. In registration based systems, measures or estimates of completeness of reporting of vital events should be known. In sample based systems, the representativeness of the sample and the **nonresponse** rate is important. In the comparison of data between two or more geographic places, it is important to ascertain if common definitions and procedures were used to collect, process, analyze, and present the data; in looking at time trends, it is essential to know if the definitions of the events and the procedures for classifying the data remained constant over the entire time period being studied. This latter point is particularly important when looking at trends in causes of death since the instrument for grouping diseases into categories for study, the ICD, is revised approximately every 10 years (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**; **Mortality, International Comparisons**). Vital statistics data are often presented in statistical compendia published by official national and international organizations that attempt to include important notes for interpretation of the data in headnotes and footnotes to tables, appendices, etc. (*see* **Data Access, National and International**). The user is cautioned to pay careful attention to such explanatory or cautionary notes.

ROBERT A. ISRAEL

Wald, Abraham

Born: October 31, 1902, in Cluj, Rumania.
Died: December 13, 1950.

Abraham Wald emigrated to the US in 1938 and, in the period from 1938 till his death in a plane crash in 1950, he studied and revolutionized modern statistics. His most important contributions were in introducing **decision theory** and **sequential analysis**.

As the son of an orthodox Jew, he would not attend school on Saturday, the Jewish sabbath, and was not admitted to the local gymnasium (high school). He studied by himself with the help of an older brother, Martin, an electrical engineer, and was later admitted to the University of Cluj. After graduating, he spent a year in the engineering school at Vienna, and was finally admitted to the University of Vienna in the fall of 1927. After introducing himself to Karl Menger and expressing his interest in geometry, he spent some time serving in the Rumanian army instead of at the university.

In February 1930, Wald began to attend Menger's lectures and became part of an exciting group of young mathematicians taking part in an active mathematical colloquium. He received his Ph.D. in 1931. At this time of political and economic unrest, it was impossible to get a position at the university, and Menger recommended that he become involved with applied mathematics. Menger introduced Wald to Karl Schlesinger, a well-to-do banker and economist who wished to broaden his knowledge of higher mathematics. The association between Schlesinger and Wald led to publications on the existence of meaningful solutions for systems of equations of the theory of production, and on the cost of living index, and to contact with Oskar Morgenstern. Morgenstern was then director of the Institut für Konjunkturforschung, and later became a coauthor with von Neumann of their book on the theory of games [5]. He employed Wald at his institute and in the late 1930s Menger, Morgenstern, and Wald emigrated to the US.

Before emigrating, in the summer of 1938, to become a fellow of the Cowles Commission for Research in Economics at the University of Chicago, Wald also worked on a problem of the consistency of the von Mises concept of "Kollektiv", which lies at the heart of the von Mises axiomatization of probability.

In the fall of 1938, the Cowles Commission released Wald to accept a fellowship of the Carnegie Corporation, obtained for him by **Harold Hotelling** at Columbia University. Wald spent a busy year learning modern statistics by reading and attending Hotelling's lectures. At the same time, he started writing the publications on probability and statistics that are the foundation of his fame. The following year, he also began his career as an outstanding teacher of statistics at Columbia University. One of his earliest contributions in statistics, one considered by his frequent collaborator Jacob Wolfowitz to be his most important paper, was published in 1939, introducing decision theory [6].

On July 1, 1942, the Statistical Research Group (SRG) was formed to assist in the war effort. It was sponsored by Columbia University under the directorship of W. Allen Wallis. Shortly afterwards, another group was formed, the Statistical Research Group at Princeton, sponsored by Princeton University under the directorship of Samuel S. Wilks. In response to a question on sampling inspection raised by Captain Schuyler of the US Navy, Wallis and Milton Friedman proposed the use of sequential methods in sampling inspection. Failing to find a satisfactory resolution, they approached Wald in April 1943 [10]. At first, Wald was cool to the concept that seemed to violate a basic dogma of statistical **inference**, but the next day he changed his mind and produced the Sequential Probability Ratio Test, and derived some of its properties the day after that.

In 1941, Wald married Lucille Lang (who died with him in the plane crash, leaving two children, Betty and Robert born in 1943 and 1947). Columbia University recognized Wald's talent and quickly promoted him from Assistant Professor of Economics to Associate Professor and then to full Professor in 1944.

In 1946, Hotelling was recruited by **Gertrude Cox** to go to the University of North Carolina in support of her grand plan for the Institute of Statistics combining departments at the University and at North Carolina State. His departure led Columbia University to start a Statistics Department in the Faculty of Political Sciences with Wald as chair. The department had Wolfowitz and T.W. Anderson, Jr as regular appointees and, to supplement this small faculty, the department invited visitors to give courses. Among these visitors were **J. Neyman**, J.L. Doob, R.C. Bose, M.M. Loeve, E.J.G. Pitman,

and S.N. Roy. In the next few years, H. Scheffé and H. Levene were added to the regular faculty. In this postwar period, many relatively mature students, supported by the G.I. bill, returned to school, and the Statistics Department had a substantial collection of students who later became prominent in the field.

Much of the above text has been paraphrased from the more detailed articles by J. Wolfowitz, K. Menger, and G. Tintner, which were written in memorials for the *Annals of Mathematical Statistics* [3, 4, 12, 13].

The theoretical work of **R.A. Fisher**, suggested by applied problems, did much to accelerate the process of introducing mathematical considerations into theoretical statistics. The **Neyman–Pearson** theory helped to clarify many of the issues of inference that had hitherto been implicit, but never clearly articulated. These developments opened up a world of research for mathematical statisticians, the recognition of which led to the publication of the *Annals of Statistics* in 1930 and The Institute of Mathematical Statistics in 1933. When Wald arrived in the US, the number of talented mathematicians working in statistics was still quite small, but ready to explode. Hotelling had published a list of problems, the solution of which he felt would contribute much to the advancement of statistical theory. This was an environment well suited for talented mathematicians, and especially for those who had good statistical insights. Wald had the ability to know which problems were important, how to solve those that were tractable, and how to get good approximations for those that were not tractable.

The first paper on decision theory did not get an exceptionally good reaction, but one of his collaborators, Henry B. Mann, introduced it in a reading course in statistics in the summer of 1945 at Brown University. Wald returned to that subject in 1946. This formulation of the problem of statistical inference completed the work of Neyman and **Pearson**, by introducing cost considerations into hypothesis testing as well as in **estimation** and inference in general. It clearly points out one essential source of subjectivity in inference, since different investigators may very well have different cost functions. This formulation may be regarded as that of a game of the statistician against nature, with the difference that nature cannot be regarded as an active opponent. It has been suggested that this paper may have been influenced in part by a 1928 paper by von Neumann on game theory [11].

Although there was considerable resistance against this formulation, and, in particular, against Wald's tentative proposal of the **minimax** criterion, that resistance has died down, and it is difficult to deny the essential clarity it has contributed to the understanding of inference. The book on the subject [8] was not easy to read, since it dealt with some of the mathematical difficulties in deriving general results in this field.

Sequential analysis was immediately accepted by theoreticians. The initial results applied to the test of a simple hypothesis against a simple alternative (*see* **Hypothesis Testing**). Wald proved that the sequential probability ratio test (SPRT) would terminate with probability one and that the error probabilities and expected sample size under both hypotheses could be approximated very accurately. In typical applications, he obtained effective savings of about 50% in the sample size required to achieve given error probabilities. (In theory, for problems involving nearby alternatives and small error probabilities, this saving approaches 75%.) Wald conjectured that the SPRT was optimal, but was unable to prove that until his paper with Wolfowitz in 1948 [9] established a unique optimal property. The SPRT minimizes the expected sample sizes for the two hypotheses among all tests that achieve a given pair of error probabilities or better. The proof in this paper had some measure-theoretic difficulties that were resolved in a later paper by Arrow et al. [2], which was a foundation paper for dynamic programing. But the essential idea of relating the SPRT to the solution of a Bayes problem appeared in the Wald–Wolfowitz paper. In fact, the original derivation of the SPRT was based on a Bayesian approach, but Wallis convinced Wald to omit this from his publications, since the published results at that time did not require prior probabilities. Wald often used Bayesian arguments as part of his analysis to derive frequentist results. At the time, **Bayesian methods** were generally regarded as unacceptable.

While the main results were for testing a simple hypothesis vs. a simple alternative, Wald extended the method for testing composite hypotheses by introducing the notion of an indifference region. As with many of his approximations, this device worked remarkably well for the typical problems dealt with by most experimenters. However, it failed to address

the real problem in a satisfactory fashion designed to derive optimal results. Wald published a remarkably clear and simple presentation of his main results in a book [7], with an elegant appendix with more mathematical detail, in 1947, before the derivation of the optimality result.

While sequential analysis was an important tool in military applications where each observation was extremely costly, and the need to reduce sample size important, it tended to be neglected in applied work until recently when it began to be used more often in **clinical trials**. In much engineering work a major cost of experimentation is the setup cost, and it is relatively inconvenient to sample and observe the results one at a time. In the early post-World War II days, the computational complexity, more apparent than real, inhibited its use. A foundational problem also played a role here. When a sequential test with significance level 0.05 leads to rejection, it is possible that the investigator, acting as though the random sample size had been selected in advance, will calculate the ***P* value** and find a value quite different than 0.05 in either direction. With a fixed sample size, rejection would always lead to a smaller P value. The naive investigator would have difficulty in interpreting the data. The sophisticated investigator with Bayesian leanings would reject the concept that the interpretation should depend on the rule that was used to decide when sampling should be stopped.

Although we have concentrated on Wald's most important contributions to the statistical literature, his publications covered an enormous range of problems of importance where his mathematical skills and his statistical insights were effective. These included contributions to asymptotic theory, econometrics, theory of **nonparametric methods, analysis of variance, experimental design, multivariate analysis**, and the exploitation of the theorem of Lyapounov on the range of a vector measure. The following is a very brief description of some of these papers.

In asymptotic theory, Wald characterized asymptotically optimal procedures, presented a clarifying proof of the consistency (*see* **Consistent Estimator**) of **maximum likelihood** estimates, treated problems where the number of parameters approached infinity, and described a calculus of stochastic limit and order relations (*see* **Order Statistics**). In econometrics he dealt with the identification problem and presented one of the earliest effective attacks on the estimation of a linear relationship when observations on both variables are subject to error (*see* **Regression**). Exploiting the Lyapounov theorem with Wolfowitz and Dvoretzky, together they showed that in problems involving continuous distributions, inference did not require **randomization** to achieve specified significance levels. Moreover, the **sufficiency** conditions of Neyman–Pearson theory were also necessary. At SRG, he was responsible for revolutionizing the Air Force view of vulnerability with a report that exploited his insight that the places where returning planes did not have bullet holes were the ones that needed reinforcement.

Wald collaborated with several statisticians. His most frequent collaborator was J. Wolfowitz. Several interesting papers were written with H.B. Mann and, as indicated above, Dvoretzky and Wolfowitz worked with Wald on the consequences of the Lyapounov theorem. He also wrote with C. Stein and M. Sobel. As one of his students, Chernoff developed his asymptotic approach to the Fisher–Behrens problem in his thesis.

I wish to thank Professor T.W. Anderson for information about Wald's life [1] and for helpful comments on a previous draft of this biography.

Wald's Identity

Wald [1, 2] discovered a remarkable identity which can solve approximately, or sometimes exactly, a number of boundary problems on random walk in one dimension with discrete time steps (*see* **Stochastic Processes**). Let $X_1, X_2, \ldots$ denote a sequence of independent and identically distributed **random variables**. Assume that $M(t) = \mathrm{E}[\exp(tX_1)]$, the **moment generating function** of the sequence $\{X_n\}$, exists for all real values t in some interval. Consider the restricted random walk problem such that the walk ends as soon as the sum

$$S_n = X_1 + \cdots + X_n$$

satisfies the condition that $S_n \geq a$ or $S_n \leq -b$, for some finite constants $a > 0$ and $b > 0$. Let $N = n$ be the first integer for which $S_n \geq a$ or $S_n \leq -b$. Then Wald shows that

$$\mathrm{E}[M(t)^{-N} \exp(tS_N)] = 1 \tag{1}$$

for every real or complex value of t for which $1 \leq |M(t)| < \infty$.

Differentiating (1) once and letting $t = 0$, we get the useful Wald equation.

Wald's Equation

Let $X_1, X_2, \ldots$ be independent and identically distributed random variables having finite expectations. Assume that the integer-valued random variable N is a *stopping time* for the sequence $X_1, X_2, \ldots$ (i.e. the event $\{N = n\}$ is independent of $X_{n+1}, X_{n+2}, \ldots$ for all $n = 1, 2, \ldots$) such that $\mathrm{E}[N] < \infty$; then

$$\mathrm{E}[S_N] = \mathrm{E}[N]\mathrm{E}[X_1]. \tag{2}$$

Differentiating (1) twice and letting $t = 0$, we get another useful equation:

$$\mathrm{E}[(S_N)^2] = \mathrm{E}[N]\mathrm{E}[X_1^2]. \tag{3}$$

Wavelet Analysis

Wavelet analysis is an approach to signal representation that has grown in popularity by virtue of its ability to overcome some of the limitations of Fourier series approximation (*see* **Time Series**; **Fast Fourier Transform (FFT)**). Whereas Fourier analysis provides a stationary approximation of a signal in terms of its frequency components but lacks the ability to capture the local features of a signal, wavelet analysis does not suffer from this drawback. It is thus used extensively to capture transient behavior in signals. The technique derives its name from the characteristic shape of the analytic functions that replace the sines and cosines used in Fourier analysis.

Like sines and cosines, wavelet functions also show oscillatory behavior about zero, but unlike sines and cosines, they decay to zero, a property underpinning their ability to detect local features in a signal (see Figure 1). The so-called "father" wavelets integrate to a value of 1, and represent the smooth low frequencies well. In contrast, "mother" wavelets integrate to a value of zero and represent the detail and high-frequency features well. There are many different types of wavelet functions, with properties that lend themselves to different approaches to wavelet analysis and the detection of different features of signals [4]. The first few wavelet coefficients contain information about the overall shape of the time series, whilst the higher-order coefficients describe localized trends.

Fundamentally, wavelet analysis involves decomposition of a signal by computation of its inner products, with analysis functions formed by dilation and translation of a prototypical wavelet. The value of a wavelet coefficient (magnitude of the inner product) will be maximal when the shape and position of a particular feature in the image match those of the chosen wavelet (hence the choice of different wavelets for the analysis of different types of signals).

Using Unser's notation [4], the so-called *continuous* wavelet transformation can be represented as

$$(W_\varphi f)(a,b) = (f, \varphi_{(a,b)})$$

$$\varphi_{(a,b)} = a^{-1/2}\varphi\left(\frac{x-b}{a}\right), \qquad (1)$$

where $\varphi_{(a,b)}$ is a set of analysis functions derived by applying scalings and translations to a wavelet. The scalings, a, capture the properties of the signal at different resolutions (analogous to the frequency representation in a Fourier series), and the translations, b, capture local behavior.

The continuous wavelet transform maps a function of a single independent variable (e.g. time) to a function of two independent variables (scale and position in the time series) and is thus redundant and computationally inefficient. This problem can be overcome by sampling the transform on a discrete grid in the scale/position plane, leading to the discrete wavelet transform (DWT). With a suitable choice of wavelet (e.g. the orthogonal wavelet set described by Daubechies [1]) and the so-called pyramidal decomposition scheme described by Mallat [3], a rapid, invertible DWT can easily be accomplished.

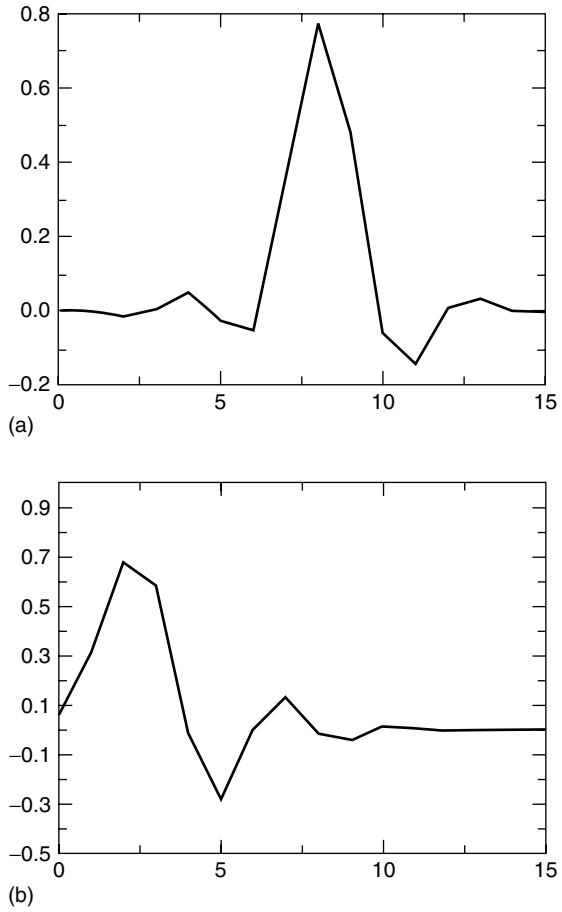

Figure 1 (a) 16 coefficient Symmlet wavelet (b) 16 coefficient Daubechies wavelet

Wavelet analysis/transformation has been extensively used in data compression, where a signal can often be represented by a number of wavelet coefficients equal to only a small fraction of the number of data points in the original data set. It has also been used for signal denoising. Donoho and his colleagues [2] have worked extensively in this area and have pioneered the technique of wavelet shrinkage. This technique involves an initial DWT, followed by computation of a threshold value for wavelet coefficients, rejection of coefficients below this threshold, and inversion of the DWT, using the modified coefficient set. Another important aspect of the DWT is its so-called decorrelating property. Thus, strong **correlations** existing in the temporal or spatial domain are often much less evident following DWT, a property that has begun to be exploited in statistical analysis.

M.J. BRAMMER

Weibull Distribution

A commonly used model for survival data is the two-parameter Weibull model with hazard rate $h(t) = \lambda\alpha t^{\alpha-1}, \alpha > 0, \lambda > 0$. This is a flexible model that has an increasing hazard rate when $\alpha > 1$, a decreasing hazard rate when $\alpha < 1$, and a constant hazard rate when $\alpha = 1$ (*see* **Exponential Distribution**). Its survival function is $S(t) = \exp(-\lambda t^{\alpha})$ and the density function $f(t) = \lambda\alpha t^{\alpha-1}\exp(-\lambda t^{\alpha})$.

The cumulative hazard rate of the Weibull is $H(t) = \lambda t^{\alpha}$, so that $\ln[H(t)] = \ln\lambda + \alpha \ln t$. This characterization can be used to assess whether the Weibull model fits data by plotting an empirical estimate of the cumulative hazard rate on a log–log scale. Such a plot should be linear if the model holds.

The rth moment of the Weibull distribution is $[\Gamma(1 + r/\alpha)]\lambda^{-r/\alpha}$. The mean and variance are $[\Gamma(1+ 1/\alpha)]\lambda^{-1/\alpha}$ and $\{\Gamma(1 + 2/\alpha) - [\Gamma(1 + 1/\alpha)]^2\}\lambda^{-2/\alpha}$, respectively, where $\Gamma(\alpha)$ is the **gamma** function. The pth **quantile** of the Weibull distribution is $x_p = \{-[\ln(1 - p)]/\lambda\}^{1/\alpha}$.

The Weibull distribution arises as a limiting distribution of the minimum of n independent random variables. If $X_1, \ldots, X_n$ are a random sample from a population with a survival function which, for t close to 0, is of the form $S(t) = 1 - \lambda t^{\alpha} + o(t^{\alpha})$, then the limiting distribution of $T_n = n^{1/\alpha}\min(X_i, \ldots, X_n)$ is Weibull with shape parameter α and scale parameter λ.

The Weibull distribution arises from a **multistage model** of carcinogenesis. In this model, cancer in a cell occurs if r different mutations in the cell occur. Suppose that θ_j is the mutation rate at the jth locus per unit time and that the probability that a mutation at the jth locus occurs in a cell prior to time t is approximately equal to $\theta_j t$, a small number. For each cell the probability that the required r mutations occur prior to time t is $(\prod_{j=1}^{r}\theta_j)t^r$. The average number of clones that develop from mutated cells up to time t is $\mu = c(\prod_{j=1}^{r}\theta_j)t^r = \lambda t^r$, where c is the number of cells at risk of mutation. If the number of clones at time t has an approximate **Poisson distribution** with mean μ, then the waiting time to first occurrence of disease follows a Weibull distribution with shape parameter r and scale parameter λ [1].

The Weibull distribution is related to the **extreme-value** distribution. If we let $Y = \ln T$, then Y has an extreme-value distribution with density function

$$\alpha\exp\left(\alpha\left[y - \left(\frac{-\ln\lambda}{\alpha}\right)\right] - \exp\left\{\alpha\left[y - \left(\frac{-\ln\lambda}{\alpha}\right)\right]\right\}\right), \quad -\infty < y < \infty.$$

If we let $\mu = -\ln\lambda/\alpha$ and $\sigma = \alpha^{-1}$, then $Y = \mu + \sigma E$, where E has the standard extreme-value distribution.

Estimation in the Weibull model based on independent, possibly right-**censored** survival times $X_1, \ldots, X_n$ is usually based on **maximum likelihood**. The estimator $(\hat{\alpha}, \hat{\lambda})$ is not given in a closed-form expression, but many of the standard software packages may be used for the estimation.

Two popular models that are used to adjust the survival function for covariates are the **proportional hazards model** (the **Cox regression model**) and the **accelerated failure-time model**. For the proportional hazards model, the conditional hazard rate of T, given a set of covariates $\mathbf{Z}$, is of the form

$$h(t|\mathbf{Z}) = h_0(t)\exp(\boldsymbol{\beta}'\mathbf{Z}),$$

while, for the accelerated failure-time model,

$$h(t|\mathbf{Z}) = h_0[t\exp(-\boldsymbol{\beta}'\mathbf{Z})]\exp(-\boldsymbol{\beta}'\mathbf{Z}),$$

where $\boldsymbol{\beta}$ is a vector of unknown parameters. The Weibull regression model is the only model which admits both an accelerated failure-time model and a proportional hazards model representation.

Weighted Distributions

Traditional statistical theory and practice have been occupied largely with statistics involving **randomization** and replication (*see* **Experimental Design**). However, in biomedical and public health work, observations also fall in the nonexperimental, nonreplicated, and nonrandom categories (*see* **Observational Study**). The problems of model specification and data interpretation acquire special importance and great concern (*see* **Misspecification**). The theory of weighted distributions provides a perceptive and unifying approach for the problems of model specification and data interpretation. Weighted distributions take into account the observer–observed interface, i.e. the method of **ascertainment**, by adjusting the probabilities of actual occurrence of events to arrive at a specification of the probabilities of those events as observed and recorded. Failure to make such adjustments can lead to wrong conclusions.

The concept of weighted distributions can be traced to the study of the effect of methods of ascertainment upon estimation of frequencies by Fisher [5]. In extending the basic ideas of Fisher, Rao [16, 17] saw the need for a unifying concept, and identified various sampling situations that can be modeled by what he called weighted distributions. Within the biomedical context of cell kinetics and the early detection of disease, Zelen [23] introduced weighted distributions to represent what he broadly perceived as **length-biased** sampling introduced earlier by Cox [1]. In a series of papers with his co-workers, Patil has pursued weighted distributions in theory and practice for purposes of encountered data analysis, equilibrium population analysis subject to harvesting and predation, **meta-analysis** incorporating publication bias and heterogeneity, modeling clumping and extraneous variation, etc. See, for example, [2, 7–13, 15], and [20], and for more references, see [14].

To introduce the concept of a weighted distribution, suppose X is a nonnegative observable **random variable** (rv) with its natural probability density function (pdf) $f(x;\theta)$, where the natural parameter $\theta \in \Omega$, the parameter space. Suppose a realization x of X under $f(x;\theta)$ enters the investigator's record with probability proportional to $w(x,\beta)$, so that

$$\frac{\Pr(\text{recording}|X=y)}{\Pr(\text{recording}|X=x)} = \frac{w(y,\beta)}{w(x,\beta)}.$$

Here, the recording (weight) function $w(x,\beta)$ is a nonnegative function with parameter β representing the recording (sighting) mechanism. Clearly, the recorded x is not an observation on X, but on the rv X^w, say, having pdf

$$f^w(x;\theta,\beta) = \frac{w(x,\beta)f(x;\theta)}{\omega},$$

where ω is the normalizing factor obtained to make the total probability equal to unity by choosing $\omega = \mathrm{E}[w(X,\beta)]$. The rv X^w is called the weighted version of X, and its distribution in relation to that of X is called the weighted distribution with weight function w. Note that the weight function $w(x,\beta)$ need not lie between zero and one, and actually may exceed unity, as, for example, when $w(x,\beta) = x$, in which case, $X^* = X^w$ is called the size-biased version of X. The distribution of X^* is called the size-biased distribution with pdf

$$f^*(x;\theta) = \frac{xf(x;\theta)}{\mu},$$

where $\mu = \mathrm{E}[X]$. The pdf f^* is called the length-biased or size-biased version of f, and the corresponding observational mechanism is called length- or size-biased sampling. The concept of weighted distributions has been much used recently as a useful tool in the selection of appropriate models for observed data, especially when samples are drawn without a proper frame. In many situations, the model given above is appropriate, and the statistical problems that arise are the determination of a suitable weight function $w(x,\beta)$ and drawing inference on θ. Appropriate statistical modeling approaches help accomplish unbiased inference in spite of the biased data and, at times, even provide a more informative and economic setup (see [13]).

The following examples may help illustrate a few situations generating weighted distributions and their applications.

Example 1: Analysis of Family Data, $w(x,\beta) = w(x) = x$

Various **demographic** studies involve family size and sex ratio as important factors which have some

Table 1 Analysis of family data

Family size	1	2	3	4	5	6	7	8	9	10	11	12	13	15	Total
No. of families	1	6	6	13	12	7	14	11	12	8	6	5	2	1	104
Brothers	1	8	12	34	34	29	59	50	54	46	32	31	16	8	414
Sisters	0	4	6	18	26	13	39	38	54	34	34	29	10	7	312

bearing on the main study. This example shows how a weighted distribution arises as a result of size-biased sampling.

Consider the data in Table 1 relating to brothers and sisters in families of 104 boys admitted to a postgraduate course. Assume that in families of given size n, the probability of a family with x boys coming into the record is proportional to x. Also, suppose that the number of boys follows a **binomial distribution** with probability parameter π. Then

$$f(x;\pi) = \binom{n}{x} \pi^x (1-\pi)^{n-x},$$

$$w(x) = x, \omega = n\pi,$$

$$f^w(x;\pi) = \binom{n-1}{x-1} \pi^{x-1} (1-\pi)^{n-x},$$

$$\mathrm{E}\left[\frac{X^w}{n}\right] = \pi + \frac{1-\pi}{n} > \pi, \quad \text{and}$$

$$\mathrm{E}\left[\frac{X^w - 1}{n-1}\right] = \pi.$$

If k boys representing families of size $n_1, n_2, \ldots, n_k$ report $x_1, x_2, \ldots, x_k$ boys, an unbiased estimate of π is

$$\tilde{\pi} = \frac{\sum x_i - k}{\sum n_i - k} = \frac{414 - 104}{726 - 104} \doteq \frac{1}{2}$$

(see [14] and [19]).

Example 2: Analysis of Intervention Data, $w(x, \beta) = w(x) = x$

The expected value of the duration to the completion of a random event sampled randomly at the end of its duration turns out to be approximately equal to the expected duration to its random intervention. This can be explained using the concept of size-biased/length-biased sampling with weight function $w(x, \beta) = w(x) = x$, where x represents the duration of the random event. The applications in medical and public health sciences include: (i) **cell cycle** analysis and pulse labeling [23]; (ii) efficacy of early **screening** for disease and scheduling of examinations [23]; and (iii) cardiac **transplantation** [22]. Simon [18] uses length-biased sampling in etiologic studies for estimation of antigen frequencies to compare patients with the antigen that are more likely to be alive and included in the study than patients without the antigen.

Example 3: Analysis with Damaged Observations, $w(x, \beta) = \beta^x$

Consider a damage model where an observation $X = x$ is reduced to y by a destructive process with pdf $d(y|x)$. Then the probability that the observation $X = x$ is undamaged is $d(x|x)$, and the distribution of the undamaged observation is the weighted distribution with $w(x) = d(x|x)$. For example, under the binomial survival model, $d(x|x) = \theta^x, 0 < \theta < 1$. An investigator recording only undamaged observations will need to work with a corresponding weighted distribution.

Example 4: Modeling Clumped Sampling, Heterogeneity, and Extraneous Variation, $w(x, \beta) = w(x, \beta, \theta)$

During their examination of the problem of toxoplasmosis, Diaconis & Efron [3, 4] looked at the data sets coming from different cities with different rainfall and found that there was more dispersion in the data sets than the existing models could accommodate (*see* **Overdispersion**), and therefore they introduced a model called the double exponential family (DEF). This family enjoys the **exponential family** properties simultaneously for the mean and the dispersion parameters. It allows the data analyst to model overdispersion while carrying out the usual regression analyses for the mean as a function of the predictors. The overdispersion may be due to one or more possible causes, such as clumped sampling (*see* **Clustering**), heterogeneity, **selection bias**, etc.

Interestingly, the DEF can be seen as a weighted distribution (see [9] and [13]). The weight function turns out to have the following interesting form:

$$w(x, \beta) = w(x, \beta, \theta) = \exp(1 - \beta) I[x, \mu(\theta)],$$

where $I(x, \mu)$ is the **Kullback–Leibler** distance function between x and $\mu(\theta) = \mu = \mathrm{E}(X)$ of the usual exponential family density function f with parameter θ. Kullback–Leibler distance increases with the distance from the mean μ, thus allowing a more distant observation larger weight and accommodating extra dispersion in the data set when $1 - \beta > 0$.

Example 5: Meta-analysis Incorporating Heterogeneity and Publication Bias

Meta-analysis consists of quantitative methods for combining evidence from different studies about a particular issue. Its objective is to summarize quantitatively a research literature with respect to a particular question and to examine systematically the manner in which a collection of studies contributes to knowledge about that question.

The weight function enters the analysis to represent the publication/selection bias and the heterogeneity among different studies. It also helps model the overdispersion/underdispersion in the data caused by publication bias and the inherent heterogeneity.

The weight functions examined include a:

1. Critical value model: $w(x) = (x/x_{\mathrm{crit}})^{\beta}$ if $|x| < x_{\mathrm{crit}}$, and $= 1$, otherwise,
2. half-normal model: $w(x) = \exp[-\beta p(x)^2]$, and
3. negative exponential model: $w(x) = \exp[-\beta p(x)]$.

Here $p(x)$ is the ***P*** **value** when the test statistic takes value x, and x_{crit} stands for the critical value under the test statistic (see [6, 7], and [13]).

Example 6: Statistical Analysis Incorporating Overdispersion and Heterogeneity in Teratologic Binary Data in Developmental Toxicity Studies

The problem of overdispersion and heterogeneity in binary data arises quite naturally in developmental toxicity studies. Since a pregnant female is exposed to the chemical dose, litter becomes the primary unit. The random effect of the litter, i.e. the biological response of the mother to the chemical dose, affects the toxic responses of the fetuses. This potential random litter effect causes heterogeneity, extravariation, and also intralitter correlation between the responses of two fetuses within the litter.

To incorporate this random litter effect in the analysis of such binary data, research workers have introduced the **beta-binomial** model. The beta-binomial model, regarded as the binomial mixture model, takes care of overdispersion, heterogeneity, and also the clumping of observations within the litter. This clumping of observations occurs because of the tendency of the fetuses within the litter to "behave" alike. For this reason, the use of the double binomial family model seems in place as an alternative model in the analysis of developmental toxicity data.

The beta-binomial model provides an estimate of the index of overdispersion and also an estimate of intralitter **correlation** coefficient, while the double-binomial model provides an estimate of the overdispersion parameter.

The problem of analysis of overdispersed binary data coming from different litters at a given dose or coming from different cities with given rainfall can also be looked upon as the problem of encounter data where one is trying to combine the observational data coming from different sources. Therefore, one can look upon both the beta-binomial and the double-binomial as weighted binomial distributions where each model has its own separate weight function.

The two distributions are quite comparable in their capability for describing overdispersed binary data. It appears that the choice between them may be made on such grounds as parameter interpretation and inferential convenience (see [15] and [21].

Wigner–Ville Distribution

The Wigner–Ville distribution is a time–frequency distribution developed for the analysis of time-varying spectra [1]. Indeed, the interpretation of classic Fourier analysis (*see* **Fast Fourier Transform (FFT)**), which decomposes the power of a signal into frequency components by quantifying the power spectrum, may became problematic when the frequency content changes over time. In fact, the power spectrum cannot indicate when specific spectral components occur or how they change in intensity and frequency. Thus, when the signal is characterized by a time-varying spectrum, it is preferable to decompose the signal power by a joint function of time and frequency. The Wigner–Ville distribution $W(t, f)$ quantifies the fraction of the power in a certain frequency band during a certain time range, representing the "instantaneous" spectrum of a nonstationary signal $s(t)$. It is defined by

$$W(t, f) = \frac{1}{2} \int s^* \left(t - \frac{1}{2}\tau \right) \times s \left(t + \frac{1}{2}\tau \right) \mathrm{e}^{-j2\pi f \tau} \, \mathrm{d}\tau, \qquad (1)$$

where $s^*(t)$ is the complex conjugate of $s(t)$.

$W(t, f)$ satisfies the marginal conditions, which means that the integral of the distribution over the frequency f at a certain time t gives the instantaneous energy of the signal, $|s(t)|^2$, and the integral over the time t at each frequency f gives the energy spectrum $E(f)$ (the power spectrum is the energy spectrum per unit of time). Thus, $W(t, f)$ satisfies the intuitive idea of a time-varying spectrum of $s(t)$, and the product $W(t, f)\,\mathrm{d}t\,\mathrm{d}f$ can be interpreted as the fraction of the $s(t)$ energy at time t and frequency f in the $(\mathrm{d}t \times \mathrm{d}f)$ cell.

The formulation of the Wigner–Ville distribution for a discrete time signal $s(n)$ is

$$W(n, \omega) = \frac{1}{\pi} \sum_{k=-\infty}^{+\infty} s^*(n-k) s(n+k) \mathrm{e}^{-j2\omega k} \qquad (2)$$

A negative characteristic of the Wigner–Ville distribution is the presence of important *interference terms*. In fact, when $s(t)$ is a multicomponent signal (e.g. the sum of sinusoids occurring at different frequencies and/or in different time ranges), the $W(t, f)$ distribution may be not zero during time periods when the signal is not expected or in frequency bands where spectral components are not expected. Moreover, interference terms may also produce negative $W(t, f)$ values, which cannot be considered energy components of $s(t)$. These undesired components have no physical meanings but can be in part suppressed by smoothing $W(t, f)$. However, a smoothed $W(t, f)$ has a lower resolution in time and frequency and might not satisfy the marginal conditions. A popular smoothed $W(t, f)$ is the smoothed pseudo-Wigner–Ville, $PSW(t, f)$, proposed in [2]:

$$PSW(t, f) = \int \left| h\left(\frac{\tau}{2}\right) \right|^2 \int g(u-t) s^* \times \left(u - \frac{1}{2}\tau \right) s \left(u + \frac{1}{2}\tau \right) \mathrm{d}u \times \mathrm{e}^{-j2\pi f \tau} \, \mathrm{d}\tau \qquad (3)$$

The $h()$ window provides frequency smoothing and $g()$ suppresses interference terms. The Wigner–Ville distribution has been successfully implemented to detect changes in the structure of several biological signals, like nonstationary cardiovascular signals, ultrasonic Doppler signals, auditory neuron activity, and acoustic signals [3] (*see* **Clinical Signals**).

Wilcoxon Signed-rank Test

The Wilcoxon signed-rank test, due to Wilcoxon [9], is a nonparametric test procedure (*see* **Nonparametric Methods**) used for the analysis of matched-pair data or for the one-sample problem. In the matched-pair setting it is used to test the hypothesis that the probability distribution of the first sample is equal to the probability distribution of the second sample (*see* **Hypothesis Testing**). This hypothesis can be tested from statistics calculated on the intrapair differences. The hypothesis commonly tested is that these differences come from a distribution centered at zero.

Consider the following example. A study was conducted in which nine people of varying weights were put on a particular exercise regimen to determine the program's effect on the resting heart rate of the subjects. Given that a low resting heart rate is beneficial in reducing blood pressure and increasing overall cardiovascular fitness, this exercise regimen was developed to help people lower their resting heart rate. To test the effectiveness of the regimen, the resting heart rate measurement for each subject was taken before the induction of the regimen, and at six months after beginning the regimen. Table 1 presents the data from this study.

Because this study involves before and after measurements of the same individuals, an independent sample test procedure cannot be executed. The **null hypothesis** in the Wilcoxon signed-rank test is that the set of pairwise differences have a probability distribution centered at zero. A key assumption is that the differences arise from a continuous, symmetric distribution. In the example, the null hypothesis would be that there is no resting heart rate difference before and after the exercise regimen ($H_0 : \mu_d = 0$). In this instance, μ_d represents the location parameter for the distribution of differences. One **alternative hypothesis** is that the resting heart rate before the exercise regimen is higher than the resting heart rate after the exercise regimen ($H_1 : \mu_d > 0$).

To execute the test, the absolute values of the differences, $|d_i|$, are computed. These values also are given in Table 1. After computing the absolute values, one must order them from smallest to largest disregarding any zeros (*see* **Ranks**). In the case of absolute differences being tied for the same ranks, the mean rank (mid-rank) is calculated and assigned to each tied value. The rankings for the absolute differences are also given in Table 1. Test statistics for the Wilcoxon signed-rank test are calculated by either summing the ranks assigned to the positive differences (T_+) or by summing the ranks assigned to the negative differences (T_-). If there are n differences, then the two sums are related through

$$T_- = \left\{\frac{[n(n+1)]}{2}\right\} - T_+. \tag{1}$$

In the example, the sum of the ranks of the positive differences is

$$T_+ = 5 + 3 + 9 + 7 + 4 + 6 + 8 = 42.$$

Note that $\{[n(n+1)]/2\} = 45$ so

$$T_- = 45 - 42 = 3.$$

To test the null hypothesis, a rejection region can be determined for the test statistic, T_+. This rejection region can be determined from the exact null hypothesis distribution of T_+. This null distribution is easily derived from a permutational argument, as each of the possible configuration of signs (+ or −) is equally likely under the null hypothesis. Tables of this exact null distribution are available in standard nonparametric texts such as [3, 4], or [7]. This null distribution depends only on n, hence the test procedure is nonparametric, i.e. distribution-free.

For **large samples** the standard normal distribution Z, can be used as an approximation to test hypotheses. For this situation a two-tailed rejection region for the null hypothesis based on T_+, is given:

$$Z_+ = \frac{\left\{\frac{[T_+ - n(n+1)]}{4}\right\}}{\left\{\frac{[n(n+1)(2n+1)]}{24}\right\}^{1/2}} > Z_{1-\alpha/2} \tag{2}$$

or

$$Z_- = \frac{\left\{\frac{[T_- - n(n+1)]}{4}\right\}}{\left\{\frac{[n(n+1)(2n+1)]}{24}\right\}^{1/2}} > Z_{1-\alpha/2}. \tag{3}$$

A one-tailed test is conducted in a similar fashion with the comparison made to $Z_{1-\alpha}$.

Table 1 Resting heart rate of nine people before and after initiation of an exercise regimen

Subject	Heart rate at baseline (y_i)	Heart rate at 6 months (x_i)	Difference $d_i = y_i - x_i$	Absolute value of difference $\lvert d_i \rvert$	Rank of absolute difference (sign)
1	80	72	+8	8	5(+)
2	76	70	+6	6	3(+)
3	78	82	−4	4	2(−)
4	90	76	+14	14	9(+)
5	84	86	−2	2	1(−)
6	86	76	+10	10	7(+)
7	81	74	+7	7	4(+)
8	84	75	+9	9	6(+)
9	88	76	+12	12	8(+)

Other issues regarding the Wilcoxon signed-rank test include its testing efficiency and the construction of estimators. The **asymptotic relative efficiency** (ARE) of this test relative to the **paired *t* test** is never less than 0.864 in the entire class of continuous symmetric distributions, and is 0.955 if the underlying distribution of differences is normal, see [2]. The handling of ties and zeros is discussed by Pratt [5] and Cureton [1]. Point and **confidence interval** estimators are easily derived from the test procedure, and details are described in Lehmann [4]. Lehmann [4] also describes power properties for the test procedure when shift alternatives are of interest. Extensions to **censored data** are discussed by Woolson & Lachenbruch [10] and Schemper [8]. References for other aspects of the Wilcoxon signed-rank test are given by Randles & Wolfe [7] and Randles [6].

R.F. WOOLSON

Wilcoxon, Frank

Born: September 2, 1892, in County Cork, Ireland.
Died: November 18, 1965, in Tallahassee, Florida.

Photograph supplied by the Department of Statistics, at Florida State University

Frank Wilcoxon is best known in statistics for his fundamental work on ranking methods (*see* **Nonparametric Methods**; **Ranks**), but he was also an excellent chemist and made research contributions to physical chemistry, biochemistry, plant pathology, and entomology. Also, Frank Wilcoxon was an outstanding human being, with an enthusiasm for understanding the world and communicating his excitement to all around him.

Wilcoxon was born in Glengarriffe Castle near Cork, Ireland, of wealthy American parents. He was raised in Catskill, New York, and developed a lasting love for nature there. In his early years, he had varied experiences as a merchant sailor, pumper of gas, and tree surgeon before receiving his B.S. degree from Pennsylvania Military College in 1917. After World War I, Wilcoxon received an M.S. degree in chemistry from Rutgers University in 1921 and a Ph.D. degree in physical chemistry from Cornell University in 1924. At Cornell, Frank met Frederica Facius, an undergraduate, and they were married in 1926. Frank and Freddie were long-time attendees at the Gordon Research Conferences on Statistics and Chemistry and Chemical Engineering, and became well known and loved in the statistical community.

From 1924 to 1950, Frank Wilcoxon did research related to chemistry, first at the Boyce Thompson Institute for Plant Research in Yonkers, New York, and later at the Nichols Copper Company in Queens, Long Island and the Ravenna Ordance Plant operated by the Atlas Power Company. He worked at the American Cyanamid Company beginning in 1943 and continued until his retirement in 1957, first with the Stamford Research Laboratories as head of a group developing insecticides and fungicides and later as head of the statistics group of the Lederle Division in Pearl River, New York. Subsequent to his retirement from American Cyanamid, he served as a consultant to various organizations until 1960, when he joined the faculty of the newly formed Department of Statistics at Florida State University in Tallahassee. He remained active in research and teaching and contributed to the development of the Department until his death in 1965. Florida State University honored Wilcoxon by designating the statistics library and reading room as the Frank Wilcoxon Memorial Room.

Wilcoxon's interest in statistics began in 1925 with a study of **R.A. Fisher's** book, then newly published, *Statistical Methods for Research Workers* [6]. This study was done in a small reading group, of which W.J. Youden was a member and **C.I. Bliss** was a visitor. Wilcoxon's first publication in a statistics journal was on the usage of statistics in plant pathology [8], and in the same year he published his most significant contributions to statistics, the two-sample rank sum statistic and the one-sample signed rank statistic, both proposed in a very brief paper [9]. These statistics are well known as the Wilcoxon two-sample rank-sum test (*see* **Wilcoxon–Mann–Whitney Test**) and the **Wilcoxon signed-rank test**, and inspired much subsequent research on ranking methods, in addition to having a major impact on applied statistics, especially for applications in the **social sciences**.

In collaboration with Bradley and other colleagues, Wilcoxon extended the basic rank procedures to sequential testing situations [2, 3, 11, 12], including **screening**-type experiments. Wilcoxon was also interested in **multiple comparisons** problems, and the 1964 revision of the booklet, *Some Rapid Approximate Statistical Procedures* [10], gives multiple comparison procedures based on the rank-sum test for one- and two-way designs. This booklet was

widely circulated and played a significant role in the widespread use of nonparametric multiple comparison procedures.

In collaboration with Cuthbert Daniel, Wilcoxon devised **factorial experimental** designs that would be **robust** against certain linear and quadratic trends. From their paper, "The basic idea, due to Frank Wilcoxon, is that certain of the ordered contrasts appearing in the 2^{p-q} system are orthogonal to linear and quadratic trends." [4].

Wilcoxon made contributions to chemistry and biochemistry with about 40 publications. His publications spanned varied areas: acidimetry and alkalimetry; the mode of action of sulphur and copper fungicides; a mercury reduction method for the determination of pyrethrin I; synthesis of a number of plant growth substances; and research leading to the development of the insecticides Parathion and Malathion.

Although Wilcoxon was not an academician for most of his career, he was a teacher and student throughout life. He communicated his enthusiasm for statistics to students at Florida State University and was always available to talk about problems. He had wide interests including being an accomplished musician, a student of languages, and was fascinated by mathematical games, puzzles, combinatorics, and other pursuits. Through middle-age, he and his wife often traveled by bicycle, and he did not own an automobile until late in life. At Florida State University, he regularly rode a motorcycle to work.

Wilcoxon was a Fellow of the **American Statistical Association** and of the American Association for the Advancement of Science. He was an early chairman and leader in the development of the Gordon Research Conferences on Statistics in Chemistry and Chemical Engineering. The Chemical Division of the American Society for Quality Control annually awards a Frank Wilcoxon prize for the best papers of the year on practical applications published in *Technometrics*.

For a fuller account of his life and work, see [1] and [5], and a complete bibliography is given in [7].

EDMUND A. GEHAN

Wilcoxon–Mann–Whitney Test

This test for comparing two samples with respect to their "general size" is based on ranking the observations – both samples combined – and then comparing the average **ranks** in the two samples. Though this idea had appeared several times in various disciplines [2], the statistical community first recognized the idea when Wilcoxon proposed it in 1945 [9]; thereafter developments followed fast, the first of which was Mann & Whitney's paper [3].

Representations of the Test

To fix ideas we introduce some notation. Until further stated, we consider continuous data, thus excluding ties. Let $X_1, X_2, \ldots, X_m$ be independent and identically distributed, with unknown cumulative distribution function F. Define

$$F_m(t) = \frac{1}{m} \sum_{i=1}^{m} u(x_i, t), \tag{1}$$

where the function $u(a, b) = 1$ if $a < b$ and zero if not.

Similarly, define $Y_1, Y_2, \ldots, Y_n$, and G,

$$G_n(t) = \frac{1}{n} \sum_{j=1}^{n} u(y_j, t), \tag{2}$$

and write $N = m + n$.

If $r_i = r(x_i)$ is the rank of x_i in the combined sample, let $R(x) = \sum_{i=1}^{m} r(x_i)$; and if $s_i = s(y_i)$ is the rank of y_j in the combined sample, let $R(y) = \sum_{j=1}^{n} s(y_j)$.

Observe that $R(x) + R(y) = N(N + 1)/2$ since each side represents the sum of the integers $1, 2, \ldots, N$.

Define

$$U(x < y) = \sum_{i=1}^{m} \sum_{j=1}^{n} u(x_i, y_j), \tag{3}$$

where again $u(x_i, y_j) = 1$ if $x_i < y_j$ and zero otherwise.

$U(x < y)$ reports how many of the mn distinct pairs comprising one x_i and one y_j have $x_i < y_j$. Mann & Whitney showed that

$$R(y) = \frac{n(n + 1)}{2} + U(x < y), \tag{4}$$

and that, hence, properties of Wilcoxon's test could be learned by studying $U(x < y)$. The relation between $R(y)$ and $U(x < y)$ also implies that one may choose to calculate whichever is more convenient with any particular data set. (In what follows we write W-M-W for Wilcoxon–Mann–Whitney.)

Because a monotone continuous **transformation** (like $x^{1/2}$ or $\log x$) does not change order relations, both $U(x < y)$ and $R(y)$ are also unaffected.

Distribution Theory When $F = G$ (i.e. H_0 Holds)

The exact distribution of $U(x < y)$ is obtained by enumeration, which is much expedited by using recursion relationships.

Under H_0 the mean and variance of $U(x < y)$ are:

$$\mathrm{E}_0[U(x < y)] = \frac{mn}{2} \tag{5}$$

and

$$\mathrm{var}_0[U(x < y)] = \frac{mn(N + 1)}{12}. \tag{6}$$

Both results are readily obtained by regarding $R(y)$ as the sum of n random observations chosen without replacement from $(1, 2, \ldots, N$; *see* **Sampling With and Without Replacement**).

Asymptotic normality (shown below) provides good approximation to the exact distribution for m and n both large ($m \geq 8, n \geq 8$, suffices at $2p = 0.05$; *see* **Large-sample Theory**).

Owen [7] tabulates distributions of both $U(x < y)$ and $R(y)$.

Distribution Theory: General Case; x and y Continuous

It is evident that

$$\begin{aligned} \mathrm{E}[u(x_i, y_j)] &= 1 \times \Pr(x < y) + 0 \times \Pr(y < x) \\ &= \Pr(x < y), \end{aligned}$$

whence

$$\mathrm{E}\left[\frac{1}{mn}U(x < y)\right] = \frac{1}{mn}\mathrm{E}\sum_{i}^{m}\sum_{j}^{n}u(x_i, y_j)$$
$$= \Pr(x < y).$$

Hereafter we write $\widehat{\Pr}(x < y)$ for $U(x < y)/mn$.

Now,

$$\widehat{\Pr}(x < y) = \frac{1}{mn}\sum_{i}^{m}\sum_{j}^{n}u(x_i, y_j)$$
$$= \frac{1}{n}\sum_{j=1}^{n}\left[\frac{1}{m}\sum_{i=1}^{m}u(x_i, y_j)\right].$$

Hence, applying (1),

$$\widehat{\Pr}(x < y) = \frac{1}{n}\sum_{j=1}^{n}F_m(y_j). \tag{7}$$

It follows that, as $m \to \infty$ [and hence $F_m(t) \to F(t)$],

$$\lim \widehat{\Pr}(x < y) = \frac{1}{n}\sum_{j=1}^{n}F(y_j). \tag{8}$$

From (8), for large m, $\widehat{\Pr}(x < y)$ is nearly an average of n independent identically distributed bounded random variables, and hence is asymptotically normally distributed as n (in addition to m) grows large (*see* **Central Limit Theory**).

From (7),

$$\widehat{\Pr}(x < y) = \frac{1}{n}\sum_{j=1}^{n}F_m(y_j) = \sum F_m \, \mathrm{d}G_n,$$

which estimates $\int F \, \mathrm{d}G$.

Examination of (8) yields a one-sample version of the Wilcoxon–Mann–Whitney test [4]. If F is known (say from census figures), then we can test whether a given set of data $(y_1, \ldots, y_n)$ comes from that distribution, against an alternative that $G(y)$ is some other distribution with $\int F \, \mathrm{d}G \neq 1/2$.

Under H_0, $G = F$ and the statistic $(1/n)\sum_{j=n}^{n}F(y_j)$ is a sum of **uniform** (0, 1) random variables; the statistic has mean 1/2, variance $1/12n$, and, if n is large (say 8 or more), its distribution is effectively normal, providing the test for H_0: $G = F$.

Some Properties of the Test

In comparison with the two-sample t test (*see* **Student's *t* Statistics**), the W-M-W enjoys a very strong property as a test against translation alternatives. First, if normality, with $\sigma_x^2 = \sigma_y^2$, governs the data, the **asymptotic relative efficiency** of the W-M-W procedure is $0.955 = 3/\pi$, which is nearly 1. Secondly, if the data come from a heavy-tailed distribution, then that efficiency rises *above* 1.0 and, for some distributions, much above 1.0. Hodges & Lehmann showed [1] that the asymptotic relative efficiency of W-M-W vs. the t test *never* falls below 0.864 for translation alternatives.

Some Practical Aspects

Where the distributions F and G are believed to differ by translation, a *confidence interval* for that translation can be constructed by a simple graphical procedure, based on W-M-W test theory [5].

The parameter $\Pr(x < y)$ and its estimate $\widehat{\Pr}(x < y)$ are sometimes readily interpretable. They are unit-free, and can serve as indicators of "effect size".

We have seen that $\widehat{\Pr}(x < y)$ is asymptotically normal, and **unbiased** for $\Pr(x < y)$ under H_0 when

$$\mathrm{var}[U(x < y)] = \frac{mn(N+1)}{12}$$

and

$$\mathrm{var}[\Pr(x < y)] = \frac{N+1}{12mn}.$$

Unfortunately, except when $F = G$, the standard error of $\widehat{\Pr}(x, y)$ is not a simple matter, though the following upper bound can be justified; $\mathrm{se}[\widehat{\Pr}(x < y)] = [p(1-p)]^{1/2}/k$, where p denotes $\Pr(x < y)$ and k denotes the smaller of m and n [7].

Tied Data (Discrete Probabilities)

When ties occur only in the xs or only the ys, they do not affect anything. However, where there are t observations, including at least one x and at least one y, sharing a common value, they are handled in the following manner. To calculate $U(x \leq y)$, count each tied pair (x_i, y_j) in the tied set as contributing 1/2 to $U(x \leq y)$.

To calculate $R(y)$, consider the t consecutive ranks that would be assigned were the tied data perturbed slightly to become distinct. The average of

those t distinct ranks is then assigned as the rank for every observation in that tied set. These two approaches are consistent – they lead to compatible values of R and U. The variance of R (and U) is somewhat reduced by the ties. Indeed, the variance appropriate for untied data is multiplied by CF (for "correction factor") as follows:

$$\mathrm{CF} = 1 - \frac{\sum(t^3 - t)}{N^3 - N},$$

where the sum runs over all the sets of x-with-y ties, and t denotes the length of such a tie.

If no x-with-y tie includes as many as half of the observations, the variance will need correction only in borderline situations, as the correction factor stays near 1.0 unless at least half the observations are in one tied set.

Example (Table 1)

$$\mathrm{CF} = 1 - \frac{\left\{\begin{array}{c}[(21^3 - 21) + (20^3 - 20)\\ +(23^3 - 23) + (24^3 - 24)]\end{array}\right\}}{88^3 - 88}$$
$$= 0.93665.$$

So the routine null standard $\sigma = [(22 \times 66 \times 89)/12]^{1/2}$ is reduced; it is multiplied by $\sqrt{0.93665} = 0.9678$.

For this table, $\widehat{\Pr}(x, y)$ is calculated thus:

$$\widehat{\Pr}(x < y) = \frac{\left\{\begin{array}{c}\{2(47) + 4(31) + 5(13) + \frac{1}{2}[2 \times 19\\ +4 \times 16 + 5 \times 18 + 11 \times 13\}\end{array}\right\}}{22 \times 66}$$
$$= 0.3103.$$

In the above calculation we have organized our work by choosing successive subgroups of x; thus, the 2 xs in "poor" form (x, y) pairs, where $x < y$, with $16 + 18 + 13 = 47$ ys, etc. The tied x, y pairs each contribute 1/2.

Table 1

	Poor	Fair	Good	Excellent		
x	2	4	5	11	22	m
y	19	16	18	13	66	n
t	21	20	23	24	88	N

The example illustrates a salient application of W-M-W methodology. It is mistaken to apply the usual **chi-square test** of significance where the categories have a relevant order, because that order, the key to the problem, is not taken into account by the χ^2 statistic. For these data $\chi_3^2 = 8.64$ ($p = 0.0345$), and the W-M-W statistic is

$$Z = \frac{0.31026 - 0.5000}{\left(\dfrac{89}{12 \times 22 \times 66}\right)^{1/2}(0.9678)} = -\frac{0.18974}{0.06917}$$
$$= -2.74 \ (2p = 0.0061).$$

A more detailed treatment of the ordered $2 \times k$ contingency table appears in [6] (*see* **Ordered Categorical Data**).

LINCOLN E. MOSES

Wilcoxon-type Scale Tests

Populations (distributions) are often described and compared on the basis of certain features or aspects called "parameters" (*see* **Estimation**). Two of the most widely used parameters are the location and the scale. The location parameter measures "central tendency" and represents the size of a typical observation, whereas the scale parameter indicates how variable or spread out the observations can be. Related to the idea of scale is the concept of dispersion, which indicates how close the observations are, on an average, to a central value. The **mean** and the **median** are two popular location parameters while the **standard deviation**, the mean absolute deviation (*see* **Mean Deviation**), the **range** and the interquartile range are often used to represent the scale or dispersion. If the application at hand permits a specific parametric model assumption (such as normality; *see* **Normal Distribution**) about the underlying distribution(s), suitably designed techniques can be used to make statistical **inference** regarding the location and/or the scale parameters. These methods are called parametric statistical methods of inference. On the other hand, if a complete model assumption is hard to justify (perhaps because not much is known about the populations), use of **nonparametric** or distribution-free methods is advocated. Nonparametric methods are often intuitively appealing and their implementation is quite simple. Of course, when the true distribution is indeed of a specific form, the nonparametric methods will be less **efficient** than their parametric counterparts, but the fact is that in many practical situations the form of the true distribution cannot be specified completely. Distribution-free methods for scale parameters are the focus of this article. We use the terms nonparametric and distribution-free interchangeably, since readers from different areas might be familiar with one of the terms and not the other.

One of the most popular distribution-free tests to compare the location parameters of two populations is the Wilcoxon rank-sum test. The rank-sum test statistic is linearly related to the Mann–Whitney statistic, so that the corresponding tests are equivalent (*see* **Wilcoxon–Mann–Whitney Test**). In the rank-sum form of the statistic, observations from two independent random samples drawn from two populations are combined into a single array and are **ranked** from the lowest to the highest, keeping track of whether each observation was from the first sample or the second. When ties occur (i.e. more than one of the observations have the same value), the average of the tied ranks is assigned to each of the tied observations. The rank-sum test is based on the sum of ranks of the observations that are, say, from the first sample. In the Mann–Whitney form of the statistic, each observation from the first sample is compared with each observation from the second, and, assuming there are no ties, a score of 1 or 0 is given depending on whether or not the observation from the first sample is larger or smaller than the observation from the second. When there is a tie, a score of 1/2 is assigned to that comparison. The test statistic is simply the sum of these scores summed over all such comparisons.

The idea behind the Wilcoxon–Mann–Whitney (WMW) test has been extended to the problem of testing for scale differences between two populations and such tests are referred to as Wilcoxon-type scale tests. Here observations are often first "centered" by subtracting some measure of the central tendency and the WMW tests is applied to the absolute values of the deviations. A nice feature of the Wilcoxon-type tests is that they lead to a **confidence interval** for the ratio of the scale parameters, which can be used for a test of **hypothesis** as well as for **estimation** purposes.

A review of Wilcoxon-type scale tests is given by Gibbons [6]. Discussions on various nonparametric tests for scale can be found, for example, in [8, Chapter 9] and [7, Chapter 10]. A general review of scale tests, including distribution-free tests, is given by Fligner [4], who also gives examples of situations where inference on the scale parameter is of interest.

Assumptions

Let $X_1, X_2, \ldots, X_m$ and $Y_1, Y_2, \ldots, Y_n$ be two independent **random samples** from continuous populations from the **"location-scale" family**, with cumulative distribution functions (cdfs) $F_1(x) = F\{(x - \theta_x)/\tau_x\}$ and $F_2(y) = F\{(y - \theta_y)/\tau_y\}$, where is some unknown continuous cdf, θ_x and θ_y are the respective location parameters, and τ_x and τ_y are the respective scale parameters. Thus, F_1 and F_2 are assumed to have the same shape, but they could have different location and/or scale parameters. To understand this better, note that we can write $X_i = \theta_x + \tau_x Z$ and

$Y_j = \theta_y + \tau_y Z$, where Z is a continuous random variable with cdf $F(\cdot)$. Therefore, X and Y can be viewed as linear functions of the random variable Z and it is clear that a change in the location parameter(s) shifts the center of the distribution(s), whereas increasing (decreasing) the scale parameter(s) causes the distribution(s) to be more (less) spread out. While the locations of two distributions are usually compared on the basis of the difference $\theta_x - \theta_y$, the scale comparison is often done in terms of the ratio $\gamma = \tau_x/\tau_y$. We are interested in distribution-free methods of inference about γ. Both tests of hypothesis and confidence intervals are considered. The latter can also be used for estimation purposes.

Tests: Locations Unknown

For ease of presentation, suppose that the location parameters are the respective medians of F_1 and F_2. Consider the situation in which the two medians are known, and we would like to test the **null hypothesis** $H_0 : \gamma = \gamma_0$, where γ_0 is some specified value. If only the equality of the scale parameters is of interest, γ_0 is set equal to 1.

Two tests are available, both based on the absolute values of the adjusted variables $S_i = (X_i - \theta_x)/\gamma_0, i = 1, 2, \ldots, m$ and $T_j = (Y_j - \theta_y), \quad j = 1, 2, \ldots, n$. Absolute values of the differences are used, since they reflect dispersion about the respective medians. Under the null hypothesis the distributions of $|S_i|$ and $|T_j|$ are identical, which implies that their medians must be the same. This leads us to proceed as in the case of the usual Wilcoxon rank-sum test for location, except that now we work with the absolute values of the deviations from the medians. Therefore, we arrange the $|S_1|, |S_2|, \ldots, |S_m|$ and $|T_1|, |T_2|, \ldots, |T_n|$, from the lowest to the highest, and assign ranks $1, 2, \ldots, m + n$ to each of the ordered values (the lowest gets rank 1, the highest gets rank $m + n$; use average ranks if there are ties), keeping track of whether an observation was an S or a T. The test statistic is W^*, the sum of the ranks of the absolute values of the Ss. The test is consistent when the $F(\cdot)$ is symmetrically distributed about 0; that is, when F_1 and F_2 are symmetrically distributed about θ_x and θ_y, respectively. The rejection regions for the test can be argued as follows. Letting F_1^* and F_2^* represent the cdfs of $|S|$ and $|T|$ respectively, it can be seen that when γ is greater (less) than γ_0, F_1^* is stochastically larger (smaller) than F_2^*. Thus, when the **alternative hypothesis** is $\gamma > (<)\gamma_0$, we should reject H_0 if W^* is large (small).

The **critical** values as well as the P values can be found from the distribution of W^* under the null hypothesis. As explained earlier, the null distribution of W^* is the same as that of the Wilcoxon rank-sum test statistic for comparing two location parameters. The latter has been shown to depend only on the sample sizes m and n and has been studied and tabulated by several authors, the most extensive tabulation being available in [16]. These tables can be used to implement the test. Note, however, that since W^* is a discrete random variable, not all commonly used levels of significance might be exactly achievable for all m and n (*see* **Level of a Test**). When the sample sizes are large, a normal approximation to the critical value or the P value can be found. This is based on the fact that the distribution of the "standardized" random variable

$$Z^* = \frac{W^* - m(m+n+1)/2}{[mn(m+n+1)/12]^{1/2}} \tag{1}$$

can be approximated by the normal distribution with mean 0 and variance 1 (the **standard normal** distribution). Using the normal approximation is convenient in practice, since the standard normal tables are widely available. The normal approximation-based rejection regions are given in Table 1. In situations in which a number of ties are present in the data, it is advisable to "correct" the null variance of W^* and use the corrected variables in the standardized statistic Z^*. The correction for ties is detailed, for example, [8, p. 300].

A continuity correction of 0.5 can improve the approximation. The **asymptotic relative efficiency** (ARE) of this test relative to the normal theory F test (*see* ***F* Distributions**) is $6/\pi^2 = 0.61$, when the underlying populations are normal.

The second test that one could use with known medians is the Sukhatme [13] test. Here the positive Ss and Ts are put in one group and the negative Ss

Table 1 Rejection regions for various alternative hypotheses

Alternative hypothesis	Rejection region
$H_a : \gamma > \gamma_0$	$Z^* > z_\alpha$
$H_a : \gamma < \gamma_0$	$Z^* < -z_\alpha$
$H_a : \gamma \neq \gamma_0$	$Z^* > z_{\alpha/2}$ or $Z^* < -z_{\alpha/2}$

and Ts are put in a second group. The first group of values are ranked and we let S^+ be the sum of the ranks of the Ss.

For the second group, absolute values are ranked and we let S^- be the sum of the ranks of the Ss. The Sukhatme test is based on $W_S = T^+ + T^-$. Actually, the original Sukhatme [13] test is based on a Mann–Whitney-type "***U*-statistic**", which is a linear function of W_S. The exact distribution of W_S is complicated, since this must be obtained conditioned on the number of positive (or negative) deviations, which itself is a random variable. For large m and n, Gibbons [6] states that normal approximation can be used with mean $m(m+n+2)/4$ and variance $mn(m+n+7)/48$, to find an approximate critical value or a P value. Sukhatme [13] showed that the test is consistent without the assumption of symmetry. When the underlying distributions are normal, the ARE of the Sukhatme test relative to the F test is 0.61, which is the same as the ARE of the W^* test relative to the F test. On the other hand, when the underlying distributions are double-**exponential**, the ARE of the Sukhatme test relative to the F test is 0.94. Laubscher & Odeh [11] showed that the normal approximation to W_S is good for m and n larger than 10, when used with a **continuity correction**. They also considered a statistic, which is a linear function of W_S and tabulated the exact critical values for $2 \le m,\ n \le 10$.

To summarize, when the populations can be assumed to be symmetrically distributed about their known medians, one should use the test based on W^*. When symmetry cannot be assumed, the test based on W_S should be used.

Tests: Locations Unknown

In many practical applications, the underlying medians θ_x and θ_y are likely to be unknown. First, assume that the two population medians are the same but the common median is unknown. Fligner & Kileen [5] suggested using the median of the combined sample of $X's$ and $Y's$, say M, to estimate the common median and applying the Wilcoxon rank-sum test, to the absolute deviations $|X_i - M|$ and $|Y_j - M|$. The resulting test, although not a linear rank test, is distribution-free and the same tables for the Wilcoxon rank-sum test, cited earlier, can be used to implement it. They showed that the test is consistent whether or not the underlying distributions are symmetric. In a small sample study with normal and double exponential distributions, the **power** of their test was found to be significantly higher than some popular linear rank tests for scale. Moreover, when the medians are unknown and unequal, their test was shown to be consistent for scale differences as long as the populations are symmetrically distributed and the sample sizes are equal.

In situations in which the population medians are both unknown and cannot be assumed to be equal, one approach would be to use the sample medians M_x and M_y to calculate $|X_i - M_x|$ and $|Y_j - M_y|$ and apply the W^* test on these absolute deviations. However, such a test might not always be distribution-free, not even when the sample sizes are large; see [4, 12] for some discussions on this issue and recommendations for tests to be used in this case.

Sukhatme's test can also be used when medians are unknown and unequal, by applying the test based on W_S discussed earlier, to $|X_i - M_x|$ and $|Y_j - M_y|$. Sukhatme [14] showed that the resulting test has the same asymptotic null distribution as that of W_S and is asymptotically distribution-free when F_1 and F_2 are symmetrically distributed about their respective medians and have bounded density functions. Fligner [4] remarked that in terms of power, these rank-like tests based on the absolute values of the estimated deviations do not compare very well with what are called *robust* (*see* **Robustness**) tests for scale. See his paper for proposed robust tests.

Confidence Intervals

If the two medians are known and the populations can be assumed to be symmetrically distributed about their respective medians, a confidence interval for γ can be constructed from the ratios $|X_i - \theta_x|/|Y_j - \theta_y|$. The procedure is similar to that of finding a confidence interval for the difference between two population medians based on the WMW test. Here, the mn values of the ratio are arranged from the lowest to the highest. The $100(1-\alpha)\%$ confidence interval is obtained simply by locating the uth smallest and the uth largest of the mn ratios. For a given confidence level, the integer u is calculated from the null distribution of a two-sample Wilcoxon rank-sum test. In fact, as described in [8], it is often convenient to think of u *as the rank of*

a left-tail critical value for the Wilcoxon rank-sum test, at a level of significance $\alpha/2$. When m and n are small, an exact table for the null distribution of the rank-sum test statistic should be used to find the confidence interval. Table J in [8] is useful for this purpose. To illustrate, suppose that $m = 4$, $n = 7$, and that a 95% confidence interval is desired. Then we have $\alpha/2 = 0.025$ and, from Table J in [8], we find that the closest we can come to the desired confidence level is $100(1 - 2 \times 0.021) = 95.8\%$ and this corresponds to a left-tail critical value of 13, which has the rank of 4. Thus, $u = 4$ and a 95.8% confidence interval for it is obtained by arranging the $mn = 28$ values of the ratio in an increasing order and locating the fourth smallest and the fourth largest (or the $28 - 4 + 1 = 25$th value from the smallest). This also highlights the fact that for small sample sizes, the desired confidence coefficient often cannot be achieved exactly. When m and n are moderately large, the normal approximation, with a continuity correction, to u can be found as

$$u = \left[\frac{mn}{2} + 0.5 - z_{\alpha/2} \left(\frac{mn(m+n+1)}{12} \right)^{1/2} \right], \tag{2}$$

where $[a]$ denotes the greatest integer in a (e.g. if $a = 3.5$, then $[a] = 3$) and $z_{\alpha/2}$ is obtained from the standard normal table, so that $\alpha/2$ is the area to the right of $z_{\alpha/2}$. For our example, $u = [4.12] = 4$, so that the normal approximation yields the same solution as the exact answer.

Corresponding to the Sukhatme test, the confidence interval for γ is obtained from the ratios $(X_i - \theta_x)/(Y_j - \theta_y)$ that are positive. It may be noted that this ratio will be positive when both the numerator and the denominator have the same sign. These positive ratio values are arranged from the lowest to the highest, and the $100(1 - \alpha)\%$ confidence interval is given by the uth smallest and the uth largest of the positive ratios. The quantity u can be found from the tables of Laubscher & Odeh [11]. For large m and n, the normal approximation to u with a continuity correction, can be found from

$$u = \left[\frac{mn}{4} + 0.5 - z_{\alpha/2} \left(\frac{mn(m+n+7)}{48} \right)^{1/2} \right]. \tag{3}$$

Generalizations

Deshpande & Kusum [2] considered a generalized version of Sukhatme's test where the location parameter is some **quantile**. When the scale parameters of more than two populations need to compared, the well-known Kruskal–Wallis test (*see* **Nonparametric Methods**) can be used after transforming the data into absolute values of the deviations from the respective locations parameters. Tsai et al. [15] compared the performance of this procedure with other multisample tests for scale. Duran [3] gave a comprehensive survey of distribution-free tests for scale.

In some situations, we are interested in comparing both the location and the scale parameters. There is a body of literature for distribution-free tests for this type of problem; see [9] for a review.

Blair & Thompson [1], following Moses [12], considered a class of distribution-free rank-like tests for scale differences when the locations are unknown. Their tests do not require the assumptions on the location parameters discussed earlier. In addition, the tests are "robust for **skewed** data, are resolving and have significant power advantages". One of their test statistics is the Wilcoxon rank-sum test applied to the absolute values of the differences $|X_i - X_j|$. They studied asymptotic properties of the tests, including a normal approximation and the asymptotic relative efficiency. The asymptotic relative efficiency was calculated for several distributions. An extension to the multisample problem was also considered.

Kössler [10], also following Moses [12], proposed a distribution-free test in the case of unequal and unknown location parameters. The two samples are randomly separated into groups of size k and the Wilcoxon test or the Savage test is applied to the ranges or the variances of the subgroups; $k = 4$ is recommended. Asymptotic power function of the proposed test is derived and **simulation** studies are carried out for small to moderate sample sizes. Power calculations suggest using the Wilcoxon test for original densities with long tails and using the Savage test for original densities with small or medium tails.

SUBHA CHAKRABORTI

Window Estimate

The most common occurrence of this terminology is in the context of frequency domain estimation in **time series** analysis. Suppose that an observed time series is a realization of a stationary random process $\{Y_t\}$ with spectral density $f(\omega) = (1/2\pi)\sum_{k=-\infty}^{\infty}\gamma_k\cos(k\omega)$, where γ_k is the autocovariance function of $\{Y_t\}$. The fundamental tool for estimating $f(\omega)$ is the periodogram, $I(\omega)$, which can be shown to be estimated by the discrete Fourier transform of the sample **autocorrelation function** r_k, of the observed series $(Y_t;\ t = 1, \ldots, n)$. It is given by $c_0\{1 + 2\sum_{k=1}^{n-1} r_k\cos(k\omega)\}$, where c_0 is the sample autocovariance at lag k [8, p. 56]. There are certain unsatisfactory statistical properties possessed by $I(\omega)$, such as inconsistency [11, p. 426]. The periodogram (*see* **Spectral Analysis**) at Fourier frequencies of the form $\omega_j = 2\pi j/n,\ j = 1, \ldots, n/2$, are asymptotically independent of each other [8, p. 96], so that if we take a simple average of the estimates $I(\omega_j)$, the resultant statistic $\hat{f}(\omega_j)$ will gain in precision as n increases. More generally, *weighted* averages are used. Thus, an equivalent way of improving the estimates is provided by introducing a nonincreasing sequence of weights, λ_k called a *lag window*, and defining $\hat{f}_\lambda(\omega) = c_0\{1 + 2\sum_{k=1}^{n-1}\lambda_k r_k\cos(k\omega)\}$. The function $\hat{f}_\lambda(\omega)$ is called the *spectral window*, after Blackman & Tukey [2].

A good deal of effort has been put into investigating the statistical properties of windowed estimates and choosing the sequence λ_k. More than 11 different lag windows are reviewed by Priestley [11, Section 6.2.3]. However, using lag windows is no longer fashionable, mainly because of computational considerations: since the periodogram is essentially a discrete Fourier transform, it can be computed very quickly using a Fast Fourier transform (FFT) [7]. In the early days of this development in spectral analysis, computing power was relatively expensive, and using lag windows reduced this cost. It is now more logical to compute the periodogram first, perhaps using a FFT, and then to smooth it. A more recent development for locally adaptive windows is given by Buhlmann [4].

The idea of window estimates also arises in the context of time domain estimation in time series analysis. Let $Y_1, Y_2, \ldots, Y_n$ be n observations from a time series $\{Y_t\}$ with mean μ, theoretical autocorrelation function ρ_k, and variance σ_Y^2. Estimates of these and other summary statistics for a time series usually use all n observations, but it is sometimes useful to divide the data up into segments or *windows* as follows. Consider a subset of m observations in the data as indicated in $Y_1, Y_2, \ldots, \boxed{Y_l, \ldots, Y_{l+m-1}}, Y_{l+m}, \ldots, Y_n$. If we let $l = 1, 2, \ldots, (n - m + 1)$ then this represents a (forward) moving window of fixed length m. If we fix $l = 1$, and let $m = p + 1, p + 2, \ldots, n$ for fixed p, this represents a window of increasing size with starting length p. The estimates of statistics within the moving window can be useful to judge whether those statistics are changing through time. In general, the statistics can be plotted against window number, and a visual assessment made of whether they are changing. Formal significance tests on the window estimates can be carried out, but these are complicated by the fact that successive estimates will be highly correlated. In the case of the window increasing in size from a fixed starting length, p, the estimates are sometimes called *recursive*. The use of recursive residuals in time series regression was pioneered by Brown et al. [3] and generalized for lagged values of the dependent variable by Kramer et al. [9] and Ploberger & Kramer [10]. Another approach is to make one- or multistep predictions of data outside the window and judge whether these are consistent with the data that actually occur.

The term *window* is also used in kernel **density estimation**. The classic books on this topic are Silverman [12] and Wand & Jones [13]. Suppose that $X_1, X_2, \ldots, X_n$ is a set of continuous random variables having common density f. A nonparametric density estimator assumes no prespecified functional form for f. Such an estimator is given by $\hat{f}(x;h) = (nh)^{-1}\sum_{i=1}^{n} K\{(x - X_i)/h\}$. Here, K is a function satisfying $\int K(x)\,dx = 1$, called the kernel, and h is a positive number called the *bandwidth* or *window width*. The simplest and most common density estimate is the histogram defined by $\hat{f}(x;h) = (nh)^{-1}$ (number of X_i in the same bin as x). Each bin, or rectangle, may be regarded as a window that summarizes the behavior of the data between the bin extremities. The choice of origin and h can greatly affect the appearance of the histogram. In the general case defined above, much effort has been put into determining optimal values for h [13, Chapter 3].

So-called *kernel* and *regression* smoothers are designed locally to smooth data by slicing through it in windows of fixed width. See, for example, [1] for an introduction to the topic. Special cases include average smoothers that use the within-slice average to summarize the data in a slice, and regression smoothers that use a fixed proportion of the data in a specified neighborhood. In this context, Cleveland [5] introduced the *lo*cally *we*ighted *s*catterplot *s*moother (*lowess*) and this has become the most commonly used method in modern graphical and regression analyses. See, for example, [6, p. 31].

NEVILLE DAVIES

Wishart Distribution

Suppose that $X_1, X_2, \ldots, X_n$ is a **random sample** from a normal population with mean μ and variance σ^2. Also let $f = n - 1$, the sample mean $\overline{X} = \sum X_i/n$, and the sample variance $s^2 = \sum(X_i - \overline{X})^2/f$. It is known that fs^2/σ^2 is distributed as χ_f^2, where χ_f^2 represents a **chi-square distributed** random variable with f **degrees of freedom**. In other words, $v = fs^2 = \sum(X_i - \overline{X})^2$ is distributed as $\sigma^2\chi_f^2$. The probability density function (pdf) of v is given by

$$f(v) = \frac{1}{\Gamma(f/2)(2\sigma^2)^{f/2}} v^{(f-2)/2} \exp\left(\frac{-v}{2\sigma^2}\right) \propto \frac{v^{(f-2)/2}}{(2\sigma^2)^{f/2}} \exp\left(\frac{-v}{2\sigma^2}\right), \quad v > 0. \tag{1}$$

It is a **gamma distribution** with parameters $f/2$ and $2\sigma^2$.

Let us now consider a **bivariate normal** random variable $\mathbf{X}$ with mean vector $\boldsymbol{\mu}$ and **covariance matrix** $\boldsymbol{\Sigma}$, where

$$\mathbf{X} = \begin{pmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{pmatrix}, \qquad \boldsymbol{\mu} = \begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix} \quad \text{and}$$

$$\boldsymbol{\Sigma} = \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \sigma_{22} \end{pmatrix}.$$

Suppose $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n$ is a random sample on $\mathbf{X}$. Define the sums of squares v_{11}, v_{22}, and the sum of cross-products v_{12} as follows:

$$v_{11} = (n-1)s_1^2 = \sum(X_{1j} - \overline{X}_1)^2,$$

$$v_{22} = (n-1)s_2^2 = \sum(X_{2j} - \overline{X}_2)^2,$$

$$v_{12} = v_{21} = (n-1)s_{12} = \sum(X_{1j} - \overline{X}_1)(X_{2j} - \overline{X}_2).$$

Also, let

$$\mathbf{V} = \begin{pmatrix} v_{11} & v_{12} \\ v_{21} & v_{22} \end{pmatrix}.$$

Then the joint distribution of v_{11}, v_{22}, and v_{12} is given by

$$f(\mathbf{V}) \equiv f(v_{11}, v_{22}, v_{12}) = c\frac{|\mathbf{V}|^{(f-3)/2}}{|\boldsymbol{\Sigma}|^{f/2}} \times \exp\left[-\frac{1}{2}\mathrm{tr}\left(\boldsymbol{\Sigma}^{-1}\mathbf{V}\right)\right], \tag{2}$$

where both $\mathbf{V}$ and $\boldsymbol{\Sigma}$ are positive definite. Here, c is a normalizing factor which is defined later.

For the sake of comparison with (1), let us assume that $\sigma_{12} = 0$. Then (2) reduces to

$$f(v_{11}, v_{22}, v_{12}) \propto \frac{(v_{11}v_{22} - v_{12}^2)^{(f-3)/2}}{(4\sigma_1^2\sigma_2^2)^{f/2}} \times \exp\left[-\frac{1}{2}\left(\frac{v_{11}}{\sigma_1^2} + \frac{v_{22}}{\sigma_2^2}\right)\right].$$

The marginal distribution of v_{11} or v_{22} is (1).

Assume that $\mathbf{X}$ is now a p-variate **multivariate normal** random vector with mean $\boldsymbol{\mu}$ and variance–covariance matrix $\boldsymbol{\Sigma}$. Define

$$\mathbf{V} = \sum_{i=1}^{n}(\mathbf{X}_i - \overline{\mathbf{X}})(\mathbf{X}_i - \overline{\mathbf{X}})'.$$

The distribution of $\mathbf{V}$ is given by

$$f(\mathbf{V}) = c\frac{|\mathbf{V}|^{(f-p-1)/2}}{|\boldsymbol{\Sigma}|^{f/2}} \exp\left[-\frac{1}{2}\ \mathrm{trace}\ \left(\boldsymbol{\Sigma}^{-1}\mathbf{V}\right)\right], \tag{3}$$

where both $\mathbf{V}$ and $\boldsymbol{\Sigma}$ are positive definite, and $f(\mathbf{V}) = 0$ otherwise. The normalizing constant is

$$c = \left[2^{fp/2}\pi^{p(p-1)/4}\prod_{j=1}^{p}\Gamma\left(\frac{f+1-j}{2}\right)\right]^{-1}.$$

The distribution with the pdf (3) is called the Wishart distribution and is denoted as $W(\boldsymbol{\Sigma}, p, f)$ or $W_p(f; \boldsymbol{\Sigma})$. It has the first moment

$$\mathrm{E}(\mathbf{V}) = f\boldsymbol{\Sigma}.$$

Furthermore, if $\mathbf{V}_1, \mathbf{V}_2, \ldots, \mathbf{V}_m$ are independently distributed as $W(\boldsymbol{\Sigma}, p, f_k)$, $k = 1, 2, \ldots, m$, then the sum $\mathbf{V} = \mathbf{V}_1 + \mathbf{V}_2 + \cdots + \mathbf{V}_m$ is distributed as $W(\boldsymbol{\Sigma}, p, \sum f_k)$. A detailed derivation of the pdf and its properties are given by Johnson & Kotz [1].

AUSTIN F.S. LEE

Women's Health Initiative: Statistical Aspects and Selected Early Results

Introduction

The women's health initiative (WHI) is perhaps the most ambitious population research investigation ever undertaken. The centerpiece of the WHI program is a randomized, controlled **clinical trial** (CT) to evaluate the health benefits and risks of three distinct interventions (dietary modification, postmenopausal hormone therapy, and calcium/vitamin D supplementation) among 68 132 postmenopausal women. Participating women were identified from the general population living in proximity to any one of 40 participating clinical centers throughout the United States. The WHI program also includes an **observational study** (OS) comprising 93 676 postmenopausal women recruited from the same population base as the CT. Enrollment into WHI began in 1993 and concluded in 1998. Intervention activities in the combined hormone therapy component of the CT ended early in July 2002 when evidence had accumulated that the risks exceed the benefits for combined hormone therapy. Follow-up on all participating women is planned through March 2005, giving an average follow-up duration of about 8.5 years in the CT and 7.5 years in the OS.

WHI Clinical Trial and Observational Study

The WHI CT includes three overlapping components, each a randomized controlled comparison among women who were postmenopausal and in the age range of 50 to 79 at randomization. The dietary modification (DM) component randomly assigned 48 835 (target 48 000) eligible women to either a sustained low-fat eating pattern (40%) or self-selected dietary behavior (60%), with breast cancer and colorectal cancer as designated primary outcomes and coronary heart disease as a secondary outcome (*see* **Outcome Measures in Clinical Trials**). From the outset, the nutrition goals for women assigned to the DM intervention group have been to reduce total dietary fat to 20%, and saturated fat to 7% of corresponding daily calories and, secondarily, to increase daily servings of vegetables and fruits to at least five and of grain products to at least six, and to maintain these changes throughout trial follow-up. The randomization of 40%, rather than 50%, of participating women to the DM intervention group was intended to reduce trial costs, while testing trial hypotheses with specified **power**.

The postmenopausal hormone therapy (PHT) component is composed of two parallel randomized, double-blind (*see* **Blinding or Masking**) trials among 27 347 (target 27 500) women, with coronary heart disease (CHD) as the primary outcome, with hip and other fractures as secondary outcomes, and with breast cancer as a potential adverse outcome. Of these, 10 739 (39.3% of total) had a hysterectomy prior to randomization, in which case there was a 1 : 1 randomized double-blind allocation between conjugated equine estrogen (E-alone) 0.625 mg/day or **placebo**. The remaining 16 608 (60.7%) of women, each having a uterus at baseline, were randomized 1 : 1 to the same preparation of estrogen plus continuous 2.5 mg/day of medroxyprogesterone (E + P) or placebo. These numbers compare to design goals of 12 375 for the E-alone comparison, and 15 125 for the E + P comparison, based on an assumption that 45% of women would be post hysterectomy. Over 8000 women were randomized to both the DM and PHT clinical trial components.

At their one-year anniversary from DM and/or PHT trial enrollment, all women were further screened for possible randomization in the calcium and vitamin D (CaD) component, a randomized double-blind trial of 1000 mg elemental calcium plus 400 international units of vitamin D_3 daily, versus placebo. Hip fracture is the designated primary outcome for the CaD component, with other fractures and colorectal cancer as secondary outcomes. A total of 36 282 (53.3% of CT enrollees) were randomized to the CaD component. While the WHI design estimated that about 45 000 women would enroll in the CaD trial component, protocol planning activities also included projected **sample sizes** of 35 000 and 40 000 and noted that most WHI objectives could be met with these smaller sample sizes.

The total CT sample size of 68 132 is only 60.6% of the sum of the individual sample sizes for the three CT components, providing a cost and logistics

justification for the use of a partial **factorial design** with overlapping components.

Postmenopausal women of ages 50 to 79 years, who were screened for the CT but proved ineligible or unwilling to be randomized, were offered the opportunity to enroll in the observational study (OS). The OS is intended to provide additional knowledge about risk factors for a range of diseases, including cancer, cardiovascular disease, and fractures. It has an emphasis on biological markers of disease risk, and on risk factor changes as modifiers of risk.

There was also an emphasis on the recruitment of women of racial/ethnic minority groups. Overall 18.5% of CT women and 16.7% of OS women identified themselves as other than white. These fractions allow meaningful study of disease risk factors within certain minority groups in the OS. Also, key CT subsamples are weighted heavily in favor of the inclusion of minority women in order to strengthen the study of intervention effects on specific intermediate outcomes (e.g. changes in blood lipids or micronutrients) within minority groups.

Age distribution goals were also specified for the CT as follows: 10%, ages 50 to 54 years; 20%, ages 55 to 59 years; 45%, ages 60 to 69 years; and 25%, ages 70 to 79 years. While there was substantial interest in assessing the benefits and risks of each CT intervention over the entire 50 to 79 year age range, there was also interest in having sufficient representation of younger (50–54 years) postmenopausal women for meaningful age group-specific intermediate outcome (biomarker) studies, and of older (70–79 years) women for studies of treatment effects on quality of life measures, including aspects of physical and cognitive function. Differing age and **incidence rates** within the 50 to 79 age range, and across the outcomes that were hypothesized to be affected, favorably or unfavorably, by the interventions under study, provided an additional motivation for a prescribed age-at-enrollment distribution.

The enrollment of such a large number of women, meeting designated **eligibility and exclusionary criteria** [11] for each CT component and for the OS proved to be a challenge, particularly for the PHT component of the CT, since many women who volunteered for WHI were already taking hormones and did not wish to be randomized to take hormones or placebo, while other women had already made a decision against the use of hormones.

Study Organization

In addition to the clinical centers, the study is implemented through a Clinical Coordinating Center (CCC) located in Seattle with various collaborators providing specific expertise, as described below (*see* **Multicenter Trials**). The National Heart Lung and Blood Institute (NHLBI) sponsors the program with input from the National Cancer Institute, the National Institute of Aging, the National Institute of Arthritis and Musculoskeletal and Skin Diseases, the NIH Office of research on women's health, and the NIH director's office. A steering committee, consisting of the principal investigators of the 40 CCs, CCC, and NHLBI representatives are responsible for major scientific and operational decisions. An executive committee identifies, prioritizes, and coordinates items for the steering committee discussion. Program activities are implemented through a regional organization that categorizes CCs geographically (West, Midwest, Northeast, Southeast). Principal investigators, and staff groups defined by project responsibilities (clinic manager, clinic practitioner, nutritionist, recruitment coordinator, data coordinator, outcomes coordinator) meet regularly through conference calls within regions to discuss implementation plans and issues, and regional staff group representatives also confer regularly to ensure national coordination. Nine standing advisory committees (behavior, calcium and vitamin D, design and analysis, dietary modification, hormone therapy, morbidity and mortality, observational study, publications and presentations, special populations) composed of study investigators having expertise in the major substantive areas involved in the program, provide recommendations on relevant issues as they arise. The CCC participates and provides liaison support in these various contexts. Figure 1 shows the WHI governance more generally, including NIH advisory committees. Specifically, the directors of participating NIH institutes and offices form a consortium that advises the NHLBI director concerning the WHI. A special working group of the NHLBI council also advises the NHLBI director concerning the WHI.

Principal Clinical Trial Comparisons, Power Calculations, and Safety and Data Monitoring

This section provides sample sizes by age for each CT component and for the OS, and provides power

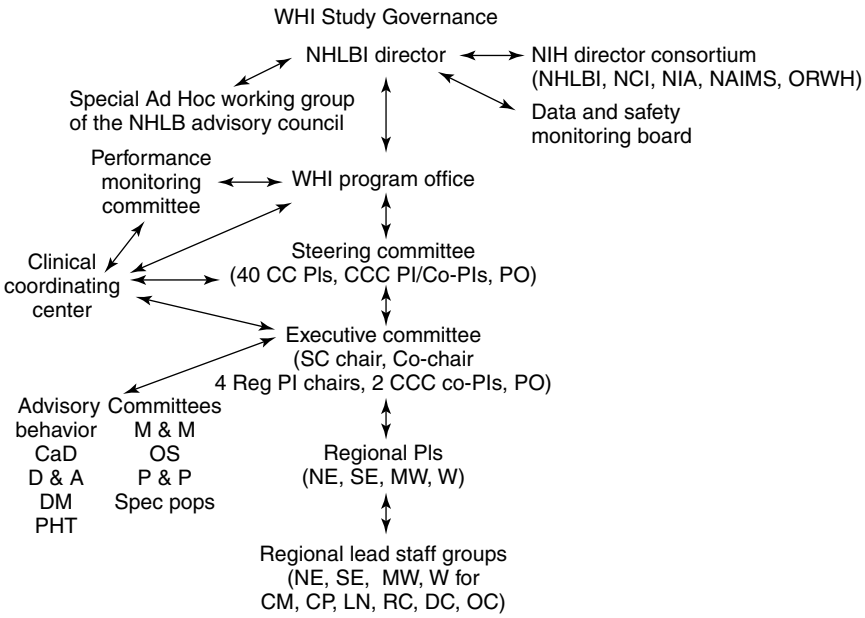

Figure 1 Organizational structure of the Women's Health Initiative. NHLBI: National Heart, Lung, and Blood Institute; NIH: National Institutes of Health; PI: Principal Investigator; SC: Steering Committee; CC: Clinical Center; CM: Clinic Manager; LN: Lead Nutritionist: CP: Clinic Practitioner; DC: Data Coordinator; OC: Outcomes Coordinator

calculations for key outcomes for each continuing CT component. Relative to the basic WHI design manuscript [11], these calculations have been updated to reflect the sample size and age distribution achieved, and to reflect the actual average follow-up duration, which will be realized by March 2005.

The target sample sizes noted above were based on consideration of the probability of rejecting the **null hypothesis** of no treatment effect (i.e. power) on the designated primary outcome under a set of design specifications concerning age-specific control group primary outcome incidence rates, intervention effects on incidence rates as a function of time from randomization, intervention adherence rates, and **competing risk** mortality rates. These assumptions have previously been listed in [11] where an extensive bibliography is cited providing the rationale for these assumptions.

The power calculations were based on weighted **logrank** statistics that accumulate the differences between the observed numbers of primary outcome events in the intervention group and the expected number of such events under the null hypothesis, across the follow-up time period. Early events that may be less likely to be affected by intervention activities are downweighted relative to later events. Specifically, the observed minus expected differences are weighted linearly from zero at randomization to a maximum value of one at a certain time from randomization and are constant(at one) thereafter. For cardiovascular disease and fracture incidence, this "certain time" was taken to be three years, whereas for cancer and mortality, it was taken to be 10 years. For coronary heart disease, incidence of the event times are grouped into three-year follow-up periods, in order to accommodate the inclusion of silent myocardial infarctions detected by routine electrocardiograms, which are to be obtained at baseline and every three years during follow-up for CT participants. A weighted **odds ratio** test statistic is then used to acknowledge this grouping.

Table 1 shows the number of enrollees, and percentages of the total, by age category for each component of the CT and the OS. Note the degree of correspondence to the target age distribution, especially in the PHT component. Such correspondence was achieved by the closure of age-specific cells as the target numbers were approached.

Table 2 shows the projected power; that is, the probability of rejecting the null hypothesis, for the

Table 1 Women's Health Initiative sample sizes (% of total) by age group (as of 4/1/00)

Age group	Dietary modification	Postmenopausal hormone therapy		Calcium and vitamin D	Observational study
		Without uterus (E-alone)	With uterus (E + P)		
50–54	6961 (14)	1396 (13)	2029 (12)	5157 (14)	12 386 (13)

Table 2 Statistical power for each component for the CT

Outcome	Disease probability (%) (×100)[a]		Intervention effect[b] (%)	Avg. follow-up duration (yrs)	Projected power (%)
	Control	Intervention			
Dietary modification component	–	–	–	–	–
Breast cancer	2.72	2.35	14	8.5	84
Colorectal cancer	1.39	1.12	19	8.5	87
CHD	3.78	3.27	14	8.5	84
Postmenopausal hormone therapy – E-alone	–	–	–	–	–
CHD	4.63	3.67	21	8.5	72
Hip fracture	2.86	2.25	21	8.5	55
Combined fracture[c]	11.02	8.81	20	8.5	97
Breast cancer	4.38	5.36	(22)	13.5	71
Calcium and vitamin D	–	–	–	–	–
Hip fracture	2.23	1.77	21	7.5	88
Combined fracture[c]	8.93	7.23	19	7.5	>99
Colorectal cancer	1.25	1.02	18	7.5	66

[a] Cumulative disease probability to planned termination (×100)
[b] One minus ratio of control to intervention cumulative incidence rates at study termination (×100)
[c] Includes proximal femur, distal forearm, proximal humerus, pelvis, and vertebra

key outcomes for each continuing component of the CT, taking account of the age-specific sample sizes in Table 1. Projected power is given at planned termination in early 2005, in which case the average follow-up duration will be about 8.5 years in the DM and PHT components and about 7.5 years in the CaD component. The intervention effects shown in Table 2 represent the projected effect size after accounting for assumed nonadherence and loss to competing risks. Comparison with projected power calculations at the design stage [11] indicates that a somewhat prolonged recruitment period, and the minor departures from target in sample sizes by age category had rather little effect on projected study power. The CHD and hip fracture power projections for the E-alone versus placebo comparison is somewhat reduced by a smaller than targeted sample size (10 739 versus 12 375) in this CT component. Power calculations for representative comparisons in the OS have been previously given [11].

An independent **Data and Safety Monitoring Board** (DSMB) is charged with monitoring the CT to ensure participant safety, to assess conformity to program goals, and to examine whether there is a need for early stoppage or other modification of any CT component. The DSMB is composed of senior researchers, otherwise not associated with the study, who have expertise in relevant areas of medicine, epidemiology, biostatistics, clinical trials, and ethics. The DSMB meets biannually to review study progress, including its status in the context of emerging external data. The Board provides recommendations to the NHLBI Director (see Figure 1). The DSMB reviewed and approved the protocol

(*see* **Clinical Trials Protocols**) and consent forms (*see* **Ethics of Randomized Trials**) prior to study implementation. They are apprised of any significant changes to protocol.

Throughout the period of study conduct, the DSMB reviews data on recruitment, adherence, retention, and outcomes. The DSMB is the only group given access to treatment arm comparisons outside of the necessary CCC and NHLBI staff. As such, they determine whether the existing data demonstrate either significant or unanticipated risk or unexpectedly strong benefits, in which case early trial termination, or modification, may be recommended (*see* **Benefit/Risk Assessment in Prevention Trials**). A particular complexity in this study, as often exists in prevention studies, is the need to consider effects on multiple disease processes that may differ in direction, timing, and magnitude.

In the WHI, CT monitoring for consideration of early stopping (*see* **Data and Safety Monitoring**) is based on the following principles and procedures:

- Each trial component (DM, Estrogen alone, Estrogen plus Progestin, CaD) is evaluated separately, so that a stopping decision for one will not necessarily impact the continuation of the other three.
- The evaluation of each intervention includes an assessment of the overall intervention effects on health, through the use of a global index. This global index is defined for each woman as time to first incident event. The events to be included were selected on the basis of *a priori* evidence for each intervention, and supplemented with evidence of death from other causes to capture serious unanticipated intervention effects, as shown in Table 3.
- Early stopping for benefit would be considered, if the primary endpoint comparison crossed a 0.05 level O'Brien–Fleming (OBF) boundary (*see* **Data and Safety Monitoring**), and the global index provided supportive evidence defined by crossing the 0.1 level OBF in favor of the intervention. For the DM, a **Bonferroni** correction is used to acknowledge the fact that there are two designated primary endpoints. This correction allows a stopping recommendation to be made if the boundary is crossed for either of the primary endpoints, without exceeding the designated probability (0.05) of falsely rejecting the overall null hypothesis.
- Early stopping for adverse effects uses a two-step procedure with a 0.1 level OBF boundary for primary safety endpoints, a Bonferroni corrected 0.1 level OBF boundary for all other safety endpoints, and a lower boundary of $z = -1.0$ for the global index to signify supportive evidence for overall harm.

As mentioned above, weighted logrank test statistics are used to test the difference between intervention and control event rates for each outcome. These weights were specified to yield efficient test statistics for the primary outcome under CT design assumptions. As such, these tests may not be sensitive to unexpected effects, whether adverse or beneficial, on any of the study outcomes. Consequently, the DSMB also informally examines unweighted logrank statistics, as well as weighted and unweighted tests for various intervals of time since randomization and for selected subgroups of participants (e.g. specific age groups), toward ensuring participant safety. Further detail on CT monitoring methods and their rationale is given in [6].

Table 3 Trial monitoring endpoints for the WHI clinical trial components

	PHT (E-alone and E + P)	DM	CaD
Primary endpoint	CHD	Breast cancer, Colorectal cancer	Hip fractures
Primary safety endpoint	Breast cancer	N/A	N/A
Other endpoints included in the global index	Stroke, Pulmonary embolism, Hip fractures, Colorectal cancer, Endometrial cancer, Death from other causes	CHD, Death from other causes	Colorectal cancer, Breast cancer, Other fractures, Death from other causes

CT monitoring reports, prepared on a semiannual basis throughout trial follow-up, also present data on the adherence to intervention goals, the rates of participation in follow-up and other program activities, and control group incidence rates. These data are used to update power calculations, along the lines of Table 2, to help assess conformity to overall design goals, and to alert the DSMB to emerging problems. Data on selected biomarkers and intermediate outcomes are also assembled, as such data can provide an objective assessment of the extent to which intervention goals are achieved, and can provide insights into processes that can explain intervention effects on disease outcomes.

Biomarkers and Intermediate Outcomes

Beyond testing primary and secondary hypotheses, the CT is designed to support specialized analyses to explain any treatment effects in terms of intermediate outcomes, and both the CT and OS are designed to produce new information on **risk factors** for cardiovascular disease, cancer, and other diseases. To do so, the basic WHI program supports a substantial infrastructure of archival blood product storage, which includes serum and plasma from CT and OS participants at baseline, and at selected follow-up times (one year from enrollment in the CT and three years from enrollment in the OS). In addition, baseline white blood cells (buffy coat) are stored in both the CT and OS. These blood specimens are used for specialized studies related to participant safety and CT intervention adherence, and for externally funded ancillary studies. Stored blood components collected from each CT and OS participant during screening include 7.2 mL serum (in 4×1.8 mL vials), 5.4 mL citrated plasma (in 3×1.8 mL vials), 5.4 mL EDTA plasma (in 3×1.8 mL vials), and two aliquots of buffy coat.

Intermediate outcome data collected in the CT include electrocardiograms (obtained as baseline, 3, 6, and 9 years among all CT women) to ascertain "silent" myocardial infarctions and other cardiac diagnoses, and bilateral mammograms (obtained annually for PHT women and biennially for other CT participants). In addition, all PHT women, 65 years of age and older, have cognitive function assessment, and a 25% sample have functional assessment, at baseline and follow-up. A sample of women in both the CT and OS (all those who are enrolled at any one of three specified clinical centers) have dual x-ray absorptiometry at baseline, and at follow-up years 1 (CT only), 3, 6, and 9, to measure change in bone mass in the hip, spine, and total body; these women also provide urine specimens that are stored for studies of the interventions' effects on bone metabolites.

Analyses to explain CT treatment effects, and CT/OS analyses to elucidate disease risk factors, generally take place in a **case–control** or **case–cohort** fashion, to limit the number of specialized analyte determinations. Extensive self-report questionnaire data at baseline and selected follow-up times are also available for use in these analyses, and can be used to inform the case–control sampling procedure.

Data Management and Computing Infrastructure

The size and scope of the WHI creates a large and rather complex data processing load (*see* **Data Management and Coordination**). Each clinical site has recruited at least 3000 participants creating a local data management load as large as that for many multicenter trial coordinating centers.

The data collected for WHI fall roughly into three categories: self-report, clinical measurements, and outcomes data. Self-reported information includes demographic, medical history, diet, reproductive history, family history, and psychosocial and behavioral factors. For these areas, standardized questionnaires were developed from instruments used in other studies of similar populations. Current use of medications and dietary supplements is captured directly from pill bottles that participating women bring to the clinic (*see* **Compliance Assessment in Clinical Trials**). To capture details of hormone therapy use prior to WHI enrollment, an in-person interview was conducted with each woman at baseline to determine her entire history of postmenopausal hormone use. For additional diet information in the DM trial beyond routine food frequency questionnaires, 4-day food records and 24-hour recall of diet are obtained from a subsample of women. Dietary records are completed by the participant, reviewed and documented by certified clinic staff, and a subsample is sent to the CCC for nutrient coding and analysis. The 24-hour recalls of diet are obtained by telephone contact from the coordinating center and these data were coded using the same methods as for the dietary records.

Clinical measures such as anthropometrics, blood pressure, functional status, and results from gynecologic exams are obtained by certified WHI clinic staff using standardized procedures and data collection forms and key-entered into the local study database. Limited blood specimen analyses are conducted locally and recorded. The remaining blood specimens are sent to a central blood repository where they are housed until the appropriate subsamples are identified and sent to the central laboratory for the selected analyses. Electrocardiogram and bone densitometry data are submitted electronically to respective central reading and coordination facilities.

Information on significant health outcomes is initially obtained by self-report. If the type of event is of particular interest for WHI research, additional documentation is obtained from local health care providers and this information is used by a clinic physician to classify and code the event. Additional details of outcomes definitions and methods appear elsewhere [5].

Data quality assurance mechanisms are incorporated at several levels, in addition to the overall quality assurance program described below (*see* **Clinical Trials Audit and Quality Control**). Data entry screens incorporate range and validity checks, and scanning software rejects forms containing critical errors. Routine audits of randomly selected charts document errors and provide feedback to CC and CCC staff. Additional data quality checks are used in creating analytic data sets. Multiple versions of most forms have been used, so some data items require mapping across versions.

To support the large requirement of local operations as well as central analyses and reporting, the CCC developed and implemented a standardized computing and **database management system** that serves each clinical center site and the coordinating center. This computing system can be logically divided into three major areas: computing at the clinical centers, computing at the CCC, and a private wide area network (WAN). The study-wide database uses this infrastructure to provide the appropriate data management tools to all sites.

Each clinical center is equipped with its own local area network consisting of a file server, ethernet switch, 10 to 20 workstations, two or more printers, a mark sense form reader, bar code readers, and a router. The router provides connectivity back to the CCC over the WAN. In some cases, the router also provides connectivity to the parent institution. The file server is configured with Windows NT Advance Server and runs its own instance of the study's Oracle database. The server also provides standardized office applications (Microsoft Office) and e-mail (Microsoft Exchange Web client). The workstations are Windows 98 clients.

The CCC maintains a cadre of application servers dedicated to the development, testing, and warehousing of the consolidated database, currently requiring 100 GB. The CCC also maintains several other servers dedicated to statistical analysis, administrative support for CCC staff, website and e-mail services for study-wide communication, and centralized automated backup for all study servers. The website and e-mail system dedicated to WHI staff and investigators is critical to managing the challenges of study communications with nearly 1500 WHI staff and investigators spread across 5 timezones. The website provides a kind of electronic glue for bringing together disparate groups. WHI e-mail access is available through the website either over the WAN or through the Internet.

The WHI WAN is a private network, which connects CCs to the CCC using a combination of 56 k and T1 frame-relay circuits. The WAN enables the CCC to conduct nightly backups of clinical center file servers. It also facilitates remote management and troubleshooting of clinical center equipment. In addition, it provides CCs direct access to the WHI e-mail system and website.

The WHI database management system is a distributed replicated database, implemented in Oracle 8.0 for Windows NT. Database design and table structure are identical across CCs but are populated only with data specific to that site. The average clinical center database currently requires approximately 15 GB of space. Data acquisition relies heavily on mark sense scanning, supplemented with traditional key entry and bar code reading. The database supports and enforces the study protocol through its participant eligibility confirmation, randomization, drug dispensing, and collection, visit and task planning, and outcomes processing functions. Security is provided both by password protection and by limiting access to specific data based on the identified role of the user. Local access to clinical site-specific data is supported through centrally defined reports and a flexible data extract system.

The CCC database provides the superstructure into which the CC data are consolidated routinely. Additional data are obtained from the central laboratories and specimen repository and are merged with, and checked against, the corresponding participant data. The central database serves as the source of all data reports and analyses.

Quality Assurance Program Overview

The WHI program involves a complex protocol, with an extensive set of required procedures. The CT intervention goals and the study timeline are demanding program elements. With these challenges, an organized quality assurance (QA) program was needed to identify and correct emerging problems. The QA program is an integral part of the study protocol, procedures, and database, and covers all aspects of WHI. The program seeks to balance the need to assure scientific quality of the study with available resources. The complexity, size, and fiscal responsibility of WHI necessitated establishing priorities to guide local and central QA activities.

The WHI QA priorities were developed by a task force comprising WHI investigators and staff, under the premise that aspects critical to the main scientific objectives of WHI would be of highest priority. As the centerpiece of WHI, the fundamental elements of the CT are considered of highest priority. The next highest priority is given to key elements of the OS and elements of the CT that are important for interpretive analyses. The remaining elements are given a lower priority. The implementation of these priorities is manifested in the frequency and level of detailed QA activities.

QA methods and responsibilities include activities performed at the CCs as well as activities initiated and coordinated by the CCC. The QA Program includes: extensive documentation of procedures; training and certification of staff; routine QA visits conducted by the CCC (all CCs received an initial and an annual QA Visit while subsequent visits are done approximately every other year, or more frequently as needed); and database reports for review by CCs and pertinent committees describing the completeness, timeliness, and reliability of tasks at the CCs. For example **moving average** monthly intervention adherence rates, and major task completeness rates, for each CC are used as one up-to-date indicator of CT status.

WHI has established performance goals for various important tasks that are centrally monitored. These goals were determined on the basis of design assumptions and, where available, on previously published standards of quality and safety.

The performance of each CC is reviewed on a regular basis under a performance monitoring plan. This plan is used to identify clinic-specific performance issues in a timely fashion, to reinforce good performance and to provide assistance or to institute corrective action if performance is inadequate. Much of this work is conducted under the auspices of a performance monitoring committee (PMC), comprising representatives of the CCC, CCs, and PO. The PMC follows up on persistent issues with specific CCs, and conducts site visits to facilitate the resolution of specific areas of concern. Some additional detail on the implementation of the WHI design is given in [2].

Early Results from the WHI Clinical Trial

In late May 2002, after an average follow-up of 5.2 years, the DSMB recommended the early stopping of the E + P trial component because the weighted logrank test for invasive breast cancer exceeded the OBF stopping boundary for this adverse effect and the global index supported risks exceeding benefits.

Participating women in the E + P trial were asked to stop taking their study pills on July 8, 2002 and principal trial results were published soon thereafter [13]. Women in the E + P trial continue to be followed without intervention through 2005, and a plan is under development for the additional nonintervention follow-up of PHT women from 2005 to 2007.

On the basis of data through April 2002, the E + P trial generated **hazard ratio** estimates and nominal 95% **confidence intervals** as follows: coronary heart disease 1.29 (1.02–1.63), breast cancer 1.26 (1.00–1.59), stroke 1.41 (1.07–1.85), pulmonary embolism 2.13 (1.39–3.25), colorectal cancer 0.63 (0.43–0.92), endometrial cancer 0.83 (0.47–1.47), hip fracture 0.66 (0.45–0.98), and death due to other causes 0.92 (0.74–1.14). The global index, defined as the earliest event of these just listed, had a hazard ratio estimate (nominal 95% confidence interval) of 1.15 (1.03–1.28). Absolute **excess risks** per 10 000 **person years** were estimated as seven for coronary

heart disease, eight for stroke, eight for pulmonary embolism, and eight for breast cancer, while corresponding absolute risk reductions were estimates as six for colorectal cancer and five for hip fracture. The absolute excess risk for global index events were estimated as 19 per 10 000 person years. Confidence intervals adjusted for sequential monitoring (*see* **Sequential Methods for Clinical Trials**), and for multiple testing (*see* **Multiplicity in Clinical Trials**) in accordance with the CT monitoring plan are also given in [13].

Even though these risk alterations are fairly modest, they have substantial population implications for morbidity and mortality. As a result of these findings, various professional organizations have altered their recommendations concerning combined hormone use, and labeling changes have been made or are under consideration. These results follow decades of observational studies supporting a cardioprotective benefit for hormone therapy, and the discussion following the reporting of E + P trial results has sharpened the understanding of comparative properties of trials and observational studies among scientific groups and the general population. Additional outcome events through July 7, 2002 have been adjudicated and several more specialized results papers have been published [1, 3, 4, 7, 8, 12]. An ancillary study examining the effects of E + P on dementia and cognitive function has also been published [9, 10].

Summary and Discussion

The WHI, CT, and OS was implemented in close correspondence to design specifications [11]. Departures from design assumptions concerning sample size, age distribution, and projected average trial follow-up have limited effect on the adequacy of primary outcome study power for continuing CT components, with the possible exception of the E-alone versus placebo comparison, where some power reduction for coronary heart disease arises from a smaller than targeted sample size. Substantial infrastructure for specimen storage, routine analyte determination, data management and computing, and for data and protocol quality control was also implemented. Principal results from the trial of combined hormones (E + P) have been presented following the early stopping of intervention.

Ongoing challenges in the CT and OS include retaining the active participation of study subjects over a lengthy follow-up period, ensuring the unbiased and timely ascertainment of outcome events in each CT component and in the OS and, perhaps the most challenging, ensuring an adequate adherence to intervention goals for each continuing CT intervention.

The astrogen-alone component of the WHI clinical trial stopped early on March 1, 2004 with principal results presented in the Journal of the American Medical Association 291; 1701–1712, 2004.

Acknowledgments

This work was supported by NIH contracts for the WHI. Parts of this entry are closely related to a forthcoming monograph chapter [2] by the authors and other WHI colleagues.

ROSS L. PRENTICE & GARNET L. ANDERSON

Worcester, Jane

Born: December 5, 1910.
Died: October 8, 1989, in Falmouth, Mass.

Jane Worcester was the first female Department Chair of Biostatistics at Harvard School of Public Health. Her career in the department spanned from 1931, when she came to the department as a mathematical computing assistant after receiving her A.B. from Smith College, to 1977, when she retired as Department Chair and Professor of Biostatistics and Epidemiology. Dr Worcester liked to relate to her students the story of her first position in the department as "Computer". Dr Worcester received a Dr. P.H. from Harvard in 1947 and an honorary Sc.D. from Smith in 1968. She was one of the earliest non-Radcliffe women to become a full professor at Harvard at a time when there were no women in the Faculty of Arts and Sciences, the Law School, or the Medical School. She served as an important role model for many women in academics.

During the 46 years that Dr Worcester spent with the department, she devoted her time to research, teaching, and service both to the School and to the discipline of biostatistics. She was the center of gravity of the department for a very long time, during which both faculty and students sought her advice. Dr Worcester stimulated her students to achieve more than they thought they could accomplish and encouraged them to grow (*see* **Teaching Medical Statistics to Statisticians**). In describing Dr Worcester's influence on the students in the department, Ray Neff, Sc.D. '77, considered her "an archetypal mentor". Charles Ralph Buncher, Sc.D. '67, remembered the story of when Dr Worcester returned from the oral qualifying examination of Joseph Brain, now Professor and Chair of the Department of Environmental Health at the School. She exclaimed, "What a joy it was because I learned so much!"

Dr Worcester provided a consulting role for research in a range of areas in public health. She worked very closely with the editors and editorial board of the *New England Journal of Medicine* and taught her students how to review the medical literature (*see* **Statistical Review for Medical Journals**). She also worked with laboratory scientists and the Department of Nutrition at the School and viewed the involvement as a tool to provide students with an active, practical, learning environment and also to offer help to other scientists. Jane Menken, Ph.D., described Dr Worcester as "someone whose intense dedication to the School and scientific inquiry were obvious to all who knew her, and those who associated with her were indeed very fortunate".

NAN M. LAIRD

World Health Organization (WHO): Biostatistics and Epidemiology

The World Health Organization (WHO) was established in April 1948 as a specialized agency of the United Nations, taking over the functions of the Office International d'Hygiène Publique, the Health Organization of the League of Nations, and the Health Division of the United Nations Relief and Rehabilitation Administration (UNRRA). The practical tasks of WHO were seen as supplying technical aid in combating epidemics such as cholera, malaria, smallpox, tuberculosis, etc., and particularly as assisting less developed and financially weak countries to improve their medical and health services.

In the general area of health statistics and epidemiological **surveillance**, WHO's responsibilities included the establishment and maintenance of administrative and technical services, including epidemiologic and statistical services; the provision of information, counseling and assistance in the field of health; and the founding, with revision where necessary, of an international nomenclature of diseases, causes of death and public health practices (*see* **International Classification of Diseases (ICD)**). Member States had corresponding obligations to communicate to WHO important laws, regulations, official reports, and statistics relating to the health field, and especially to provide appropriate statistical and epidemiologic reports. For a more detailed historical account of developments over the period 1948–1988, see the excellent review by Uemura [8].

In addition to WHO's headquarters (WHO/HQ) in Geneva, there are separate Regional Offices in the six regions of Africa, the Americas, Eastern Mediterranean, Europe, South-East Asia and the Western Pacific, besides several other special offices. Like many other international organizations, WHO's staff and responsibilities are widely, but thinly, spread and increasingly insufficiently funded. Despite these difficulties, much excellent work is carried out in maintaining a high standard of public health review through the mechanism of Expert Committees, promotion of collaboration with country projects, development of advisory services and training programs, etc.

Essential statistical activities were developed and formulated by the WHO Expert Committee on Health Statistics, and in 1949 a Health Statistics Division was created in WHO/HQ. The direct use of biostatistical methods expanded only gradually until in 1967 a special effort was made to establish at HQ a Division of Research in Epidemiology and Communication Science (RECS). This Division incorporated individual units covering **communicable diseases**, noncommunicable diseases, social systems, environmental aspects, **operational research**, and computer science – following the installation of a central computer facility in 1966.

In principle, this development should have greatly increased WHO's stature and capabilities over the whole area of applied biostatistics. Unfortunately, the expected collaboration between RECS and the long-standing Units and Divisions of WHO/HQ never took place. A great deal of first class research work was carried out and duly published, but as the initial expectations were not realized, RECS was disbanded in 1972 after five years of serious biostatistical efforts.

Most of the RECS technical staff were then transferred to other areas of WHO/HQ, and the Division of Health Statistics was itself greatly strengthened in this way. In particular, one can cite the development of dynamic modeling applied to several communicable diseases including typhoid fever, cholera, tetanus, diphtheria, whooping cough, and tuberculosis. Early on there was the epidemiologic modeling of the spread and control of tuberculosis by Waaler & Piot [9] in the Tuberculosis Unit which involved some discussions with RECS. Later on it became clear that one of the most significant achievements of RECS was the construction of a malaria model closely tied to field investigations in Africa (see Dietz et al. [4]). Also to be mentioned are the books by Bailey on the mathematical theory of infectious diseases [1] and the biomathematics of malaria [2]. Many other studies, such as the MONICA project on monitoring trends and determinants in cardiovascular disease [10], carried out in a large number of countries, were also promoted and strengthened by the spread of ideas and techniques arising from the RECS period. For further discussion of these matters see Uemura [8], as already mentioned above.

On the other hand, there is the failure of WHO's communicable disease statistics, dealing largely with limited country-by-country data, to elucidate the worldwide process of spatial diffusion. Much important work of direct practical relevance has already been done by geographers and statisticians. See, for example, Cliff et al. [3] on the spread of measles; Gould [5], and Gould & Wallace [6], on the spatial diffusion of HIV and **AIDS**; as well as a whole recent issue of *Statistical Methods in Medical Research* [7] entitled "Spatial Epidemiology" (*see* **Epidemic Models, Spatial**).

Now, what is the role of biostatistics in the whole WHO program? Most technical biostatistical publications are highly mathematical, and are largely not understood, even in principle, by those who might use the methods and results in practical applications to medicine, epidemiology, and public health. Even when the research papers seem to be applied they are often using simplified real data only for illustrative purposes. The real-life problems faced by administrators and decision-makers are therefore mostly neglected. A fully effective application of biostatistics in the whole public health field requires a major collaborative effort of an operational research character.

Finally, let us consider what should be done. Well-organized multidisciplinary teams to cover the epidemiologic modeling of both communicable and noncommunicable diseases, involving relatively small groups of individuals with overlapping skills, should be established so as to include a spectrum from purely scientific expertise to those engaged in real-life decision-making. This implies operational research on a global level.

The world clearly needs all the applied technical skills it can get to control, and eradicate where possible, a very wide range of life-threatening diseases – some well known, others newly emerging.

World Health Organization (WHO): Global Health Situation

To recognize the development of epidemiologic and statistical activities and trend assessment in the World Health Organization (WHO), it is first important to review the contribution of epidemiology to world health. Epidemiology originated in response to a need to understand and control the highly infectious epidemic diseases, such as cholera, plague, smallpox, and yellow fever. It was only with time that appreciation grew of the fact that all conditions of disease and ill-health are interrelated, and that the emerging science of epidemiology provided the tools for helping to understand the major factors underlying these issues as well [1].

International health work also began with a concentration on infectious diseases (*see* **Communicable Diseases**), and then moved towards a wider concept of health as part of overall development. The roots of the World Health Organization, as an international health agency, go back to efforts in the last century, and early in this century, particularly to the Rome Agreement of 1907, which established the Office International d'Hygiène Publique, with the express purpose "to combat infectious diseases". The progressive shift of the concept of health, from the prevention of infectious diseases to viewing health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity", is reflected in the successive evolution of the Pan American Sanitary Bureau, founded in 1902, the health services arm of the League of Nations, founded in 1918, and finally WHO, founded in 1948 [1].

Epidemiology has provided the tools for a better understanding of the incidence, **prevalence, natural history**, causes (*see* **Causation**), and effects of control and other measures that are relevant to each of the communicable disease control programs of WHO. More than this, the epidemiologic sciences have enabled us also to understand noncommunicable diseases such as cancer (*see* **Oncology**), cardiovascular diseases, (*see* **Cardiology and Cardiovascular Disease**), and genetic disorders (*see* **Genetic Epidemiology**). In the area of primary prevention this understanding has allowed for intervention before the onset of disease [1].

WHO has a constitutional responsibility for the global epidemiologic **surveillance of disease**. It receives information on outbreaks of communicable disease and distributes this information throughout the world by telecommunication and its publication *Weekly Epidemiological Record*. The WHO system of international epidemiologic surveillance provides countries with access to information. This includes the countries that otherwise would not be able to communicate directly with each other. WHO is responsible for the *International Health Regulations*, the **International Classification of Diseases**, and a great many international standards, which together make international epidemiologic comparisons possible. WHO also publishes the *World Health Statistics Quarterly*, the *World Health Statistics Annual*, the *World Health Report*, and other publications of an epidemiologic nature [1].

Twenty years ago, the Thirtieth World Health Assembly decided that the main social target of governments and WHO in the coming decades should be health for all by the year 2000. One year later, in 1978, at a major international conference at Alma-Ata, primary health care was declared to be the key to attaining this goal, in the spirit of social justice. The policies and strategies for "health for all" have subsequently been defined by the World Health Assembly at an international level, in the light of its own health and socioeconomic situation. Furthermore, WHO Member States have committed themselves, with the Organization, to monitoring progress towards and evaluating the attainment of this common goal, using a basic set of global indicators in addition to those applicable within each country. For the first time in the history of international health work, an epidemiologic framework is being applied on a global scale. The implication is that the science of epidemiology must be applied for strategic health planning and evaluation, in a systematic manner, in practically all countries of the world, for national and international health development purposes [1].

The health-for-all monitoring and evaluation process is intended to establish a baseline of current health and socioeconomic conditions, against which progress towards defined targets and objectives can be measured. Periodic measurement should establish trends that will permit anticipation of future conditions, and to start planning for them in advance. The three cycles of monitoring and evaluation of the health-for-all strategy that have taken place so far

make WHO optimistic that the information obtained can be used to reorient national and international priorities and directions for health development work, on the basis of sound epidemiologic evidence, reported by countries with honesty [1].

The latest evaluation was carried out late 1996/early 1997; national reports will be consolidated into regional reports to be reviewed by WHO regional committees in September–October 1997; the global findings will be reported to WHO Governing Bodies in 1998.

At the present time epidemiology and evaluation are used substantially to support health future trend assessment through scenario planning at the global, regional, and country level. A new reorientation of health statistics is also taking place in response to the trend for broader and higher-quality data requested by users. In WHO, approaching the end of the twentieth century, epidemiology, statistics, and future trend assessment provide a substantive contribution to the formulation of the health-for-all policy and strategy for the next century.

Program Activities to the End of the Twentieth Century

The Health Situation and Trend Assessment Program is at present responsible for global health situation analysis and projection; strengthening of country health information; and partnerships and coordination of epidemiology, statistics, and trend assessment. Global epidemiologic surveillance is under the responsibility of the Emerging and other Communicable Diseases Surveillance and Control Program. Various epidemiologic and statistical activities are also carried out by technical programs at WHO headquarters, e.g. Expanded Program on Immunization; Health and Environment; Information System Management; Special Program of Research, Development, and Research Training in Human Reproduction; Special Program for Research and Training in Tropical Diseases; and also its six regional offices.

As already mentioned, one of the normative functions of WHO is monitoring the health situation and trends throughout the world, for which the compilation, use, and coordination of relevant health information and statistical activities are essential. WHO evaluates the world health status and trends every 6 years and publishes its findings. It also assesses the global health status annually and, since 1995, has published *The World Health Report*. The report gives an overview of the global situation and identifies priority areas for international health action; it also links the work of WHO to global health needs and priorities (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**; **Mortality, International Comparisons**).

In headquarters this Program is carried out by the Division of Health Situation and Trend Assessment, which is comprised of the Units of Health Situation Analysis and Projection and Strengthening Country Health Information, and the Director's Office responsible for partnerships and coordination in epidemiology, statistics, and trend assessment and the *International Statistical Classification of Diseases and Related Health Problems* (ICD) besides providing direction and supervision of the Program.

The six regional offices of WHO also undertake health situation and trend assessment activities. From the Program review in 1995 the focus of the regional programs is as follows.

African Region

In the African Region priority is given to generation and utilization of epidemiologic and health information, particularly through the strengthening of national health information systems (*see* **Administrative Databases**) and epidemiologic surveillance systems. The development of epidemiology practice is based on the following approaches: integrated management of epidemiologic information systems; strengthening both data management capacity and decision-making processes, particularly at local level; combined training in epidemiology and management of health programs and health systems. Efforts are made to equip all district teams with a set of essential epidemiologic capabilities. WHO established a position of epidemiologist in each Country Office in order to support this effort.

Region of the Americas

The major achievements of the Region of the Americas include coordinating the response to the cholera epidemic, supporting the evaluation and strengthening of national health surveillance systems, support for modernization of records and statistical information systems, implementation and application of

the ICD-10, Geographic–Epidemiologic Information Systems (*see* **Geographic Patterns of Disease**; **Geographic Epidemiology**), supporting national studies of social inequities that affect health status, producing regional publications of the health situation (*Health Conditions in the Americas, Strategies to Monitor Health for All (HFA), PAHO Epidemiological Bulletin*, and *Health Statistics from the Americas*), and establishing a technical information system including country profiles, databases on mortality and population, and a bibliography on epidemiology. Efforts will continue to strengthen national epidemiologic capacities, to study inequity in health, training in epidemiology, statistics, and health situation analysis and systems, and to disseminate information (*see* **Health Services Data Sources in Canada**; **Health Services Data Sources in the US**).

Eastern Mediterranean Region

The Eastern Mediterranean Region has cooperated and will continue to cooperate in the development of health information systems in Member States, by providing technical support, strengthening national capabilities through fellowships and workshops, developing a regional database and publishing guidelines and manuals to improve health information management design, implementation, and use in the decision making process.

European Region

In the European Region the main tasks are collecting and analyzing health information for periodic reports of progress towards health for all by the year 2000 (entitled "Health in Europe"), regularly updating and disseminating information from the health-for-all database to Member States (available also from `http://www.who.dk`), and supporting training in epidemiology and health information. A European Public Health Information Network (EUPHIN) is being established (together with the EC) to enable telematic reporting and exchange of data for international comparisons. As part of this initiative, efforts continue to improve international data comparability by developing and encouraging countries to use standard definitions, measurement instruments, and methods.

At the country level, the European Regional Office assists countries in developing and using national health and health service databases like the health-for-all database, as a means for making better use of available health data at national and local level. The European Regional Office also produces country "highlights" which give an overview of the health and health-related situation in a given country and compare, where possible, its position in relation to other countries in the WHO European Region (also available from `http://www.who.dk`).

The intention in all cases is to make better use of available health information, which will in itself help to improve data quality and comparability, and enable national and local agencies and institutions with health responsibilities to have easy access and benefit from the activities and product of the European Regional Office (*see* **Health Services Data Sources in Europe**).

Southeast Asia Region

In the Southeast Asia Region support to countries has focused on the strengthening of health management information systems at the central and district level, and the enhancement of mortality and morbidity statistics (*see* **Vital Statistics, Overview**). Attention will continue to focus on developing health management information systems in interested countries. Epidemiologic surveillance, the use of "health futures" methodology, and health data processing and rational use is being further enhanced.

Western Pacific Region

The Western Pacific Region is engaged in technical cooperation to strengthen epidemiologic surveillance and cholera control, support field epidemiology training, improve medical records, birth registration documentation and health information systems, and provide guidelines and manuals. Future activities include reformulation and construction of a new regional database, increased coordination with technical units, strengthening of current activities, and research on more sensitive indicators and associated analytic methods for monitoring and evaluation.

Main Activities at Global and Regional Level

The Program's main activities at the global and regional level from around 1997 to 1999 can be summarized as follows:

1. *Global health situation analysis and projection*. Updating databases on mortality, health-for-all data resulting from the third global evaluation and global health futures information; reporting on the third global evaluation of the implementation of the health-for-all strategy (to be published in the *World Health Report 1998*); improving and formulating new indicators and updating the common framework for the fourth monitoring of the implementation of the health-for-all strategy; issuing the *World Health Statistics Annual 1997 and 1998*, and the *World Health Statistics Quarterly*, volumes 51 and 52; updating the documents "Global health situation analysis and projection" and "Demographic data for health situation and projections"; and validating global health and health-related data and information. At the regional level preparing and distributing regional reports on the world health situation; maintaining and updating databases of health statistics; and improving the health-for-all strategy through the findings of the third evaluation of the implementation of the Strategy.
2. *Strengthening country health information*. Contributing to defining universal public health functions; providing guidance on assessing performance of public health functions and defining the minimum information required for their monitoring and management; preparing methodology for rapidly assessing availability and use of information for managing the essential public health functions; preparing guidance materials and supporting processes for enhancing various information functions and support systems; and undertaking a series of applications of the above methods within interested countries. At the regional level providing advisory services and support to countries; enhancing national information systems and assisting countries in applying various methodologies such as health futures and rapid evaluation.
3. *Partnerships and coordination in epidemiology, statistics, and trend assessment*. Forming partnerships and coordination in epidemiology, statistics and trend assessment with related WHO programs, regional offices and international organizations; preparing an international agreement on a taxonomic approach for medical procedures and guidelines for establishing national classifications; providing guidance on medical certification of causes of death. At the regional level improving partnerships in epidemiology, statistics, and trend assessment, and holding computer-based training courses in the use of ICD-10.

It is important to note that the Division of Health Situation and Trend Assessment is responsible for the development, maintenance, and coordination of the *International Statistical Classification of Diseases and Related Health Problems* (ICD) and other members of the "family" of disease and health-related classifications in both English and French.

The future prospect of ICD can be highlighted as follows. More than 60 Member States submit national mortality data to WHO on a routine basis. Twenty-eight of these Member States have already implemented the tenth revision of the ICD (ICD-10), which was published by WHO in 1992–93, for either mortality or morbidity coding or both. Twenty-two Member States in the Region for the Americas have received training in the use of ICD-10 but have not yet implemented it. A further nine Member States have indicated that they plan to implement it before the year 2000. It can be assumed, therefore, that by the year 2000 the vast majority of the countries currently submitting mortality data will have moved to ICD-10, though the actual data may not be available until some 2–3 years later. It is hoped that the planned publication of a simplified three-character version of ICD-10 will encourage more developing countries to use the classification. In general, it is estimated that, approaching the twenty-first century, most developed countries will have implemented ICD-10. On the other hand, in developing countries the classification will be implemented step by step in line with the speed of the strengthening of the capability of their vital and health statistical infrastructures.

At the global level the Division of Emerging and other Communicable Diseases Surveillance and Control publishes the *Weekly Epidemiological Record*; updates annually *International Travel and Health*; revises the International Health Regulations; and rapidly exchanges information through electronic media with WHO Collaborating Centers, public health administrations and the general public.

At the present time the Health Situation and Trend Assessment Program is implemented with support from various professional staff, especially

epidemiologists, statisticians, medical officers, and public health specialists.

Vision for the Use and Generation of Data in the First Quarter of the Twenty-first Century

Epidemiologic and health statistical activities in WHO are now operational through dynamic networking with various parties at the global, regional, and country level. From experience at the global and regional level and in many countries, the trend of information required by users is towards more specific and higher-quality information. Figure 1 highlights the information on health status and determinants required by most users.
The generation of data and information can usually be grouped into four main activities:

1. Collection, validation, analyses, and dissemination of data and information.
2. Support activities and resources, especially through cooperation with Member States in strengthening country health information.
3. Research and development activities.
4. Partnerships and coordination of information activities.

Figure 2 shows these activities and their interconnection. From experience this diagram is helpful in visualizing the complex issues of information activities.

On the basis of experience and future prospects the trends of the use and generation of information are briefly described in Table 1. The trends here shown take into consideration the main change in the use of data and the various activities involved in the generation of data. It is hoped that the main trends from 1975 to the end of the century are clearly highlighted in the table.

From the WHO Global Health Situation Analysis and Projection from 1950 to 2025 it is possible to foresee the future prospects of health situation and trend assessment in the early part of the twenty-first century, as summarized below.

1. The various users of information will request many types of information or data, all of which should be up-to-date and of high quality. This kind of request will not only come from the user in developed countries but also from many users in developing countries.
2. On the generation of information:
   (i) In the collection, validation, analysis and dissemination of data and information the emphasis will be on data concerning health status (*see* **Quality of Life and Health Status**) (health, **life expectancy**, mortality, disability, morbidity), health resources (including financial) (*see* **Health Care Financing**), physical and manpower resources (*see* **Health Workforce Modeling**), health services,

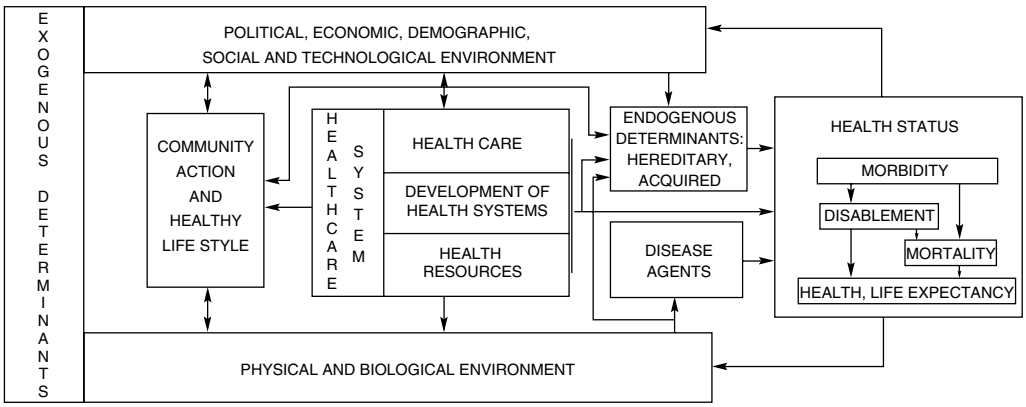

Figure 1 Health status and determinants. Adapted from *Sistem Kesehatan Nasional [National Health System]*, Annex 1. Jakarta, Ministry of Health, 1984 and *Public Health Status and Forecast*, Figure 1.3.3, The Hague, National Institute of Public Health and Environmental Protection, 1994

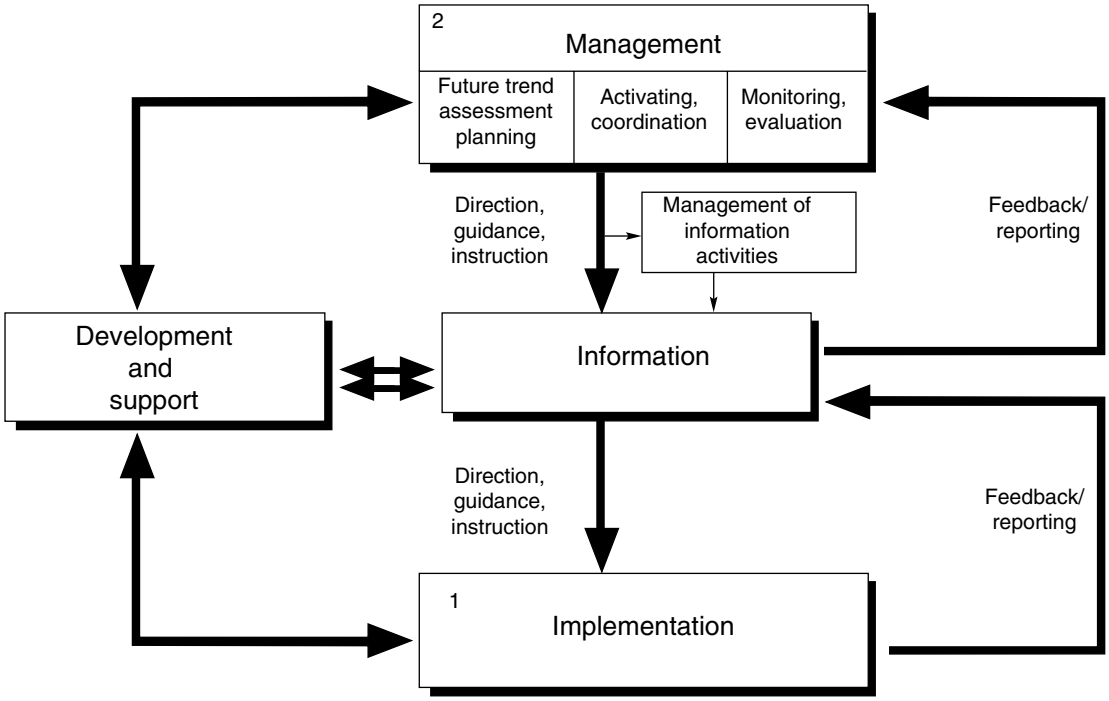

Figure 2 Relationship between information and implementation, management and development activities

Table 1 Brief review of development of main health situation and trend assessment activities at country, regional, and global level

Main activities	1975–87	1988–95	1996–2001
1. *The use of information*	For planning, management and evaluation Limited quality of data could be tolerated	Limited use of information for past and present trends Limited quality of some data could be tolerated	Broader use, including future trends, of information and data High quality of data is needed
2. *The generation of information*			
(i) Collect, validate, analyze, and disseminate data and information	Data on health status, utilization of services, resources, and demographic, social and environmental data	Emphasis on data on monitoring and evaluation of Health for All Partial support of informatics	Emphasis on data on mortality, morbidity, disability Continue to give emphasis to data on monitoring and evaluation of Health for All Full support of informatics
(ii) Research and development activities	Developments of indicators; methods of presentation and dissemination; operational research methods	Development of monitoring and evaluation	Further development of health indicators

Table 1 (*continued*)

Main activities		1975–87	1988–95	1996–2001
		Statistical support to health research	Started health futures trend assessment	Health futures trend assessment
		ICD	ICD, ICIDH	Further development of health futures methods
				Implementation of ICD
(iii)	Support activities and resources	Support given country by country	Strengthening country health information – started cooperation with Member States, especially developing countries and countries in transition, through regional offices	More on strengthening country health information through regional offices
				Support health futures trend assessment
				Support the monitoring and evaluation of HFA
				Support the enhancement of statistical capabilities
				Support the use of computers
(iv)	Partnerships and coordination of information activities	Improve the uniformity and comparability of data		Dynamic networking of health information and statistical activities
		Balancing between decentralized and centralized systems		Coordination of various information, statistical activities, and trend assessment
		Cooperation between statisticians and users	Started through dynamic networking of health information and statistical activities	

Source: Division of Health Situation and Trend Assessment, WHO.

socioeconomic environment (especially economic, sociocultural, and technological environment), and biological and physical environments (including pollution) (*see* **Environmental Epidemiology**). Full informatic support in these information activities will become a reality.

(ii) The future focus on research and development will be on health measurement of the above-mentioned data and various health classifications in a more elaborated way. Besides this, further development of future trend assessment in support of scenario planning will be needed by many countries.

(iii) The trend in support activities and resources will continue to focus on providing support to many developing countries, especially to the least developed countries in strengthening their country health information. The specific support activities and resources as mentioned in Table 1 will continue throughout the beginning of the twenty-first century.

(iv) Partnerships, coordination and provision of direction of information activities will become WHO's most important and challenging tasks in health situation and trend assessment in the future.

X-Linkage

In humans, there are 22 pairs of homologous chromosomes called *autosomes*, and an additional pair of *sex chromosomes*, denoted by X and Y. Normal females are XX and normal males are XY. The Y chromosome is small and lacks most of the loci found on the X chromosome; loci found only on the X chromosome are called *X-linked loci*. Regions of homology between the X and Y chromosomes are called the *pseudo-autosomal regions* (see below).

The phenomenon of X-linked inheritance has been recognized since ancient times in the case of hemophilia. Jewish law banned the circumcision of male offspring of females with a family history of bleeding; however, this ban did not apply to the offspring of males who were members of families with a history of bleeding. Hemophilia became infamous in the nineteenth and early twentieth centuries with the spread of hemophilia through the royal houses of Europe. Queen Victoria of Great Britain was a carrier of the disease gene, which she passed on to her son Prince Leopold as well as to numerous other members of the royal family. The most famous victim was her great-grandson Alexis Romanov who met his demise not from hemophilia but when he was executed at the age of 14 with his family at Ekaterinburg in 1918. The causes of X-linked recessive hemophilia A and hemophilia B are now known to be due to **mutations** in the factor VIII **gene**, which maps to Xq28 and in the factor IX gene mapping to Xq27.1–q27.2, respectively.

In 1911, color blindness was localized to the X chromosome [27]. This was the first trait to be mapped to the X chromosome in mammals. To date a large number of genes for X-linked traits have been mapped and isolated. They include the genes for retinitis pigmentosa 2 [26], retinitis pigmentosa 3 [25], and X-linked Alport syndrome [1]. These are a few examples of the over 1000 X-linked traits and genes described in Online Mendelian Inheritance in Man [22].

X-linked Transmission and Modes of Inheritance

For X-linked diseases, affected males pass their only X chromosome to all their female offspring, therefore 100% of their female children carry a chromosome with the disease gene. Since males can only pass their Y chromosome to their male offspring, there is no male-to-male transmission for X-linked traits. A **heterozygous** female has two copies of the X chromosome and therefore passes the X chromosome carrying the disease gene to 50% of her children, regardless of their sex. For many X-linked recessive traits (*see* **Genotype**), females are unaffected carriers of the trait, while males express the disease phenotype; a female is affected only in the rare circumstance of receiving a copy of the mutated gene from both her mother and father. As an example, X-linked color blindness has a frequency of 8% in western European males but also affects about 0.6 % of females. In X-linked dominant inheritance, both males and females who carry only one copy of the disease allele are affected.

For some X-linked recessive traits, female carriers display a milder phenotype than affected males. For example, for sensorineural deafness caused by the DFN4 gene, affected males display congenital bilateral profound sensorineural hearing impairment affecting all frequencies, while female carriers manifest a much milder phenotype of bilateral mild to moderate high frequency sensorineural hearing impairment with onset during adulthood [17]. In the case of retinitis pigmentosa 3, carrier females display tapetal-like retinal reflex (a brilliant, scintillating, golden-hued, patchy appearance most striking around the macula), but no visual defect [10].

Ascertainment of Families

From which individuals should DNA samples be collected, when ascertaining a kindred segregating an X-linked recessive trait? For the example in Figure 1 (the “a” indicates the family member should be genotyped), all females are phenotypically normal and it is only possible to determine whether they are carriers if they have an affected son. For example, it is not possible to determine the carrier status of II.4 or II.5, since neither female has a male offspring. Therefore, they do not provide **linkage** information. In addition, the affected male II.10 cannot pass the disease gene to his sons (who need not be ascertained), but his daughter III.10 has an affected son and therefore is a carrier; III.10 and her son IV.1 should be ascertained.

Even if DNA cannot be collected for an individual, in certain circumstances they should still be retained

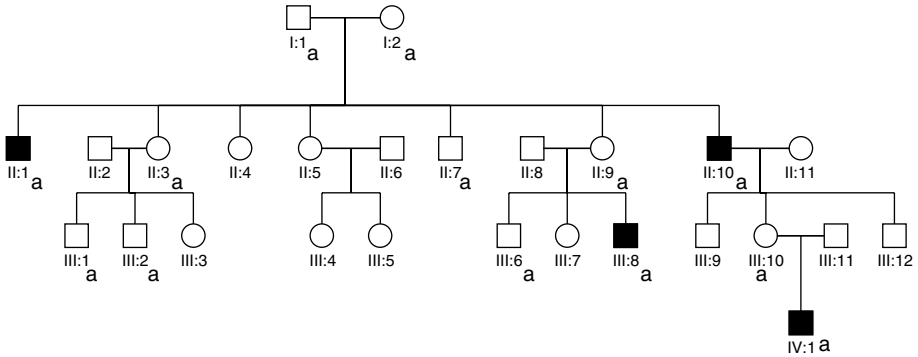

Figure 1 Pedigree 1: ascertainment scheme for an X-linked recessive trait. Individuals marked with an "a" subscript are appropriate for ascertainment for a linkage study

in the pedigree for linkage analysis. For example, individuals III.1 and III.2 should be retained in the analysis even if they lack genotypic information, since the number of unaffected sons that II.3 has changes the probability of whether or not she is a mutant allele carrier, with the probability of her being a carrier decreasing with increasing number of unaffected sons. In addition, affected male offspring III.8 and IV.1 should be retained in the analysis even if a DNA sample cannot be obtained; including them in the analysis classifies the carrier status of their mothers II.9 and III.10.

If it is possible to identify whether or not the females are carriers (or the trait is X-linked dominant and females with one copy of a mutated allele are affected), then ascertainment should be extended to include additional females whose affection or carrier status is known.

Linkage Analysis for X-linked Loci

For **complex diseases**, it may be difficult to determine whether one or more susceptibility loci are X-linked; in this case, the whole genome, including the X chromosome, should be scanned. In general, the phenomenon of X-linkage can be distinguished from other sex-related phenomena, such as **parental effects** and sex-dependent **penetrances**. **Segregation analyses** may be carried out to determine whether or not an X-linked model of inheritance best fits a set of pedigree data.

If there is strong evidence that a disease or trait segregating in a pedigree is X-linked, then genotyping of **markers** is usually restricted to the X chromosome. Markers that are located on the X chromosome can be selected from a variety of genetic maps; for example, maps created at the Marshfield Medical Center for Medical Genetics [2] and the Foundation Jean Dausset Centre d'Etude du Polymorphisme Humain (CEPH) [7]. Markers that are approximately 5 cM–10 cM apart can be genotyped initially to perform a scan of the X chromosome. Additional markers can then be genotyped to aid in establishing linkage and to fine map a locus to a region.

Model-based Linkage Analysis

Model-based methods for X-linked loci may be viewed as modifications of model-based methods for autosomal diseases (*see* **Linkage Analysis, Model-based**; **Linkage Analysis, Multipoint**); as a result, relatively little methodologic literature on analysis of X-linkage is available. A summary of early work is given by Edwards [9]. For X-linked loci, the transmission probability (the probability that an individual of a given genotype transmits a particular gamete to his or her offspring) depends on the sex of both parent and offspring. First, consider a single X-linked locus [6]. Let $k = 1, 2, \ldots, K$ denote the possible alleles at a given locus and let 0 denote a null (absent) allele. For a male parent, the genotype is in a haploid state for one of these possible alleles. Let $\tau_{k0m \to k'm}$ ($\tau_{k0m \to k'f}$) be the probability that a male parent with genotype $k0$ transmits a k' allele to a male (female) offspring. Then $\tau_{km \to k'm} = 0$ for all k, k', and $\tau_{k0m \to k'f} = 1$, if $k = k'$, and 0 otherwise. For a female parent, the transmission probabilities

are the same as in the autosomal case, regardless of offspring sex.

When two loci are analyzed together in a linkage analysis, the recombination fraction is included as a parameter in the transmission probabilities. For X-linked loci, no recombination occurs in the male parent and the transmission probabilities are the same as above, substituting the two-locus haploid genotype for the single locus haploid genotype. Only the transmission probabilities associated with the female parent include the (female) recombination fraction; these transmission probabilities are the same as in the autosomal case.

Next, consider the mode of inheritance. For X-linked traits, the penetrance functions are usually defined separately for males and females. For a two-allele locus, the possible genotypes for a female are DD, D+ or ++, where D is the disease allele and + is the wild type allele. The male has only one copy of the X chromosome; the Y chromosome does not carry the locus. The possible genotypes for a male are therefore DY or +Y. As examples of X-linked traits with full penetrance for disease genotypes and no phenocopies, Table 1 gives penetrances for an X-linked recessive trait, Table 2 for an X-linked dominant trait, and Table 3 for an X-linked recessive trait for which female carriers can be identified.

Morton [20] recommends using, as a critical value, a lod score of 2.0 in order to establish linkage of a trait locus to the X chromosome. For a scan of only the X chromosome using a dense map of markers [18], a lod score of 2.0 corresponds to a significance level of 0.024 (*see* **Genome-wide Significance**).

Model-free Linkage Analysis

For model-free methods, sometimes called nonparametric methods, the mode of inheritance of a trait is not specified a priori (*see* **Linkage Analysis, Model-free**). Like the case of model-based analysis, model-free linkage analysis of X-linked traits can be viewed as a modification of model-free linkage analysis of autosomal traits. When analyzing relative-pair data, the number of alleles shared identical-by-descent (ibd) (*see* **Identity Coefficients**) between the members of the pair is estimated, conditional on the available marker data. For an autosomal marker, siblings can share either 0 or 1 maternal alleles (each with probability $\frac{1}{2}$) and 0 or 1 paternal alleles (each with probability $\frac{1}{2}$). Therefore, for autosomal markers and under the null hypothesis of no linkage, the expected probabilities of sibs sharing 0, 1, and 2 alleles ibd are $\frac{1}{4}$, $\frac{1}{2}$ and $\frac{1}{4}$, respectively.

For X-linked markers, female–female sib pairs must share exactly 1 paternal allele ibd, male–male sib pairs must share exactly 0 paternal alleles ibd (because the Y chromosome does not carry the locus of interest), and opposite-sex sib pairs must also share exactly 0 paternal alleles ibd. For alleles inherited from the mother, both same-sex and opposite-sex sib pairs can share either 0 or 1 allele ibd (each with probability $\frac{1}{2}$). Therefore, under the null hypothesis of no linkage, female–female sib pairs can share either 1 or 2 alleles ibd (each with probability $\frac{1}{2}$), male–male sib pairs can share either 0 or 1 allele ibd (each with probability $\frac{1}{2}$), and opposite-sex sib pairs can share 0 or 1 allele (each with probability $\frac{1}{2}$).

Once ibd-sharing probabilities are estimated, they can be incorporated into standard methods of model-free analysis, with the caveat that, for some methods, different parameters are estimated for the three types

Table 1 Penetrances for an X-linked recessive trait without phenocopies or reduced penetrance

	Female			Male	
Disease status	DD	D+	++	DY	+Y
Affected	1	0	0	1	0
Unaffected	0	1	1	0	1

Carriers	0	1	0	–	–
Unaffected	0	0	1	0	1

of sex-specific pairs (female–female, male–male, and male–female), and the results then combined for an overall test of linkage. For example, Cordell et al. [4] gives an extension of the Risch [24] affected-relative-pair likelihood method for autosomal loci to the analysis of X-linked loci. To derive their method, they specify sex-specific genetic **variances** and covariances and use them to obtain sex- and pair-type-specific recurrence **risk ratio** parameters and their corresponding multinomial parameters.

In general, let z_{Ri} be the probability that an affected relative pair of type R (sex-specific) shares i alleles ibd, for $i = 0, 1, 2$, and let α_{Ri} be the associated prior probability. In the case of sib pairs, $\alpha_{bb2} = \alpha_{bs2} = \alpha_{ss0} = z_{bb2} = z_{bs2} = z_{ss0} = 0$ (where bb = brother–brother, bs = brother–sister, and ss = sister–sister). The remaining αs equal $\frac{1}{2}$. Within each sex-specific pair type, the zs must sum to one; therefore, there are three free parameters in the likelihood: z_{bb0}, z_{bs0}, and z_{ss1}. For each sex-specific pair type, the lod score is maximized, subject to constraints on the parameters consistent with genetic inheritance. The asymptotic distribution of the corresponding likelihood ratio statistic is a 50 : 50 mixture of a point mass at zero (χ_0^2) and χ_1^2.

The three lod scores can then be summed to give an overall lod score; the asymptotic distribution of the corresponding **likelihood ratio** statistic is a mixture of χ_0^2, χ_1^2, χ_2^2, and χ_3^2, with mixing proportions equal to the binomial probabilities 0.125, 0.375, 0.375, and 0.125, respectively. To achieve the nominal (point-wise) significance level of 0.05, a lod score exceeding 1.18 is required [21]. If the entire genome is scanned, then the Lander & Kruglyak [18] criteria for suggestive and significant linkage correspond to lod scores equaling 3.06 and 4.62, respectively, on the X chromosome [21].

The Cordell et al. [4] method is general, allowing for different recurrence risk ratio parameters for each sex-specific sib-pair type at the expense of additional degrees of freedom. For X-linked recessive inheritance, the probabilities of sharing a maternal allele are the same for each type of affected sib pair [13]. As a result, all maternal ibd sharing can be combined and a single parameter (here denoted as z_1) to be estimated. The null hypothesis H_0: $z_1 = \frac{1}{2}$ is tested against the alternative H_a: $z_1 > \frac{1}{2}$; the asymptotic distribution of the corresponding likelihood ratio statistic is distributed as a 50 : 50 mixture of χ_0^2 and χ_1^2. Nyholt [21] argues that this statistic has the same properties as the likelihood ratio statistic from a model-based analysis and that, as a result, the Morton [20] criterion applies if only the X chromosome is scanned and the standard Lander & Kruglyak [18] criteria for model-based analysis apply if the entire genome is scanned.

The Pseudo-autosomal Regions

There are two small regions on the X chromosome where recombination does occur with the Y chromosome, the distal regions on Xp [3] and on Xq [11]. These are known as the pseudo-autosomal regions; inheritance of loci and traits in these regions of the sex chromosomes mimic autosomal inheritance. As a result, when testing for linkage within the pseudo-autosomal regions, penetrance functions take the same form as for the autosomal case (i.e autosomal dominant or recessive) [23]. If the trait locus is within a pseudo-autosomal region and the marker locus/loci lies outside this region, a different set of penetrance functions must be used (see [23]).

Dupuis & Van Eerdewegh [8] present a method to carry out affected-sib-pair analysis within the pseudo-autosomal regions. This method takes into account the fact that, in the pseudo-autosomal regions, same-sex siblings will share more genetic material ibd, even when a disease locus is not present. This increased sharing will be greater in those regions closer to the sex-specific region. Likewise, opposite-sex siblings will share less genetic material ibd. If this difference is not taken into account, for either dichotomous or quantitative traits, then those samples with more same-sex siblings will have higher type I error rates, while samples with an abundance of opposite-sex siblings will have reduced power to detect linkage.

Software for Analysis of X-linked Traits

Programs that can be used to carry out model-based linkage analysis for X-linkage include LINKAGE [19], FASTLINK [5], GENEHUNTER2.1 [16], and ALLEGRO1.1 [12]. For affected-sib-pair data, programs include MAPMAKER/SIBS [15], which incorporates the methods of Cordell et al. [4], and ASPEX, an exclusion mapping program that incorporates a one-parameter model [14]. GENEHUNTER2.1 and ALLEGRO1.1 also perform non-parametric analysis of more general pedigrees (*see* **Software for Genetic Epidemiology**).

Yates's Algorithm

Yates's **algorithm** is a computationally efficient method of calculating main effects and **interactions** in a balanced **factorial experiment**. The method, developed by **Frank Yates** [13] in 1937, originally applied to designs in which all factors have two levels, but it is easily extended to include factors with three or more levels. The calculations can be performed readily by hand through a series of multiplications and additions, and are easily programmed. A reverse algorithm yields fitted values and **residuals**.

The structural characteristics that lead to the computational efficiency of Yates's algorithm form the basis of the **fast Fourier transform** [1, 5, 8, 9], and also bear a direct relationship to computational aspects of **wavelet** shrinkage [7, 11] in, for example, **nonparametric regression**.

Standard Order of Experimental Conditions

The calculations for Yates's algorithm are organized in a table, with the data arranged in what is known as *standard order* in the first column. Before illustrating the method through examples, let us establish some notation. Consider an experiment with three factors, A, B, and C, each at two levels, designated "high" and "low". Combinations of the lowercase letters a, b, and c represent experimental conditions defined by the levels of these factors. The presence of a letter indicates that the corresponding factor is at its higher level, and its absence indicates that the factor is at its lower level. Accordingly, ab denotes observations at the high levels of A and B and the low level of C. Now suppose that an additional factor, D, with three levels, is included in the design. Successive levels of this factor are written, 1, d, and d^2. Hence, the letters bd^2 stand for an observation at the low levels of A and C, the high level of B, and the highest level of D. The observation at the lowest level of all factors is denoted 1. For factors with unordered levels, the designations "low" and "high" are, of course, arbitrary.

Observations arranged in standard order start at the lowest level of all factors, and cycle through the levels of the first factor most rapidly. In the notation just introduced, this consists of writing the levels of the first factor, then writing the letters for each level of the next factor times these terms, one level at a time, and continuing on to succeeding factors in the same manner. For example, the standard order for three factors A, B, and C with two levels each is:

$$1 \quad a \quad b \quad ab \quad c \quad ac \quad bc \quad abc.$$

Standard order for a $2 \times 2 \times 3$ design with factors A, B, and D is:

$$1 \quad a \quad b \quad ab \quad d \quad ad \quad bd \quad abd \quad d^2 \quad ad^2 \quad bd^2 \quad abd^2.$$

Notice that the first four symbols are like those for a 2×2 experiment, that multiplying each of these by d produces the next four symbols, and multiplying them by d^2 produces the last four.

Yates's Algorithm for 2^k Factorial Designs

Table 1 illustrates the steps of Yates's algorithm for a 2^4 factorial design. The column labeled Treatment total contains the data, the totals over r replications for each experimental condition, arranged in standard order. Columns (1)–(4) are calculated from these totals as follows. To generate column (1), first group the data in the preceding column into pairs. Then calculate the top half of the column as the sums of these pairs and the bottom half as their differences, subtracting the second member of the pair from the first. Thus, the entries in the top half of column (1) are $24.9 = 15.8 + 9.1$ through $63.0 = 22.6 + 40.4$, and the entries in the bottom half are $-6.7 = 9.1 - 15.8$ through $17.8 = 40.4 - 22.6$. Generate columns (2) and (3) from their preceding columns in the same manner, with sums of pairs in the top half and differences in the bottom. The number of columns calculated in this way is the same as the number of factors in the design. The final such column contains the *effect totals*, or raw effects.

The *mean effects*, which are the main effects and interactions identified in the final column, are obtained by dividing the effect totals by $r2^k$ for the average effect and by $r2^{k-1}$ for all other effects. These effects are **orthogonal**, and their corresponding one-degree-of-freedom sums of squares are calculated as $[\text{effect total}]^2/2^k$. The **standard errors** of the mean effects are $(2\sigma^2/r2^{k-1})^{1/2}$. Replicates, when available, provide an estimate of the error **variance**. In the absence of replication,

Table 1 Yates's algorithm for a 2^4 design

Experimental condition	Treatment total	(1)	(2)	(3)	Effect total (4)	Divisor	Mean effect = Effect total/ divisor	Sum of squares = Effect total^2/ $r2^k$	Identification

cd	22.2	−1.0	11.3	1.2	16.8	8	2.10	17.64	*CD*
acd	26.8	11.0	11.5	3.0	10.4	8	1.30	6.76	*ACD*
bcd	22.6	4.6	12.0	0.2	1.8	8	0.23	0.20	*BCD*
abcd	40.4	17.8	13.2	1.2	1.0	8	0.13	0.06	*ABCD*

the higher-order interactions are often taken to be zero, and their effects pooled to obtain an estimate of σ^2. A **half-normal** plot of the absolute standardized effects [|effect total|/(divisor)$^{1/2}$], preferably excluding main effects, is useful in determining which higher-order effects to pool.

Yates's Algorithm for Factors with More than Two Levels

In general, orthogonal **contrasts** among factor levels determine the steps of Yates's algorithm. For a factor with two levels, the contrasts are unique, but for a factor with three or more levels, these contrasts, which decompose the average and main effect into one-degree-of-freedom effects, can be chosen in any number of ways. If the factor levels are quantitative and evenly spaced, then **polynomial** contrasts are appropriate. The columns of $\mathbf{C}_2$ and $\mathbf{C}_3$ below contain the polynomial contrast coefficients for two and three factors, with the sums of squared coefficients in the margins. The steps just described for a 2^k design clearly correspond to use of the coefficients in the columns of $\mathbf{C}_2$:

$$\begin{array}{c} \\ \mathbf{C}_2 = \\ \\ \end{array} \begin{array}{c} \text{Average} \quad \text{Linear} \\ \left[\begin{array}{cc} 1 & -1 \\ 1 & 1 \\ 2 & 2 \end{array}\right], \end{array}$$

$$\begin{array}{c} \\ \mathbf{C}_3 = \\ \\ \end{array} \begin{array}{c} \text{Average} \quad \text{Linear} \quad \text{Quadratic} \\ \left[\begin{array}{ccc} 1 & -1 & 1 \\ 1 & 0 & -2 \\ 1 & 1 & 1 \\ 3 & 2 & 6 \end{array}\right] \end{array}$$

Table 2 contains the steps of Yates's algorithm for a $2 \times 3 \times 2$ design using polynomial contrasts. Because *A* and *C* each have two levels, columns (1) and (3) are calculated from the preceding columns by computing sums and differences of pairs as described above for 2^k designs. Thus, only calculation of column (2) corresponding to the three-level factor *B* remains to be explained. To obtain this column, first divide the preceding column into groups of three (the number of levels of the factor). Then apply the coefficients in the columns of $\mathbf{C}_3$ to these groups. That is, compute the first third of column (2) as the sums of each group, compute the middle third using the coefficients −1, 0, 1 for the linear contrast, and compute the last third using the coefficients 1, −2, 1 for the quadratic contrast. Thus, the first four entries in column (2) are $74.5 = 21.8 + 18.0 + 14.7$ through $53.5 = 12.1 + 15.6 + 25.8$; the next four are $12.9 = 34.7 - 21.8$ through $13.7 = 25.8 - 12.1$, and the last four are $20.5 = 21.8 - 2 \times 18.0 + 34.7$ through $6.7 = 12.1 + 2 \times 15.6 + 25.8$.

The contrasts not only define the operations on the column elements in Yates's algorithm, but also

Table 2 Yates's algorithm for a $2 \times 3 \times 2$ design using polynomial contrasts

determine the divisors used to obtain mean effects and sums of squares from effect totals. The divisors are products of the sums of squared contract coefficients, with each factor in the design contributing to the product. If a particular factor is not involved in the effect (e.g. C is not in the AB interaction), then its average contrast supplies its contribution to the divisor. Thus, the divisor for the A main effect is $2 \times 3 \times 2 = 12(A_{\text{linear}} \times B_{\text{average}} \times C_{\text{average}})$; the divisor for the AB_Q interaction is $2 \times 6 \times 2 = 24(A_{\text{linear}} \times B_{\text{quadratic}} \times C_{\text{average}})$.

The Reverse Algorithm

The reverse algorithm operating on the mean or raw effects produces the original data. If certain effects that are considered negligible or nonsignificant are set to zero, then the reverse algorithm produces the fitted values for the corresponding model. On the other hand, if significant effects are set to zero and the values for the nonsignificant effects retained, then this back-transformation produces residuals.

The reverse algorithm for 2^k designs is straightforward. Starting with raw effects, columns are again generated as sums and differences of pairs of elements in the preceding column. However, in the reverse algorithm, the bottom half of the column consists of sums of pairs and the top half of differences obtained by subtracting the second member of the pair from the first. These steps correspond to taking linear combinations with coefficients from the columns of $\mathbf{C}_2'$. Equivalently, the reverse algorithm can be implemented by applying the forward algorithm to the raw effects listed in reverse standard order, which produces the original data (fitted values, residuals) in reverse order as well [2].

When the design includes factors with more than two levels, the reverse algorithm is applied to mean effects rather than effect totals and no divisors are used. The steps for two-level factors are as described above. The columns of $\mathbf{C}_3'$ contain the coefficients for calculating each third of a column corresponding to a three-level factor, assuming polynomial contrasts have been used in the forward algorithm:

$$\mathbf{C}_2' = \begin{bmatrix} 1 & 1 \\ -1 & 1 \end{bmatrix}, \qquad \mathbf{C}_3' = \begin{bmatrix} 1 & 1 & 1 \\ -1 & 0 & 1 \\ 1 & -2 & 1 \end{bmatrix}.$$

Table 3 The reverse algorithm for a $2 \times 3 \times 2$ design using polynomial contrasts
(a) Fitted values

Identification	Mean effect	(1)	(2)	Fitted values (3)	Experimental condition

	Coefficients:	1st half: 1, −1 2nd half: 1, 1	1st third: 1, −1, 1 2nd third: 1, 0, −2 Last third: 1, 1, 1	1st half: 1, −1 2nd half: 1, 1	

Table 3 illustrates the reverse algorithm for the $2 \times 3 \times 2$ example presented in Table 2, with two-way interactions involving the quadratic effect of B and all three-way interactions set to zero a priori. Calculations of fitted values and **residuals** follow exactly the same steps, so we describe only the former. To compute column (1) corresponding to the first factor which has two levels, group the preceding column into pairs. Apply the coefficients −1, 1 from the first column of $\mathbf{C}_2'$ to obtain the differences $9.52 = 15.32 - 5.80$, and so forth in the top half of column (1). Similarly, apply the coefficients in the second column of $\mathbf{C}_2'$ to obtain the sums of each pair in the bottom half of column (1). Since the second factor has three levels, compute column (2) by first dividing the preceding column into groups of three. Then apply the coefficients in each column of $\mathbf{C}_3'$ to obtain the linear combinations that fill each third of the

column:

$$\begin{aligned} 10.26 &= 9.52 - 1.07 + 1.81 \text{ using } 1, -1, 1 \\ &\vdots \qquad\quad \vdots \\ 5.90 &= 9.52 - 2 \times 1.81 \text{ using } 1, 0, -2 \\ &\vdots \qquad\quad \vdots \\ 12.40 &= 9.52 + 1.07 + 1.81 \text{ using } 1, 1, 1 \\ &\vdots \qquad\quad \vdots \end{aligned}$$

Column (3), the last column calculated in this manner, contains the estimated effects for the fitted model with terms $A + B_L + B_Q + C + AB_L + AC + B_LC$.

Computational Efficiency: Yates's Algorithm, and the Fast Fourier and Wavelet Transforms

Yates's algorithm for a $t_1 \times t_2 \times \ldots \times t_k$ design requires $(t_1 + t_2 + \ldots + t_k)N$ multiplications and additions, in contrast to the N^2 operations in direct calculation from the design matrix, $\mathbf{X}$. The former quantity is proportional to $N \log_2 N$, with constant of proportionality that is a weighted average of $t_1/\log_2 t_1, \ldots, t_k/\log_2 t_k$ [8, 5]. The computational efficiency of Yates's algorithm derives from the fact that $\mathbf{X}'$, which is the direct (Kronecker) product of the transposes of the relevant $t \times t$ contrast matrices, can be written as the usual matrix product of sparse $N \times N$ matrices with at most $t \times N$ nonzero elements. Calculation of columns (1) through (k) in Yates's table corresponds to multiplication by these sparse matrices.

Good [8, 9] generalized Yates's algorithm as presented above and demonstrated its application to the calculation of Fourier series. Cooley & Tukey [5] developed the fast Fourier transform based on this work. McCullagh [11] noted the similarity in thresholding of wavelet coefficients and back-transformation in Yates's algorithm, and Donoho & Johnstone [7] verified that the formal manipulations of Yates's algorithm are exactly the same as computations in particular cases of wavelet transformation.

Yates's algorithm is described and illustrated in various books on the statistical analysis of designed experiments in addition to those cited, such as Box et al. [3], Cochran & Cox [4], Daniel [6], Johnson & Leone [10], and Miller & Freund [12].

Yates's Continuity Correction

For testing the null hypothesis of independence in a **2 × 2 contingency table**,

$$\begin{array}{cc|c} a & b & n_1 \\ c & d & n_2 \\ \hline m_1 & m_2 & N \end{array},$$

Yates [4] defined a continuity correction to provide a P value that approximates the P value from **Fisher's exact test** better than that based on the uncorrected **chi-square test** statistic,

$$T = \frac{N(ad - bc)^2}{m_1 m_2 n_1 n_2}. \tag{1}$$

Yates's continuity-corrected chi-square statistic is

$$T_c = \frac{N\left(|ad - bc| - \frac{1}{2}N\right)^2}{m_1 m_2 n_1 n_2}. \tag{2}$$

Conditional on the table's margins, only one cell count, say $A = a$, is random (A denotes a random variable taking value a). The discrepancy of outcome A from its expected value under H_0, $A' = A - E(A)$, where $E(A) = m_1 n_1 / N$, identifies outcomes in opposite tails of the distribution. Keeping these tails distinct, Yates's [4, 5] two-sided exact P value is twice the one-sided P value, with a maximum of one:

$$P = \begin{cases} 2\ \Pr(A' \le a'), & \text{if } a' < 0, \\ 2\ \Pr(A' \ge a'), & \text{if } a' > 0, \end{cases} \tag{3}$$

where $\Pr(A' = a') = \Pr(A = a)$ is the **hypergeometric probability** of outcome a,

$$\Pr(A = a) = \frac{\binom{n_1}{a}\binom{n_2}{m_1 - a}}{\binom{N}{m_1}}, \tag{4}$$

and $\max(0, m_1 + n_1 - N) \le a \le \min(m_1, n_1)$.

A two-sided asymptotic P value, $\overline{F}(t)$ [or $\overline{F}(t_c)$], is found by referring t (or t_c) to the **chi-square distribution** with 1 df; F is the cumulative distribution function of this distribution and $\overline{F} = 1 - F$.

The exact distribution is discrete and its tails $\Pr(A' \le a')$ and $\Pr(A' \ge a')$ can be asymmetric, whereas the approximating distribution is continuous and assumes that these tails are symmetric. The continuity-corrected chi-square P value greatly improves the approximation to the exact P value.

Example

For the 2×2 table with $a = 5$ and margins $\{m_1 = 6, n_1 = 8, N = 14\}$, we obtain $E(A) = 3.429$ and $a' = 1.571$. Table 1 lists the seven possible values of a, conditional on the margins, showing the two tails of the distribution. The two-sided exact conditional P value is $2\Pr(A' \ge 3.429) = 0.2424$. The chi-square statistics are $t = 2.941$ (uncorrected) and $t_c = 1.367$ (continuity-corrected); the asymptotic P values are $\overline{F}(t) = 0.0864$ and $\overline{F}(t_c) = 0.2423$, respectively. Table 1 illustrates general results: $\overline{F}(t)$ underestimates the exact distribution, while $\overline{F}(t_c)$ is nearly identical to it, and $\overline{F}(t_c)$ is slightly conservative when very small (but can be improved by using the Fisher–Yates reference table VIII [2]).

Table 1 Two-sided exact and asymptotic P values for all 2×2 contingency tables with margins $\{m_1 = 6, n_1 = 8, N = 14\}$

			Exact	Not corrected		Corrected	
a	a'	$\Pr(A = a)$	P	t	$\overline{F}(t)$	t_c	$\overline{F}(t_c)$
0	−3.429	0.0003	0.0006	14.00	0.0002	10.21	0.0014
1	−2.429	0.0160	0.0326	7.024	0.0080	4.430	0.0353

4	0.571	0.3497	0.9418	0.3889	0.5329	0.0061	0.9379
5	1.571	0.1119	0.2424	2.941	0.0864	1.367	0.2423
6	2.571	0.0093	0.0186	7.875	0.0050	5.110	0.0238

Discussion

Much of the continuing controversy over Yates's continuity correction is really over the exact reference distribution. It makes sense to use this correction if one believes that the conditioning used in Fisher's exact test is appropriate. Opponents argue that the reference distribution should sometimes be unconditional, depending on the underlying sampling process [3, 5].

In addition, Yates's reference P value, [3], which is based on outcomes in the observed tail only, has been misrepresented by a P value based on outcomes in both tails [$\Pr(|A'| \geq |a'|)$], and, in turn, his approximation has been miscalculated [1, 5]. Eq. (3) is increasingly recognized as correct [3, p. 369]; it is a smooth function of $|a'|$, while the miscalculated P value is not.

Yates recommends the continuity correction whenever the smallest expected value is less than 500 [2]. In practice, however, the exact P value itself is typically computed today (*see* **Exact Inference for Categorical Data**).

JOAN F. HILTON

Yates, Frank

Born: May 12, 1902, in Manchester, UK.
Died: June 17, 1994, in Harpenden, UK.

Reproduced by permission of the Royal Statistical Society

Frank Yates spent almost the whole of his working life as Head of the Statistics Department at Rothamsted Experimental Station, the large agricultural research station situated some 40 km northwest of London. The department had been founded by **R.A. Fisher** on his appointment to Rothamsted in 1919. He recruited Yates in 1931 and, shortly afterwards, left to take the Chair of Eugenics at University College, London. Yates was left in charge with just one other member of staff; his long career saw the department grow to a total of over 20 statisticians and he maintained its reputation as one of the world's leading centers of statistical research.

Before going to Rothamsted, Yates had been working in the Gold Coast (present-day Ghana) as mathematician to the colony's geodetic survey. Here, he obtained a thorough grounding in the theory and practice of **least squares** calculations, a body of knowledge that provided a foundation for much of his future work. At Rothamsted, his first main field of interest was **experimental design**. Fisher had laid down the basic principles of replication, **randomization, stratification**, and factorial treatment structure (*see* **Factorial Experiments**) in the 1920s and these had been adopted remarkably quickly by agricultural research workers, but some of the complexities had been imperfectly appreciated, even by members of Fisher's staff. Yates was able to put the subject onto a sound footing and to relate it properly to the **analysis of variance**, a technique at which he became a virtuoso. His work on factorial designs, including mixed factorials and **Latin square designs**, was expounded in his booklet *The Design and Analysis of Factorial Experiments* [5], which was, for several years, the only available manual on the subject. At the same time, he developed the wide range of **incomplete block designs**, including the quasi-factorial lattices (*see* **Lattice Designs**), and solved a variety of the associated combinatorial problems [8].

Throughout this period and later, the Rothamsted department was responsible for the analysis of the field experiments done on the Rothamsted farm, as well as for many other calculations. Yates brought to this work an unrivaled concern for numerical accuracy, which he had developed during his work on geodetic surveys. His ongoing interest in computational matters was to bear fruit later on.

During World War II, Yates's interests moved to different areas. He was responsible for undertaking several large exercises in what would today be called **meta-analysis**, examining and summarizing all the available evidence on responses to fertilizers and on the feeding of dairy cattle [1]. These studies – a good deal more sophisticated than most in current practice – were the basis for the wartime control of imported fertilizers and animal feedstuffs. He was also engaged in **operations research** work under S. Zuckerman. At the same time, he and the Rothamsted department became involved in the design and analysis of several large-scale sample surveys, and the theory and practice of survey work became the second of Yates's main areas of interest. His work was summarized in his book *Sampling Methods for Censuses and Surveys* [6].

Yates's interest in computation led him to experiment productively with punched-card equipment, but came to full fruition with the advent of electronic computers in the 1950s. He was, in fact, among the first to realize the enormous potential importance of these machines for the development of statistics. In 1954, Rothamsted was able to install the first British electronic computer to operate away from its designers. Within a year or two this machine (unimaginably

small-scale and primitive by today's standards) was in regular use for the analysis of experiments and surveys on a large scale, and for much other work, notably in the area of **multivariate analysis**. Yates played a leading role in the design and construction of the necessary programs, insisting from the start on a degree of discipline and user-friendliness that was most unfamiliar at the time.

Experimental design, sample survey, and computing were the three main headings under which Yates's work can be classified, but there were other notable contributions. An important and neglected article [7] discussed an economic argument for deciding upon the amount of experimentation justifiable on a given topic, showing that in an agricultural context a much larger number of experiments than usually envisaged would amply pay for themselves. It should be noted that concepts of size and **power**, the conventional determinants of sample size (*see* **Sample Size Determination**), did not enter into the case. An important paper on the analysis of **two-by-two tables** was published in 1934 [4] and followed (surely uniquely) by a substantial sequel just 50 years later [9] during his active retirement. It is ironic that **"Yates's continuity correction"**, which he may not even have originated, seems to be his best-known contribution among non-statisticians. Also worthy of mention are the several editions of Fisher and Yates's Statistical Tables [2], a collection (with its substantial introduction) that is still useful even in the computer era.

Yates's working life was spent mainly in an agricultural research setting. He is a giant figure from the heroic age of modern statistics, rivaling Student (**William Sealy Gosset**) as the greatest of applied statisticians, and much of his work has yet to be taken full advantage of by the biostatistical community.

A fuller account of Yates's career appears in [3].

M.J.R. HEALY

Youden Squares and Row–Column Designs

The technique of **blocking** is used to control variability due to extraneous sources, each source of variability constituting a blocking factor. Two sources can be controlled using a Youden square or a row–column design, the rows and columns comprising two different systems of blocking. For example, in a medical study, if each subject is to be used several times, then rows and columns may represent subjects and occasions, respectively. In an animal experiment conducted over several days, litters of animals and days may comprise the row and column blocking factors, respectively. As an illustration, the following design is a row–column design for four treatments in four rows and six columns:

1	3	1	4	4	2
2	1	2	3	1	4
4	4	3	2	2	3
3	2	4	1	3	1

Let D_1 be the block design obtained by taking rows as blocks, ignoring the columns. Similarly, D_2 denotes the design obtained by taking columns as blocks, ignoring the rows. D_1 and D_2 are called the row and column component designs, respectively. In the above design the row component design D_1 is variance balanced for estimating **paired comparisons** of treatment 1 with treatments 2, 3, and 4. The column component D_2 is a **randomized complete blocks design**. It is important to arrange the treatments in rows and columns so that the design has a high overall efficiency factor and the individual **contrasts** of interest are also estimated with high efficiencies. With this in mind, classes of row–column designs have been defined based upon the **orthogonality** of the component designs D_1 and D_2. A design in which both D_1 and D_2 are randomized complete block designs is called a **Latin square**. Therefore, Latin squares are row–column designs with the numbers of rows, columns, and treatments all equal, and all the treatments occur once in each row and in each column. If practical constraints do not make it possible to have both D_1 and D_2 as randomized complete block designs, one of them may be taken to be an **incomplete block design**. A row–column design in which D_1 is a randomized complete block design and the other component D_2 is a **balanced incomplete block design** is called a Youden square. Obviously, the roles of D_1 and D_2 are interchangeable. Incomplete Latin squares of Yates [60], obtained by deleting a row or a column from a Latin square, are examples of Youden squares. Youden [61] constructed them using symmetrical balanced incomplete block designs; the construction method was later provided by Smith & Hartley [57] for all symmetrical balanced incomplete block designs. A Youden square for seven treatments in three rows and seven columns is shown below:

1	2	3	4	5	6	7
2	3	4	5	6	7	1
4	5	6	7	1	2	3

Analysis of Designs

We first consider the analysis of a general row–column design for v treatments arranged in p rows and q columns. The analysis of a Youden square design will be provided later as particular case. It is assumed that a treatment is allocated to each of the combinations of rows and columns, which means that the row and column classifications are orthogonal. For a valid **randomization** of row–column designs, we first randomly permute the rows and then randomly permute the columns [47]. Let treatment t be assigned to the experimental unit in the ith row and jth column, and let y_{ijt} be the observed response from this unit. Then, the model for the data is assumed to be

$$y_{ijt} = \mu + \rho_i + \gamma_j + \tau_t + \in_{ijt},$$

where μ is the overall mean, ρ_i and γ_j are the effects of the ith row and jth column, respectively, τ_t is the effect of the tth treatment, and $\in_{ijt}$ are **random errors** assumed to be independently distributed with zero **mean** and a constant **variance** σ^2, $i = 1, 2, \ldots, p$; $j = 1, 2, \ldots, q$; $t = 1, 2, \ldots, v$. Let $\mathbf{N}_1$ and $\mathbf{N}_2$ be the incidence matrices of the row and column component designs D_1 and D_2, respectively. The (i, j)th element of $\mathbf{N}_1(\mathbf{N}_2)$ equals 1 if the ith treatment occurs in the jth row (column), and is zero otherwise. Then the reduced normal equations for estimating treatment parameters are given by $\mathbf{C}\tau = \mathbf{Q}$, where $\boldsymbol{\tau} = (\tau_1, \tau_2, \ldots, \tau_v)'$,

$$\mathbf{C} = \mathbf{r}^{\delta} - \frac{1}{q}\mathbf{N}_1\mathbf{N}_1' - \frac{1}{p}\mathbf{N}_2\mathbf{N}_2' + \frac{1}{n}\mathbf{r}\mathbf{r}'$$

is the **information matrix** of the design, $\mathbf{r} = r_1, r_2, \ldots, r_v)'$, r_i is the number of replications of treatment i, $\mathbf{r}^\delta$ is the diagonal matrix with elements those of $\mathbf{r}$, a prime denotes transpose,

$$\mathbf{Q} = \mathbf{T} - \frac{1}{q}\mathbf{N}_1\mathbf{T}_1 - \frac{1}{p}\mathbf{N}_2\mathbf{T}_2 + \frac{G}{n}\mathbf{1}$$

is the vector of adjusted treatment totals, $\mathbf{1}$ is a column vector of ones, $\mathbf{T}$, $\mathbf{T}_1$, $\mathbf{T}_2$ are the vectors of treatment, row and column totals, respectively, G is the grand total of observations, and $n = pq$ is the total number of observations. A solution to the normal equations is given by $\hat{\boldsymbol{\tau}} = \boldsymbol{\Omega}\mathbf{Q}$, where $\boldsymbol{\Omega}$ is a generalized inverse of $\mathbf{C}$ satisfying $\mathbf{C}\boldsymbol{\Omega}\mathbf{C} = \mathbf{C}$. It is important to note that $\boldsymbol{\tau}$ cannot be estimated uniquely, and only contrasts among treatment parameters are estimable. The adjusted treatment sum of squares is $\hat{\boldsymbol{\tau}}'\mathbf{Q} = \mathbf{Q}'\boldsymbol{\Omega}\mathbf{Q}$. The **analysis of variance** table is constructed as shown in Table 1.

The sum of squares due to error is

$$SSE = \mathbf{Y}'\mathbf{Y} - \frac{\mathbf{T}_1'\mathbf{T}_1}{q} - \frac{\mathbf{T}_2'\mathbf{T}_2}{p} - \mathbf{Q}'\boldsymbol{\Omega}\mathbf{Q} + \frac{G^2}{n}.$$

The information matrix $\mathbf{C}$ has rank less than or equal to $v - 1$. A design is said to be connected if the rank of $\mathbf{C}$ is equal to $v - 1$, otherwise it is said to be disconnected. All treatment comparisons are estimable in a connected design. We will assume that all comparisons among treatments are of interest, and thus we restrict our attention to connected designs only. Connectedness in row–column designs has been considered by Shah & Khatri [54], Raghavarao & Federer [49], Russell [50], and Sia [56]. Let $\mathbf{s}'\boldsymbol{\tau}$, $\mathbf{s}'\mathbf{1} = 0$, be a contrast of interest. The (unique) **least squares** estimate of $\mathbf{s}'\boldsymbol{\tau}$ is given by $\mathbf{s}'\hat{\boldsymbol{\tau}} = \mathbf{s}'\boldsymbol{\Omega}\mathbf{Q}$ with variance $\mathrm{var}(\mathbf{s}'\hat{\boldsymbol{\tau}}) = \mathbf{s}'\boldsymbol{\Omega}\mathbf{s}\sigma^2$. The sum of squares due to $\mathbf{s}'\boldsymbol{\tau}$ is $(\mathbf{s}'\boldsymbol{\Omega}\mathbf{Q})^2/\mathbf{s}'\boldsymbol{\Omega}\mathbf{s}$. For a Youden square, $\mathbf{C} = (\lambda v/p)(\mathbf{I} - 1/vJ)$ and $\boldsymbol{\Omega} = (p/\lambda v)\mathbf{I}$, where λ is the number of times each pair of treatments occurs in D_2. Therefore, the adjusted treatment sum of squares is $(p/\lambda v)\mathbf{Q}'\mathbf{Q}$, and $\mathbf{s}'\hat{\boldsymbol{\tau}} = (p/\lambda v)\mathbf{s}'\mathbf{Q}$ with $\mathrm{var}(\mathbf{s}'\hat{\boldsymbol{\tau}}) = (p/\lambda v)\mathbf{s}'\mathbf{s}\sigma^2$.

Table 1 Analysis of variance calculations

Source of variation	Degrees of freedom	Sum of squares
Treatments (adjusted)	$v - 1$	$\mathbf{Q}'\boldsymbol{\Omega}\mathbf{Q}$
Rows	$p - 1$	$\frac{\mathbf{T}_1'\mathbf{T}_1}{q} - \frac{G^2}{n}$
Columns	$q - 1$	$\frac{\mathbf{T}_2'\mathbf{T}_2}{p} - \frac{G^2}{n}$
Error	$(p-1)(q-1) \times (v-1)$	SSE (by subtraction)
Total (corrected)	$n - 1$	$\mathbf{Y}'\mathbf{Y} - \frac{G^2}{n}$

Classes of Designs

A design is variance-balanced if all pairwise comparisons between treatments are estimated with the same variance. For variance-balanced designs $\mathbf{C} = \alpha[\mathbf{I} - 1/v\mathbf{J}]$ and $\boldsymbol{\Omega} = 1/\alpha\mathbf{I}$, where $\mathbf{I}$ is the identity matrix, $\mathbf{J}$ is the square matrix of 1s, and α is a constant whose value depends upon the design. Youden squares are variance-balanced since for these designs $\mathrm{var}(\hat{\tau}_i - \hat{\tau}_j) = (2p/\lambda v)\sigma^2$, $i \neq j = 1, 2, \ldots, v$. The following design given by Pearce [46] is also variance-balanced:

1	4	2	3	1	4
3	3	4	1	2	2
4	2	3	2	4	1
2	1	4	1	3	3
2	2	3	4	1	1
3	4	1	4	3	2

For this design, $\mathrm{var}(\hat{\tau}_i - \hat{\tau}_j) = (3/25)\sigma^2$, $i \neq j = 1, 2, 3, 4$. Generalized Youden designs by Kiefer [33], which have been listed by Ash [2], provide a large class of variance-balanced designs. The earliest example of a variance-balanced design in which both D_1 and D_2 are partially balanced appears to be the design of Kshirsagar [34] for $v = 9$, $p = q = 6$. In some experiments all pairwise comparisons among treatment parameters are not of equal importance. Supplemented balanced, or S, designs introduced by Hoblyn et al. [22] and Pearce [45] are useful where the main object is to compare several test or new treatments with a standard treatment which is called the control treatment. With treatment 1 coded as the control, in these designs, $\mathrm{var}(\hat{\tau}_1 - \hat{\tau}_i) = a_1\sigma^2$ and $\mathrm{var}(\hat{\tau}_i - \hat{\tau}_j) = a_2\sigma^2$, $i \neq j = 2, 3, \ldots, v$, where a_1 and a_2 are some constants. In the block design setting, reinforced designs of Das [11] obtained by augmenting each block of a balanced incomplete block design with a constant number of replications of the control treatment are of type S. In the incomplete block design setting, Bechhofer & Tamhane [5] called type S designs balanced treatment incomplete block designs.

Several methods of constructing optimal type S block designs have been provided in the literature; excellent review are by Hedayat et al. [21] and Majumdar [40]. The row–column design for four treatments in four rows and six columns which was given in the introduction is an S design with $\text{var}(\hat{\tau}_1 - \hat{\tau}_i) = (51/140)\sigma^2$, $\text{var}(\hat{\tau}_i - \hat{\tau}_j) = (48/140)\sigma^2$, $i \neq j = 2, 3, 4$. Note that there is only a small difference between the two variances, such designs being called nearly balanced. In general, $\text{var}(\hat{\tau}_1 - \hat{\tau}_i) < \text{var}(\hat{\tau}_i - \hat{\tau}_j)$, $i \neq j = 2, 3, \ldots, v$, for S designs, as is the case for the following design:

1	1	2	3	4
1	1	4	2	3
2	3	1	4	1
3	4	1	1	2
4	2	3	1	1

For this design $\text{var}(\hat{\tau}_1 - \hat{\tau}_i) = 0.3\sigma^2$, $\text{var}(\hat{\tau}_i - \hat{\tau}_j) = 0.4\sigma^2$, $i \neq j = 2, 3, 4$. Ture [59] gave a catalog of efficient type S row–column designs. Some type S row–column designs can be constructed using the methods of Gupta et al. [20], Kumari et al. [36], Majumdar [39], Majumdar and Tamhane [41] and Pearce [48]. Nair & Rao [43] defined intra- and inter-group balanced designs that are not restricted to two types of treatments; Pearce [46] referred to them as multipartite designs. In **factorial experiments** the contrasts of interest among treatment parameters represent different main effects and **interactions**. Let $\mathbf{s}_i'\boldsymbol{\tau}$ represent these single df main effects and interaction normalized contrasts, normalized such that $\mathbf{s}_i'\mathbf{s}_i = 1$, $i = 1, 2, \ldots, v - 1$. Then var $(\mathbf{s}_i'\hat{\boldsymbol{\tau}}) = a\sigma^2$ in a variance-balance design, where a is some constant. The variance-balanced design given earlier in this Section for $v = 2^2$, $p = q = 6$, is appropriate for a 2^2 experiment for which $\text{var}(\mathbf{s}_i'\hat{\boldsymbol{\tau}}) = 0.06\sigma^2$, $i = 1, 2, 3$. Practical constraints often dictate the use of a partially variance-balanced design for factorial experiments. In a partially balanced design with factorial balance (Shah [52], and Kshirsagar [35]), or balanced confounded designs of Nair & Rao [44], all the single df contrasts belonging to the same main effect or interaction are estimated with the same variance. The contrasts belonging to two different factorial effects may have unequal variances. A wide class of such designs for two-factor experiments is provided by group divisible designs. Some group divisible designs may have factorial balance even when more than two factors are involved. In a group divisible design treatments are divided into m groups, each group containing n treatments, and $v = mn$. Pairwise comparisons of any two treatments in the same group are all estimated with the same variance, say $a_1\sigma^2$, and pairwise comparisons of any two treatments belonging to two different groups are also estimated with the same variance, say $a_2\sigma^2$, with $a_1 \neq a_2$, where a_1, a_2 are some constants. With appropriate coding of the treatment labels, as mentioned earlier these designs are balanced factorially as well for two-factor experiments. A group divisible row–column design is shown below:

1	4	2	6	5	3
2	5	1	3	4	6
3	6	5	1	2	4
4	1	3	2	6	5

Several designs for two or more than two factors have been given by Suen & Chakravarty [58]. John & Lewis [29] gave a wide class of row–column designs for factorial experiments using a generalized cyclic method of construction, but their designs may not be factorially balanced. Under the general setting, Freeman [18] gave several series of partially balanced designs and Freeman [19] considered designs with unequal replications.

A design is called row-orthogonal if the row component D_1 is orthogonal to the treatments. The group-divisible design given above satisfies the condition of row orthogonality. Statistical properties of a row-orthogonal design can be evaluated from its column component D_2. Several group divisible designs listed by Clatworthy [6] can be rearranged to provide row-orthogonal row–column designs. Cyclic designs of John et al. [31] and Lamacraft & Hall [37] also provide a wide class of efficient row-orthogonal designs. A row–column design has adjusted orthogonality [15, 16] if the estimates of the row (column) parameters do not depend on whether or not column (row) parameters are included in the model. For adjusted orthogonal designs, the information matrices of D_1, D_2 and the row–column designs have the same **eigenvectors** [14]. All row-orthogonal designs have adjusted orthogonality. The α-designs of John & Eccleston [28] provide a wide class of efficient adjusted orthogonal designs. Some useful adjusted orthogonal designs have also been considered [1, 4, 12, 38, 53]. Row–column designs satisfying various optimality criteria have been considered in [3, 7–10,

17, 23–27, 30, 39, 42, 55], and [59]. General **algorithms** for constructing row–column designs using computers have been considered in [13, 32, 49], and [51].

SUDHIR GUPTA

Yule Process

The Yule process is a birth process (*see* **Stochastic Processes**) based on the assumptions of independence and of a constant birth rate, λ. Consider a time interval (t_0, t) and let $X(t)$ be the number of individuals present at time t, with the initial number $X(0) = n_0$ at $t = t_0$. The transition **(conditional) probabilities** of $X(t)$,

$$P_{n_0,n}(t_0, t) = \Pr[X(t) = n | X(0) = n_0], \quad n = n_0, n_0 + 1, \ldots, \tag{1}$$

satisfy the differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}t} P_{n_0,n_0}(t_0, t) = -n_0 \lambda P_{n_0,n_0}(t_0, t) \tag{2a}$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t} P_{n_0,n}(t_0, t) = -n\lambda P_{n_0,n}(t_0, t) + (n-1)\lambda P_{n_0,n-1}(t_0, t), \tag{2b}$$

for $n = n_0 + 1, n_0 + 2, \ldots$, with the initial conditions at $t = t_0$,

$$P_{n_0,n_0}(t_0, t_0) = 1 \quad \text{and} \quad P_{n_0,n}(t_0, t_0) = 0, \quad \text{for} \quad n \neq n_0.$$

Solving the differential equations (2a) and then (2b) successively, beginning with $n = n_0 + 1$, we find:

$$P_{n_0,n}(0, t) = \binom{n-1}{n-n_0} [\exp(-\lambda t)]^{n_0} \times [1 - \exp(-\lambda t)]^{n-n_0}, \quad n = n_0, n_0 + 1, \ldots. \tag{3}$$

Now let $Y(t) = X(t) - n_0$ be the number of births occurring during the interval (t_0, t). Then

$$\Pr[Y(t) = k] = \Pr[X(t) = k + n_0 | X(0) = n_0] = \binom{k + n_0 - 1}{k} [\exp(-\lambda t)]^{n_0} \times [1 - \exp(-\lambda t)]^k, \quad k = 0, 1, \ldots, \tag{4}$$

which is a **negative binomial distribution** with parameters n_0 and $\exp(-\lambda t)$. The expectations of $Y(t)$ and $X(t)$ are

$$\mathrm{E}[Y(t)] = \mathrm{E}[X(t)] - n_0 = n_0[\exp(\lambda t) - 1],$$

and the variances are

$$\mathrm{var}[Y(t)] = \mathrm{var}[X(t)] = n_0 \exp(\lambda t)[\exp(\lambda t) - 1].$$

This type of distribution was first studied by **G.U. Yule** [2, 3]. In his mathematical theory of evolution, Yule studied the number of species in a genus, where n_0 is the number of species at initial time $t = t_0$, $Y(t)$ is the number of species produced during the time period $(0, t)$, and $X(t)$ is total number of species in a genus present at time t. Yule did not use differential equations, but derived formulas (3) and (4) by a limiting process.

A General Case

Suppose r observations $[X(t_1), X(t_2), \ldots, X(t_r)]$ are made at r points $[t_1, t_2, \ldots, t_r]$ on the time axis. Since clearly the distribution of any random variable $X(t_i)$ depends only on the values of the random variable $X(t_{i-1})$, and not on any random variable before t_{i-1}, the joint probability distribution of $[X(t_1), X(t_2), \ldots, X(t_r)]$ is a product of r conditional probabilities:

$$\begin{aligned}\Pr[X(t_1) = n_1, X(t_2) = n_2, \ldots, X(t_r) = n_r | X(t_0)] &= \prod_{i=1}^{r} \Pr[X(t_i) = n_i | X(t_{i-1}) = n_{i-1}] \\ &= \prod_{i=1}^{r} \binom{n_i - 1}{n_i - n_{i-1}} [\exp(-\lambda \tau_i)]^{n_{i-1}} \\ &\quad \times [1 - \exp(-\lambda \tau_i)]^{n_i - n_{i-1}},\end{aligned} \tag{5}$$

where $\tau_i = t_i - t_{i-1}$, for any positive integer r.

Now let $Y(t_i) = X(t_i) - n_{i-1}$ be the number of births taking place during the interval (t_{i-1}, t_i). The joint distribution of $[Y(t_1), Y(t_2), \ldots, Y(t_r)]$ is obtained directly from formula (5) with the substitution of $n_i - n_{i-1} = k_i$:

$$\Pr[Y(t_1) = k_1, Y(t_2) = k_2, \ldots, Y(t_r) = k_r] = \prod_{i=1}^{r} \binom{n_i - 1}{k_i} [\exp(-\lambda \tau_i)]^{n_{i-1}} \times [1 - \exp(-\lambda \tau_i)]^{k_i}, \tag{6}$$

for any positive integer r. Formula (6) is a chain of negative binomial distributions [1].

CHIN LONG CHIANG

Yule, George Udny

Born: February 18, 1871, near Haddington, Scotland.
Died: June 26, 1951, in Cambridge, UK.

Reproduced by permission of the Royal Statistical Society

George Udny Yule was educated at Winchester College from where, at the age of only 16, he transferred to University College London to study engineering. **Karl Pearson**, then Professor of Applied Mathematics, was beginning to develop his own interest in statistics, and in 1892 offered Yule a post as demonstrator. In 1896, Yule was appointed Assistant Professor of Applied Mathematics, a post that he held for three years, until he resigned it in favor of more remunerative employment.

His continuing interest in statistics, however, led to his appointment as Newmarch Lecturer in Statistics at University College in 1902, a post which he held concurrently with his other work until 1909, and which led to the publication of the book which made his name, *An Introduction to the Theory of Statistics*. The first edition appeared in 1911 [4], and during his lifetime there were 13 further editions. The 11th edition was the first to be jointly undertaken with **M.G. Kendall** [6], and by the time of the 14th and last edition of "Yule & Kendall", in 1950, Kendall's own two-volume *The Advanced Theory of Statistics* was already establishing itself. It, and its present-day descendants, still bear the marks of Yule's pioneering effort.

In 1912, a Lectureship in Statistics was established for Yule by the University of Cambridge, to be held in the Faculty of Agriculture, and this, coupled with a Fellowship at St John's College from 1922, provided him with congenial employment (save for the war years) until 1931 when he retired, by then Reader in Statistics. He kept up his College teaching until the second war, and died in Cambridge in 1951.

Yule played an important part in the affairs of the **Royal Statistical Society**, of which he was honorary secretary for 12 years and subsequently President (1924–1926). He was elected a Fellow of the Royal Society in 1922.

Yule's main contributions in the theoretical field were concerned with **regression** and **correlation**, association in **contingency tables**, Mendelian genetics (*see* **Mendel's Laws**), epidemiology, and **time series**. In the Pearsonian fields of regression and correlation he gave more prominence than his mentor to the former, perhaps easing the path toward **R.A. Fisher's** invention of the **analysis of variance**.

Yule's studies of the correlation of continuous variables led him, in 1900 [1], to study measures of association for discrete variables, in particular the cross ratio θ (**odds ratio**) in a **two-by-two table** and its transform $Q = (1-\theta)/(1+\theta)$, now known as "Yule's coefficient". This led to an altercation with Pearson, in which Pearson's capacity for acrimonious and ill-directed criticism was displayed, in marked contrast to Yule's gentler mode of expression. Even Fisher, who as a young man had also felt the sharpness of Pearson's pen, was later moved to remark "Pearson attacked Yule's work at one time much more violently than ever he did mine". In 1903 [3], Yule, making use of his understanding of partial correlation, described what was much later to be termed **Simpson's paradox**, in which the pairwise associations at two levels in a $2 \times 2 \times 2$ table can be seemingly incompatible with the marginal association. In his work on association, all of his numeric examples were drawn from biology.

In Mendelian genetics, Yule [2] was the pioneer in suggesting that the observed correlations between parent and offspring could be accounted for by

multifactorial Mendelian inheritance, as Fisher fully acknowledged in his classic treatment of the correlation between relatives in 1918.

In 1914, in collaboration with F.L. Engledow, Yule invented the method of minimum chi-square for estimating a genetic recombination fraction, and the following year, with **M. Greenwood**, he was the first to recognize that there was something wrong with Pearson's **chi-square test** of association in respect of the **degrees of freedom** used, as Fisher was later to prove. He introduced the simple birth process of stochastic theory (the "**Yule process**") in connection with evolution in 1924 [5].

F. Yates ended his Royal Society obituary notice of Yule as follows: "We may ... justly conclude that although Yule did not fully develop any completely new branches of statistical theory, he took the first steps in many directions which were later to prove fruitful lines for further progress. ... In the biological field ... his work provided a corrective to many of the errors committed by the biometric school, and served to spread the use of statistical methods amongst biologists who might otherwise have been wholly repelled by them. He can indeed rightly claim to be one of the pioneers of modern statistics."

Yule–Walker Equations

The sequence $\{X_t : t = 0, \pm 1, \pm 2, \ldots\}$, defined by

$$X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \cdots + \phi_p X_{t-p} + e_t, \quad (1)$$

where $\phi_p \neq 0$ and $\{e_t\}$ is a sequence of uncorrelated random variables each with zero mean and variance σ^2, is called an *autoregressive time series of order p* (*see* **ARMA and ARIMA Models**). The notation AR(p) is commonly used. Define $\phi(B) = 1 - \phi_1 B - \phi_2 B^2 - \cdots - \phi_p B^p$, where B is the backward shift operator (*see* **Backward and Forward Shift Operators**) such that $BX_t = X_{t-1}$. Then the condition for **stationarity** is that the roots of the equation $\phi(Z) = 0$ must lie outside the unit circle [1, Section 3.2]. Under this condition, X_t may be expressed as a convergent (in the mean square sense) series in terms of e_s, $s \leq t$.

An important recurrence relation for the **autocorrelation function** of a stationary autoregressive process AR(p) is found by multiplying by X_{t-k} throughout (1) to obtain

$$X_{t-k}X_t = \phi_1 X_{t-k}X_{t-1} + \phi_2 X_{t-k} X_{t-2} + \cdots + \phi_p X_{t-k}X_{t-p} + X_{t-k}e_t, \quad (2)$$

On taking expected values in (2), we obtain the difference equation

$$\gamma_k = \phi_1 \gamma_{k-1} + \phi_2 \gamma_{k-2} + \cdots + \phi_p \gamma_{k-p}, \quad k > 0, \quad (3)$$

where γ_k is the autocovariance function, defined by

$$\gamma_k = \mathrm{E}[(X_t - \mathrm{E}X_t)(X_{t-k} - \mathrm{E}X_{t-k})] = \mathrm{E}X_t X_{t-k},$$

since $\mathrm{E}X_t = \mathrm{E}X_{t-k} = 0$. Note that the expectation $\mathrm{E}(X_{t-k}e_t)$ vanishes when $k > 0$, since X_{t-k} is a linear combination of e_s up to $t - k$, which are uncorrelated with e_t. On dividing through in (3) by γ_0, it is seen that the autocorrelation function satisfies the same form of the difference equation

$$\rho_k = \phi_1 \rho_{k-1} + \phi_2 \rho_{k-2} + \cdots + \phi_p \rho_{k-p}, \quad k > 0, \quad (4)$$

where the autocorrelation function ρ_k is defined by $\rho_k = \gamma_k/\gamma_0$.

If we substitute $k = 1, 2, \ldots, p$ in (4) and use $\rho_k = \rho_{-k}$, we obtain a set of linear equations for $\phi_1, \phi_2, \ldots, \phi_p$ in terms of $\rho_1, \rho_2, \ldots, \rho_p$. Then

$$\begin{array}{lcllll} \rho_1 & = & \phi_1 & + \phi_2\rho_1 & \cdots & + \phi_p\rho_{p-1} \\ \rho_2 & = & \phi_1\rho_1 & + \phi_2 & \cdots & + \phi_p\rho_{p-2} \\ \vdots & & \vdots & \vdots & \cdots & \vdots \\ \rho_p & = & \phi_1\rho_{p-1} & + \phi_2\rho_{p-2} & \cdots & + \phi_p. \end{array} \quad (5)$$

These are usually called the *Yule–Walker equations* [3, 4]. If we first estimate the autocorrelation functions by moment estimators we can then use the Yule–Walker equations to obtain estimators of $\{\phi_1, \ldots, \phi_p\}$. These estimators are called the *Yule–Walker estimators*.

For the multivariate Yule–Walker equations, see [2, Section 2.8].

Z Analysis

Z-analysis is a method for determining the **association** between two probabilistic events, A and B, on the basis of the calculation of a statistical link coefficient, $Z(A, B)$. The $Z(A, B)$ coefficient may range between -1, when A and B are mutually exclusive events, and $+1$, when A is included within B; it is equal to 0 when A and B are independent. Intermediate values between -1 and 0 quantify the partial exclusion of B by A, while values between 0 and $+1$ quantify the partial dependence of B on A.

Let us call $p(A)$ and $p(B)$ the probabilities of A and B, and $p(B|A)$ the probability of B when A occurred. $Z(A, B)$ is defined as [2]

$$Z(A, B) = \frac{[p(B|A) - p(B)]}{[1 - p(B)]} \quad \text{when } p(B|A) - p(B) \geq 0 \qquad (1)$$

$$Z(A, B) = \frac{[p(B|A) - p(B)]}{p(B)} \quad \text{when } p(B|A) - p(B) < 0. \qquad (2)$$

$Z(A, B)$ is continuous in zero because both (1) and (2) tend to 0 when $p(B|A)$ tends to $p(B)$. If A and B are mutually exclusive, $p(B|A) = 0$ and $Z(A, B) = -1$ from (2). If A is included within B, then $p(B|A) = 1$ and $Z(A, B) = 1$ from (1).

$Z(A, B)$ can be estimated by approximating the probabilities by the observed frequencies:

$$Z^{\wedge}(A, B) = \frac{[n_{AB}/n_A - n_B/N]}{[1 - n_B/N]} \quad \text{when } \frac{n_{AB}/n_A - n_B}{N} \geq 0 \qquad (3)$$

$$Z^{\wedge}(A, B) = \frac{[n_{AB}/n_A - n_B/N]}{[n_B/N]} \quad \text{when } \frac{n_{AB}/n_A - n_B}{N} < 0, \qquad (4)$$

where n_A = number of times that A occurred, n_B = number of times that B occurred, n_{AB} = number of times that A and B occurred simultaneously, and N = total number of observations. Simulations showed that $Z^{\wedge}(A, B)$ is an unbiased estimator of $Z(A, B)$ [2].

The computation of Z can be clarified by the following fictitious study investigating the association between the **smoking** habit and educational level in a sample of 48 subjects. Three educational levels are considered: lower than high school ($L1$), high school graduate ($L2$), and college graduate ($L3$). Subjects are classified as heavy smokers (h, more than 10 cigarettes smoked daily), mild smokers (m, less than 10 cigarettes), or nonsmokers (n). Data are summarized in Table 1.

The association between heavy smoking and each educational level is quantified by $Z(L3, h)$, $Z(L2, h)$, and $Z(L1, h)$. To calculate $Z(L3, h)$, we first observe that the number of heavy smokers in the $L3$ class is $\mathrm{n}_{L3,h} = 2$ (first cell of the last column) and that $(\mathrm{n}_{L3,h}/\mathrm{n}_{L3}\text{-}\mathrm{n}_h/\mathrm{N}) = (2/15\text{–}17/48)$ is lower than 0. Thus, we should use (4), obtaining

$$Z(L3, h) = \frac{(\mathrm{n}_{L3,h}/\mathrm{n}_{L3} - \mathrm{n}_h/\mathrm{N})}{(\mathrm{n}_h/\mathrm{N})} = \frac{(2/15 - 17/48)}{(17/48)} = -0.62. \qquad (5)$$

Similarly, we also obtain

$$Z(L2, h) = \frac{(\mathrm{n}_{L2,h}/\mathrm{n}_{L2} - \mathrm{n}_h/\mathrm{N})}{(\mathrm{n}_h/\mathrm{N})} = \frac{(6/17 - 17/48)}{(17/48)} = -0.003. \qquad (6)$$

Since $(\mathrm{n}_{L1,h}/\mathrm{n}_{L1} - \mathrm{n}_h/\mathrm{N}) = (9/16 - 17/48)$ is greater than 0, we calculate $Z(L1, h)$ from (3):

$$Z(L1, h) = \frac{(\mathrm{n}_{L1,h}/\mathrm{n}_{L1} - \mathrm{n}_h/\mathrm{N})}{(1 - \mathrm{n}_h/\mathrm{N})} = \frac{(9/16 - 17/48)}{(1 - 17/48)} = +0.34. \qquad (7)$$

$Z(L3, h) < 0$ and $Z(L1, h) > 0$ indicate respectively that heavy smoking is partially excluded by the highest educational level and associated with the lowest level. $Z(L2, h)$ close to 0 means that the probability

Table 1 Number of heavy (h), mild (m), or non (n) smokers in each educational level

Smoking habit	Educational level			
	$L1$	$L2$	$L3$	
h	9	6	2	$\mathrm{n}_h = 17$
m	5	5	4	$\mathrm{n}_m = 14$
n	2	6	9	$\mathrm{n}_n = 17$
	$\mathrm{n}_{L1} = 16$	$\mathrm{n}_{L2} = 17$	$\mathrm{n}_{L3} = 15$	$\mathrm{N} = 48$

Table 2 Example of Z-analysis to assess the links between systolic blood pressure (SBP) and RR-interval (RR) series; beat-by-beat data is derived from a 24-h recording in a healthy subject. First row and first column contain 10 SBP and 8 RR classes, cells show $Z^{\wedge}(A, B)$ only for couples of classes with $n_{AB} > 10$. Black, grey, and white backgrounds indicate cells of exclusion ($Z^{\wedge} \leq -0.2$), independence ($-0.2 < Z^{\wedge} < 0.2$), and bond ($Z^{\wedge} \geq 0.2$) respectively

SBP(mmHg) / *RR (ms)*	<80	80–97.5	97.5–115	115–132.5	132.5–150	150–167.5	167.5–185	185–202.5	202.5–220	>220
<500					−0.83	0.00	0.02	0.04		
500–625			−0.97	−0.77	−0.11	0.02	0.07	0.15	0.20	0.29
625–750		−0.29	−0.91	−0.56	−0.09	0.12	0.41	0.53	0.45	0.22
750–875		−0.61	−0.82	0.00	0.07	0.06	−0.02	−0.29	0.01	
875–1000	0.17	−0.05	−0.36	0.04	0.09	0.01	−0.58	−0.87		
1000–1125	0.01	0.33	0.39	0.07	−0.20	−0.43	−0.77			
1125–1250		−0.42	0.14	0.03	−0.55	−0.80	−0.80			
1250–1375			0.02	0.01	−0.84					

of finding a heavy smoker does not change if we know that the subject belongs to the $L2$ educational class.

Z-analysis can be also used to quantify the statistical link between two time series, $\{x_n\}$ and $\{y_n\}$ (*see* **Coherence Between Time Series**). In this case, the A and B events are the occurrence of x_n and y_n within specific amplitude intervals. By choosing N intervals for $\{x_n\}$ and M for $\{y_n\}$, $Z(A, B)$ is defined over a grid of $N \times M$ couples of (A, B) events. An example is shown in Table 2, where a matrix of $Z(A, B)$ estimates is obtained from a 24-h monitoring of systolic blood pressure and RR-interval data. Similar grids of $Z(A, B)$ have been used to separately quantify the links between blood pressure and heart rate time series due to direct central controls and those due to the baroreflex control of blood pressure [1].

Zelen Leadership Award and Lecture

The Marvin Zelen Leadership award was instituted by the Department of Biostatistics at the Harvard School of Public Health (HSPH) in 1997 to commemorate Professor Zelen's contributions to statistical science. The award recognizes an individual in government, industry, or academia, who by virtue of his/her outstanding leadership, has greatly influenced the theory and practice of statistical science. While individual accomplishments are considered, the most distinguishing criterion is the awardee's contribution to the creation of an environment in which statistical science and its applications have flourished. The selection committee consists of two members from the Department of Biostatistics (HSPH), and the three previous awardees. Nominations for candidates for the award are solicited from all members of the profession and are due in the fall of each year. Nominators should include a letter describing the contributions of a candidate, specifically highlighting the criteria for the award, and a curriculum vita.

The award is given annually each spring at a ceremony in Boston in which the awardee delivers a lecture of their choosing. The awardees and the lecture titles are:

1997 Dr. C. Frederick Mosteller, Professor Emeritus, Harvard University, "The Importance of Clinical Trials in Education"

1998 Sir David Cox, Nuffield College, University of Oxford, "Graphical Models in Statistics: A Review"

1999 Dr. **John W. Tukey**, Professor Emeritus, Princeton University, "A Smorgasbord of Handy Techniques That Can Help In Analyzing Data"

2000 Dr. Lincoln Moses, Professor Emeritus, Stanford University, "Deciding Whether Large Clinical Trials And Meta-Analyses Agree Or Not"

2001 Professor Niels Keiding, Professor of Biostatistics, University of Copenhagen, "Event Histories And Their Analysis"

2002 Dr. Robert O'Neill, Director of the Office of Biostatistics, Center for Drug Evaluation and Research, U.S. Food and Drug Administration, "A Perspective on the Development and Future of Statistics at the FDA"

2003 Dr. Wayne A. Fuller, Emeritus Distinguished Professor in Liberal Arts and Sciences, Iowa State University, "Analytic Studies with Complex Survey Data"

2004 Professor Robert C. Elston, Case Western University, "The analysis of Case-control Data to Detect Candidates Genes"

DAVID HARRINGTON

Zero Padding

Zero-padding is a procedure that consists of extending the length of a **time series** by adding zeros. For instance, if $\{x_0, x_1, \ldots, x_{M-1}\}$ is a sequence of M data, the zero-padded sequence of length $N = M + 5$ is $\{x_0, x_1, \ldots, x_{M-1}, 0, 0, 0, 0, 0\}$.

Adding zeros to a time series before computing the Discrete Fourier Transform (DFT) results in the evaluation of a Fourier transform with additional interpolated values. In fact, if $\{y_k\}$ is obtained by padding P zeros to a time series $\{x_k\}$ of length M, the DFTs before and after appending zeros are

$$X_m = \sum_{k=0}^{M-1} x_k e^{-j2\pi mk/M} \qquad m = 0, 1, \ldots, \frac{M}{2}. \tag{1}$$

$$Y_m = \sum_{k=0}^{M+P-1} y_k e^{-j2\pi mk/(M+P)} = \sum_{k=0}^{M-1} x_k e^{-j2\pi mk/(M+P)} \qquad m = 0, 1, \ldots, \frac{M+P}{2}. \tag{2}$$

The equations differ for the exponents only, indicating that the two DFTs provide components of the same Fourier transform evaluated, however, at different frequencies. In both cases, the maximum angular frequency is π, but after zero-padding, there are $P/2$ additional components, resulting in a more densely spaced DFT. Interpolation by zero-padding does not improve the basic resolution of the spectral estimate, but results are smoother and the identification of spectral peaks may be easier (Figure 1).

Zero-padding is also used when **Fast Fourier Transform (FFT)** algorithms, which require the number of data to be a power of two, are applied on shorter time series. Zeros are appended to cause the sequence length to become a power of two, and the FFT is calculated on the zero-padded sequence.

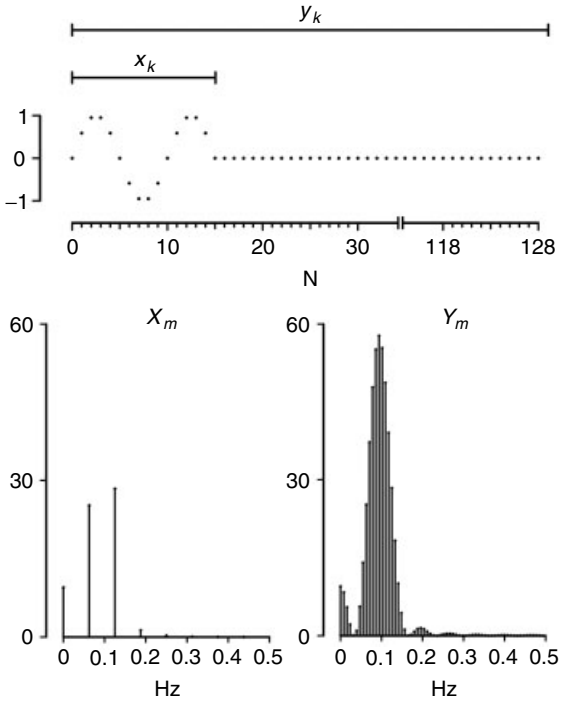

Figure 1 Effects of zero-padding. The series $\{x_k\}$ contains 16 samples of a 0.1-Hz sinusoid sampled at 1 Hz (1 cycle and half), and its DFT $\{X_m\}$ has 8 components only; $\{y_k\}$ is obtained by adding 112 zeros to $\{x_k\}$, and the DFT $\{Y_m\}$ has 64 components, 8 of which coincide with $\{X_m\}$. Although the frequency resolution of the two DFTs is the same, the 0.1-Hz spectral peak is much more easily identifiable after zero-padding

Zero-padding can be also applied to a DFT in order to interpolate in the time domain. Given a DFT $\{X_m\}_{m=0,1,\ldots,M/2}$, complex zeros are added after the component with $m = M/2$. The frequency of this component is half the sampling rate of the input series $\{x_k\}$ of length M. The maximum frequency of the DFT increases by adding $P/2$ zeros, and the padded DFT corresponds to the DFT of a new series $\{y_k\}$ sampled at a higher rate. The inverse DFT after zero-padding gives the series $\{y_k\}$ of length $M + P$, which is an interpolation of $\{x_k\}$ of length M.

PAOLO CASTIGLIONI

Zygosity Determination

Accurate determination of whether a twin pair is identical/monozygotic or fraternal/dizygotic has important implications with regard to the validity of research studies utilizing twins to assess the importance of genetic and/or environmental factors in explaining observed variation in specific traits or disease susceptibilities (*see* **Twin Analysis**). It is also important to an individual twin pair where questions of organ transplantation or risk for specific inherited diseases might arise. The approaches used in assigning zygosity include: (i) **genetic markers**, (ii) use of questionnaires to obtain self- or surrogate-reported information related to the similarity of pair members, (iii) number of fetal membranes, (iv) comparison of physical similarities of pair members, and (v) Weinberg's differential rule.

Zygosity Determination Using Genetic Markers

Zygosity determination methods using polymorphic marker systems (*see* **Polymorphism**) such as blood type (*see* **Blood Groups**), red cell enzymes, or **DNA sequence** markers have the advantage over other methods in that they provide an objective measure of **twin concordance** that is based upon qualitative genetically determined biological markers whose population frequency and modes of transmission are known. The efficiency of a given genetic marker is dependent upon the number of alleles and their frequency in the population from which the twin pair has been sampled. Since the chance of differentiating a dizygotic (DZ) twin pair from a monozygotic (MZ) pair increases with the inclusion of additional independent genetic markers, zygosity determination is usually based on typing information for a number of marker systems. Opposite-sexed pairs are assumed to be DZ on the basis of the sex difference, so that zygosity determination using genetic marker information is usually only done on like-sexed twin pairs. Any like-sexed pair that is found to be discordant for any marker is automatically classified as dizygotic. Since all MZ pairs and only a few DZ pairs will be concordant for all of the genetic markers examined, the probability statistic that is of primary interest with regard to an individual twin pair is the likelihood that that pair, if concordant, is DZ.

The probability that a pair of DZ twins will be concordant for all of n independent loci is $\prod_{i=1}^{n} \Pr_i(C|D)$, where $\Pr_i(C|D)$ is the probability of concordance for marker i given that the twin pair is dizygotic. As Lykken [13] has shown, this probability can be written in terms of the odds that a concordant twin pair is DZ, where

$$\text{odds}_{\text{DZ}|C_i} = \frac{\Pr_i(C|D)}{\Pr_i(C|M)} = \Pr_i(C|D).$$

In the situation where parental **genotype** is completely known, the final probability of dizygosity is simply the product of all of the probabilities that both members of the dizygotic pair are concordant, i.e. received the same allele from each parent, for each of the genetic makers examined. In most cases, however, marker information is available for only the twin pair, the probability that a DZ twin pair will be concordant for a given marker must be inferred from population frequencies, and all possible mating combinations capable of producing the observed phenotypes must be taken into account.

The estimate of the total probability that a random DZ twin will be concordant for a given genetic marker or markers provides a measure of the efficiency of the markers used in distinguishing MZ from DZ twins. A more detailed discussion of the estimation of the probability of mono- or dizygosity using genetic marker information has been provided in [17] and [18]. Historically, the genetic marker systems typically used in zygosity determination have included blood group type (*see* **Blood Groups**) (ABO, Rh, MNS, P, Lewis, Lutheran, Kidd, Kell, and Duffy), serum group (haptoglobin, C3, Gc, and lipoprotein), and red cell enzyme (PGM, adenylate kinase, adenosine deaminase, and acid phosphatase). Jablon et al. [11] found an average "efficiency" of 4% for five marker systems that included ABO, Rh, MN, haptoglobin, and Gm, while Magnus et al. [14] calculated it in their sample to be 0.0023 using 17 marker systems. DNA polymorphisms have come into wide use in zygosity determination as increased numbers of markers have become available and the cost associated with the molecular genetic analyses involved has decreased. In comparisons of DNA with other markers, both Derom et al. [5] and Eufinger et al. [8] have found DNA markers to be more

efficient in determining the correct zygosity than the other markers used in the past. Another important advantage of this method lies in the extremely small DNA sample needed to carry out analyses. This method is less invasive than those requiring larger samples because adequate amounts of DNA for zygosity determination can be extracted from buccal scrapings or from blood spots obtained as part of newborn screening.

Zygosity Assignment by Questionnaire

Issues of cost and efficiency generally preclude the use of genetic markers or DNA as a means of assigning twin zygosity in large-scale epidemiologic studies. As has been shown by a number of investigators, the use of self- or surrogate-reported information on the degree of similarity of twin pair members has been found to be an inexpensive and generally reliable method for zygosity determination in large-scale questionnaire surveys.

Cederlöf et al. [4] examined the accuracy of questions about the twins' similarity when growing up and the degree to which they were confused as children when both questionnaire and genotyping information were available on five independent blood group systems. On the basis of responses to two questions: "When growing up, were you and your twin 'as alike as two peas in a pod' or of ordinary family likeness only?" and "Were you and your twin mixed up as children by parents, brothers and sisters or teachers?" the diagnosis of monozygosity agreed with blood-typing results in 72 of 73 cases for MZ twins and 99 of 108 cases for DZ twins, with 19 pairs being unclassifiable on the basis of questionnaire information. Over all, it was possible to assign the correct zygosity accurately in 92% of the twin pairs examined using questionnaire information. In a similar study of twins identified from a sample of US high school juniors who took the Nation Merit Scholarship Qualifying examination, Nichols & Bilbro [15] found that zygosity could be accurately assigned on the basis of questionnaire information on physical similarity of pair members in 93% of cases; however, as was found previously, zygosity determination using this approach was more accurate for MZ than for DZ pairs. Magnus et al. [14] examined the accuracy of questionnaire information in determining zygosity in a sample of Norwegian twin pairs where zygosity had been previously established using genetic markers for 17 polymorphic systems. Twins were queried as to whether they were as alike as "two drops of water" in childhood, or were just as alike as siblings; the extent to which parents, siblings, grandparents, classmates, teachers and strangers had difficulty in telling the twins apart; the degree of similarity of eye color, hair color, hair type, height, weight, teeth, voice, muscular strength, dexterity, temperament, musicality, and language ability; whether they thought they were identical or fraternal or did not know; and why they thought they were identical or fraternal. Results of discriminant analyses of this information estimated that the zygosity would be misclassified for 2.4% of the pairs if the questionnaire responses of both pair members were used and for 3.9% of the pairs if questionnaire information was provided by only a single pair member. These results indicated that zygosity could be reasonably accurately assigned on the basis of information provided by a single twin pair member. Eisen et al. [7] obtained similar results for male veteran twin pairs, which suggested that the results obtained were independent of nationality and provided further evidence that questionnaire surveys are a reliable means of assigning twin zygosity in large epidemiologic studies.

Although a number of studies have been conducted to establish the reliability of questionnaire information obtained from adults as a method of zygosity determination, less information is available with regard to the reliability of this method for children. Bønnelykke et al. [2] examined the reliability of information on twin pair similarity obtained from mothers of twins between 6 months and $6\frac{1}{2}$ years of age. When compared to the results of zygosity determination based on genotyping information, the frequency of misclassification using information provided by the mother concerning whether the twins had ordinary or more than ordinary family likeness, the same hair and eye color or different hair and/or eye color, and whether the mother did or did not have difficulty in telling the twins apart was 4%. Five percent of pairs could not be classified using questionnaire information. Goldsmith [9] has constructed a zygosity determination questionnaire specifically for use in studies of infants and young children. However, information on the validity and reliability of this instrument in assigning correct zygosity is not available.

Zygosity Determination Based upon the Number of Fetal Membranes

Dizygotic twins arise from the independent fertilization of two eggs by two sperm. The two blastocysts then implant separately in the wall of the uterus, which results in each embryo being wrapped it its own chorionic membrane. Although these membranes can fuse as a result of the blastocysts being implanted in close proximity in the uterus, the placenta is always of the dichorionic-diamniotic type, i.e. two chorions and two amnions. Fusion between the chorionic membranes of DZ twins occurs in about 50% of cases. Monozygotic twins, on the other hand, arise from a division of the embryo that can occur either before or after the formation of the blastocyst, or, if it occurs after implantation of the blastocyst in the uterine wall, before or after the development of the amnionic membranes. If the division occurs before development of the blastocyst, placental development will occur in the same manner as seen for DZ twins and the placenta will be dichorionic-diamniotic. This occurs in approximately one third of MZ twin pairs making them indistinguishable from DZ pairs with regard to placenta type. If the division of the embryo occurs after implantation of the blastocyst in the uterus, there is only one chorion and the placenta is of the monochorionic type. MZ twin pairs arising from the division of the blastocyst after implantation but before the development of the amniotic cavity have individual amnions but only one chorionic membrane and are termed monochorionic-diamniotic. Those arising from division of the blastocyst after development of the amniotic cavity share that cavity and have a single chorionic membrane and are termed monochorionic-monoamniotic.

Since DZ twins cannot have monochorionic placentas, examination of the number of fetal membranes present in a twin placenta can be and has been successfully used for zygosity determination with regard to MZ pairs. In general, examination of fetal membranes is the only method currently available for identifying MZ twins with complete certainty [6]. An accurate assessment of fetal membranes, however, can only be made by an experienced pathologist since, in many cases, it will require microscopic examination of a cross-section of the placenta. Since fused dichorionic placentas are virtually indistinguishable to the naked eye from monochorionic placentas, information that there was only a single placenta at birth, in the absence of a pathology report, does not support the conclusion that the twin pair is identical.

Zygosity Determination Based on Comparisons of Physical Similarities

Similarity for physical characteristics such as height, weight, hair and eye color, and dermatoglyphic or fingerprint patterns have also been used in assigning twin zygosity. Allen [1] examined the diagnostic efficiency of fingerprint differences in zygosity determination and found both finger ridge count and pattern type to be useful in discriminating between MZ and DZ twin pairs. Jablon et al. [11] examined the reliability of zygosity determination on the basis of recorded height and weight, hair and eye color and fingerprints in 2805 twin pairs who served in the Armed Forces of the US during World War II. On the basis of fingerprint information alone, the average rate of zygosity misclassification was 22.6%. When fingerprint data were supplemented by information on height, weight, hair color and eye color, the average misclassification rate dropped to approximately 13%. Segal [16] found results of dermatoglyphic analyses to agree with those based on blood typing in 85% of cases and noted that, although fingerprint patterns are highly heritable, they are sensitive to environmental influences inutero which can differ between members of a twin pair depending upon the type of placental membrane structure present and should not be used as primary indices for assigning zygosity. Similar caution should be exerted when zygosity determination is based on a global impression of zygosity reached during a face to face contact with a twin pair. It should be noted that the effects of twin–twin transfusion syndrome can still be seen in many cases even into adulthood, and there can be significant differences in heights and body sizes of affected MZ twin pair members.

Weinberg's Differential Rule

In large population studies where it is only possible to obtain the sex of the twin pair, the frequency of MZ and DZ twin pairs can be estimated for that population using Weinberg's Differential rule. Under the assumptions that males account for 50% of DZ twins and the sex of both members of a

DZ pair is independently determined, this method estimates the number of MZ twins as $L - U$ and the number of DZ twins as $2U$, where L is the number of like-sexed pairs and U is the number of unlike-sexed pairs. Bulmer [3] has shown that the effects of violating the first assumption are negligible. Although James [12] has raised a number of points that suggest that Weinberg's rule is flawed, Vlietinck et al. [19] and Husby et al. [10] found the observed distributions of MZ and DZ pairs in two consecutive series of twins to be in agreement with those predicted using Weinberg's rule. This suggests that this method is valid as a rule of thumb but should not be considered as definitive for estimating the distribution of MZ and DZ twin pairs within a given population.
